Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

About the Authors

Kevin Patton has taught anatomy and physiology to high school, community college, and university students from various backgrounds for three decades. Kevin found that the work that led him to a PhD in vertebrate anatomy and physiology instilled in him an appreciation for the "Big Picture" of human structure and function. This experience has helped him produce a text that will be easier to understand for all students. He has earned several citations for teaching anatomy and physiology, including the Missouri Governor's Award for Excellence in Teaching. "One thing I've learned," says Kevin, "is that most of us learn scientific concepts more easily when we can see what's going on." His talent for using imagery to teach is evident throughout this edition with its extensive array of visual resources. Kevin's interest in promoting excellence in teaching anatomy and physiology has led him to take an active role in the Human Anatomy and Physiology Society (HAPS), where he is a President Emeritus and was the founding director of the HAPS Institute. In 2008, he was awarded the HAPS President's Medal for outstanding contributions in promoting the mission of excellence in A&P teaching and learning. Kevin also teaches graduate courses to prospective and current A&P professors and produces online resources for A&P students and teachers, including *theAPstudent.org* and *theAPprofessor.org*.

To my family and friends, who never let me forget the joys of discovery, adventure, and good humor.

To the many teachers who taught me more by who they were than by what they said.

To my students who help me keep the thrill of learning fresh and exciting.

Kevin T. Patton

Gary Thibodeau has been teaching anatomy and physiology for more than three decades. Since 1975, *Anatomy & Physiology* has been a logical extension of his interest and commitment to education. Gary's teaching style encourages active interaction with students, and he uses a wide variety of teaching methodologies—a style that has been incorporated into every aspect of this edition. He is considered a pioneer in the introduction of collaborative learning strategies to the teaching of anatomy and physiology. Recent conferral of Emeritus status in the University of Wisconsin System has provided him with additional time to interact with students and teachers across the country and around the world. His focus continues to be successful student-centered learning—leveraged by text, Web-based, and ancillary teaching materials. Over the years, his success as a teacher has resulted in numerous awards from both students and professional colleagues. Gary is active in numerous professional organizations including the Human Anatomy and Physiology Society (HAPS), The American Association of Anatomists, and the American Association of Clinical Anatomists. His biography is included in numerous publications, including *Who's Who in America*; *Who's Who in American Education*; *Outstanding Educators in America*; *American Men and Women of Science*; and *Who's Who in Medicine and Healthcare*. While earning master's degrees in both zoology and pharmacology, as well as a PhD in physiology, Gary says that he became "fascinated by the connectedness of the life sciences." That fascination has led to this edition's unifying themes that focus on how each concept fits into the "Big Picture" of the human body.

To my parents, M.A. Thibodeau and Florence Thibodeau, who had a deep respect for education at all levels and who truly believed that you never give up being a student.

To my wife, Emogene, an ever-generous and uncommonly discerning critic, for her love, support, and encouragement over the years.

To my children, Douglas and Beth, for making it all worthwhile.

Gary A. Thibodeau

Preface

Success in both teaching and learning is, in many ways, determined by how effective we are in transforming information into knowledge. This is especially true in scientific disciplines, such as anatomy and physiology, where both student and teacher continue to be confronted with an enormous accumulation of factual information. *Anatomy & Physiology* is intended to help transform that information into a manageable knowledge base by effective use of unifying themes and by focusing on the significant and on what is truly relevant in both disciplines.

This textbook is intended for use as both a teaching tool and a learning tool. It was written to help students unify information, stimulate critical thinking, and acquire a taste for knowledge about the wonders of the human body. This textbook will help students avoid becoming lost in a maze of facts in a complex learning environment. It will encourage them to explore, to question, and to look for relationships, not only between related facts in a single discipline, but also between fields of academic inquiry and personal experience. It is our hope that *Anatomy & Physiology* will help both students and teachers transform information into knowledge.

This new edition of the text has been extensively revised. We built upon the successful art revision program begun in the previous edition by adding several new illustrations and photographs. Several of the longer chapters were split into smaller chapters to improve comprehension and better organize study. We also improved our execution of a page design and layout that maximizes learning effectiveness. As with each new edition, we added carefully selected new information on both anatomy and physiology to provide an accurate and up-to-date presentation. We have retained the basic philosophy of personal and interactive teaching that characterized previous editions. In addition, essential, accurate, and current information continues to be presented in a comfortable writing style. Emphasis is placed on concepts rather than descriptions, and the "connectedness" of human structure and function is repeatedly reinforced by unifying themes.

UNIFYING THEMES

Anatomy and physiology encompasses a body of knowledge that is large and complex. Students are faced with the need to know and understand a multitude of individual structures and functions that constitute a bewildering array of seemingly disjointed information. Ultimately, the student of anatomy and physiology must be able to "pull together" this information to view the body as a whole—to see the "Big Picture." If a textbook is to be successful as a teaching tool in such a complex learning environment, it must help unify information, stimulate critical thinking, and motivate students to master a new vocabulary.

To accomplish this synthesis of information, unifying themes are required. In addition, a mechanism to position and implement these themes must be an integral part of each chapter. Unit One begins with "Seeing the Big Picture," an overview that encourages students to place individual structures or functions into an integrated framework. Then, throughout the book, the specific information presented is highlighted in a special "The Big Picture" section so that it can be viewed as an integral component of a single multifaceted organism.

Anatomy & Physiology is dominated by two major unifying themes: (1) the complementarity of normal structure and function and (2) homeostasis. The student is shown, in every chapter of the book, how organized anatomical structures of a particular size, shape, form, or placement serve unique and specialized functions. The integrating principle of homeostasis is used to show how the "normal" interaction of structure and function is achieved and maintained by counterbalancing forces within the body. Repeated emphasis of these principles encourages students to integrate otherwise isolated factual information into a cohesive and understandable whole. "The Big Picture" summarizes the larger interaction between structures and functions of the different body systems. As a result, anatomy and physiology emerge as living and dynamic topics of personal interest and importance to students.

AIMS OF THE REVISION

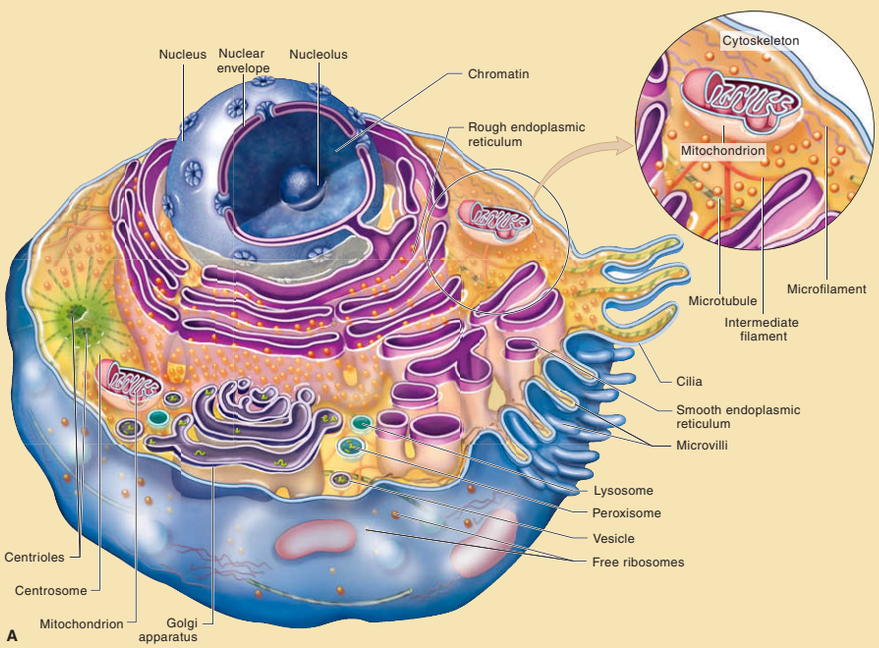
As in past editions, our revision efforts focused on identifying the need for new or revised information and for additional visual presentations that clarify important, yet sometimes difficult, content areas.

In this eighth edition, we have included information on new concepts in many areas of anatomy and physiology. For example, new data on the description of cranial nerves, protein structure, and updates in terminology have been included. Most of these changes are subtle adjustments to our current understanding of human science. However, the accumulation of all of these subtle changes makes this edition the most up-to-date textbook available.

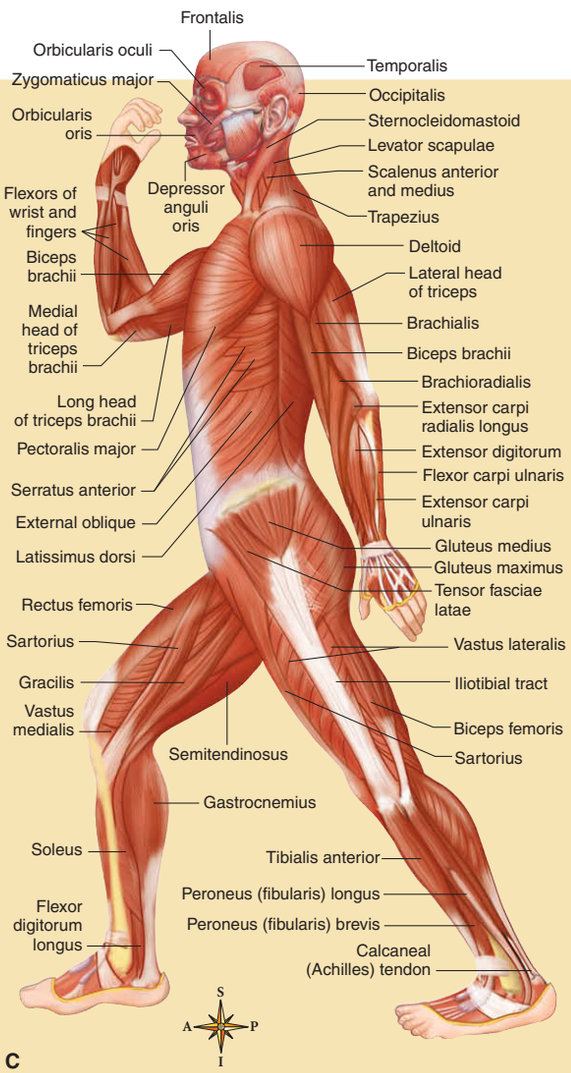
One of the most apparent changes that you will notice in this new edition is a reorganization of chapters. Three of the longer chapters have been split into small chapters. In cell biology, we moved *cell growth and reproduction* to its own chapter (Chapter 5). In the nervous system, we moved the *autonomic nervous system* into its own chapter (Chapter 16). And the endocrine system was split into an introductory chapter on *endocrine regulation*

(Chapter 18) followed by a survey of major *endocrine glands* (Chapter 19). A hallmark of our textbook has been its effective "chunking" of material into manageable chapters and these changes reflect our continuing commitment to that approach.

The previous edition featured a complete redesign of the page layouts and the art program. This enabled us to make the textbook easier to use by putting the illustrations, graphs, and tables closer to the related text. In this edition, we have improved the creative layout even more. Additional tables help students visually organize important concepts and complement the improved design to provide a multisensory learning tool. We have expanded the art program, while preserving a style as consistent as possible throughout the book. In this edition, we have expanded and improved the use of a consistent Color Key (pp. xxiv-xxv) for certain cell parts, tissue types, and biomolecules to help make learning easier for beginning students.



In this edition, great effort has been made to make this text accessible to students whose first language is not English. After consulting with ESL specialists and ESL learners, we have continued to enhance our word lists and improve our readability to make the concepts of human structure and function more understandable for all students.

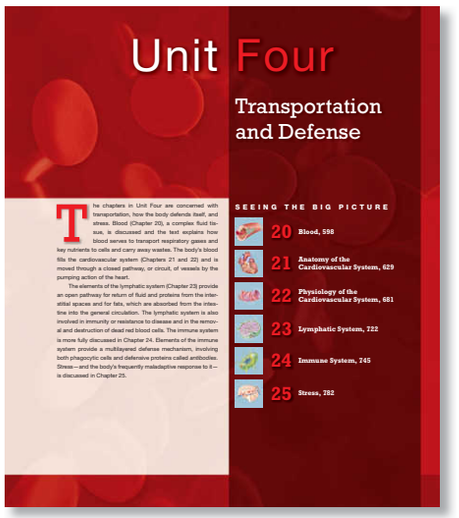


As teachers of anatomy and physiology, we know that to be effective a text must be readable, and it must challenge and excite the student. This text remains one that students will read—one designed to help the teacher teach and the student learn. To accomplish this end, we facilitated the comprehension of difficult material for students with thorough, consistent, and nonintimidating explanations that are free of unnecessary terminology and extraneous information. This easy access to complex ideas remains the single most striking hallmark of our textbook.

ILLUSTRATIONS AND DESIGN

A major strength of this text has always been the exceptional quality, accuracy, and beauty of the illustration program. It is the original "visual" anatomy and physiology textbook. We have worked very closely with scientific illustrators to provide attractive and colorful images that clearly and accurately portray the major concepts of anatomy and physiology.

The truest test of any illustration is how effectively it can complement and strengthen the written information in the text and how successfully it can be used by the student as a learning tool. Each illustration is explicitly referred to in the text and is designed to support the text discussion. Careful attention has been



LEARNING AIDS

Anatomy & Physiology is a student-oriented text. Written in a readable style, the text is designed with many different pedagogical aids to motivate and maintain interest. The special features and learning aids listed below are intended to facilitate learning and retention of information in the most effective and efficient manner.

No textbook can replace the direction and stimulation provided by an enthusiastic teacher to a curious and involved student. However, a full complement of innovative pedagogical aids that are carefully planned and implemented can contribute a great deal to the success of a text as a learning tool. An excellent textbook can and should be enjoyable to read and should be helpful to both student and teacher. We hope you agree that the learning aids in *Anatomy & Physiology* meet the high expectations we have set.

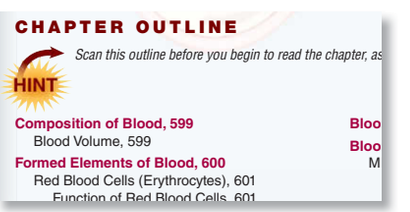
Unit Introductions

Each of the six major units of the text begins with a brief overview statement. The general content of the unit is discussed, and the chapters and their topics are listed. Before beginning the study of material in a new unit, students are encouraged to scan the introduction and each of the chapter outlines in the unit to understand the relationship and "connectedness" of the material to be studied. Each unit has a color-coded tab at the outside edge of every page to help you quickly find the information you need.

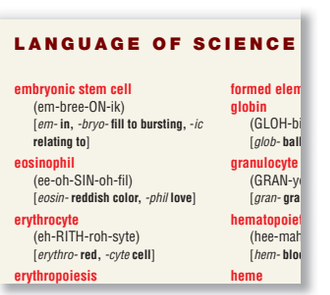
Unit Four
Transportation and Defense
SEEING THE BIG PICTURE
20 Blood, 598
21 Anatomy of the Cardiovascular System, 629
22 Physiology of the Cardiovascular System, 681
23 Lymphatic System, 722
24 Immune System, 745
25 Stress, 782

paid to placement and sizing of the illustrations to maximize usefulness and clarity. Each figure and all labels are relevant to—and consistent with—the text discussion. Each illustration has a boldface title for easy identification. Most illustrations also include a concise explanation that guides the student through the image as a complement to the nearby text narrative.

The artistically drawn, full-color artwork is both aesthetically pleasing and functional. Color is used to highlight specific structures in drawings to help organize or highlight complex material in illustrated tables or conceptual flow charts. The text is also filled with dissection photographs, exceptional light micrographs, and scanning (SEM) and transmission (TEM) electron micro-graphs, some of which are new to this edition. In addition, examples of medical imagery, including CT scans, PET scans, MRIs, and x-ray photographs, are used throughout the text to show structural detail, explain medical procedures, and enhance the understanding of differences that distinguish pathological conditions from normal structure and function. All illustrations used in the text are an integral part of the learning process and should be carefully studied by the student.

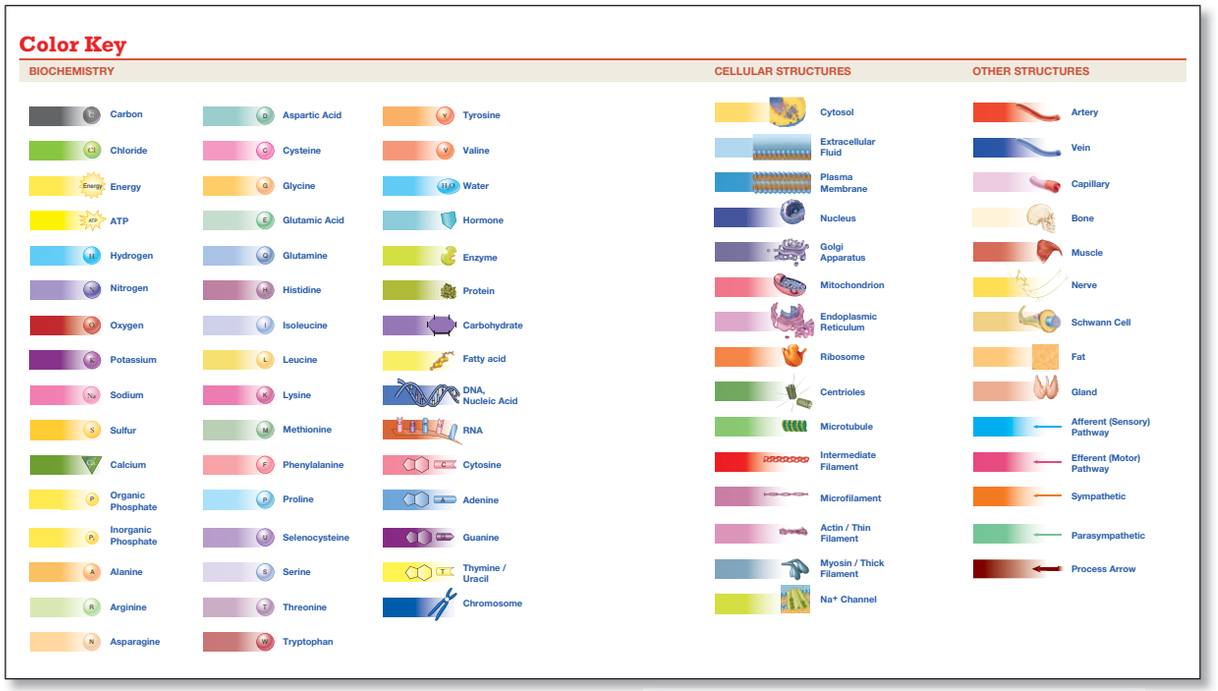


Chapter Learning Aids



- **Study Hints**—*give specific suggestions for using many of the learning aids found in each chapter.* Because many readers have never learned the special skills needed to make effective use of pedagogical resources found in science textbooks, helpful tips are embedded within each Chapter Outline, Language of Science & Medicine list, Case Study, Chapter Summary, Review Question set, and Critical Thinking section. Answers for all of the case study questions and also the review and critical thinking questions are in the Instructor's Resource Manual, the Instructor's Electronic Resource DVD, and the instructor's EVOLVE site for *Anatomy & Physiology*. Teachers can then choose to use the questions as homework assignments or include them on tests.

HINT



- **Chapter Outline**—*summarizes the contents of a chapter at a glance.* An overview outline introduces each chapter and enables the student to preview the content and direction of the chapter at the major concept level before beginning a detailed reading. Page references enable students to quickly locate topics in the chapter.

CHAPTER OUTLINE
Scan this outline before you begin to read the chapter, as
HINT
Composition of Blood, 599
Blood Volume, 599
Formed Elements of Blood, 600
Red Blood Cells (Erythrocytes), 601
Function of Red Blood Cells, 601
Bloo
Bloo
M

- **Language of Science**—*introduces you to new scientific terms in the chapter.* A comprehensive list of new terms is presented at the beginning of the chapter. Each term in the list has an easy-to-use pronunciation guide to help the learner easily "own" the word by being able to say it. Literal translations of the term or its word parts are included to help students learn how to deduce the meaning of new terms themselves. The listed terms are defined in the text body, where they appear in boldface type, and may also be found in the glossary at

LANGUAGE OF SCIENCE
embryonic stem cell
(em-bree-ON-ik)
[*em-* in, *-bryo-* fill to bursting, *-ic* relating to]
eosinophil
(ee-oh-SIN-oh-fil)
[*eosin-* reddish color, *-phil* love]
erythrocyte
(eh-RITH-roh-syte)
[*erythro-* red, *-cyte* cell]
erythropoiesis
formed elem
globin
(GLOH-bi
[*glob-* ball
granulocyte
(GRAN-y
[*gran-* gra
hematopoiet
(hee-mah
[*hem-* bloo
heme

the back of the book. The boldface type feature enables students to scan the text for new words before beginning their first detailed reading of the material, so they may read without having to disrupt the flow to grapple with new words or phrases. The Language of Science word list includes terms related to the essential anatomy and physiology presented in the chapter. Another word list near the end of the chapter, a feature described below as the Language of Medicine, is an inventory of all the new clinical terms introduced in the chapter.

- **Color-Coded Illustrations**—*help beginning students appreciate the "Big Picture" of human structure and function.* A special feature of the illustrations in this text is the careful and consistent use of color to identify important structures and substances that recur throughout the book. Consistent use of a color key helps beginning students appreciate the "Big Picture" of human structure and function each time they see a familiar structure in a new illustration. For an explanation of the color scheme, see the Color Key on pp. xxiv-xxv.

- **Directional Rosettes**—*help students learn the orientation of anatomical structures.* Where appropriate, small orientation diagrams and directional rosettes are included as part of an illustration to help students locate a structure with reference to the body as a whole or orient a small structure in a larger view.

- **Quick Check questions**—*test your knowledge of material just read.* Short objective-type questions are located immediately following major topic discussions throughout the body of the text. These questions cover important information presented in the preceding section. Students unable to answer the questions should reread that section before proceeding. This feature therefore enhances reading comprehension. Quick Check items are numbered by chapter, and a numerical listing of their answers can be found on the EVOLVE site (http://evolve.elsevier.com/Patton/AP/).

| QUICK CHECK |

1. Name the fluid portion of whole blood.
2. What constitutes the formed elements of blood?
3. What factors influence blood volume?
4. Identify the component percentages of the normal hematocrit.

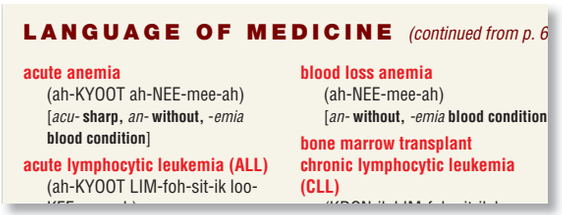
- **A&P Connect features**—*call the reader's attention to online articles that illustrate, clarify, and apply concepts encountered in the text.* Embedded within the text narrative, these boxes connect you with interesting, brief online articles that stimulate thinking, satisfy your curiosity, and help you apply important concepts. They are often illustrated with micrographs, medical images, and medical illustrations.

| A&P CONNECT |

Blood transfusions are an important therapeutic tool. Learn more about blood transfusions, blood banking, and even *artificial* blood in ***Blood Transfusions*** online at ***A&P Connect.***

evolve

- **Cycle of Life**—*describes major changes that occur over a person's lifetime.* In many body systems, changes in structure and function are frequently related to a person's age or state of development. In appropriate chapters of the text, these changes are highlighted in this special section.



- **The Big Picture**—*explains the interactions of the system discussed in a particular chapter with the body as a whole.* This helps students relate information about body structures or functions that are discussed in the chapter to the body as a whole. The Big Picture feature helps you improve critical thinking by focusing on how structures and functions relate to one another on a global basis.

- **Mechanisms of Disease**—*helps you understand the basic principles of human structure and function by showing what happens when things go wrong.* Examples of pathology, or disease, are included in many chapters of the book to stimulate student interest and to help students understand that the disease process is a disruption in homeostasis, a breakdown of normal integration of form and function. The intent of the ***Mechanisms of Disease*** section is to reinforce the normal structures and mechanisms of the body while highlighting the general causes of disorders for a particular body system.

- **Language of Medicine**—*introduces you to new clinical terms in the chapter.* A brief list of clinical terms is presented near the end of each chapter. As in the ***Language of Science***

LANGUAGE OF MEDICINE (continued from p. 6

acute anemia
(ah-KYOOT ah-NEE-mee-ah)
[*acu-* **sharp**, *an-* **without**, *-emia* **blood condition**]

acute lymphocytic leukemia (ALL)
(ah-KYOOT LIM-foh-sit-ik loo-

blood loss anemia
(ah-NEE-mee-ah)
[*an-* **without**, *-emia* **blood condition**]

bone marrow transplant

chronic lymphocytic leukemia (CLL)

list at the beginning of the chapter, each term has a phonetic pronunciation guide and translations of word parts. The listed terms are defined in the text body, where they appear in boldface type.

- **Case Study**—*challenges you with "real-life" clinical or other practical situations so you can creatively apply what you have learned.* Every chapter has a case study preceding the chapter summary. The case study consists of a description of a real-life situation and a series of questions that require the student to use critical thinking skills to determine the answers.
- **Chapter Summary**—*outlines essential information in a way that helps you organize your study.* Detailed end-of-chapter summaries provide excellent guides for students as they review the text materials before examinations. Many students also find the summaries to be useful as a chapter preview in conjunction with the chapter outline.
- **Audio Chapter Summaries**—*allow you to listen and learn wherever you may be.* For the first time, the chapter summaries are now available in MP3 format for download at the EVOLVE site. You can play them on your computer, import them into your portable media device, or burn them onto a CD for playback in your stereo or car.
- **Review Questions**—*help you determine whether you have mastered the important concepts of each chapter.* Review questions at the end of each chapter give students practice in using a narrative format to discuss the concepts presented in the chapter.
- **Critical Thinking Questions**—*actively engage and challenge you to evaluate and synthesize the chapter content.* Critical thinking questions require students to use their higher level reasoning skills and demonstrate their understanding of, not just their repetition of, complex concepts.

Boxed Information

As always, we made every effort to update factual information and incorporate the most current anatomy and physiology research findings in this edition. Although there continues to be an incredible explosion of knowledge in the life sciences, not all new information is appropriate for inclusion in a fundamental-level textbook. Therefore we were selective in choosing new clinical, pathological, or special-interest material to include in this edition. This text remains focused on normal anatomy and physiology. The addition of new boxed content is intended to stimulate student interest and provide examples that reinforce the immediate personal relevance of anatomy and physiology as important disciplines for study.

- **General Interest Boxes**—*provide an expanded explanation of specific chapter content.* Many chapters contain boxed essays, occasionally clinical in nature, that expand on or relate to material covered in the text. Examples of subjects include the RNA revolution and the enteric nervous system.
- **Health Matters**—*present current information on diseases, disorders, treatments, and other health issues related to normal structure and function.* These boxes contain information related to health issues or clinical applications. In some instances, examples of structural anomalies or pathophysiology are presented. Information of this type is often useful in helping students understand the mechanisms involved in maintaining the "normal" interaction of structure and function.
- **Diagnostic Study**—*keep you abreast of developments in diagnosing diseases and disorders.* These boxes deal with specific diagnostic tests used in clinical medicine or research. Lumbar puncture, angiography, and antenatal diagnosis and treatment are examples.
- **FYI**—*give you more in-depth information on interesting topics mentioned in the text.* Topics of current interest, such as new advances in anatomy and physiology research, are covered in these "for your information" boxes.
- **Sports and Fitness**—*highlight sports-related topics.* Exercise physiology, sports injury, and physical education applications are highlighted in these boxes.
- **Career Choices**—*highlight individuals in health-related careers.* A Career Choices box appears at the end of each unit. These boxes describe some of the diverse opportunities currently available in health-related occupations and also demonstrate the importance of how an understanding of anatomy and physiology will be useful to students in their futures.

Glossary

A comprehensive glossary of terms is located at the end of the text. Accurate, concise definitions and phonetic pronunciation guides are provided. In this edition, word parts have also been added to each glossary entry. An audio glossary is also available on the expanded EVOLVE site (http://evolve.elsevier.com/Patton/AP/) with definitions and audio pronunciations for most of the key terms in the text.

LEARNING SUPPLEMENTS FOR STUDENTS

Brief Atlas of Human Anatomy

A full-color *Brief Atlas of Human Anatomy* containing cadaver dissections, osteology, organ casts, histology specimens, and surface anatomy photographs is packaged with every new copy of this edition of *Anatomy & Physiology*. This helpful supplement serves as a handy reference for students as they study the human body in class and in the laboratory—and even later on in clinical and career contexts.

summaries of landmark features used to distinguish microscopic specimens. Each exercise concludes with a lab report that may also serve as a homework assignment or self-test.

The new edition of the lab manual includes *eLabs for Anatomy & Physiology*, an online lab program designed to complement traditional lab exercises. The lab exercises, both anatomy and physiology based, are separated into modules. Each lab is composed of a variety of learning activities, animations, simulations, and quizzes. The labs are designed so that students can easily navigate between activities, allowing them the freedom to focus on the areas where they need the most help.

TEACHING SUPPLEMENTS FOR INSTRUCTORS

Instructor Resources on Evolve

The *Instructor's Resource* was written and developed specifically for this new edition of *Anatomy & Physiology*. Available on Evolve, it provides critical thinking questions, learning objectives and activities, teaching tips for the text, synopses of difficult concepts, and clinical applications exercises. To make lecture preparations a little easier, the Instructor's Resource also includes lesson plans that allow you to hit the ground running. The Evolve website for instructors also includes a **Computerized Test Bank** with more than 7000 multiple choice, true/false, short answer, and challenge questions (which you can also import into your **Classroom Performance System** to quickly assess student comprehension and monitor your classroom's response), an **Electronic Image Collection** to accompany *Anatomy & Physiology*, featuring hundreds of full-color illustrations and photographs, with labels and lead lines that you can turn off and on, **Powerpoint Presentations**, and much more!

Instructor's Guide for the Laboratory Manual

The Instructor's Guide for the ***Laboratory Manual*** on Evolve offers detailed information to help the instructor prepare for the laboratory exercises. Alternate activities, substitutions, student handouts, and other resources help instructors tailor the use of the ***A&P Laboratory Manual*** to their own course. Answers for all questions on the lab reports in the ***A&P Laboratory Manual*** are also provided either to check student work or to provide for students who use lab reports as self tests. Also included is a **cadaver dissection video**—shot in high definition— that you can use in lecture or lab.

Acknowledgments

Over the years, many people have contributed to the development and success of *Anatomy & Physiology*. We extend our thanks and deep appreciation to all the students and classroom instructors who have provided us with helpful suggestions. We also thank the many contributors who have, over the last several editions, provided us with extraordinary insights and useful features that we have added to our textbook.

Dan Matusiak and Izak Paul helped us produce our word lists. This was a huge task, and we appreciate their help. Paul Krieger helped us design the *Clear View of the Human Body*, for which we are grateful. Thanks to Betsy Brantley, who contributed many of the case studies found in this edition. Thanks also to Jean Proehl, Monteo Myers, Mark Alderman, Dominic Steward, Craig Huard, and Christina Zaleski for their insights in the Career Choices boxes.

Kevin Petti served as Lead Consultant, helping to improve our art program and providing valuable insights and analysis of content and approach during several stages of revision.

To those at Elsevier who put their best efforts into producing this edition, we are indebted. This new edition, and its ever-expanding library of ancillary resources, would not have been possible without the efforts of Becky Swisher, our Content Manager, and Kellie White, Executive Content Strategist. In addition, we are grateful to Tom Wilhelm, Executive Publisher, and Sally Schrefer, Executive Vice President, for their continuing guidance and support. And where the rubber meets the road, we were fortunate to have a wonderful team of professionals working with us to keep it all on track and moving along: Emily Thomson, Content Coordinator; Deborah Vogel, Publishing Services Manager; and John Gabbert, Project Manager. We are also grateful to our friends at Electronic Publishing Services Inc., who helped us develop and implement our integrated design, layout, and art program.

Kevin T. Patton
Gary A. Thibodeau

Contents

UNIT ONE The Body as a Whole, 1

INTRODUCTION Seeing the Big Picture, 2

CHAPTER 1 Organization of the Body, 3

- Science and Society, 4
- Anatomy and Physiology, 5
  - Anatomy, 5
  - Physiology, 5
- Language of Science and Medicine, 5
- Characteristics of Life, 6
- Levels of Organization, 7
  - Chemical Level—Basis for Life, 7
  - Organelle Level, 8
  - Cellular Level, 8
  - Tissue Level, 8
  - Organ Level, 8
  - System Level, 8
  - Organism Level, 9
- Anatomical Position, 10
- Body Cavities, 10
- Body Regions, 12
  - Abdominal Regions, 14
  - Abdominopelvic Quadrants, 14
- Terms Used in Describing Body Structure, 15
  - Directional Terms, 15
  - Terms Related to Organs, 15
- Body Planes and Sections, 15
- Interaction of Structure and Function, 17
- Homeostasis, 18
- Homeostatic Control Mechanisms, 20
  - Basic Components of Control Mechanisms, 20
  - Negative Feedback Control Systems, 21
  - Positive Feedback Control Systems, 22
  - Feed-Forward in Control Systems, 22
  - Levels of Control, 23
  - Summary of Homeostasis, 24
- Cycle of Life: Life Span Considerations, 24
- The Big Picture: Organization of the Body, 24
- Mechanisms of Disease, 25
- Case Study, 29

CHAPTER 2 The Chemical Basis of Life, 33

- Basic Chemistry, 34
  - Elements and Compounds, 34
  - Atoms, 36
  - Attractions Between Atoms—Chemical Bonds, 38
  - Attractions Between Molecules, 39
  - Chemical Reactions, 40
- Metabolism, 41
  - Catabolism, 41
  - Anabolism, 42
- Organic and Inorganic Compounds, 42
- Inorganic Molecules, 42
  - Water, 42
  - Oxygen and Carbon Dioxide, 43
  - Electrolytes, 44
- Organic Molecules, 45
  - Carbohydrates, 46
  - Lipids, 48
  - Proteins, 51
  - Nucleic Acids and Related Molecules, 55
  - Combined Forms, 59
- The Big Picture: The Chemical Basis of Life, 59
- Mechanisms of Disease, 60
- Case Study, 61

CHAPTER 3 Anatomy of Cells, 66

- Functional Anatomy of Cells, 67
  - The Typical Cell, 67
  - Cell Structures, 68
- Cell Membranes, 70
  - Membrane Structure, 70
  - Membrane Function, 72
- Cytoplasm and Organelles, 73
  - Endoplasmic Reticulum (ER), 73
  - Ribosomes, 74
  - Golgi Apparatus, 74
  - Lysosomes, 76
  - Proteasomes, 76
  - Peroxisomes, 76
  - Mitochondria, 77
- Nucleus, 78
- Cytoskeleton, 79
  - Cell Fibers, 79
  - Centrosome, 81
  - Molecular Motors, 81
  - Cell Extensions, 82
- Cell Connections, 83

The Big Picture: Cell Anatomy and the Whole Body, 84
Mechanisms of Disease, 85
Case Study, 85

CHAPTER 4 Physiology of Cells, 90
Movement of Substances Through Cell Membranes, 91
Passive Transport Processes, 91
Active Transport Processes, 97
Cell Metabolism, 102
Role of Enzymes, 102
Catabolism, 105
Anabolism, 108
The Big Picture: Cell Physiology and the Whole Body, 108
Mechanisms of Disease, 108
Case Study, 110

CHAPTER 5 Cell Growth and Reproduction, 113
Protein Synthesis, 114
Deoxyribonucleic Acid (DNA), 114
Ribonucleic Acid (RNA), 115
Transcription, 116
Editing The Transcript, 116
Translation, 117
Cell Growth, 121
Production of Cytoplasm, 121
DNA Replication, 122
Cell Reproduction, 123
Mitosis, 123
Meiosis, 124
Regulating the Cell Life Cycle, 125
Cycle of Life: Cells, 127
The Big Picture: Cell Growth, Reproduction, and the Whole Body, 127
Mechanisms of Disease, 127

CHAPTER 6 Tissues, 131
Introduction to Tissues, 132
Principal Types of Tissue, 132
Extracellular Matrix, 134
Epithelial Tissue, 135
Types and Locations of Epithelial Tissue, 135
Functions of Epithelial Tissue, 135
Generalizations About Epithelial Tissue, 135
Classification of Epithelial Tissue, 137
Connective Tissue, 143
Functions of Connective Tissue, 143
Characteristics of Connective Tissue, 143
Classification of Connective Tissue, 144
Fibrous Connective Tissue, 145
Bone Tissue, 149
Cartilage Tissue, 151
Blood Tissue, 152
Muscle Tissue, 152
Nervous Tissue, 154
Tissue Repair, 154
Body Membranes, 155
Epithelial Membranes, 156
Connective Tissue Membranes, 157
The Big Picture: Tissues, Membranes, and the Whole Body, 158
Mechanisms of Disease, 158
Case Study, 162

UNIT TWO Support and Movement, 169

CHAPTER 7 Skin and Its Appendages, 170
Structure of the Skin, 171
Thin and Thick Skin, 172
Epidermis, 173
Dermoepidermal Junction, 176
Dermis, 176
Hypodermis, 178
Skin Color, 178
Melanin, 178
Other Pigments, 180
Functions of the Skin, 181
Protection, 181
Sensation, 182
Flexibility, 182
Excretion, 182
Hormone (Vitamin D) Production, 182
Immunity, 182
Homeostasis of Body Temperature, 182
Appendages of the Skin, 185
Hair, 185
Nails, 186
Skin Glands, 187
Cycle of Life: Skin, 188
The Big Picture: Skin and the Whole Body, 189
Mechanisms of Disease, 189
Case Study, 195

CHAPTER 8 Skeletal Tissues, 199
Functions of Bone, 200
Types of Bones, 200
Parts of a Long Bone, 202
Parts of a Flat Bones and Other Bones, 203
Bone Tissue, 203
Composition of Bone Matrix, 203
Microscopic Structure of Bone, 204
Compact Bone, 204
Cancellous Bone, 206
Types of Bone Cells, 206
Bone Marrow, 207
Regulation of Blood Calcium Levels, 208
Mechanisms of Calcium Homeostasis, 208
Development of Bone, 209
Intramembranous Ossification, 209
Endochondral Ossification, 210
Bone Remodeling, 212

Repair of Bone Fractures, 213
Cartilage, 214
Types of Cartilage, 214
Function of Cartilage, 215
Growth of Cartilage, 215
Cycle of Life: Skeletal Tissues, 216
The Big Picture: Skeletal Tissues, 216
Mechanisms of Disease, 216
Case Study, 219

CHAPTER 9 Skeletal System, 223
Divisions of the Skeleton, 224
Axial Skeleton, 226
Skull, 226
Hyoid Bone, 243
Vertebral Column, 245
Sternum, 248
Ribs, 248
Appendicular Skeleton, 250
Upper Extremity, 250
Lower Extremity, 255
Skeletal Differences Between Men and Women, 261
Cycle of Life: Skeletal System, 262
The Big Picture: Skeletal System, 263
Mechanisms of Disease, 263
Case Study, 267

CHAPTER 10 Articulations, 271
Classification of Joints, 272
Fibrous Joints (Synarthroses), 272
Cartilaginous Joints (Amphiarthroses), 272
Synovial Joints (Diarthroses), 274
Representative Synovial Joints, 277
Humeroscapular Joint, 277
Elbow Joint, 278
Forearm, Wrist, Hand, and Finger Joints, 279
Hip Joint, 281
Knee Joint, 281
Ankle Joint, 283
Vertebral Joints, 285
Types and Range of Movement at Synovial Joints, 286
Measuring Range of Motion, 286
Angular Movements, 291
Circular Movements, 291
Gliding Movements, 292
Special Movements, 292
Cycle of Life: Articulations, 292
The Big Picture: Articulations, 292
Mechanisms of Disease, 293
Case Study, 297

CHAPTER 11 Anatomy of the Muscular System, 301
Skeletal Muscle Structure, 302
Connective Tissue Components, 302
Size, Shape, and Fiber Arrangement, 304
Attachment of Muscles, 305
Muscle Actions, 305
Lever Systems, 306
How Muscles Are Named, 308
Hints on How to Deduce Muscle Actions, 311
Important Skeletal Muscles, 311
Muscles of Facial Expression, 312
Muscles of Mastication, 313
Muscles That Move the Head, 314
Trunk Muscles, 315
Muscles of the Thorax, 315
Muscles of the Abdominal Wall, 316
Muscles of the Back, 318
Muscles of the Pelvic Floor, 320
Upper Limb Muscles, 322
Muscles Acting on the Shoulder Girdle, 322
Muscles That Move the Upper Arm, 325
Muscles That Move the Forearm, 326
Muscles That Move the Wrist, Hand, and Fingers, 329
Lower Limb Muscles, 333
Muscles That Move the Thigh and Lower Leg, 333
Muscles That Move the Ankle and Foot, 340
Posture, 341
How Posture Is Maintained, 341
Cycle of Life: Muscular System, 342
The Big Picture: Skeletal Muscles and the Whole Body, 342
Case Study, 344

CHAPTER 12 Physiology of the Muscular System, 347
General Functions, 348
Function of Skeletal Muscle Tissue, 348
Overview of the Muscle Cell, 348
Myofilaments, 352
Mechanism of Contraction, 352
Energy Sources for Muscle Contraction, 356
Function of Skeletal Muscle Organs, 360
Motor Unit, 360
Myography, 361
The Twitch Contraction, 361
Treppe: The Staircase Phenomenon, 362
Tetanus, 362
Muscle Tone, 363
The Graded Strength Principle, 364
Isotonic and Isometric Contractions, 366
Function of Cardiac and Smooth Muscle Tissue, 368
Cardiac Muscle, 368
Smooth Muscle, 369
The Big Picture: Muscle Tissue and the Whole Body, 371
Mechanisms of Disease, 372
Case Study, 374

UNIT THREE Communication, Control, and Integration, 379

CHAPTER 13 Nervous System Cells, 380
Organization of the Nervous System, 382
Central and Peripheral Nervous Systems, 382
Afferent and Efferent Divisions, 383
Somatic and Autonomic Nervous Systems, 383

Cells of the Nervous System, 383
Glia, 383
Neurons, 387
Classification of Neurons, 390
Reflex Arc, 391
Nerves and Tracts, 392
Repair of Nerve Fibers, 392
Nerve Impulses, 393
Membrane Potentials, 393
Resting Membrane Potentials, 394
Local Potentials, 395
Action Potential, 395
Refractory Period, 397
Conduction of the Action Potential, 398
Synaptic Transmission, 399
Structure of the Synapse, 399
Types of Synapses, 399
Mechanisms of Synaptic Transmission, 401
Summation, 403
Synapses and Memory, 404
Neurotransmitters, 404
Classification of Neurotransmitters, 404
Acetylcholine, 406
Amines, 406
Amino Acids, 408
Other Small-Molecule Transmitters, 408
Neuropeptides, 408
Role of Nervous System Cells, 410
Cycle of Life: Nervous System Cells, 411
The Big Picture: Nervous System Cells and the Whole Body, 411
Mechanisms of Disease, 411
Case Study, 414

CHAPTER 14 Central Nervous System, 420
Coverings of the Brain and Spinal Cord, 421
Cerebrospinal Fluid, 424
Fluid Spaces, 424
Formation and Circulation of Cerebrospinal Fluid, 424
Spinal Cord, 426
Structure of the Spinal Cord, 426
Functions of the Spinal Cord, 427
Brain, 429
Structure of the Brainstem, 429
Functions of the Brainstem, 432
Structure of the Cerebellum, 432
Functions of the Cerebellum, 433
Diencephalon, 434
Structure of the Cerebrum, 437
Functions of the Cerebral Cortex, 440
Consciousness, 443
Language, 444
Emotions, 444
Memory, 445
Somatic Sensory Pathways in the Central Nervous System, 448
Somatic Motor Pathways in the Central Nervous System, 449
Pyramidal Tracts, 450
Extrapyramidal Tracts, 450
Cycle of Life: Central Nervous System, 451
The Big Picture: The Central Nervous System and the Whole Body, 452
Mechanisms of Disease, 452
Case Study, 456

CHAPTER 15 Peripheral Nervous System, 463
Spinal Nerves, 464
Structure of Spinal Nerves, 466
Nerve Plexuses, 466
Dermatomes and Myotomes, 472
Cranial Nerves, 473
Olfactory Nerve (I), 474
Optic Nerve (II), 474
Oculomotor Nerve (III), 474
Trochlear Nerve (IV), 474
Trigeminal Nerve (V), 476
Abducens Nerve (VI), 477
Facial Nerve (VII), 477
Vestibulocochlear Nerve (VIII), 478
Glossopharyngeal Nerve (IX), 479
Vagus Nerve (X), 479
Accessory Nerve (XI), 480
Hypoglossal Nerve (XII), 480
Somatic Motor Nervous System, 481
Divisions of the Peripheral Nervous System, 481
The Big Picture: Peripheral Nervous System and the Whole Body, 483
Case Study, 484

CHAPTER 16 Autonomic Nervous System, 488
Overview of the Autonomic Nervous System, 489
Role of the Autonomic Nervous System, 489
Divisions of the Autonomic Nervous System, 490
Structure of the Autonomic Nervous System, 490
Basic Plan of Autonomic Pathways, 490
Structure of the Sympathetic Pathways, 490
Structure of the Parasympathetic Pathways, 492
Autonomic Neurotransmitters and Receptors, 494
Functions of the Autonomic Nervous System, 498
Overview of Autonomic Function, 498
Functions of the Sympathetic Division, 499
Functions of the Parasympathetic Division, 501
The Big Picture: Autonomic Nervous System and the Whole Body, 501
Case Study, 502

CHAPTER 17 Sense Organs, 505
Sensory Receptors, 506
Receptor Response, 506
Distribution of Receptors, 506
Classification of Receptors, 507
Classification by Location, 507
Classification by Stimulus Detected, 507
Classification by Structure, 507
Sense of Smell, 513

Olfactory Receptors, 513
Olfactory Pathway, 515
Sense of Taste, 516
Taste Buds, 516
Neural Pathway for Taste, 517
Senses of Hearing and Balance: The Ear, 517
External Ear, 518
Middle Ear, 519
Inner Ear, 519
Vision: The Eye, 524
Structure of the Eye, 524
The Process of Seeing, 529
Cycle of Life: Sense Organs, 534
The Big Picture: Sense Organs, 534
Mechanisms of Disease, 534
Case Study, 539

CHAPTER 18 Endocrine System, 545
Organization of the Endocrine System, 546
Hormones, 547
Classification of Hormones, 547
How Hormones Work, 550
Regulation of Hormone Secretion, 553
Regulation of Target Cell Sensitivity, 555
Prostaglandins, 556
The Big Picture: The Endocrine System and the Whole Body, 569
Mechanisms of Disease, 569
Case Study, 573

CHAPTER 19 Endocrine Glands, 563
Pituitary Gland, 564
Structure of the Pituitary Gland, 564
Adenohypophysis (Anterior Lobe of Pituitary), 564
Neurohypophysis (Posterior Lobe of Pituitary), 570
Pineal Gland, 571
Thyroid Gland, 572
Structure of the Thyroid Gland, 572
Thyroid Hormone, 572
Calcitonin, 574
Parathyroid Glands, 575
Structure of the Parathyroid Glands, 575
Parathyroid Hormone, 576
Adrenal Glands, 577
Structure of the Adrenal Glands, 577
Adrenal Cortex, 578
Adrenal Medulla, 580
Pancreatic Islet, 580
Structure of the Pancreatic Islets, 580
Pancreatic Hormones, 582
Gonads, 584
Testes, 584
Ovaries, 585
Placenta, 585
Thymus, 585
Gastric and Intestinal Mucosa, 586
Heart, 586
Other Endocrine Glands and Hormones, 586
Cycle of Life: Endocrine System, 586
The Big Picture: The Endocrine System and the Whole Body, 587
Mechanisms of Disease, 587
Case Study, 590

UNIT FOUR Transportation and Defense, 597

CHAPTER 20 Blood, 598
Composition of Blood, 599
Blood Volume, 599
Formed Elements of Blood, 600
Red Blood Cells (Erythrocytes), 601
White Blood Cells (Leukocytes), 605
Platelets, 608
Blood Types (Blood Groups), 609
The ABO System, 609
The Rh System, 610
Blood Plasma, 613
Blood Clotting (Coagulation), 613
Mechanism of Blood Clotting, 614
Conditions That Oppose Clotting, 617
Conditions That Hasten Clotting, 617
Clot Dissolution, 618
The Big Picture: Blood and the Whole Body, 619
Mechanisms of Disease, 619
Case Study, 625

CHAPTER 21 Anatomy of the Cardiovascular System, 629
Heart, 630
Location of the Heart, 630
Size and Shape of the Heart, 630
Coverings of the Heart, 634
Structure of the Heart, 635
Blood Vessel Types, 642
Arteries, 642
Capillaries, 644
Veins, 645
Structure of Blood Vessels, 645
Major Blood Vessels, 647
Circulatory Routes, 647
Systemic Circulation, 648
Cycle of Life: Cardiovascular Anatomy, 669
The Big Picture: Cardiovascular Anatomy and the Whole Body, 669
Mechanisms of Disease, 669
Case Study, 676

CHAPTER 22 Physiology of the Cardiovascular System, 681
Hemodynamics, 682
The Heart as a Pump, 683
Conduction System of the Heart, 683
Electrocardiogram (ECG), 684
Cardiac Cycle, 687
Heart Sounds, 689

Primary Principle of Circulation, 690
Arterial Blood Pressure, 691
Cardiac Output, 691
Peripheral Resistance, 695
Venous Return to the Heart, 701
Venous Pumps, 701
Total Blood Volume, 702
Measuring Blood Pressure, 705
Arterial Blood Pressure, 705
Blood Pressure and Bleeding, 707
Minute Volume of Blood, 707
Velocity of Blood Flow, 708
Pulse, 709
Mechanism, 709
Pulse Wave, 709
Where the Pulse Can Be Felt, 710
Venous Pulse, 711
Cycle of Life: Cardiovascular Physiology, 711
The Big Picture: Blood Flow and the Whole Body, 712
Mechanisms of Disease, 712
Case Study, 716

CHAPTER 23 Lymphatic System, 722
Overview of the Lymphatic System, 723
Lymph and Interstitial Fluid, 724
Lymphatic Vessels, 724
Distribution of Lymphatic Vessels, 724
Structure of Lymphatic Vessels, 725
Functions of Lymphatic Vessels, 725
Circulation of Lymph, 726
The Lymphatic Pump, 727
Lymph Nodes, 728
Structure of Lymph Nodes, 728
Locations of Lymph Nodes, 729
Functions of Lymph Nodes, 730
Lymphatic Drainage of the Breast, 732
Distribution of Lymphatics in the Breast, 732
Lymph Nodes Associated with the Breast, 733
Tonsils, 733
Thymus, 734
Location and Appearance of the Thymus, 734
Structure of the Thymus, 734
Function of the Thymus, 734
Spleen, 735
Location of the Spleen, 735
Structure of the Spleen, 735
Functions of the Spleen, 735
Cycle of Life: Lymphatic System, 737
The Big Picture: Lymphatic System and the Whole Body, 737
Mechanisms of Disease, 738
Case Study, 741

CHAPTER 24 Immune System, 745
Organization of the Immune System, 746
Innate Immunity, 748
Species Resistance, 748
Mechanical and Chemical Barriers, 748
Inflammation and Fever, 749
Phagocytosis, 752
Natural Killer Cells, 753
Interferon, 755
Complement, 755
Toll-like Receptors, 755
Overview of Adaptive Immunity, 756
B Cells and Antibody-Mediated Immunity, 758
Development and Activation of B Cells, 758
Antibodies (Immunoglobulins), 758
Clonal Selection Theory, 764
T Cells and Cell-Mediated Immunity, 764
Development of T Cells, 764
Activation and Functions of T Cells, 764
Types of Adaptive Immunity, 768
Summary of Adaptive Immunity, 769
The Big Picture: Immune System and the Whole Body, 772
Mechanisms of Disease, 772
Case Study, 777

CHAPTER 25 Stress, 782
Selye's Concept of Stress, 783
Development of the Stress Concept, 783
Definitions, 784
Stressors, 784
General Adaptation Syndrome, 784
Mechanism of Stress, 786
Some Current Concepts About Stress, 788
Definitions, 788
Stress Syndrome, 788
Stress and Disease, 788
Indicators of Stress, 790
Corticoids and Resistance to Stress, 790
Psychological Stress, 790
Effects of Intrauterine Stress, 792
The Big Picture: Stress and the Whole Body, 793
Case Study, 794

UNIT FIVE Respiration, Nutrition, and Excretion, 797

CHAPTER 26 Anatomy of the Respiratory System, 798
Structural Plan of the Respiratory System, 799
Upper Respiratory Tract, 800
Nose, 800
Pharynx, 802
Larynx, 803
Lower Respiratory Tract, 807
Trachea, 807
Bronchi and Alveoli, 808
Lungs, 812
Thorax, 814
Cycle of Life: Respiratory System, 816
The Big Picture: Anatomy of the Respiratory System, 816
Mechanisms of Disease, 816
Case Study, 820

CHAPTER 27 Physiology of the Respiratory System, 823

Respiratory Physiology, 824
Pulmonary Ventilation, 824
- Mechanism of Pulmonary Ventilation, 824
- Pulmonary Volumes and Capacities, 831

Pulmonary Gas Exchange, 838
- Partial Pressure, 838
- Exchange of Gases in the Lungs, 839

How Blood Transports Gases, 841
- Hemoglobin, 842
- Transport of Oxygen, 842
- Transport of Carbon Dioxide, 844

Systemic Gas Exchange, 846
Regulation of Pulmonary Function, 848
- Respiratory Control Centers, 848
- Factors That Influence Breathing, 849
- Ventilation and Perfusion, 852

The Big Picture: Respiratory Physiology and the Whole Body, 853
Mechanisms of Disease, 854
Case Study, 857

CHAPTER 28 Anatomy of the Digestive System, 861

Organization of the Digestive System, 862
- Organs of Digestion, 862
- Wall of the GI Tract, 862

Mouth, 864
- Structure of the Oral Cavity, 864
- Salivary Glands, 867
- Teeth, 868

Pharynx, 870
Esophagus, 870
Stomach, 872
- Size and Position of the Stomach, 872
- Divisions of the Stomach, 872
- Curves of the Stomach, 872
- Sphincter Muscles, 872
- Stomach Wall, 873
- Functions of the Stomach, 874

Small Intestine, 875
- Size and Position of the Small Intestine, 875
- Divisions of the Small Intestine, 878
- Wall of the Small Intestine, 879

Large Intestine, 877
- Size of the Large Intestine, 877
- Divisions of the Large Intestine, 878
- Wall of the Large Intestine, 879

Vermiform Appendix, 879
Peritoneum, 880
Liver, 882
- Location and Size of the Liver, 882
- Liver Lobes and Lobules, 882
- Bile Ducts, 884
- Functions of the Liver, 884

Gallbladder, 885
- Size and Location of the Gallbladder, 885
- Structure of the Gallbladder, 885
- Functions of the Gallbladder, 885

Pancreas, 886
- Size and Location of the Pancreas, 886
- Structure of the Pancreas, 886
- Functions of the Pancreas, 886

Cycle of Life: Digestive System, 887
The Big Picture: Anatomy of the Digestive System, 888
Mechanisms of Disease, 888
Case Study, 897

CHAPTER 29 Physiology of the Digestive System, 901

Overview of Digestive Function, 902
Digestion, 904
- Mechanical Digestion, 904
- Chemical Digestion, 908

Secretion, 914
- Saliva, 914
- Gastric Juice, 914
- Pancreatic Juice, 916
- Bile, 916
- Intestinal Juice, 917

Control of Digestive Gland Secretion, 918
- Control of Salivary Secretion, 918
- Control of Gastric Secretion, 918
- Control of Pancreatic Secretion, 920
- Control of Bile Secretion, 920
- Control of Intestinal Secretion, 920

Absorption, 921
- Process of Absorption, 921
- Mechanisms of Absorption, 921

Elimination, 924
The Big Picture: Digestion and the Whole Body, 925
Case Study, 927

CHAPTER 30 Nutrition and Metabolism, 931

Overview of Nutrition and Metabolism, 932
Carbohydrates, 934
- Dietary Sources of Carbohydrates, 934
- Carbohydrate Metabolism, 934

Lipids, 946
- Dietary Sources of Lipids, 946
- Transport of Lipids, 947
- Lipid Metabolism, 947

Proteins, 948
- Sources of Proteins, 948
- Protein Metabolism, 949

Vitamins and Minerals, 952
- Vitamins, 952
- Minerals, 953

Metabolic Rates, 955
- Basal Metabolic Rate, 955
- Total Metabolic Rate, 958
- Energy Balance and Body Weight, 958

Mechanisms for Regulating Food Intake, 958

Cycle of Life: Nutrition and Metabolism, 960
The Big Picture: Nutrition, Metabolism, and the Whole Body, 960
Mechanisms of Disease, 961
Case Study, 965

CHAPTER 31 Urinary System, 970

Anatomy of the Urinary System, 971
Gross Structure, 971
Microscopic Structure, 976
Physiology of the Urinary System, 982
Overview of Kidney Function, 982
Filtration, 982
Reabsorption, 984
Tubular Secretion, 989
Regulation of Urine Volume, 989
Urine Composition, 992
Cycle of Life: Urinary System, 993
The Big Picture: Urinary System and the Whole Body, 993
Mechanisms of Disease, 994
Case Study, 999

CHAPTER 32 Fluid and Electrolyte Balance, 1003

Interrelationship of Fluid and Electrolyte Balance, 1004
Total Body Water, 1004
Body Fluid Compartments, 1005
Chemical Content, Distribution, and Measurement of Electrolytes in Body Fluids, 1005
Extracellular vs. Intracellular Fluids, 1006
Measuring Electrolyte Reactivity, 1007
Avenues by Which Water Enters and Leaves the Body, 1009
Some General Principles About Fluid Balance, 1009
Mechanisms That Maintain Homeostasis of Total Fluid Volume, 1010
Regulation of Fluid Intake, 1010
Regulation of Urine Volume, 1010
Factors That Alter Fluid Loss Under Abnormal Conditions, 1012
Regulation of Water and Electrolyte Levels in Plasma and Interstitial Fluid, 1012
Edema, 1015
Regulation of Water and Electrolyte Levels in ICF, 1016
Regulation of Sodium and Potassium Levels in Body Fluids, 1017
Cycle of Life: Fluid and Electrolyte Balance, 1018
The Big Picture: Fluid and Electrolyte Balance, 1019
Mechanisms of Disease, 1019
Case Study, 1021

CHAPTER 33 Acid-Base Balance, 1025

Mechanisms That Control pH of Body Fluids, 1025
Review of the pH Concept, 1025
Sources of pH-Influencing Elements, 1027
Types of pH Control Mechanisms, 1027
Effectiveness of pH Control Mechanisms—Range of pH, 1028
Buffer Mechanisms for Controlling pH of Body Fluids, 1028
Buffers Defined, 1028
Buffer Pairs Present in Body Fluids, 1028
Buffer Actions That Prevent Marked Changes in pH of Body Fluids, 1028
Evaluation of the Role of Buffers in pH Control, 1032
Respiratory Mechanisms of pH Control, 1032
Explanation of Respiratory Mechanisms, 1032
Respirations' Adjustment to Counter pH Imbalance of Arterial Blood, 1032
Principles That Relate Respirations to pH Value, 1032
Urinary Mechanisms That Control pH, 1032
General Principles Concerning Urinary Mechanisms, 1033
Mechanisms That Control Urine pH, 1034
The Big Picture: Acid-Base Balance, 1036
Mechanisms of Disease, 1036
Case Study, 1039

UNIT SIX Reproduction and Development, 1043

CHAPTER 34 Male Reproductive System, 1044

Sexual Reproduction, 1045
Male Reproductive Organs, 1045
Perineum, 1046
Testes, 1046
Structure and Location, 1046
Microscopic Anatomy of the Testis, 1047
Testes Functions, 1048
Spermatozoa, 1050
Reproductive Ducts, 1051
Epididymis, 1051
Vas Deferens, 1051
Ejaculatory Duct, 1052
Urethra, 1052
Accessory Reproductive Glands, 1053
Seminal Vesicles, 1053
Prostate Gland, 1053
Bulbourethral Glands, 1054
Supporting Structures, 1054
Scrotum, 1054
Penis, 1054
Spermatic Cords, 1055
Composition and Course of Seminal Fluid, 1055
Male Fertility, 1055
Cycle of Life: Male Reproductive System, 1056
The Big Picture: Male Reproductive System, 1057
Mechanisms of Disease, 1057
Case Study, 1059

CHAPTER 35 Female Reproductive System, 1063

Overview of the Female Reproductive System, 1064
- Function of the Female Reproductive System, 1064
- Structural Plan of the Female Reproductive System, 1064
- Perineum, 1065

Ovaries, 1066
- Location of the Ovaries, 1066
- Microscopic Structure of the Ovaries, 1066
- Functions of the Ovaries, 1068

Uterus, 1068
- Structure of the Uterus, 1068
- Functions of the Uterus, 1070

Uterine Tubes, 1070
- Location of the Uterine Tubes, 1070
- Structure of the Uterine Tubes, 1070
- Function of the Uterine Tubes, 1071

Vagina, 1071
- Location of the Vagina, 1071
- Structure of the Vagina, 1072
- Functions of the Vagina, 1072

Vulva, 1072
- Structure of the Vulva, 1072
- Functions of the Vulva, 1074

Female Reproductive Cycles, 1074
- Recurring Cycles, 1074
- Control of Female Reproductive Cycles, 1076
- Importance of Female Reproductive Cycles, 1079
- Infertility and Use of Fertility Drugs, 1081
- Menarche and Menopause, 1081

Breasts, 1082
- Location and Size of the Breasts, 1082
- Structure of the Breasts, 1082
- Function of the Breasts, 1084

Cycle of Life: Female Reproductive System, 1085

The Big Picture: Female Reproductive System and the Whole Body, 1086

Mechanisms of Disease, 1086

Case Study, 1092

CHAPTER 36 Growth and Development, 1096

A New Human Life, 1097
- Production of Sex Cells, 1097
- Ovulation and Insemination, 1101
- Fertilization, 1101

Prenatal Period, 1103
- Cleavage and Implantation, 1103
- Placenta, 1105
- Periods of Development, 1107
- Stem Cells, 1110
- Formation of the Primary Germ Layers, 1111
- Histogenesis and Organogenesis, 1111
- Birth, or Parturition, 1114
- Stages of Labor, 1115
- Multiple Births, 1115

Postnatal Period, 1116
- Infancy, 1116
- Childhood, 1117
- Adolescence and Adulthood, 1118
- Older Adulthood and Senescence, 1118

Effects of Aging, 1120
- Skeletal System, 1120
- Muscular System, 1120
- Integumentary System (Skin), 1120
- Urinary System, 1121
- Respiratory System, 1121
- Cardiovascular System, 1122
- Special Senses, 1122
- Reproductive Systems, 1122
- Benefits of Aging, 1122

Causes of Death, 1122

The Big Picture: Growth, Development, and the Whole Body, 1123

Mechanisms of Disease, 1124

Case Study, 1126

CHAPTER 37 Genetics and Heredity, 1131

The Science of Genetics, 1132

Chromosomes and Genes, 1132
- Mechanism of Gene Function, 1132
- The Human Genome, 1133
- Distribution of Chromosomes to Offspring, 1135

Gene Expression, 1136
- Hereditary Traits, 1136
- Sex-Linked Traits, 1138
- Genetic Mutations, 1140

Medical Genetics, 1141
- Mechanisms of Genetic Diseases, 1141
- Single-Gene Diseases, 1142
- Chromosomal Diseases, 1144
- Genetic Basis of Cancer, 1145

Prevention and Treatment of Genetic Diseases, 1146
- Genetic Counseling, 1146
- Treating Genetic Diseases, 1148

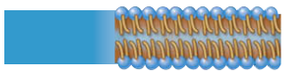
The Big Picture: Genetics, Heredity, and the Whole Body, 1149

Case Study, 1151

Glossary, G-1

Index, I-1

Color Key



BIOCHEMISTRY

- C — Carbon
- Cl — Chloride
- Energy — Energy
- ATP — ATP
- H — Hydrogen
- N — Nitrogen
- O — Oxygen
- K — Potassium
- Na — Sodium
- S — Sulfur
- Ca — Calcium
- P — Organic Phosphate
- P_i — Inorganic Phosphate
- A — Alanine
- R — Arginine
- N — Asparagine
- D — Aspartic Acid
- C — Cysteine
- G — Glycine
- E — Glutamic Acid
- Q — Glutamine
- H — Histidine
- I — Isoleucine
- L — Leucine
- K — Lysine
- M — Methionine
- F — Phenylalanine
- P — Proline
- U — Selenocysteine
- S — Serine
- T — Threonine
- W — Tryptophan
- Y — Tyrosine
- V — Valine
- H_2O — Water
- Hormone
- Enzyme
- Protein
- Carbohydrate
- Fatty acid
- DNA, Nucleic Acid
- RNA
- C — Cytosine
- A — Adenine
- G — Guanine
- T — Thymine / Uracil
- Chromosome

CELLULAR STRUCTURES

Cytosol

Extracellular Fluid

Plasma Membrane

Nucleus

Golgi Apparatus

Mitochondrion

Endoplasmic Reticulum

Ribosome

Centrioles

Microtubule

Intermediate Filament

Microfilament

Actin / Thin Filament

Myosin / Thick Filament

Na^+ Channel

OTHER STRUCTURES

Artery

Vein

Capillary

Bone

Wexler, PhD, Columbia University.

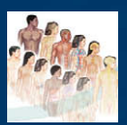
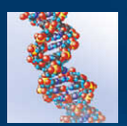
Unit One



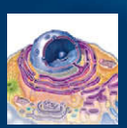
The Body as a Whole

The six chapters in Unit One "set the stage" for the study of human anatomy and physiology. They provide the unifying information required to understand the "connectedness" of human structure and function. They will help you understand how organized anatomical structures of a particular size, shape, form, or placement serve important functions. The illustration that opens this unit shows the body not as a jumble of isolated parts but as an integrated whole.

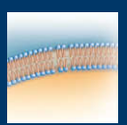


In Chapter 1 the concept of levels of organization in the body is presented, and the unifying theme of homeostasis is introduced to explain how the interaction of structure and function at chemical, organelle, cellular, tissue, organ, and system levels is achieved and maintained by dynamic counterbalancing forces within the body. The material presented in Chapter 2—The Chemical Basis of Life—provides an understanding of the basic chemical interactions that influence the control, integration, and regulation of these counterbalancing forces in every organ system of the body.

Unit One concludes with information that builds on the organizational and biochemical information presented in the first two chapters. The structure and function of cells presented in Chapters 3, 4, and 5 explain why physiologists often state that "all body functions are cellular functions." Grouping similar cells into functioning tissues is accomplished in Chapter 6. Subsequent chapters of the text focus on the remaining organ systems of the body.

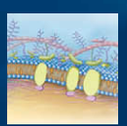


SEEING THE BIG PICTURE



1 **Organization of the Body, 3**

2 **The Chemical Basis of Life, 33**



3 **Anatomy of Cells, 66**

4 **Physiology of Cells, 90**

5 **Cell Growth and Reproduction, 113**

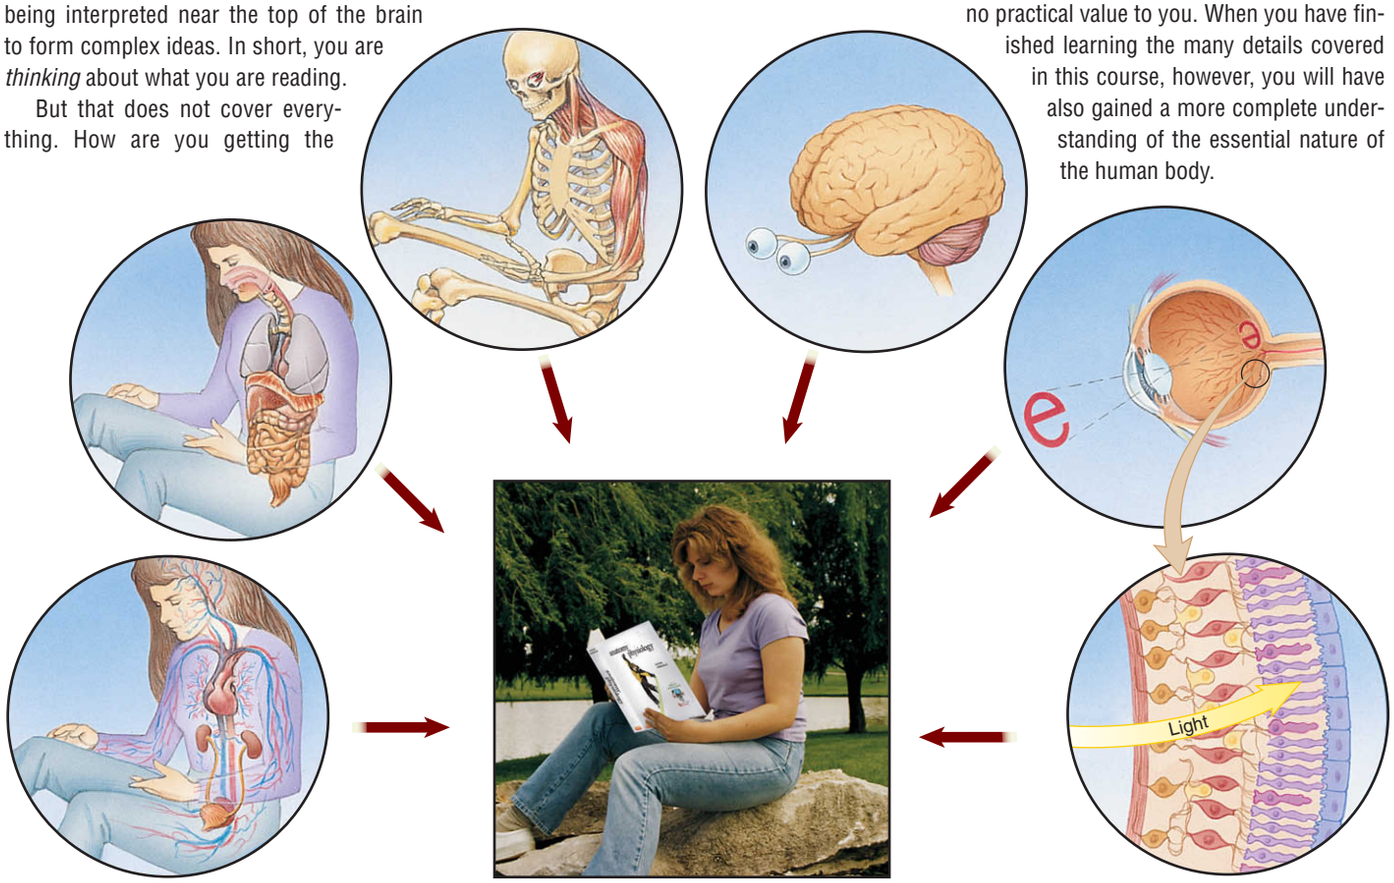
6 **Tissues, 131**

the BIG picture

Seeing the BIG picture

Before reading this introduction, you probably spent a few minutes flipping through this book. Naturally, you are curious about your course in human anatomy and physiology, and you wanted to see what lies ahead. It is more than that. You are curious about the human body—about yourself, really. We all have that desire to learn more about how our bodies are put together and how all the parts work. Unlike many other people, though, you now have the opportunity to gain an understanding of the underlying scientific principles of human structure and function.

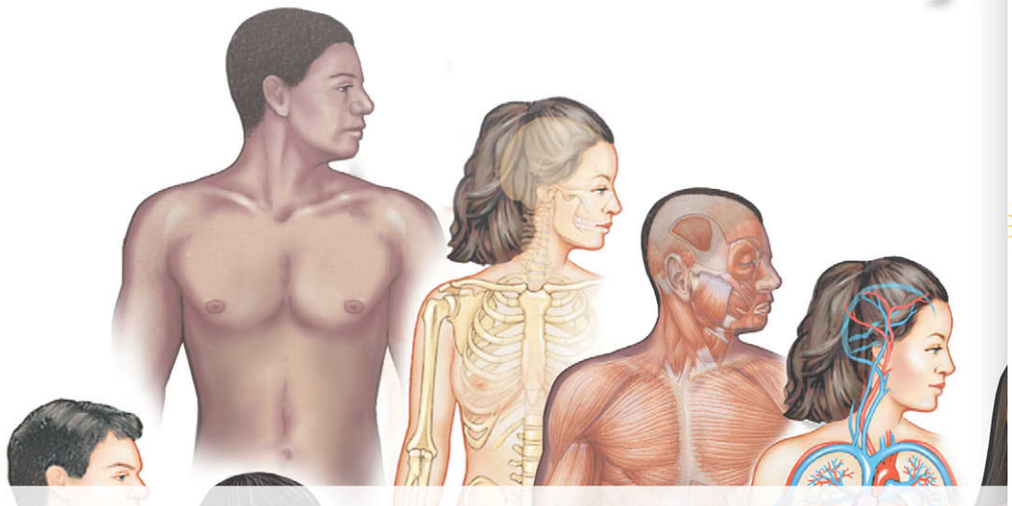
To truly understand the nature of the human body requires an ability to appreciate "the parts" and "the whole" at the same time. As you flipped through this book for the first time, you probably looked at many different body parts. Some were microscopic—such as muscle cells—and some were very large—such as arms and legs. In looking at these parts, however, you gained very little insight about how they worked together to allow you to sit here, alive and breathing, and read and comprehend these words.



Think about it for a moment. What does it take to be able to read these words and understand them? You might begin by thinking about the eye. How do all of its many intricate parts work together to form an image? The eye is not the only organ you are using right now. What about the bones, joints, and muscles you are using to hold the book, to turn the pages, and to move your eyes as they scan this paragraph? Let's not forget the nervous system. The brain, spinal cord, and nerves are receiving information from the eyes, evaluating it, and using it to coordinate the muscle movements. The squiggles we call letters are being interpreted near the top of the brain to form complex ideas. In short, you are *thinking* about what you are reading.

But that does not cover everything. How are you getting the energy to operate your eyes, muscles, brain, and nerves? Energetic chemical reactions inside each cell of these organs require oxygen and nutrients captured by the lungs and digestive tract and delivered by the heart and blood vessels. These chemical reactions produce wastes that are handled by the liver, kidneys, and other organs. All these functions must be coordinated, a feat accomplished by regulation of body organs by hormones, nerves, and other mechanisms.

Learning to name the various body parts, to describe their detailed structure, and to explain the mechanisms that produce their functions is an essential step that leads to the goal of understanding the human body. To actually reach that goal, however, you must be able to draw together isolated facts and concepts. In other words, understanding the nature of individual body parts becomes more meaningful when you understand how the parts work together in a living, whole person.



Many textbooks are written like reference books—dictionaries, for example. They provide detailed descriptions of the structure and function of individual body parts, often in logical groupings, while rarely stopping to step back and look at the whole person. In this book, however, we have incorporated the "whole body" aspect into the discussion of every major topic. In chapter and unit introductions, in appropriate paragraphs within each section, and in specific sections near the end of each chapter, we have stepped back from the topic at hand and refocused attention to the broader view.

We are confident that the "whole body" approach will help you put each new fact or concept you learn into its proper place within a larger framework of understanding. You may also better appreciate why it is important to learn some detailed facts that may at first seem to have no practical value to you. When you have finished learning the many details covered in this course, however, you will have also gained a more complete understanding of the essential nature of the human body.

Organization of the Body

You have just begun the study of one of nature's most wondrous structures—the human body. ***Anatomy*** *(ah-NAT-o-mee) and* ***physiology*** *(fiz-ee-OL-o-jee) are branches of biology that are concerned with the form and functions of the body. Anatomy is the study of body structure, whereas physiology deals with body function. As you learn about the complex interdependence of structure and function in the human body, you become, in a very real sense, the subject of your own study.*

Regardless of your field of study or your future career goals, acquiring and using information about your body structure and functions will enable you to live a more knowledgeable, involved, and healthy life in this science-conscious age. Your study of anatomy and physiology provides a unique and fascinating understanding of self, and this knowledge allows for more active and informed participation in your own personal health care decisions. If you are pursuing a health or science-related athletic career, your study of anatomy and physiology takes on added significance. It provides the necessary concepts you will need to understand your professional courses and succeed in clinical experiences.

SCIENCE AND SOCIETY

Before we get to the details, we should emphasize that everything you will read in this book is in the context of a broad field of inquiry called *science*. Science is a style of inquiry that attempts to understand nature in a rational, logical manner. Using detailed observations and vigorous tests, or *experiments*, scientists winnow out each element of an idea or **hypothesis** (hye-POTH-eh-sis) until a reasonable conclusion about its validity can be made. Rigorous experiments that eliminate any influences or biases not being directly tested are called *controlled experiments*. If the results of observations and experiments are repeatable, they may verify a hypothesis and eventually lead to enough confidence in the concept to call it a *theory*. Theories in which scientists have an unusually high level of confidence are sometimes called *laws*. Experiments may disprove a hypothesis, a result that often leads to the formation of new hypotheses (hye-POTH-eh-seez) to be tested.

Figure 1-1 summarizes some of the basic concepts of how new scientific principles are developed. As you can see, science is a dynamic process of getting closer and closer to the truth about nature, including the nature of the human body. Science is definitely not a set of unchanging facts as many people in our culture often assume.

We should also take this opportunity to point out the social and cultural context of the science presented in this book. Scientists drive the process of science, but our culture drives the kinds of questions we ask about nature and how we attempt to answer them. For example, cutting apart human *cadavers* (dead bodies) for the purpose of studying them has not always been an acceptable activity in all cultures. Today the debate faced by our culture concerns the acceptability of using live animals in scientific experiments. Because our culture does not condone most experiments involving living humans, we have until now often conducted testing on animals that are similar to humans. In fact, most of the theories presented in this book are based on animal experimentation, but cultural influences now are pulling scientists in other experimental directions they otherwise may not have taken.

Similarly, science affects culture. Recent advances in understanding human genes and technological advances in our ability to use so-called "stem cells" and other tissues from human embryos, human cadavers, and living donors to treat devastating diseases have sparked new debates concerning how our culture defines what it means to be a human being.

As you study the concepts presented in this book, keep in mind that they are not set in stone. Science is a rapidly changing set of ideas and processes that not only is influenced by our cultural biases but also affects our cultural awareness of who we are.

evolve

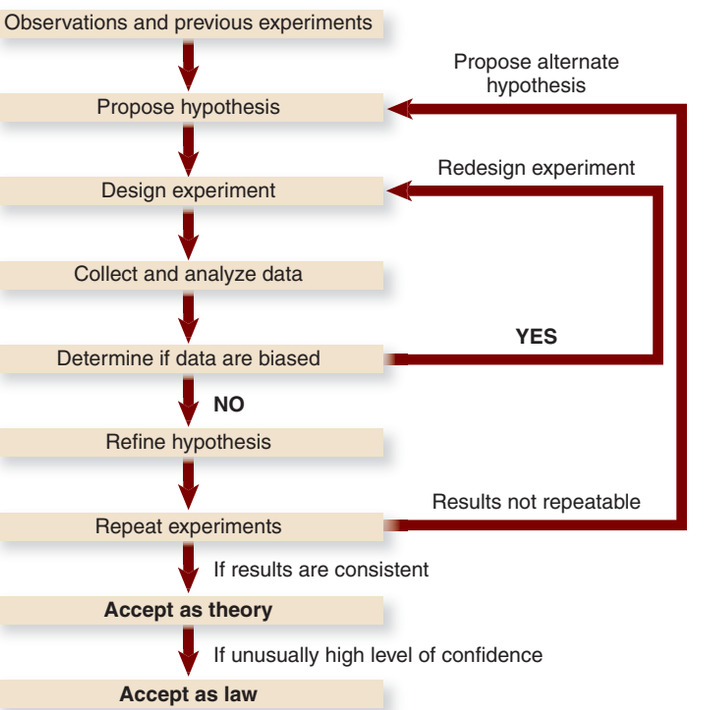

FIGURE 1-1

The scientific method. This flowchart summarizes the classic ideal of how new principles of science are developed. Initial observations or results from other experiments may lead to the formation of a new hypothesis. As more testing is performed to eliminate outside influences or biases and ensure consistent results, scientists begin to have more confidence in the principle and call it a *theory* or *law.*

ANATOMY AND PHYSIOLOGY

Anatomy

Anatomy is often defined as study of the structure of an organism and the relationships of its parts. The word *anatomy* is derived from Greek word parts that mean "to cut apart." Students of anatomy still learn about the structure of the human body by literally cutting it apart. This process, called *dissection*, remains a principal technique used to isolate and study the structural components or parts of the human body.

Biology is defined as the scientific study of life. Both anatomy and physiology are subdivisions of this very broad area of inquiry. Each of these subdivisions can be further divided into smaller areas of study. For example, the term **gross anatomy** is used to describe the study of body parts visible to the naked eye. Before invention of the microscope, anatomists had to study human structure relying only on the eye during dissection. These early anatomists could make only a gross, or whole, examination, as you can see in Figure 1-2. With the use of modern microscopes, many anatomists now specialize in **microscopic anatomy,** including the study of cells, called *cytology* (sye-TOL-o-jee), and tissues, called *histology* (hiss-TOL-o-jee).

Other branches of anatomy include the study of human growth and development (*developmental anatomy*) and the study of diseased body structures (*pathological anatomy*). In the chapters that follow, you will study the body by systems—a process called *systemic anatomy*. Systems are groups of organs that have a common function, such as the bones in the skeletal system and the muscles in the muscular system.

Physiology

Physiology is the science that deals with the functions of the living organism and its parts. The term is a combination of two Greek words (*physis*, "nature," and *logos*, "words or study"). Simply stated, it is the study of physiology that helps us understand how the body works. Physiologists attempt to discover and understand the intricate control systems that permit the body to operate and survive in an often hostile environment.

As a scientific discipline, physiology can be subdivided according to (1) the type of organism involved, such as human physiology or plant physiology; (2) the organizational level studied, such as molecular or cellular physiology; or (3) a specific or *systemic* function being studied, such as neurophysiology, respiratory physiology, or cardiovascular physiology.

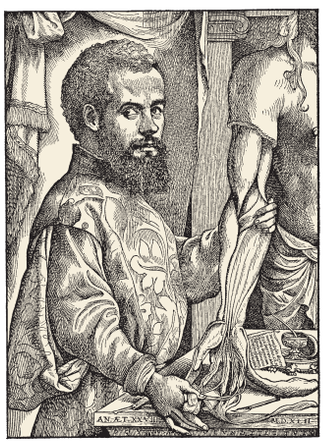

FIGURE 1-2

Gross anatomy. This famous woodcut of a gross dissection appeared in the world's first modern anatomy textbook, *De Humani Corporis Fabrica (On the Structure of the Human Body)* in 1543. This woodcut features the book's author, Andreas Vesalius, who is considered to be the founder of modern anatomy. The body being dissected is called a *cadaver*.

In the chapters that follow, both anatomy and physiology are studied by dividing the human body into specific organ systems. This unit begins with an overview of the body as a whole. In subsequent chapters the body is dissected and studied, both structurally (anatomy) and functionally (physiology), into "levels of organization" so that its component parts can be more easily understood and then "fit together" into a living and integrated whole. It is knowledge of anatomy and physiology that allows us to understand how nerve impulses travel from one part of the body to another; how muscles contract; how light energy can be transformed into visual images; how we breathe, digest food, reproduce, excrete wastes, and sense changes in our environment; and even how we think and reason.

| QUICK CHECK |

1. Describe how science develops new principles.
2. Define anatomy and physiology.
3. List the three ways in which physiology can be subdivided as a scientific discipline.
4. What name is used to describe the study of the body that focuses on groups of organs that have a common function?

LANGUAGE OF SCIENCE AND MEDICINE

You may have noticed by now that many scientific terms, such as anatomy and physiology, are made up of non-English word parts. Many such terms make up the core of the language used to communicate ideas in science and medicine. Learning in science thus begins with learning a new vocabulary, just as when you learn a new language to help you understand and communicate in a region of the world other than the one you call home.

To help you learn the vocabulary of anatomy and physiology, we have provided several helpful tools for you. Within each chapter, lists of new terms titled *Language of Science* and *Language of Medicine* give you each new key (boldface) term that you will be learning in that chapter. Each term in the list has a pronunciation guide and an explanation (or meaning) of each of the word parts that make up the term.

We have also included a separate compact reference called *Language of Science and Medicine* with this textbook. Take a moment now to locate it. After you have finished reading this chapter, quickly review the tips for learning scientific language. Then keep it nearby so that you will have a handy list of commonly used word parts at your fingertips.

You will see that most scientific terms are made up of word parts from Latin or Greek. Most Western scientists first began corresponding with each other in these languages, because it was commonly the first written language learned by educated people. Other languages such as German, French, and Japanese are also sources of some scientific word parts.

As with any language, scientific language changes constantly. This is useful because we often need to fine-tune our terminology to reflect changes in our understanding of science and to accommodate new discoveries. But it also sometimes leads to confusion. In an attempt to clear up some of the confusion, the International Federation of Associations of Anatomists (IFAA) formed a worldwide committee to publish a list of "universal" or standard anatomical terminology. The list for *gross anatomy*, the structure we can see without magnification, was published in 1998 as *Terminologia Anatomica (TA)*. In 2008

the *Terminologia Histologica (TH)* was published for *microscopic anatomy*—the study of body structure requiring significant magnification for the purpose of visualization.

Although there remain some alternate (and newer) terms used in anatomy, the lists are useful standard references. The lists show each term in Latin and English (based on the Latin form), along with a reference number. In this textbook we use the English terms from the published lists as our standard reference, but we do occasionally refer to the pure Latin form or an alternate term when appropriate for beginning students.

One of the basic principles of the standardizing terminology is the avoidance of **eponyms** (EP-o-nimz), or terms that are based on a person's name. Instead, a more descriptive Latin-based term is always preferred. Thus the term *eustachian tube* (tube connected to the middle ear, named after the famed Italian anatomist Eustachius) is now replaced with the more descriptive *auditory tube*. Likewise, the *islets of Langerhans* (in the pancreas) are now simply *pancreatic islets*. In the rare cases where eponyms do appear in a standard list, we now avoid the possessive form. Thus *Bowman's capsule* (in kidney tissue) is now either *glomerular capsule* or *Bowman capsule*.

There are no such standard lists of physiological terms. However, many principles used in anatomical terminology are used in physiology. For example, most terms have an English spelling but are based on Latin or Greek word parts. And, as in anatomy, eponyms are less favored than descriptive terms.

This may all seem like a lot more than you want to know right now. However, if you focus on learning the new words as you begin each new topic, as though you are in a foreign land and need to pick up a few phrases to get by, you will find your study of anatomy and physiology easy and enjoyable.

CHARACTERISTICS OF LIFE

Anatomy and physiology are important disciplines in biology—the study of life. But what is life? What is the quality that distinguishes a vital and functional being from a dead body? We know that a living organism is endowed with certain characteristics not associated with inorganic matter. However, it is sometimes hard to find a single criterion to define life. One could say that living organisms are self-organizing or self-maintaining and nonliving structures are not. This concept is called autopoiesis (aw-toe-poy-EE-sis), which literally means "self making." Another idea, called the *cell theory*, states that any independent structure made up of one or more microscopic units called *cells* is a living organism.

Instead of trying to find a single difference that separates living and nonliving things, scientists sometimes define life by listing what are often called *characteristics of life*. Lists of characteristics of life may differ from one physiologist to the next, depending on the type of organism being studied and the way in which life functions are grouped and defined. Attributes that characterize life in bacteria, plants, or animals may vary. Characteristics of life that are considered most important in humans are described in Table 1-1.

Each characteristic of life is related to the sum total of all the physical and chemical reactions occurring in the body. The term **metabolism** is used to describe these various processes. They include the steps involved in the breakdown of nutrient materials to produce energy and the transformation of one material into another. For example, if we eat and absorb more sugar than needed for the body's immediate energy requirements, it is converted into an alternate form, such as fat, that can be stored in the body. Metabolic reactions are also required for making complex compounds out of simpler ones, as in tissue growth, wound repair, or manufacture of body secretions.

Each characteristic of life—its functional manifestation in the body, its integration with other body functions and structures, and its mechanism of control—is the subject of study in subsequent chapters of the text.

| QUICK CHECK |

5. What is an *eponym*?
6. What single criterion might be used to define life?
7. Define the term *metabolism* as it applies to the characteristics of life.

TABLE 1-1 Characteristics of Human Life

CHARACTERISTIC	DESCRIPTION
Responsiveness	Ability of an organism to sense, monitor, and respond to changes in both its external and internal environments
Conductivity	Capacity of living cells to transmit a wave of electrical disturbance from one point to another within the body
Growth	Organized increase in the size and number of cells and therefore an increase in size of the individual or a particular organ or part
Respiration	Exchange of respiratory gases (oxygen and carbon dioxide) between an organism and its environment
Digestion	Process by which complex food products are broken down into simpler substances that can be absorbed and used by individual body cells
Absorption	Movement of molecules, such as respiratory gases or digested nutrients through a membrane and into the body fluids for transport to cells for use
Secretion	Production and release of important substances, such as digestive juices and hormones, for diverse body functions
Excretion	Removal of waste products from the body
Circulation	Movement of body fluids containing many substances from one body area to another in a continuous, circular route through hollow vessels
Reproduction	Formation of new individual offspring

LEVELS OF ORGANIZATION

Before you begin the study of the structure and function of the human body and its many parts, it is important to think about how the parts are organized and how they might logically fit together and function effectively. The differing levels of organization that influence body structure and function are illustrated in Figure 1-3.

Chemical Level—Basis for Life

Note that organization of the body begins at the chemical level (see Figure 1-3). There are more than 100 different chemical building blocks of nature called *atoms*—tiny spheres of matter so small they are invisible. Every material thing in our universe, including the human body, is composed of atoms.

Combinations of atoms form larger chemical groupings, called *molecules*. Molecules, in turn, often combine with other atoms and molecules to form larger and more complex chemicals, called *macromolecules*.

The unique and complex relationships that exist between atoms, molecules, and macromolecules in living material form a gel-like material made of fluids, particles, and membranes called *cytoplasm* (SYE-toe-plaz-em)—the essential material of human life. Unless proper relationships between chemical elements are

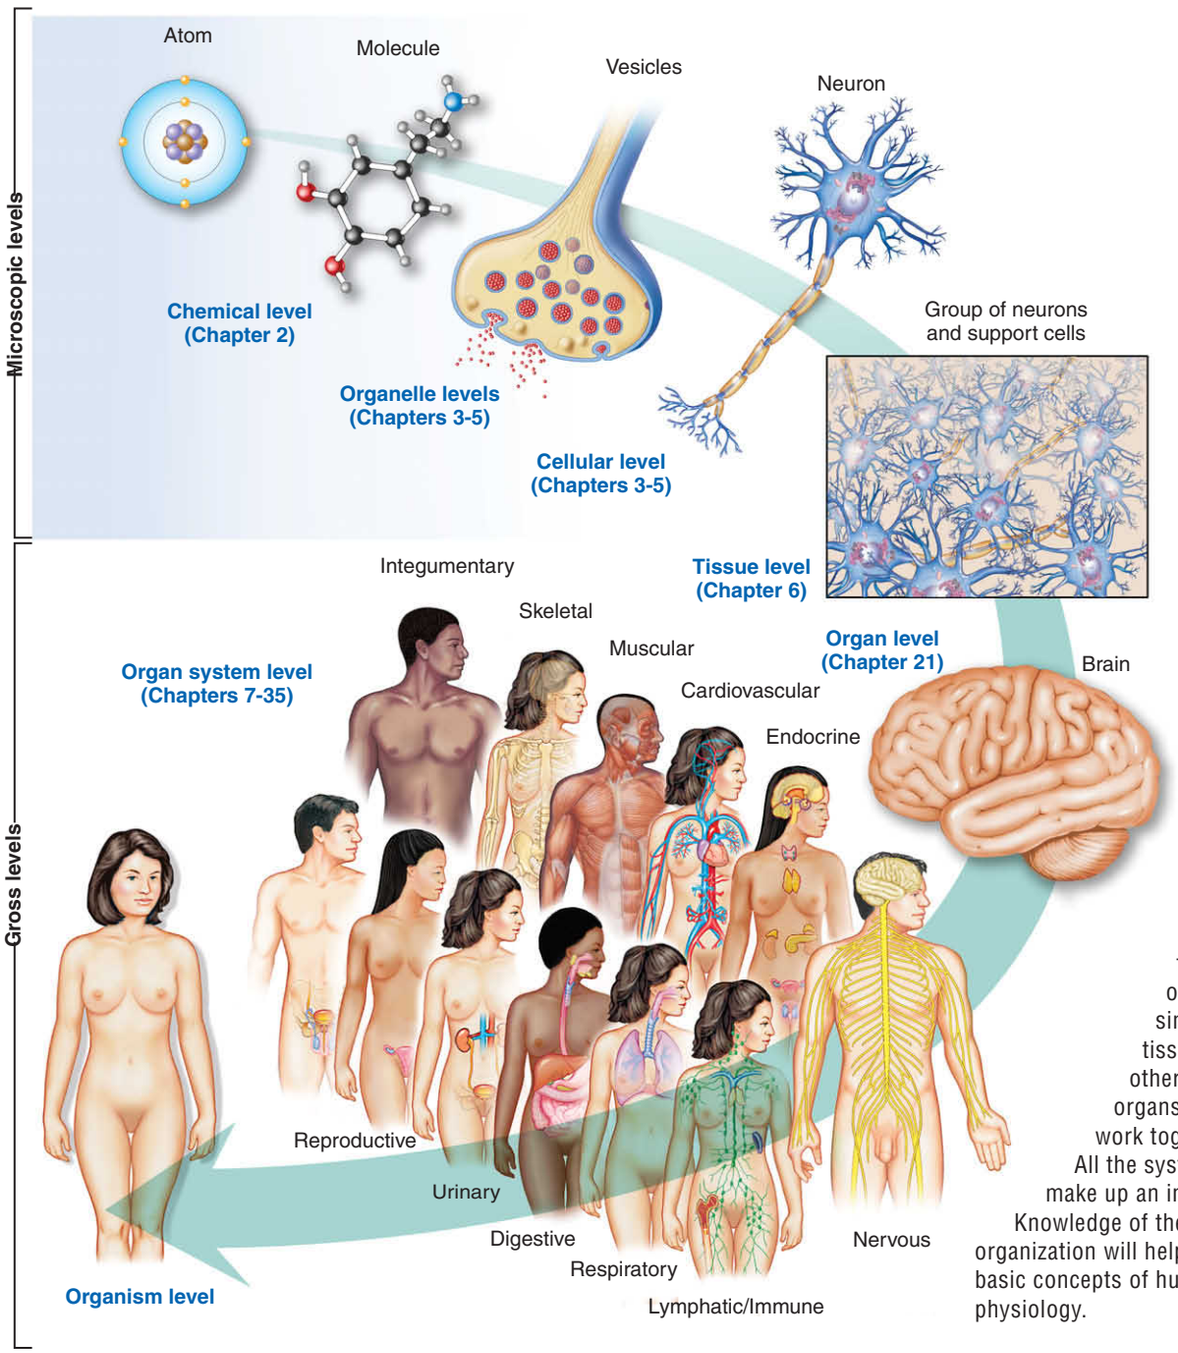

FIGURE 1-3

Levels of organization. The smallest parts of the body are the atoms that make up the chemicals, or molecules, of the body. Molecules, in turn, make up microscopic parts called organelles that fit together to form each cell of the body. Groups of similar cells are called tissues, which combine with other tissues to form individual organs. Groups of organs that work together are called systems. All the systems of the body together make up an individual organism. Knowledge of the different levels of organization will help you understand the basic concepts of human anatomy and physiology.

maintained, death results. Maintaining the type of chemical organization in cytoplasm required for life requires the expenditure of energy. In Chapter 2 important information related to the chemistry of life is discussed in more detail.

Organelle Level

Chemical structures may be organized within larger units called *cells* to form various structures called **organelles** (or-gah-NELLZ), the next level of organization (see Figure 1-3). An organelle may be defined as a structure made of molecules organized in such a way that it can perform a specific function. Organelles are the "tiny organs" that allow each cell to live. Organelles cannot survive outside the cell, but without organelles the cell itself could not survive either.

Dozens of different kinds of organelles have been identified. A few examples include *mitochondria* (my-toe-KON-dree-ah), the "power houses" of cells that provide the energy needed by the cell to carry on day-to-day functioning, growth, and repair; *Golgi* (GOL-jee) *apparatus*, which provides a "packaging" service to the cell by storing material for future internal use or for export from the cell; and *endoplasmic reticulum*, the network of transport channels within the cell that act as "highways" for the movement of chemicals. Chapter 3 contains a complete discussion of organelles and their functions.

Cellular Level

The characteristics of life ultimately result from a hierarchy of structure and function that begins with the organization of atoms, molecules, and macromolecules. Further organization that results in organelles is the next step. However, in the view of the anatomist, the most important function of the chemical and organelle levels of organization is that of furnishing the basic building blocks required for the next higher level of body structure—*the cellular level.*

Cells are the smallest and most numerous structural units that possess and exhibit the basic characteristics of living matter. How many cells are there in the body? One estimate places the number of cells in a 150-pound adult human body at 100,000,000,000,000.

In case you are having trouble translating this number—1 with 14 zeroes after it—it is 100 trillion! or 100,000 billion! or 100 million million!

Each cell is surrounded by a membrane and is characterized by a single nucleus surrounded by cytoplasm that includes the numerous organelles required for the normal processes of living. Although all cells have certain features in common, they specialize or *differentiate* to perform unique functions. Fat cells, for example, are structurally modified to permit the storage of fats, whereas other cells, such as cardiac muscle cells, are able to contract with great force (see Figure 1-3). Muscle, bone, nerve, and blood cells are other examples of structurally and functionally unique cells.

Tissue Level

The next higher level of organization beyond the cell is the *tissue level* (see Figure 1-3). Tissues represent another step in the progressive organization of living matter. By definition, a **tissue** is a group of a great many similar cells that all developed together from the same part of the embryo and all perform a certain function. Tissue cells are surrounded by varying amounts and kinds of nonliving, intercellular substances, or the matrix. Tissues are the "fabric" of the body.

There are four major or principal tissue types: *epithelial*, *connective*, *muscle*, and *nervous*. Considering the complex nature of the human body, this is a surprisingly short list of major tissues. Each of the four major tissues, however, can be subdivided into several distinct subtypes. Together the body tissues are able to meet all the structural and functional needs of the body.

The tissue used as an example in Figure 1-3 is a type of muscle called *cardiac muscle*. Note how the cells are branching and interconnected. The details of tissue structure and function are covered in Chapter 6.

Organ Level

Organ units are more complex than tissues. An **organ** is defined as a structure made up of several different kinds of tissues arranged so that, together, they can perform a special function.

If tissues are the "fabric" of the body, an organ is like an item of clothing with a specific function made up of different fabrics. The heart is an example of the *organ level:* muscle and connective tissues give it shape and pump blood; epithelial tissues line the cavities, or chambers; and nervous tissues permit control of the pumping contractions of the heart.

Tissues seldom exist in isolation. Instead, joined together, they form organs that represent discrete, but functionally complex, operational units. Each organ has a unique shape, size, appearance, and placement in the body, and each can be identified by the pattern of tissues that form it. The lungs, heart, brain, kidneys, liver, and spleen are all examples of organs.

System Level

Systems are the most complex of the organizational units of the body. The **system** level of organization involves varying numbers and kinds of organs arranged so that, together, they can perform complex functions for the body.

Eleven major systems compose the human body: integumentary, skeletal, muscular, nervous, endocrine, circulatory, lymphatic/immune, respiratory, digestive, urinary, and reproductive. Systems that work together to accomplish the general needs of the body are summarized in Table 1-2.

Take a few minutes to read through Table 1-2. The left column points out that several different systems often work together to accomplish some overall goal. For example, the first three systems

TABLE 1-2 Body Systems (With Unit and Chapter References)

FUNCTIONAL CATEGORY	SYSTEM	PRINCIPAL ORGANS	PRIMARY FUNCTIONS
Support and movement (Unit One)	Integumentary (Chapter 7)	Skin	Protection, temperature regulation, sensation
	Skeletal (Chapters 8–10)	Bones, ligaments	Support, protection, movement, mineral and fat storage, blood production
	Muscular (Chapters 11–12)	Skeletal muscles, tendons	Movement, posture, heat production
Communication, control, and integration (Unit Two)	Nervous (Chapters 13–17)	Brain, spinal cord, nerves, sensory organs	Control, regulation, and coordination of other systems, sensation, memory
	Endocrine (Chapters 18–19)	Pituitary gland, adrenals, pancreas, thyroid, parathyroids, and other glands	Control and regulation of other systems
Transportation and defense (Unit Three)	Cardiovascular (Chapters 20–22)	Heart, arteries, veins, capillaries	Exchange and transport of materials
	Lymphatic (Chapters 23–25)	Lymph nodes, lymphatic vessels, spleen, thymus, tonsils	Immunity, fluid balance
Respiration, nutrition, and excretion (Unit Four)	Respiratory (Chapters 26–27)	Lungs, bronchial tree, trachea, larynx, nasal cavity	Gas exchange, acid-base balance
	Digestive (Chapters 28–30)	Stomach, small and large intestines, esophagus, liver, mouth, pancreas	Breakdown and absorption of nutrients, elimination of waste
	Urinary (Chapters 31–33)	Kidneys, ureters, bladder, urethra	Excretion of waste, fluid and electrolyte balance, acid-base balance
Reproduction and development (Unit Five)	Reproductive (Chapters 34–37)	*Male:* Testes, vas deferens, prostate, seminal vesicles, penis *Female:* Ovaries, fallopian tubes, uterus, vagina, breasts	Reproduction, continuity of genetic information, nurturing of offspring

listed (integumentary, skeletal, muscular) make up the framework of the body and therefore provide support and movement. Notice also that this table corresponds to the organization of this book. Once we get to the system level of organization, we will study each system one by one, chapter by chapter. To help you navigate through the book, we have organized the chapters into units of several systems each—units that group the systems by common or overlapping functions.

You are probably aware that some systems can be grouped together or split apart. We use those groupings that are most useful to us. For example, because both the skeletal and muscular systems work together to produce athletic movements, an athletic trainer may study them together as the *skeletomuscular system.* A physical therapist may also include concepts of nervous control of movement and study the *neuroskeletomuscular system.* On the other hand, a neurologist may find it useful to keep in mind a distinction between the sensory nervous system and the motor nervous system. In any case, the idea of levels of organization is universal, and once you know how it works, you can adapt it to suit your own changing needs. The plan of dividing the body into 11 major systems is widely used among biologists, so we will use it as the basis of our study too.

Organism Level

The living human **organism** is certainly more than the sum of its parts. It is a marvelously coordinated team of interactive structures that is able to survive and flourish in an often hostile environment. Not only can the human body reproduce itself (and its genetic information) and maintain ongoing repair and replacement of worn or damaged parts, it can also maintain—in a constant and predictable way—an incredible number of variables required for a human to lead a healthy, productive life.

We are able to maintain a "normal" body temperature and fluid balance under widely varying environmental extremes. We maintain constant blood levels of many important chemicals and nutrients. We experience effective protection against disease, elimination of waste products, and coordinated movement. We correctly and quickly interpret sound, visual images, and other external stimuli with great regularity. These are a few examples of how the different levels of organization in the human organism permit expression of the characteristics associated with life.

As you study the structure and function of the human body, it is too easy to think of each part or function in isolation from the

body as a whole. Always remember that you are ultimately dealing with information related to the entire human organism—not information limited to an understanding of the structure and function of a single organelle, cell, tissue, organ, or organ system. Do not limit your learning to the memorization of facts. Instead, connect and integrate factual information so that your understanding of human structure and function is related not to a part of the body but to the body as a whole.

| QUICK CHECK |

8. List the seven levels of organization.
9. Identify three organelles.
10. List the four major tissue types.
11. List the 11 major organ systems.

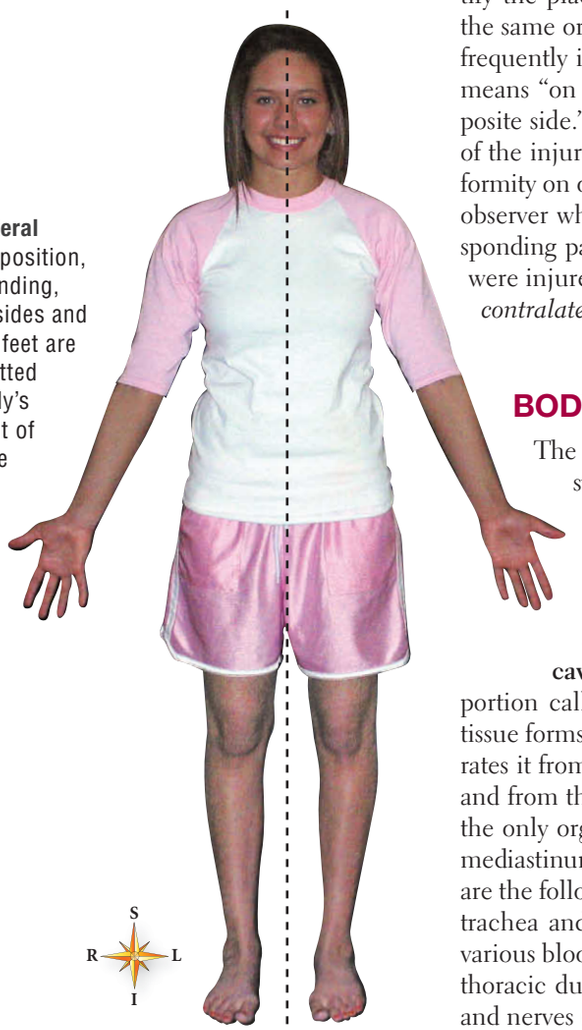

FIGURE 1-4

Anatomical position and bilateral symmetry. In the anatomical position, the body is in an erect, or standing, posture with the arms at the sides and palms forward. The head and feet are also pointing forward. The dotted line shows the axis of the body's bilateral symmetry. As a result of this organizational feature, the right and left sides of the body are mirror images of each other.

ANATOMICAL POSITION

Discussions about the body, how it moves, its posture, or the relationship of one area to another, assume that the body as a whole is in a specific position called the **anatomical position.** In this reference position the body is in an erect, or standing, posture with the arms at the sides and palms turned forward (Figure 1-4). The head and feet are also pointing forward. The anatomical position is a reference position that gives meaning to the directional terms used to describe the body parts and regions.

Bilateral symmetry is one of the most obvious of the external organizational features in humans. The person shown in Figure 1-4 is divided by a line into bilaterally symmetrical sides. To say that humans are bilaterally symmetrical simply means that the right and left sides of the body are mirror images of each other and only one plane can divide the body into left and right halves. One of the most important features of bilateral symmetry is balanced proportions. There is a remarkable correspondence in size and shape when comparing similar anatomical parts or external areas on opposite sides of the body.

The terms *ipsilateral* and *contralateral* are often used to identify the placement of one body part with respect to another on the same or opposite side of the body. These terms are used most frequently in describing injury to an extremity. *Ipsilateral* simply means "on the same side," and *contralateral* means "on the opposite side." Injuries to an arm or leg require careful comparison of the injured with the noninjured side. Minimal swelling or deformity on one side of the body is often apparent only to a trained observer who compares a suspected area of injury with its corresponding part on the opposite side of the body. If the right knee were injured, for example, the left knee would be designated the *contralateral knee.*

BODY CAVITIES

The body, contrary to its external appearance, is not a solid structure. It contains two major sets of cavities that each house compact, well-ordered arrangements of internal organs. The location and outlines of the body cavities are illustrated in Figure 1-5.

The **ventral cavities** include the *thoracic*, or *chest, cavity* and the *abdominopelvic cavity*. The **thoracic cavity** includes a right and a left *pleural cavity* and a midportion called the *mediastinum* (mee-dee-ass-TI-num). Fibrous tissue forms a wall around the mediastinum that completely separates it from the right pleural cavity, in which the right lung lies, and from the left pleural cavity, in which the left lung lies. Thus the only organs in the thoracic cavity that are not located in the mediastinum are the lungs. Organs located in the mediastinum are the following: the heart (enclosed in its pericardial cavity), the trachea and right and left bronchi, the esophagus, the thymus, various blood vessels (e.g., thoracic aorta, superior vena cava), the thoracic duct and other lymphatic vessels, various lymph nodes, and nerves (such as the phrenic and vagus nerves).

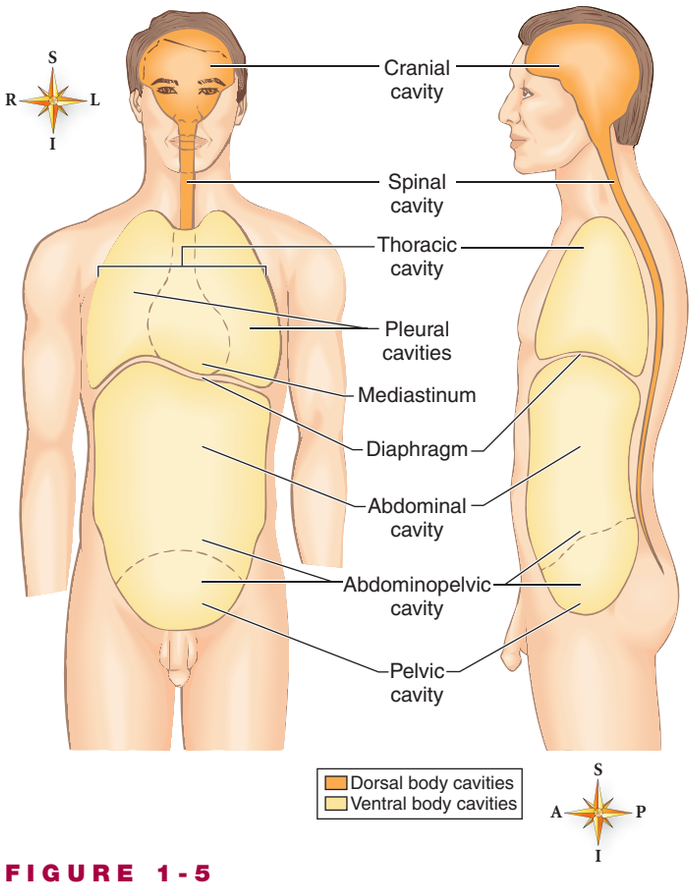

FIGURE 1-5

Major body cavities. The dorsal body cavity is in the dorsal (back) part of the body and is subdivided into a cranial cavity above and a spinal cavity below. The ventral body cavity is on the ventral (front) side of the trunk and is subdivided into the thoracic cavity above the diaphragm and the abdominopelvic cavity below the diaphragm. The thoracic cavity is subdivided into the mediastinum in the center and pleural cavities to the sides. The abdominopelvic cavity is subdivided into the abdominal cavity above the pelvis and the pelvic cavity within the pelvis.

TABLE 1-3 Organs in Ventral Body Cavities

AREAS	ORGANS
Thoracic Cavity	
Right pleural cavity	Right lung
Mediastinum	Heart
	Trachea
	Right and left bronchi
	Esophagus
	Thymus gland
	Aortic arch and thoracic aorta
	Venae cavae
	Various lymph nodes and nerves
	Thoracic duct
Left pleural cavity	Left lung
Abdominopelvic Cavity	
Abdominal cavity	Liver
	Gallbladder
	Stomach
	Pancreas
	Intestines
	Spleen
	Kidneys
	Ureters
Pelvic cavity	Urinary bladder
	Female reproductive organs
	Uterus
	Uterine tubes
	Ovaries
	Male reproductive organs
	Prostate gland
	Seminal vesicles
	Part of vas deferens
	Part of large intestine, namely, sigmoid colon and rectum

The **abdominopelvic cavity** has an upper portion, the *abdominal cavity*, and a lower portion, the *pelvic cavity*. The abdominal cavity contains the liver, gallbladder, stomach, pancreas, intestines, spleen, kidneys, and ureters. The bladder, certain reproductive organs (uterus, uterine tubes, and ovaries in females; prostate gland, seminal vesicles, and part of the vas deferens in males), and part of the large intestine (namely, the sigmoid colon and rectum) lie in the pelvic cavity (Table 1-3).

The **dorsal cavities** include the *cranial* and *spinal cavities*. The cranial cavity lies in the skull and houses the brain. The spinal cavity lies in the spinal column and houses the spinal cord (see Figure 1-5).

The thin filmy membranes that line body cavities or cover the surfaces of organs within body cavities also have special names. The term **parietal** refers to the actual wall of a body cavity or the lining membrane that covers its surface. **Visceral** refers not to the wall or lining of a body cavity but to the thin membrane that covers the organs, or viscera, within a cavity.

The membrane lining the inside of the abdominal cavity, for example, is called the *parietal peritoneum*. The membrane that covers the organs within the abdominal cavity is called the *visceral peritoneum*. If you skip ahead to Figure 1-10, you will see that there is a space or opening between the two membranes in the abdomen. This is called the *peritoneal cavity*. Body membranes are discussed in greater detail in Chapter 6.

BODY REGIONS

Identification of an object begins with overall recognition of its structure and form. Initially, it is in this way that the human form can be distinguished from other creatures or objects. Recognition occurs as soon as you can identify the overall shape and basic outline. For more specific identification to occur, details of size, shape, and appearance of individual body areas must be described. Individuals differ in overall appearance because specific body areas, such as the face or torso, have unique identifying characteristics. Detailed descriptions of the human form require that specific regions be identified and appropriate terms be used to describe them (Figure 1-6 and Table 1-4).

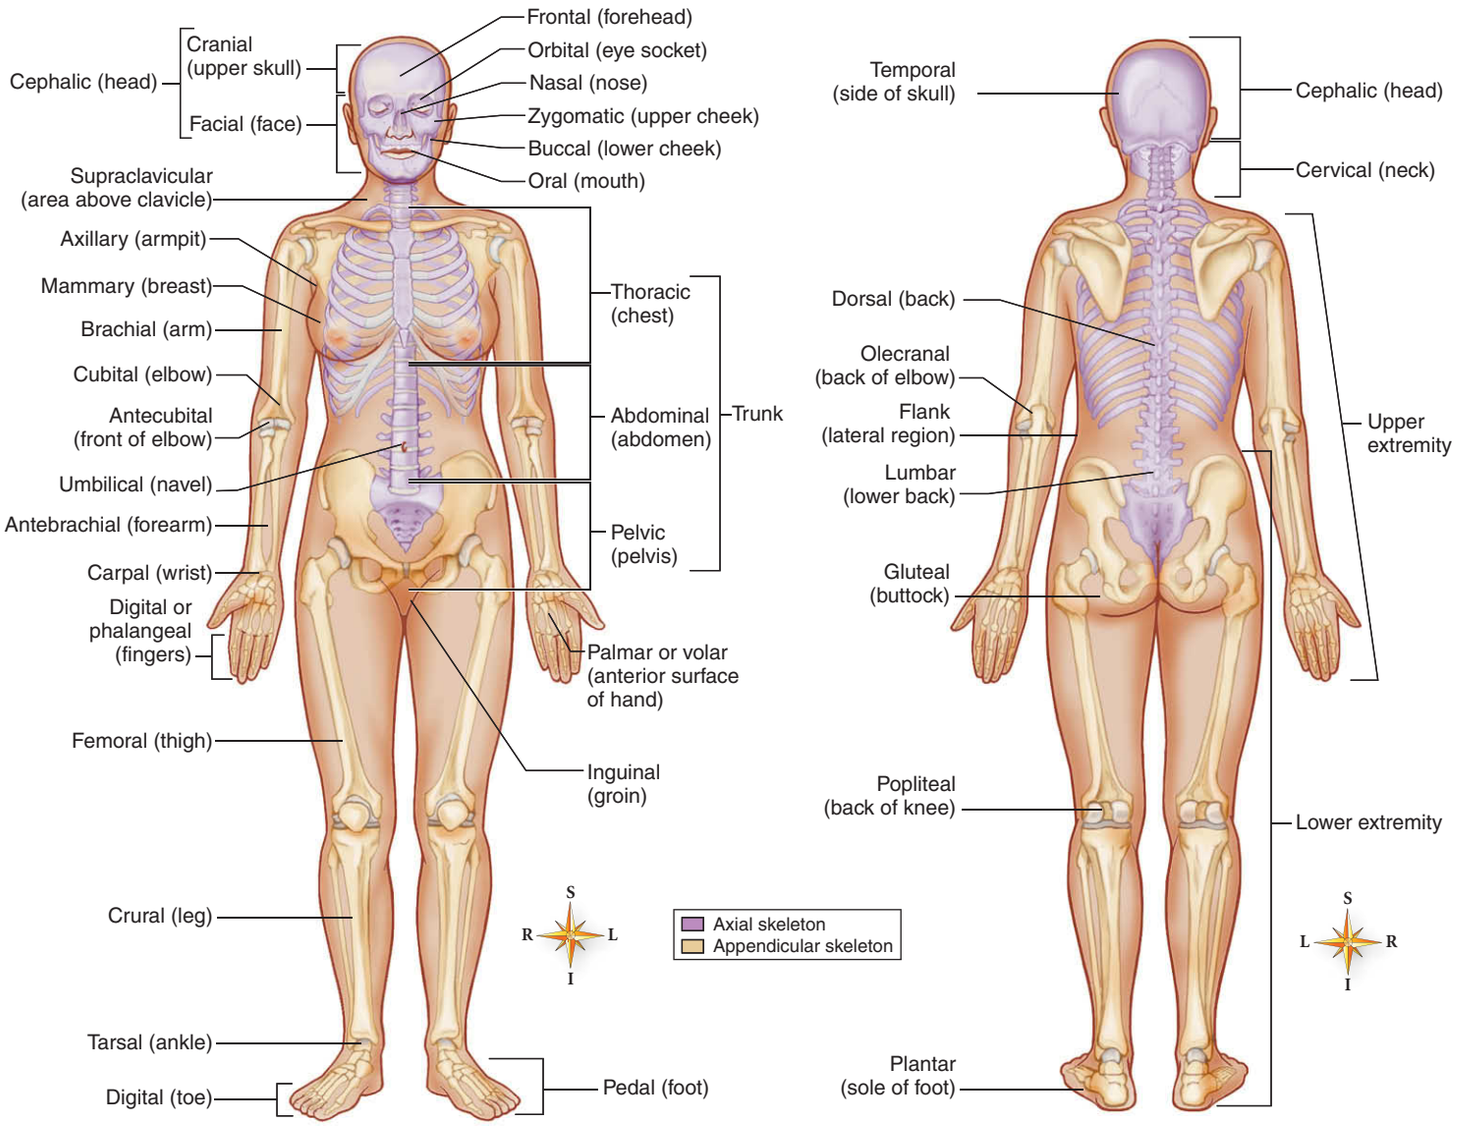

FIGURE 1-6

Specific body regions. Note that the body as a whole can be subdivided into two major portions: axial (along the middle, or *axis,* of the body) and appendicular (the arms and legs, or *appendages*). Names of specific body regions follow the Latin form, with the English equivalent in parentheses.

The body as a whole can be subdivided into two major portions or components: *axial* and *appendicular*. The axial portion of the body consists of the head, neck, and torso, or trunk; the appendicular portion consists of the upper and lower extremities and their connections to the axial portion. Each major area is subdivided as shown in Figure 1-6. Note, for example, that the torso is composed of the thoracic, abdominal, and pelvic areas and the upper extremity is divided into arm, forearm, wrist, and hand components. Although most terms used to describe gross body regions are familiar, misuse is common. The term *leg* is a good example. To an anatomist, "leg" refers to the area of the lower extremity between the knee and ankle and not to the entire lower extremity.

TABLE 1-4 Latin-Based Descriptive Terms for Body Regions*

BODY REGION	AREA OR EXAMPLE	BODY REGION	AREA OR EXAMPLE
Abdominal (ab-DOM-in-al)	Anterior torso below diaphragm	**Mammary** (MAM-er-ee)	Breast
Acromial (ah-KRO-mee-al)	Shoulder	**Manual** (MAN-yoo-al)	Hand
Antebrachial (an-tee-BRAY-kee-al)	Forearm	**Mental** (MEN-tal)	Chin
Antecubital (an-tee-KYOO-bi-tal)	Depressed area just in front of elbow (cubital fossa)	**Nasal** (NAY-zal	Nose
Axillary (AK-si-lair-ee)	Armpit (axilla)	**Navel** (NAY-vel)	Area around navel, or umbilicus
Brachial (BRAY-kee-al)	Arm	**Occipital** (ok-SIP-i-tal)	Back of lower part of skull
Buccal (BUK- al)	Cheek (inside)	**Olecranal** (o-LECK-ra-nal)	Back of elbow
Calcaneal (cal-CANE-ee-al)	Heel of foot	**Oral** (OR-al)	Mouth
Carpal (KAR-pal)	Wrist	**Orbital** or **ophthalmic** (OR-bi-tal *or* op-THAL-mik)	Eyes
Cephalic (se-FAL-ik)	Head	**Otic** (O-tick)	Ear
Cervical (SER-vi-kal)	Neck	**Palmar** (PAHL-mar)	Palm of hand
Coxal (COX-al)	Hip	**Patellar** (pa-TELL-er)	Front of knee
Cranial (KRAY-nee-al)	Skull	**Pedal** (PED-al)	Foot
Crural (KROOR-al)	Leg	**Pelvic** (PEL-vik)	Lower portion of torso
Cubital (KYOO-bi-tal)	Elbow	**Perineal** (pair-i-NEE-al)	Area (perineum) between anus and genitals
Cutaneous (kyoo-TANE-ee-us)	Skin (or body surface)	**Plantar** (PLAN-tar)	Sole of foot
Digital (DIJ-i-tal)	Fingers or toes	**Pollex** (POL-ex)	Thumb
Dorsal (DOR-sal)	Back or top	**Popliteal** (pop-li-TEE-al)	Area behind knee
Facial (FAY-shal)	Face	**Pubic** (PYOO-bik)	Pubis
Femoral (FEM-or-al)	Thigh	**Supraclavicular** (soo-pra-cla-VIK-yoo-lar)	Area above clavicle
Frontal (FRON-tal)	Forehead	**Sural** (SUR-al)	Calf
Gluteal (GLOO-tee-al)	Buttock	**Tarsal** (TAR-sal)	Ankle
Hallux (HAL-luks)	Great toe	**Temporal** (TEM-por-al)	Side of skull
Inguinal (ING-gwi-nal)	Groin	**Thoracic** (tho-RAS-ik)	Chest
Lumbar (LUM-bar)	Lower part of back between ribs and pelvis	**Zygomatic** (zye-go-MAT-ik)	Cheek

*The left column lists English adjectives based on Latin terms that describe the body parts listed in English in the right column.

Abdominopelvic Regions

For convenience in locating abdominopelvic organs, anatomists divide the abdominopelvic cavity like a tic-tac-toe grid into nine imaginary regions. The following is a list of the nine regions (Figure 1-7) identified from right to left and from top to bottom:

1. Right hypochondriac region
2. Epigastric region
3. Left hypochondriac region
4. Right lumbar region
5. Umbilical region
6. Left lumbar region
7. Right iliac (inguinal) region
8. Hypogastric region
9. Left iliac (inguinal) region

The most superficial organs located in each of the nine abdominopelvic regions are shown in Figure 1-7. In the right hypochondriac region the right lobe of the liver and the gallbladder are visible. In the epigastric area, parts of the right and left lobes of the liver and a large portion of the stomach can be seen. Viewed superficially, only a portion of the stomach and a small portion of the large intestine is visible in the left hypochondriac area. Note that the right lumbar region includes parts of the large and small intestines (see Figure 1-7). The superficial organs seen in the umbilical region include a portion of the transverse colon and loops of the small intestine. Additional loops of the small intestine and a part of the colon can be seen in the left lumbar region. The right iliac region contains the cecum and parts of the small intestine. Only loops of the small intestine, the urinary bladder, and the appendix are seen in the hypogastric region. The left iliac region shows portions of the colon and the small intestine.

Abdominal Quadrants

Physicians and other health professionals frequently use a simpler method and divide the abdomen into four quadrants to describe the site of abdominopelvic pain or locate some type of internal pathology such as a tumor or abscess (Figure 1-8). One horizontal line and one vertical line passing through the umbilicus (navel) divide the abdomen into *right* and *left upper quadrants* and *right* and *left lower quadrants* (see Figure 1-8).

| QUICK CHECK |

12. Define the term *anatomical position* and explain its importance.
13. Name the two major subdivisions of the body as a whole.
14. Identify the two major body cavities and the subdivisions of each.
15. List the nine abdominopelvic regions and four abdominal quadrants.

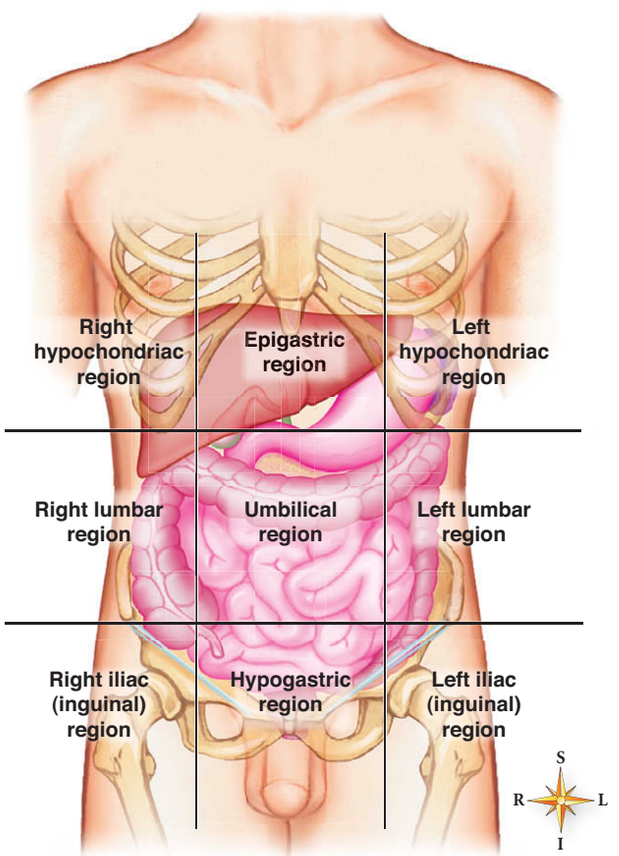

FIGURE 1-7

Nine regions of the abdominopelvic cavity. Only the most superficial structures of the internal organs are shown here.

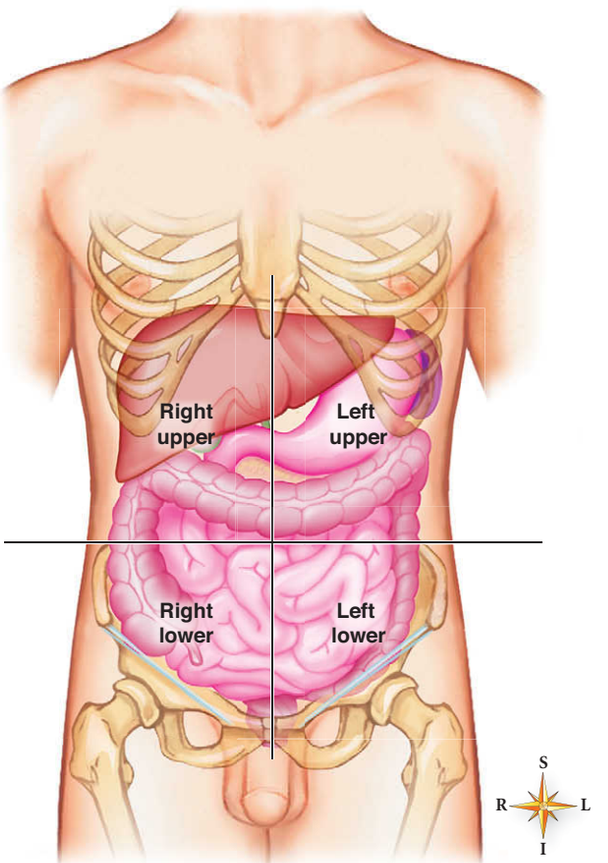

FIGURE 1-8

Division of the abdomen into four quadrants. The diagram shows the relationship of internal organs to the four abdominal quadrants.

TERMS USED IN DESCRIBING BODY STRUCTURE

Directional Terms

To minimize confusion when discussing the relationship between body areas or the location of a particular anatomical structure, specific terms must be used. When the body is in the anatomical position, the following directional terms can be used to describe the location of one body part with respect to another (Figure 1-9).

Superior and ***inferior.*** **Superior** means "toward the head," and **inferior** means "toward the feet." Superior also means "upper" or "above," and inferior means "lower" or "below." For example, the lungs are located superior to the diaphragm, whereas the stomach is located inferior to it.

Anterior and ***posterior.*** **Anterior** means "front" or "in front of"; **posterior** means "back" or "in back of." In humans—who walk in an upright position—*ventral* (toward the belly) can be used in place of anterior, and *dorsal* (toward the back) can be used for posterior. For example, the nose is on the anterior surface of the body, and the shoulder blades are on its posterior surface.

Medial and ***lateral.*** **Medial** means "toward the midline of the body"; **lateral** means "toward the side of the body, or away from its midline." For example, the great toe is at the medial side of the foot, and the little toe is at its lateral side. The heart lies medial to the lungs, and the lungs lie lateral to the heart.

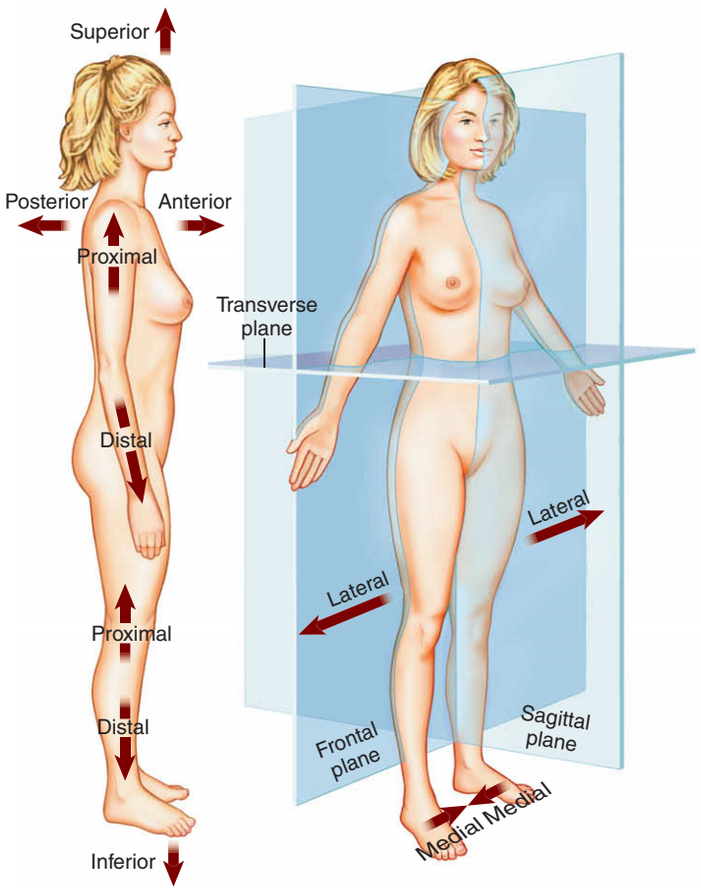

FIGURE 1-9
Directions and planes of the body.

Proximal and ***distal.*** **Proximal** means "toward or nearest the trunk of the body, or nearest the point of origin of one of its parts"; **distal** means "away from or farthest from the trunk or the point of origin of a body part." For example, the elbow lies at the proximal end of the forearm, whereas the hand lies at its distal end.

Superficial and ***deep.*** **Superficial** means "nearer the surface"; **deep** means "farther away from the body surface." For example, the skin of the arm is superficial to the muscles below it, and the bone of the upper part of the arm is deep to the muscles that surround and cover it. Refer often to the table of anatomical directions on the inside front cover. It is intended to serve as a useful and ready reference for review.

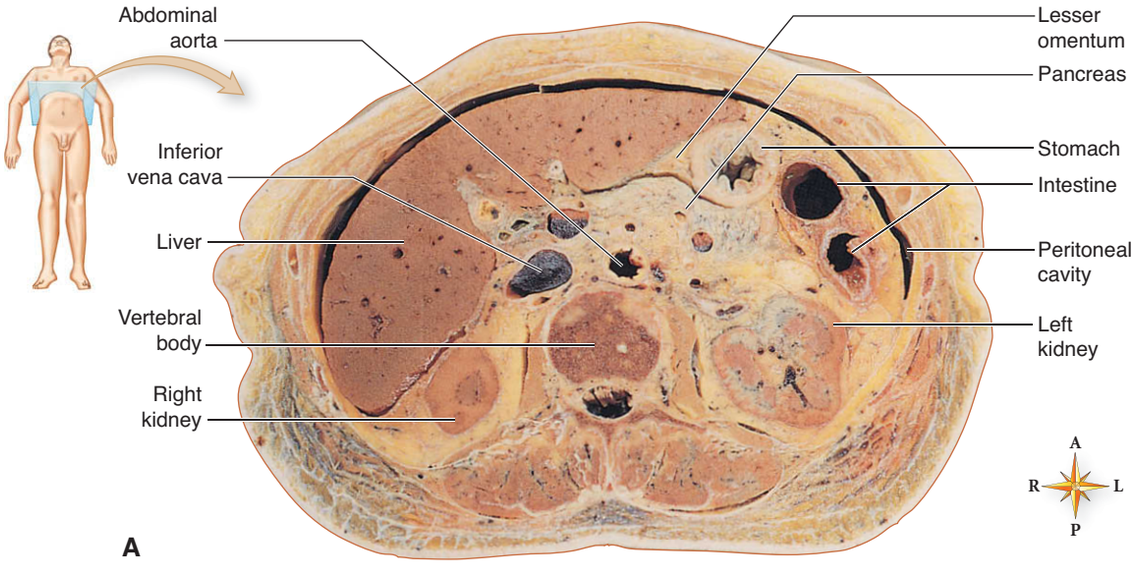
Terms Related to Organs

When discussing anatomical relationships among organs in a system or region, or anatomical relationships within an organ, additional terms are often useful.

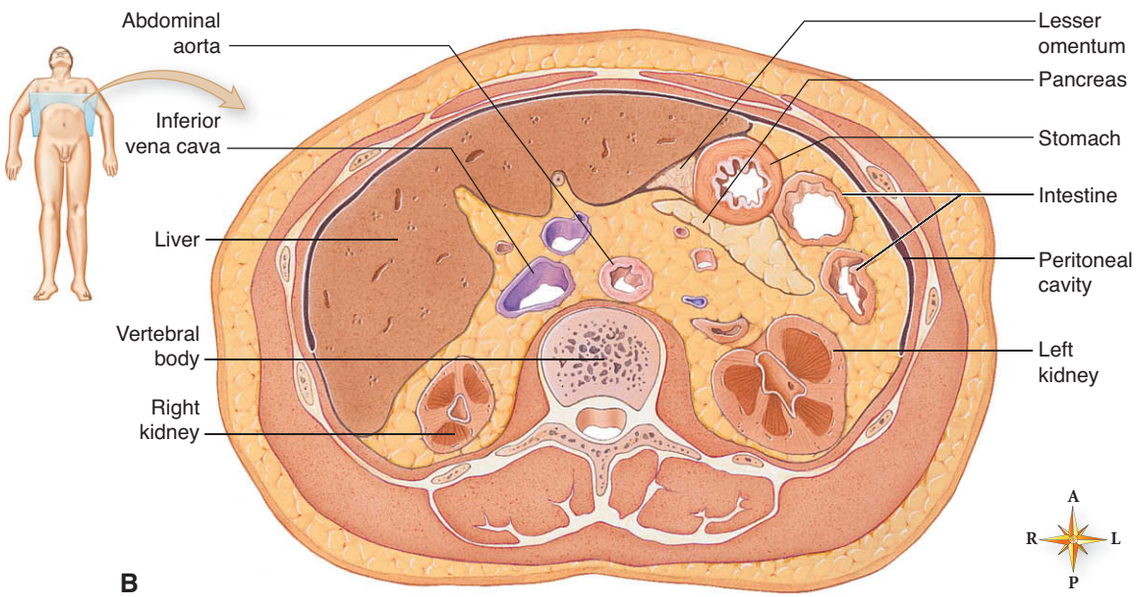
Lumen. Many organs of the body are hollow, such as the stomach, small intestine, blood vessels, urinary organs, and so on. The hollow area of any of these organs is called the **lumen**. The term *luminal* means "of or near the lumen."

Central and ***peripheral.*** **Central** means "near the center;" **peripheral** means "around the boundary." For example, the central nervous system includes the brain and spinal cord, which are near the center of the body. The peripheral nervous system, on the other hand, includes the nerves of the muscles, skin, and other organs that are nearer the periphery, or outer boundaries, of the body.

Medullary and ***cortical.*** **Medullary** refers to an inner region of an organ; **cortical** refers to an outer region or layer of an organ. For example, the inner region of the kidney is the *medulla*, and any structures there are described as medullary. Similarly, the term *cortical* describes structures found in the outer layer of kidney tissue (the *cortex* of the kidney).



Basal and apical. Some organs, such as the heart and each lung, are somewhat cone-shaped. Thus we borrow terms that describe the point or *apex* of a cone and the flat part or *base* of a cone. **Basal** refers to the base or widest part of an organ; **apical** refers to the narrow tip of an organ. For example, in the heart the term *apical* refers to the "point" of the heart that rests on the diaphragm. Basal and apical may also refer to individual cells: the apical surface faces the lumen of a hollow organ, and the basal surface of the cell faces away from the lumen. Many of the more common directional terms that you will use in this course are listed in a handy table inside the front cover of the book.



BODY PLANES AND SECTIONS

The transparent glasslike plates in Figure 1-9 that divide the body into parts represent cuts, or *sections*, that can be made along a particular axis, or line of orientation, called a *plane*. There are three major **body planes** that lie at right angles to each other. They are called the *sagittal* (SAJ-i-tal), *coronal* (ko-RO-nal), and *transverse* (or *horizontal*) planes. Literally hundreds of sections can be made in each plane, and each section made is named after

FIGURE 1-10

Transverse section of the abdomen. A, A transverse, or horizontal, plane through the abdomen shows the position of various organs within the cavity. **B,** A drawing of the photograph helps clarify the photo. Compare these views, both seen from below, with the medical image shown in the box on p. 17.

the particular plane along which it occurs. For example, the transverse plane in Figure 1-9 is shown dividing the individual into upper and lower parts at about the level of the umbilicus. Many other transverse sections are possible in parallel transverse planes. A transverse section through the knee would amputate the lower extremity at that joint, and a transverse section through the neck would result in decapitation.

Read the following definitions and identify each term in Figure 1-9:

Sagittal plane. A lengthwise plane running from front to back; divides the body or any of its parts into right and left sides. If a sagittal section is made in the exact midline, resulting in equal and symmetrical right and left halves, the plane is called a *median sagittal plane* or *midsagittal plane* (see Figure 1-9).

Coronal plane. A lengthwise plane running from side to side; divides the body or any of its parts into anterior and posterior portions; also called a *frontal plane.*

Transverse plane. A crosswise plane; divides the body or any of its parts into upper and lower parts; also called a *horizontal plane.*

Figure 1-10 shows the organs of the abdominal cavity as they would appear in the transverse, or horizontal, plane or "cut" through the abdomen represented in Figure 1-9. In addition to the actual photograph, a simplified line diagram helps in identifying the primary organs. Note that organs near the bottom of the photo or line drawing are in a posterior position. The cut vertebra of the spine, for example, can be identified in its position behind, or posterior, to the stomach. The kidneys are located on either side of the vertebra—they are *lateral* and the vertebra is *medial.* To make the reading of anatomical figures a little easier, an *anatomical rosette* is used throughout this book. On many figures, you will notice a small compass rosette similar to those on geographical maps. Rather than being labeled N, S, E, and W, the anatomical rosette is labeled with abbreviated anatomical directions:

A = Anterior	**P** (opposite A) = Posterior
D = Distal	**P** (opposite D) = Proximal
I = Inferior	**S** = Superior
L (opposite M) = Lateral	**M** = Medial
L (opposite R) = Left	**R** = Right

For your convenience, the compass rosette and its possible directions, a helpful diagram of the planes and directions of the body, and a summary table are found on the inside front cover of this book. Refer to it frequently until you are familiar enough with anatomy to do without it.

| QUICK CHECK |

16. Define and contrast each term in these pairs: superior/inferior, anterior/posterior, medial/lateral, dorsal/ventral.
17. How is anatomical left different from your left?
18. List and define the three major planes that are used to divide the body into parts.
19. Explain how an anatomical rosette is used in anatomical illustrations.

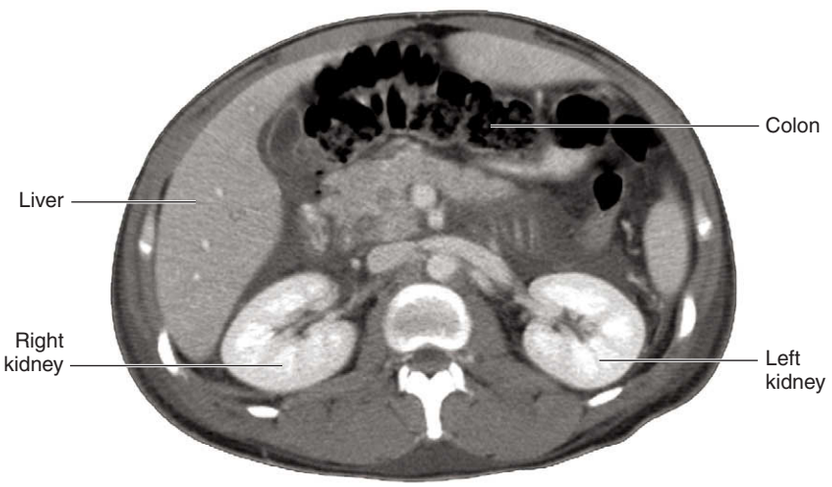
INTERACTION OF STRUCTURE AND FUNCTION

One of the most unifying and important concepts of the study of anatomy and physiology is the principle of *complementarity of structure and function*. In the chapters that follow, you will note again and again that anatomical structures are adapted to perform specific functions. Each structure has a particular size, shape, form, or placement in the body that makes it especially efficient at performing a unique and important activity.

The relationships between the levels of structural organization will take on added meaning as you study the various organ systems in the chapters that follow. For example, as you study the respiratory system in Chapter 27, you will learn about a special chemical substance secreted by cells in the lungs that help to keep tiny air sacs in these organs from collapsing during respiration. Hereditary material called *DNA* (a macromolecule) "directs" the differentiation of specialized cells in the lungs during development so that they can effectively contribute to respiratory function. As a result of DNA activity, special chemicals are produced, cells are modified, and tissues appear that are uniquely suited to this organ system. The cilia (organelles), which cover the exposed surface of cells that form the tissues lining the respiratory passageways, help trap and eliminate inhaled contaminants such as dust. The structures of the respiratory tubes and lungs assist in efficient and rapid movement of air and also make possible the exchange of critical respiratory gases such as oxygen and carbon dioxide between the air in the lungs and the blood. Working together as the respiratory system, specialized chemicals, organelles, cells, tissues, and organs supply every cell of the human body with necessary oxygen and constantly remove carbon dioxide.

Structure determines function, and function influences the actual anatomy of an organism over time. Understanding this fact helps students better understand the mechanisms of disease and the structural abnormalities often associated with pathology. Box 1-1 gives one example of the relationship between body structure, function, and disease. Current research in the study of human biology is now focused in large part on integration, interaction, development, modification, and control of functioning body structures.

By applying the principle of complementarity of structure and function as you study the structural and functional levels of the body's organization in each organ system, you will be able to integrate otherwise isolated factual information into a cohesive and understandable whole. A memorized set of individual and isolated facts is soon forgotten—the parts of an anatomical structure that can be related to its function are not.



| QUICK CHECK |

20. Define what is meant by "complementarity of structure and function."
21. Give an example of how the chemical macromolecule DNA can have an influence on body structure.

| A&P CONNECT |

Why bother to learn about sections of the body? In the short term, you'll need to understand how to interpret the many illustrations like Figure 1-10 in this book. In the long term, you will use them in clinical settings—as in medical imaging.

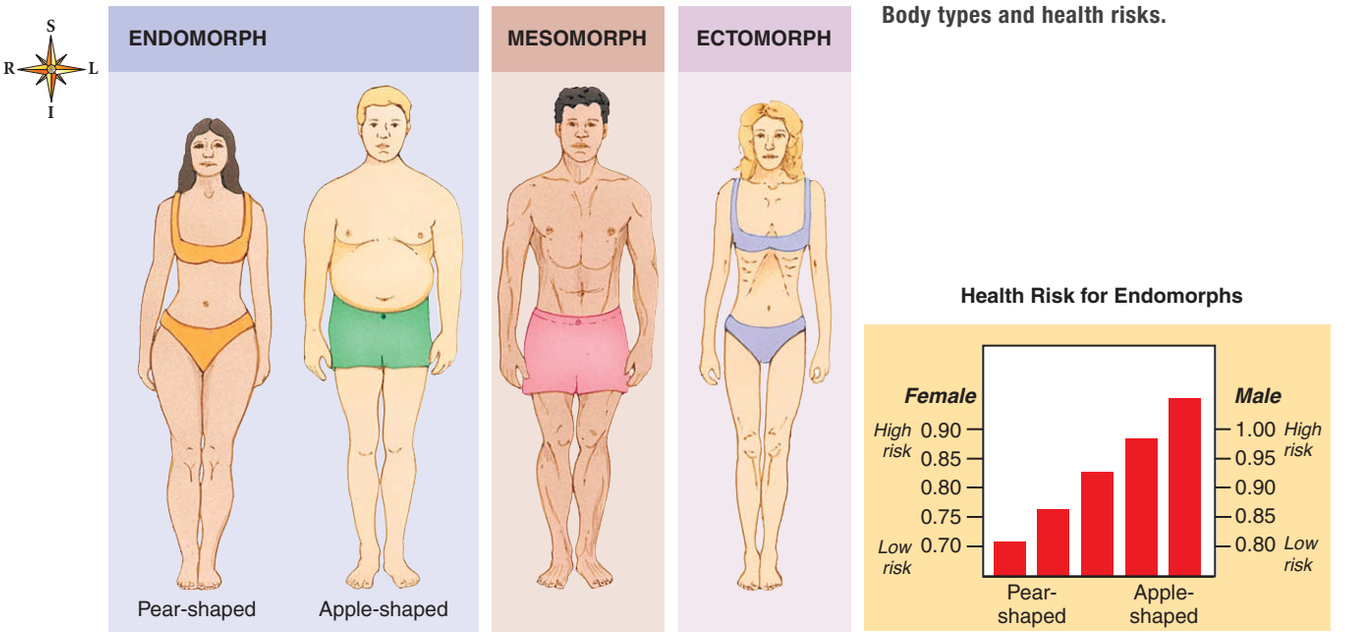
Cadavers (preserved human bodies used for scientific study) can be cut into sagittal, frontal, or transverse sections for easy viewing of internal structures, but living bodies, of course, cannot. This fact has been troublesome for medical professionals who must determine whether internal organs are injured or diseased. In some cases the only sure way to detect a lesion or variation from normal is extensive exploratory surgery. Fortunately, advances in medical imaging allow physicians to visualize internal structures of the body without risking the trauma or other complications associated with extensive surgery. This figure shows a CT (computed tomography) scan similar to the perspective of Figure 1-10. CT scanning and some of the other widely used techniques are illustrated and described in ***Medical Imaging of the Body*** online at ***A&P Connect.***

Box 1-1 | DIAGNOSTIC study

Body Type and Disease

The concept of body types is a good example of how structure and function are interrelated. The term **somatotype** is used to describe a particular category of body build, or physique. Although the human body comes in many sizes and shapes, every individual can be classified as belonging to one of three basic body types, or somatotypes. The names used to describe these body types are as follows:

Ectomorph: thin, fragile physique characterized by little body fat accumulation



Mesomorph: muscular physique

Endomorph: heavy, rounded physique characterized by large accumulations of fat in the trunk and thighs

The figure shows extreme examples of the three somatotypes. By carefully studying the body build of numerous individuals, scientists have found that the basic components that determine the different categories of physique occur in varying degrees in every person—both men and women. Only in very rare instances does an individual show almost total dominance by a single somatotype component.

Until recently the concept of somatotype was considered largely "historical" and of relatively little practical importance. However, new research findings have rekindled interest in this area. We now know, for example, that knowledge of physique can provide health care professionals and educators with vital information useful in such areas as disease screening procedures, programs designed to identify individuals who may be at risk for certain diseases, and prediction of performance capability in selected physical education programs.

Researchers have discovered that individuals (especially endomorphs) who have large waistlines and are "apple-shaped," or fattest in the abdomen, have a greater risk for heart disease, stroke, high blood pressure, and diabetes than do individuals with a lower "pear-shaped" distribution pattern of fat in the hips, thighs, and buttocks. Breast cancer in postmenopausal women is also associated with storage of fat in the abdomen and upper body area (apple shape). In both sexes, endomorphic individuals of the same height and weight but with a lower, or pear-shaped, body fat distribution pattern contracted these diseases more frequently than mesomorphs and ectomorphs but less frequently than endomorphs with an apple-shaped, or high body fat distribution pattern.

Body types and health risks.

HOMEOSTASIS

More than a century ago a great French physiologist, Claude Bernard (1813-1878), made a remarkable observation. He noted that body cells survived in a healthy condition only when the temperature, pressure, and chemical composition of their fluid environment remained relatively constant. He called the environment of cells the *internal environment*, or *milieu intérieur*. Bernard realized that although many elements of the external environment in which we live are in a constant state of change, important elements of the internal environment, such as body temperature, remain remarkably stable. For example, Bernard's neighbor, who travels from his Paris home heated with a fireplace to the snowy slopes of the Alps in January, is exposed to dramatic changes in air temperature within a few hours.

Fortunately, in a healthy individual, body temperature will remain at or very near normal regardless of temperature changes that may occur in the external environment. Just as the external environment surrounding the body as a whole is subject to

change, so too is the fluid environment surrounding each body cell. The remarkable fluid that bathes each cell contains literally dozens of different substances. Good health, indeed life itself, depends on the correct and constant amount of each substance in the blood and other body fluids. The precise and constant chemical composition of the internal environment must be maintained within very narrow limits ("normal ranges"), or sickness and death will result.

In 1932 a famous American physiologist, Walter B. Cannon, suggested the name **homeostasis** (ho-me-o-STAY-sis) for the relatively constant states maintained by the body. Homeostasis is a key word in modern physiology. It comes from two Greek words (*homoios*, "the same," and *stasis*, "standing"). "Standing or staying the same," then, is the literal meaning of homeostasis. In his classic publication titled *The Wisdom of the Body*, Cannon advanced one of the most unifying and important themes of physiology. He suggested that every regulatory mechanism of the body existed to maintain homeostasis, or constancy, of the body's internal fluid environment.

However, as Cannon emphasized, homeostasis does not mean something set and immobile that stays exactly the same all the time. In his words, homeostasis "means a condition that may vary, but which is relatively constant." It is the maintenance of relatively constant internal conditions despite changes in either the internal or the external environment that characterizes homeostasis. For example, even if external temperatures vary, homeostasis of body temperature means that it remains relatively constant at about 37° C (98.6° F), although it may vary slightly above or below that point and still be "normal." The fasting concentration of blood glucose, an important nutrient, can also vary somewhat and still remain within normal limits (Figure 1-11).

This normal reading or range of normal is called the **set point** or **set point range.** A value between 80 and 100 mg of glucose per milliliter of blood, depending on dietary intake and timing of meals, is typical. Although levels of the important gases oxygen and carbon dioxide also vary with the respiratory rate, these substances, like body temperature and blood glucose levels, must be maintained within very narrow limits.

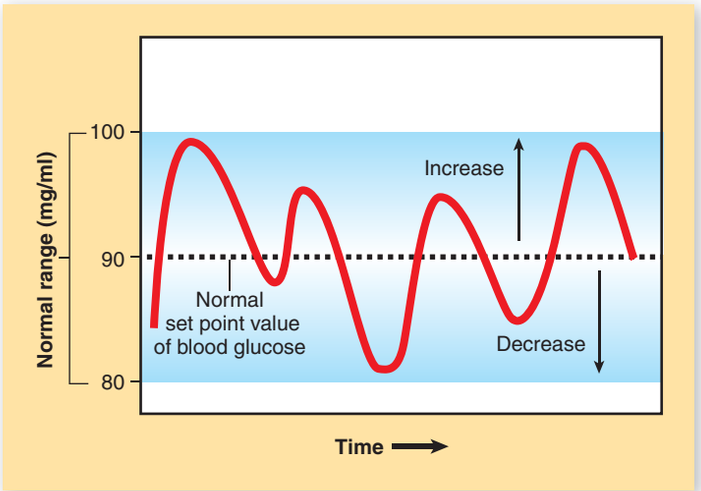


FIGURE 1-11

Homeostasis of blood glucose. The range over which a given value, such as the blood glucose concentration, is maintained is accomplished through homeostasis. Note that the concentration of glucose fluctuates above and below a normal set point value (90 mg/ml) within a normal set point range (80 to 100 mg/ml).

| A&P CONNECT |

What are the normal set point values for the concentration of clinically important substances found in the body? Check out ***Clinical and Laboratory Values*** online at ***A&P Connect.***

evolve

Specific regulatory mechanisms are responsible for adjusting body systems to maintain homeostasis. This ability of the body to "self-regulate," or "return to normal" to maintain homeostasis, is a critically important concept in modern physiology and also serves as a basis for understanding mechanisms of disease. Each cell of the body, each tissue, and each organ system plays an important role in homeostasis. Each of the diverse regulatory systems described in subsequent chapters of the text is explained as a function of homeostasis. You will learn how specific regulatory activities such as temperature control or carbon dioxide elimination are accomplished. In addition, an understanding of the relationship of homeostasis to healthy survival helps explain why such mechanisms are necessary.

Take a moment to study Figure 1-12. This diagram is a classic way of envisioning the idea of the body as a "bag of fluid." The fluid inside the bag is our internal environment, and it is this fluid that must be kept at a relatively constant temperature, glucose level, and so on, if the cells that make up the body are to survive. It is like a big, walking fishbowl, and our cells are the fish. All the little tubes and gizmos you see in Figure 1-12 are the systems that keep the "water in the fishbowl"—your internal fluid environment—stable. For example, the tube representing the digestive tract is a way for food in the external environment to be absorbed into the internal environment. So, just as you feed your goldfish every day, keeping the nutrient level in the fishbowl relatively constant over the years, your digestive tract keeps your body's nutrient levels relatively constant over the years.

All the other "accessories" in Figure 1-12 are like the accessories you may use in your fishbowl. The urinary system is like a filter that keeps waste levels constantly low. The respiratory system is like an aquarium's air pump and gets oxygen deep into the body to keep oxygen levels high for your cells. Throughout the book, we will regularly refer back to this diagram and the idea it represents—because this idea is the foundation for understanding all of physiology. If you know that everything functions to keep your "fishbowl" of a body constant so that your "fish," or cells, will stay alive, you can understand the basic function of every organ of every system!

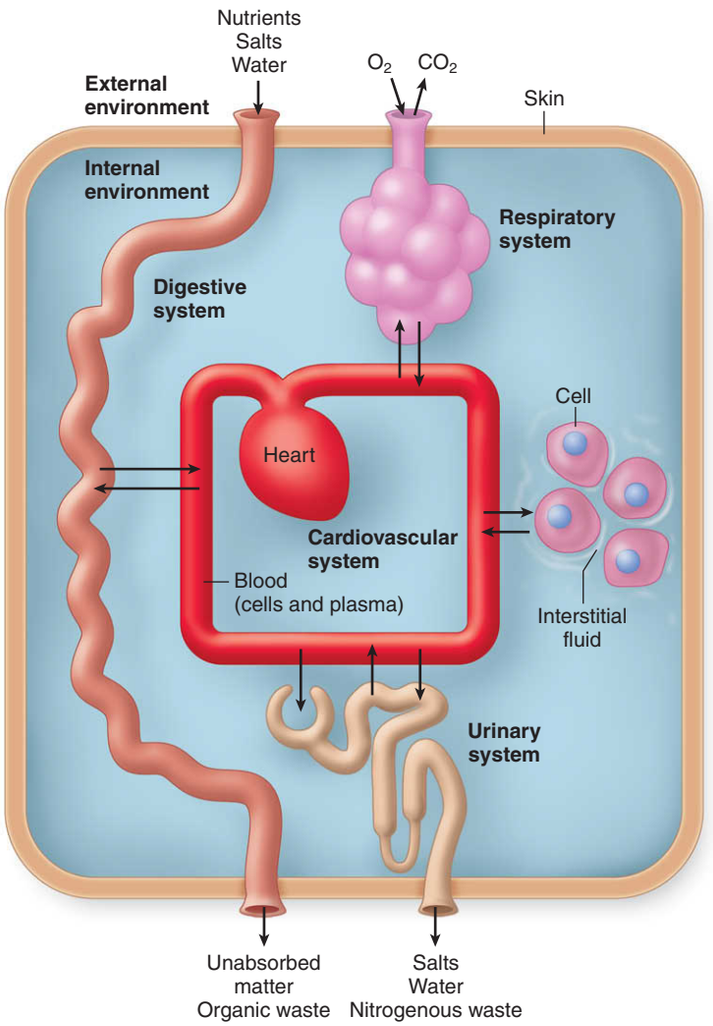

FIGURE 1-12

Diagram of the body's internal environment. The human body is like a bag of fluid separated from the external environment. Tubes, such as the digestive tract and respiratory tract, bring the external environment to deeper parts of the bag where substances may be absorbed into the internal fluid environment or excreted into the external environment. All the "accessories" somehow help maintain a constant environment inside the bag that allows the cells that live there to survive.

HOMEOSTATIC CONTROL MECHANISMS

Maintaining homeostasis means that the cells of the body are in an environment that meets their needs and permits them to function normally under changing external conditions. Processes for maintaining or restoring homeostasis are known as *homeostatic control mechanisms*. They involve virtually all of the body's organs and systems. If circumstances occur that require changes or more active regulation in some aspect of the internal environment, the body must have appropriate control mechanisms available that respond to these changing needs and then restore and maintain a healthy internal environment. For example, exercise increases the need for oxygen and results in accumulation of the waste product carbon dioxide. By increasing our breathing rate above its average of about 17 breaths per minute, we can maintain an adequate blood oxygen level and also increase the elimination of carbon dioxide. When exercise stops, the need for an increased respiratory rate no longer exists and the frequency of breathing returns to normal.

To accomplish this self-regulation, a highly complex and integrated communication control system or network is required. This type of network is called a **feedback control loop.** Different networks in the body control such diverse functions as blood carbon dioxide levels, temperature, heart rate, sleep cycles, and thirst. Information may be transmitted in these control loops by nervous impulses or by specific chemical messengers called *hormones*, which are secreted into the blood. Regardless of the body function being regulated or the mechanism of information transfer (nerve impulse or hormone secretion), these feedback control loops have the same basic components and work in the same way.

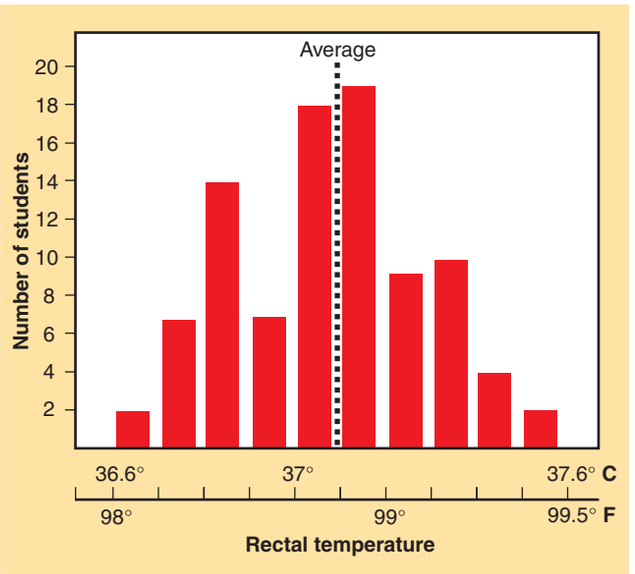
Basic Components of Control Mechanisms

There is a minimum of four basic components in every feedback control loop:

1. Sensor mechanism
2. Integrating, or control, center
3. Effector mechanism
4. Feedback

The terms *afferent* and *efferent* are important directional terms frequently used in physiology. They are used to describe movement of a signal from a sensor mechanism to a particular integrating or control center and, in turn, movement of a signal from that center to some type of effector mechanism. *Afferent* means that a signal is traveling toward a particular center or point of reference, and *efferent* means that the signal is moving away from a center or other point of reference. These terms are of particular importance in the study of the nervous and endocrine systems in Unit Three.

The process of regulation and the concept of return to normal require that the body be able to "sense" or identify the variable being controlled. Sensory nerve cells or hormone-producing (endocrine) glands frequently act as homeostatic sensors. To function in this way, a sensor must be able to identify the element being controlled. It must also be able to respond to any changes that may occur from the normal set point range. If deviations from the normal set point range occur, the sensor generates an afferent signal (nerve impulse or hormone) to transmit that information to the second component of the feedback loop—the integration or control center (Box 1-2).



When the integration or control center of the feedback loop (often a discrete area of the brain) receives input from a homeostatic sensor, that information is analyzed and integrated with input from other sensors, and then an efferent signal travels from the center to some type of effector mechanism, where a specific action is initiated, if necessary, to maintain homeostasis. First, the level or magnitude of the variable being measured by the sensor is compared with the normal set point level that must be maintained for homeostasis. If significant deviation from that predetermined level exists, the integration/control center sends its own signal to the third component of the control loop—the effector mechanism.

Effectors are organs, such as muscles or glands, that directly influence controlled physiological variables. For example, it is

Box 1-2 | FYI

Changing the Set Point

Like the set point on a furnace, the physiological set points in your body can be changed. Your body's set point temperature is a good example. First, not everyone's set point, or "normal," body temperature is the same. The figure at right shows the difference in body temperatures observed in a group of healthy students. You can see that temperatures varied widely. This explains why some people are comfortable at a temperature that is too cold for others around them—their temperature set point must be lower. However, your set point can also change under varying circumstances. For example, we know a fellow who once turned up the thermostat in his house to get the temperature warm enough to get some unwelcome visitors to leave. Likewise, during a bacterial infection, your immune system sends chemicals to signal the brain's hypothalamus to "turn up the set point temperature." Your body shivers, and you may ask for a blanket as your body tries to reach this new higher set point. You now have a fever. The bacteria that have invaded your body did so because they liked the temperature of your body. When you are experiencing a fever, your body becomes uncomfortably warm for the bacteria, and they slow down their reproductive rate, which slows the infection. At the same time, the warmer temperature helps improve the immune system's function as it deals with the bacteria. After the infection is over, the hypothalamus returns to its usual set point and your fever goes away.

Range of normal body temperatures. In a well-controlled experiment, a group of healthy students show a wide range of normal rectal temperatures. The average (mean) temperature of the group is 37.1° C (98.8° F).

effector action that increases or decreases variables such as body temperature, heart rate, blood pressure, or blood sugar concentration to keep them within their normal range. The activity of effectors is ultimately regulated by feedback of information regarding their own effects on a controlled variable.

Many instructors use the example of a furnace controlled by a thermostat to explain how feedback control systems work. This analogy is a good one because it parallels the homeostatic mechanism used to control body temperature. Note that changes in room temperature (the controlled variable) are detected by a thermometer (sensor) attached to the thermostat (integrator) (Figure 1-13, A). The thermostat contains a switch that controls the furnace (effector). When cold weather causes a decrease in room temperature, the change is detected by the thermometer and relayed to the thermostat. The thermostat compares the actual room temperature with the set point temperature. After the integrator determines that the actual temperature is too low, it sends a "correction" signal by switching on the furnace. The furnace produces heat and thus increases room temperature back toward normal. As the room temperature increases above normal, feedback information from the thermometer causes the thermostat to switch off the furnace. Thus by intermittently switching the furnace off and on, a relatively constant room temperature can be maintained.

Body temperature can be regulated in much the same way as room temperature is regulated by the furnace system just described (see Figure 1-13, B). Here, sensory receptors in the skin and other tissues act as sensors by monitoring body temperature. When cold weather causes the body temperature to decrease, feedback information is relayed through the nerves to the "thermostat" in a part of the brain called the *hypothalamus* (hye-poh-THAL-ah-muss). The hypothalamic integrator compares the actual body temperature with the "built-in" set point body temperature and subsequently sends a nerve signal to effectors. In this example, the skeletal muscles act as effectors by shivering and thus producing heat. Shivering increases body temperature back to normal, at which point it stops as a result of feedback information that causes the hypothalamus to shut off its stimulation of the skeletal muscles. More specifics of body temperature control are discussed in Chapter 7.

The impact of effector activity on sensors may be positive or negative. Therefore, homeostatic control mechanisms are categorized as negative or positive feedback systems. By far the most important and numerous of the homeostatic control mechanisms are negative feedback systems.

Negative Feedback Control Systems

The example of temperature regulation by action of a thermostatically regulated furnace is a classic example of **negative feedback.** Negative feedback control systems are inhibitory. They oppose a change (such as a drop in temperature) by creating a response (production of heat) that is opposite in direction to the initial disturbance (fall in temperature below a normal set point). All negative feedback mechanisms in the body respond in this way regardless of the variable being controlled. They produce an action that is opposite to the change that activated the system. It is important to emphasize that negative feedback control systems

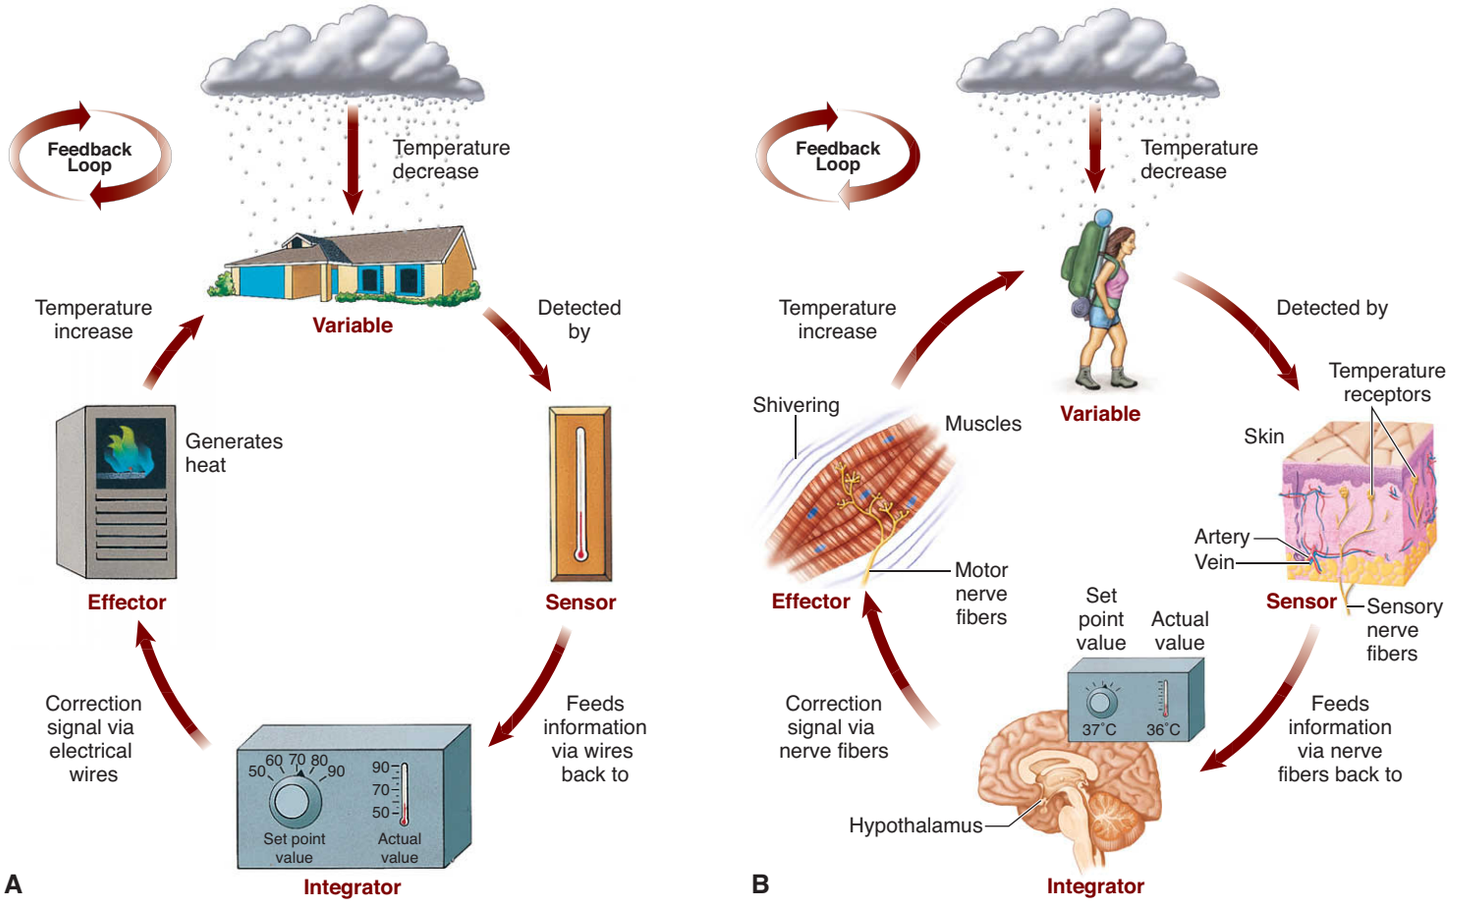


FIGURE 1-13

Basic components of homeostatic control mechanisms. **A,** Heat regulation by a furnace controlled by a thermostat. **B,** Homeostasis of body temperature. Note that in both examples **A** and **B,** a stimulus (drop in temperature) activates a sensor mechanism (thermostat or body temperature receptor) that sends input to an integrating, or control, center (on-off switch or hypothalamus), which then sends input to an effector mechanism (furnace or contracting muscle). The resulting heat that is produced maintains the temperature in a "normal range." Feedback of effector activity to the sensor mechanism completes the control loop. Both are examples of negative feedback loops.

stabilize physiological variables. They keep variables from straying too far outside their normal ranges. Negative feedback systems are responsible for maintaining a constant internal environment.

Positive Feedback Control Systems

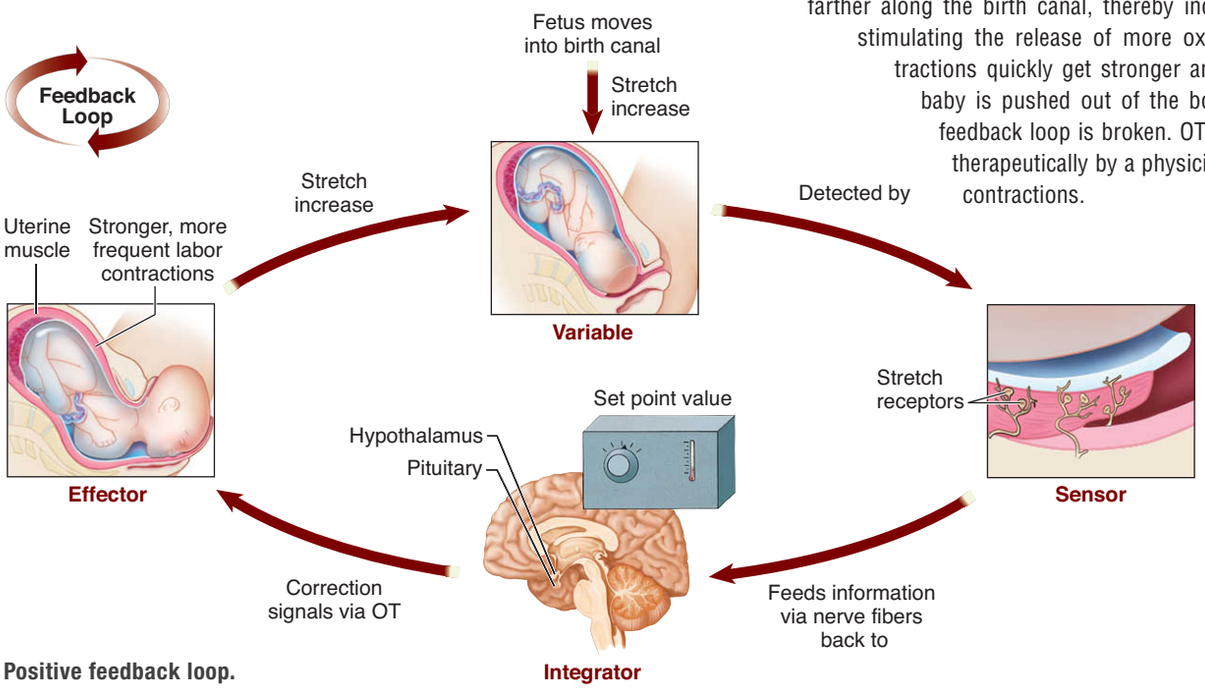
Positive feedback is also possible in control systems. However, because positive feedback does not operate to help the body maintain a stable, or homeostatic, condition, it is often harmful, even disastrous, to survival. Positive feedback control systems are stimulatory.

Instead of opposing a change in the internal environment and causing a return to normal, positive feedback tends to amplify or reinforce the change that is occurring. In the example of the furnace controlled by a thermostat, a positive feedback loop continues to increase the temperature. It does so by stimulating the furnace to produce more and more heat. Each increase in heat production is followed by a positive stimulation to increase the temperature even more. Typically, such responses result in instability and disrupt homeostasis because the variable in question continues to deviate further and further away from its normal range.

Only a few examples of positive feedback operate in the body under normal conditions. In each case, positive feedback accelerates the process in question. The feedback causes an ever-increasing rate of events to occur until something stops the process. In other words, positive feedback loops tend to amplify or accelerate a change—in contrast to negative feedback loops, which reverse a change. Although positive feedback is not the usual type of feedback in the body, it is no less important (Box 1-3).

Events that lead to a simple sneeze, the birth of a baby, an immune response to an infection, or the formation of a blood clot are all examples of positive feedback.

Feed-Forward in Control Systems



As you study the complexity of control systems throughout the body, you will no doubt run into cases of *feed-forward* in control systems. Feed-forward is the concept that information may flow ahead to another process to trigger a change in anticipation of an event that will follow. For example, when you eat a meal, the stomach stretches and this triggers stretch sensors in the stomach wall. As you would expect, the stretch sensors trigger a feedback response that causes the release of digestive juices and contraction of stomach muscles. This is normal negative feedback because secretion and muscle activity eventually get rid of the food and bring the stretch of the stomach back down to normal. It will continue as long as there is food to

Box 1-3 | FYI

Positive Feedback During Childbirth

One of the mechanisms that operates during delivery of a newborn illustrates the concept of positive feedback. As delivery begins, the baby is pushed from the *womb,* or *uterus,* into the birth canal, or *vagina.* Stretch receptors in the wall of the reproductive tract detect the increased stretch caused by movement of the baby. Information regarding increased stretch is fed back to the brain, which triggers the pituitary gland to secrete a hormone called *oxytocin* (OT).

Oxytocin travels through the bloodstream to the uterus, where it stimulates stronger contractions. Stronger contractions push the baby farther along the birth canal, thereby increasing stretch and stimulating the release of more oxytocin. Uterine contractions quickly get stronger and stronger until the baby is pushed out of the body and the positive feedback loop is broken. OT can also be injected therapeutically by a physician to stimulate labor contractions.

Positive feedback loop.

stretch the stomach. At the same time, the stretch stimulus is triggering the small intestine and related organs to increase secretion there as well—*before* the food has arrived. In other words, information from one feedback loop (in the stomach) has leaped ahead to the next logical feedback loop (in the intestines) to get the second loop ready ahead of time. Feed-forward causes a feedback loop to anticipate a stimulus (in this case, stretch of the intestinal wall caused by food moving down from the stomach) before it actually happens.

Levels of Control

One of the first principles that will occur to you as you study human physiology is that the functions of cells, tissues, organs, and systems are integrated into a coordinated whole. This is accomplished by many different feedback loops and feed-forward systems operating at many different levels of organization within the body (Figure 1-14).

Intracellular control mechanisms operate at the cell level. These mechanisms regulate functions within the cell, often by means of genes and enzymes. The role of genes and enzymes is discussed further in Chapters 4 and 5.

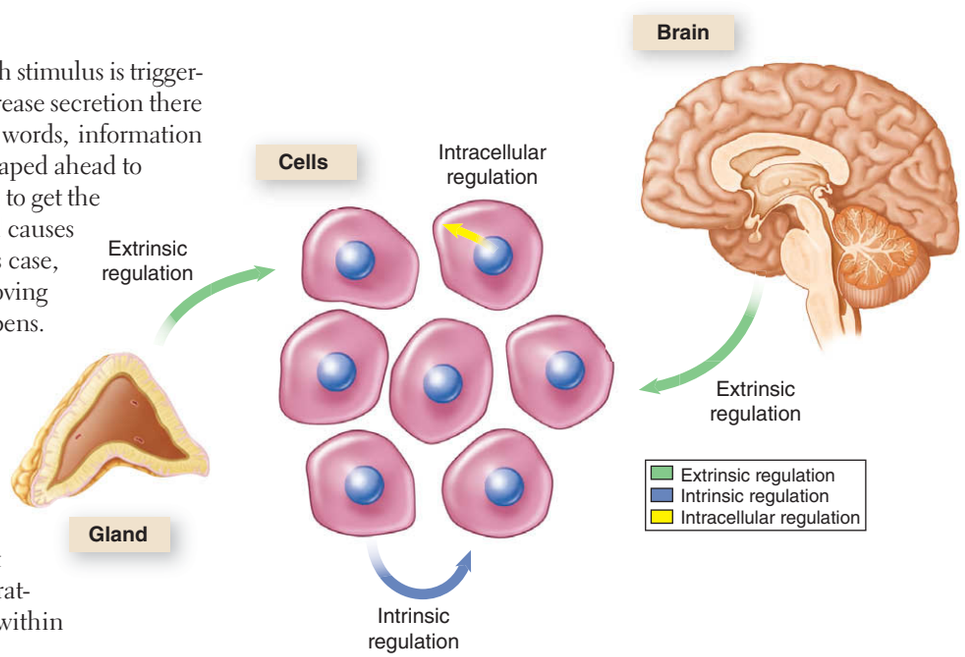


FIGURE 1-14

Levels of control. The many complex processes of the body are coordinated at many levels: intracellular (within cells), intrinsic (within tissues/organs), and extrinsic (organ to organ).

Intrinsic control mechanisms operate at the tissue and organ levels. Sometimes also called local control or *autoregulation*, intrinsic mechanisms often make use of chemical signals. For example, prostaglandins are molecules sent as signals to other nearby cells. Intrinsic regulation may also be "built in" to the tissue or organ. For instance, when cardiac muscle in the heart is stretched, the muscle automatically contracts with more force. Prostaglandins are discussed further in Chapters 2 and 18. Many other examples of intrinsic control are discussed throughout the book.

Extrinsic control means "outside" control and operates at the system and organism levels. Extrinsic control usually involves nervous and endocrine (hormonal) regulation. It is called "extrinsic" control because the nerve signals and hormones originate outside the controlled organ. Nervous regulation is introduced in more detail in Chapters 13 through 17 and endocrine regulation is introduced in Chapter 18.

Summary of Homeostasis

In summary, many homeostatic mechanisms operate on the negative feedback principle. They are activated, or turned on, by changes in the environment that surround every body cell. Negative feedback systems are inhibitory. They reverse the change that initially activated the homeostatic mechanism. By reversing the initial change, a homeostatic mechanism tends to maintain or restore internal constancy. Occasionally, a positive (stimulatory) feedback mechanism helps promote survival. Such positive or stimulatory feedback systems may be required to bring specific body functions to swift completion (see Box 1-3). Feed-forward occurs when sensory information "jumps ahead" to a feedback loop to get it started before the stimulus actually changes the controlled physiological variable.

Homeostatic control systems can operate at any (or all) of several different levels: within the cell, from cell to cell within a tissue, and throughout the body. This layering of regulation allows for precise coordination of functions within organs as well as in the whole body.

| QUICK CHECK |

22. Define the term *homeostasis.*
23. List the basic components of every feedback control system.
24. Explain the mechanism of action of negative and positive feedback control systems.
25. Contrast intracellular, intrinsic, and extrinsic levels of control.

Cycle of LIFE

Life Span Considerations

An important generalization about body structure is that every organ, regardless of location or function, undergoes change over the years. In general, the body performs its functions least well at both ends of life—in infancy and in old age. Organs develop and grow during the years before maturity, and body functions gradually become more and more efficient and effective. In a healthy young adult all body systems are mature and fully operational. Homeostatic mechanisms tend to function most effectively during this period of life to maintain the constancy of one's internal environment.

After maturity, effective repair and replacement of the body's structural components often decrease. The term **atrophy** is used to describe the wasting effects of advancing age. In addition to structural atrophy, the functioning of many physiological control mechanisms also decreases and becomes less precise with advancing age. The changes in functions that occur during the early years are called *developmental processes.* Those that occur during the late years are called *aging processes.* The study of aging processes and other changes that occur in our lives as we get older is called *gerontology.* Many specific age changes are noted in the chapters that follow.

the BIG picture

Organization of the Body

Ultimately, your success in the study of anatomy and physiology, your ability to see the "big picture," will require understanding, synthesis, and integration of structural information and functional concepts. After you have completed your study of the individual organ systems of the body presented in the chapters that follow, you must be able to reassemble the parts and view the body in a holistic, integrated way.

The body is truly more than the sum of the parts, and understanding the connectedness of human structure and function is the real challenge—and the greatest reward—in the study of anatomy and physiology. Your ability to integrate otherwise isolated factual information about bones, muscles, nerves, and blood vessels, for example, will allow you to view anatomical components of the body and their functions in a more cohesive and understandable way. This chapter introduces the principle of homeostasis as the glue that integrates and explains how the normal interaction of structure and function is achieved and maintained and how a breakdown of this integration results in disease. Furthermore, it provides the basis for understanding and integrating the body of knowledge, both factual and conceptual, that anatomy and physiology encompass.

Mastery of any academic discipline or achieving success in any health care–related work environment requires the ability to communicate effectively. The ability to understand and appropriately use the vocabulary of anatomy and physiology allows you to accurately describe the body itself, the orientation of the body in its surrounding environment, and the relationships that exist between its component parts in both health and disease. This chapter provides you with information necessary to be successful in seeing "the big picture" as you master the details of each organ system that, although presented separately in subsequent chapters of the text, are in reality part of a marvelously integrated whole.

MECHANISMS of DISEASE

SOME GENERAL CONSIDERATIONS

A clearer understanding of the normal function of the body often comes from our study of disease (Box 1-4). **Pathophysiology** is the organized study of the underlying physiological processes associated with disease. Pathophysiologists attempt to understand the mechanisms of a disease and its course of development, or *pathogenesis*. Near the end of each chapter of this book we briefly describe some important disease mechanisms that illustrate the breakdown of normal functions described in that chapter.

Many diseases are best understood as disturbances to homeostasis, the relative constancy of the body's internal environment. If homeostasis is disturbed, various negative feedback mechanisms usually return the body to normal. When a disturbance goes beyond the normal fluctuation of everyday life, we can say that a disease condition exists. In acute conditions the body recovers its homeostatic balance quickly. In chronic diseases a normal state of balance may never be restored. If the disturbance keeps the body's internal environment too far from normal for too long, death may result.

Basic Mechanisms of Disease

Disturbances to homeostasis and the body's responses are the basic mechanisms of disease. Because of their variety, disease mechanisms can be categorized for easier study:

Genetic mechanisms. Altered, or mutated, genes can cause abnormal proteins to be made. These abnormal proteins often do not perform their intended function—resulting in the absence of an essential function. On the other hand, such proteins may instead perform an abnormal, disruptive function. Either case poses a potential threat to the constancy of the body's internal environment. The action of genes is first discussed in Chapter 3, and the mechanisms by which genes are inherited are discussed in Chapter 37.

Pathogenic organisms. Many important disorders are caused by pathogenic (disease-causing) organisms or particles that damage the body in some way (Figure 1-15). Any organism that lives in or on another organism to obtain its nutrients is called a *parasite*.

Box 1-4 | HEALTH matters

Disease Terminology

Everyone is interested in **pathology**—the study of disease. Researchers want to know the scientific basis of abnormal conditions. Health practitioners want to know how to prevent and treat various diseases. Every one of us, when we suffer from the inevitable head cold or something more serious, want to know what is going on and how best to deal with it. Pathology has its own terminology, as in any specialized field. Just as with other scientific terms, most disease-related terms are derived from Latin and Greek word parts. For example, patho- comes from the Greek word for disease (*pathos*) and is used in many terms, including "pathology" itself.

Disease conditions are usually *diagnosed* or identified by **signs** and **symptoms.** Signs are objective abnormalities that can be seen or measured by someone other than the patient, whereas symptoms are the subjective abnormalities that are felt only by the patient. Although *sign* and *symptom* are distinct terms, we often use them interchangeably. A **syndrome** is a collection of different signs and symptoms that occur together. When signs and symptoms appear suddenly, persist for a short time, and then disappear, we say that the disease is **acute.** On the other hand, diseases that develop slowly and last for a long time (perhaps for life) are labeled **chronic** diseases. The term *subacute* refers to diseases with characteristics somewhere between acute and chronic.

The study of all the factors involved in causing a disease is its **etiology.** The etiology of a skin infection often involves a cut or abrasion and subsequent invasion and growth of a bacterial colony. Diseases with undetermined causes are said to be **idiopathic. Communicable** diseases are those that can be transmitted from one person to another.

The term *etiology* refers to the theory of a disease's cause, but the actual pattern of a disease's development is called its **pathogenesis.** The common cold, for example, begins with a *latent,* or "hidden," stage during which the cold virus establishes itself in the patient. No signs of the cold are yet evident. In infectious diseases, the latent stage is also called **incubation.** The cold may then manifest itself as a mild nasal drip and trigger a few sneezes. It subsequently progresses to its full fury and continues for a few days. After the cold infection has run its course, a period of *convalescence,* or recovery, occurs. During this stage, body functions return to normal. Some chronic diseases, such as cancer, exhibit a temporary reversal that seems to be a recovery. Such reversal of a chronic disease is called a **remission.** If a remission is permanent, we say that the person is "cured."

Epidemiology is the study of the occurrence, distribution, and transmission of diseases in human populations. A disease that is native to a local region is called an **endemic** disease. If the disease spreads to many individuals in a relatively short time, the situation is called an **epidemic. Pandemics** are epidemics that affect large geographic regions, perhaps spreading worldwide. Because of the speed and availability of modern air travel, pandemics are more common than they once were. Almost every flu season we see a new strain of influenza virus quickly spreading from continent to continent.

Names of specific diseases are often descriptive, such as *rheumatoid arthritis* (meaning "autoimmune inflammation of joints"). Some disease names are eponyms, with a person's name incorporated into the term, as in *Parkinson disease (PD).* Notice that we follow the American Medical Association (AMA) format for eponyms in this textbook, which prohibits adding the possessive ('s) to a person's name. Notice also that some disease names are abbreviated with an acronym such as *DMD* (for *Duchenne muscular dystrophy*).

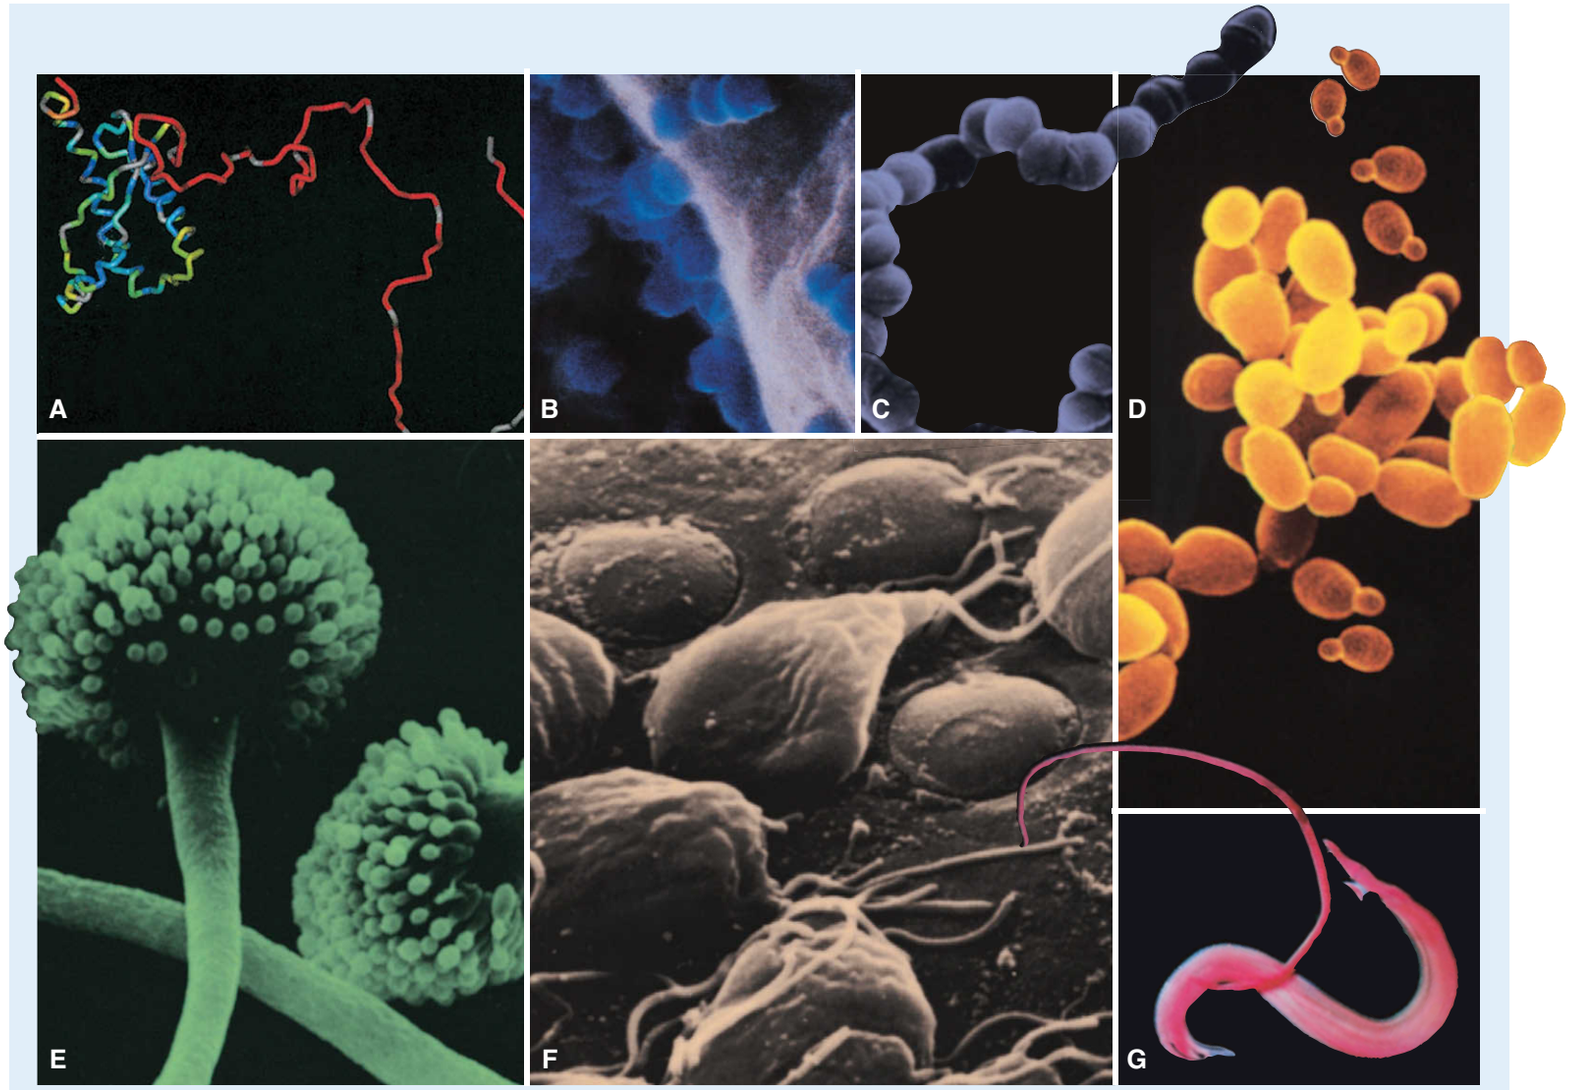

FIGURE 1-15

Pathogenic organisms. A, Prion (cause of variant Creutzfeldt-Jakob disease). **B,** Viruses (the human immunodeficiency virus [HIV] that causes AIDS). **C,** Bacteria (Streptococcus bacteria that cause strep throat and other infections). **D,** Fungi (yeast cells that commonly infect the urinary and reproductive tracts). **E,** Fungi (the mold that causes aspergillosis). **F,** Protozoans (the flagellated cells that cause traveler's diarrhea). **G,** Pathogenic animals (the parasitic worms that cause snail fever).

The presence of microscopic or larger parasites may interfere with normal body functions of the host and cause disease. Besides parasites, there are organisms that poison or otherwise damage the human body to cause disease. Some of the major pathogenic organisms and particles include the following:

Prions (proteinaceous infectious particles) are proteins that convert normal proteins of the nervous system into abnormal proteins, thereby causing loss of nervous system function. The abnormal form of the protein may also be inherited. Prion protein (also called *PrP*) molecules are a newly discovered type of pathogen, and not much is known about how the prion works to cause such diseases as bovine spongiform encephalopathy (BSE; "mad cow disease") or variant Creutzfeldt-Jakob disease (vCJD). However, not all prions cause disease. Some are now known to be involved in memory formation and the normal maintenance of the insulating sheath around many nerve fibers.

Viruses are intracellular parasites that consist of a DNA or RNA core surrounded by a protein coat and, sometimes, a lipoprotein envelope. They are particles that invade human cells and cause them to produce viral components. Sometimes, the term *virion* is used to designate the complete virus particle as it exists outside the host cell.

Bacteria are tiny, primitive cells that lack nuclei. They cause infection by parasitizing tissues or otherwise disrupting normal function.

Fungi are simple organisms similar to plants but lack the chlorophyll pigments that allow plants to make their own food. Because they cannot make their own food, fungi must parasitize other tissues, including those of the human body. **Protozoa** are protists, one-celled organisms larger than bacteria whose DNA is organized into a nucleus. Many types of protozoa parasitize human tissues. **Pathogenic animals** are large, multicellular organisms such as

insects and worms. Such animals can parasitize human tissues, bite or sting, or otherwise disrupt normal body function.

Examples of infections or other conditions caused by pathogenic organisms are given in many chapters throughout this book.

- **Tumors and cancer.** Abnormal tissue growths, or neoplasms, can cause various physiological disturbances, as described in Chapter 6.
- **Physical and chemical agents.** Agents such as toxic or destructive chemicals, extreme heat or cold, mechanical injury, and radiation can each affect the normal homeostasis of the body. Examples of healing of tissues damaged by physical agents are discussed in Chapters 6, 7, and a few other chapters.
- **Malnutrition.** Insufficient or imbalanced intake of nutrients causes various diseases; these are outlined in Chapters 29 and 30.
- **Autoimmunity.** Some diseases result from the immune system attacking one's own body (*autoimmunity*) or from other mistakes or overreactions of the immune response. Autoimmunity, literally "self-immunity," is discussed in Chapter 24 along with other disturbances of the immune system.
- **Inflammation.** The body often responds to disturbances with an *inflammatory response*. The inflammatory response, which is described in Chapters 6 and 24, is a normal mechanism that usually speeds recovery from an infection or injury. However, when the inflammatory response occurs at inappropriate times or is abnormally prolonged or severe, normal tissues may become damaged. Thus some disease symptoms are caused by the inflammatory response.
- **Degeneration.** By means of many still unknown processes, tissues sometimes break apart or *degenerate*. Although a normal consequence of aging, degeneration of one or more tissues resulting from disease can occur at any time. The degeneration of tissues associated with aging is discussed in nearly every chapter of this book.

Risk Factors

Other than direct causes or disease mechanisms, certain predisposing conditions may exist that make a disease more likely to develop. Usually called *risk factors*, they often do not actually cause a disease but just put one "at risk" for it. Risk factors can combine and increase a person's chance for contracting a specific disease even more. Some of the major types of risk factors are as follows:

Genetic factors. There are several types of genetic risk factors. Sometimes an inherited trait puts one at greater than normal risk for development of a specific disease. For example, light-skinned people are more at risk for certain forms of skin cancer than are dark-skinned people. This occurs because light-skinned people have less pigment in their skin to protect them from cancer-causing ultraviolet radiation (see Chapter 7). Membership in a certain ethnic group, or *gene pool*, involves the "risk" of inheriting a disease-causing gene that is common in that gene pool. For example, certain Africans and their descendants are at greater than average risk of inheriting *sickle cell anemia*—a serious blood disorder.

Age. Biological and behavioral variations during different phases of the human life cycle put us at greater risk for certain diseases at certain times in our life. For example, middle ear infections are more common in infants than in adults because of the difference in ear structure at different ages.

Lifestyle. The way we live and work can put us at risk for some diseases. People whose work or personal activity puts them in direct sunlight for long periods have a greater chance for development of skin cancer because this puts them in more frequent contact with ultraviolet radiation from the sun. Some researchers believe that the high-fat, low-fiber diet common among people in the "developed" nations increases the risk for certain types of cancer.

Stress. Physical, psychological, or emotional stress can put one at risk for problems such as chronic high blood pressure (hypertension), peptic ulcers, and headaches. Conditions caused by psychological factors are sometimes called *psychogenic* (mind-caused) disorders. Chapter 25 discusses the concept of stress and its effect on health.

Environmental factors. Although environmental factors such as climate and pollution can actually cause injury or disease, some environmental situations simply put us at greater risk for getting certain diseases. For example, because some parasites survive only in tropical environments, we are not at risk of being infected with them if we live in a temperate climate.

Microorganisms. Different types of pathological organisms, such as viruses and bacteria, are now suspected of being "infectious cofactors" in the development of certain noninfectious diseases that in the past were not considered to result directly from their presence in the body. For example, we now have very strong evidence to link infections caused by hepatitis B virus with liver cancer and human papillomavirus with cervical cancer. We also know that the bacterium *Helicobacter pylori*, which causes ulcers, is in some way also a factor in the development of certain types of stomach cancer.

Preexisting conditions. A preexisting condition can adversely affect our capacity to defend ourselves against an entirely different condition or disease. Thus the *primary* (preexisting) condition can put a person at risk for development of a *secondary* condition. For example, in individuals with AIDS the primary condition is characterized by a suppressed immune system. As a result, secondary or "opportunistic" infections such as pneumonia often develop. Obesity is a risk factor for many conditions, including heart disease, diabetes, stroke, some forms of cancer, and high blood pressure.

| A&P CONNECT |

World events have shown us that the intentional transmission of disease can be used as a weapon of terror. For example, the bacterial infection anthrax usually infects grazing animals such as sheep, but has been used as a weapon against people. For more, check out ***Disease as a Weapon*** online at ***A&P Connect.***

CASE study

Seamus is just starting his first year in college, and he's been thinking about going into the medical field—maybe nursing. To find out what nursing is really like, Seamus signed up for a "shadow a nurse" day at the local hospital. He's scheduled to follow a nurse in the emergency department to see what the job involves.

Everything is rather boring and quiet for the first hour; then suddenly an ambulance pulls into the bay and a paramedic rushes a patient in on a stretcher. The paramedic gives a quick patient report, and Seamus hears, "Stab wound to the right upper quadrant. He has additional cuts to his brachial region and a large contusion on his right lower extremity just proximal to the knee."

Seamus feels like he's listening to a foreign language! Can you help him interpret the paramedic's report?

1. Where was the patient stabbed?
   a. In his thoracic cavity
   b. In his abdominopelvic cavity
   c. In his pericardial cavity
   d. In his pleural cavity
2. What organ is most likely to have been damaged by the attack?
   a. His heart
   b. His lungs
   c. His liver
   d. His spleen
3. Where is the bruise (contusion) on the patient's body?
   a. Near his groin
   b. Just above his ankle
   c. His lower thigh
   d. Behind his knee
4. Where is the patient's brachial region?
   a. His femoral region
   b. His crural region
   c. His humoral region
   d. His popliteal region

HINT *To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook,* ***A&P Connect,*** *and other resources.*

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

SCIENCE AND SOCIETY

A. Science involves logical inquiry based on experimentation (Figure 1-1)
   1. Hypothesis—idea or principle to be tested in experiments
   2. Experiment—series of tests of a hypothesis; a controlled experiment eliminates biases or outside influences

3. Theory—a hypothesis that has been proved by experiments to have a high degree of confidence
4. Law—a theory that has an unusually high level of confidence

B. The process of science is active and changing as new experiments add new knowledge
C. Science is affected by culture and culture is affected by society

ANATOMY AND PHYSIOLOGY

A. Anatomy and physiology are branches of biology concerned with the form and functions of the body
B. Anatomy—science of the structure of an organism and the relationship of its parts
   1. Gross anatomy—study of the body and its parts relying only on the naked eye as a tool for observation (Figure 1-2)
   2. Microscopic anatomy—study of body parts with a microscope
      a. Cytology—study of cells
      b. Histology—study of tissues
   3. Developmental anatomy—study of human growth and development
   4. Pathological anatomy—study of diseased body structures
   5. Systemic anatomy—study of the body by systems
C. Physiology—science of the functions of organisms; subdivisions named according to:
   1. Organism involved—human or plant physiology
   2. Organizational level—molecular or cellular physiology
   3. Systemic function—respiratory physiology, neurophysiology, or cardiovascular physiology

LANGUAGE OF SCIENCE AND MEDICINE

A. Scientific terms are often based on Latin or Greek word parts
B. A terminology tool is provided in the pull-out section near the front of this textbook
C. *Terminologia Anatomica (TA)* and *Terminologia Histologica (TH)*
   1. Official lists of anatomical terms (*TA*, gross anatomy; *TH*, microscopic anatomy)
   2. Terms listed in Latin, English, and by number
   3. Avoids use of eponyms (terms based on a person's name)
D. Physiology terms do not have an official list but follow the same principles as *TA* and *TH*

CHARACTERISTICS OF LIFE

A. A single criterion may be adequate to describe life, for example:
   1. Autopoiesis—living organisms are self-organized and self-maintaining
   2. Cell theory—if it is made of one or more cells, it is alive
B. Characteristics of life considered most important in humans are summarized in Table 1-1
C. Metabolism—sum total of all physical and chemical reactions occurring in the living body

LEVELS OF ORGANIZATION (FIGURE 1-3)

A. Chemical level—basis for life
   1. Organization of chemical structures separates living material from nonliving material
   2. Organization of atoms, molecules, and macromolecules results in living matter—a gel called *cytoplasm*
B. Organelle level
   1. Chemical structures organized to form organelles that perform individual functions
   2. It is the functions of the organelles that allow the cell to live
   3. Dozens of organelles have been identified, including:
      a. Mitochondria
      b. Golgi apparatus
      c. Endoplasmic reticulum
C. Cellular level
   1. Cells—smallest and most numerous units that possess and exhibit characteristics of life
   2. Each cell has a nucleus surrounded by cytoplasm within a limiting membrane
   3. Cells differentiate to perform unique functions
D. Tissue level
   1. Tissue—an organization of similar cells specialized to perform a certain function
   2. Tissue cells are surrounded by nonliving matrix
   3. Four major tissue types
      a. Epithelial tissue
      b. Connective tissue
      c. Muscle tissue
      d. Nervous tissue
E. Organ level
   1. Organ—organization of several different kinds of tissues to perform a special function
   2. Organs represent discrete and functionally complex operational units
   3. Each organ has a unique size, shape, appearance, and placement in the body
F. System level
   1. Systems—most complex organizational units of the body
   2. System level involves varying numbers and kinds of organs arranged to perform complex functions (Table 1-2):
      a. Support and movement
      b. Communication, control, and integration
      c. Transportation and defense
      d. Respiration, nutrition, and excretion
      e. Reproduction and development
G. Organism level
   1. The living human organism is greater than the sum of its parts
   2. All of the components interact to allow the human to survive and flourish

ANATOMICAL POSITION (FIGURE 1-4)

A. Reference position
B. Body erect with arms at sides and palms forward

C. Head and feet pointing forward
D. *Bilateral symmetry*—a term meaning that right and left sides of the body are mirror images
   1. Bilateral symmetry confers balanced proportions
   2. Remarkable correspondence of size and shape between body parts on opposite sides of the body
   3. Ipsilateral structures are on the same side of the body in anatomical position
   4. Contralateral structures are on opposite sides of the body in anatomical position

BODY CAVITIES (FIGURE 1-5; TABLE 1-3)

A. Ventral body cavity
   1. Thoracic cavity
      a. Right and left pleural cavities
      b. Mediastinum
   2. Abdominopelvic cavity
      a. Abdominal cavity
      b. Pelvic cavity
B. Dorsal body cavity
   1. Cranial cavity
   2. Spinal cavity

BODY REGIONS (FIGURE 1-6; TABLE 1-4)

A. Axial subdivision
   1. Head
   2. Neck
   3. Torso, or trunk, and its subdivisions
B. Appendicular subdivision
   1. Upper extremity and subdivisions
   2. Lower extremity and subdivisions
C. Abdominopelvic regions (Figure 1-7)
   1. Right hypochondriac region
   2. Epigastric region
   3. Left hypochondriac region
   4. Right lumbar region
   5. Umbilical region
   6. Left lumbar region
   7. Right iliac (inguinal) region
   8. Hypogastric region
   9. Left iliac (inguinal) region
D. Abdominal quadrants (Figure 1-8)
   1. Right upper quadrant
   2. Left upper quadrant
   3. Right lower quadrant
   4. Left lower quadrant

TERMS USED IN DESCRIBING BODY STRUCTURE

A. Directional terms (Figure 1-9)
   1. Superior and inferior
   2. Anterior (ventral) and posterior (dorsal)
   3. Medial and lateral
   4. Proximal and distal
   5. Superficial and deep
B. Terms related to organs
   1. Lumen (luminal)
   2. Central and peripheral
   3. Medullary (medulla) and cortical (cortex)
   4. Apical (apex) and basal (base)
C. Many directional terms are listed inside the front cover of the book

BODY PLANES AND SECTIONS (FIGURES 1-9 AND 1-10)

A. Planes are lines of orientation along which cuts or sections can be made to divide the body, or a body part, into smaller pieces
B. There are three major planes, which lie at right angles to each other:
   1. Sagittal plane runs front to back so that sections through this plane divide the body (or body part) into right and left sides
      a. If section divides the body (or part) into symmetrical right and left halves, the plane is called *midsagittal* or *median sagittal*
   2. Frontal (coronal) plane runs lengthwise (side to side) and divides the body (or part) into anterior and posterior portions
   3. Transverse (horizontal) plane is a "crosswise" plane and it divides the body (or part) into upper and lower parts

INTERACTION OF STRUCTURE AND FUNCTION

A. Complementarity of structure and function is an important and unifying concept in the study of anatomy and physiology
B. Anatomical structures are adapted to perform specific functions because of their unique size, shape, form, or body location
C. Understanding the interaction of structure and function assists in the integration of otherwise isolated factual information

HOMEOSTASIS (FIGURE 1-13)

A. Term *homeostasis* coined by American physiologist Walter B. Cannon
B. *Homeostasis* is used to describe the relatively constant states maintained by the body—internal environment around body cells remains constant
C. Body adjusts important variables from a normal "set point" in an acceptable or normal range
D. Examples of homeostasis
   1. Temperature regulation
   2. Regulation of blood carbon dioxide level
   3. Regulation of blood glucose level

HOMEOSTATIC CONTROL MECHANISMS

A. Devices for maintaining or restoring homeostasis by self-regulation through feedback control loops
B. Basic components of control mechanisms

1. Sensor mechanism—specific sensors detect and react to any changes from normal
2. Integrating, or control, center—information is analyzed and integrated, and then if needed, a specific action is initiated
3. Effector mechanism—effectors directly influence controlled physiological variables
4. Feedback—process of information about a variable constantly flowing back from the sensor to the integrator

C. Negative feedback control systems
1. Are inhibitory
2. Stabilize physiological variables
3. Produce an action that is opposite to the change that activated the system
4. Are responsible for maintaining homeostasis
5. Are much more common than positive feedback control systems

D. Positive feedback control systems
1. Are stimulatory
2. Amplify or reinforce the change that is occurring
3. Tend to produce destabilizing effects and disrupt homeostasis
4. Bring specific body functions to swift completion

E. Feed-forward control systems occur when information flows ahead to another process or feedback loop to trigger a change in anticipation of an event that will follow

F. Levels of control (Figure 1-14)
1. Intracellular control
   a. Regulation within cells
   b. Genes or enzymes can regulate cell processes
2. Intrinsic control (autoregulation)
   a. Regulation within tissues or organs
   b. May involve chemical signals (e.g., prostaglandins)
   c. May involve other "built in" mechanisms
3. Extrinsic control
   a. Regulation from organ to organ
   b. May involve nerve signals
   c. May involve endocrine signals (hormones)

CYCLE OF LIFE: LIFE SPAN CONSIDERATIONS

A. Structure and function of body undergo changes over the early years (developmental processes) and late years (aging processes)

B. Infancy and old age are periods when the body functions least well

C. Young adulthood is period of greatest homeostatic efficiency

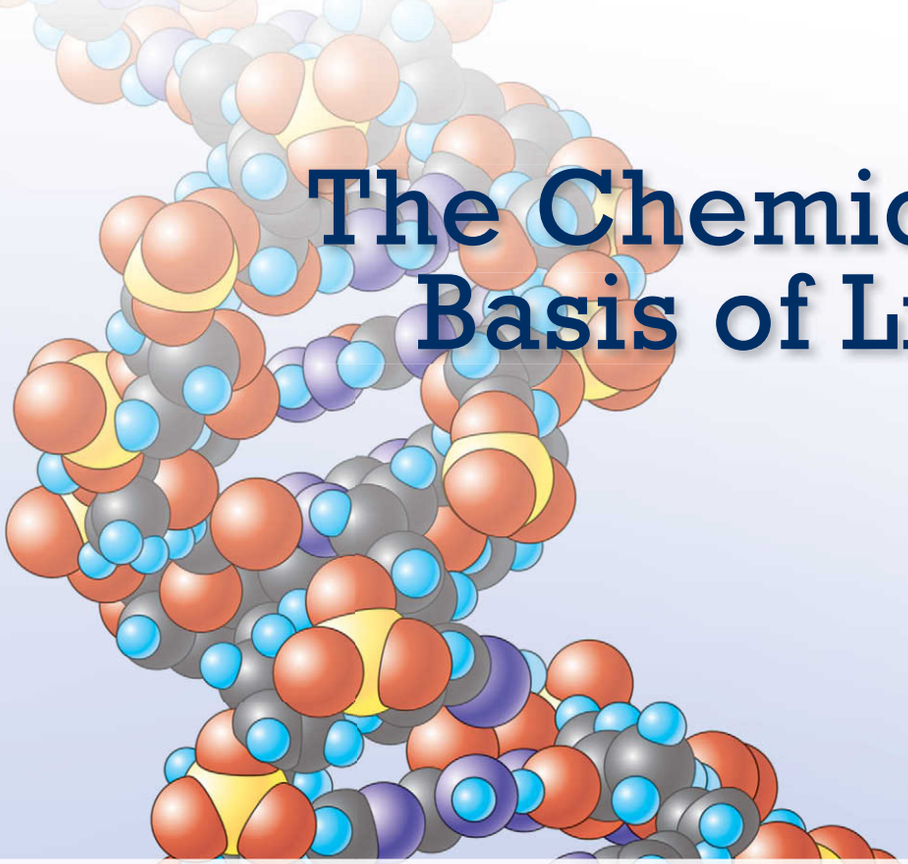
D. Atrophy—term to describe the wasting effects of advancing age

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the terms *anatomy* and *physiology.*
2. List and briefly describe the levels of organization that relate the structure of an organism to its function. Give examples characteristic of each level.
3. Give examples of each system level of organization in the body and briefly discuss the function of each.
4. What is meant by the term *anatomical position?* How do the specific anatomical terms of position or direction relate to this body orientation?
5. What is *bilateral symmetry?* What terms are used to identify placement of one body part with respect to another on the same or opposite sides of the body?
6. What does the term *somatotype* mean? Name the three major somatotype categories and briefly describe the general characteristics of each.
7. Define briefly each of the following terms: anterior, distal, sagittal plane, medial, dorsal, coronal plane, organ, parietal peritoneum, superior, tissue.
8. Locate the mediastinum.
9. What does the term *homeostasis* mean? Illustrate some generalizations about body function using homeostatic mechanisms as examples.
10. Define *homeostatic control mechanisms* and *feedback control loops.*
11. Identify the four basic components of a control loop.
12. Discuss in general terms the *principle of complementarity of structure and function.*
13. Briefly describe medical imaging techniques that allow physicians to examine internal structures in a noninvasive manner.
14. List the major types of risk factors that may increase a person's chance of a specific disease developing.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Each characteristic of life is related to body metabolism. Explain how digestion, circulation, and growth are metabolically related.
2. What diseases may result in a patient with an endomorph somatotype and a waist-to-hip ratio of 1:2?
3. An x-ray technician has been asked to take x rays of the entire large intestine (colon), including the appendix. Which of the nine abdominopelvic regions must be included in the x ray?
4. Body cavities can be subdivided into smaller and smaller sections. Identify, from largest to smallest, the cavities in which the urinary bladder can be placed.
5. When driving in traffic, it is important to stay in your own lane. If you see that you are drifting out of your lane, your brain tells your arms and hands to move in such a way that you get back in your lane. Identify the three components of a control loop in this example. Explain why this would be a negative feedback loop.

The Chemical Basis of Life

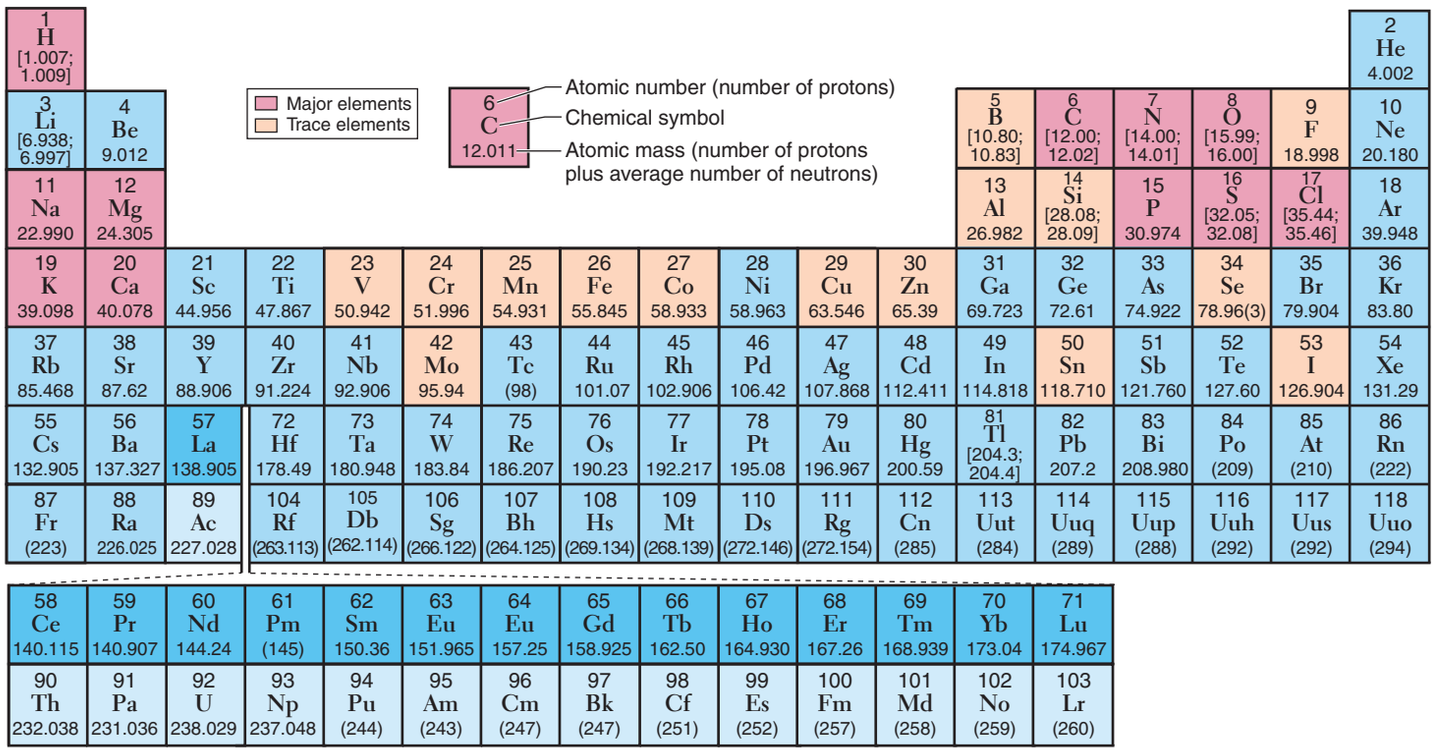
continued on p. 60

Anatomy and physiology are subdivisions of biology—the study of life. To best understand the characteristics of life, what living matter is, how it is organized, and what it can do, we must appreciate and understand certain basic principles of chemistry that apply to the life process.

Life itself depends on proper levels and proportions of chemical substances in the cytoplasm of cells. The various structural levels of organization described in Chapter 1 are ultimately based on the existence and interrelationships of atoms and molecules. Chemistry, like biology, is a very broad scientific discipline. It deals with the structure, arrangement, and composition of substances and the reactions they undergo. Just as biology may be subdivided into many sub-disciplines or branches, like anatomy and physiology, chemistry may also be divided into focused areas. Biochemistry is the field of chemistry that deals with living organisms and life processes. It deals directly with the chemical composition of living matter and the processes that underlie life activities such as growth, muscle contraction, and transmission of nervous impulses.



BASIC CHEMISTRY

Elements and Compounds

Chemists use the term *matter* to describe in a general sense all of the materials or substances around us. Anything that has mass and occupies space is matter.

Substances are either **elements** or **compounds.** An element is said to be "pure" in the sense that it cannot be broken down or decomposed into two or more different substances. Carbon and oxygen are good examples of elements. In most living material, elements do not exist alone in their pure state. Instead, two or more elements are joined to form chemical combinations called *compounds.* Compounds can be broken down or decomposed into the elements that are contained within them. Water is a compound (H_2O). It can be broken down into atoms of hydrogen and atoms of oxygen in a 2:1 ratio.

Other examples of elements include phosphorus, copper, and nitrogen (Figure 2-1). For convenience in writing chemical formulas and in other types of notation, chemists assign a symbol to each element, usually the first letter or two of the English or Latin name of the element: P, phosphorus; Cu, copper (Latin *cuprum*); N, nitrogen (see Figure 2-1). Note in Table 2-1 that 26 elements

1 H [1.007; 1.009]																	2 He 4.002
3 Li [6.938; 6.997]	4 Be 9.012											5 B [10.80; 10.83]	6 C [12.00; 12.02]	7 N [14.00; 14.01]	8 O [15.99; 16.00]	9 F 18.998	10 Ne 20.180

FIGURE 2-1

Periodic table of elements. The major elements found in the body are highlighted in pink. The trace elements, found in very tiny quantities in the body, are highlighted in orange. (Atomic mass numbers in brackets show the natural range of isotopes; those in parentheses are uncertain or theoretical.)

TABLE 2-1 Elements in the Human Body

ELEMENT	SYMBOL	HUMAN BODY WEIGHT (%)	IMPORTANCE OR FUNCTION
Major Elements			
Oxygen	O	65.0	Necessary for cellular respiration; component of water
Carbon	C	18.5	Backbone of organic molecules
Hydrogen	H	9.5	Component of water and most organic molecules; necessary for energy transfer and respiration
Nitrogen	N	3.3	Component of all proteins and nucleic acids
Calcium	Ca	1.5	Component of bones and teeth; triggers muscle contraction
Phosphorus	P	1.0	Principal component in the backbone of nucleic acids; important in energy transfer
Potassium	K	0.4	Principal positive ion within cells; important in nerve function
Sulfur	S	0.3	Component of many energy-transferring enzymes
Sodium	Na	0.2	Important positive ion surrounding cells
Chlorine	Cl	0.2	Important negative ion surrounding cells
Magnesium	Mg	0.1	Component of many energy-transferring enzymes
Trace Elements			
Silicone	Si	<0.1	Uncertain
Aluminum	Al	<0.1	Uncertain
Iron	Fe	<0.1	Critical component of hemoglobin in the blood
Manganese	Mn	<0.1	Component of many energy-transferring enzymes
Fluorine	F	<0.1	Hardens crystals that form teeth and bones
Vanadium	V	<0.1	Uncertain
Chromium	Cr	<0.1	Alters insulin (hormone) effects which regulates carbohydrate lipid and protein metabolism
Copper	Cu	<0.1	Key component of many enzymes
Boron	B	<0.1	May strengthen cell membranes; plays a role in brain and bone development
Cobalt	Co	<0.1	Component of vitamin B_{12}
Zinc	Zn	<0.1	Key component of some enzymes
Selenium	Se	<0.1	Component of an antioxidant enzyme
Molybdenum	Mo	<0.1	Key component of some enzymes
Tin	Sn	<0.1	Uncertain
Iodine	I	<0.1	Component of thyroid hormone

are listed as being present in the human body. Although all are important, 11 are called *major elements*. Four of these major elements—carbon, oxygen, hydrogen, and nitrogen—make up about 96% of the material in the human body (Figure 2-2). The 15 remaining elements are present in amounts that are less than 0.1% of body weight and are called *trace elements*. The unique "aliveness" of a living organism does not depend on a single element or mixture of elements but on the complexity, organization, and interrelationships of all elements required for life.

| QUICK CHECK |

1. What is biochemistry?
2. What is the difference between an element and a compound?
3. What elements make up 96% of the material in the human body?

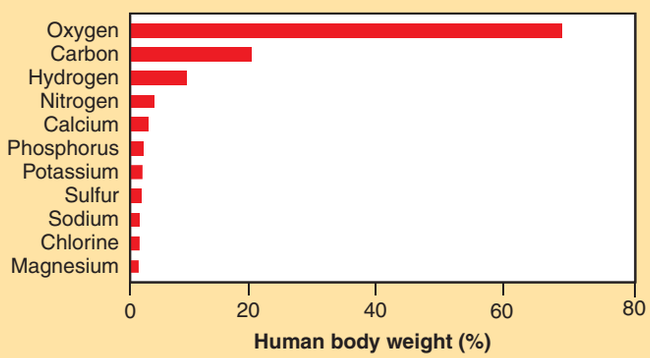

FIGURE 2-2

Major elements of the body. These elements are found in great quantity in the body (see Figure 2-1). The graph shows the relative abundance of each in the body. Notice that oxygen (O), carbon (C), hydrogen (H), and nitrogen (N) predominate.

Atoms

The most important of all chemical theories was advanced in 1805 by the English chemist John Dalton. He proposed the concept that matter is composed of **atoms** (from the Greek *atomos*, "indivisible"). His idea was revolutionary and yet simple—that all matter, regardless of the form it may assume (liquid, gas, or solid), is composed of units he called *atoms*.

Dalton conceived of atoms as solid, indivisible particles, and for about 100 years this was believed to be true. We now know that atoms are divisible into even smaller or *subatomic* particles, some of which exist in a "cloud" surrounding a dense central core called a *nucleus*. More than 100 million atoms of even very dense and heavy substances, if lined up, would measure barely an inch and would consist mostly of empty space! Our knowledge about the number and nature of subatomic particles and the central nucleus around which they move continues to grow as a result of ongoing research.

ATOMIC STRUCTURE

Atoms contain several different kinds of smaller or subatomic particles that are found in either a central nucleus or its surrounding "electron cloud" or "field." Figure 2-3, A, shows an atomic model of carbon illustrating the most important types of subatomic particles:

- Protons (p^+)
- Neutrons (n^0)
- Electrons (e^-)

Note that the carbon atom in Figure 2-3 has a central corelike *nucleus*. It is located deep inside the atom and is made up of six positively charged *protons (p)* and six uncharged *neutrons (n)*. Note also that the nucleus is surrounded by a cloud or field of six negatively charged *electrons (e)*. Because protons are positively charged and neutrons are neutral, the nucleus of an atom bears a positive electrical charge equal to the number of protons that are present in it. Electrons move around the atom's nucleus in what can be represented as an electron cloud or field (Figure 2-3, B). The number of negatively charged electrons moving around an atom's nucleus equals the number of positively charged protons in the nucleus. The opposite charges therefore cancel or neutralize each other, which means atoms are electrically neutral particles.

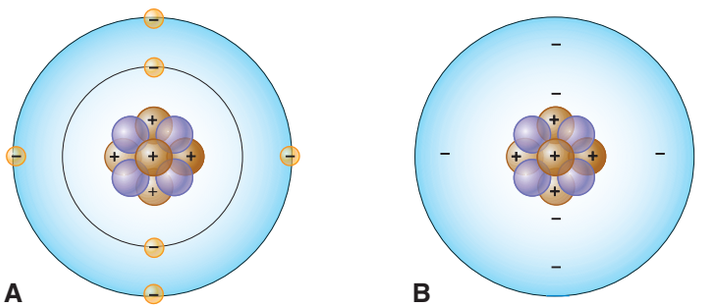

FIGURE 2-3

Models of the atom. The nucleus—protons (+) and neutrons—is at the core. Electrons inhabit outer regions called electron *shells* or energy levels **(A)** or probability distributions called electron clouds **(B)**. This drawing depicts a carbon atom. All carbon atoms (and *only* carbon atoms) have six protons. (Not all of the protons in the nucleus are visible in this illustration.)

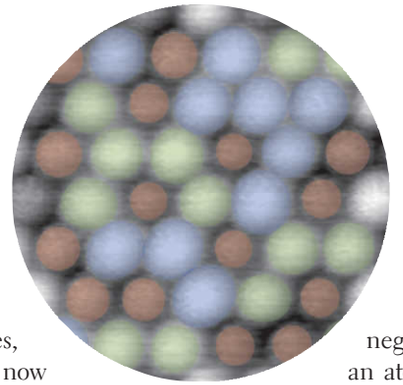

FIGURE 2-4

Atoms. The cloudlike structures seen here were recorded using an atomic force microscope (AFM) and represent the outer surfaces of individual atoms along the flat surface of a crystal. Different colors represent different kinds of atoms.

The so-called electron clouds are really just areas where the electrons are most likely to be found moving about rapidly. However, they can sometimes be visualized with a special form of microscope, as you can see in Figure 2-4.

ATOMIC NUMBER AND MASS NUMBER

Elements differ in their chemical and physical properties because of differences in the number of protons in their atomic nuclei. The number of protons in an atom's nucleus, called its *atomic number*, is therefore critically important—it identifies the kind of element it is.

Look again at the elements important in living organisms listed in Table 2-1. Each element is identified by its symbol and atomic number. Hydrogen, for example, has an atomic number of 1; this means that all hydrogen atoms—and *only* hydrogen atoms—have one proton in their nucleus. All carbon atoms—and *only* carbon atoms—contain six protons and have an atomic number of 6. All oxygen atoms, and only oxygen atoms, have eight protons and an atomic number of 8. In short, each element is identified by its own unique number of protons, that is, by its own unique atomic number. If two atoms contain a different number of protons, they are different elements.

There are 92 elements that occur naturally on earth. Because each element is characterized by the number of protons in its atoms (atomic number), there are atoms that contain from 1 to 92 protons. Additional elements have been discovered as a result of sophisticated research in the area of particle physics.

The term *mass number* refers to the mass of a single atom. The mass number is sometimes called the *atomic mass*. It equals the number of protons plus the number of neutrons in the atom's nucleus. The weight of electrons is, for practical purposes, negligible. Because protons and neutrons weigh almost exactly the same, the equation for determining mass number is as follows:

$$\text{Mass number} = (p + n)$$

The largest naturally occurring atom is uranium. It has a mass number of 238, with a nucleus containing 92 protons and 146 neutrons. In contrast, hydrogen, which has only one proton and no neutrons in its nucleus, has a mass number of 1.

ENERGY LEVELS

The total number of electrons in an atom equals the number of protons in its nucleus (see Figure 2-3). These electrons are known to exist in regions surrounding the atom's nucleus.

No single model of the atom sufficiently explains all we know about atomic structure. However, two simple models of atoms may be useful here to begin our discussion.

The cloud model suggests that any one electron cannot be exactly located at a specific point at any particular time. This concept is called a *probability distribution* and refers to the probability of finding an electron at any specific location outside the nucleus. Earlier models based on the work of a Danish physicist, Niels Bohr, who won the 1922 Nobel Prize in Physics for his groundbreaking contributions, suggested that electrons moved in regular patterns around the nucleus much like the planets in our solar system move around the sun. A simplified version of the Bohr model of the atom (see Figure 2-3, A) is perhaps most useful in visualizing the structure of atoms as they enter into chemical reactions.

In the Bohr model, the electrons are shown in shells or concentric circles. The different shells show the relative distances of the electrons from the nucleus. The electrons surrounding the atom's nucleus are seen in this model as existing in simple rings or shells. Each ring represents a different **energy level,** and each can hold only a certain maximum number of electrons (Figure 2-5). The number and arrangement of electrons orbiting in an atom's energy levels are important because they determine whether the atom is chemically reactive.

In chemical reactions between atoms, it is the electrons in the outermost energy level that participate in the formation of chemical bonds. In each energy level, electrons tend to group in pairs. As a rule, an atom can be listed as chemically stable and unable to react with another atom if its outermost energy level has four pairs of electrons, or a total of eight. Such an atom is said to have a stable electron configuration. The pairing of electrons is important. If the outer energy level contains single, unpaired electrons, the atom will be chemically reactive. Atoms with fewer than eight electrons in the outer energy level will attempt to lose, gain, or share electrons with other atoms to achieve stability. This tendency is called the **octet rule.**

Consider an atom of oxygen, which has a total of six electrons in its outer energy level. As you can see in Figure 2-6, it has two unpaired electrons so it is two electrons short of satisfying the octet rule. Oxygen is likely to enter into chemical reactions to gain or share electrons with other atoms. By doing so, the oxygen atom will fill in its outer energy level and thus satisfy the octet rule.

The octet rule holds true except for atoms that are limited to a single energy level that is filled by a maximum of two electrons. For example, hydrogen has but one electron in its single energy level. It therefore has an incomplete energy level with an unpaired electron. The result is a highly reactive tendency of hydrogen to enter into many chemical reactions. Helium, however, has two electrons in its single energy level. Because this is the maximum number for this energy level, no chemical activity is possible, and no naturally occurring compound containing helium exists. Helium is an *inert*, or stable, element.

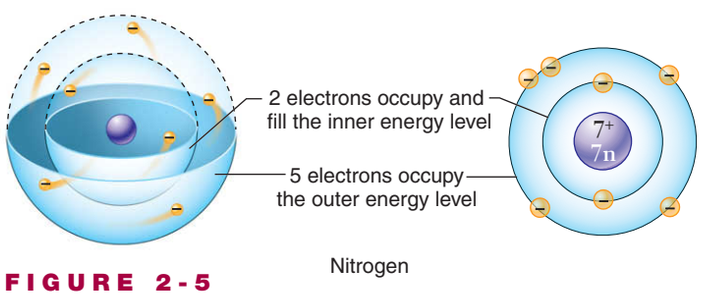

FIGURE 2-5

Energy levels (electron shells) surrounding the nucleus of an atom. Each concentric shell represents a different electron energy level.

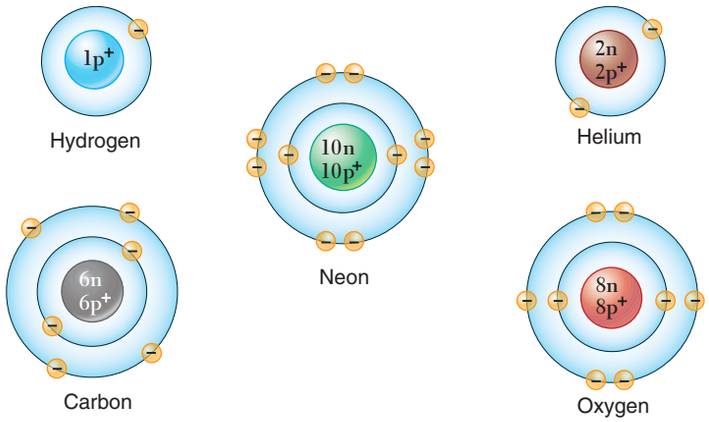

FIGURE 2-6

Energy levels (shells) of five common elements. All atoms are balanced with respect to positive and negative charges. In atoms with a single energy level, two electrons are required for stability. Hydrogen with its single electron is reactive, whereas helium with its full energy level is not. In atoms with more than one energy level, eight electrons in the outermost energy level are required for stability. Neon is stable because its outer energy level has eight electrons. Oxygen and carbon, with six and four electrons, respectively, in their outer energy levels, are chemically reactive.

The atoms shown in Figure 2-6 illustrate several of the most important facts related to energy levels. Note that even in the hydrogen atom with its very basic structure, positive and negative charges balance. Hydrogen, carbon, and oxygen will react chemically because they do not satisfy the octet rule.

5. How are the atomic number and atomic weight of an atom defined?
6. What is an energy level?
7. Explain what is meant by the *octet rule.*

ISOTOPES

All atoms of the same element contain the same number of protons but do not necessarily contain the same number of neutrons. **Isotopes** of an element contain the same number of protons, but different numbers of neutrons.

Isotopes have the same basic chemical properties as any other atom of the same element, and they also have the same atomic number. However, because they have a different number of neutrons, they differ in mass number. Usually a hydrogen atom has only one proton and no neutrons (atomic number, 1; mass number, 1). Figure 2-7 illustrates this most common type of hydrogen and two of its isotopes. Note that the isotope of hydrogen called

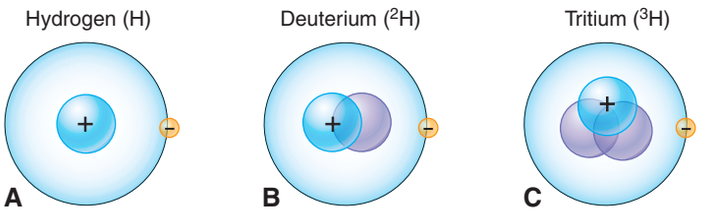

FIGURE 2-7

Structure of hydrogen and two of its isotopes. A, The most common form of hydrogen. **B,** An isotope of hydrogen called *deuterium (^2H).* **C,** The hydrogen isotope *tritium (^3H).* Note that isotopes of an element differ only in the number of its neutrons.

deuterium (^2H) has one proton and one neutron (mass number, 2). *Tritium (^3H)* is the isotope of hydrogen that has one proton and two neutrons (mass number, 3).

The term *atomic weight* refers to the average mass number for a particular element based on the typical proportion of different isotopes found in nature. Atomic weights are shown in the periodic table of elements illustrated in Figure 2-1, below each chemical symbol. Notice that the atomic weights for some elements, such as hydrogen and carbon, are listed as ranges instead of averages. For elements with isotope proportions that vary widely in nature, chemists find ranges more useful than averages.

The atomic nuclei of more than 99% of all carbon atoms in nature have six protons and six neutrons (atomic number, 6; mass number, 12). An important isotope of carbon has seven neutrons instead of six and is called *carbon-13 (^{13}C)*. Carbon-13 makes up about 1% of the world's carbon atoms. The presence of carbon-13 in human tissues is useful in molecular studies of metabolic processes in the body. Another important carbon isotope has eight neutrons instead of six; it is called *carbon-14 (^{14}C)*. Carbon-14 is an example of a special type of isotope that is unstable and undergoes nuclear breakdown—it is designated as a *radioactive isotope*, or **radioisotope.** During breakdown, radioactive isotopes emit nuclear particles and radiation—a process called *decay.*

| A&P CONNECT |

Radioactivity is the emission of radiation from an atom's nucleus. Alpha particles, beta particles, and gamma rays are the three kinds of radiation.

Alpha particles are relatively heavy particles consisting of two protons plus two neutrons. They shoot out of a radioactive atom's nucleus at a reported speed of 18,000 miles per second. *Beta particles* are electrons formed in a radioactive atom's nucleus by one of its neutrons breaking down into a proton and an electron. The proton remains behind in the nucleus, and the electron is ejected from it as a beta particle. Beta particles, because they are electrons, are much smaller than alpha particles, which consist of two protons and two neutrons. In addition, beta particles travel at a much greater speed than alpha particles do. *Gamma rays* are electromagnetic radiation, a form of light energy.

Radioactivity differs from chemical activity because it can change the number of protons in an atom, thus changing the atom from one element to another!

Check out ***Radioactivity*** online at ***A&P Connect*** to find out how radioactivity affects the human body.

Attractions Between Atoms—Chemical Bonds

Interactions between two or more atoms occur largely as a result of activity between electrons in their outermost energy level. The result, called a *chemical reaction*, most often involves unpaired electrons.

Ultimately, in atoms with fewer or more than eight electrons in the outer energy level, reactions will occur that result in the loss, gain, or sharing of one atom's unpaired electrons with those of another atom to satisfy the octet rule for both atoms. The result of such reactions between atoms is the formation of larger chemical structures such as *crystals* and **molecules.** For example, two atoms of oxygen can combine with one carbon atom to form molecular carbon dioxide, or CO_2. If atoms of more than one element combine, the result, as defined earlier, is a compound. In other words, oxygen exists as a molecule (O_2) and is an element. Water exists as a molecule (H_2O) and is a compound. Reactions that hold atoms together do so by the formation of *chemical bonds.* There are two types of chemical bonds that unite atoms into larger structures: ionic (or electrovalent) bonds and covalent bonds.

IONIC BONDS

A chemical bond formed by the transfer of electrons from one atom to another is called an *ionic*, or *electrovalent, bond.* Such a bond occurs as a result of the attraction between atoms that have become electrically charged by the loss or gain of electrons. When dissolved in water (Figure 2-8), such atoms are separate into **ions.** It is important to remember that ions can be positively or negatively charged and that ions with opposite charges are attracted to each other.

Note in Figure 2-8, A, that in the outer energy level of the sodium atom there is a single unpaired electron. If this electron were "lost," the outer ring would be stable because it would have a full outer octet (four pairs of electrons). The loss of the electron would result in the formation of a sodium ion (Na^+) with a positive charge. This is because there is now one more proton (+) than electron (–).

The chlorine atom, in contrast, has one unpaired electron plus three paired electrons, or a total of seven electrons, in its outer energy level. By the addition of another electron, chlorine would satisfy the octet rule—its outer energy level would have a full complement of four paired electrons. The addition of another electron would result in the formation of a negatively charged chloride ion (Cl^-).

Sodium transfers or donates its one unpaired electron to chlorine and becomes a positively charged sodium ion (Na^+). Chlorine accepts the electron from sodium and pairs it with its one unpaired electron, thereby filling its outer energy level with the maximum of four electron pairs and becoming a negatively charged chloride ion (Cl^-). The positively charged sodium ion (Na^+) is attracted to the negatively charged chloride ion (Cl^-), and the formation of NaCl crystals, ordinary table salt, results. This process illustrates ionic or electrovalent bonding.

The electron transfer changed the two atoms of the elements sodium and chlorine into ions. An **ionic bond** is simply the strong electrostatic force that binds the positively and negatively charged ions together in a crystal.

COVALENT BONDS

Just as atoms can be held together in crystals by ionic bonds formed when atoms gain or lose electrons, atoms can also be bonded together into molecules by *sharing* electrons. A chemical bond

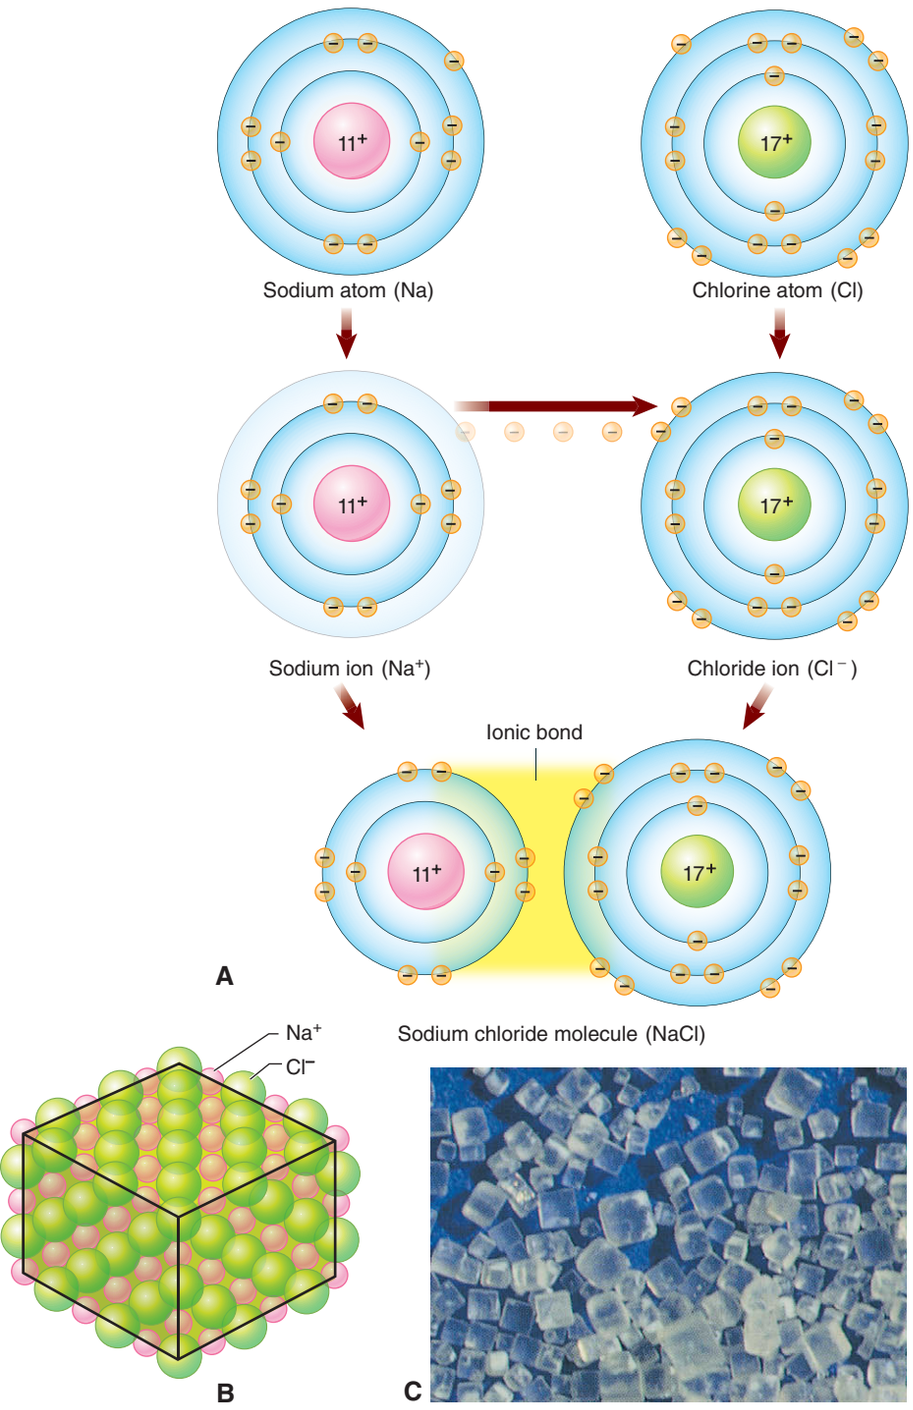

FIGURE 2-8

Example of an ionic bond. A, Energy-level models show the steps involved in forming an ionic bond between atoms of sodium and chlorine within the internal fluid environment of the body (water). Sodium "donates" an electron to chlorine, thereby forming a positive sodium ion and a negative chloride ion. The electrical attraction between the now oppositely charged ions forms an ionic bond. **B,** The space-filling model shows a crystal of sodium chloride (table salt) in the typical cube-shaped formation. **C,** Photomicrograph showing cubic crystals of sodium chloride after the removal of water.

formed by the sharing of one or more pairs of electrons between the outer energy levels of two atoms is called a **covalent bond.** This type of chemical bonding is of great significance in physiology.

The major elements of the body (carbon, oxygen, hydrogen, and nitrogen) almost always share electrons to form covalent bonds. For example, if two atoms of hydrogen are bound together by the sharing of one electron pair, a *single* covalent bond is said to exist, and a molecule of hydrogen gas results (Figure 2-9, A). Covalent bonds that bind atoms together by sharing *two* pairs of electrons are called *double bonds* (Figure 2-9, B). The example shown illustrates two atoms of oxygen, each sharing two electrons with a carbon atom to acquire a complete outer energy level of eight electrons and thus satisfy the octet rule. A molecule of carbon dioxide results.

Attractions Between Molecules

HYDROGEN BONDS

In addition to ionic and covalent bonds, another type of attractive force, called a *hydrogen bond*, can exist between biologically important molecules. Hydrogen bonds are much weaker forces than ionic or covalent bonds because they require less energy to break. Although an individual hydrogen bond is weak, large numbers of these bonds can collectively exert a strong attractive force. Instead of forming as a result of transfer or sharing of electrons between atoms, hydrogen bonds result from unequal charge distribution on a molecule. Such molecules are said to be **polar.**

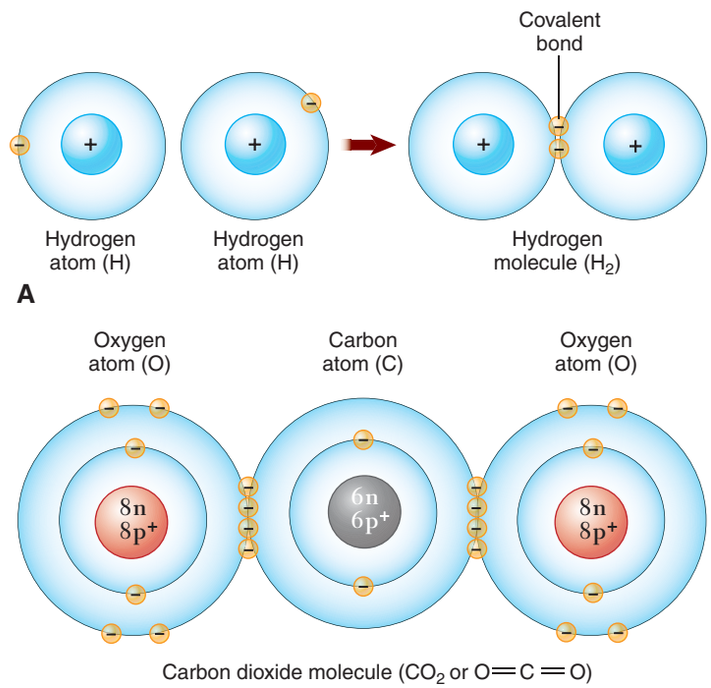

FIGURE 2-9

Types of covalent bonds. A, A single covalent bond formed by the sharing of one electron pair between two atoms of hydrogen results in a molecule of hydrogen gas. **B,** A double covalent bond (double bond) forms by the sharing of *two* pairs of electrons between two atoms. In this case, two double bonds form—one between carbon and *each* of the two oxygen atoms forming a molecule of carbon dioxide.

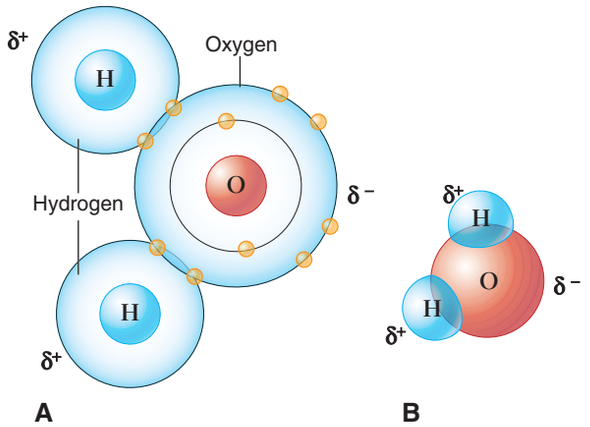

FIGURE 2-10

Water—example of a polar molecule. The polar nature of water is represented in an energy-level model **(A)** and a space-filling model **(B)**. The two hydrogen atoms are nearer one end of the molecule and give that end a partial positive charge (δ+). The "oxygen end" of the molecule attracts the electrons more strongly and thus has a partial negative charge(δ–). Notice that a lowercase Greek letter delta (δ) represents a partial charge.

Water is a good example of a polar molecule. Note in Figure 2-10 that although an atom of water is electrically neutral (the number of negative charges equals the number of positive charges), it has a partial positive charge (the hydrogen side) and a partial negative charge (the oxygen side). That is, the water molecule has a positive pole and a negative pole. The partial charges result from the electrons having a higher probability of being found nearer the highly positive oxygen nucleus than either hydrogen nucleus. That is, the electrons are not shared equally within the molecule. Thus water is said to be "polar" because it has regions with different partial charges. Hydrogen bonds serve to weakly attach the partially negative (oxygen) side of one water molecule to the partially positive (hydrogen) side of an adjacent water molecule.

Figure 2-11 illustrates hydrogen bonding between water molecules. Depending on how many of these hydrogen bonds are intact at one instant, the water may be either liquid (few bonds) or solid (many bonds). If the water molecules are too far apart to form any hydrogen bonds, then the water is a gas, such as steam.

Hydrogen bonds form only between H atoms that are covalently bonded to an oxygen, nitrogen, or fluorine atom. In water molecules H is bonded to O, thus producing the polarity that permits the formation of hydrogen bonds between water molecules.

The ability of water molecules to form hydrogen bonds between molecules accounts for many of the unique properties of water that make it an ideal medium for the chemistry of life. Hydrogen bonds are also important in maintaining the three-dimensional structure of proteins and nucleic acids, also described later in the chapter.

OTHER WEAK ATTRACTIONS

Other weak attractions sometimes attract molecules to each other, even if only temporarily. Shifts in the locations of electrons within each molecule result in fleeting changes in the partial electrical charge of some regions of the molecule. This change in electrical charge may result in attraction to oppositely charged regions of another molecule. In the scope of our course, however, we will not concern ourselves with the different varieties of weak attractions or how they are produced. It is important to know only that they exist and sometimes play an underlying role in holding the material of the body together.

Chemical Reactions

Chemical reactions involve interactions between atoms and molecules, which in turn involves the formation or breaking of chemical bonds. Three basic types of chemical reactions that you will learn to recognize as you study physiology are the following:

1. Synthesis reactions
2. Decomposition reactions
3. Exchange reactions

To the chemist, reactions can be symbolized by variations on a simple formula. In *synthesis reactions*, two or more substances called *reactants* combine to form a different, more complex substance called a *product*. Synthesis literally means "putting together." The process can be summarized by the following formula:

$$\underset{\text{(Reactants)}}{A + B} \xrightarrow{\text{Energy}} \underset{\text{(Product)}}{AB}$$

Synthesis reactions result in the formation of new bonds, and energy is required for the reaction to occur and the new product to form. Many such reactions occur in the body. Every cell, for example, combines amino acid molecules as reactants to form complex protein compounds as products. The ability of the body to synthesize new tissue in wound repair is a good example of this type of reaction.

Decomposition reactions result in the breakdown of a complex substance into two or more simpler substances. In this type of reaction, chemical bonds are broken and energy is released. Energy can be released in the form of heat, or it can be captured

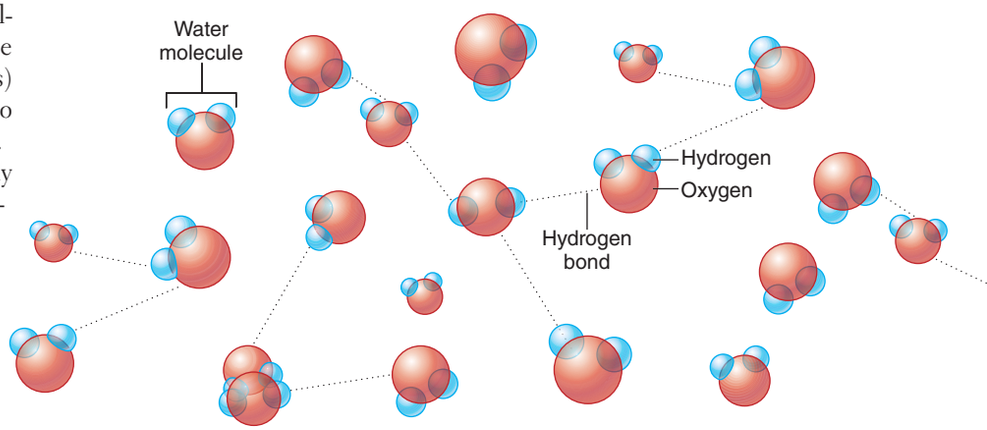

FIGURE 2-11

Hydrogen bonds between water molecules. Hydrogen bonds serve to weakly attach the negative (oxygen) side of one water molecule to the positive (hydrogen) side of a nearby water molecule. This diagram depicts a few bonded molecules, as one would expect in liquid water. Ice would instead have more hydrogen bonds; steam would have no such bonds.

for storage and future use. Decomposition reactions can be summarized by the following formula:

$$AB \longrightarrow A + B + \text{Energy}$$

Decomposition reactions occur when a complex nutrient is broken down in a cell to release energy for other cellular functions. The products of such a reaction are ultimately waste products. Decomposition and synthesis are opposites. Synthesis builds up; decomposition breaks down. Synthesis forms chemical bonds; decomposition breaks chemical bonds. Decomposition and synthesis reactions are often coupled with one another in such a way that the energy released by a decomposition reaction can be used to drive a synthesis reaction.

The nature of **exchange reactions** permits two different reactants to exchange components and, as a result, form two new products. An exchange reaction is often symbolized by the following formula:

$$AB + CD \longrightarrow AD + CB$$

Exchange reactions break down, or decompose, two compounds and, in exchange, synthesize two new compounds. Certain exchange reactions take place in the blood. One example is the reaction between lactic acid and sodium bicarbonate. The decomposition of both substances is exchanged for the synthesis of sodium lactate and carbonic acid. These changes can be seen more easily in the following equation:

$$H \cdot Lactate + NaHCO_3 \longrightarrow Na \cdot Lactate + H \cdot HCO_3$$

The formula $H \cdot Lactate$ represents lactic acid; $NaHCO_3$ is the formula for sodium bicarbonate; $Na \cdot Lactate$ represents sodium lactate; and $H \cdot HCO_3$ represents carbonic acid.

Reversible reactions, as the name suggests, proceed in both directions. A great many synthesis, decomposition, or exchange reactions are reversible, and a number of them are cited in later chapters of this book. An arrow pointing in both directions is used to denote a reversible reaction:

$$A + B \rightleftharpoons AB$$

8. List the two types of chemical bonds between atoms and explain how they are formed.
9. What type of bonds attract one molecule to another?
10. Diagram the three basic types of chemical reactions.

METABOLISM

The term **metabolism** is used to describe all the chemical reactions that occur in body cells. The important topics of nutrition and metabolism are discussed fully in Chapter 30. Nutrition and metabolism are described together because the total of all the chemical reactions or *metabolic activity* occurring in cells is associated with the use the body makes of foods after they have been digested, absorbed, and circulated to cells. The terms *catabolism* and *anabolism* are used to describe the two major types of metabolic activity.

Catabolism describes chemical reactions that break down larger food molecules into smaller chemical units and, in so doing, often *release energy*. The release of energy is related to the disruption of chemical bonds. This breakdown of bonds in the chemical compounds contained in the foods and beverages that we consume provides the energy to power all of our activities.

Anabolism involves the many chemical reactions that build larger and more complex chemical molecules from smaller subunits (Figure 2-12). Anabolic chemical reactions *require energy*—energy most often made available by the breakdown of **adenosine triphosphate (ATP).**

Catabolism

Catabolism consists of chemical reactions that not only break down relatively complex compounds into simpler ones but also release energy from them. This breakdown process represents a type of chemical reaction called **hydrolysis** (see Figure 2-12). As a result of hydrolysis occurring during catabolism, a water molecule is added to break a larger compound into smaller subunits. For example, hydrolysis of a fat molecule breaks it down into its subunits—glycerol and fatty acid molecules; a disaccharide such as sucrose breaks down into its monosaccharide subunits—glucose and fructose; and the subunits of protein hydrolysis are amino acids.

Ultimately, catabolic reactions will further degrade these building blocks of food compounds—glycerol, fatty acids, monosaccharides, and amino acids—into the end products carbon dioxide, water, and other waste products. During this process, energy is released. Some of the energy released by catabolism is heat energy, the heat that keeps our bodies warm. However, more than half the energy released is immediately recaptured and transferred

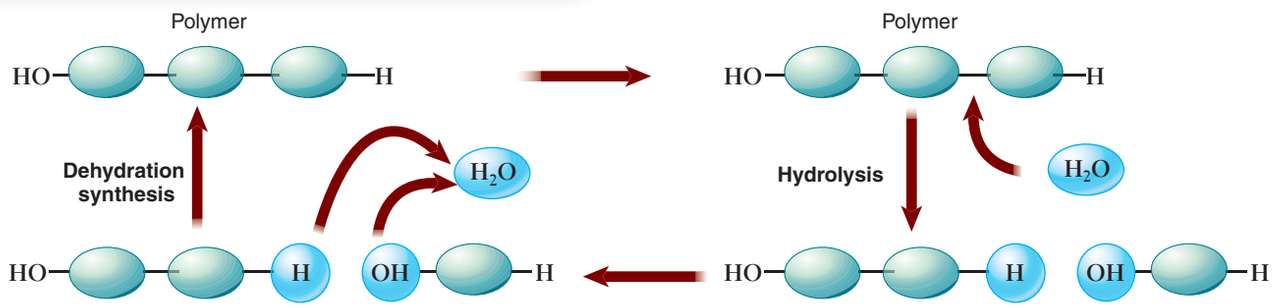

FIGURE 2-12

Metabolic reactions. Hydrolysis is a catabolic reaction that adds water to break down large molecules into smaller molecules, or subunits. Dehydration synthesis is an anabolic reaction that operates in the reverse fashion: small molecules are assembled into large molecules by removing water. Note that specific examples of dehydration synthesis are shown in Figures 2-18 and 2-27.

to a molecule called *ATP*, which transfers the energy to cell components that need it to do work. ATP is discussed in more detail later in this chapter.

Anabolism

Anabolism is the term used to describe chemical reactions that join simple molecules together to form more complex biomolecules—notably, carbohydrates, lipids, proteins, and nucleic acids. Literally thousands of anabolic reactions take place continually in the body. The type of chemical reaction responsible for this joining together of smaller units to form larger molecules is called *condensation* or **dehydration synthesis** (see Figure 2-12). It is a key reaction during anabolism. As a result of dehydration synthesis, water is removed as smaller subunits are fused together.

Anabolism requires energy, which is transferred from ATP molecules. Anabolic reactions use energy to join monosaccharide units to form larger carbohydrates, fuse amino acids into peptide chains, and form fat molecules from glycerol and fatty acid subunits.

| QUICK CHECK |

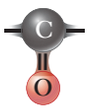
11. What does the term *metabolism* mean?
12. What is the difference between *anabolism* and *catabolism?*
13. What is the role of *ATP* in the body?

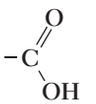
ORGANIC AND INORGANIC COMPOUNDS

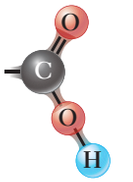
In living organisms, there are two kinds of compounds: *organic* and *inorganic*. Organic compounds are generally defined as compounds composed of molecules that contain carbon–carbon (C–C) covalent bonds or carbon–hydrogen (C–H) covalent bonds—or both kinds of bonds. Few inorganic compounds have carbon atoms in them, and none have C–C or C–H bonds. Organic molecules are generally larger and more complex than inorganic molecules.

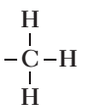
The term **functional groups** is often used to describe certain arrangements of atoms attached to the carbon core of many organic molecules. Different functional groups confer unique chemical properties. Our later discussions will occasionally involve some of these functional groups. Take a moment now to preview the examples shown in Figure 2-13.

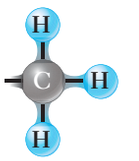
The human body has inorganic and organic compounds because both are equally important to the chemistry of life.

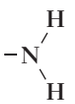


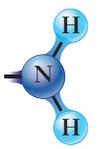


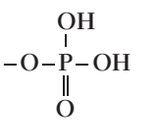


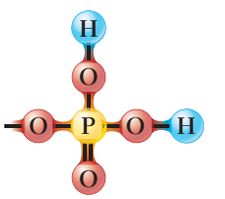


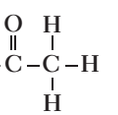


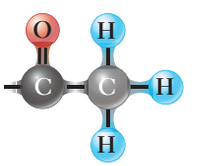












Functional Group	Structural Formula	Models
Hydroxyl	–OH	
Carbonyl		
Carboxyl		
Methyl		
Amino		
Sulfhydryl	–SH	
Phosphate		
Acetyl		

FIGURE 2-13

The principal functional chemical groups. Each functional group confers specific chemical properties on the molecules that possess them.

INORGANIC MOLECULES

Water

Water has been called the "cradle of life" because all living organisms require water to survive. Each body cell is bathed in fluid, and it is only in this precisely regulated and homeostatically controlled environment that cells can function. In addition to water surrounding the cell, the basic substance of each cell, *cytoplasm*, is itself largely water. Water is certainly the body's most abundant and important compound. Fifty percent or more of a normal adult's body weight is water, which serves a host of vital functions. Because of water's pervasive importance in all living organisms, an understanding of the basics of water chemistry is important. In a very real sense, *water chemistry forms the basis for the chemistry of life.*

PROPERTIES OF WATER

The chemist views water as a simple and stable compound. It has an atomic structure that results from the combination of two covalent bonds between a single oxygen atom and two hydrogen atoms.

Recall that water molecules are polar molecules and interact with one another because they have a partial positive charge at one end and a partial negative charge at their other end. Take a moment to go back and review Figure 2-10. This simple chemical property, called *polarity*, allows water to act as a very effective *solvent*. Proper functioning of a cell requires the presence of many chemical substances. Many of these compounds are quite large and must be broken into smaller and more reactive particles (ions) for reactions to occur. Because of its polar nature, water tends to dissociate ionic compounds in solution and surround any molecule that has an electrical charge (Figure 2-14). The fact that so many substances dissolve in water is of utmost importance in the life process.

The critical role that water plays as a solvent permits the *transportation* of many essential materials within the body. By dissolving nutrient molecules in blood, for instance, water enables these materials to enter and leave the blood capillaries in the digestive organs and eventually enter cells in every area of the body. In turn, waste products are transported from where they are produced to excretory organs for elimination from the body.

Another important function of water stems from the fact that water both absorbs and gives up heat slowly. These properties of water enable it to maintain a relatively constant temperature. This allows the body, which has a large water content, to resist sudden changes in temperature. Chemists describe this property by saying that water has a high *specific heat*; that is, water can lose and gain large amounts of heat with little change in temperature. As a result, excess body heat produced by the contraction of muscles during exercise, for example, can be transported by blood to the body surface and dissipated into the environment with little actual change in core temperature.

Chemists and biologists recognize water's high *heat of vaporization* as another important physical quality. This characteristic requires the absorption of significant amounts of heat to change water from a liquid to a gas. The energy is required to break the many hydrogen bonds that hold adjacent water molecules together in the liquid state. Thus the body can dissipate excess heat and maintain a normal temperature by evaporation of water (sweat) from the skin surface whenever excess heat is being produced.

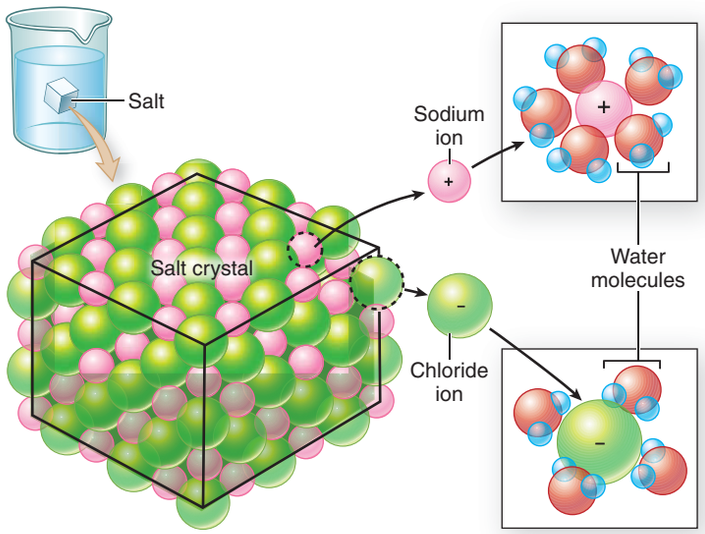


FIGURE 2-14

Water as a solvent. The polar nature of water (blue) favors ionization of substances in solution. Sodium (Na^+) ions (pink) and chloride (Cl^-) ions (green) dissociate in the solution.

Understanding and appreciating the importance of water in the life process are critical. Water does more than act as a solvent, produce ionization, and facilitate chemical reactions. It has essential chemical roles of its own in addition to the many important physical qualities it brings to body function (Table 2-2). It plays a key role in such processes as cell permeability, active transport of materials, secretion, and membrane potential, to name a few.

Oxygen and Carbon Dioxide

Oxygen (O_2) and carbon dioxide (CO_2) are important inorganic substances that are closely related to cellular respiration.

Molecular oxygen in the body is present as two oxygen atoms joined by a double covalent bond. Oxygen is required to complete the decomposition reactions required for the release of energy from nutrients burned by the cell.

TABLE 2-2 Properties of Water

PROPERTY	DESCRIPTION	EXAMPLE OF BENEFIT TO THE BODY
Strong polarity	Polar water molecules attract other polar compounds, which causes them to dissociate	Many kinds of molecules can dissolve in cells, thereby permitting a variety of chemical reactions and allowing many substances to be transported
High specific heat	Hydrogen bonds absorb heat when they break and release heat when they form, thereby minimizing temperature changes	Body temperature stays relatively constant
High heat of vaporization	Many hydrogen bonds must be broken for water to evaporate	Evaporation of water in perspiration cools the body
Cohesion	Hydrogen bonds hold molecules of water together	Water works as lubricant or cushion to protect against damage from friction or trauma

Carbon dioxide is considered one of a group of very simple carbon-containing inorganic compounds. It is an important exception to the "rule of thumb" that inorganic substances do not contain carbon. Like oxygen, carbon dioxide is involved in cellular respiration. It is produced as a waste product during the breakdown of complex nutrients and also serves an important role in maintaining the appropriate acid-base balance in the body.

Electrolytes

Other inorganic substances include acids, bases, and salts. These substances belong to a large group of compounds called **electrolytes** (e-LEK-tro-lites). Electrolytes are substances that break up, or *dissociate*, in solution to form charged particles, or ions. Sometimes the ions themselves are also called electrolytes. Ions with a positive charge are called *cations*, and those with a negative charge are called *anions*. Figure 2-14 shows the way in which water molecules work to dissociate a common electrolyte, sodium chloride (NaCl), into Na^+ cations and Cl^- anions.

ACIDS AND BASES

Acids and bases are common and very important chemical substances in the body. Early chemists categorized acids and bases by such characteristics as taste or the ability to change the color of certain dyes. Acids, for example, taste sour and bases taste bitter. The dye *litmus* will turn blue in the presence of a base and red when exposed to an acid. These and other observations illustrate a fundamental point, namely, that acids and bases are chemical opposites. Although acids and bases dissociate in solution, both release different types of ions. The unique chemical properties of acids and bases when they are in solution are perhaps the best way to differentiate them.

Acids

By definition, an **acid** is any substance that will release a hydrogen ion (H^+) when in solution. A hydrogen ion is simply a bare proton—the nucleus of a hydrogen atom. Therefore, acids are frequently called *proton donors*. It is the concentration of hydrogen ions that accounts for the chemical properties of acids. The level of "acidity" of a solution depends on the number of hydrogen ions a particular acid will release.

One particular point should be understood about water. Water molecules dissociate continually in a reversible reaction to form hydrogen ions (H^+) and hydroxide ions (OH^-):

$$H_2O \rightleftharpoons H^+ + OH^-$$

Recall from our discussion of ionic bonds (p. 38) that having a single unpaired electron in the outer energy level makes an atom unstable and that losing that electron results in a more stable structure. This is precisely the reason dissociation of water occurs. In pure water, the balance between these two ions is equal. However, when an acid such as hydrochloric acid (HCl) dissociates into H^+ and Cl^-, it shifts the H^+/OH^- balance in favor of excess H^+ ions, thus increasing the level of acidity. The more hydrogen ions (H^+) produced, the stronger the acid.

A *strong acid* is an acid that completely, or almost completely, dissociates to form H^+ ions. A *weak acid*, on the other hand, dissociates very little and therefore produces few excess H^+ ions in solution. There are many important acids in the body, and they perform many functions. Hydrochloric acid, for example, is the acid produced in the stomach to aid the digestive process.

Bases

Bases, or *alkaline* compounds, are electrolytes that when dissociated in solution, shift the H^+/OH^- balance in favor of OH^-. This can be accomplished by increasing the number of hydroxide ions (OH^-) in solution or decreasing the number of H^+ ions present. The fact that bases will combine with or accept H^+ ions (protons) is the reason the term *proton acceptor* is used to describe these substances. The dissociation of a common base, sodium hydroxide, yields the cation Na^+ and the OH^- anion.

Like acids, bases are classified as strong or weak, depending on how readily and completely they dissociate into ions. Important bases in the body, such as the bicarbonate ion (HCO_3^-), play critical roles in the transportation of respiratory gases, maintaining normal pH balance, and in the elimination of waste products from the body.

The pH Scale

The term **pH** is literally an abbreviation for a phrase meaning "the power of hydrogen" and is used to mean the relative H^+ ion concentration of a solution. As you can see at the left side of Figure 2-15, the pH value is the negative of the base-10 logarithm of the H^+ ion concentration. The pH indicates the degree of *acidity* or *alkalinity* of a solution. As the concentration of H^+ ions increases, the pH goes down and the solution becomes more acidic; a decrease in H^+ ion concentration makes the solution more alkaline and the pH goes up:

- A pH of 7 indicates neutrality (equal amounts of H^+ and OH^-)
- A pH of less than 7 indicates acidity (more H^+ than OH^-)
- A pH greater than 7 indicates alkalinity (more OH^- than H^+)

The overall pH range is often expressed numerically on a logarithmic scale of 1 to 14. Keep in mind that a change of 1 pH unit on this type of scale represents a 10-fold difference in actual concentration of H^+ ions (Box 2-1).

BUFFERS

The normal pH range of blood and other body fluids is extremely narrow. For example, venous blood (pH 7.36) is only slightly more

Box 2-1 | FYI

The pH Unit

A pH value of 7, for example, means that a solution with that measurement contains 10^{-7} grams of hydrogen ions per liter. Translating this logarithm into a number, a pH of 7 means that such a solution contains 0.0000001 (that is, 1/10,000,000) gram of hydrogen ions per liter. A solution with a measurement of pH 6 contains 0.000001 (1/1,000,000) gram of hydrogen ions per liter, and one of pH 8 contains 0.00000001 (1/100,000,000) gram of hydrogen ions per liter. Note that a solution with pH 7 contains *10 times* as many hydrogen ions as a solution with pH 8 and that pH decreases as the hydrogen ion concentration increases.

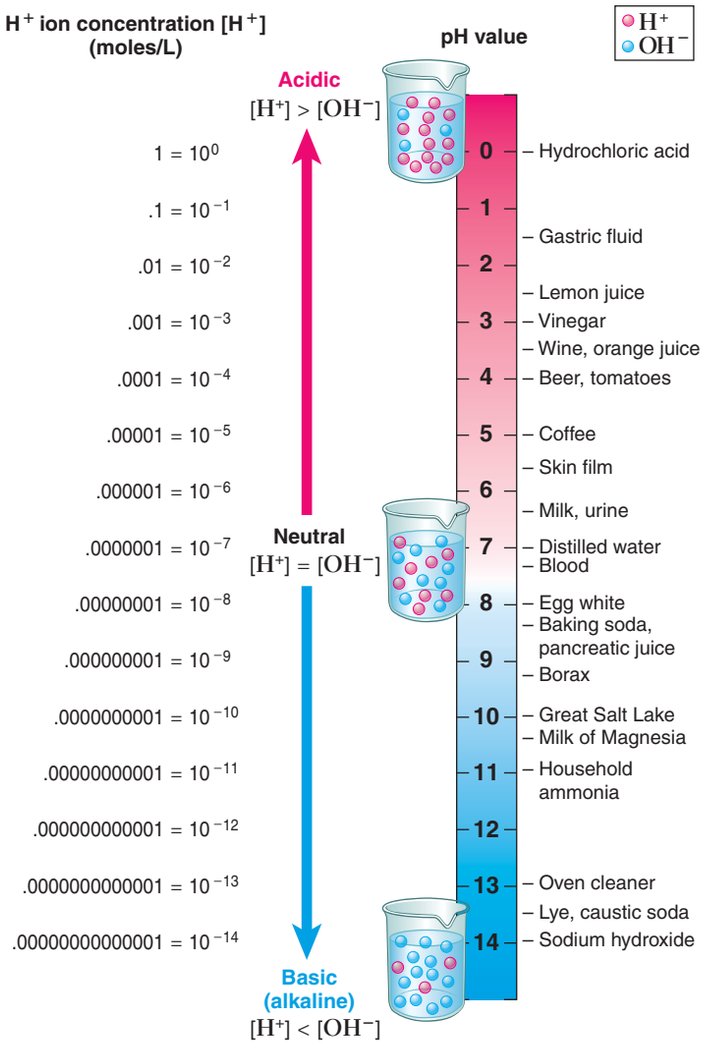

FIGURE 2-15

The pH scale. Note that as the concentration of H^+ increases, the solution becomes increasingly acidic and the pH value decreases. As the H^+ concentration decreases, the pH value increases, and the solution becomes more and more basic, or alkaline. (The scale on the left side of the diagram shows the actual concentrations of H^+ in moles per liter, or molar concentration, as an ordinary number and expressed as an exponent [logarithm] of 10. You can see that the pH scale is simply the negative of the exponent of 10.)

acidic than arterial blood (pH 7.41). The difference results primarily from carbon dioxide entering venous blood as a waste product of cellular metabolism. Carbon dioxide is carried as carbonic acid (H_2CO_3) and therefore lowers the pH of venous blood. More than 30 *liters* of carbonic acid is transported in venous blood each day and eliminated as carbon dioxide by the lungs, and yet 1 liter of venous blood contains only about 1/100,000,000 gram more H^+ ions than 1 liter of arterial blood does!

The incredible constancy of the pH homeostatic mechanism relies partly on the presence of substances, called **buffers,** that minimize changes in the concentrations of H^+ and OH^- ions in our body fluids. Buffers are said to act as a "reservoir" for H^+ ions. They donate, or remove, H^+ ions to a solution if that becomes necessary to maintain a constant pH. Examples of important buffer systems and specifics of buffer action are discussed in Chapter 33.

SALTS

A salt is any compound that results from the chemical interaction of an acid and a base. Salts, like acids and bases, are electrolyte compounds and dissociate in solution to form positively and negatively charged ions. Ions exist in solution. If the water is removed, the ions will crystallize and form salt. When mixed and allowed to react, the positive ion (cation) of a base and the negative ion (anion) of an acid will join to form a salt and additional water in the manner of a typical exchange reaction. The reaction between an acid and base to form a salt and water is called a *neutralization reaction:*

AB	+	CD	⟶	CB	+	AD
HCl	+	NaOH	⟶	NaCl	+	H_2O
Acid		Base		Salt		Water

Note that the sodium and the chloride join to form the salt whereas the hydroxide ion "accepts" or combines with a hydrogen ion to form water.

The sources of many of the major and trace mineral elements listed in Table 2-1 are inorganic salts, which are common in many body fluids and certain tissues such as bone. These elements often exert their full physiological effects only when present as charged atoms or ions in solution.

The proper amount and concentration of such mineral ions as potassium (K^+), calcium (Ca^{++}), and sodium (Na^+) are required for proper functioning of nerves and for contraction of muscle tissue. See Chapter 32 for specific homeostatic control mechanisms that regulate electrolyte balance in blood and other body fluids.

ORGANIC MOLECULES

The term *organic* is used to describe the enormous number of compounds that contain carbon—specifically C–C or C–H bonds. Recall that carbon atoms have only four electrons in their outer energy level (see Figure 2-3, A); it requires four electrons to satisfy the octet rule. As a result, each carbon atom can join with up to four other atoms to form literally thousands of molecules of varying size and shape. Although some organic molecules are small and have only one or two functional groups, the large *macromolecules* often have many functional groups attached to one another or to other chemical compounds (Figure 2-16). In the human body, the following four major groups of organic substances are very important:

1. Carbohydrates
2. Lipids
3. Proteins
4. Nucleic acids and related molecules

Figure 2-16 shows examples of the four major organic substances represented by three-dimensional models. Many macromolecules are composed of basic building blocks, such as glucose or amino acids, that are joined in chains of varying length by covalent bonds. Table 2-3 identifies important biological molecules (or biomolecules), including macromolecules and combined forms, shows the type of subunit present, gives a typical function, and lists one or more examples of each. Refer to this table as you read about the large biological molecules in the paragraphs that follow.

Carbohydrates

All **carbohydrate** compounds contain the elements carbon, hydrogen, and oxygen—usually in the ratio of 1 to 2 to 1. The carbon atoms link to one another in chains or rings. Carbohydrates include the substances commonly called *sugars* and *starches* and represent the primary source of chemical energy needed by every body cell. In addition, carbohydrates serve a structural role as components of such critically important molecules as RNA and DNA, which are involved in cell reproduction and protein synthesis.

As a group, carbohydrates are divided into three types or classes that are characterized by the length of their carbon chains. The three types are named as follows:

1. Monosaccharides (simple sugars)
2. Disaccharides (double sugars)
3. Polysaccharides (complex sugars)

MONOSACCHARIDES

Monosaccharides, or simple sugars, are relatively small carbohydrates. The most important simple sugar is *glucose*. It is a six-carbon sugar with the formula $C_6H_{12}O_6$. The chemical formula indicates that each molecule of glucose contains 6 atoms of carbon, 12 atoms of hydrogen, and 6 atoms of oxygen. Because it has six carbon atoms, it is called a *hexose* (*hexa*, "six"). Glucose is present in the dry state as a *straight chain* but forms a *cyclic* compound (ring) when dissolved in water. In Figure 2-17 the straight chain and cyclic arrangements are shown with a three-dimensional model of the molecule. However, it is important to remember that all forms of glucose represented in models or illustrations are the same molecule.

In addition to glucose, other important hexoses, or six-carbon simple sugars, include fructose and galactose. Not all monosaccharides, however, are hexoses. Some are *pentoses* (from *penta*, five), so named because they contain five carbon atoms. *Ribose* and *deoxyribose* are pentose monosaccharides of great importance in the body—they are covered further when we study nucleic acids later in this chapter. Like all monosaccharides, ribose and deoxyribose are simple sugars—but strange sugars in that they are not sweet.

DISACCHARIDES AND POLYSACCHARIDES

Substances classified as *disaccharides* (double sugars) or *polysaccharides* (complex sugars) are carbohydrates composed of two or more simple sugars that are bonded together through a dehydration synthesis reaction that involves the removal of water. Sucrose (table sugar), maltose, and lactose are all disaccharides. Each consists of two monosaccharides linked together. Figure 2-18 shows the formation of sucrose from glucose and fructose. Note that a hydrogen atom from the glucose molecule combines with a hydroxyl group (OH) from the fructose molecule to form water, with an oxygen atom left to bind the two subunits together. Lactose is likewise synthesized from glucose and galactose. Two glucose molecules join to form maltose.

Polysaccharides consist of many monosaccharides chemically joined to form straight or branched chains. Once again, water is removed as the many monosaccharide subunits are joined. Any large molecule made up of many identical small molecules is called a *polymer*. Polysaccharides are polymers of monosaccharides. *Glycogen*, a polymer of glucose, is sometimes referred to as *animal starch*. It is the main polysaccharide in the body and has an estimated molecular weight of several million—truly a macromolecule.

TABLE 2-3 Examples of Important Biomolecules

MACROMOLECULE	SUBUNIT	FUNCTION	EXAMPLE
Carbohydrates			
Glucose	Simple sugar (hexose: $C_6H_{12}O_6$)	Stores energy	Blood glucose
Ribose	Simple sugar (pentose: $C_5H_{10}O_5$)	Plays role in expression of hereditary information	Component of RNA
Deoxyribose	Simple sugar (pentose: $C_5H_{10}O_4$)	Plays role in storage and transmission of hereditary information	Component of DNA
Glycogen	Glucose	Stores energy	Liver glycogen
Lipids			
Triglycerides	Glycerol + 3 fatty acids	Store energy	Body fat
Phospholipids	Glycerol + phosphate + 2 fatty acids	Make up cell membranes	Plasma membrane of cell
Steroids	Steroid nucleus (4-carbon ring)	Make up cell membranes Hormone synthesis	Cholesterol, various steroid hormones Estrogen
Prostaglandins	20-carbon unsaturated fatty acid containing 5-carbon ring	Regulate hormone action; enhance immune system; affect inflammatory response	Prostaglandin E, prostaglandin A
Proteins			
Functional proteins	Amino acids	Regulate chemical reactions	Hemoglobin, antibodies, enzymes
Structural proteins	Amino acids	Component of body support tissues	Muscle filaments, tendons, ligaments
Nucleic Acids			
DNA	Nucleotides (sugar, phosphate, base)	Encodes hereditary information	Chromatin, chromosomes
RNA	Nucleotides (sugar, phosphate, base)	Helps decode hereditary information; acts as "RNA enzyme"; silencing of gene expression	Transfer RNA (tRNA), messenger RNA (mRNA), double-strand RNA (dsRNA)
Nucleotides and Related Molecules			
Adenosine triphosphate (ATP)	Phosphorylated nucleotide (adenine + ribose + 3 phosphates)	Transfers energy from fuel molecules to working molecules	ATP present in every cell of the body
Creatine phosphate (CP)	Amino acid derivative + phosphate	Transfers energy from fuel to ATP	CP present in muscle fiber as "backup" to ATP
Nicotinic adenine dinucleotide (NAD)	Combination of two ribonucleotides	Acts as coenzyme to transfer high-energy particles from one chemical process to another	NAD present in every cell of the body
Combined or Altered Forms			
Glycoproteins	Large proteins with small carbohydrate groups, attached	Similar to functional proteins	Some hormones, antibodies, enzymes, cell membrane components
Proteoglycans	Large polysaccharides with small polypeptide chains attached	Lubrication; increases thickness of fluid	Component of mucous fluid and many tissue fluids in the body
Lipoproteins	Protein complex containing lipid groups	Transport lipids in the blood	LDLs (low-density lipoproteins); HDLs (high-density lipoproteins)
Glycolipids	Lipid molecule with attached carbohydrate group	Component of cell membranes	Component of membranes of nerve cells
Ribonucleoprotein	Combination of RNA nucleotide and protein	Enzyme-like actions such as splicing mRNA	Small nuclear ribonucleoproteins (snRNPs or "snurps") that make up the spliceosome structure in a cell

Formation of sucrose. Glucose and fructose are joined in a synthesis reaction that involves the removal of water.

| QUICK CHECK |

18. List the four major groups of organic substances.
19. Identify the most important monosaccharide, or simple sugar.
20. Identify a carbohydrate polymer and explain how it is formed.

Lipids

Lipids, according to one definition, are water-insoluble organic biomolecules. Lipids ordinarily do not dissolve in water because lipid molecules are generally **nonpolar.** Because electrons are shared equally within a molecule there are no partially charged regions and thus lipids do not cling to the partially charged areas of the polar water molecules. Although insoluble in water, most lipids, many with an oil-like consistency and greasy feel, dissolve readily in some organic solvents such as ether, alcohol, or benzene.

Like the carbohydrates, lipids are composed largely of carbon, hydrogen, and oxygen. However, the proportion of oxygen in lipids is much lower than that in carbohydrates. Many lipids also contain other elements such as nitrogen and phosphorus. As a group, lipids include a large assortment of compounds that have been classified in several ways. Classification of lipids includes triglycerides or fats, phospholipids, steroids, and prostaglandins.

Lipids are critically important biological compounds and have several major roles in the body (Table 2-4). Many are used for energy purposes, whereas others serve a structural role and function as integral parts of cell membranes. Other important lipid compounds serve as vitamins or protect vital organs by serving as "fat pads," or shock absorbers, in certain body areas. One type of lipid material actually serves as "insulator material" around nerves, thus serving to prevent "short circuits" and speed nervous impulse transmissions.

TABLE 2-4 Major Functions of Human Lipid Compounds

FUNCTION	EXAMPLE
Energy	Lipids can be stored and broken down later for energy; they yield more energy per unit of weight than carbohydrates or proteins do
Structure	Phospholipids and cholesterol are required components of cell membranes
Vitamins	Fat-soluble vitamins: vitamin A forms retinal (necessary for night vision); vitamin D increases calcium uptake; vitamin E promotes wound healing; and vitamin K is required for the synthesis of blood-clotting proteins
Protection	Fat surrounds and protects organs
Insulation	Fat under the skin minimizes heat loss; fatty tissue (myelin) covers nerve cells and electrically insulates them
Regulation	Steroid hormones regulate many physiological processes; for example, estrogen and testosterone are responsible for many of the differences between females and males; prostaglandins help regulate inflammation and tissue repair

TRIGLYCERIDES OR FATS

Triglycerides (triacylglycerols), or fats, are the most abundant lipids, and they function as the body's most concentrated source of energy. Two types of building blocks are needed to synthesize or build a fat molecule: *glycerol* and *fatty acids.* Each glycerol unit is joined to three fatty acids, and the glycerol building block is the same in each fat molecule. Therefore, it is the specific type of fatty acid molecule or component that identifies and determines the chemical nature of any fat.

Types of Fatty Acids

Fatty acids vary in the length of their carbon chains (number of carbon atoms) and in the number of hydrogen atoms that are attached to, or "saturate," the available bonds around each carbon in the chain. Naturally occurring fatty acids have an even number of carbons, usually numbering between 12 and 18. Figure 2-19 shows a structural formula and three-dimensional model for a saturated (palmitic) and unsaturated (linolenic) fatty acid.

By definition, a *saturated fatty acid* is one in which all available bonds of its hydrocarbon chain are filled, that is, saturated, with hydrogen atoms. The chain contains no double bonds (Figure 2-19, A). In contrast, an *unsaturated fatty acid* has one or more double bonds in its hydrocarbon chain because not all the chain's carbon atoms are saturated with hydrogen atoms. Looking at Figure 2-19, B, you can easily see that some of the hydrogens are missing from the carbon backbone of the unsaturated fatty acid.

The degree of saturation is the most important factor in determining the physical and chemical properties of fatty acids. For example, animal fats such as tallow and lard are solids at room temperature, whereas vegetable oils are typically liquids. The difference lies in the extent of unsaturation—animal fats are mostly saturated, whereas most vegetable oils are not. Note in Figure 2-19, B, that the presence of double bonds in a fatty acid molecule will cause the chain to kink or bend.

Fats become more oily and liquid as the number of unsaturated double bonds increases. The kinks and bends in the unsaturated molecules keep them from fitting closely together. In contrast, the lack of kinks in saturated fatty acids allows the molecules to fit tightly together to form a solid mass at higher temperatures.

Formation of Triglycerides

Figure 2-20 shows the formation of a triglyceride. Its name, *glycerol tricaproate,* suggests that it contains three molecules of the

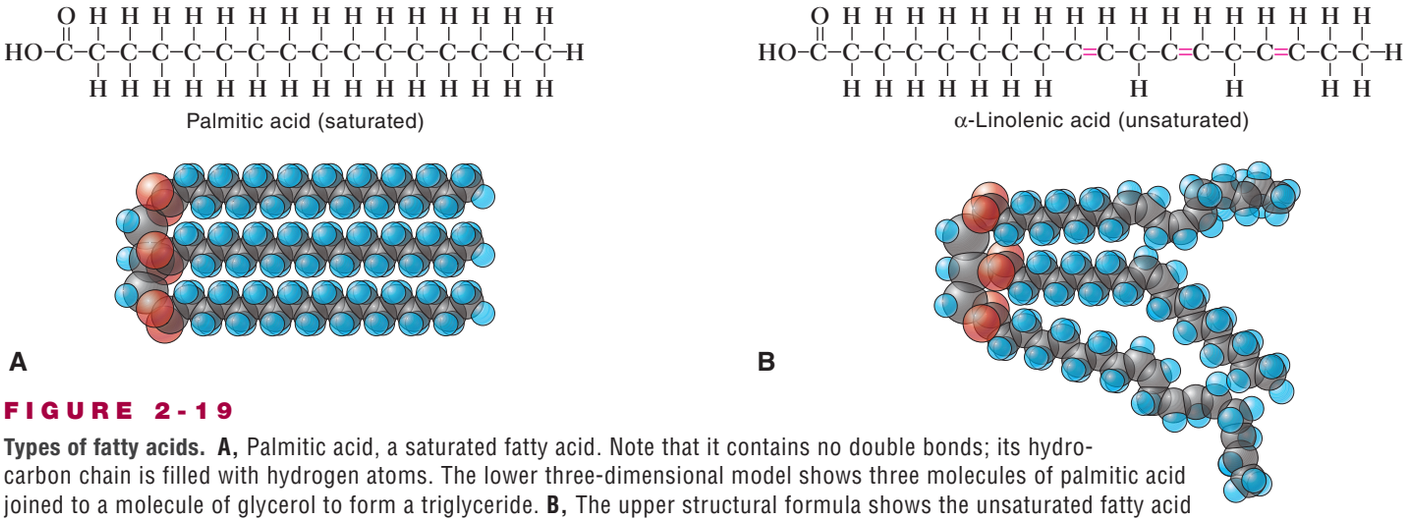

FIGURE 2-19

Types of fatty acids. A, Palmitic acid, a saturated fatty acid. Note that it contains no double bonds; its hydrocarbon chain is filled with hydrogen atoms. The lower three-dimensional model shows three molecules of palmitic acid joined to a molecule of glycerol to form a triglyceride. **B,** The upper structural formula shows the unsaturated fatty acid α-linolenic acid (double bonds shown in red). The lower three-dimensional model shows triglyceride exhibiting "kinks" caused by the presence of double bonds in the component fatty acids.

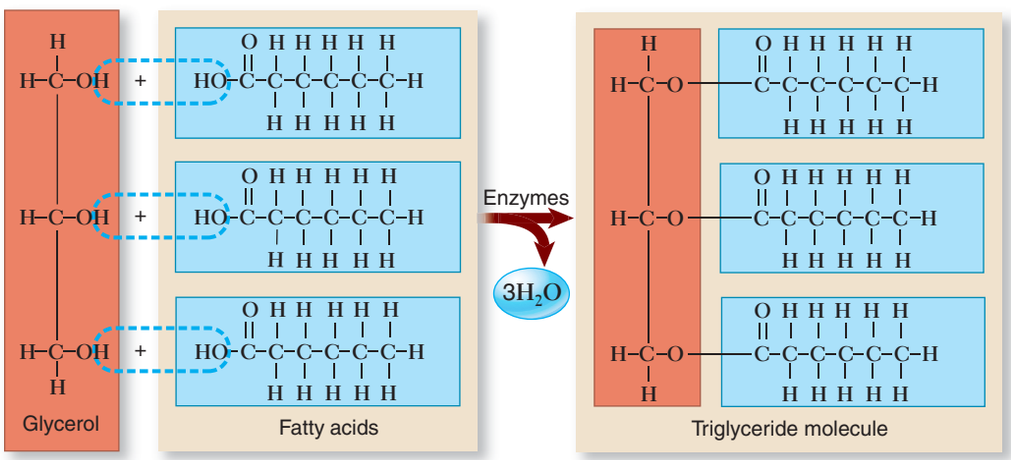

FIGURE 2-20

Formation of triglyceride. Glycerol tricaproate is a composite molecule made up of three molecules of caproic acid (a six-carbon fatty acid) coupled in a dehydration synthesis reaction to a single glycerol backbone. In addition to the triglyceride, this process results in the formation of three molecules of water.

six-carbon fatty acid *caproic acid* attached to a glycerol molecule. Note that the three caproic acid building blocks attach by their carboxyl groups (COOH) to the three hydroxyl groups (OH) of the glycerol molecule to form the triglyceride and three molecules of water. The process is one you are now familiar with—it is a dehydration synthesis reaction. Keep in mind that although some fats, such as glycerol tricaproate, contain three molecules of the same fatty acid, others may have two or three different fatty acids attached to glycerol. Caproic acid is considered to be a *short-chain* fatty acid; some triglycerides contain fatty acids with a carbon backbone several times longer, thus forming *long-chain* fatty acids.

PHOSPHOLIPIDS

Phospholipids are fat compounds similar to triglycerides. They are modified, however, in that one of the three fatty acids attached to glycerol in a triglyceride is replaced in a phospholipid by another type of chemical structure containing phosphorus and nitrogen. The structural formula of a phospholipid is shown in Figure 2-21. Observe that the phospholipid molecule contains glycerol. Joined to the glycerol at one end of the molecule are two fatty acids. Attached to glycerol but extending in the opposite direction is the phosphate group, which is attached to a nitrogen-containing compound.

The head, or end of the molecule containing the phosphorus group, in a phospholipid molecule is polar and is therefore water

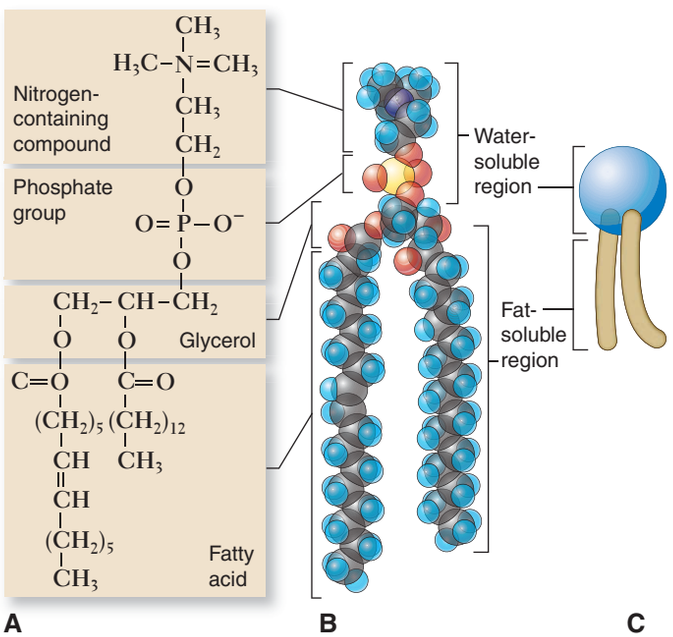

FIGURE 2-21

Phospholipid molecule. A, Chemical formula of a phospholipid molecule. **B,** Molecular model showing water- and fat-soluble regions. **C,** Cartoon often used to represent the double-tailed phospholipid molecule.

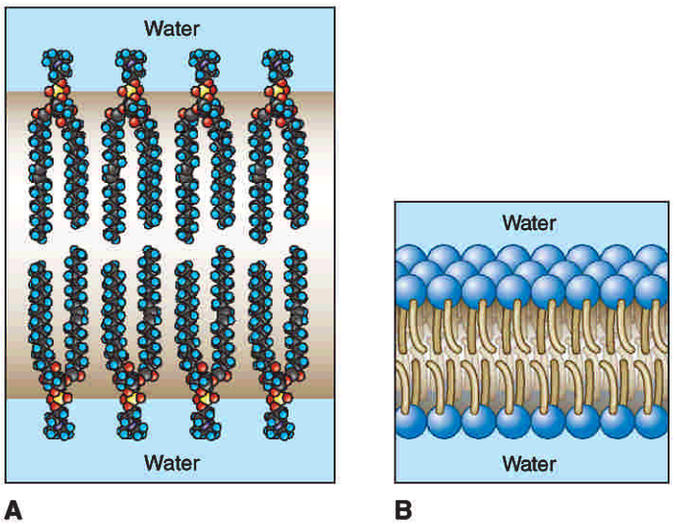

FIGURE 2-22

Phospholipid bilayer. A, Orientation of phospholipid molecules when surrounded by water and forming a bilayer. **B,** Cartoon commonly used to depict a phospholipid bilayer.

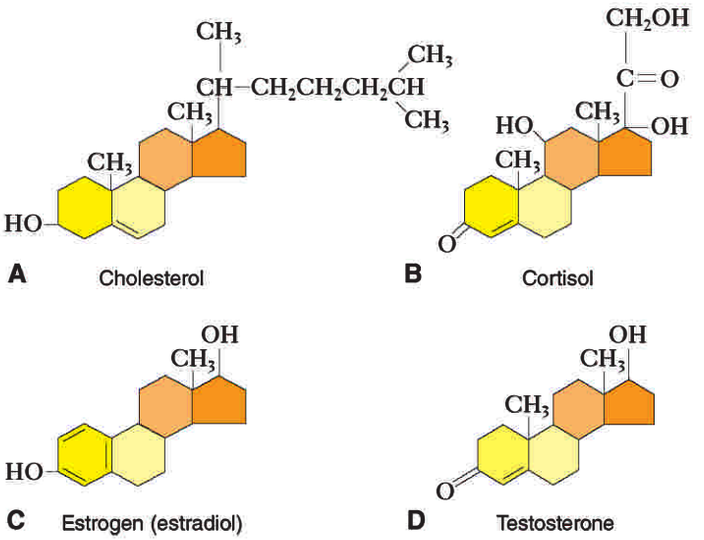

FIGURE 2-23

Steroid compounds. The steroid nucleus—highlighted in yellow—found in cholesterol **(A)** forms the basis for many other important compounds such as cortisol **(B)**, estradiol (an estrogen) **(C)**, and testosterone **(D)**.

soluble. The term *hydrophilic*, meaning "water loving," also applies to the phospholipid head. The end formed by the two fatty acids is nonpolar and is therefore fat soluble or *hydrophobic* ("water fearing"). This unique property means that phospholipid molecules can bridge, or join, two different chemical environments—a water environment on one side and a lipid environment on the other. Thus in water they often form bilayers (double layers) with the fatty tails facing toward one another and the heads forming sheets that face the water on either side of the bilayer (Figure 2-22). For this reason, phospholipids are a primary component of cell membranes (which are bilayers); they are discussed further in Chapter 3.

STEROIDS

Steroids are a large and important class of lipids whose molecules have as their main feature the *steroid nucleus* (Figure 2-23). The steroid nucleus is composed of four attached rings that are structurally similar but may have widely diverse functions related to the differing functional groups that are attached to them.

Steroids, some of which are called *sterols*, are widely distributed in the body and are involved in many important structural and functional roles. Cholesterol is a steroid found in the plasma membrane surrounding every body cell (see Chapter 3 and Box 2-2). Its presence helps stabilize this important cellular structure and is required for many reactions that cells must perform to survive. In addition, the body slightly modifies cholesterol molecules to form such important hormones as cortisone, estrogen, and testosterone. It is also used to make the bile salts needed for digestion. The steroid nucleus is also a part of the active hormone form of vitamin D called *calcitriol*.

PROSTAGLANDINS

Prostaglandins, often called *tissue hormones*, are lipids composed of a 20-carbon unsaturated fatty acid that contains a five-carbon ring (Figure 2-24). Many different kinds of prostaglandins exist in the body. We now classify 16 prostaglandin types (PGs) into nine broad categories, called PGA to PGI. Each major grouping of prostaglandins can be further subdivided according to chemical structure and function.

Prostaglandins were first associated with prostate tissue and were named accordingly. Subsequent discoveries, however, have shown that these biologically powerful chemical substances are produced by cell membranes located in almost every body tissue. They are formed and then released from cell membranes in response to a particular stimulus. Once released, they have a very local effect and are then inactivated.

The effects of prostaglandins in the body are many and varied. They play a crucial role in regulating the effects of several hormones, influence blood pressure and the secretion of digestive juices, enhance the body's immune system and inflammatory response (Box 2-3), and have an important role in blood clotting and respiration, to name a few. The use of prostaglandins and prostaglandin inhibitors as drugs is an exciting and rapidly growing area in clinical medicine.

24. Identify an important steroid.

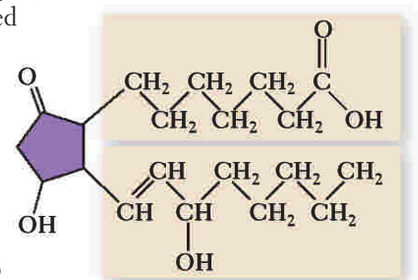

FIGURE 2-24

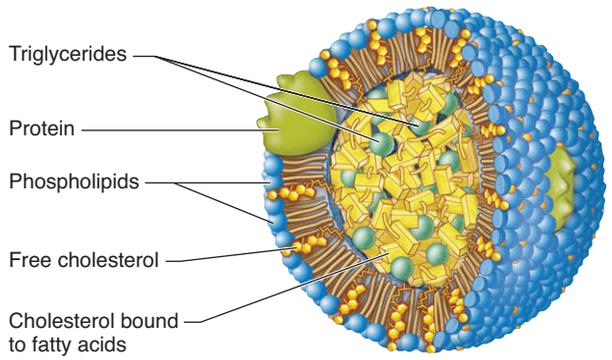


Prostaglandin. Prostaglandins such as this example of prostaglandin E (PGE) are 20-carbon unsaturated fatty acids with a 5-carbon ring. Prostaglandins act as local regulators in the body.

Box 2-2 | HEALTH matters

Blood Lipoproteins

A lipid such as cholesterol can travel in the blood only after it has attached to a protein molecule—forming a lipoprotein. Some of these molecules are called *high-density lipoproteins* (HDLs) because they have a high density due to having more protein than cholesterol. Another type of molecule contains less protein than cholesterol, so it is called *low-density lipoprotein* (LDL). The composite nature of a lipoprotein molecule is shown in the figure.

The cholesterol in LDLs is often called "bad" cholesterol because high blood levels of LDL are associated with *atherosclerosis,* a life-threatening blockage of arteries. LDLs carry cholesterol to cells, including the cells that line blood vessels. HDLs, on the other hand, carry so-called "good" cholesterol *away from cells* and toward the liver for elimination from the body. A high proportion of HDL in the blood is associated with a low risk for atherosclerosis.

Structure of a lipoprotein.

Proteins

All **proteins** have four elements: carbon, oxygen, hydrogen, and nitrogen. Many proteins also contain small amounts of sulfur, iron, magnesium, zinc, and other trace metals. Some also contain phosphorus. Proteins (from word parts meaning "first-rank substance") are the most abundant of the organic compounds in the body. As their name implies, their functions are of first-rank importance. Protein molecules are among the giant sized macromolecules, along with many of the polysaccharides and nucleic acids.

The many roles played by proteins in the body can be divided into two broad categories: *structural* and *functional*. Structural proteins form the structure of the cells, tissues, and organs of the body. Various unique shapes and compositions such as flexible strands, elastic strands, and waterproof layers allow structural proteins to form the many different building blocks of the body. Functional proteins are chemists. The unique shape of each functional protein allows it to fit with certain other chemicals and cause some change in the molecules. For example, **enzymes** are functional proteins that bring molecules together or split them apart in chemical reactions. Protein hormones such as insulin trigger chemical changes in cells to produce the hormone's effects.

It is the *shape* of a protein that determines how it performs. The main principle in understanding how proteins work is that form and function go hand in hand—the right shape for the right job.

Compared with water with a total mass number of of 18, giant protein molecules may have a total mass number of several million! However, all protein molecules, regardless of size, have a similar basic structure. They are chainlike polymers composed of multiple subunits, or building blocks, linked end to end. The building blocks of all proteins are called *amino acids.*

AMINO ACIDS

The elements that make up a protein molecule are bonded together to form chemical units called **amino acids.** Proteins are composed

Box 2-3 | FYI

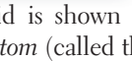
Aspirin and Prostaglandins

In the presence of an appropriate stimulus such as irritation or injury, fatty acids required for prostaglandin synthesis are released by cell membranes. If a specific type of enzyme, *cyclooxygenase (COX),* is present to interact with these fatty acids, prostaglandins will be synthesized and released from the cell membrane into the surrounding tissue fluid.

Prostaglandins sometimes serve as inflammatory agents. They cause local dilation of blood vessels with resulting heat (fever), swelling, redness, and pain. Aspirin (acetylsalicylic acid [ASA]) is a *COX inhibitor* and thus works to relieve these symptoms by blocking the activity of the COX–1 and COX–2 enzymes. If these enzymes cannot function properly, prostaglandin synthesis will be inhibited, and symptoms will be relieved.

Prostaglandins sometimes serve to regulate blood clotting. Again, aspirin can inhibit prostaglandin synthesis and play a therapeutic role in preventing abnormal blood clots or reducing abnormal clots that have already begun forming. For this reason, some people at risk for a heart attack triggered by abnormal blood clots are advised to take daily low-dose aspirin to reduce the formation of abnormal clots. If a heart attack has already begun, full-dose aspirin taken immediately may stop the clotting and thus increases a person's chances of surviving the episode by about 25%.

The functions of prostaglandins and the actions of other COX enzyme inhibitors are discussed further in Chapter 18.



Aspirin. Acetylsalicylic acid (aspirin) is a commonly used COX inhibitor that reduces prostaglandin effects in the body such as inflammation, fever, and blood clotting.

of 21 naturally occurring amino acids, and nearly all of the 21 amino acids are usually present in every protein. Of these 21, 8 are known as *essential amino acids*. They cannot be produced by the body and must be included in the adult diet. The 13 remaining *nonessential amino acids* can be produced from other amino acids or from simple organic molecules readily available to the body cells.

| A&P CONNECT |

Some scientists state that there are 20 amino acids making up proteins, and others 21 or 22. Why is this? Find out in ***Amazing Amino Acids*** online at ***A&P Connect.***

The basic structural formula for an amino acid is shown in Figure 2-25. As you can see, it consists of a *carbon atom* (called the *alpha* carbon) to which are bonded a positive *amino group* (NH_3^+), a negative *carboxyl group* (COO^-), a *hydrogen atom*, and a *side group* of elements designated by the letter *R*. It is this side group that constitutes the unique, identifying part of an amino acid.

The 21 amino acids that make up most human proteins are shown in Figure 2-26. You can see that each individual amino acid has its own chemical nature because of its unique side group. Some are more acid, some more basic. Some tend to ionize and thus have an electric charge. Others have regions of different partial charges and are therefore polar. On the other hand, some amino acids tend to be nonpolar. Some are large and some are small. Individual amino acids are often compared with the letters of the alphabet. Just as combinations of individual letters form word combinations, different amino acids form protein chains. Think of amino acids as the alphabet of proteins.

The ability of amino acids to "link up" in all possible combinations allows the body to build or synthesize an almost infinite variety of different protein "words" or chains that may contain a dozen, several hundred, or even thousands of amino acids. Each of these chains can have different regions with different chemical characteristics.

Amino acids frequently become joined by peptide bonds. A **peptide bond** is one that binds the carboxyl group of one amino acid to the amino group of another amino acid. O from the negative carboxyl group of one amino acid and two H atoms from the positive amino group of another amino acid split off to form water plus a new compound called a *peptide*. A peptide made up of only two amino acids linked by a peptide bond is a *dipeptide*. A *tripeptide* consists of three amino acids linked by two bonds. The linkage of four amino acids by these peptide bonds is shown in Figure 2-27, A. A long sequence or chain of amino acids—usually 100 or more—linked by peptide bonds constitutes a *polypeptide*. When the length of the polymer chain exceeds about 100 amino acids, the molecule is called a *protein* rather than a polypeptide.

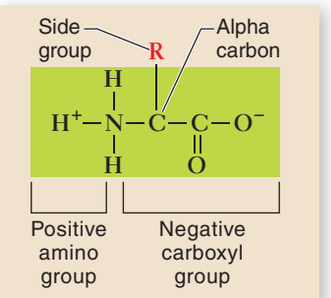
Do you see a similarity between the formation of a polysaccharide, such as glycogen, from simple sugar "building blocks" and the formation of a polypeptide from amino acid building blocks? In both processes, many subunits are joined together, resulting in the loss of water molecules. Thus, both are examples of the *condensation* or *dehydration synthesis* reactions that are very common in living organisms. A decomposition reaction called *hydrolysis* requires the addition of a water molecule to break a bond. During hydrolysis of a peptide chain, the peptide linkages between adjacent amino acids in the sequence are broken by the addition of water, and individual amino acids are released (Figure 2-27, B).

LEVELS OF PROTEIN STRUCTURE

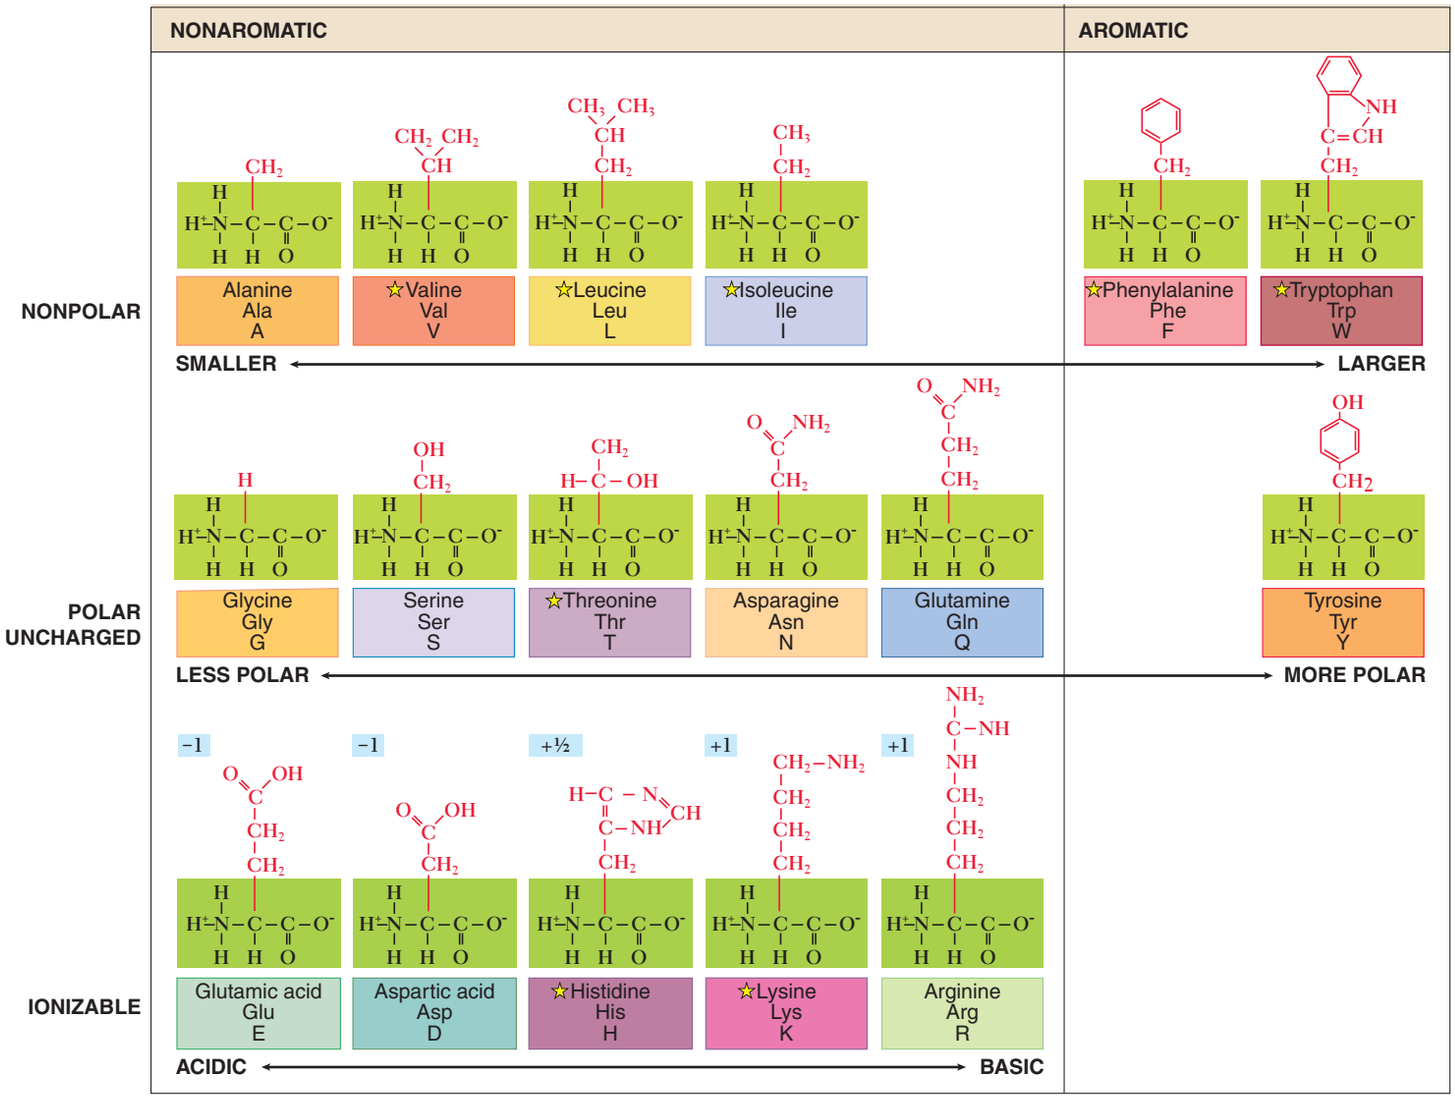
Biochemists often describe four levels of increasing complexity in protein organization:

1. Primary (first level)
2. Secondary (second level)
3. Tertiary (third level)
4. Quaternary (fourth level)

The four levels of protein structure are illustrated in Figure 2-28.



The *primary structure* of a protein refers simply to the number, kind, and sequence of amino acids that make up the polypeptide chain. The hormone of the human parathyroid gland, parathyroid hormone (PTH), is a protein that retains its primary structure—it is a noodle-like molecule consisting of only one polypeptide chain of 84 amino acids.



Most polypeptides do not exist as a straight chain. Instead, they show a *secondary structure* in which the chains are coiled or bent into pleated sheets. The most common type of coil takes a clockwise direction and is called an *alpha helix*. In this type of secondary structure, the coils of the protein chain resemble a spiral staircase, with the coils stabilized by hydrogen bonds between successive turns of the spiral. Pleated *beta sheets* are likewise stabilized by hydrogen bonds. This stabilizing function of hydrogen bonding in protein structure is critical. A commonly occurring pattern of alpha helices and/or beta sheets within the secondary structure is called a *motif*. A motif often imparts a specific function to each protein in which it appears.

Just as a primary structure polypeptide chain can pleat or bend into a helical secondary structure, so too can a secondary structure protein chain undergo other contortions and be further twisted so that a globular-shaped *tertiary structure* of a protein is formed. In this structure, the polypeptide chain is so twisted that its coils touch one another in many places, and "spot welds," or interlocking connections, occur. Some of these linkages may be strong covalent bonds between amino acid units that exist in the same chain (Box 2-4). Most of the linkages are ionic bonds. Hydrogen bonds, and other weak attractions also help stabilize the twisted and convoluted loops of the structure. A tertiary structure may include several complicated "knots" called *domains*. Each specific type of domain has specific functions that contribute to the overall function of a protein.

FIGURE 2-25

Basic structural formula for an amino acid. Note relationship of the side group (R), amino group, and carboxyl group to the alpha carbon. The amino group (NH_2) is depicted in the Figure as H_2N to show that the *nitrogen* atom of the group bonds to the alpha carbon.

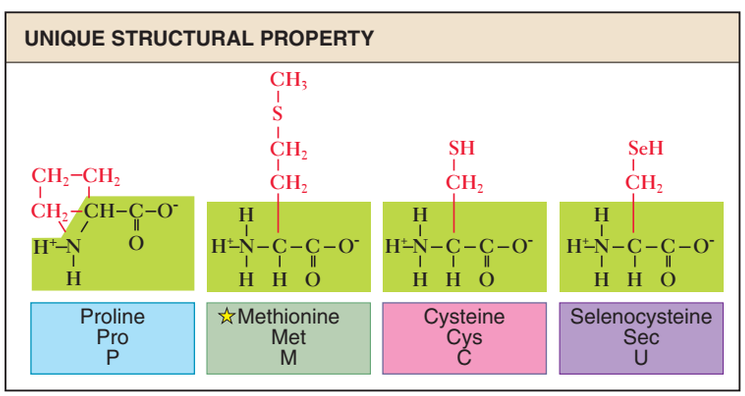


FIGURE 2-26

The standard amino acids of the human body. The full name for each is given, followed by the three-letter abbreviation and the one-letter symbol. The structural formulas show that each amino acid has the same chemical backbone (green highlight) but differs from the others in the side, or R, group that it possesses (red). Essential amino acids are indicated by a star preceding the name. Notice the great variety of sizes among the amino acids, the different polarities or charges, the different levels of acidity, and the other differing chemical characteristics. Like different kinds of blocks in a set of toy blocks, this makes it possible to build different proteins with a wide variety of chemical characteristics and functions. (Additional types of amino acids may be added to proteins after their initial structure is formed.)

The red muscle protein myoglobin, which is discussed in Chapter 12 is an example of a protein with a tertiary structure.

A *quaternary structure* protein is one that contains clusters of more than one polypeptide chain, all linked together into one giant molecule. Antibody molecules that protect us from disease (see Chapter 24) and hemoglobin molecules in red blood cells (see Chapter 20) are examples.

A group of proteins called *chaperones*, which are present in every body cell, acts to direct the steps required for many proteins to fold into the twisted and convoluted shape required for them to function properly (Box 2-5). Some of these chaperone proteins are called *chaperonins*. Inappropriate folding of some proteins is known to be associated with certain diseases. The critically important chemical reactions that permit chaperonins to organize proteins into the different organizational levels required for a particular function can occur only within a very narrow pH range. Maintaining acid-base balance and normal pH in body cells and fluids is discussed in depth in Chapter 33.

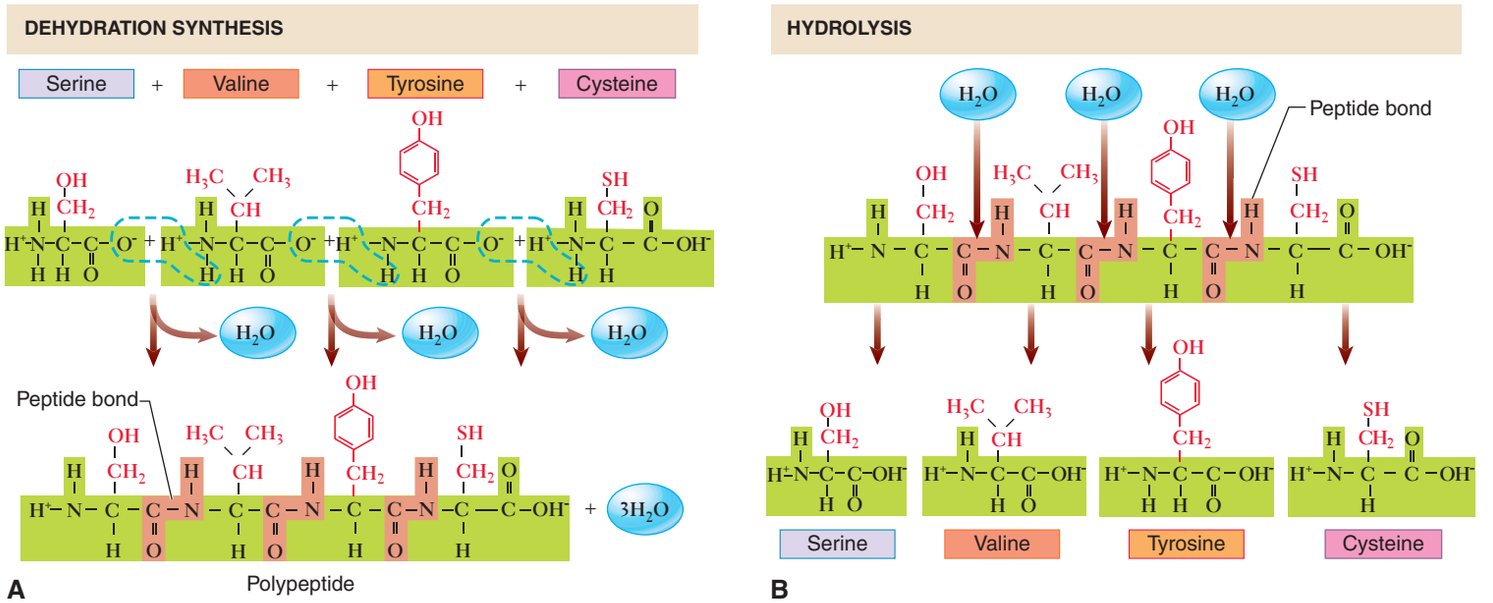

FIGURE 2-27

Formation (dehydration synthesis) and decomposition (hydrolysis) of a polypeptide. A, Linkage of four amino acids by three peptide bonds resulting in the dehydration synthesis of a polypeptide chain and three molecules of water. **B,** Decomposition (hydrolysis) reaction resulting from the addition of three molecules of water. Peptide bonds are broken and individual amino acids are released.

IMPORTANCE OF PROTEIN SHAPE

Properly folded protein molecules are highly organized in their structure and show a very definite relationship between their shape and their function. The final, functioning shape for a protein is often called its *native state.* The native states of the strong **structural proteins** found in tendons and ligaments are fibrous, or threadlike, insoluble, and very stable (Figure 2-29). In contrast, **functional proteins** such as enzymes, certain protein hormones, antibodies, albumin, and hemoglobin have native states that are globular (ball-shaped), often soluble, and have chemically reactive regions. Table 2-5 summarizes some of the important roles played by proteins.

Simply stated, proteins perform their roles by having the right shape for their job—whatever that job is. Given the nearly infinite variety of different amino acid sequences and the complexity of how proteins are folded, you can see that the body can make just about any tool or building block it needs for a variety of jobs. Consider also that if one of the body's proteins loses its shape, or **denatures,** it will lose its function (Figure 2-30). If a protein is built incorrectly or it denatures, the whole body may be in peril (Box 2-6). Factors that can cause a protein to denature include changes in temperature, changes in pH, radiation, and the presence of certain hazardous

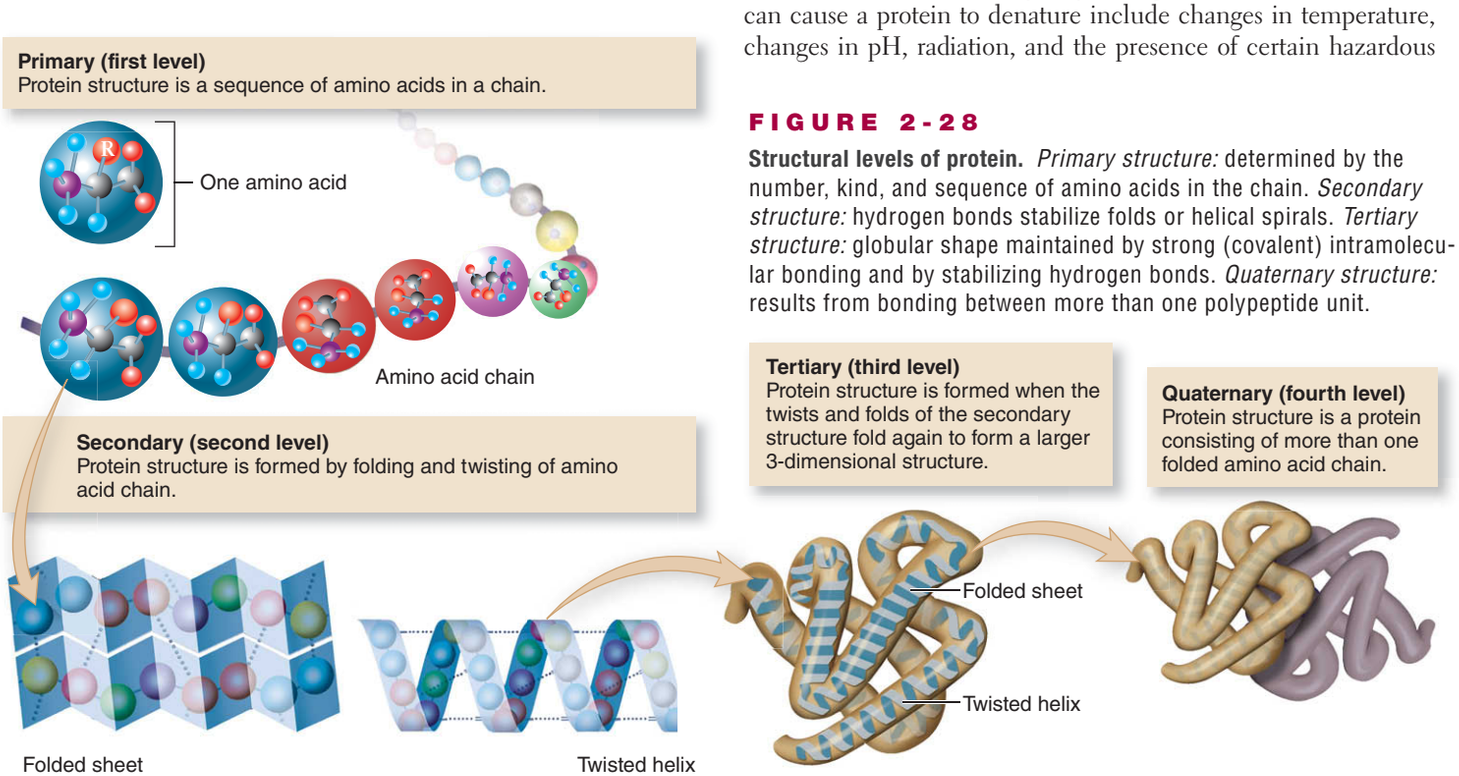

FIGURE 2-28

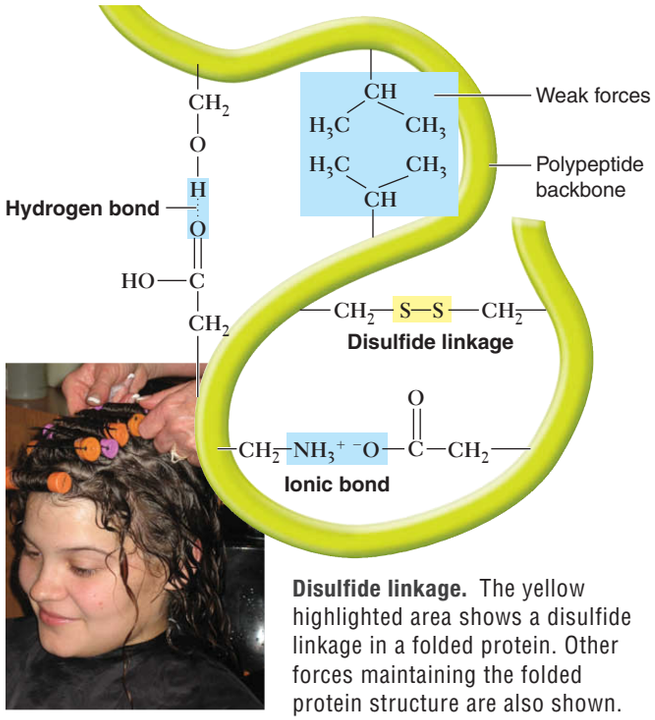


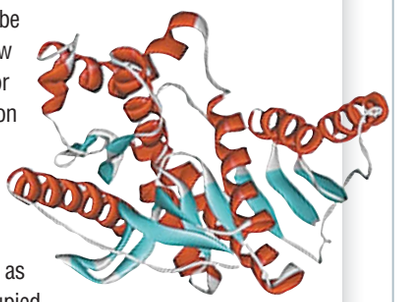
Structural levels of protein. *Primary structure:* determined by the number, kind, and sequence of amino acids in the chain. *Secondary structure:* hydrogen bonds stabilize folds or helical spirals. *Tertiary structure:* globular shape maintained by strong (covalent) intramolecular bonding and by stabilizing hydrogen bonds. *Quaternary structure:* results from bonding between more than one polypeptide unit.

Box 2-4 | FYI

Disulfide Linkages

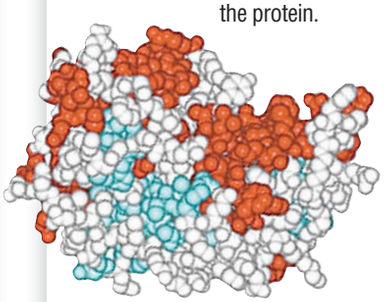
Hair contains a threadlike fibrous protein called *keratin* that is rich in the sulfur-containing amino acid cysteine. The protein chains in keratin are linked in numerous places by S—S bonds that form between cysteines within each hair shaft. These bonds are called *disulfide linkages*.

The object of a "permanent wave" is to change the arrangement of these bonds by breaking the naturally occurring disulfide linkages and then causing them to reform in another pattern. Strong chemicals are applied to the hair that break the existing or "natural" disulfide linkages. The hair is then curled on some type of roller and then another chemical is applied that causes the disulfide bridges to become reestablished in the new or reoriented configuration.



Disulfide linkage. The yellow highlighted area shows a disulfide linkage in a folded protein. Other forces maintaining the folded protein structure are also shown.

Box 2-5 | FYI



Visualizing Proteins

Only a few decades ago, the usual way for a biochemist to demonstrate the three-dimensional structure of a protein molecule was by building wooden ball-and-stick models. These models were less than ideal because they took a long time to build, often fell apart, and were not easy to handle. Now there are many sophisticated, but easy-to-use, computer programs that can "build" protein molecules on the monitor screen. These *virtual protein molecules* can be rotated and viewed from nearly any angle. They can also be changed when trying to design a new protein molecule for therapeutic or other purposes. Here, three common types of protein models are shown. The *ribbon model* shows the areas where alpha helices and folded sheets form within the molecule. The *space-filling model* shows each atom as a "cloud" filling up the space occupied by that atom. The *surface-rendering model* shows the three-dimensional boundaries of the whole protein molecule, often also color-coding for charged regions on the surface of the protein.

Three ways to visualize the same folded protein molecule.

chemicals. Depending on the circumstances, restoring the proper chemical environment of a protein may allow it to *renature* to its native state and begin functioning normally once again.

One last thing to remember about protein shape is that it is often dynamic. That is, proteins often move as they perform their functions. Besides the occasional bend or twist, many proteins have moving parts that resemble hinges, spinning rotors, and grabbing pinchers that permit proteins to move in interesting and useful ways—as you shall see in later chapters.

Nucleic Acids and Related Molecules

DNA AND RNA

Survival of humans as a species—and survival of every other species—depends largely on two kinds of **nucleic acid** molecules. Almost everyone has heard or seen their abbreviated names, DNA and RNA, but their full names are much less familiar. They are deoxyribonucleic and ribonucleic acids (i.e., DNA and RNA). Nucleic acid molecules are polymers of thousands and thousands of smaller molecules called **nucleotides**—deoxyribonucleotides in DNA molecules and ribonucleotides in RNA molecules.

A *deoxyribonucleotide* consists of the pentose sugar named *deoxyribose*, a nitrogenous base (either adenine, cytosine, guanine, or thymine), and a phosphate group (Figure 2-31). *Ribonucleotides* are similar but contain the sugar ribose instead of deoxyribose and the nitrogenous base uracil instead of thymine (Table 2-6).

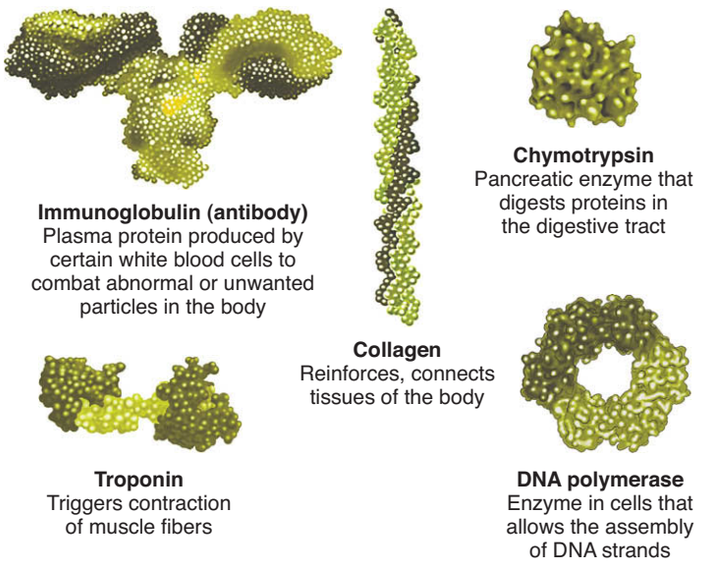

FIGURE 2-29

Variety of protein shapes. These images of folded protein structures provide examples of the wide variety of shapes that proteins have in the human body.

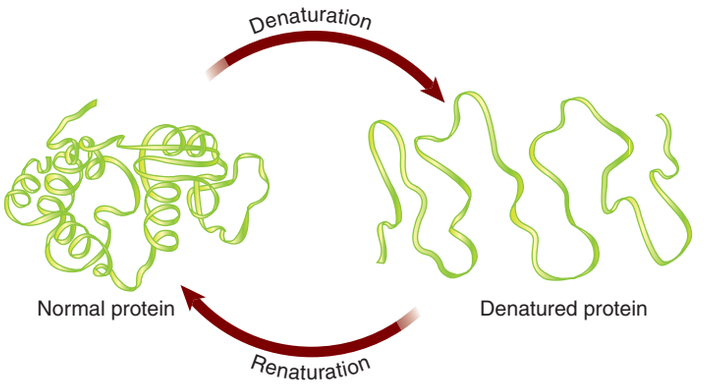

FIGURE 2-30

Denatured protein. When a protein loses its normal folded organization and thus loses its functional shape, it is called a *denatured protein.* Denatured proteins are not able to function normally. However, if the protein shape is restored, the *renatured protein* may resume its normal function.

Two of the bases in a deoxyribonucleotide, specifically adenine and guanine, are called *purine bases* because they derive from *purine.* Purines have a double ring structure. Cytosine and thymine derive from *pyrimidine*, so they are known as *pyrimidine bases.* Pyrimidines have a single ring structure. The pyrimidine base uracil replaces thymine in RNA. More about the differences between DNA and RNA is discussed in Chapter 5.

DNA molecules, the largest molecules in the body, are very large polymers composed of many nucleotides. The nucleotides

TABLE 2-5 Major Functions of Human Protein Compounds

FUNCTION	EXAMPLE
Provide structure	Structural proteins include keratin of skin, hair, and nails; parts of cell membranes; tendons
Catalyze chemical reactions	Lactase (enzyme in intestinal digestive juice) catalyzes chemical reaction that changes lactose to glucose and galactose
Transport substances in blood	Proteins classified as albumins combine with fatty acids to transport them in form of lipoproteins
Communicate information to cells	Insulin, a protein hormone, serves as chemical message from islet cells of the pancreas to cells all over the body
Act as receptors	Binding sites of certain proteins on surfaces of cell membranes serve as receptors for insulin and various other hormones
Defend body against many harmful agents	Proteins called *antibodies* or *immunoglobulins* combine with various harmful agents to render those agents harmless
Provide energy	Proteins can be metabolized for energy

Box 2-6 | HEALTH matters

Phenylketonuria

Phenylketonuria (PKU) is a genetic disease caused by the lack of a single enzyme *(phenylalanine hydroxylase)* required to break down or metabolize the amino acid phenylalanine. PKU is one example of a group of genetic diseases called *inborn errors of metabolism,* which are discussed in Chapter 37. In this instance, phenylalanine metabolism is impaired because the gene required to produce the necessary enzyme for its breakdown is defective. The disease occurs in 1 of every 12,000 births in North America and, if untreated, causes a buildup of phenylalanine in the tissues that results in severe mental retardation and other neurobehavioral symptoms. Traditional treatment of PKU consisted of strict dietary restriction of phenylalanine-containing foods during the first 4 to 8 years of life, followed by some liberalization of diet. Continuation of the diet into adulthood may be necessary (see Figure).

PKU Diet. A preadolescent girl with PKU prepares a special diet low in phenylalanine.

Since the mid-1960s every state has mandated testing of newborn infants for PKU before discharge from the nursery. As a result, the number of undiagnosed and untreated PKU cases that formerly resulted in mental retardation has decreased dramatically. A phenylalanine level above 4 mg/dl is considered positive for the disease. However, the screening procedure, called the *Guthrie test,* is less accurate if blood is drawn before the infant is 48 hours old. Because early discharge of both the mother and baby from the hospital after childbirth is becoming more common, a second, or repeat, screening test at 2 weeks of age may be necessary. The test is performed on a drop of blood, which is obtained from the baby by a *heel stick* and adsorbed onto a piece of filter paper.

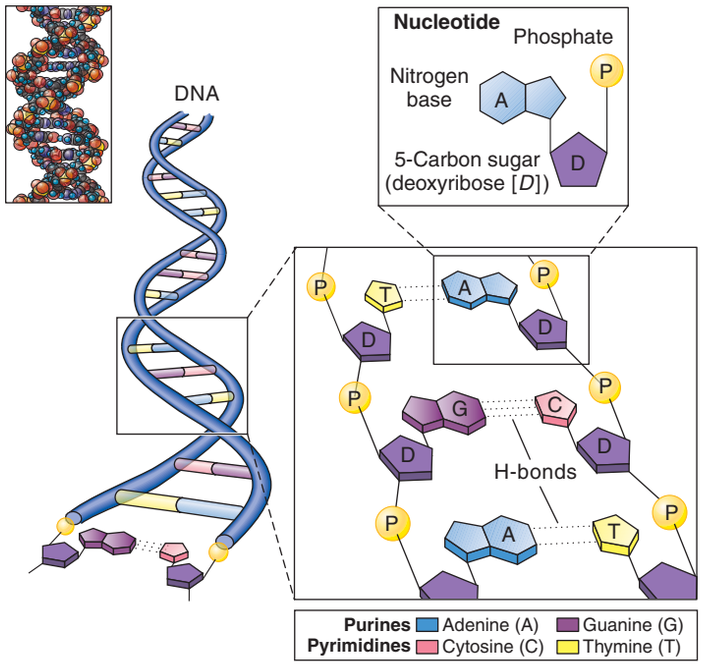

FIGURE 2-31

The DNA molecule. Representation of the DNA double helix showing the general structure of a nucleotide and the two kinds of *base pairs:* adenine (A) (blue) with thymine (T) (yellow) and guanine (G) (purple) with cytosine (C) (red). Note that the G–C base pair has three hydrogen bonds and an A–T base pair has two. Hydrogen bonds are extremely important in maintaining the structure of this molecule.

are joined together, saccharide group to phosphate group, by dehydration synthesis (condensation) to form a long sugar-phosphate backbone. Two of these long polynucleotide chains compose a single DNA molecule. The chains coil around each other to form a double helix. A helix is a spiral shape similar to the shape of a wire in a spring. Figure 2-31 is a diagram of the double-helix DNA.

Each helical chain in a DNA molecule has its phosphate-sugar backbone toward the outside and its bases pointing inward toward the bases of the other chain. More than that, each base in one chain is joined to a base in the other chain by means of either two or three hydrogen bonds to form what is known as a *base pair.* The two polynucleotide chains of a DNA molecule are thus held together by hydrogen bonds between the two members of each base pair (see Figure 2-31).

One important principle to remember is that only two kinds of base pairs are present in DNA. What are they? Symbols used to represent them are A≡T and G≡C. Although a DNA molecule contains only these two kinds of base pairs, it contains millions of them—more than 100 million pairs estimated in one human DNA molecule! Two other impressive facts are that the millions of base pairs occur in the same sequence in all the millions of DNA molecules in one individual's body but in a slightly different sequence in the DNA of all other individuals. In short, the base pair sequence in DNA is unique to each individual. This fact has momentous significance because DNA functions as the molecule of heredity. It has a weighty responsibility: that of passing the traits of one generation to the next. DNA accomplishes this feat by acting as an "information molecule" that stores the master code of all the recipes (the *genes*) needed to make the various RNA and protein molecules of the body.

The details of how the information is stored and retrieved by the cells is introduced in Chapter 5, and then Chapter 37 features even more discussion of the processes of heredity.

Most types of RNA molecules consist of a single strand, but the strand often folds on itself to form a compact folded structure. Each RNA strand is a sequence of ribonucleotides that is essentially copied from a portion of a DNA molecule. Thus RNA molecules act as "temporary copies" of the master code of hereditary information in the DNA molecules. These RNA "copies" are involved in the process of protein synthesis.

Figure 2-32 shows a type of RNA called *transfer RNA (tRNA).* tRNA is used by the cell to "grab" a specific amino acid and place it in the correct sequence when building a primary protein strand. The correct location in the sequence is guaranteed by matching tRNA's three-base *anticodon* to the complementary *codon* copied from a gene (a "protein recipe" in the genetic code). Chapter 5 outlines the process by which all of this takes place in the cell.

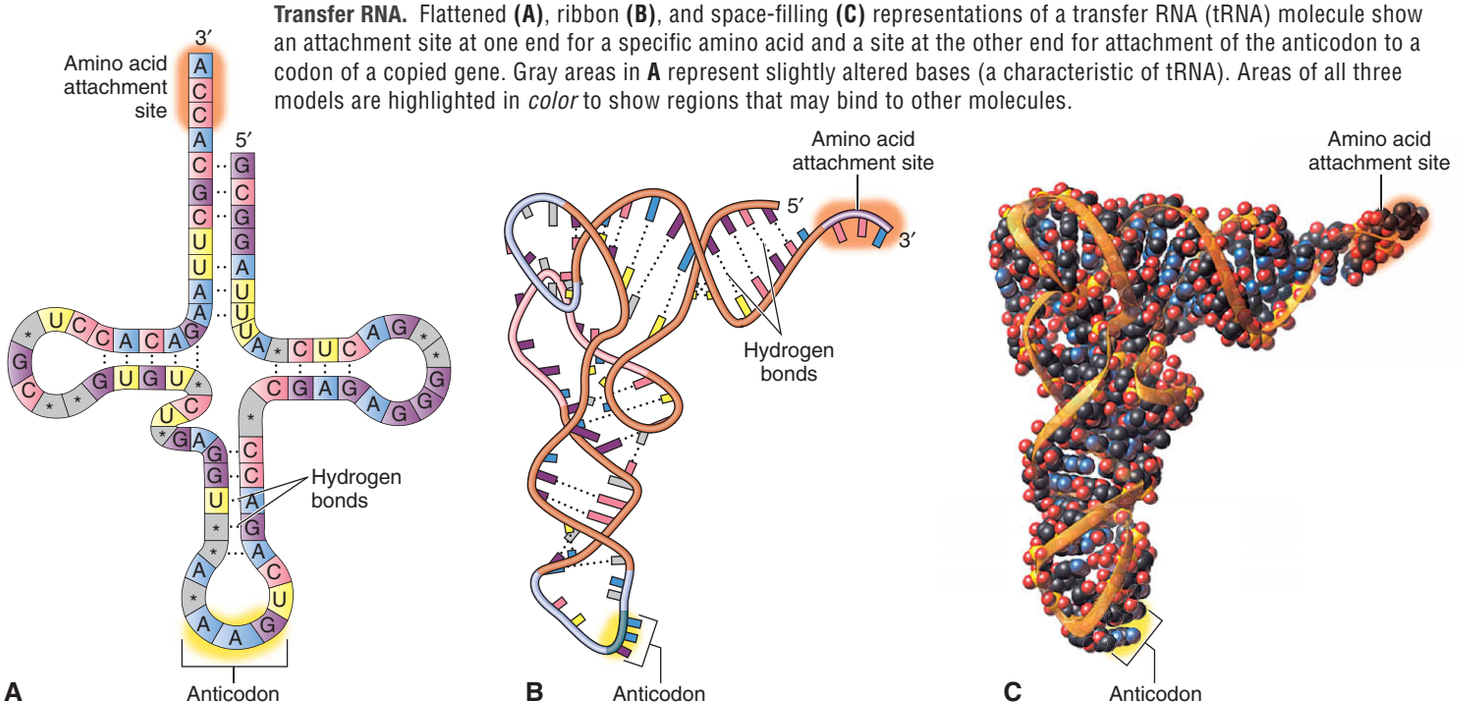
Instead of acting as "information molecules," some RNA molecules regulate cell function. For example, a type of RNA enzyme sometimes called a *ribozyme* is involved in editing the code of RNA strands by removing sections of the code and joining the remaining pieces. A recently discovered type of *double-strand RNA (dsRNA)* is now known to regulate cell function by silencing gene expression in a process called *RNA interference (RNAi).* These processes are discussed further in Chapter 5.

Thus we can say that RNA can act as either an "information molecule" or as a regulatory molecule.

TABLE 2-6 Comparison of DNA and RNA Structure

	DNA	RNA
Polynucleotide strands	Double; very long	Single or double; short
Sugar	Deoxyribose	Ribose
Base pairing	Adenine-thymine (A-T)	Adenine-uracil (A-U)
	Guanine-cytosine (G-C)	Guanine-cytosine (G-C)

NUCLEOTIDES AND RELATED MOLECULES



Besides joining together to form nucleic acids, nucleotides and related molecules also play other important roles in the body.

Adenosine triphosphate (ATP) is a very important molecule composed of an adenine and ribose sugar (a combination called *adenosine*) to which are attached a string of three phosphate groups (Figure 2-33, A). Thus ATP is really an adenine ribonucleotide with two "extra" phosphate groups attached. The "squiggle" lines indicate covalent bonds that link the phosphate groups. These bonds are called **high-energy bonds** because when they are broken during catabolic chemical reactions, the energy released is used to form new compounds. The energy carried by ATP can thus be used in doing the body's work—the work of muscle contraction and movement, of active transport, and of biosynthesis (Figure 2-33, B).

Because ATP is the form of energy that cells generally use, it is an especially important organic molecule. ATP is a molecule that can pick up energy and give it to another chemical process; therefore, it is often called the *energy currency* of cells. A set of enzyme reactions releases the energy that is stored in ATP by splitting it into *adenosine diphosphate (ADP)* and an inorganic phosphate group. It

FIGURE 2-32

Transfer RNA. Flattened **(A)**, ribbon **(B)**, and space-filling **(C)** representations of a transfer RNA (tRNA) molecule show an attachment site at one end for a specific amino acid and a site at the other end for attachment of the anticodon to a codon of a copied gene. Gray areas in **A** represent slightly altered bases (a characteristic of tRNA). Areas of all three models are highlighted in *color* to show regions that may bind to other molecules.

is also possible to split ADP into *adenosine monophosphate (AMP)* and phosphate, with the release of energy. In this case the bond between the second and third phosphate groups is broken.

In prolonged or intense exercise, when ATP is in short supply, muscles turn to *creatine phosphate (CP)* for extra energy. Creatine phosphate is another high-energy molecule made up of an amino acid derivative and a phosphate connected with a high-energy bond. When CP releases its phosphate group, the energy can be used to add a phosphate to ADP, thus "recharging" ATP. In extreme cases, a cell may use ADP for energy by breaking another phosphate bond.

Chapters 4 and 30 discuss in detail the metabolic pathways that are involved in ATP synthesis and breakdown. A cell at rest has a relatively high ATP concentration, whereas an active cell has less ATP but is constantly rebuilding its stores. An exhausted cell has a high ADP concentration and very low levels of ATP. It must resynthesize needed ATP to sustain its activity over time. Fortunately, cells at rest can recycle ADP and ATP and then reverse the cycle, thus reusing small amounts of ATP on a continuing basis. Exercise physiologists estimate that the body can use up to 0.5 kilograms (1.1 pounds) of ATP per minute during very strenuous physical activity. If reuse was impossible, we would require about 40 kilograms (88 pounds) of ATP per day to remain active.

Other energy-transferring nucleotides such as nicotinamide adenine dinucleotide (NAD^+) and flavin adenine dinucleotide (FAD) are also used by cells to transfer energy among molecules (Figure 2-34, A). NAD^+ and FAD act as coenzymes (see Table 2-6) to shuttle energy-carrying particles (electrons) from one metabolic pathway to another during the many complicated steps of transferring energy from food molecules to ATP (Figure 2-34, B). The entire process of energy transfer, including the role of NAD^+ and FAD, is discussed in detail in Chapter 30.

Nucleotides are also sometimes used as a signal inside the cell. ATP is used throughout the body as a signal between cells. ATP can also break down to a one-phosphate molecule called *cAMP (cyclic*

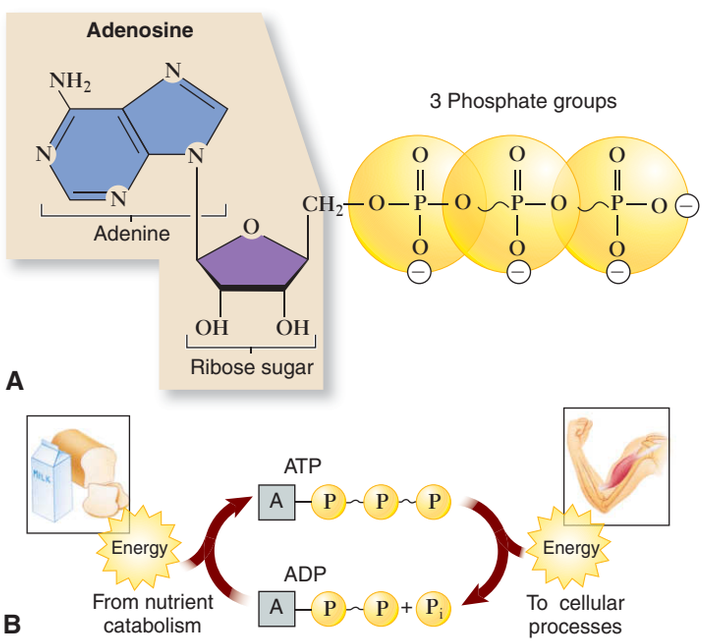


FIGURE 2-33

Adenosine triphosphate (ATP). A, Structure of ATP. A single adenosine group (A) has three attached phosphate groups (P). High-energy bonds between the phosphate groups can release chemical energy to do cellular work. **B,** General scheme of the ATP energy cycle. ATP stores energy in its last high-energy phosphate bond. When that bond is later broken, energy is transferred as important intermediate compounds are formed. The adenosine diphosphate (ADP) and phosphate groups that result can be resynthesized into ATP, thereby capturing additional energy from nutrient catabolism. Note that energy is transferred from nutrient catabolism to ADP, thus converting it to ATP, and energy is transferred *from* ATP to provide the energy required for anabolic reactions or cellular processes as it reverts back to ADP.

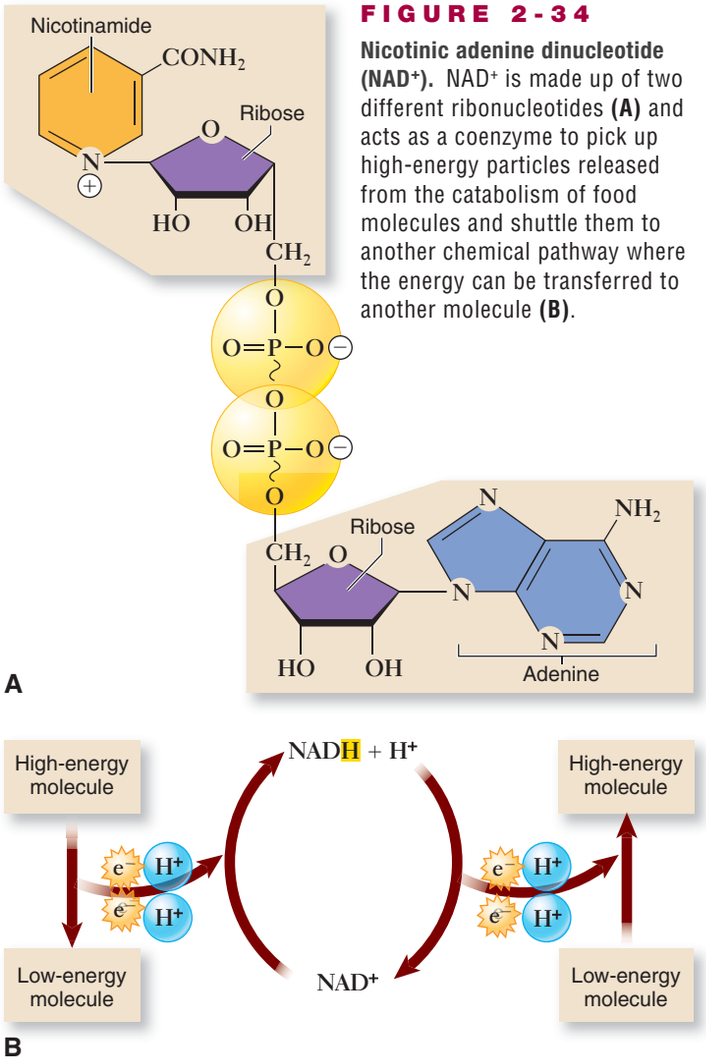

FIGURE 2-34

Nicotinic adenine dinucleotide (NAD^+). NAD^+ is made up of two different ribonucleotides **(A)** and acts as a coenzyme to pick up high-energy particles released from the catabolism of food molecules and shuttle them to another chemical pathway where the energy can be transferred to another molecule **(B)**.

adenosine monophosphate) that is used as an intracellular signal within cells. This role of cAMP is outlined in Chapters 13 and 18.

Combined Forms

You have already noticed that large molecules can be joined together to form even larger molecules. Sometimes, only a small addition or alteration is made. For example, in the case of adenosine triphosphate (ATP), two extra phosphate groups are added to an adenine-containing RNA nucleotide. This gives the nucleotide a completely different function. Instead of becoming involved in storing or transmitting genetic information, the ATP molecule transfers energy from one chemical pathway to another. We will learn much more about ATP later. The point now is that macromolecules can be joined to other molecules to make them even larger and to change their functions.

Table 2-3 lists some of the combined or altered macromolecules you will encounter in your study. Notice also the many different important functions performed by these molecules. The names of the combined molecules usually tell you what is in them. *Lipoproteins* contain lipid and protein groups combined into a single molecule. *Glycoproteins* contain carbohydrate (*glyco*, "sweet") and protein. Often, the base word (*protein* in this case) indicates which component is dominant. The prefix represents the component found in a lesser amount. Thus glycoproteins have more protein than they do carbohydrate. Review the examples of combined forms in Table 2-3 and their functions in the body.

the BIG picture

The Chemical Basis of Life

The importance of the concept of organization at all levels of body structure and function was introduced in Chapter 1 and will be reinforced as you study the individual organ systems of the body in subsequent chapters of the text. Understanding the information in this chapter is a critical first step in connecting the chemistry of life with a real understanding of how the body functions and the relationships that exist between differing functions and body structures.

How the basic chemical building blocks of the body are organized and how they relate to one another are key determinants in understanding normal structure and function, as well as understanding pathological anatomy and disease.

As you learn about the structure and functioning of the various organ systems of the body, the information contained in this chapter will take on new meaning and practical significance. It will help you fully understand and answer many questions that require you to integrate otherwise isolated factual information to make anatomy and physiology emerge as living and dynamic topics of personal interest. Consider the following questions. Each one relates to the study of one or more organ systems covered in subsequent chapters. Your ability to answer these and many other questions correctly will require knowledge of basic chemistry.

- How do common antacids, such as Tums or Rolaids, work?
- Is an electrolyte-rich sports drink better than plain water in replacing fluids lost during prolonged, vigorous exercise?
- Why are high dietary levels of saturated fat considered inappropriate?
- How do we digest our food?
- Why must individuals with diabetes restrict their intake of sugars and other sweets?
- How do muscles contract or nerve impulses race from one body area to another?
- Why do some people inherit a particular disease and others do not?
- What food substances produce the most energy?
- Why does breathing oxygen at the end of a marathon run help an athlete recover more quickly?

These are the types of real-world, end-of-chapter questions that you will encounter throughout the text that require the application of basic chemistry. Refer often to the information in this chapter as you formulate your answers. Think of chemistry as an important part of the Big Picture in your study of anatomy and physiology.

MECHANISMS of DISEASE

CHEMICALS OUT OF BALANCE

As we have learned in this chapter, all the various classes of chemicals in the body each have their particular functions in maintaining the life of the body. If the balances among various groups of chemicals fluctuate too far from their set point values, the homeostatic balance of the body is threatened.

Let's examine just one common example of such an imbalance. The carbon dioxide (CO_2) concentration in the blood will climb too high, a condition called **hypercapnia,** when the respiratory system fails to remove it from the blood at the normal rate. Thus we have a CO_2 imbalance. This will have several effects. For one, the high CO_2 levels will inhibit cell metabolism and thus reduce the normal activity of the body. For another, because CO_2 tends to form an acid, the pH of the body's internal environment will drop to below the set point level—a condition called **acidosis.** Acidosis, in turn, may disrupt the shapes of proteins throughout the body and thus interfere with the normal structure and function of the body. Unless CO_2 balance is restored quickly, a person will die.

Various elements of the scenario we just described are touched on later in appropriate places in the book. However, this is just one of many examples of chemical imbalances that can serve as a mechanism of disease. Nutrient imbalances, ion imbalances, and so on, can all be life threatening.

Missing and Damaged Molecules

We all know that if we don't eat, we die. Of course, the process of digestion is the method by which we absorb new molecules into our internal environment. These nutrients are needed to replace molecules that have been lost or have been used up in the manufacture of molecules needed for body structure and function. Thus digestive and eating disorders are in fact disorders of "missing molecules."

We've learned in this chapter that the genes in DNA molecules serve as "recipes" for the structural and functional proteins of the body, which in turn make many other types of molecules in the body such as lipids and carbohydrates. If even one amino acid is missing or out of place, it may not fold correctly and thus the entire protein (and whatever molecule is made by the protein) will be ruined. Even if the protein has a normal sequence of amino acids, it may not fold correctly because of an improper pH or extreme body temperature. Although some types of molecules can be obtained from our food, others must be made in the body. If certain genes are damaged or missing, we cannot manufacture the chemicals needed for proper body function. For example, in "brittle bone disease" or *osteogenesis imperfecta*, the body fails to make normal *collagen*. Collagen is a structural protein needed to hold bones and other tissues together. Consequently, in a person with osteogenesis imperfecta, the body's bones are brittle and cannot bear much weight. Most genetic disorders are really disorders of "missing or damaged molecules."

Molecules in the body can also be damaged by physical agents such as radiation or other chemicals. For example, the ultraviolet radiation of the sun can sometimes damage the DNA in skin and cause skin cancer, or radiation from radioactive materials can cause a body-wide breakdown of molecules that results in **radiation sickness.**

| A&P CONNECT |

Check out ***Radioactivity*** online at ***A&P Connect*** for more on radiation and its adverse effect on health.

Some chemicals called **toxins** that enter the body can cause damage to our own molecules. Toxins, or poisons, cause their damage by destroying our molecules, combining with our molecules to render them useless, or otherwise disrupting the normal chemical balance and chemical activity of our bodies. For example, *carbon monoxide (CO)* is a gas that binds to hemoglobin in our blood so tightly that the hemoglobin can no longer carry the oxygen needed for life. Mercury (Hg), a toxic metal that was once used frequently in industry and health care, can enter cells and bind to sulfur-containing molecules in the organelles. Mercury can thus damage cell functions throughout the body.

Most diseases are ultimately chemical disorders—missing or malfunctioning molecules. Watch for these chemical problems as we explore mechanisms of disease in later chapters.

CASE study

This year, during her college's spring break, Calleigh is visiting Florida for the first time. On the first night of her vacation, she and her friends go out to dinner. Feeling rather adventurous, Calleigh eats raw oysters as an appetizer. Unfortunately, the oysters she ate had high concentrations of bacteria, and 24 hours later, Calleigh is experiencing the "adventure" of food poisoning. Among her symptoms are nausea, vomiting, abdominal pain, and diarrhea.

1. With continued vomiting, Calleigh keeps losing _____ from her stomach, which could make her entire body too _____.
   a. acid; acidic
   b. base; basic
   c. acid; basic
   d. base; acidic
2. When we talk about measuring the pH of a substance, we are measuring the concentration of what ions in that substance?
   a. Oxygen ions
   b. Carbon ions
   c. Phosphate ions
   d. Hydrogen ions

Finally, after another 24 hours, Calleigh is able to keep clear liquids down.

3. Why should she not drink just plain water?
   a. Water cannot replenish the electrolytes she has lost.
   b. Flavored liquids will more effectively stimulate her appetite.
   c. Water can irritate the stomach lining.
   d. Plain water is just fine; it will quickly replace her body's lost fluid.

When Calleigh feels well enough to try eating something, her first food items should provide energy but be easy to digest.

4. Which organic molecule best fits that description—high energy, easily digested?
   a. Protein
   b. Carbohydrates
   c. Triglycerides
   d. Nucleic acids

HINT *To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook,* ***A&P Connect,*** *and other resources.*

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

BASIC CHEMISTRY

A. Elements and compounds (Figure 2-1)
   1. Matter—anything that has mass and occupies space
   2. Element—simple form of matter, a substance that cannot be broken down into two or more different substances
      a. There are 26 elements in the human body
      b. There are 11 *major elements*, 4 of which (carbon, oxygen, hydrogen, and nitrogen) make up 96% of the human body (Figure 2-2)
      c. There are 15 *trace elements* that make up less than 2% of body weight
   3. Compound—atoms of two or more elements joined to form chemical combinations

B. Atoms (Figure 2-3)
   1. The concept of an atom was proposed by the English chemist John Dalton
   2. Atomic structure—atoms contain several different kinds of subatomic particles; the most important are:
      a. Protons (*p*)—positively charged subatomic particles found in the nucleus
      b. Neutrons (*n*)—neutral subatomic particles found in the nucleus
      c. Electrons (*e*)—negatively charged subatomic particles found in the electron cloud (Figure 2-4)
   3. Atomic number and mass number
      a. Atomic number (Table 2-1)
         (1) Number of protons in an atom's nucleus
         (2) Critically important; atomic number identifies the kind of element
      b. Mass number
         (1) Mass of a single atom
         (2) Equal to the number of protons plus the number of neutrons in the nucleus (p + n)
   4. Energy levels (Figures 2-5 and 2-6)
      a. Total number of electrons in an atom equals the number of protons in the nucleus (in a stable atom)
      b. Electrons form a "cloud" around the nucleus
      c. *Bohr model*—a model resembling planets revolving around the sun; useful in visualizing the structure of atoms
         (1) Exhibits electrons in concentric circles showing relative distances of the electrons from the nucleus
         (2) Each ring or shell represents a specific energy level and can hold only a certain number of electrons
         (3) Number and arrangement of electrons determine whether an atom is chemically stable
         (4) An atom with eight, or four pairs, of electrons in the outermost energy level is chemically stable
         (5) An atom without a full outermost energy level is chemically reactive
      d. *Octet rule*—atoms with fewer or more than eight electrons in the outer energy level will attempt to lose, gain, or share electrons with other atoms to achieve stability
   5. Isotopes (Figure 2-7)
      a. Isotopes of an element contain the same number of protons but different numbers of neutrons
      b. Isotopes have the same atomic number and therefore the same basic chemical properties as any other atom of the same element, but they have a different mass number
      c. Atomic weight—the average mass number of isotopes typically found among atoms in nature
      d. Radioactive isotope (radioisotope)—an unstable isotope that undergoes nuclear breakdown and emits nuclear particles and radiation

C. Attractions between atoms—chemical bonds
   1. Chemical reaction—interaction between two or more atoms that occurs as a result of activity between electrons in their outermost energy levels
   2. Molecule—two or more atoms covalently joined together
   3. Compound—consists of groupings of atoms of two or more elements
   4. Chemical bonds—two types unite atoms into groupings such as crystals and molecules
      a. Ionic, or electrovalent, bond (Figure 2-8)—formed by transfer of electrons; strong electrostatic force that binds positively and negatively charged ions together
      b. Covalent bond (Figure 2-9)—formed by sharing of electron pairs between atoms
   5. Hydrogen bond (Figures 2-10 and 2-11)
      a. Much weaker than ionic or covalent bonds
      b. Results from unequal charge distribution on molecules

D. Attractions between molecules
   1. Hydrogen bonds
      a. Form when electrons are unequally shared
         (1) Example: water molecule
         (2) Polar molecules have regions with partial electrical charges resulting from unequal sharing of electrons among atoms
      b. Areas of different partial charges attract one another and form hydrogen bonds
      c. Occur between a hydrogen bonded to an O, N, or F, and another hydrogen bonded to an O, N, or F
   2. Other weak attractions—molecules are attracted to each other through differences in electrical charge

E. Chemical reactions
   1. Involve the formation or breaking of chemical bonds
   2. Three basic types of chemical reactions are involved in physiology:
      a. Synthesis reaction—combining of two or more substances to form a more complex substance; formation of new chemical bonds: $A + B \longrightarrow AB$

b. Decomposition reaction—breaking down of a substance into two or more simpler substances; breaking of chemical bonds: AB ⟶ A + B
c. Exchange reaction—decomposition of two substances and, in exchange, synthesis of two new compounds from them: AB + CD ⟶ AD + CB
d. Reversible reactions—occur in both directions

METABOLISM

A. Metabolism—all of the chemical reactions that occur in body cells (Figure 2-12)
B. Catabolism
1. Chemical reactions that break down complex compounds into simpler ones and release energy; hydrolysis is a common catabolic reaction
2. Ultimately, the end products of catabolism are carbon dioxide, water, and other waste products
3. Some of the energy released is transferred to ATP, which is then used to do cellular work (Figure 2-33)
C. Anabolism
1. Chemical reactions that join simple molecules together to form more complex molecules
2. Chemical reaction responsible for anabolism is dehydration synthesis (condensation)

ORGANIC AND INORGANIC COMPOUNDS

A. Inorganic compounds—few have carbon atoms and none have C–C or C–H bonds
B. Organic molecules
1. Have at least one carbon atom and at least one C–C or C–H bond in each molecule
2. Often have functional groups attached to the carbon-containing core of the molecule (Figure 2-13)

INORGANIC MOLECULES

A. Water
1. Most abundant and important compound in the body
2. Properties of water (Table 2-2)
a. Polarity—allows water to act as an effective solvent in the body; ionizes substances in solution (Figure 2-10)
b. Solvent allows transportation of essential materials throughout the body (Figure 2-14)
c. High specific heat—water can lose and gain large amounts of heat with little change in its own temperature; enables the body to maintain a relatively constant temperature
d. High heat of vaporization—water requires the absorption of significant amounts of heat to change it from a liquid to a gas; allows the body to dissipate excess heat
B. Oxygen and carbon dioxide—closely related to cellular respiration
1. Oxygen—required to complete decomposition reactions necessary for the release of energy in the body
2. Carbon dioxide—produced as a waste product and also helps maintain the appropriate acid-base balance in the body
C. Electrolytes
1. Large group of inorganic compounds that includes acids, bases, and salts
2. Substances that dissociate in solution to form ions (the resulting ions are also sometimes called *electrolytes*)
3. Positively charged ions are cations; negatively charged ions are anions
4. Acids and bases—common and important chemical substances that are chemical opposites
a. Acids
(1) Any substance that releases a hydrogen ion (H^+) when in solution—*proton donor*
(2) Level of *acidity* depends on the number of hydrogen ions a particular acid will release
b. Bases
(1) Electrolytes that dissociate to yield hydroxide ions (OH^-) or other electrolytes that combine with hydrogen ions (H^+)
(2) Described as *proton acceptors*
c. pH scale—assigns a value to measures of acidity and alkalinity (Figure 2-15)
(1) pH indicates the degree of acidity or alkalinity of a solution
(2) pH of 7 indicates neutrality (equal amounts of H^+ and OH^-); a pH less than 7 indicates acidity; a pH higher than 7 indicates alkalinity
5. Buffers
a. Maintain the constancy of pH
b. Minimize changes in the concentrations of H^+ and OH^- ions
c. Act as a *reservoir* for hydrogen ions
6. Salts
a. Compound that results from chemical interaction of an acid and a base
b. Reaction between an acid and a base to form a salt and water is called a *neutralization reaction*

ORGANIC MOLECULES

A. *Organic* describes compounds that contain C–C or C–H bonds (Figure 2-16; Table 2-3)
B. Carbohydrates—organic compounds containing carbon, hydrogen, and oxygen (usual ratio 1:2:1); commonly called *sugars* and *starches*
1. Monosaccharides—simple sugars with short carbon chains; those with six carbons are hexoses (e.g., glucose), whereas those with five are pentoses (e.g., ribose, deoxyribose) (Figure 2-17)
2. Disaccharides and polysaccharides—two (di-) or more (poly-) simple sugars that are bonded together through a dehydration synthesis (condensation) reaction (Figure 2-18)
C. Lipids (Table 2-4)
1. Water-insoluble organic molecules that are critically important biological compounds
2. Major roles:
a. Energy source
b. Structural role
c. Integral parts of cell membranes

3. Triglycerides or fats (Figures 2-19 and 2-20)
   a. Most abundant lipids and most concentrated source of energy
   b. Building blocks of triglycerides are glycerol (the same for each fat molecule) and fatty acids (different for each fat and determine the chemical nature)
      (1) Types of fatty acids—saturated fatty acid (all available bonds are filled) and unsaturated fatty acid (has one or more double bonds)
      (2) Triglycerides are formed by a dehydration synthesis (condensation)
4. Phospholipids (Figure 2-21)
   a. Fat compounds similar to triglycerides
   b. One end of the phospholipid is water soluble (hydrophilic); the other end is fat soluble (hydrophobic)
   c. Phospholipids can join two different chemical environments
   d. Phospholipids may form double layers called *bilayers* that make up cell membranes (Figure 2-22)
5. Steroids (Figure 2-23)
   a. Main component is steroid nucleus
   b. Involved in many structural and functional roles
6. Prostaglandins (Figure 2-24)
   a. Commonly called *tissue hormones*; produced by cell membranes throughout the body
   b. Effects are many and varied; however, they are released in response to a specific stimulus and are then inactivated

D. Proteins (Table 2-5)
1. Most abundant organic compounds
2. Chainlike polymers of amino acids held together by peptide bonds to form a polypeptide
3. Amino acids—building blocks of proteins (Figures 2-25 to 2-27)
   a. Essential amino acids—eight amino acids that cannot be produced by the adult human body
   b. Nonessential amino acids—13 amino acids can be produced from molecules available in the adult human body
   c. Amino acids consist of a carbon atom, an amino group, a carboxyl group, a hydrogen atom, and a side group
4. Levels of protein structure (Figure 2-28)
   a. Protein molecules are highly organized and show a definite relationship between structure and function
   b. Four levels of protein organization
      (1) Primary structure—refers to the number, kind, and sequence of amino acids that make up the polypeptide chain held together by peptide bonds
      (2) Secondary structure—polypeptide is coiled or bent into helices (spirals) and pleated sheets stabilized by hydrogen bonds; may include recurring patterns of helices and/or sheets called motifs
      (3) Tertiary structure—a secondary structure can be further twisted and converted to a complex globular shape
         (a) The helices and pleated sheets touch in many places and are "welded" by covalent disulfide bonds, hydrogen bonds, and other attractive forces
         (b) May including regions called domains that act as functional units
      (4) Quaternary structure—highest level of organization occurring when protein contains more than one polypeptide chain
5. Importance of protein shape—shape of protein molecules determines their function (Figure 2-29)
   a. Final functional shape of the protein molecule is called its *native state*
   b. Structural proteins form the structures of the body
   c. Functional proteins cause chemical changes in the molecules
   d. Denatured proteins have lost their shape and therefore their function (Figure 2-30)
   e. Proteins can be denatured by changes in pH, temperature, radiation, and other chemicals
   f. If the chemical environment is restored, proteins may be renatured and function normally
   g. Proteins often have parts that move to perform their functions

E. Nucleic acids and related molecules
1. DNA (deoxyribonucleic acid)
   a. Composed of deoxyribonucleotides, that is, structural units composed of the pentose sugar (deoxyribose), phosphate group, and nitrogenous base (cytosine, thymine, guanine, or adenine)
   b. DNA molecule consists of two long chains of deoxyribonucleotides coiled into a double-helix shape (Figure 2-31)
   c. Alternating deoxyribose and phosphate units form the backbone of the chains
   d. Base pairs hold the two chains of DNA molecule together by hydrogen bonding
      (1) Adenine binds to thymine (two hydrogen bonds)
      (2) Cytosine binds to guanine (three hydrogen bonds)
   e. Specific sequence of more than 100 million base pairs constitutes one human DNA molecule; all DNA molecules in one individual are identical and different from those of all other individuals
   f. DNA functions as the molecule of heredity
2. RNA (ribonucleic acid) (Figure 2-32, Table 2-6)
   a. Composed of the pentose sugar (ribose), phosphate group, and a nitrogenous base
   b. Nitrogenous bases for RNA are adenine, uracil, guanine, or cytosine (uracil replaces thymine)
   c. Some RNA molecules are temporary copies of segments (genes) of the DNA code and are involved in synthesizing proteins
   d. Some RNA molecules are regulatory and act as enzymes (ribozymes) or silence gene expression (RNA interference)
3. Nucleotides
   a. Nucleotides have other important roles in the body
   b. ATP (Figure 2-33)
      (1) Composition
         (a) Adenosine
            i. Ribose—a pentose sugar
            ii. Adenine—a nitrogen-containing molecule
         (b) Three phosphate subunits
            i. High-energy bonds present between phosphate groups

ii. Cleavage of high-energy bonds releases energy during catabolic reactions
(2) Energy stored in ATP is used to do the body's work
(3) ATP often called the *energy currency* of cells
(4) ATP splits into adenosine diphosphate (ADP) and an inorganic phosphate group by special enzymes
(5) If ATP is depleted during prolonged exercise, creatine phosphate (CP) or ADP can be used for energy

c. NAD^+ and FAD (Figure 2-34)
(1) Used as coenzymes to transfer energy from one chemical pathway to another

d. cAMP (cyclic AMP)
(1) Made from ATP by removing two phosphate groups to form a monophosphate
(2) Used as an intracellular signal

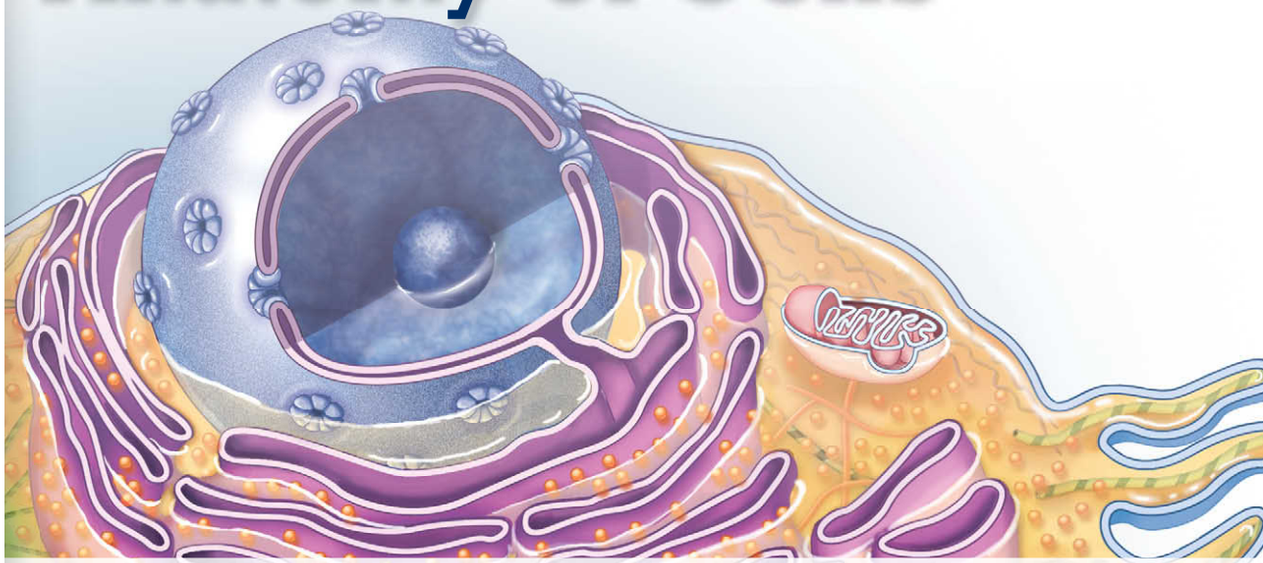
F. Combined forms—large molecules can be joined together to form even larger molecules
1. Gives the molecules a completely different function
2. Names of combined molecules tell you what is in them
a. Base word tells which component is dominant
b. Prefix is the component found in a lesser amount
3. Examples
a. Adenosine triphosphate (ATP)—two extra phosphate groups to a nucleotide
b. Lipoproteins—lipid and protein groups combined into a single molecule
c. Glycoproteins—carbohydrate (*glyco*, "sweet") and protein
d. Examples of combined forms and their functions in the body listed in Table 2-3

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the following terms: element, compound, atom, molecule.
2. Compare early nineteenth century and present-day concepts of atomic structure.
3. Name and define three kinds of subatomic particles.
4. Are atoms electrically charged particles? Give the reason for your answer.
5. What four elements make up approximately 96% of the body's weight?
6. Define and contrast meanings of the terms *atomic number* and *mass number*.
7. Explain the general rule by which an atom can be listed as chemically stable and unable to react with another atom.
8. Define and give an example of an isotope.
9. Explain what the term *radioactivity* means.
10. How does radioactivity differ from chemical activity?
11. Define these terms: alpha particles, beta particles, and gamma rays.
12. Explain how radioactive atoms become transformed into atoms of a different element.
13. Explain what the term *chemical reaction* means.
14. Identify and differentiate between the three basic types of chemical reactions.
15. Define the term *inorganic*.
16. Explain why water is said to be polar and list at least four functions of water that are crucial to survival.
17. What are electrolytes and how are they formed?
18. What is a cation? an anion? an ion? Give an example of each.
19. Define the terms *acid*, *base*, *salt*, and *buffer*.
20. Explain how pH indicates the degree of acidity or alkalinity of a solution.
21. What are the structural units, or building blocks, of proteins? of carbohydrates? of triglycerides? of DNA?
22. Explain what a protein molecule's binding site is. What function does it serve in enzymes?
23. Describe some of the functions proteins perform.
24. Proteins, carbohydrates, lipids—which of these are insoluble in water? contain nitrogen? include prostaglandins? include phospholipids?
25. What groups make up a nucleotide?
26. What pentose sugar is present in a deoxyribonucleotide?
27. Describe the size, shape, and chemical structure of the DNA molecule.
28. What base is thymine always paired with in the DNA molecule? What other two bases are always paired?
29. What is the function of DNA?
30. What is catabolism? What function does it serve?
31. Compare catabolism, anabolism, and metabolism.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Identify the specific areas of chemistry that would be of interest to a biochemist.
2. In modern blimps, the gas of choice used to inflate them is helium rather than hydrogen. Hydrogen would be lighter, but helium is safer. Compare and contrast the atomic structure of hydrogen and helium. What characteristics of the atomic structure of helium make it so much less reactive than hydrogen?
3. How would you contrast single covalent bonds, double covalent bonds, and ionic bonds?
4. If an adult has a body weight of 170 pounds, how much of that weight consists of water?
5. Amylase is an enzyme present in saliva that begins the breakdown of starch. As with all enzymes, amylase is specific to this particular chemical reaction. Explain how a change in the shape of this protein might affect this reaction.
6. Amino acids are the building blocks of proteins. Less than a dozen amino acids make up most of our proteins. Explain how so few amino acids are responsible for the billions of proteins that are used by the body.
7. How does ATP supply the cells with the energy they need to work? Outline the general scheme of the ATP energy cycle.

Case Study, 86

In the 1830s, two German scientists, Matthias Schleiden (SHLY-den) and Theodor Schwann, advanced one of the most important and unifying concepts in biology—the cell theory. *It states simply that the cell is the fundamental organizational unit of life. Although earlier scientists had seen cells, Schleiden and Schwann were the first to suggest that all living things are composed of cells. Some 100 trillion of them make up the human body. Actually, the study of cells has captivated the interest of countless scientists for over 300 years. However, these small structures have not yet yielded all their secrets, not even to the probing tools of present-day researchers.*

To introduce you to the world of cells, three brief chapters summarize the essential concepts of cell structure and function. This chapter begins the discussion by describing the functional anatomy of common cell structures. The term functional anatomy *refers to the study of structures as they relate to function. Chapter 4,* Physiology of Cells, *continues the discussion by outlining in more detail some important and representative cellular processes. Chapter 5 goes on to discuss the growth and reproduction of cells.*

| A&P CONNECT |

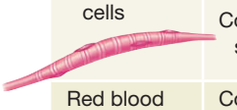
What *are* the probing tools available to today's cell scientists? Mostly, they are the tools used in various forms of **microscopy.** Check out ***Tools of Microscopic Anatomy*** online at ***A&P Connect*** to see explanations and examples of *light microscopy (LM), scanning* and *transmission electron microscopy (SEM and TEM),* and *atomic force microscopy (AFM)* that are used throughout this book.

evolve

FUNCTIONAL ANATOMY OF CELLS

The principle of complementarity of structure and function was introduced in Chapter 1 and is evident in the relationships that exist between cell size, shape, and function. Almost all human cells are microscopic in size (Table 3-1). Their diameters range from 7.5 micrometers (μm) (example, red blood cells) to about 150 μm (example, female sex cell or ovum). The period at the end of this sentence measures about 100 μm—roughly 13 times as large as our smallest cells and two thirds the size of the human ovum. Like other anatomical structures, cells exhibit a particular size or form because they are intended to perform a certain activity. A nerve cell, for example, may have threadlike extensions over a meter in length! Such a cell is ideally suited to transmit nervous impulses from one area of the body to another. Muscle cells are adapted to contract, that is, to shorten or lengthen with pulling strength. Other types of cells may serve protective or secretory functions (Table 3-2).

| A&P CONNECT |



Are you a little confused by the metric size units used in science? Check out ***Metric Measurements and Their Equivalents*** online at ***A&P Connect.***

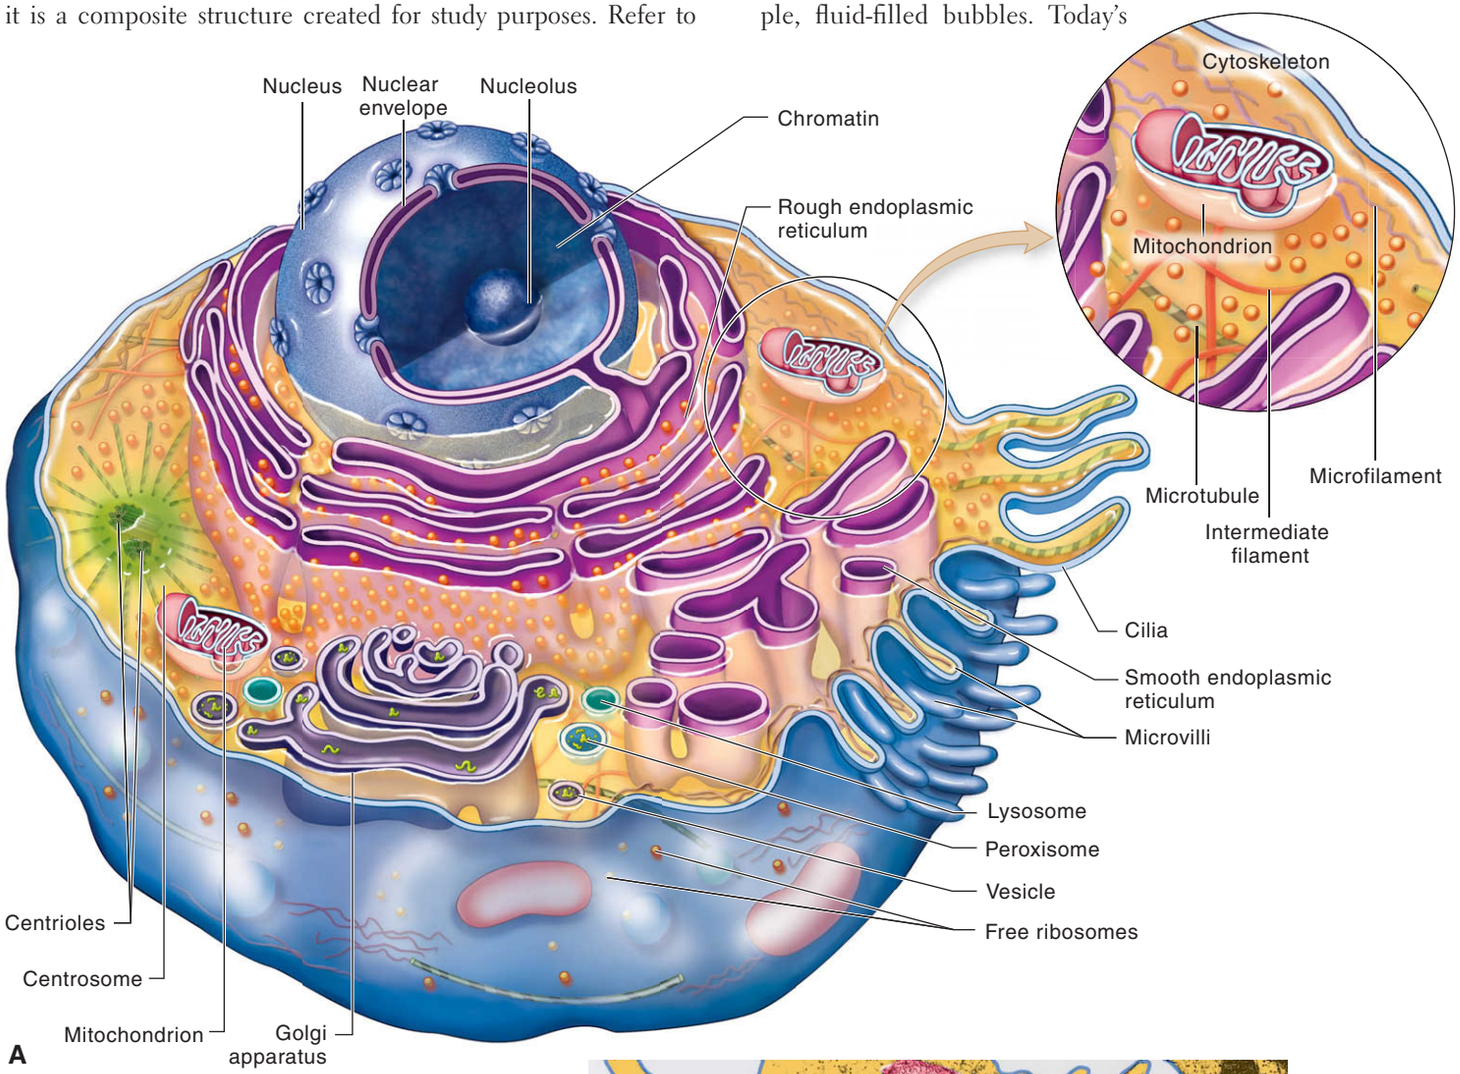
evolve

TABLE 3-1 Units of Size

UNIT	SYMBOL	EQUAL TO	USED TO MEASURE
Centimeter	cm	1/100 meter	Objects visible to the eye
Millimeter	mm	1/1,000 meter (1/10 cm)	Very large cells; groups of cells
Micrometer (micron)	μm	1/1,000,000 meter (1/1000 mm)	Most cells; large organelles
Nanometer	nm	1/1,000,000,000 meter (1/1,000 μm)	Small organelles; large biomolecules
Angstrom	Å	1/10,000,000,000 meter (1/10 nm)	Molecules; atoms

TABLE 3-2 Example of Cell Types

TYPE	STRUCTURAL FEATURES	FUNCTIONS
Nerve cells 	Surface that is sensitive to stimuli Long extensions	Detect changes in internal or external environment Transmit nerve impulses from one part of the body to another
Muscle cells 	Elongated, threadlike Contain tiny fibers that slide together forcefully	Contract (shorten) to allow movement of body parts
Red blood cells 	Contain hemoglobin, a red pigment that attracts, then releases, oxygen	Transport oxygen in the bloodstream (from lungs to other parts of the body)
Gland cells 	Contain sacs that release a secretion to the outside of the cell	Release substances such as hormones, enzymes, mucus, and sweat
Immune cells 	Some have outer membranes able to engulf other cells Some have systems that manufacture antibodies Some are able to destroy other cells	Recognize and destroy "nonself" cells such as cancer cells and invading bacteria



The Typical Cell

Despite their distinctive anatomical characteristics and specialized functions, the cells of your body have many similarities. There is no cell that truly represents or contains all of the various

components found in the many types of human body cells. As a result, students are often introduced to the anatomy of cells by studying a so-called *typical* or **composite cell**—one that exhibits the most important characteristics of many different human cell types. Such a generalized cell is illustrated in Figure 3-1. Keep in mind that no such "typical" cell actually exists in the body; it is a composite structure created for study purposes. Refer to Figure 3-1 and Table 3-3 often as you learn about the principal cell structures described in the paragraphs that follow.

Cell Structures

Ideas about cell structure have changed considerably over the years. Early biologists saw cells as simple, fluid-filled bubbles. Today's

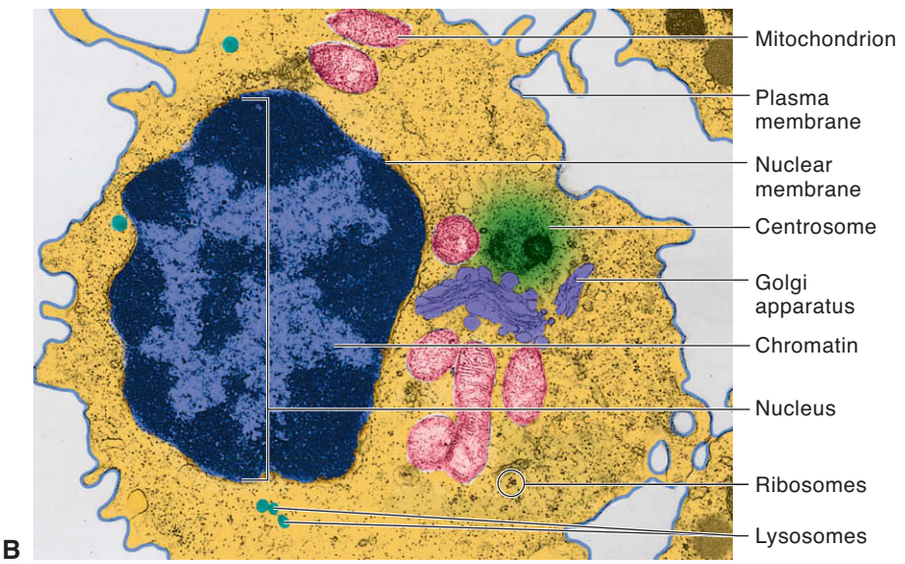


FIGURE 3-1

Typical, or composite, cell. A, Artist's interpretation of cell structure. **B,** Color-enhanced electron micrograph of a cell. Both show mitochondria, known as the "power plants of the cell." Note the innumerable dots bordering the endoplasmic reticulum. These are ribosomes, the cell's "protein factories."

TABLE 3-3 Some Major Cell Structures and Their Functions

CELL STRUCTURE	DESCRIPTION	FUNCTIONS
Membranous		
Plasma membrane	Phospholipid bilayer reinforced with cholesterol and embedded with proteins and other organic molecules	Serves as the boundary of the cell, maintains its integrity; protein molecules embedded in plasma membrane perform various functions; for example, they serve as markers that identify cells of each individual, as receptor molecules for certain hormones and other molecules, and as transport mechanisms
Endoplasmic reticulum (ER)	Network of canals and sacs extending from the nuclear envelope; may have ribosomes attached	Ribosomes attached to rough ER synthesize proteins that leave cells via the Golgi apparatus; smooth ER synthesizes lipids incorporated in cell membranes, steroid hormones, and certain carbohydrates used to form glycoproteins—also removes and stores Ca^{++} from the cell's interior
Golgi apparatus	Stack of flattened sacs (cisternae) surrounded by vesicles	Synthesizes carbohydrate, combines it with protein, and packages the product as globules of glycoprotein
Vesicles	Tiny membranous bags	Temporarily contain molecules for transport or later use
Lysosomes	Tiny membranous bags containing enzymes	Digestive enzymes break down defective cell parts and ingested particles; a cell's "digestive system"
Peroxisomes	Tiny membranous bags containing enzymes	Enzymes detoxify harmful substances in the cell
Mitochondria	Tiny membranous capsule surrounding an inner, highly folded membrane embedded with enzymes; has small, ringlike chromosome (DNA)	Catabolism; adenosine triphosphate (ATP) synthesis; a cell's "power plants"
Nucleus	A usually central, spherical double-membrane container of chromatin (DNA); has large pores	Houses the genetic code, which in turn dictates protein synthesis, thereby playing an essential role in other cell activities, namely, cell transport, metabolism, and growth
Nonmembranous		
Ribosomes	Small particles assembled from two tiny subunits of rRNA and protein	Site of protein synthesis; a cell's "protein factories"
Proteasomes	Hollow protein cylinders with embedded enzymes	Destroys misfolded or otherwise abnormal proteins manufactured by the cell; a "quality control" mechanism for protein synthesis
Cytoskeleton	Network of interconnecting flexible filaments, stiff tubules, and molecular motors within the cell	Supporting framework of the cell and its organelles; functions in cell movement (using molecular motors); forms cell extensions (microvilli, cilia, flagella)
Centrosome	Region of cytoskeleton that includes two cylindrical groupings of microtubules called centrioles	Acts as the microtubule-organizing center (MTOC) of the cell; centrioles assist in forming and organizing microtubules
Microvilli	Short, fingerlike extensions of plasma membrane; supported internally by microfilaments	Tiny, fingerlike extensions that increase a cell's absorptive surface area
Cilia and flagella	Moderate (cilia) to long (flagella) hairlike extensions of plasma membrane; supported internally by cylindrical formation of microtubules, sometimes with attached molecular motors	Cilia move substances over the cell surface or detect changes outside the cell; flagella propel sperm cells
Nucleolus	Dense area of chromatin and related molecules within nucleus	Site of formation of ribosome subunits

biologists know that cells are far more complex than this. Each cell is surrounded by a plasma membrane that separates the cell from its surrounding environment. The inside of the cell is composed largely of a gel-like substance called **cytoplasm** (literally, "cell substance"). The cytoplasm is made of various organelles and molecules suspended in a watery fluid called *cytosol*, or sometimes *intracellular fluid*. As Figure 3-2 shows, the cytoplasm is crowded with large and small molecules—and various organelles. This dense crowding of molecules and organelles actually helps improve the efficiency of chemical reactions in the cell.

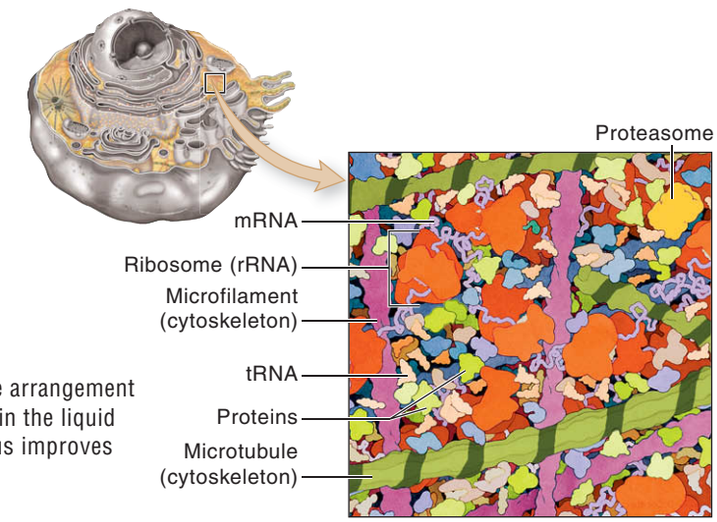

FIGURE 3-2

Cytoplasm. This drawing shows that the cytoplasm is made up of a dense arrangement of fibers, protein molecules, organelles, and other structures, suspended in the liquid cytosol. Such crowding helps molecules interact with one another and thus improves the efficiency of cellular metabolism.

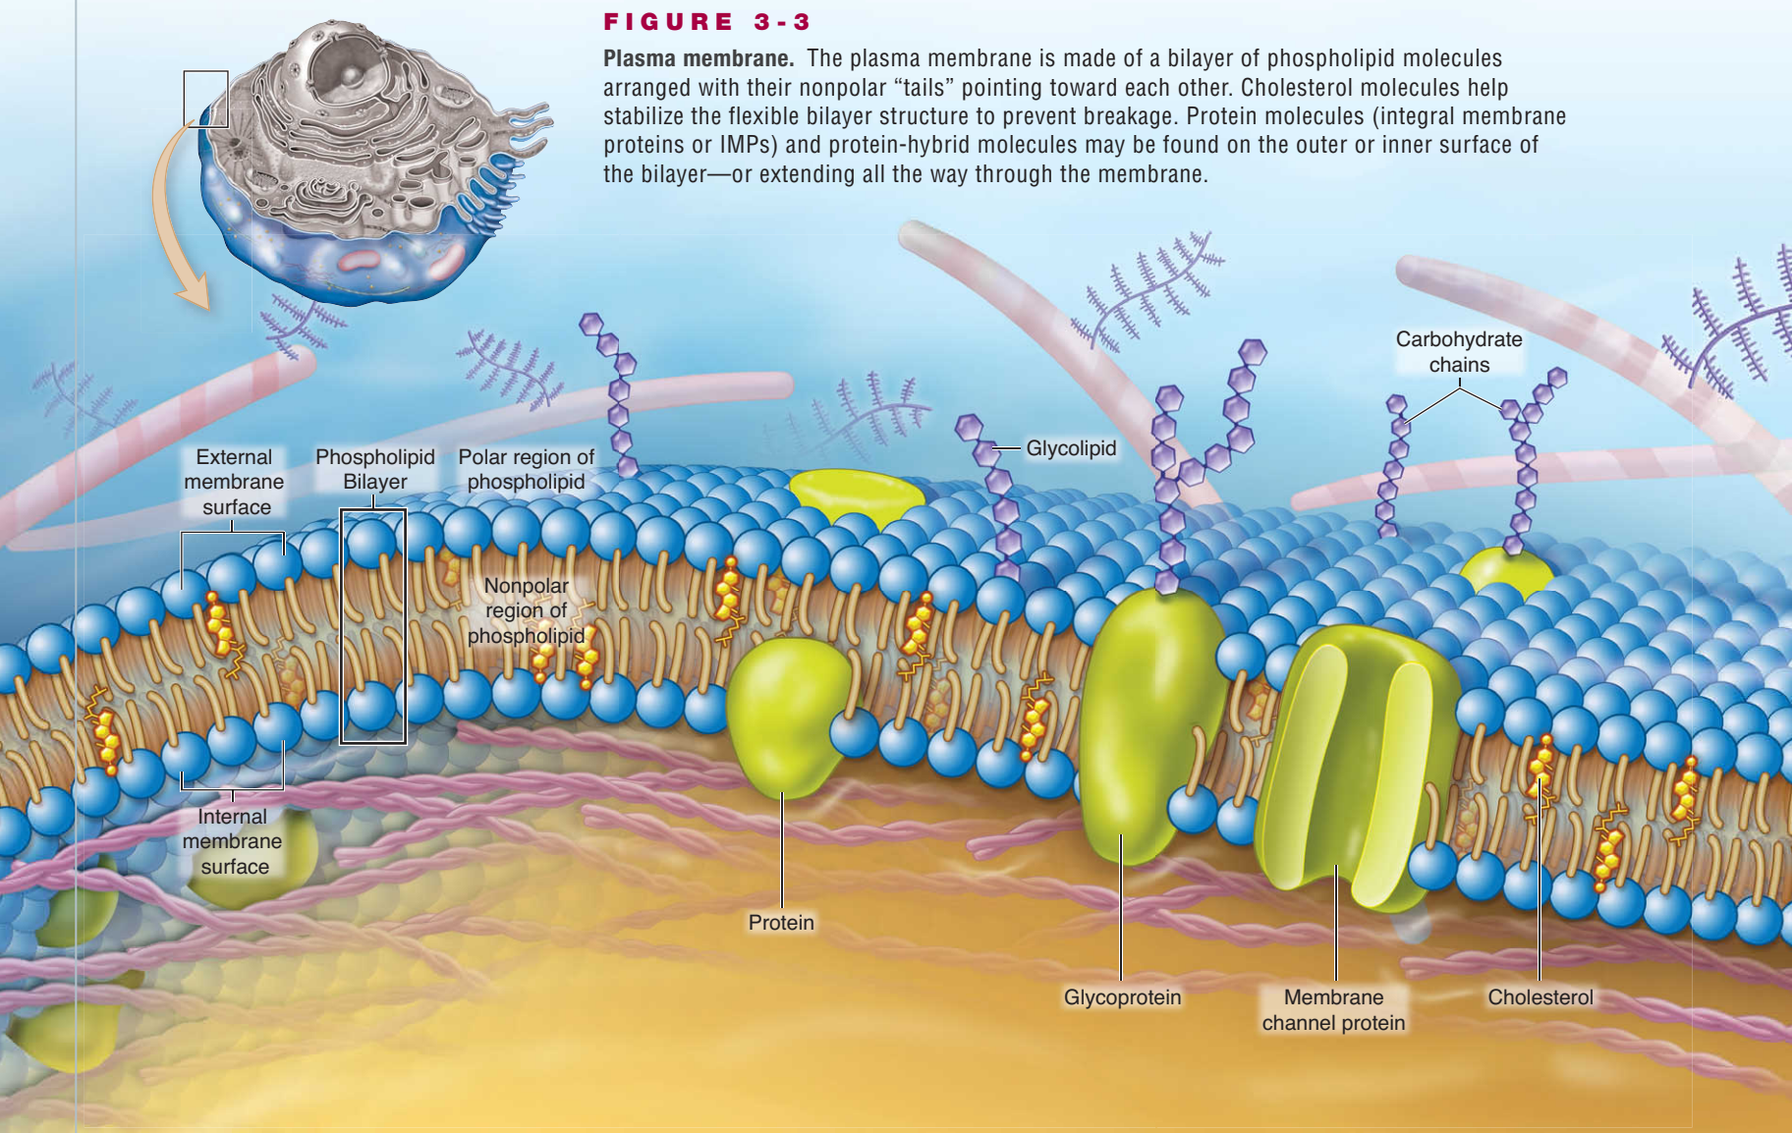
The nucleus, which is not usually considered to be part of the cytoplasm, is generally at the center of the cell. Each different cell part is structurally suited to perform a specific function within the cell—much as each of your organs is suited to a specific function within your body. In short, the main cell structures are (1) the plasma membrane; (2) cytoplasm, including the organelles; and (3) the nucleus (see Figure 3-1).

| QUICK CHECK |

1. What important concept in biology was proposed by Schleiden and Schwann?
2. Give an example of how cell structure relates to its function.
3. List the three main structural components of a typical cell.

CELL MEMBRANES

Figure 3-1 shows that a typical cell contains a variety of membranes. The outer boundary of the cell, or **plasma membrane,** is just one of these membranes. Each cell also has various *membranous organelles.* Membranous organelles are sacs and canals made of the same type of membrane material as the plasma membrane. This membrane material is a very thin sheet—averaging only about 75 angstroms (Å) or 0.0000003 inch thick—made of lipid, protein, and other molecules (Table 3-1).



Membrane Structure

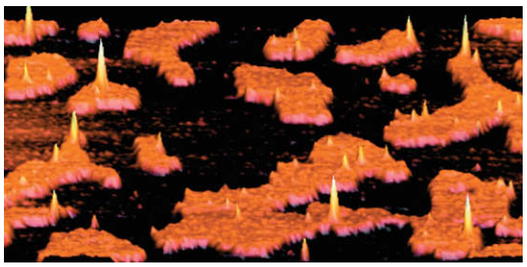


Figure 3-3 shows a simplified view of the evolving model of cell membrane structure. This concept of cell membranes is called the **fluid mosaic model.** Like the tiles in an art mosaic, the different molecules that make up a cell membrane are arranged in a sheet. Unlike art mosaics, however, this mosaic of molecules is *fluid;* that is, the molecules are able to slowly float around the membrane like icebergs in the ocean. The fluid mosaic model shows us that the molecules of a cell membrane are bound tightly enough to form a continuous sheet but loosely enough that the molecules can slip past one another.

What are the forces that hold a cell membrane together? The short answer to that question is chemical attractions. The primary structure of a cell membrane is a double layer of phospholipid molecules. Recall from Chapter 2 that phospholipid molecules have "heads" that are water soluble and double "tails" that are lipid soluble (see Figure 2-21 on p. 49). Because their heads are **hydrophilic** (water loving) and their tails are **hydrophobic** (water fearing), phospholipid molecules naturally arrange themselves into double layers, or *bilayers,* in water. This allows all the hydrophilic heads to face toward water and all the hydrophobic tails to face away from water (see Figure 2-22 on p. 50).

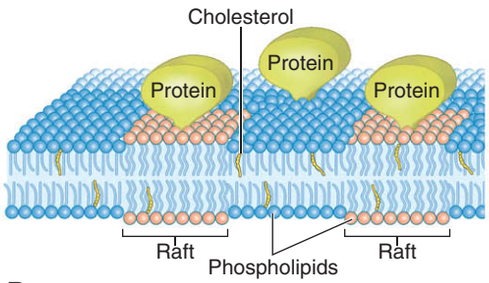

FIGURE 3-3

Plasma membrane. The plasma membrane is made of a bilayer of phospholipid molecules arranged with their nonpolar "tails" pointing toward each other. Cholesterol molecules help stabilize the flexible bilayer structure to prevent breakage. Protein molecules (integral membrane proteins or IMPs) and protein-hybrid molecules may be found on the outer or inner surface of the bilayer—or extending all the way through the membrane.

A

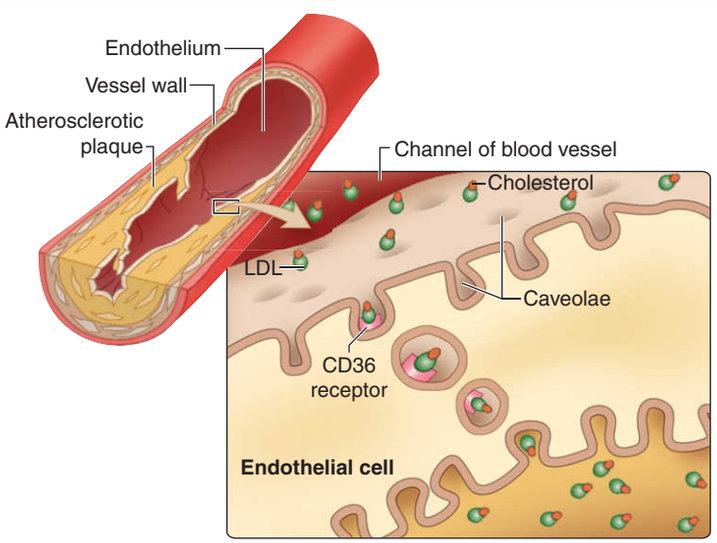
B

FIGURE 3-4

Rafts. A, Atomic force micrograph (AFM) in which an extremely fine-tipped needle drags over the surface of a cell membrane to reveal detailed surface features. Rafts are seen here as raised, orange areas surrounded by black areas of less rigid phospholipid structure. **B,** Diagram showing the basic structure of a membrane with rafts. The raft phospholipids have a richer supply of cholesterol than surrounding regions do and, along with attached integral membrane proteins, form rather rigid floating platforms in the surface of the membrane. Rafts help organize functions at the surfaces of cells and organelles.

Because the internal environment of the body is simply a water-based solution, phospholipid bilayers appear wherever phospholipid molecules are scattered among the water molecules. Cholesterol is a steroid lipid that mixes with phospholipid molecules to form a blend of lipids that stays just fluid enough to function properly at body temperature. Without cholesterol, cell membranes would break far too easily.

Each human cell manufactures various kinds of phospholipid and cholesterol molecules, which then arrange in a bilayer to form a natural "fencing" material of varying thickness that can be used throughout the cell. This "fence" allows many lipid-soluble molecules to pass through easily—just like a picket fence allows air and water to pass through easily. However, because most of the phospholipid bilayer is hydrophobic, cell membranes do not allow water or water-soluble molecules to pass through easily. This characteristic of cell membranes is ideal because most of the substances in the internal environment are water soluble. What good is a membrane boundary if it allows just about everything to pass through it?



Just as there are different fencing materials for different kinds of fences, cells can make any of a variety of different phospholipids for different areas of a cell membrane. For example, some areas of a membrane are stiff and less fluid; others are somewhat flimsy. Many cell membranes are packed more densely with proteins than seen in Figure 3-3; other membranes have less protein.

Some membrane lipids combine with carbohydrates to form glycolipids, and some unite with protein to form lipoproteins easily. Recall from Chapter 2 that proteins are made up of many amino acids, some of which are polar, some nonpolar (see Figure 2-26, p. 53). By having different kinds of amino acids in specific locations, protein molecules may become anchored within the bilayer of phospholipid heads and tails or attached to one side or the other of the membrane.

The different molecular interactions within the membrane allow the formation of lipid **rafts,** which are stiff groupings of membrane molecules (often very rich in cholesterol) that travel together like a log raft on the surface of a lake (Figure 3-4). Rafts help organize the various components of a membrane. Rafts play an important role in the pinching of a parent cell into two daughter cells during cell division. Rafts may also sometimes allow the cell to form depressions that pouch inward and then pinch off as

Box 3-1 | Caveolae

The list of organelles inside human cells that have been identified with new techniques of cell imaging (see ***Tools of Microscopic Anatomy*** online at ***A&P Connect***) and biochemical analysis has continued to grow. Among the more recently discovered organelles are the "little caves," or *caveolae* (*singular,* caveola). Caveolae are tiny indentations of the plasma membrane that indeed resemble tiny caves (see the figure). Caveolae appear to form from rafts of lipid and protein molecules in the plasma membrane that pinch in and move inside the cell. Caveolae can capture extracellular material and shuttle it inside the cell or even all the way across the cell (see the figure). Although there is much yet to understand about the many functions of caveolae, one possible problem that they may cause has already been outlined. Some caveolae in the cells that line blood vessels may have CD36 cholesterol receptors that attract low-density lipoproteins (LDLs, which carry the so-called *bad cholesterol*). As the figure shows, once the LDLs attach to the receptor, the caveola closes and migrates to the other side of the cell. There, the LDL molecules are released to build up behind the lining of the blood vessel. As the LDLs accumulate, the blood vessel channel narrows and obstructs the flow of blood—a major cause of stroke and heart disease.

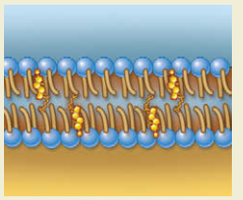
Researchers believe that other diseases, such as certain forms of diabetes, cancer, and muscular dystrophy, may also result from inappropriate actions taken by caveolae.

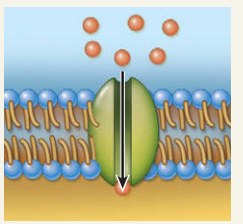
a means of carrying substances into the cell (Box 3-1). Human immunodeficiency virus (HIV), for example, enters cells by first connecting to a raft protein in the plasma membrane and then subsequently being pulled into the cell.

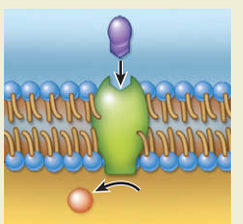
Membrane Function

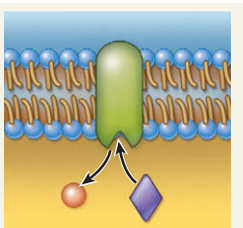
Embedded within the phospholipid bilayer are a variety of **integral membrane proteins (IMPs).** As their name implies, they are integrated into structure of the membrane itself. Proteins that have some functional regions or *domains* that are hydrophilic and other domains that are hydrophobic can be integrated into a phospholipid bilayer and remain stable. IMPs have many different structural forms that allow them to serve various functions (see Table 3-3).

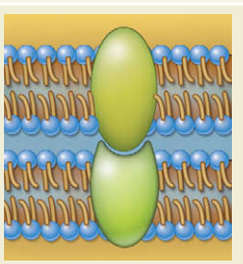
A cell can control what moves through any section of membrane by means of IMPs that act as transporters (see Figure 3-3). Many of these transporters have domains forming openings that, like gates in a fence, allow water-soluble molecules to pass through the membrane. Specific kinds of transporterss allow only certain kinds of molecules to pass through—and the cell can determine whether these "gates" are open or closed at any particular time. We consider this function of integral membrane proteins again in Chapter 4 when we study transport mechanisms in the cell.

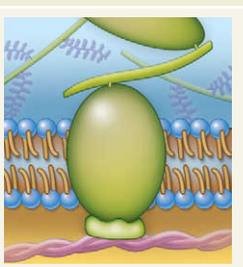


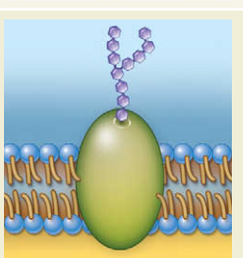












Some IMPs have carbohydrates attached to their outer surface—forming *glycoprotein* molecules—that act as identification markers. Such markers, which are recognized by other molecules, act as signs on a fence that identify the enclosed area. Cells and molecules of the immune system can thus distinguish between normal "self" cells and abnormal or "nonself" cells. Not only does this mechanism allow us to attack cancer or bacterial cells, it also prevents us from receiving blood donations from people who don't have cell markers similar to our own. Some membrane proteins are enzymes that catalyze cellular reactions. Some IMPs bind to other IMPs to form connections between cells or bind to support filaments within the cell to anchor them.

Other IMPs are **receptors** that can react to the presence of hormones or other regulatory chemicals and thereby trigger metabolic changes in the cell. The process by which cells translate the signal received by a membrane receptor into a specific chemical change in the cell is called **signal transduction.** The word *transduction* means "carry across," as a message being carried across a membrane. Recent discoveries continue to show the vital importance of signal transduction in the normal function of cells and therefore the whole body. Being one of the most active areas of biomedical research, the study of signal transduction has provided many answers to the causes of diseases, which in turn has led to effective treatments and cures. As you continue your study of human structure and function, try to find instances of signal transduction in cells that provide a vital link in important processes throughout the body. By doing so, you will better understand the "big picture" of human structure and function.

Some IMPs connect the cell membrane to another membrane, as when two cells join together to form a larger mass of tissue. Other IMPs connect a membrane to the framework of fibers inside the cell or to the mass of fibers and other molecules that make up the extracellular matrix (ECM).

Table 3-4 summarizes the functional anatomy of cell membranes.

TABLE 3-4 Functional Anatomy of Cell Membranes

	**Structure:** Sheet (bilayer) of phospholipids stabilized by cholesterol **Function:** Maintains boundary (integrity) of a cell or membranous organelle
	**Structure:** Integral membrane proteins that act as channels or carriers of molecules **Function:** Controlled transport of water-soluble molecules from one compartment to another
	**Structure:** Receptor molecules that trigger metabolic changes in membrane (or on other side of membrane) **Function:** Sensitivity to hormones and other regulatory chemicals; involved in signal transduction
	**Structure:** Enzyme molecules that catalyze specific chemical reactions **Function:** Regulation of metabolic reactions
	**Structure:** Integral membrane proteins that bind to molecules outside the cell **Function:** Form connections between one cell and another
	**Structure:** Integral membrane proteins that bind to support structures **Function:** Support and maintain the shape of a cell or membranous organelle; participate in cell movement; bind to fibers of the extracellular matrix (ECM)
	**Structure:** Glycoproteins or proteins in the membrane that act as markers **Function:** Recognition of cells or organelles

CYTOPLASM AND ORGANELLES

Cytoplasm is the gel-like internal substance of cells that contains many tiny suspended structures. Early cell scientists believed cytoplasm to be a rather uniform fluid filling the space between the plasma membrane and the nucleus. We now know that the cytoplasm of each cell is actually a watery solution called *cytosol* plus hundreds or even thousands of "little organs," or **organelles,** that thicken the cytoplasm and result in its gel-like consistency. Table 3-3 lists some of the major types of organelles that we will encounter in this book. Until relatively recently, when newer microscope technology became available, many of these organelles simply could not be seen. Those that could be seen were simply called *inclusions* because their roles as integral parts of the cell were not yet recognized. Undoubtedly, some of the cellular structures we now call inclusions will eventually be recognized as organelles and given specific names.

Many types of organelles have been identified in various cells of the body. To make it easier to study them, they have been classified into two major groups: *membranous organelles* and *nonmembranous organelles.* Membranous organelles are those that are described as sacs or canals made of cell membrane. Nonmembranous organelles are not made of membrane; they are made of microscopic filaments or other particles. As you read through the following sections, be sure to note whether the organelle being discussed is membranous or nonmembranous (see Table 3-3).

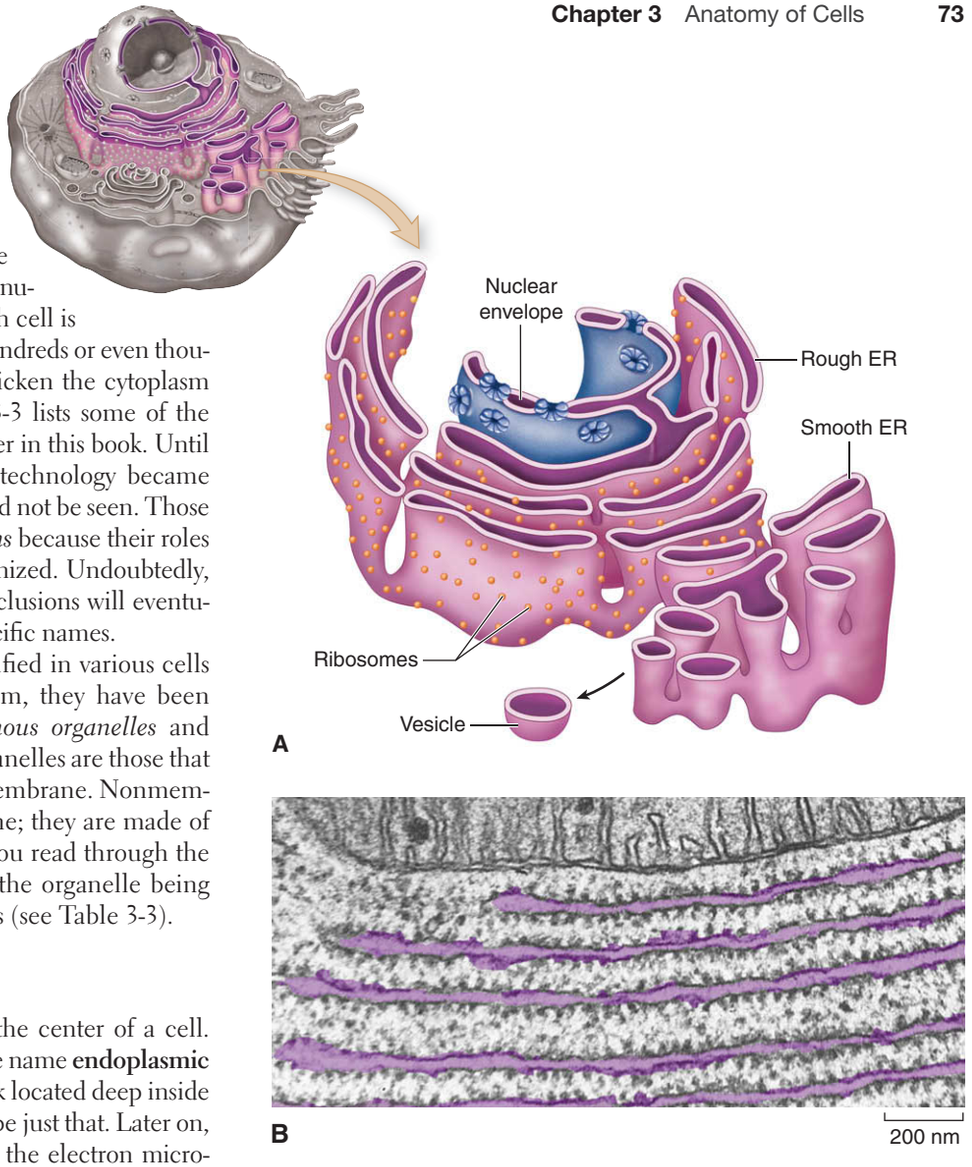


FIGURE 3-5

Endoplasmic reticulum (ER). In both the drawing **(A)** and the transmission electron micrograph **(B),** the rough ER (RER) is distinguished by the presence of tiny ribosomes dotting the boundary of flattened membrane sacs. The smooth ER (SER) is more tubular in structure and lacks ribosomes on its surface. Note also that the ER is continuous with the outer membrane of the nuclear envelope.

Endoplasmic Reticulum (ER)

Endoplasm is the cytoplasm located toward the center of a cell. *Reticulum* means small network. Therefore, the name **endoplasmic reticulum (ER)** means literally a small network located deep inside the cytoplasm. When first seen, it appeared to be just that. Later on, however, more highly magnified views under the electron microscope showed the ER to be distributed throughout the cytoplasm (see Figure 3-1). ER consists of membranous-walled canals and flat, curving sacs that are arranged in parallel rows.

The endoplasmic reticulum can serve a variety of functions in a cell. There are two types of ER: *rough ER (RER)* and *smooth ER (SER).*

ROUGH ER (RER)

Rough ER is made up of broad, flattened sacs that extend outward from the boundary of the nucleus. RER sacs are dotted with innumerable small granules called *ribosomes.* The granules give rough ER the "rough" appearance of sandpaper as you can see in Figure 3-5. Ribosomes are themselves distinct organelles for making proteins.

As new polypeptide strands are released from the ribosomes that "dock" at the RER surface, they enter the lumen (cavity) of the RER network. Once inside, the polypeptide strands fold and sometimes unite with other proteins to form larger molecules. The proteins made in the RER move through the lumen of the ER network, or become imbedded in the cell membrane (phospholipid bilayer) that forms the wall of each sac. Many of these molecules eventually move toward the Golgi apparatus, where they are processed further, and some of them eventually leave the cell.

SMOOTH ER (SER)

No ribosomes border the membranous wall of the smooth ER—hence its smooth appearance and its name. The SER part of the network is usually more tubular in structure than the flattened sacs of the RER, as you can see in Figure 3-5. The smooth ER contains enzymes and other molecules processed in the RER. Some of the enzymes synthesize certain lipids and carbohydrates. Included among these are the steroid hormones and some of the carbohydrates used to form glycoproteins. Lipids that form cell membranes are also synthesized here. As these membrane lipids are made, they simply become part of the smooth ER's wall. Bits of the ER break off from time to time and travel to other membranous organelles—even to the plasma membrane—and become

part of the membrane of those organelles. The smooth ER, then, is the organelle that makes membrane for use throughout the cell.

Smooth ER also transports calcium ions (Ca^{++}) from the cytosol into the sacs of the ER, thus helping maintain a low concentration of Ca^{++} in a cell's interior. Knowing that Ca^{++} is moved into the ER and stored there is a fact that will prove useful in helping you understand the information in later chapters.

Ribosomes

Every cell contains thousands of **ribosomes.** Many of them are attached to the rough endoplasmic reticulum, and many of them lie free, scattered throughout the cytoplasm. Find them in both locations in Figure 3-1. Because ribosomes are too small to be seen with a light microscope, no one knew they existed until the electron microscope revealed them in 1955. We now know that each ribosome is a nonmembranous structure made of two tiny, interlocking pieces. One piece is a *large subunit* and the other a *small subunit* (Figure 3-6).

Each subunit of the ribosome is composed of ribonucleic acid (RNA) bonded to protein. Ribosomal RNA is often abbreviated as rRNA. Other types of ribonucleic acid in the cell include messenger RNA (mRNA) and transfer RNA (tRNA), among others. Figure 3-6 shows a threadlike mRNA molecule moving through a ribosome, providing the "recipe" for a polypeptide strand. You can also see a tiny tRNA particle inside the cavity between the ribosomal subunits. tRNA's job is to bring (i.e., transfer) an amino acid to the correct location in the mRNA recipe sequence. The major types of RNA and their roles in the cell are discussed in more detail in Chapter 5.

The function of ribosomes is protein synthesis. Ribosomes are the molecular machines that translate the genetic code to make proteins, or to use a popular term, they are the cell's "protein factories." They make both its structural and its functional proteins (enzymes).

A ribosome is a temporary structure. The two ribosomal subunits link together only when there is an mRNA present and ready to direct the formation of a new polypeptide strand. When the polypeptide is finished, the subunits fall away from each other. The subunits may be used again in another round of protein synthesis.

Working ribosomes usually function in groups called *polyribosomes* or *polysomes.* Polyribosomes form when more than one ribosome begins translating the same long, threadlike mRNA molecule. Under the electron microscope, polyribosomes look like short strings of beads.

In Chapter 5, after you have learned a little more about cell structures, you will be ready to look at the details of how ribosomes carry out protein synthesis.

Golgi Apparatus

The **Golgi apparatus** is a membranous organelle consisting of separate tiny sacs, or *cisternae*, stacked on one another and located near the nucleus (Figure 3-7; see also Figure 3-1). Sometimes also called the *Golgi complex*, it was first noticed in the nineteenth century by the Italian biologist Camillo Golgi. Like the endoplasmic reticulum, the Golgi apparatus processes molecules within its membranes. The Golgi apparatus seems to be part of the same system that prepares protein molecules for export from the cell.

The role of the Golgi apparatus in processing and packaging protein molecules for export from the cell is summarized in Figure 3-8. First, proteins synthesized by ribosomes and transported to the end of

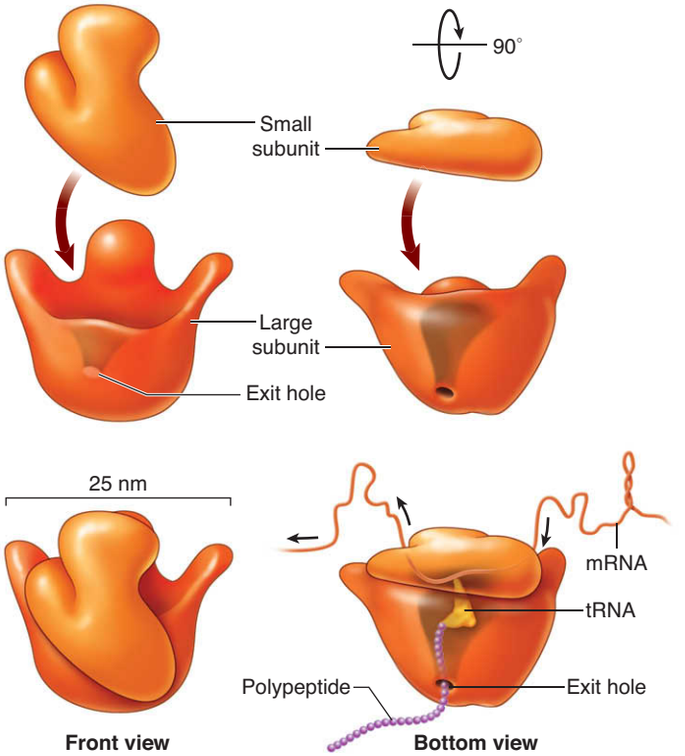

FIGURE 3-6

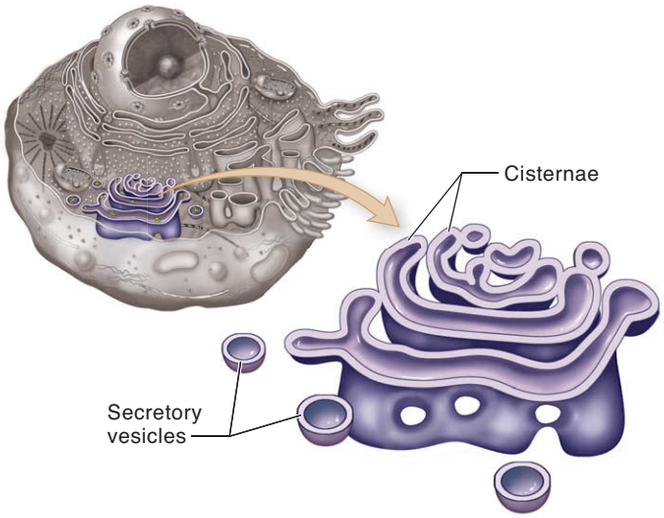
Ribosome. A ribosome is composed of a small subunit and a large subunit, shown here from two different perspectives. After the small subunit attaches to a messenger RNA (mRNA) strand containing the genetic "recipe" for a polypeptide strand, the subunits come together to form a complete ribosome. Transfer RNA (tRNA) brings amino acids into the cavity between subunits, where they are assembled into a strand according to the mRNA code. As the polypeptide strand elongates, it moves out through a tunnel and a tiny exit hole in the large subunit.



an endoplasmic reticulum canal are packaged into tiny membranous bubbles, or **vesicles,** that break away from the endoplasmic reticulum. The vesicles then move to the Golgi apparatus and fuse with the first cisterna. Protein molecules thus released into the cisterna are then chemically altered by enzymes present there. For example, the enzymes may attach carbohydrate molecules synthesized in the Golgi apparatus to form glycoproteins.

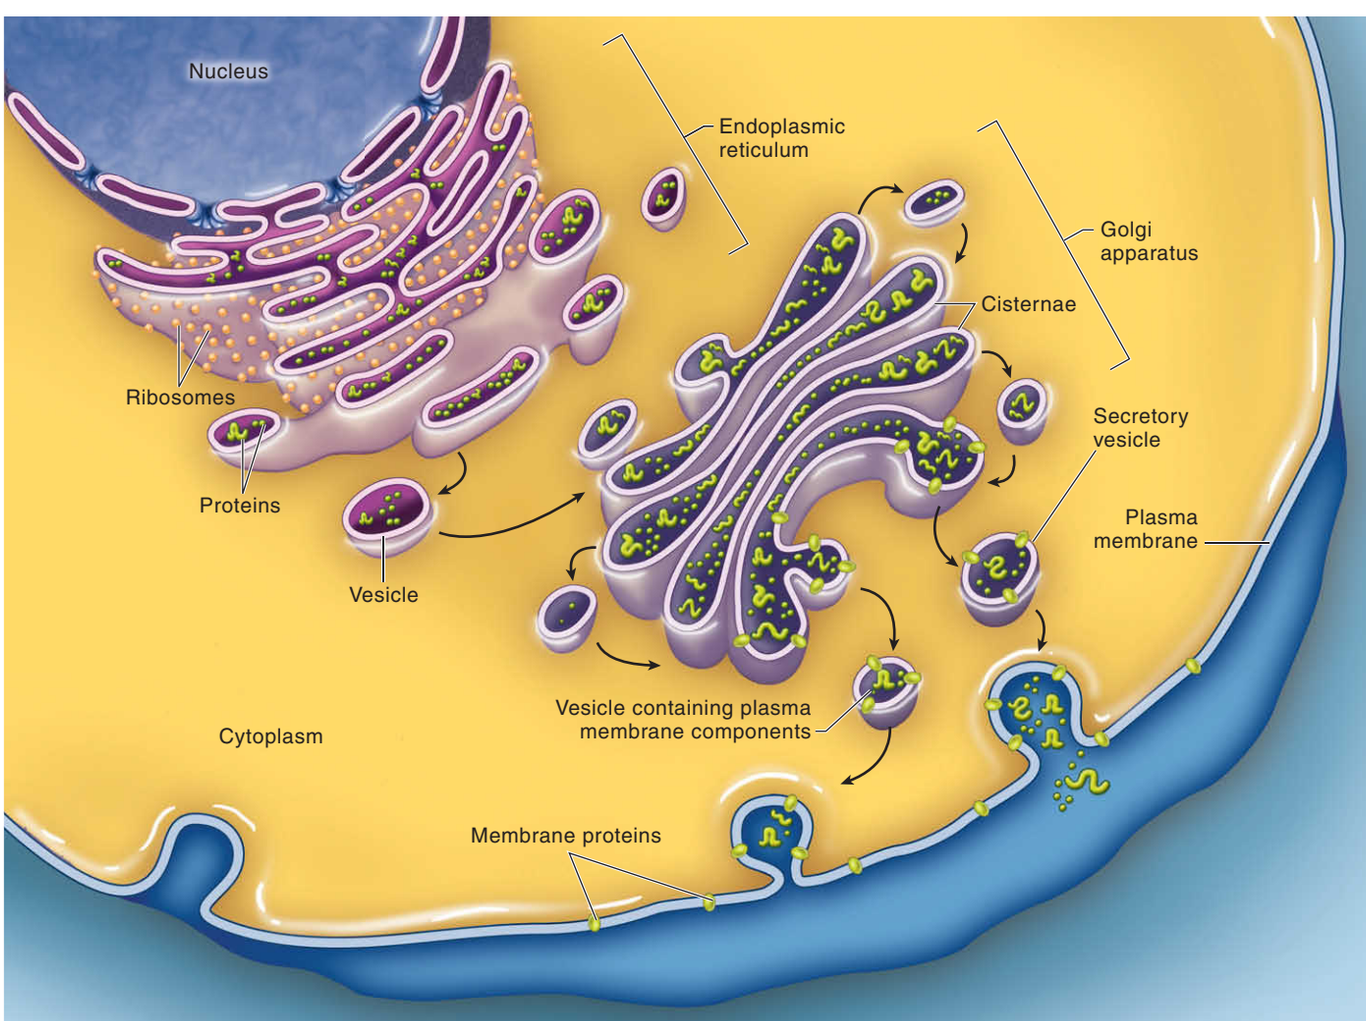
The processed and sorted molecules are then "pinched off" into another vesicle, which moves to the next cisterna for further processing. The proteins and glycoproteins eventually end up in the outermost cisterna, from which vesicles pinch off and move to another part of the cell. Often, the final destination is the plasma membrane.

At the plasma membrane, the vesicles release their contents outside the cell in a process called *secretion.* Other protein and glycoprotein molecules may instead be incorporated into the membrane of a Golgi vesicle. This means that these molecules eventually become part of the plasma membrane, as seen in Figure 3-3 and Table 3-2.

| A&P CONNECT |

Scientists are using their knowledge of the Golgi apparatus to mimic the cell's chemical-making functions in order to manufacture therapeutic treatments more efficiently. Check out ***Biomimicry*** online at ***A&P Connect.***

A



B

FIGURE 3-7

Golgi apparatus. A, Sketch of the structure of the Golgi apparatus showing a stack of flattened sacs, or *cisternae,* and numerous small membranous bubbles, or *secretory vesicles.* **B,** Transmission electron micrograph (TEM) showing the Golgi apparatus highlighted with color.

FIGURE 3-8

The cell's protein export system. The Golgi apparatus processes and packages protein molecules delivered from the endoplasmic reticulum by small vesicles. After entering the first cisterna of the Golgi apparatus, a protein molecule undergoes a series of chemical modifications, is sent (by means of a vesicle) to the next cisterna for further modification, and so on, until it is ready to exit the last cisterna. When it is ready to exit, a molecule is packaged in a membranous secretory vesicle that migrates to the surface of the cell and "pops open" to release its contents into the space outside the cell. The vesicle membrane, including any integral membrane proteins, then becomes part of the plasma membrane. Some vesicles remain inside the cell for some time and serve as storage vessels for the substance to be secreted.

Lysosomes

Like the endoplasmic reticulum and Golgi apparatus, **lysosomes** have membranous walls—indeed, they are vesicles that have pinched off from the Golgi apparatus. The size and shape of lysosomes change with the stage of their activity. In their earliest, inactive stage, they look like mere granules. Later, as they become active, they take on the appearance of small vesicles or sacs (see Figure 3-1). The interior of the lysosome contains various kinds of enzymes capable of breaking down all the protein components of cells.

Lysosomal enzymes have several important functions in cells. Chiefly, they help the cell break down proteins that are not needed to get them out of the way; the amino acids resulting from the breakdown process can be reused by the cell. In the process illustrated in Figure 3-9, defective organelles can be thus recycled. Integral membrane proteins from the plasma membrane can pinch off inside the cell and be recycled in the same manner. Likewise, cells may engulf bacteria or other extracellular particles and destroy them with lysosomal enzymes. Thus lysosomes deserve their nicknames of "digestive bags" and "cellular garbage disposals."

Proteasomes

The **proteasome** is another protein-destroying organelle in the cell. As Figure 3-10 shows, the proteasome is a hollow, cylindrical "drum" made up of protein subunits. Found throughout the cytoplasm, the proteasome is responsible for breaking down abnormal and misfolded proteins released from the ER, as well as destroying normal regulatory proteins in the cytoplasm that are no longer needed. But unlike the lysosome, which destroys large groups of protein molecules all at once, the proteasome destroys protein molecules one at a time.

Before a protein enters the hollow interior of the proteasome, it must be tagged with a chain of very small proteins called *ubiquitins*. The ubiquitin chain then enters the proteasome and subsequently "pulls" the rest of the protein in after it. As it passes through the cap of the proteasome, the protein is unfolded. Then active sites inside the central chamber break apart the peptide bonds. The resulting short peptide chains, 4 to 25 amino acids long, exit through the other end of the proteasome. The short peptides are easily broken down into their component amino acids for recycling by the cell.

Proper functioning of proteasomes is important in prevention of abnormal cell function and possibly severe disease. For example, in *Parkinson disease (PD)* the proteasome system fails, and consequently, the still intact improperly folded proteins kill nerve cells in the brain that are needed to regulate muscle tension.

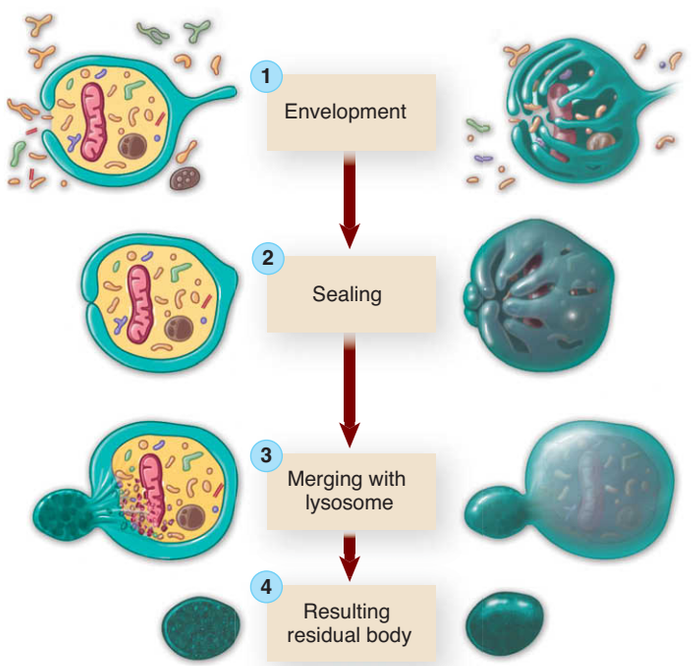


FIGURE 3-9

Lysosome. The process of destroying old cell parts follows these steps: (1) Membrane from the endoplasmic reticulum (ER) or Golgi apparatus encircles the material to be destroyed. (2) A membrane capsule completely traps the material. (3) A lysosome fuses with the membrane capsule, and digestive enzymes from the lysosome enter the capsule and destroy the contents. (4) Undigested material remains in a compact *residual body.*

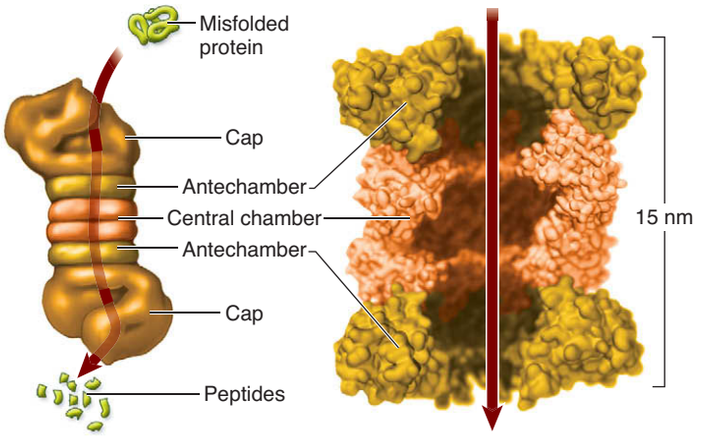

FIGURE 3-10

Proteasome. Made up of protein subunits, the proteasome is a hollow cylinder with regulatory end caps. Following the path shown by *arrows,* an ubiquitin-tagged protein molecule unfolds as it enters the cap and is then broken down into small peptide chains (4 to 25 amino acids), which leave through the other end of the proteasome. The peptides are subsequently broken down into amino acids, which are recycled by the cell. The proteasome is a little over half the size of a ribosome.

Peroxisomes

The **peroxisome** is another type of vesicle containing enzymes that is present in the cytoplasm of some cells. These organelles, which pinch off from the ER, detoxify harmful substances that may enter cells. They are often seen in kidney and liver cells and serve important detoxification functions in the body. Peroxisomes

contain the enzymes *peroxidase* and *catalase*, which are important in detoxification reactions involving hydrogen peroxide (H_2O_2). Hydrogen peroxide is the chemical that gives this organelle its name.

Mitochondria

Find the cell's little "power plants" called **mitochondria** shown in Figures 3-1 and 3-11. Magnified thousands of times, as they are there, they look like small, partitioned sausages—if you can imagine sausages only 1.5 µm (1500 nanometers [nm]) long and half as wide. (In case you are better at visualizing in inches than micrometers, 1.5 µm equals about 3/50,000 of an inch.) Yet, like all organelles, even as tiny as they are, mitochondria have a highly organized molecular structure.

Their membranous walls consist of not one but two delicate membranes. They form a sac within a sac. The inner membrane is contorted into folds called **cristae.** The large number and size of these folds gives the inner membrane a comparatively huge surface area for such a small organelle.

Embedded in the inner membrane are enzymes that are essential for assembling a chemical vital for life: *adenosine triphosphate (ATP)*. ATP was first introduced in Chapter 2 as the molecule that transfers energy from food to cellular processes. It is the job of each mitochondrion to extract energy from food molecules and use it to build ATP molecules. Then the ATP molecules leave the mitochondrion and break apart to release the energy in a variety of specific chemical reactions throughout the cell. Thus each mitochondrion acts as a tiny "power plant" that converts energy from a stored form to a more directly useable form (temporarily stored in ATP). Chapters 4 and 30 present more detailed information about this vital process that provides useable energy for the cell.

Both the inner and outer membranes of the mitochondrion have essentially the same molecular structure as the cell's plasma membrane. All evidence gathered so far indicates that the functional proteins in the membranes of the cristae are arranged precisely in the order of their functioning. This is another example, but surely an impressive one, of the principle stressed in Chapter 1—self-organization is a foundation stone and a vital characteristic of life.

The fact that mitochondria generate most of the power for cellular work suggests that the number of mitochondria in a cell might be directly related to its amount of activity. This principle does seem to hold true. In general, the more work a cell does, the more mitochondria its cytoplasm contains. Liver cells, for example, do more work and have more mitochondria than sperm cells do. A single liver cell contains 1000 or more mitochondria, whereas only about 25 mitochondria are present in a single sperm cell. The mitochondria in some cells multiply when energy consumption increases. For example, frequent aerobic exercise can increase the number of mitochondria inside skeletal muscle cells.

Each mitochondrion has its own DNA molecule, a very surprising discovery indeed! This enables each mitochondrion to make some of its own enzymes. Having its own DNA also enables each mitochondrion to divide and produce genetically identical daughter mitochondria. Scientists believe that mitochondria are bacteria that have become part of our cells—a concept that has several useful applications discussed more thoroughly in Chapter 37.

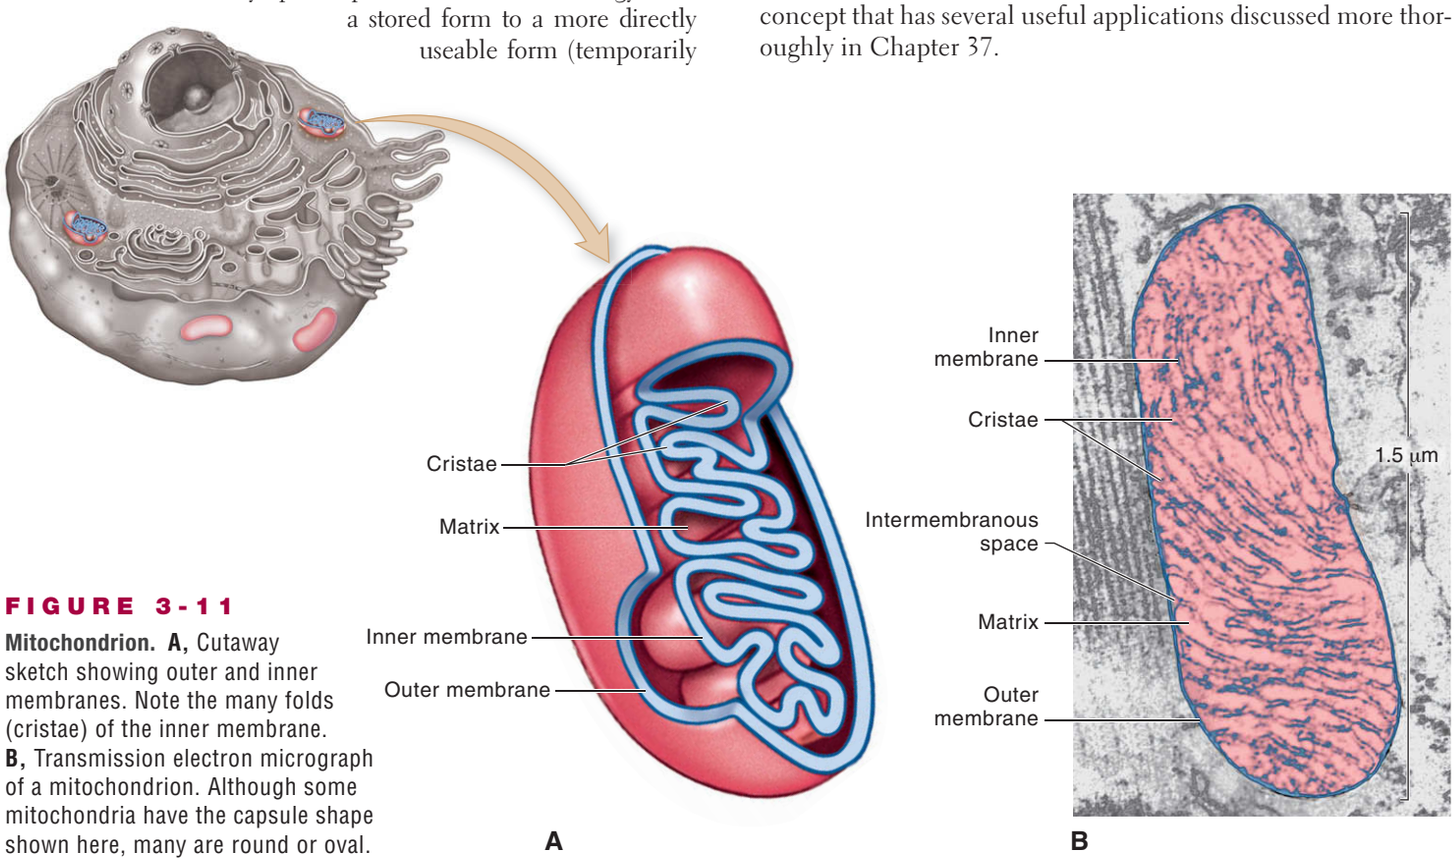

FIGURE 3-11

Mitochondrion. A, Cutaway sketch showing outer and inner membranes. Note the many folds (cristae) of the inner membrane. **B,** Transmission electron micrograph of a mitochondrion. Although some mitochondria have the capsule shape shown here, many are round or oval.

NUCLEUS

The **nucleus,** one of the largest cell structures (see Figure 3-1), usually occupies the central portion of the cell. The shape of the nucleus and the number of nuclei present in a cell vary. One spherical nucleus per cell, however, is common.

Electron micrographs show that two membranes perforated by openings, or pores, enclose the *nucleoplasm* (nuclear substance) (Figure 3-12). *Nuclear pores* are intricate structures often called *nuclear pore complexes* (NPCs) (Figure 3-13). Nuclear pore complexes act as gatekeepers and transport mechanisms that selectively permit molecules and other structures to enter or leave the nucleus. Organelles called *vaults* may also assist with such transport, as described in Box 3-2.

The two nuclear membranes, together called the *nuclear envelope,* have essentially the same type of structure as other cell membranes. The membranous walls of the endoplasmic reticulum extend outward from the membranes of the nuclear envelope.

Probably the most important fact to remember about the nucleus is that it contains DNA molecules, the well-known heredity molecules often referred to in news stories. In nondividing cells, the DNA molecules appear as tiny bunches of tangled threads sprinkled with granules. This material is named **chromatin.** Chromatin is from the Greek *chroma,* "color," so named because it readily takes the color of stains. These chromatin tufts are not randomly spread throughout the nucleus. They continually move like dancers into various positions within the nucleus as the DNA performs its functions.

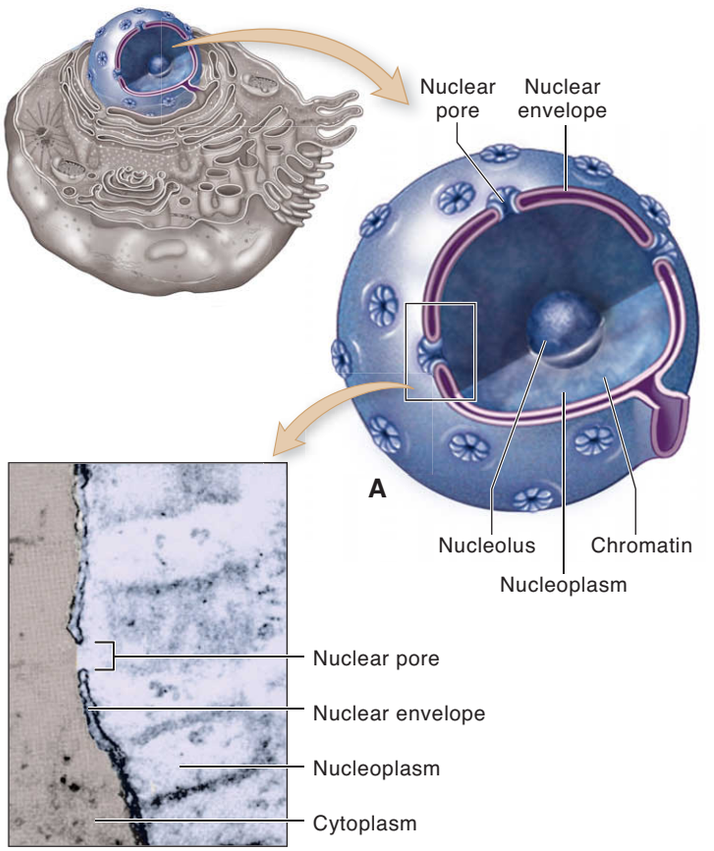

FIGURE 3-12

Nucleus. A, An artist's rendering and, **B,** an electron micrograph show that the nuclear envelope is composed of two separate membranes and is perforated by large openings, or nuclear pores.

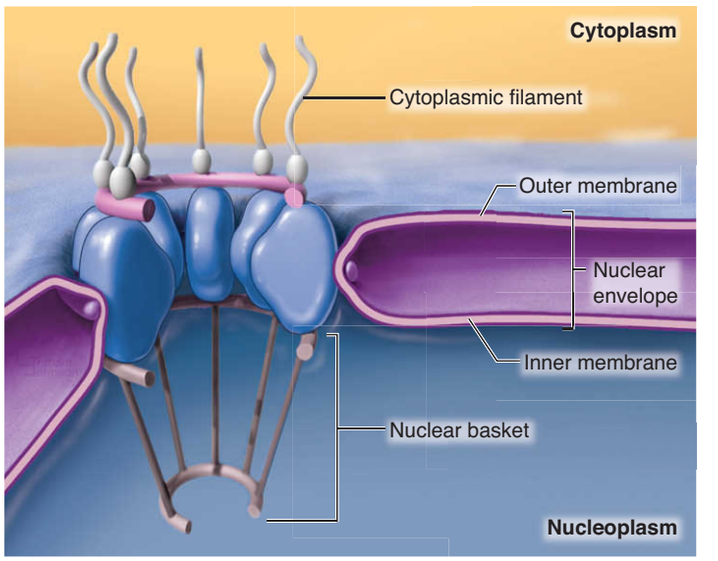

FIGURE 3-13

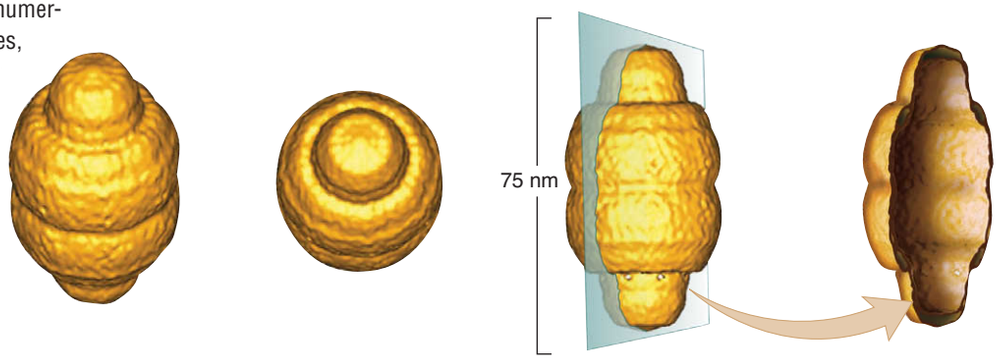
Nuclear pore complex (NPC). The elaborate structure of the nuclear pore complex hints at its many roles in regulating the movement of small particles between the inside and outside of the nucleus.

When the process of cell division begins, DNA molecules become more tightly coiled. They then become so compact that they look like short, rodlike structures and are then called **chromosomes.** All normal human cells (except mature sex cells) contain 46 chromosomes, and each chromosome consists of one DNA molecule plus some protein molecules.

The functions of the nucleus are primarily functions of DNA molecules. In brief, DNA molecules contain the master code for making all the RNA plus the many enzymes and other proteins of a cell. Therefore, DNA molecules ultimately dictate both the structure and the function of cells. Chapter 5 briefly discusses how a cell transcribes and translates the master code to synthesize specific proteins. DNA molecules are inherited, so DNA plays a pivotal role in the process of heredity—a concept we explore further in Chapter 37.

| A&P CONNECT |

In nondividing cells, chromosomes are found in the form of chromatin strands that occupy specific **chromosome territories (CTs)** within the nucleus. See an example of a CT map in ***Chromosome Territories*** online at ***A&P Connect.***



evolve

The most prominent structure visible in the nucleus is a small nonmembranous body that stains densely when studied in the laboratory setting and is called the **nucleolus** (Figure 3-12, A). Like chromosomes, it consists chiefly of a nucleic acid, but the nucleic acid is not DNA. It is RNA, or ribonucleic acid (see pp. 115–116).

The nucleolus functions to synthesize ribosomal RNA (rRNA) and combine it with protein to form the subunits that will later combine to form ribosomes, the protein factories of cells (see

Box 3-2 | Vaults

One cellular structure recently added to the list of organelles is a barrel-shaped structure called a *vault.* It is a very tiny capsule that, like the vaulted ceiling of a cathedral, is composed of a set of tapered pieces that fit together to form a rounded structure. They contain a small bit of RNA (*vault RNA* or *vRNA*) along with proteins. One proposed function for vaults, which are thought to be very numerous in each cell, is to fit into nuclear pores, where they open up one end to pick up or drop off small structures such as RNA molecules or ribosome subunits. The vaults may then connect to a microtubule and slide rapidly along to another part of the cell—acting like miniature railway cars. Besides shuttling molecules to and from the nucleus, vaults probably participate in a number of other transport roles in the cell.

Vaults. This computer reconstruction of electron microscopy (EM) data shows the shape of vaults. The right image reveals the thin wall and hollow interior of a vault, which may act as a tiny transport shuttle for small cellular structures.

Figure 3-6). You might guess, therefore, and correctly so, that the more protein a cell makes, the larger its nucleolus appears. Cells of the pancreas, to cite just one example, make large amounts of protein and have large nucleoli.

| QUICK CHECK |

4. List at least three functions of the plasma membrane.
5. Define the term *organelle.*
6. Identify three organelles by name and give one function of each.
7. Distinguish between membranous and nonmembranous organelles.

CYTOSKELETON

As its name implies, the **cytoskeleton** is the cell's internal supporting framework. Like the bony skeleton of the body, the cytoskeleton is made up of rather rigid, rodlike pieces that not only provide support but also allow movement. Like the body's musculoskeletal framework, the cytoskeleton has muscle-like groups of fibers and other mechanisms that move the cell, or parts of the cell, with great strength and mobility. In this section, we take a look at the basic characteristics of the cell's internal skeleton, as well as several organelles that are associated with it.

Cell Fibers

No one knew much about *cell fibers* until the development of two new research methods: one with fluorescent molecules and the other with stereomicroscopy, that is, three-dimensional pictures of whole, unsliced cells made with high-voltage electron microscopes. Using these techniques, investigators discovered intricate arrangements of fibers of varying widths. The smallest fibers seen have a width of about 3 to 6 nanometers (nm)—less than 1 millionth of an inch! Of particular interest is their arrangement. They form a three-dimensional, chaotic lattice, a kind of scaffolding in the cell. These fibers appear to support parts of the cell formerly thought to float free in the cytoplasm—the endoplasmic reticulum, mitochondria, and "free" ribosomes (Figure 3-14; see also

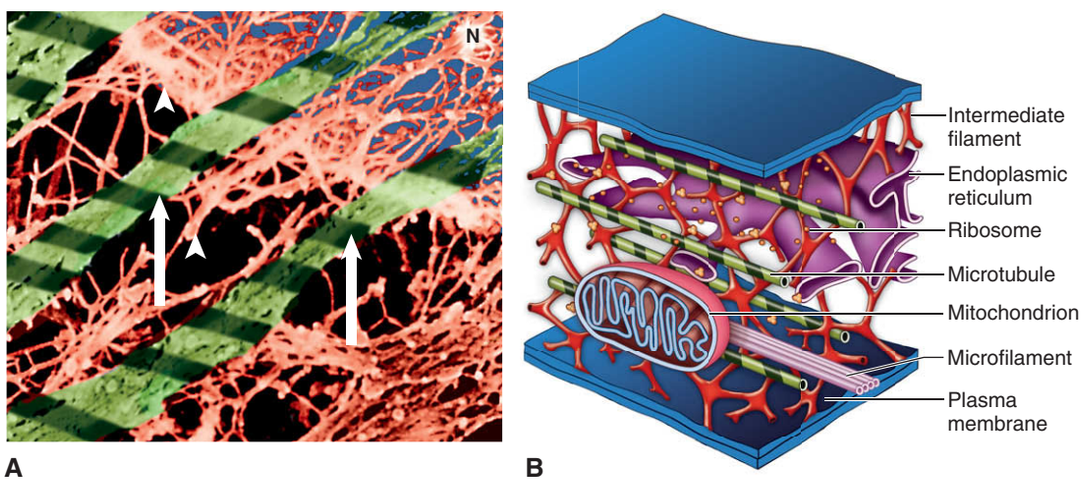


FIGURE 3-14

The cytoskeleton. A, Color-enhanced electron micrograph of a portion of the cell's internal framework. The letter *N* marks the nucleus, the *arrowheads* mark the intermediate filaments, and the *complete arrows* mark the microtubules. **B,** Artist's interpretation of the cell's internal framework. Notice that the "free" ribosomes and other organelles are not really freely floating in the cell.

Figures 3-1 and 3-2). Cytoskeletal fibers may even "fence in" regions of the plasma membrane to prevent free-floating movement of embedded proteins.

The smallest cell fibers are called **microfilaments.** Microfilaments often serve as part of our "cellular muscles." They are made of thin, twisted strands of protein molecules (Figure 3-15, A). In some microfilaments, the proteins can be pulled by little "motors" and slide past one another to cause shortening of the cell. The most obvious example of such shortening occurs in muscle cells, where many bundles of microfilaments are pulled together to shorten the cells with great force.

Cell fibers called **intermediate filaments** are twisted protein strands that are slightly thicker than microfilaments (Figure 3-15, B). Intermediate filaments are thought to form much of the supporting framework in many types of cells. They act as the tendons and ligaments of the cell, holding the cell together as it is pushed and pulled. For example, the protective cells in the outer layer of skin are filled with a dense arrangement of tough intermediate filaments.

The thickest of the cell fibers are tiny, hollow tubes called **microtubules.** As Figure 3-15, C, shows, microtubules are made of protein subunits arranged in a spiral fashion. Microtubules are sometimes called the "engines" of the cell because they often move things around in the cell—or even cause movement of the entire cell. For example, both the movement of vesicles within the cell and the movement of chromosomes during cell division are thought to be accomplished by microtubules.

Just as the body's musculoskeletal system helps us sense our body's position and environmental impacts, the cell's cytoskeleton can detect changes in the cell's position and impacts that affect the cell.

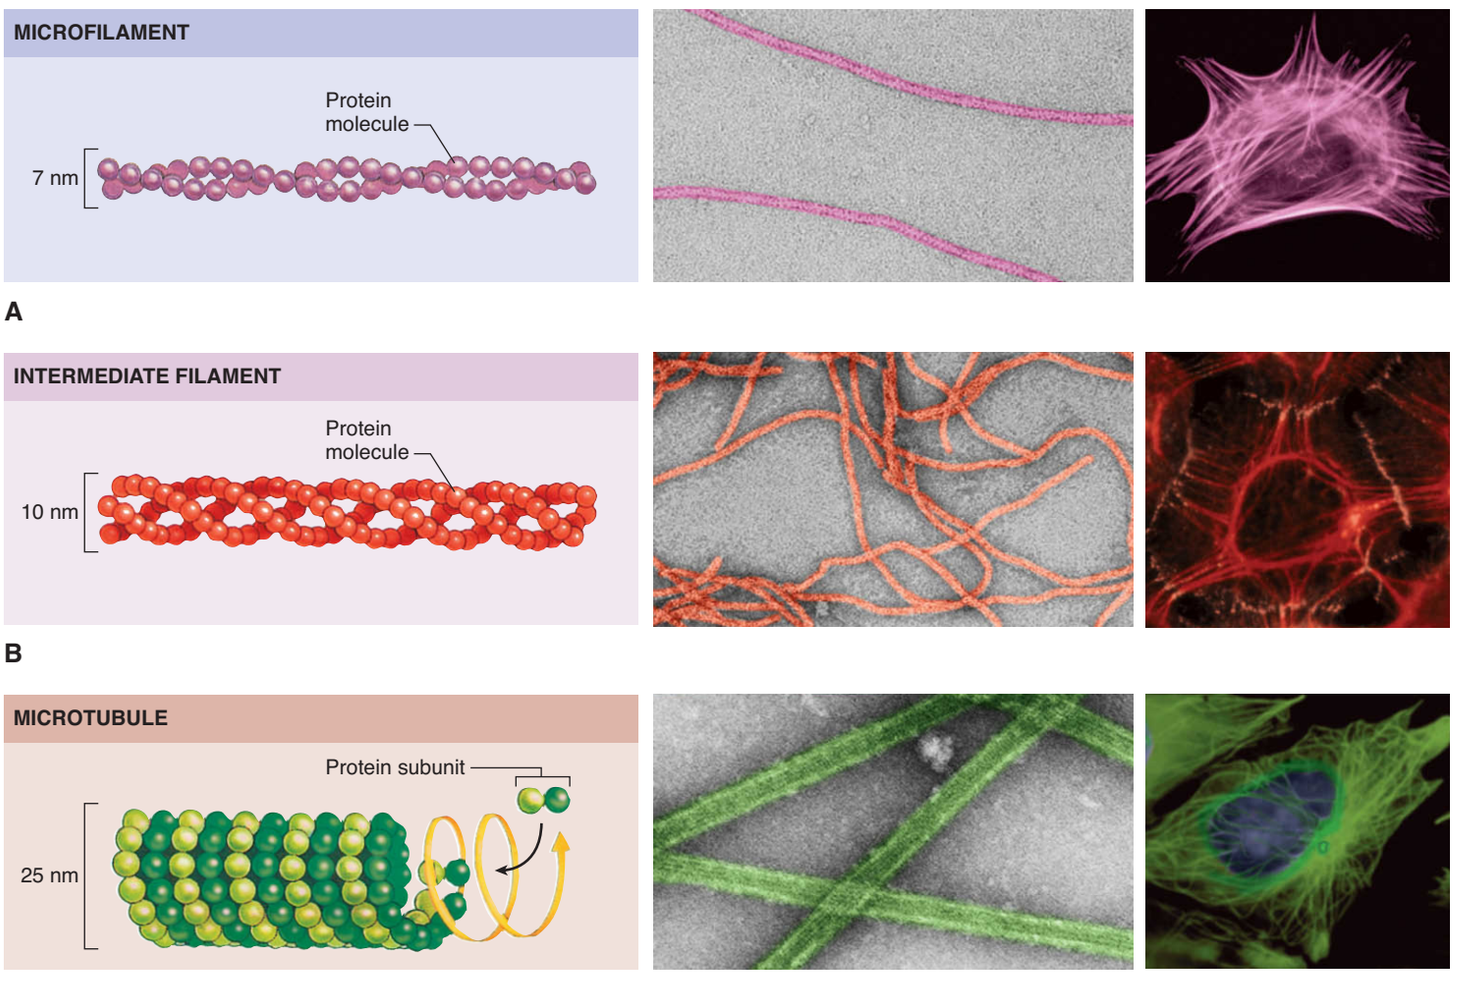

FIGURE 3-15

Cell fibers. The left panel of each part is a sketch, the middle panel is a transmission electron micrograph (TEM), and the right panel is a light micrograph using fluorescent stains to highlight specific molecules within each cell. **A,** *Microfilaments* are thin, twisted strands of protein molecules. **B,** *Intermediate filaments* are thicker, twisted protein strands. **C,** *Microtubules* are hollow fibers that consist of a spiral arrangement of protein subunits. Note the bright yellow-green microtubule-organizing center (centrosome) near the large purple nucleus in the bottomright panel.

In addition to the "bones" and "muscles" that make up the cytoskeleton, there are many types of functional proteins that allow the various parts to interact with one another. For example, receptor molecules help parts link to one another and may even permit signals to be sent between parts. Molecular motors, described later, move parts. Other functional proteins such as enzymes keep everything running smoothly, too.

Centrosome

An example of an area of the cytoskeleton that is very active and requires coordination by functional proteins is the **centrosome.** The centrosome is a region of the cytoplasm near the nucleus that coordinates the building and breaking apart of microtubules in the cell. For this reason, this nonmembranous structure is often called the *microtubule-organizing center (MTOC).*

Look for the tiny yellow-green centrosome in Figure 3-15, part C (right panel). You can see, radiating out from the centrosome in this micrograph, the green-stained microtubules organized around it.

The boundaries of the centrosome are rather indistinct because it lacks a membranous wall. However, the general location of the centrosome is easy to find because of a pair of cylindrical structures called **centrioles.**

Under the light microscope, centrioles appear as two dots located near the nucleus. The electron microscope, however, reveals them to be not mere dots but tiny cylinders (Figure 3-16). The walls of the cylinders consist of nine bundles of microtubules, with three tubules in each bundle. A curious fact about these two tubular-walled cylinders is that they are tethered by tiny fibers and sit at right angles to each other. This special arrangement occurs when the centrioles separate in preparation for cell division (see Table 5-5 on p. 123). Before separating, a daughter centriole is formed perpendicular to each member of the original pair (both become "mother" centrioles) so that a complete pair may be distributed to each new cell.

A cloudlike mass of material surrounding the centrioles is called the *pericentriolar material (PCM).* The PCM is active in starting the growth of new microtubules. The distal and subdistal appendages on the mother centriole that you can see in Figure 3-16, A, are anchor points for microtubules.

The microtubule organizing function of the centrosome plays an important role during cell division, when a special "spindle" of microtubules is constructed for the purpose of pulling chromosomes apart and toward each daughter cell. As this spindle forms, the centrosome is anchored by an **aster,** which is a formation of microtubules radiating outward from the centrioles.

In addition to their involvement in forming the spindle that appears during cell division and other key components of the cytoskeleton, the centrosome is involved in the formation of microtubular cell extensions (discussed in a later section).

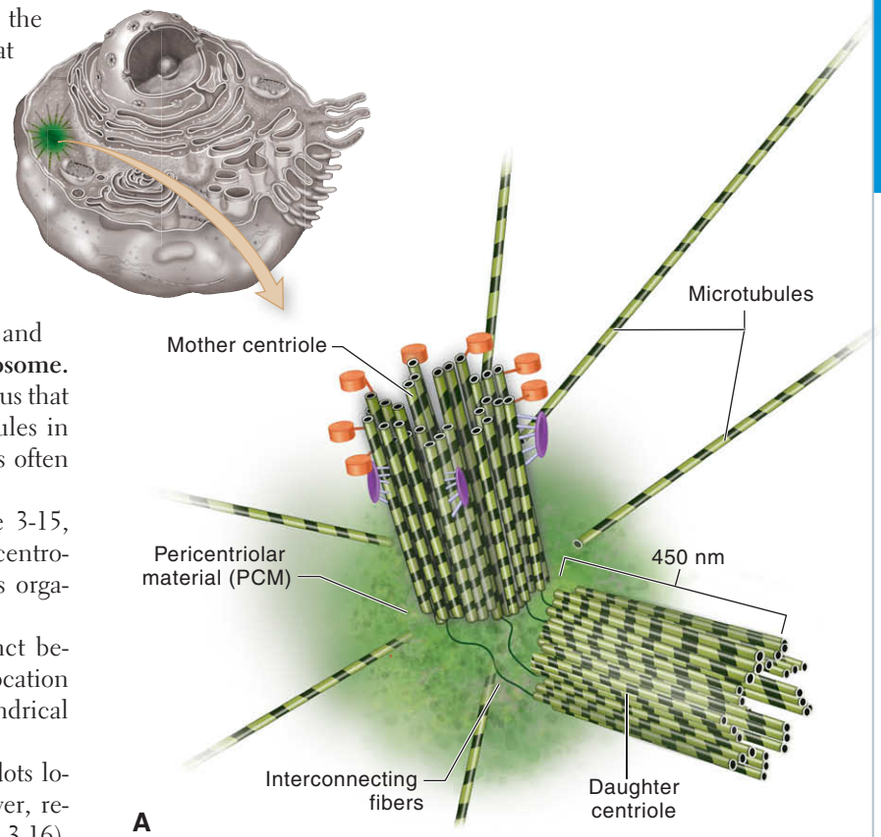

FIGURE 3-16

Centrosome. Sketch **(A)** and transmission electron micrograph (TEM) **(B)** showing the structure of the centrosome, which acts as a microtubule-organizing center for the cell's cytoskeleton.

Molecular Motors

Have you wondered as you read along how all the little vesicles, organelles, and molecules always seem to be able to move on their own power to where they need to go in a cell? Vesicles don't have feet! So how do they move from place to place in an organized way? The answer is surprising: cellular movement *does* rely on "foot" power! The cell's internal "feet" are actually little protein structures called **molecular motors.** As you can see in

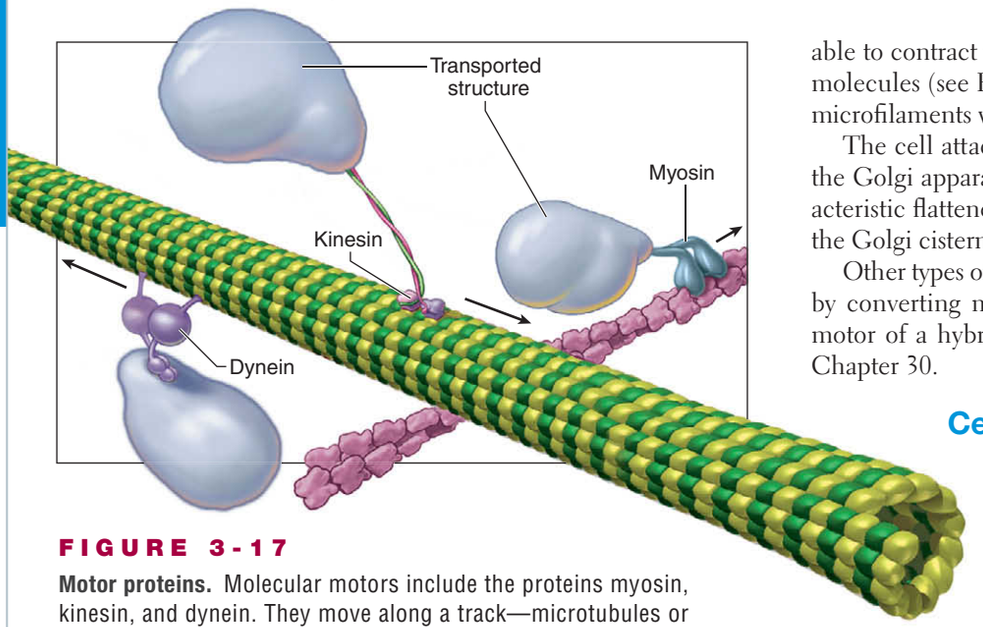

FIGURE 3-17

Motor proteins. Molecular motors include the proteins myosin, kinesin, and dynein. They move along a track—microtubules or microfilaments—and pull larger structures such as vesicles, fibers, or particles. Such movement can be used for intracellular transport or movement of the cell's entire framework.

Figure 3-17, these little motors are like tiny feet that pull huge loads along the microtubules and microfilaments of the cytoskeleton. The loads may be vesicles or other small organelles, fibers, or large molecules. The tiny *motor proteins* transport organelles along a microtubule or fiber as if they were railway cars being pulled along a track. This system provides rapid, orderly movement of structures and materials around the cell. It also allows the cell's framework to move with force, extending and contracting to create movements of the cell. In fact, muscles in your body are able to contract with force because of the action of many myosin molecules (see Figure 3-17) pulling together overlapping rows of microfilaments within each muscle cell, as mentioned earlier.

The cell attaches motor molecules to the ends of cisternae in the Golgi apparatus and pulls these sacs outward into their characteristic flattened shape. This action eventually pulls vesicles off the Golgi cisternae.

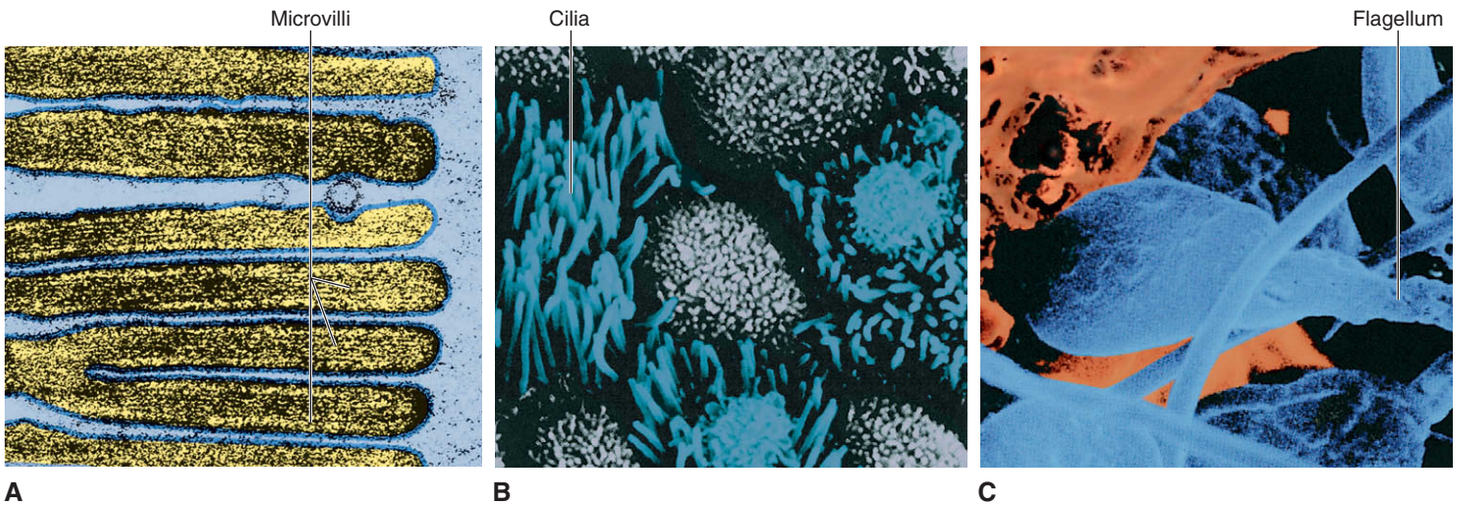
Other types of molecular motors can be used to generate power by converting mechanical energy to chemical energy, like the motor of a hybrid automobile—an example that we explore in Chapter 30.

Cell Extensions

In some cells the cytoskeleton forms projections that extend the plasma membrane outward to form tiny, fingerlike processes. These processes, *microvilli*, *cilia*, and *flagella*, are present only in certain types of cells—depending, of course, on a cell's particular functions.

Microvilli are found in epithelial cells that line the intestines and other areas where absorption is important (Figure 3-18, A). Like tiny fingers crowded against each other, microvilli cover part of the surface of a cell (see Figure 3-1). A single microvillus measures about 0.5 µm long and only 0.1 µm or less across. Inside each microvillus are microfilament bundles that provide both structural support and the ability to move. Because one cell has hundreds of these projections, the surface area of the cell is increased manyfold—a structural feature that enables the cell to perform its function of absorption at a faster rate.

Cilia and **flagella** are cell processes that have cylinders made of microtubules at their core. Each cylinder is composed of nine double microtubules arranged around two single microtubules in



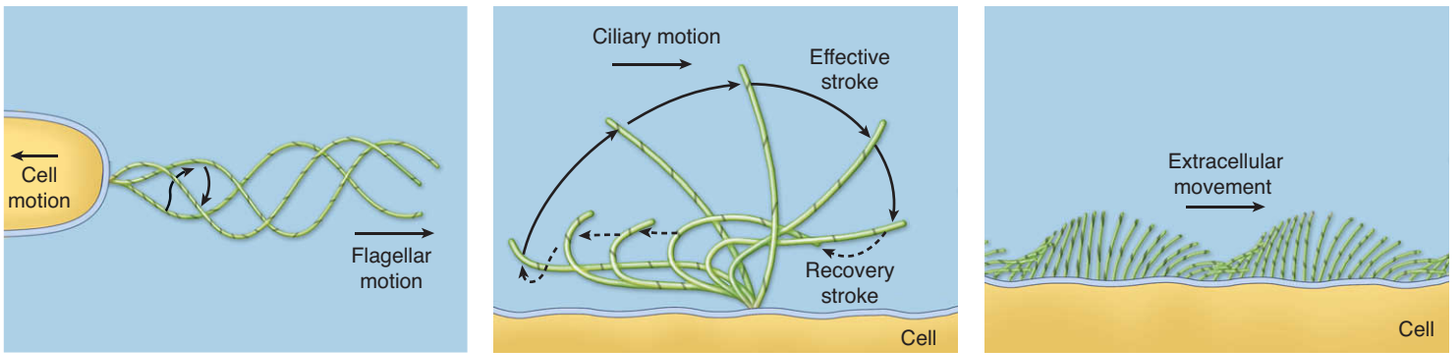


FIGURE 3-18

Cell processes. A, *Microvilli* are numerous, fingerlike projections that increase the surface area of absorptive cells. This electron micrograph shows a longitudinal section of microvilli from a cell lining the small intestine. Note the bundles of microfilaments that support the microvilli. **B,** *Cilia* are numerous, fine processes that transport fluid across the surface of the cell. This electron micrograph shows cilia (long projections) and microvilli (small bumps) on cells lining the lung airways. **C,** In humans, *flagella* are single, elongated processes on sperm cells that enable these cells to "swim."

Flagellum **Cilium** **Cilia**

FIGURE 3-19

Movement patterns. A flagellum (left) produces wavelike movements, which propels a sperm cell forward—like the tail of an eel. In humans, cilia (middle and right) found in groups on stationary cells beat in a coordinated oarlike pattern to push fluid and particles in the extracellular fluid along the outer cell surface.

the center—a slightly different arrangement than in centrioles. With the addition of molecular motors, this particular arrangement is suited to movement. Dynein, a type of motor protein (see Figure 3-17), moves the microtubule pairs so they slip back and forth past one another to produce a "wiggling" movement.

Among human cells, what distinguishes cilia from flagella are their size, number, and pattern of movement. Human cilia are shorter and more numerous than flagella (Figure 3-18, B). Under low magnification, cilia look like tiny hairs. The cilia often move in a rhythmic, coordinated way to push substances such as mucus along the cell surface, as explained in Figure 3-19. In the lining of the respiratory tract, the movement of cilia keeps contaminated mucus on cell surfaces moving toward the throat, where it can be swallowed. In the lining of the female reproductive tract, cilia keep the ovum moving toward the uterus. Cilia also have a sensory function, detecting changes in the mucus being moved.

Except for blood cells, most cell types have a single *primary cilium*. The primary cilium lacks the center pair of microtubules and certain motor molecules, such as dynein (see Figure 3-17). Therefore, the primary cilium cannot move like other types of cilia. However, they have other important functions. For example, primary cilia often act as sensory organelles that permit sensations such as vision, hearing, balance, and so on, as you will learn in Chapter 17. In the kidney, primary cilia monitor urine flow—and if damaged—can cause kidney failure. Primary cilia also play a critical role in centriole replication and regulation of cell reproduction (Chapter 5).

Flagella are single, long structures in the only type of human cell that has this feature: the human sperm cell (see Figure 3-18, C). A sperm cell's flagellum moves like the tail of an eel (as you can see in Figure 3-19) to allow the cell to "swim" toward the female sex cell (ovum).

Each year brings with it the discovery of new types of cytoskeletal components. As we tease out their functions, we find that the cytoskeleton is an amazingly rich network that is literally the "bones and muscles" of the cell. It provides a variety of many different types of cell movement, both internal and external, depending on the cell and the circumstances. It provides many different kinds of structural support for the cell and its parts—and even becomes involved in connections with other cells. Most amazing of all, the cytoskeleton has the ability to organize itself by means of a complex set of signals and reactions so that it can quickly respond to the needs of the cell.

CELL CONNECTIONS

The tissues and organs of the body must be held together, so they must, of course, be connected in some way. Many cells attach directly to the extracellular material, or *matrix*, that surrounds them. A group of integral membrane proteins called *integrins* helps hold cells in their place in a tissue. Some integrin molecules span the plasma membrane and often connect the fibers of the cytoskeleton inside the cell to the extracellular fibers of the matrix, thereby anchoring the cell in place. In this manner, also, some cells are held to one another indirectly by fibrous nets that surround groups of cells. Certain muscle cells are held together this way.

Cells may form direct connections with each other. Integrins are sometimes involved in direct cell connections, but other connecting proteins, such as *selectins*, *cadherins*, and *immunoglobulins*, help form most cell-to-cell connections. Not only do such connections hold the cells together, they sometimes also allow direct communication between the cells. The major types of direct cell connections are summarized in Figure 3-20.

Desmosomes sometimes have the appearance of small "spot welds" that hold adjacent cells together. Adjacent skin cells are held together this way. Notice in Figure 3-20 that fibers on the outer surface of each *spot desmosome* interlock with each other. This arrangement resembles Velcro, which holds things together tightly when tiny plastic hooks become interlocked with fabric loops. Notice also that the desmosomes are anchored internally by intermediate filaments of the cytoskeleton. Some cells have a belt-like version of the desmosome structure that completely encircles the cell. This form may be called a *belt desmosome* to distinguish it from a spot desmosome.

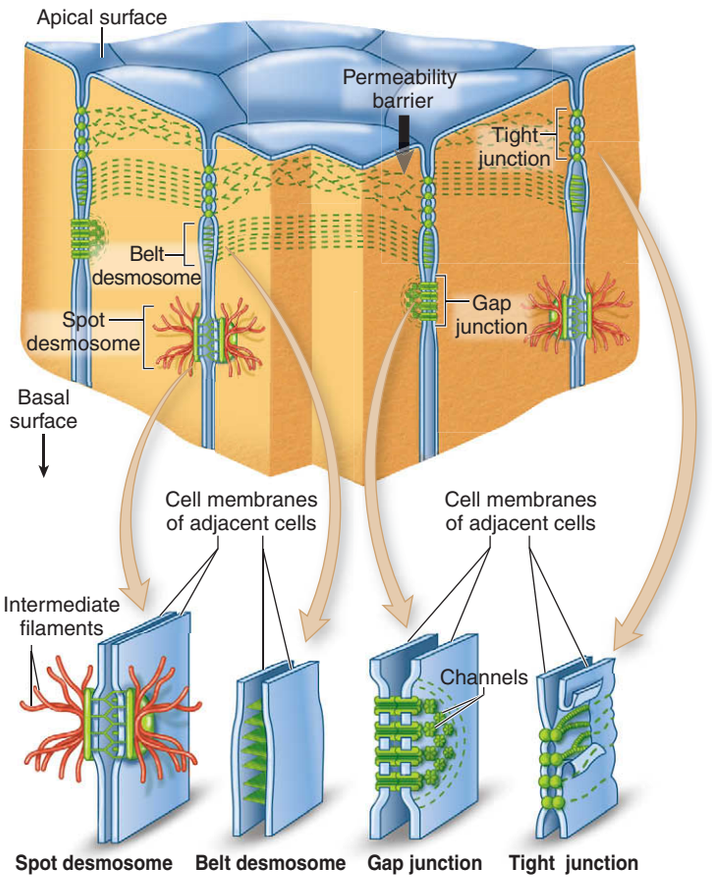

FIGURE 3-20

Cell connections. Spot and belt desmosomes, gap junction, and tight junction.

Gap junctions form when membrane channels of adjacent plasma membranes connect to each other. As Figure 3-20 shows, such junctions have the following two effects: (1) they form gaps or "tunnels" that join the cytoplasm of two cells, and (2) they fuse the two plasma membranes into a single structure. One advantage of this arrangement is that certain molecules can pass directly from one cell to another. Another advantage is that electrical impulses traveling along a membrane can travel over many cell membranes in a row without stopping in between separate membranes because they have "run out of membrane." Heart muscle cells are joined by gap junctions so that a single impulse can travel to, and thus stimulate, many cells at the same time.

Tight junctions occur in cells that are joined near their apical surfaces by "collars" of tightly fused membrane. As you can see in Figure 3-20, rows of integral membrane proteins that extend all the way around a cell fuse with similar integral membrane proteins in neighboring cells. An entire sheet of cells can be bound together the way soft drink cans are held in a six-pack by plastic collars—only more tightly. When tight junctions hold a sheet of cells together, molecules cannot easily *permeate*, or spread through, the cracks between the cells. Tight junctions occur in the lining of the intestines and other parts of the body, where it is important to control what gets past a sheet of cells. The only way for a molecule to get past the intestinal lining is through controlled channel, or carrier, molecules in the plasma membranes of the cells.

8. Describe the three types of fibers in the cytoskeleton.
9. What is the function of the centrosome?
10. Name each of the three typical types of cell junctions and describe them.

the BIG picture

Cell Anatomy and the Whole Body

Probably one of the most difficult things to do when first exploring the microscopic world of the cell is to appreciate the structural significance a single cell has to the whole body. Where are these unseen cells? How does each relate to this big thing I call my body?

One useful way to approach the structural role of cells in the whole body is to think of a large, complicated building. For example, the building in which you take your anatomy and physiology course is made up of thousands, perhaps hundreds of thousands, of structural subunits. Bricks, blocks, metal or wood studs, boards, and so on are individual structures within the building that each have specific parts, or organelles, that somehow contribute to overall function. A brick often has sides of certain dimensions that allow it to fit easily with other bricks or with other building materials. Three or four surfaces are usually textured in an aesthetically pleasing manner, and holes in two of the brick surfaces lighten the weight of the brick, allow other materials such as wires or reinforcing rods to pass through, and permit mortar to form a stronger joint with the brick. The material from which each brick is made has been formulated with certain ratios of sand, clay, pigments, or other materials. Each structural feature of each brick has a functional role to play. Likewise, each brick and other structural subunits of the building have an important role to play in supporting the building and making it a pleasing, functional place to study.

Like the structural features of a brick, each organelle of each cell has a functional role to play within the cell. In fact, you can often guess a cell's function by the proportion and variety of different organelles it has. Each cell, like each brick in a building, has a role to play in providing its tiny portion of the overall support and function of the whole body. Where are these cells? In the same place you would find bricks and other structural subunits in a building—everywhere! Like bricks and mortar, everything in your body is made of cells and the extracellular material surrounding them. How do cells relate to the whole body? Like bricks that are held together to form a building, cells form the body.

Just as a brick building is made of many different materials, the human body includes many structural subunits, each with its own structural features or organelles that contribute to the function of the cell—and therefore to the whole body.

MECHANISMS of DISEASE

CELLULAR DISEASE

The more that we learn about the mechanisms of disease, the more apparent it becomes that most diseases known to medicine involve abnormalities of cells. Even a few abnormal cells can so disrupt the internal environment of the body that a person's health can be in immediate danger. The following paragraphs list several important categories of disease that are caused by cell abnormalities. Specific diseases belonging to these categories are discussed further in later chapters. The sampler here and in the next couple of chapters about cell function will start you off with a basic understanding of cellular mechanisms of disease.

Disorders Involving Cell Membranes

Disorders involving cell membrane receptors are being actively investigated by biologists. One such particularly common disorder is a form of **diabetes mellitus (DM)** called *type 2 diabetes*. This condition is often produced by a cellular response to obesity that triggers a reduction in the number of functioning membrane receptors for the hormone *insulin*. Cells throughout the body thus become less sensitive to insulin, the hormone that allows glucose molecules to enter the plasma membrane. Without sufficient stimulation by insulin, the cells literally starve for energy-rich glucose, even though it is available outside the cell.

Duchenne muscular dystrophy (DMD), a severe inherited condition, results from "leaky" membranes in muscle cells. *Dystrophin*, a protein that normally helps connect a muscle cell's cytoskeleton to the plasma membrane and to the surrounding extracellular matrix, is missing (Figure 3-21). Muscle contractions pull at the weakened connections to the plasma membrane and rip holes that allow calcium ions (Ca^{++}) to enter the cell. This flood of Ca^{++} triggers chemical reactions that destroy the muscle, causing life-threatening paralysis.

Disorders Involving Organelles

Any abnormality of any of the organelles is likely to produce disease. Knowing the functions of the organelles helps health professionals understand the nature and symptoms of these disorders.

Failure of mitochondria reduces the cell's ability to produce enough energy for normal function. Mitochondrial abnormalities resulting from chemical damage are known to be a factor in many significant degenerative diseases, such as **Parkinson disease (PD).** PD affects the areas of the brain that control muscles, progressively making effective movement more difficult. Mitochondrial dysfunction is also thought to be involved in the normal degeneration associated with aging.

Some degenerative diseases may also involve the breakdown of the microtubules of the cytoskeleton, which often happens in PD.

Failure of the protein-making system of the ribosomes, ER, and Golgi apparatus can produce many types of diseases that are caused by the absence of one or more proteins critical for body function. Failure of the quality control system provided by proteasomes has been implicated in the buildup of abnormal proteins that form the plaques that characterize **Alzheimer disease (AD)** and other degenerative disorders.

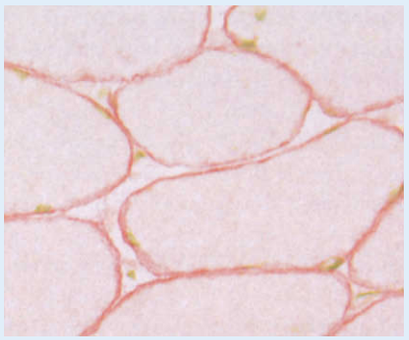

FIGURE 3-21

Dystrophin. This cross section of muscle fibers has been stained for the presence of dystrophin (seen along each cell's plasma membrane). In Duchenne muscular dystrophy (DMD), this protein would be completely absent, thus causing damage to the membranes of muscle fibers that results in destruction of muscle tissue.

CASE study

Sunil had been looking forward to the Elementary Science Fair for weeks. His third-grade class had just finished a section on the biological cell, and he couldn't wait to walk through the greatly oversized cell model that was on display. His father seemed just as excited, maybe more, if that were possible. When they got to the cell model, their first challenge was figuring out how to get inside. The "membrane" of the cell had no holes in it. They walked around the cell and finally found a small doorway. A sign above the doorway identified this type of structure, through which they could crawl to enter the cell.

1. Which membrane structure could these hydrophilic molecules (people) pass through?
   a. A phospholipid
   b. A glycolipid
   c. A transmembrane cholesterol
   d. A channel protein

Farther into the cell, Sunil and his father entered what looked like a maze or a network of tunnels. Some of the transparent walls were studded on the outside with what looked like rocks, while other branching tunnels had smooth walls. They followed this maze until they came to another sign telling them they had arrived at the nucleus.

2. What organelle did the maze represent?
   a. Golgi apparatus
   b. Endoplasmic reticulum
   c. Mitochondrion
   d. Microtubules
3. What were the "rocks" stuck to the outside of the walls?
   a. Lysosomes
   b. Peroxisomes
   c. Ribosomes
   d. Mitochondria

After exploring the nucleus, Sunil and his father looked for a way to exit the cell. They had to work their way through a meshwork of plastic pipes, ropes, and yarn designed to represent the cell's cytoskeleton.

4. Which cell fiber type did the pipes (the thickest of the strands) represent?
   a. Microtubules
   b. Microfilaments
   c. Microvilli
   d. Intermediate filaments

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

FUNCTIONAL ANATOMY OF CELLS

A. The typical cell (Figure 3-1)
   1. Also called *composite cell*
   2. Vary in size; all are microscopic (Table 3-1)
   3. Vary in structure and function (Table 3-2)

B. Cell structures
   1. Plasma membrane—separates the cell from its surrounding environment
   2. Cytoplasm—thick gel-like substance inside the cell composed of numerous organelles suspended in watery cytosol; each type of organelle is suited to perform particular functions (Figure 3-2)
   3. Nucleus—large membranous structure near the center of the cell

CELL MEMBRANES

A. Each cell contains a variety of membranes
   1. Plasma membrane (Figure 3-3)—outer boundary of cell
   2. Membranous organelles—sacs and canals made of the same material as the plasma membrane

B. Fluid mosaic model—theory explaining how cell membranes are constructed
   1. Molecules of the cell membrane are arranged in a sheet
   2. The mosaic of molecules is fluid; that is, the molecules are able to float around slowly
   3. This model illustrates that the molecules of the cell membrane form a continuous sheet

C. Chemical attractions are the forces that hold membranes together

D. Groupings of membrane molecules form rafts that float as a unit in the membrane (Figure 3-4)
   1. Rafts may pinch inward to bring material into the cell or organelle
   2. Primary structure of a cell membrane is a double layer of phospholipid molecules
   3. Heads are hydrophilic (water loving)
   4. Tails are hydrophobic (water fearing)
   5. They arrange themselves in bilayers in water
   6. Cholesterol molecules are scattered among the phospholipids to allow the membrane to function properly at body temperature
   7. Most of the bilayer is hydrophobic; therefore water or water-soluble molecules do not pass through easily

E. Integral membrane proteins (IMPs) (Table 3-4)
   1. A cell controls what moves through the membrane by means of IMPs embedded in the phospholipid bilayer
   2. Some IMPs have carbohydrates attached to them and as a result form glycoproteins that act as identification markers
   3. Some IMPs are receptors that react to specific chemicals, sometimes permitting a process called *signal transduction*

CYTOPLASM AND ORGANELLES

A. Cytoplasm—gel-like internal substance of cells that includes many organelles suspended in watery intracellular fluid called *cytosol*

B. Two major groups of organelles (Table 3-3)
   1. Membranous organelles are sacs or canals made of cell membranes
   2. Nonmembranous organelles are made of microscopic filaments or other nonmembranous materials

C. Endoplasmic reticulum (Figure 3-5)
   1. Made of membranous-walled canals and flat, curving sacs arranged in parallel rows throughout the cytoplasm; extend from the plasma membrane to the nucleus
   2. Proteins move through the canals
   3. Two types of endoplasmic reticulum
      a. Rough endoplasmic reticulum
         (1) Ribosomes dot the outer surface of the membranous walls
         (2) Ribosomes synthesize proteins, which move toward the Golgi apparatus and then eventually leave the cell
         (3) Function in protein synthesis and intracellular transportation
      b. Smooth endoplasmic reticulum
         (1) No ribosomes border the membranous wall
         (2) Functions are less well established and probably more varied than for the rough endoplasmic reticulum
         (3) Synthesizes certain lipids and carbohydrates and creates membranes for use throughout the cell
         (4) Removes and stores Ca^{++} from the cell's interior

D. Ribosomes (Figure 3-6)
   1. Many are attached to the rough endoplasmic reticulum and many lie free, scattered throughout the cytoplasm
   2. Each ribosome is a nonmembranous structure made of two pieces, a large subunit and a small subunit; each subunit is composed of rRNA and protein
   3. Ribosomes in the endoplasmic reticulum make proteins for "export" or to be embedded in the plasma membrane; free ribosomes make proteins for the cell's domestic use

E. Golgi apparatus
   1. Membranous organelle consisting of cisternae stacked on one another and located near the nucleus (Figure 3-7)
   2. Processes protein molecules from the endoplasmic reticulum (Figure 3-8)
   3. Processed proteins leave the final cisterna in a vesicle; contents may then be secreted to outside the cell

F. Lysosomes (Figure 3-9)
   1. Made of microscopic membranous sacs that have "pinched off" from Golgi apparatus
   2. The cell's own digestive system; enzymes in lysosomes digest the protein structures of defective cell parts, including integral membrane proteins, and particles that have become trapped in the cell

G. Proteasomes (Figure 3-10)
   1. Hollow, protein cylinders found throughout the cytoplasm
   2. Break down abnormal/misfolded proteins and normal proteins no longer needed by the cell (and which may cause disease)
   3. Break down protein molecules one at a time by tagging each one with a chain of ubiquitin molecules, unfolding it as it enters the proteasome, and then breaking apart peptide bonds

H. Peroxisomes
   1. Small membranous sacs containing enzymes that detoxify harmful substances that enter the cells
   2. Often seen in kidney and liver cells

I. Mitochondria (Figure 3-11)
   1. Made up of microscopic sacs; wall composed of inner and outer membranes separated by fluid; thousands of particles make up enzyme molecules attached to both membranes
   2. The "power plants" of cells; mitochondrial enzymes catalyze series of oxidation reactions that provide nearly most of a cell's energy supply
   3. Each mitochondrion has a DNA molecule, which allows it to produce its own enzymes and replicate copies of itself

NUCLEUS

A. Definition—spherical body in center of cell; enclosed by an envelope with many pores

B. Structure (Figure 3-12)
   1. Consists of a nuclear envelope (composed of two membranes, each with essentially the same molecular structure as the plasma membrane) surrounding nucleoplasm
      a. Nuclear envelope has holes called *nuclear pores*
      b. Nuclear pore complexes (NPCs) are elaborate gateways into and out of the nucleus (Figure 3-13)
   2. Contains DNA (heredity molecules), which appear as:
      a. Chromatin threads or granules in nondividing cells
      b. Chromosomes in early stages of cell division

C. Functions of the nucleus are functions of DNA molecules; DNA determines both the structure and function of cells and heredity

CYTOSKELETON

A. The cell's internal supporting framework (Figure 3-14)
   1. Made up of tiny, flexible fibers and rigid, rodlike pieces
   2. Provides support for cell shape
   3. Can move the cell or its parts
   4. Detects changes inside and outside the cell

B. Cell fibers
   1. Intricately arranged fibers of varying length that form a three-dimensional, irregularly shaped lattice
   2. Fibers appear to support the endoplasmic reticulum, mitochondria, and "free" ribosomes
   3. Microfilaments (Figure 3-15)—smallest cell fibers
      a. Serve as "cellular muscles"
      b. Made of thin, twisted strands of protein molecules that lie parallel to the long axis of the cell
      c. Can slide past each other and cause shortening of the cell
   4. Intermediate filaments—twisted protein strands slightly thicker than microfilaments; form much of the supporting framework in many types of cells
   5. Microtubules—tiny, hollow tubes that are the thickest of the cell fibers
      a. Made of protein subunits arranged in a spiral fashion
      b. Their function is to move things around inside the cell

C. Centrosome (Figure 3-16)
   1. An area of the cytoplasm near the nucleus that coordinates the building and breaking apart of microtubules in the cell
   2. Nonmembranous structure also called the *microtubule organizing center (MTOC)*
   3. Plays an important role during cell division
   4. The general location of the centrosome is identified by the centrioles

D. Molecular motors
   1. Motor proteins (Figure 3-17) include dynein, myosin, and kinesin
   2. Molecular motors can pull larger structures along microtubules and microfilaments as if along a track—providing intracellular transport and movements of the entire cell

E. Cell extensions
   1. Cytoskeleton forms projections that extend the plasma membrane outward to form tiny, fingerlike processes
   2. There are three types of these processes; each has specific functions (Figure 3-18)
      a. Microvilli—found in epithelial cells that line the intestines and other areas where absorption is important; they help increase the surface area manyfold
      b. Cilia and flagella—cell processes that have cylinders made of microtubules and molecular motors at their core (Figure 3-19)
         (1) Cilia are shorter and more numerous than flagella; some cilia found in groups have coordinated oarlike movements that brush material past the cell's surface; all cilia have sensory functions
         (2) Flagella are found only on human sperm cells; flagella move with a tail-like movement that propels the sperm cell forward

CELL CONNECTIONS

A. Cells are held together by fibrous nets that surround groups of cells (e.g., muscle cells), or cells have direct connections to each other

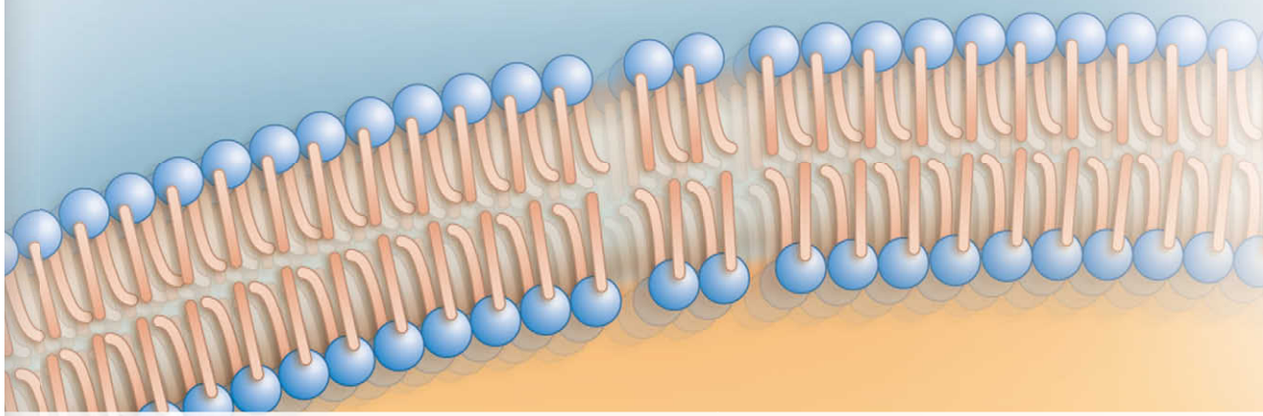
B. Three types of direct cell connections (Figure 3-20)
   1. Desmosome
      a. Fibers on the outer surface of each desmosome interlock with each other; anchored internally by intermediate filaments of the cytoskeleton
      b. Spot desmosomes are like "spot welds" at various points connecting adjacent membranes
      c. Belt desmosomes encircle the entire cell

2. Gap junctions—membrane channels of adjacent plasma membranes adhere to each other; have two effects:
   a. Form gaps or "tunnels" that join the cytoplasm of two cells
   b. Fuse two plasma membranes into a single structure
3. Tight junctions
   a. Occur in cells that are joined by "collars" of tightly fused material
   b. Molecules cannot permeate the cracks of tight junctions
   c. Occur in the lining of the intestines and other parts of the body where it is important to control what gets through a sheet of cells

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. What is the range in human cell diameters?
2. List the three main cell structures.
3. Describe the location, molecular structure, and width of the plasma membrane.
4. Explain the communication function of the plasma membrane, its transportation function, and its identification function.
5. Briefly describe the structure and function of the following cellular structures/organelles: endoplasmic reticulum, ribosomes, Golgi apparatus, mitochondria, lysosomes, proteasomes, peroxisomes, cytoskeleton, cell fibers, centrosome, centrioles, and cell extensions.
6. Describe the three types of intercellular junctions. What are the special functional advantages of each?
7. Describe briefly the functions of the nucleus and the nucleoli.
8. Name three kinds of micrography used in this book to illustrate cell structures. What perspective does each give that the other two do not?



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Using the complementarity principle that cell structure is related to its function, discuss how the shapes of the nerve cell and muscle cell are specific to their respective functions.
2. What is the relationship among ribosomes, endoplasmic reticulum, Golgi apparatus, and plasma membrane? How do they work together as a system?

The Big Picture: Cell Physiology and the Whole Body, 108

Mechanisms of Disease, 108

Case Study, 110

The cell is the basic functional unit of the body, so it is no wonder that a good understanding of human physiology begins with an overview of cell function. In Chapter 3, you were introduced to the basic structures of the cell. That discussion also included an introduction to some of the important functions of the cell. In this chapter, we take that a step further.

We begin with a brief study of cell membrane transport—a concept that is the foundation for understanding the function of muscles, nerves, glands, hormones, and most other concepts of human physiology. Then, an overview of cell metabolism will set the stage for understanding the "body chemistry" of the whole human organism. That will lead us into Chapter 5, where we explore concepts of cell growth and reproduction.

MOVEMENT OF SUBSTANCES THROUGH CELL MEMBRANES

If a cell is to survive, it must be able to move substances to where they are needed. We already know one way that cells move organelles within the cytoplasm: pushing or pulling performed by the cytoskeleton. A cell must also be able to move various molecules in and out through the plasma membrane, as well as from one membranous compartment to another within the cell. In this first part of the chapter, we explore some of the basic mechanisms a cell uses to move substances across its membranes.

Before beginning a discussion of individual processes, we must realize that membrane transport processes can be labeled as *passive* or *active*. Passive processes do not require any energy expenditure or "activity" of the cell membrane—the particles move by using energy that they already have. Active processes, on the other hand, do require the expenditure of metabolic energy by the cell. In active processes the transported particles are actively "pulled" across the membrane. Keep this distinction in mind as we explore the basic mechanisms of cell membrane transport.

Passive Transport Processes

DIFFUSION

Often, molecules simply spread or *diffuse* through the membranes. The term **diffusion** refers to a natural phenomenon caused by the tendency of small particles to spread out evenly within any given space. All molecules in a solution bounce around in short, chaotic paths. As they collide with one another, they tend to spread out, or diffuse. Think of the example of a lump of sugar dissolving in water (Figure 4-1). Right after the lump is placed in the water, the sugar molecules are very close to one another—the sugar concentration in the lump is very high. As the sugar molecules dissolve, they begin colliding with one another and thus push each other away. Given enough time, the sugar molecules eventually diffuse evenly throughout the water.

Notice that during diffusion, molecules move from an area of high concentration to an area of low concentration. It is not surprising, then, that molecules tend to move from the side of the membrane with high concentration to the side of the membrane with a lower concentration of that molecule. Another way of stating this principle is to say that diffusion occurs down a **concentration gradient.** A concentration gradient is simply a measurable difference in concentration from one area to another. Because molecules spread from the area of *high* concentration to the area of *low* concentration, they spread down the concentration gradient.

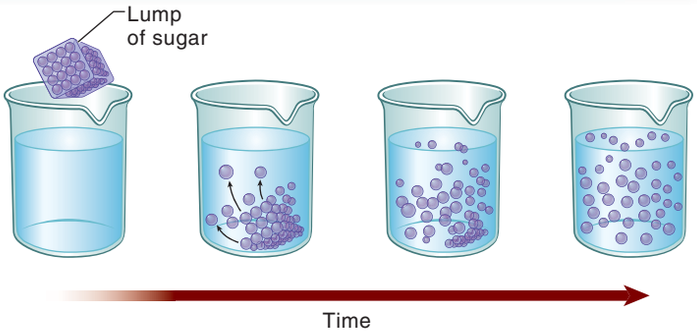

FIGURE 4-1

Diffusion. The molecules of a lump of sugar are very densely packed when they enter the water. As sugar molecules collide frequently in the area of high concentration, they gradually spread away from each other—toward the area of lower concentration. Eventually, the sugar molecules become evenly distributed.

Perhaps the best way to learn the principle of diffusion across a membrane is to look at the example illustrated in Figure 4-2. Here we have different mixtures of a *solute* (dissolved substance) in water. Suppose a 10% solute mixture is separated from a 20% solution by an artificial membrane. Suppose further that the membrane has pores in it that allow solute molecules to pass through, as well as pores that allow water molecules to pass. Solute particles and water molecules darting about the solution collide with each

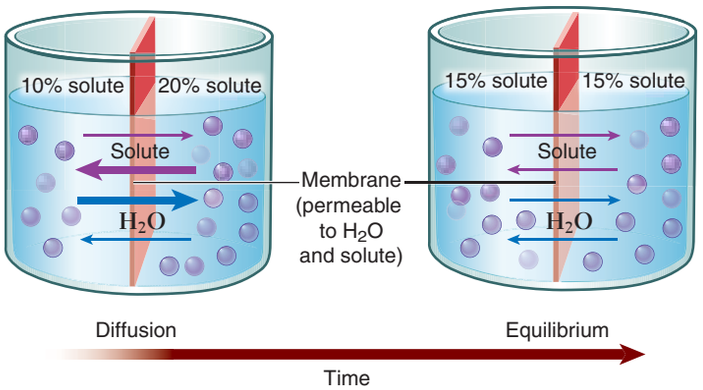

FIGURE 4-2

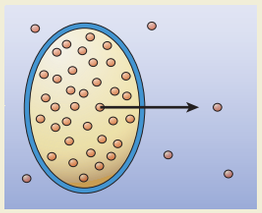
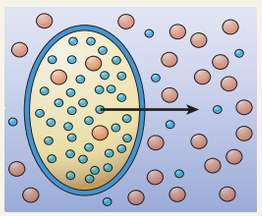
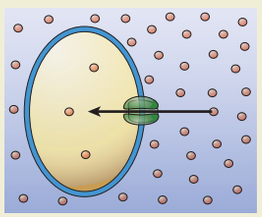
Diffusion through a membrane. Note that the membrane allows solute (a dissolved particle) and water to pass and that it separates a 10% solution from a 20% solution. The container on the left shows the two solutions separated by the membrane at the start of diffusion. The container on the right shows the result of diffusion after time.

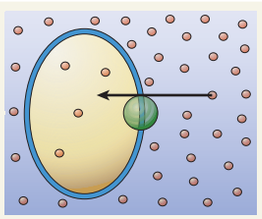
other and with the membrane. Some inevitably hit the membrane pores from the 20% solute side, and some hit the membrane pores from the 10% side. Just as inevitably, some pass through the pores in both directions. For a while, more solute particles enter the pores from the 20% side simply because they are more numerous there than on the 10% side. More of these particles, therefore, move through the membrane from the 20% solute solution into the 10% solute solution than diffuse through it in the opposite direction. In other words, the overall direction of diffusion is from the side where the concentration is higher (20%) to the side where the concentration is lower (10%).

During the time that diffusion of solute particles is taking place, diffusion of water molecules is also going on. Remember, the direction of diffusion of any substance is always down that substance's concentration gradient. Water molecules are more concentrated on the 10% solute solution side because the solution is more dilute—or watery—on that side. Thus water molecules move from the 10% solute solution side to the 20% solute solution side. As Figure 4-2 shows, diffusion of both kinds of molecules eventually produces a dynamic form of equilibrium in which both solutions have equal concentrations. We say that *equilibration* has occurred.









Dynamic equilibrium is not a static state with no movement of molecules across the membrane. Instead, it is a balanced state in which the number of molecules of a substance bouncing to one side of the membrane exactly equals the number of molecules of that substance that are bouncing to the other side. Once equilibration has occurred, overall diffusion may have stopped, but balanced diffusion of small numbers of molecules may continue.

SIMPLE DIFFUSION

Now that we know that concentration gradients drive diffusion, we can explore how the molecules actually find a way through a cell membrane (Table 4-1). Sometimes molecules diffuse directly through the bilayer of phospholipid molecules that forms most of a cell membrane. As discussed in Chapter 3, lipid-soluble molecules can pass through easily. As Figure 4-3 shows, small hydrophobic molecules such as oxygen (O_2) and carbon dioxide (CO_2) can diffuse directly through the phospholipid bilayer. Small, uncharged particles such as water (H_2O) and urea can diffuse only slightly. Such molecules simply dissolve in the phospholipid fluid, diffuse through this fluid, and then move into the water solution on the other side of the membrane. When molecules pass directly through the membrane, the process is called **simple diffusion.**

When molecules are allowed to cross a membrane, they are said to *permeate* the membrane. Thus a particular membrane is *permeable* to a particular molecule only if it can pass through that

TABLE 4-1 Passive Transport Processes

PROCESS		DESCRIPTION	EXAMPLES
Simple diffusion		Movement of particles through the phospholipid bilayer or through channels from an area of high concentration to an area of low concentration—that is, down the concentration gradient	Movement of carbon dioxide out of all cells
Osmosis		Diffusion of water through a selectively permeable membrane in the presence of at least one impermeant solute (often involves both simple and channel-mediated diffusion)	Diffusion of water molecules into and out of cells to correct imbalances in water concentration
Channel-mediated passive transport (facilitated diffusion)		Diffusion of particles through a membrane by means of channel structures in the membrane (particles move down their concentration gradient)	Diffusion of sodium ions into nerve cells during a nerve impulse
Carrier-mediated passive transport (facilitated diffusion)		Diffusion of particles through a membrane by means of carrier structures in the membrane (particles move down their concentration gradient)	Diffusion of glucose molecules into most cells

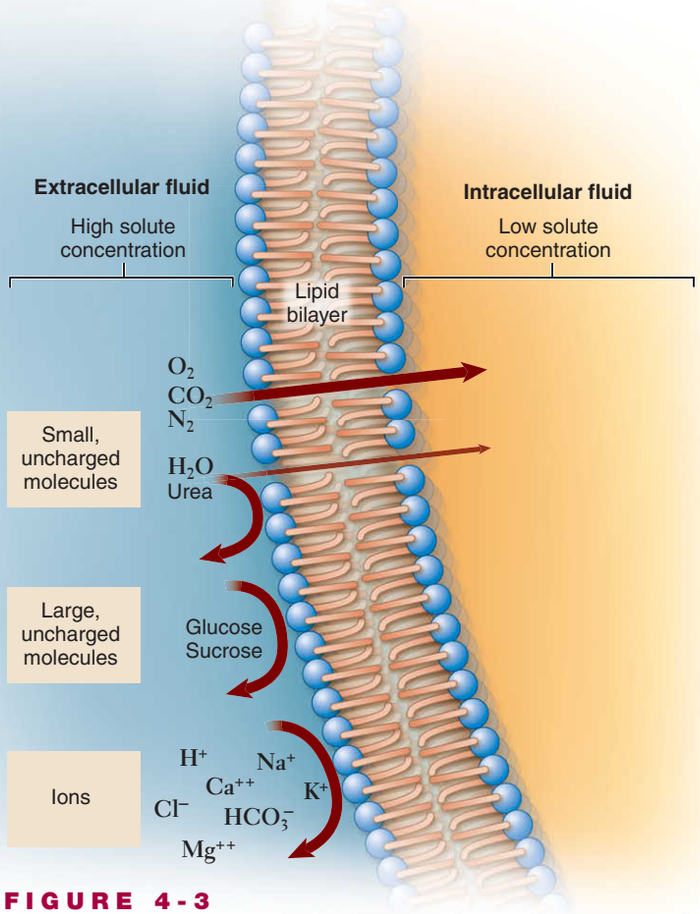


FIGURE 4-3

Simple diffusion through a phospholipid bilayer. Some small, uncharged molecules can easily pass through the phospholipid membrane, but water and urea (a waste product of protein catabolism) rarely get through the membrane. Larger uncharged molecules and ions (charged molecules) may not pass through the phospholipid membrane at all.

membrane. We say that a molecule is *permeant* if it is able to diffuse across a particular membrane. It is *impermeant* if it is unable to diffuse across the membrane.

Box 4-1 shows how the process of diffusion can be harnessed to "clean up" the blood after a person's kidneys fail.

OSMOSIS

A special case of diffusion is called **osmosis.** Osmosis is the diffusion of water through a selectively permeable membrane. Often, water is able to diffuse across a living membrane that does not allow diffusion of one or more other substances. Thus water is permeant and therefore can equilibrate its concentration on both sides of the membrane, but the impermeant solutes cannot.

But how can this be? If you look at Figure 4-3, you see that water barely passes through phospholipid membranes! In 1988 Peter Agre finally solved this mystery by proving the existence of small water channels in cell membranes called *aquaporins* (meaning "water pores"). It is the presence of aquaporins that make membranes permeable to water. We will see how such channels allow other substances to move easily across membranes later. For now, let us focus on osmosis—a very important type of diffusion in the body.

First, let us look at an example of osmosis. Imagine that you have a 10% albumin solution separated by a membrane from a 5% albumin solution (Figure 4-4). Assume that the membrane has water pores and is freely permeable to water but impermeable to albumin. The water molecules diffuse or *osmose* through the membrane from the area of high water concentration to the area of low water concentration. That is, the water moves from the more dilute 5% albumin solution to the less dilute 10% albumin solution. Although equilibrium is eventually reached, the albumin does not diffuse across the membrane. Only the water diffuses. Because of this osmosis, one solution loses volume and the other solution gains volume (see Figure 4-4).

Unlike the open container pictured in Figure 4-4, cells are closed containers. They are enclosed by their plasma membranes. Actually, most of the body is composed of closed compartments such as cells, blood vessels, tubes, and bladders. In closed compartments, such as a toy water balloon, changes in volume also mean changes in pressure. Adding volume to a cell by osmosis increases its pressure, just as adding volume to a water balloon increases its pressure. Water pressure that develops in a solution as a result of osmosis into that solution is called **osmotic pressure.** Taking this principle a step further, we can state that osmotic pressure develops in the solution that originally has the higher concentration of impermeant solute.

Potential osmotic pressure is the maximum osmotic pressure that *could develop* in a solution when it is separated from pure water by a selectively permeable membrane. **Actual osmotic pressure,** on the other hand, is pressure that *already has developed* in a solution by means of osmosis. Actual osmotic pressure is easy to measure because it is already there.

Because potential osmotic pressure is a *prediction* of what the actual osmotic pressure would be, it cannot be measured directly. What determines a solution's potential osmotic pressure? The answer, simply put, is the concentration of particles of impermeant

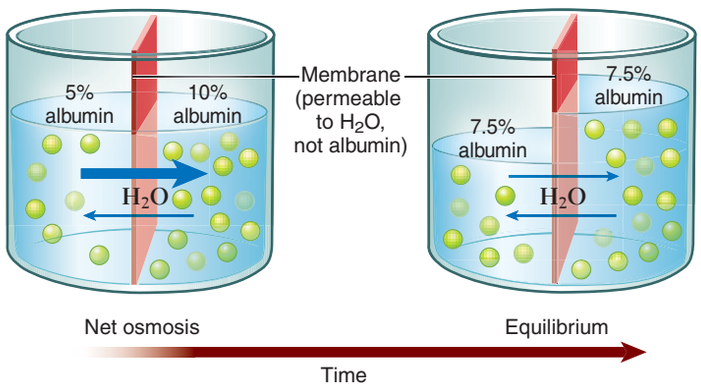

FIGURE 4-4

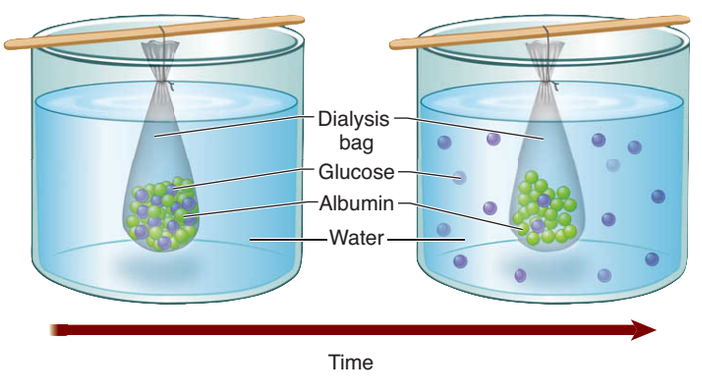
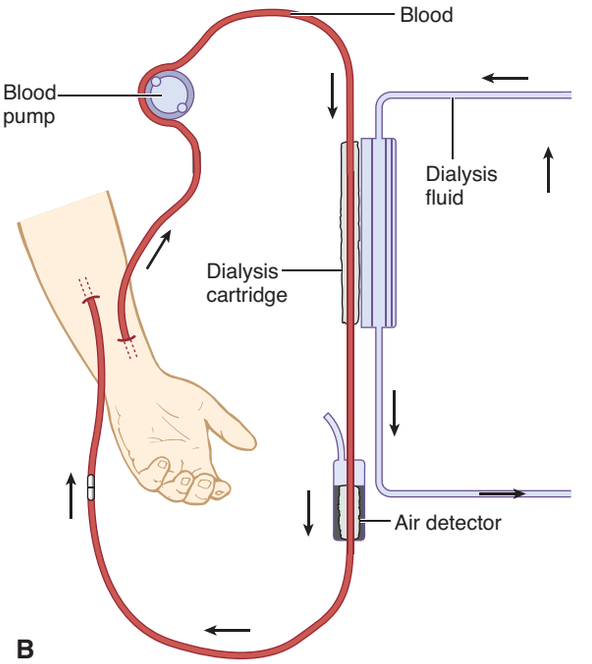


Osmosis. Osmosis is the diffusion of water through a selectively permeable membrane. The membrane shown in this diagram is permeable to water but not to albumin. Because there are relatively more water molecules in 5% albumin than 10% albumin, more water molecules osmose from the more dilute into the more concentrated solution (as indicated by the larger arrow in the left diagram) than osmose in the opposite direction. The overall direction of osmosis, in other words, is toward the more concentrated solution. Net osmosis produces the following changes in these solutions: (1) their concentrations equilibrate, (2) the volume and pressure of the originally more concentrated solution increase, and (3) the volume and pressure of the other solution decrease proportionately.

Box 4-1 | Dialysis



Under certain circumstances, a type of diffusion called **dialysis** may occur. Dialysis is a form of diffusion in which the selectively permeable nature of a membrane causes the separation of smaller solute particles from larger solute particles. *Solutes* are the particles dissolved in a *solvent* such as water. Together, the solutes and solvents form a mixture called a *solution.*

Part A of the figure illustrates the principle of dialysis. A bag made of dialysis membrane—material with microscopic pores—is filled with a solution containing glucose, water, and albumin (protein) molecules and immersed in a container of pure water. Both water and glucose molecules are small enough to pass through the pores in the dialysis membrane. Albumin molecules, like all protein molecules, are very large and do not pass through the membrane's pores. Because of differences in concentration, glucose molecules diffuse out of the bag as small water molecules diffuse into the bag. Despite a concentration gradient, the albumin molecules do not diffuse out of the bag. Why not? Because they simply will not fit through the tiny pores in the membrane. After some time has passed, the large solutes are still trapped within the bag, but most of the smaller solutes are outside of it.

The principle of dialysis can be used in medicine to treat patients with kidney failure. In **hemodialysis** (part B of the figure), blood pumped from a patient is exposed to a dialysis membrane that separates the blood from a clean, osmotically balanced dialysis fluid. Small solutes such as urea and various ions can diffuse through the membrane to reach an equilibrium, thus removing them from the blood. The larger plasma proteins (including albumin) and blood cells remain in the blood, which is returned to the patient's body. In hemodialysis, the process of dialysis is used to "clean up" the patient's blood because the kidneys have failed to perform this task.

A

B

A, Dialysis. A dialysis bag containing glucose, water, and albumin (protein) molecules is suspended in pure water. Over time, the smaller solute molecules (glucose) diffuse out of the bag. The larger solute molecules (albumin) remain trapped in the bag because the bag is impermeable to them. Thus dialysis is diffusion that results in separation of small and large solute particles. **B, Hemodialysis.** In hemodialysis, the patient's blood is pumped through a dialysis cartridge, which has a semipermeable membrane that separates the blood from the clean dialysis fluid. As dialysis occurs, some of the urea and other small solutes in the blood diffuse into the dialysis fluid whereas the larger solutes (plasma proteins) and blood cells remain in the blood.

solutes dissolved in the solution. Thus one can predict the direction of osmosis and the amount of pressure it will produce by knowing the concentrations of impermeant solutes in two solutions.

The concept of osmosis and osmotic pressure has very important practical consequences in human physiology and medicine. Homeostasis of volume and pressure is necessary to maintain the healthy functioning of human cells. The volume and pressure of body cells tend to remain fairly constant because intracellular fluid (fluid inside the cell) is maintained at about the same potential osmotic pressure as extracellular fluid (fluid outside the cell). A fluid that has the same potential osmotic pressure as a cell is said to be **isotonic** to the cell (Figure 4-5, B). Isotonic comes from the word parts *iso-*, meaning "same," and *-tonic*, referring to "pressure." The isotonic solution and cytosol have the same potential osmotic pressure because they have the same concentration of impermeant solutes.

A human cell placed in a concentrated solution of impermeant solutes will shrivel up. Look at the example of a red blood cell in Figure 4-5, C. The pictured cell is in a solution with a higher concentration of impermeant solutes than that found in the cell and, therefore, has a higher potential osmotic pressure. The extracellular solution is said to be **hypertonic** (higher pressure) to

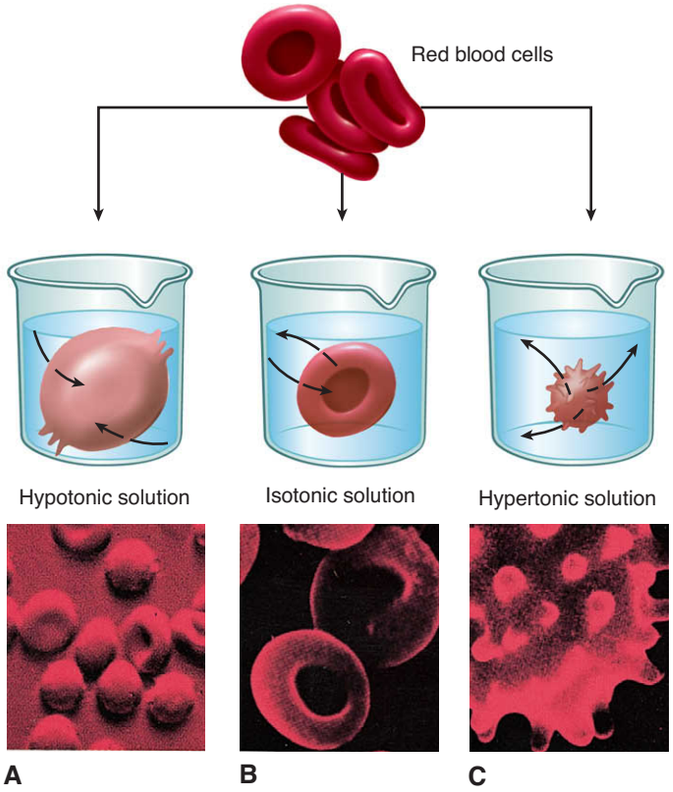


FIGURE 4-5

Effects of osmosis on cells. A, Normal red blood cells placed in a hypotonic solution may swell (as the scanning electron micrograph shows) or even burst (as the drawing shows). This change results from the inward diffusion of water (osmosis). **B,** Cells placed in an isotonic solution maintain constant volume and pressure because the potential osmotic pressure of the intracellular fluid matches that of the extracellular fluid. **C,** Cells placed in a solution that is hypertonic lose volume and pressure as water osmoses out of the cell into the hypertonic solution. The "spikes" seen in the scanning electron micrograph are rigid microtubules of the cytoskeleton. These supports become visible as the cell "deflates."

the intracellular solution (cytosol). Cells placed in solutions that are hypertonic to intracellular fluid always shrivel. If cells shrivel too much, they may become permanently damaged—or even die. Obviously, this fact is medically important. Large amounts of solutes cannot be introduced into the body without considering the effect they will have on the concentration of impermeant solutes in the extracellular fluid. If a treatment or procedure causes extracellular fluid to become hypertonic to the cells of the body, serious damage may occur.

If a human cell is placed in a very dilute solution, such as pure water, the cell may swell. If it expands enough, the cell may burst, or *lyse*. Look at the example of a red blood cell in Figure 4-5, A. This cell is placed in a solution that is **hypotonic** (lower pressure) to the intracellular fluid. Hypotonic solutions tend to lose pressure because they have a lower concentration of impermeant solutes, and thus a higher water concentration, than the opposite solution. Water always osmoses from the hypotonic solution to the cytosol.

In summary, we can make several generalizations about osmosis. First, osmosis is the diffusion of water across a membrane that limits the diffusion of at least some of the solute molecules. That is, at least one impermeant solute must be present. Second, osmosis results in the gain of volume (and thus pressure) on one side of the membrane and loss of volume (and pressure) on the other side of the membrane. Third, the direction of osmosis and the resulting changes in pressure can be predicted if you know the potential osmotic pressure or *tonicity* of the solution outside the plasma membrane.

Do you want to know how to calculate the potential osmotic pressure of any solution? Check out ***Determining the Potential Osmotic Pressure of a Solution*** online at ***A&P Connect.***

evolve

FACILITATED DIFFUSION

For a long time, biologists thought that simple diffusion was the only way that molecules could diffuse through a cell membrane. They found that water-soluble molecules such as sodium ions (Na^+) and glucose molecules could not pass through an artificial phospholipid bilayer easily (see Figure 4-3). However, they also found that indeed such small, water-soluble molecules could pass through living cell membranes quickly. Even water molecules, which pass through the thin phospholipid membrane only rarely, diffuse very rapidly through most living cell membranes. It was not until the presence of various transport proteins, such as membrane channels and membrane carriers, was discovered that we understood how these molecules diffuse across cell membranes. These membrane transporters enable a kind of mediated passive transport that is often called **facilitated diffusion.**

Channel-Mediated Passive Transport

As you already know, cell membranes possess protein "tunnels," better known as *membrane channels* (see Table 3-4, p. 72, and Figure 4-6). Membrane channels are pores through which water

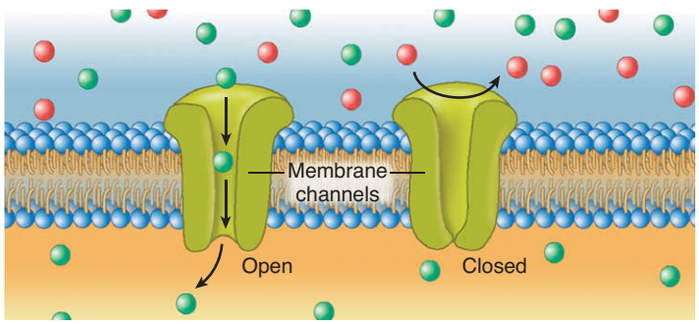

FIGURE 4-6

Membrane channels. Gated channel proteins form tunnels through which only specific molecules may pass—as long as the "gates" are open. Molecules that do not have a specific shape and charge are never permitted to pass through the channel. Notice that the transported molecules move from an area of high concentration to an area of low concentration. The cell membrane is said to be permeable to the type of molecule in question. Filtration, another type of passive transport process, is discussed in Box 4-2 on p. 97.

molecules, specific ions, or other small, water-soluble molecules can pass. For example, sodium ions (Na^+) pass only through *sodium channels* and chloride ions (Cl^-) pass only through *chloride channels*. Recall that water diffuses through aquaporins, which are water-specific channels, during osmosis. Membrane channels can exhibit such *specificity* because their molecular structure prevents molecules of the wrong shape and the wrong pattern of charges to pass through the channel. Thus living membranes can be permeable to some molecules but not to others, depending on the type of channels present.

As Figure 4-6 shows, the permeability of a membrane can also be affected by the opening and closing of membrane channels. Because channels can open or close, they are sometimes called *gated channels*. The active or "open" state can be almost immediately changed to the "closed" state, or changed from closed to open, by various triggering mechanisms. Some gated channels are triggered by electrical changes (voltage), others by light, and still others by mechanical or chemical stimuli. We will look at these various types of triggering mechanisms in later chapters. Open-gated channels may under certain conditions become inactive, stopping the flow of molecules and becoming insensitive to trigger stimuli, before actually closing and resuming sensitivity to stimuli.

Because a living cell membrane can limit the diffusion of some molecules by opening or closing channels in different situations, we say the membrane is *selectively permeable*. Membrane channel structure often permits diffusion in only one direction. So the cell can also determine whether to allow certain molecules to pass in either direction (depending on the concentration gradient, of course) or in only one direction (when the concentration gradient permits).

Aquaporins are among the more recently discovered types of membrane channels. As their name suggests, these channels permit water molecules to diffuse through a cell membrane much more rapidly than by simple diffusion. Aquaporins are thought to be responsible for the very rapid changes in blood cell volume during osmosis illustrated in Figure 4-5.

Because ions move down their concentration gradients as they pass through channels, this type of facilitated diffusion is passive and thus called *channel-mediated passive transport*.

Carrier-Mediated Passive Transport

Molecules may move down their concentration gradient by passing through a different type of membrane transporter called a *membrane carrier*. Thus the carrier may facilitate diffusion in a process called *carrier-mediated passive transport*.

As Figure 4-7 shows, the carrier structure attracts a solute to a binding site, changes its shape, and then releases the solute to the other side of the membrane. This mechanism differs from channel-mediated transport, which does not involve binding the solute molecule and changing shape to release the bound solute. Carrier reactions are reversible and may thus transport molecules in either direction, depending on the concentration gradient.

As in channel-mediated and simple diffusion, carrier-mediated diffusion also transports substances down a concentration gradient (that is, from high to low concentration). An example is the

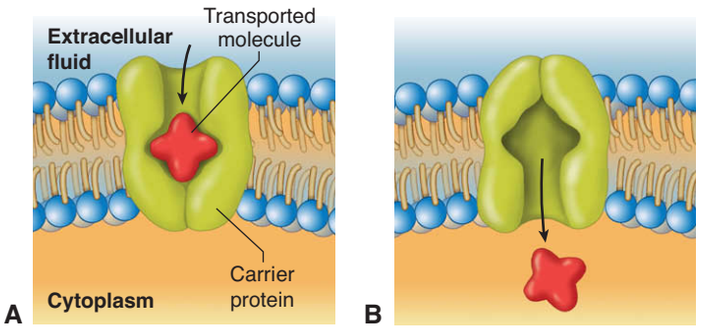

FIGURE 4-7

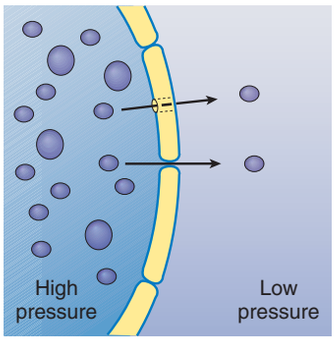
Membrane carrier. In carrier-mediated transport, a membrane-bound carrier protein attracts a solute molecule to a binding site **(A)** and changes shape in a manner that allows the solute to move to the other side of the membrane **(B)**. Passive carriers may transport molecules in either direction, depending on the concentration gradient.

ADP-ATP (adenosine diphosphate–adenosine triphosphate) carrier found in the membranes of the mitochondrion. This carrier moves ADP into the mitochondrion because the ADP concentration inside is kept low by constant conversion to ATP. Because ATP is thus kept constantly high inside the mitochondrion, ATP passes down its concentration gradient through the ADP-ATP carrier to the outside, where ATP is continually dropping (through use by cell processes).

ROLE OF PASSIVE TRANSPORT PROCESSES

Diffusion of any type is a passive process. In other words, the energy for transport through a membrane does not come from the membrane but from the energy of collision already possessed by the moving molecule. The only requirement of the cell is that it be permeable to the type of molecule in question. Because substances are moved down their concentration gradients, such passive transport tends to maintain an equilibrium of these substances.

We have explored many varieties of diffusion across a membrane, summarized in Table 4-1. Simple diffusion occurs when molecules dissolve directly through the phospholipid bilayer. Facilitated diffusion requires transport proteins in the membrane. The transporters could be channels, such as the water channels needed for osmosis or the ion channels needed to move sodium or potassium ions. The transporters could instead be carriers, such as those needed to move ADP and ATP into and out of the mitochondrion. Filtration, yet another type of passive transport process, is discussed in Box 4-2.



All of these passive transport mechanisms are needed to move critical substances into or out of cells and organelles to maintain an equilibrium. Considering the importance of homeostatic balance, you can see that passive transport is critical to human function. As you will discover in the last part of the chapter, many diseases and even death can result from malfunctions of these passive transport processes.

Box 4-2 | Filtration

Another important passive process for transport in the body is **filtration.** This form of transport involves the passing of water and permeable solutes through a membrane by the force of hydrostatic pressure. *Hydrostatic pressure* is the force, or weight, of a fluid pushing against a surface.

Filtration is movement of molecules through a membrane from an area of high hydrostatic pressure to an area of low hydrostatic pressure—that is, down a hydrostatic pressure gradient. Filtration most often transports substances through a sheet of cells. The force of pressure pushes the molecules through or between the cells that form the sheet. Because the filtration membrane does not allow larger particles through, filtration results in the separation of large and small particles, as you can see in the figure. This is similar to dialysis (Box 4-1, p. 94), except that dialysis is driven by a *concentration gradient.* Filtration is instead driven by a *hydrostatic pressure gradient.*

A simple model of filtration is found in many drip-type coffee makers. Ground coffee is placed in a porous paper filter cup in an upper container and boiling water is added. Gravity pulls downward on the mixture in the upper container, generating hydrostatic pressure against the bottom of the filter. The pores in the paper filter are large enough to let water molecules and other small particles pass through to a coffee pot below the filter. Most of the coffee grounds are too large to pass through the filter. The coffee in the pot below is called the *filtrate.*

Filtration. Particles small enough to fit through the pores in the filtration membrane move from the area of high hydrostatic pressure to the area of low hydrostatic pressure. This results in separation of small particles from larger particles.

How and where does filtration occur in the body? Most often, it occurs in tiny blood vessels called *capillaries,* which are found throughout the body. Hydrostatic pressure of the blood (blood pressure) generated by heart contractions, gravity, and other forces pushes water and small solutes out of the capillaries and into the interstitial spaces of a tissue. Blood cells and large blood proteins are too large to fit through pores in the capillary wall; therefore, they cannot be filtered out of the blood. Capillary filtration allows the blood vessels to supply tissues with water and other essential substances quickly and easily without losing its cells and blood proteins. Capillary filtration is also the first step used by the kidney to form urine.

Active Transport Processes

All the membrane transport processes that we have seen so far are passive processes. The force of movement comes from the concentration gradient—that is, from a physical force of nature. The driving force for active transport processes, on the other hand, comes from the cell itself. Energy of metabolism must be used by cells to force particles across a membrane that otherwise would not move across.

TRANSPORT BY PUMPS

Membrane transporters called *membrane pumps* carry out a transport process in which cellular energy is used to move molecules "uphill" through a cell membrane. By "uphill," we mean that the substance moves from an area of low concentration to an area of higher concentration. An actively transported substance moves *against* its concentration gradient. This is exactly the opposite of diffusion, in which a substance is transported *down* its concentration gradient—or "downhill." It is important to remember that molecules will not travel uphill on their own, anymore than a ball will roll uphill by itself. Molecules will travel uphill only when they are forced by pump mechanisms powered by cellular energy. Moving solutes in different directions is discussed in Box 4-3.

Active pumping is an extremely important process. It allows cells to move certain ions or other water-soluble particles to specific areas. For example, active *calcium pumps* in the membranes of muscle cells allow the cell to force nearly all of the intracellular calcium ions (Ca^{++}) into special compartments—or out of the cell entirely (Figure 4-8). This is important because a muscle cell cannot operate properly unless the intracellular Ca^{++} concentration

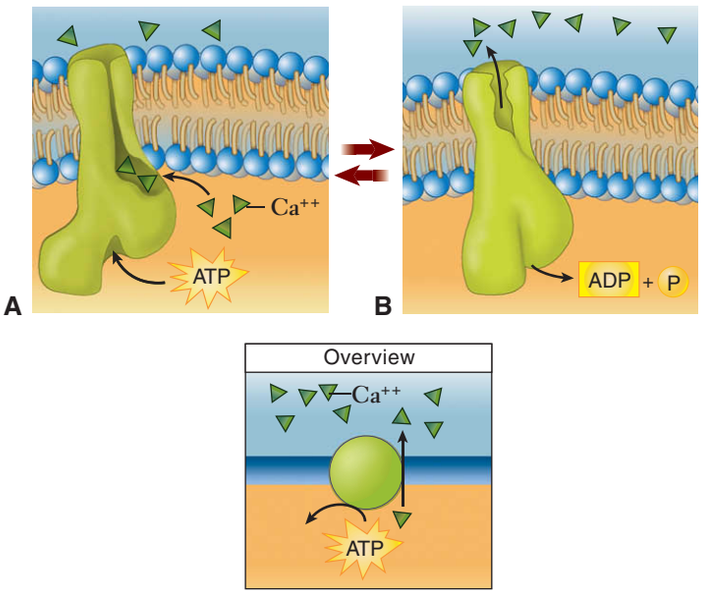


FIGURE 4-8

Calcium pump. A, Two calcium ions (Ca^{++}) enter the pump, and then adenosine triphosphate (ATP) associates with the activating center of the pump. **B,** As the energy released from ATP (forming adenosine diphosphate [ADP] + phosphate [P]) changes the shape of the pump, the Ca^{++} ions are released on the opposite side of the membrane. The small inset shows a simplified view of a calcium pump's action.

Box 4-3 | Transport of Different Solutes

In looking at different types of carriers and pumps in the body, we see that some transport only one type of molecule at a time. This type of transporter is often called a *uniporter.* For example, the GLUT uniporters in many cells passively move glucose from blood plasma into cells. *GLUT* is an acronym for *GLU*cose *T*ransporter. Figure 4-8 shows uniport of two Ca^{++} ions by a calcium pump.

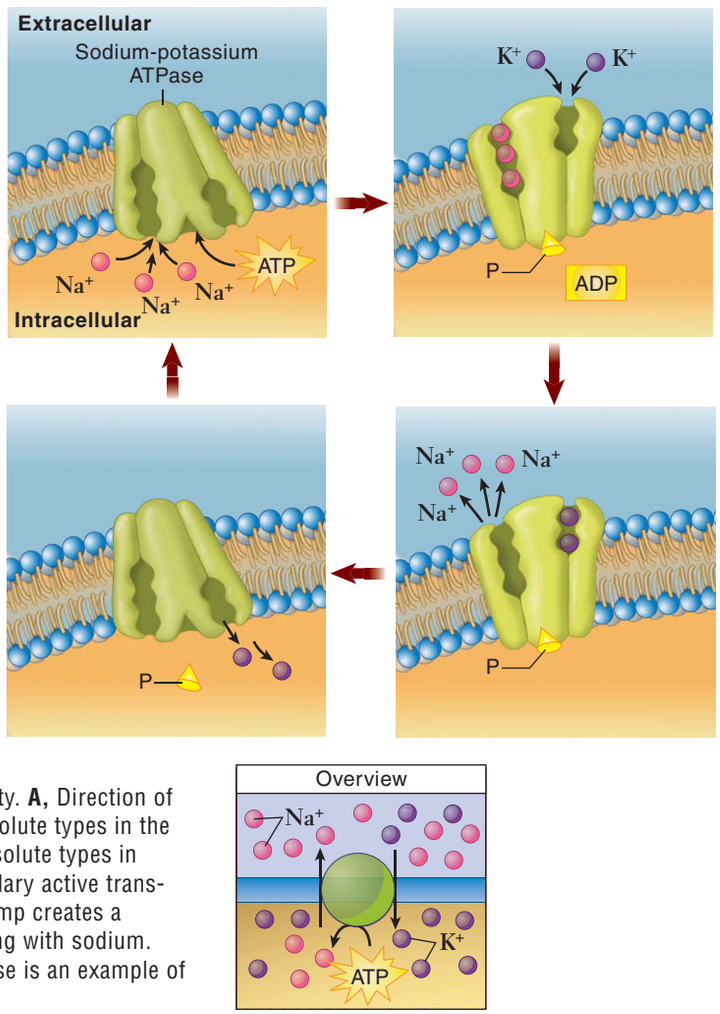
Symporters instead move two or more types of molecule in the same direction through a membrane. For example, the SGLT1 symporter in the digestive tract transports sodium ions and glucose together into absorptive cells. *SGLT1* is the acronym for *S*odium-*GL*ucose *T*ransporter *1.* Symport can also be called **cotransport.**

Antiporters, on the other hand, are transporters that move two different types of molecule in opposite directions at the same time. For example, *Band 3* antiporters in red blood cells passively exchange bicarbonate ions (HCO_3^-) for chloride ions (Cl^-) in opposite directions at the same time. Na^+-K^+-ATPase (sodium-potassium pump) actively antiports sodium ions and potassium ions in all cells of the body. Antiport can also be called **countertransport.**

Sometimes, active transport of one type of solute creates a concentration gradient that drives the passive transport of another solute. For example, in part B of the figure the active transport of sodium ions creates a concentration gradient that drives the cotransport of glucose along with sodium by a symport mechanism. In this case, the movement of sodium is an example of *primary active transport.* The movement of glucose, which depends on the sodium concentration gradient created by primary active transport, is an example of *secondary active transport.* This particular example of secondary active transport is often referred to as *sodium cotransport of glucose.*

is kept low during rest. Other cells use active transport pumps for similar purposes—that is, to create a concentration gradient of a particular solute.

One type of active transport pump, the *sodium-potassium pump*, operates in the plasma membrane of all human cells (Figure 4-9). It is essential for healthy cell survival. As its name suggests, the sodium-potassium pump actively transports sodium ions (Na^+) and potassium ions (K^+)—but in opposite directions. It transports sodium ions *out* of cells and potassium ions *into* cells. By so doing, the sodium-potassium pump maintains a lower sodium concentration in intracellular fluid than in the surrounding extracellular fluid. At the same time, this pump maintains a higher potassium concentration in the intracellular fluid than in the surrounding extracellular fluid. Both ions bind to the same membrane transporter, a molecule known as *sodium-potassium adenosine triphosphatase (Na-K ATPase).* Figure 4-9 shows that three Na^+ ions bind to sodium-binding sites on the pump's inner face. At the same time, an energy-containing adenosine triphosphate (ATP) molecule produced by the cell's mitochondria binds to the pump. The ATP breaks apart, and its stored energy is transferred to the pump. The pump then changes shape, releases the three Na^+ ions to the outside of the cell, and attracts two K^+ ions to its potassium-binding sites. The pump then returns to its original shape and releases the two K^+ ions and the remnant of the ATP molecule to the inside of the cell.



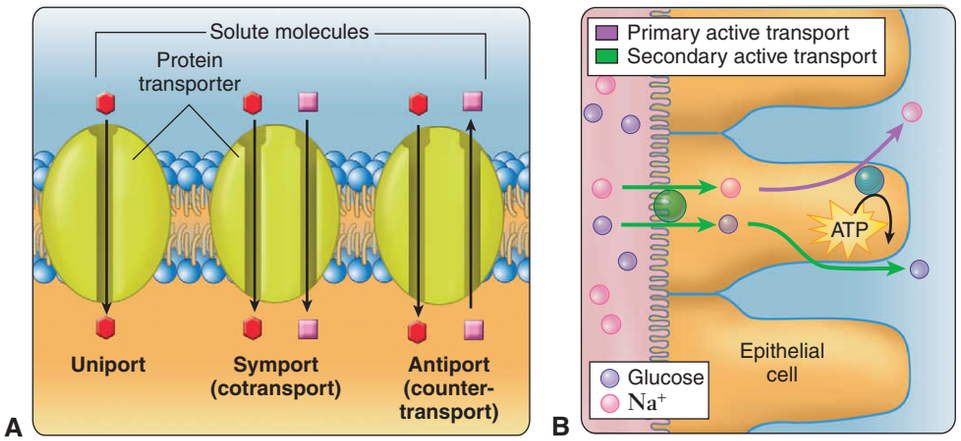


FIGURE 4-9

Sodium-potassium pump. Three sodium ions (Na^+) bind to sodium binding sites on the pump's inner face. At the same time, an energy-containing adenosine triphosphate (ATP) molecule produced by the cell's mitochondria binds to the pump. The ATP breaks apart, and its stored energy is transferred to the pump. The pump then changes shape, releases the three Na^+ ions to the outside of the cell, and attracts two potassium ions (K^+) to its potassium binding sites. The pump then returns to its original shape, and the two K^+ ions and the remnant of the ATP molecule are released to the inside of the cell. The pump is now ready for another pumping cycle. *ATPase,* Adenosine triphosphatase. The small inset is a simplified view of Na^+-K^+ pump activity. **A,** Direction of transport. Movement of one solute (uniport), movement of two or more solute types in the same direction (symport or cotransport), and movement of two or more solute types in opposite directions (antiport or countertransport). **B,** Primary and secondary active transport. In this example, primary active transport of sodium by a sodium pump creates a concentration gradient that drives the passive cotransport of glucose along with sodium. Because it depends on the sodium gradient, sodium cotransport of glucose is an example of secondary active transport. *ATP,* Adenosine triphosphate.

A, Direction of transport. Movement of one solute (uniport), movement of two or more solute types in the same direction (symport or cotransport), and movement of two or more solute types in opposite directions (antiport or countertransport). **B,** Primary and secondary active transport. In this example, primary active transport of sodium by a sodium pump creates a concentration gradient that drives the passive cotransport of glucose along with sodium. Because it depends on the sodium gradient, sodium cotransport of glucose is an example of secondary active transport. *ATP,* Adenosine triphosphate.

TRANSPORT BY VESICLES

Like active transport pumps, mechanisms that carry large groups of molecules into or out of the cell by means of vesicles require the expenditure of metabolic energy by the cell. Such bulk transport mechanisms differ from pump mechanisms in that they allow substances to enter or leave the interior of a cell without actually moving through its plasma membrane (Figure 4-10).

Endocytosis

In **endocytosis** the plasma membrane "traps" some extracellular material and brings it into the cell. The basic mechanism of endocytosis is summarized in Figure 4-10. In endocytosis, the cytoskeleton does all the work by pulling part of the plasma membrane inward, thereby forming a depression, while at the same time pushing the membrane at the edges to form a sort of trap for extracellular material. When the

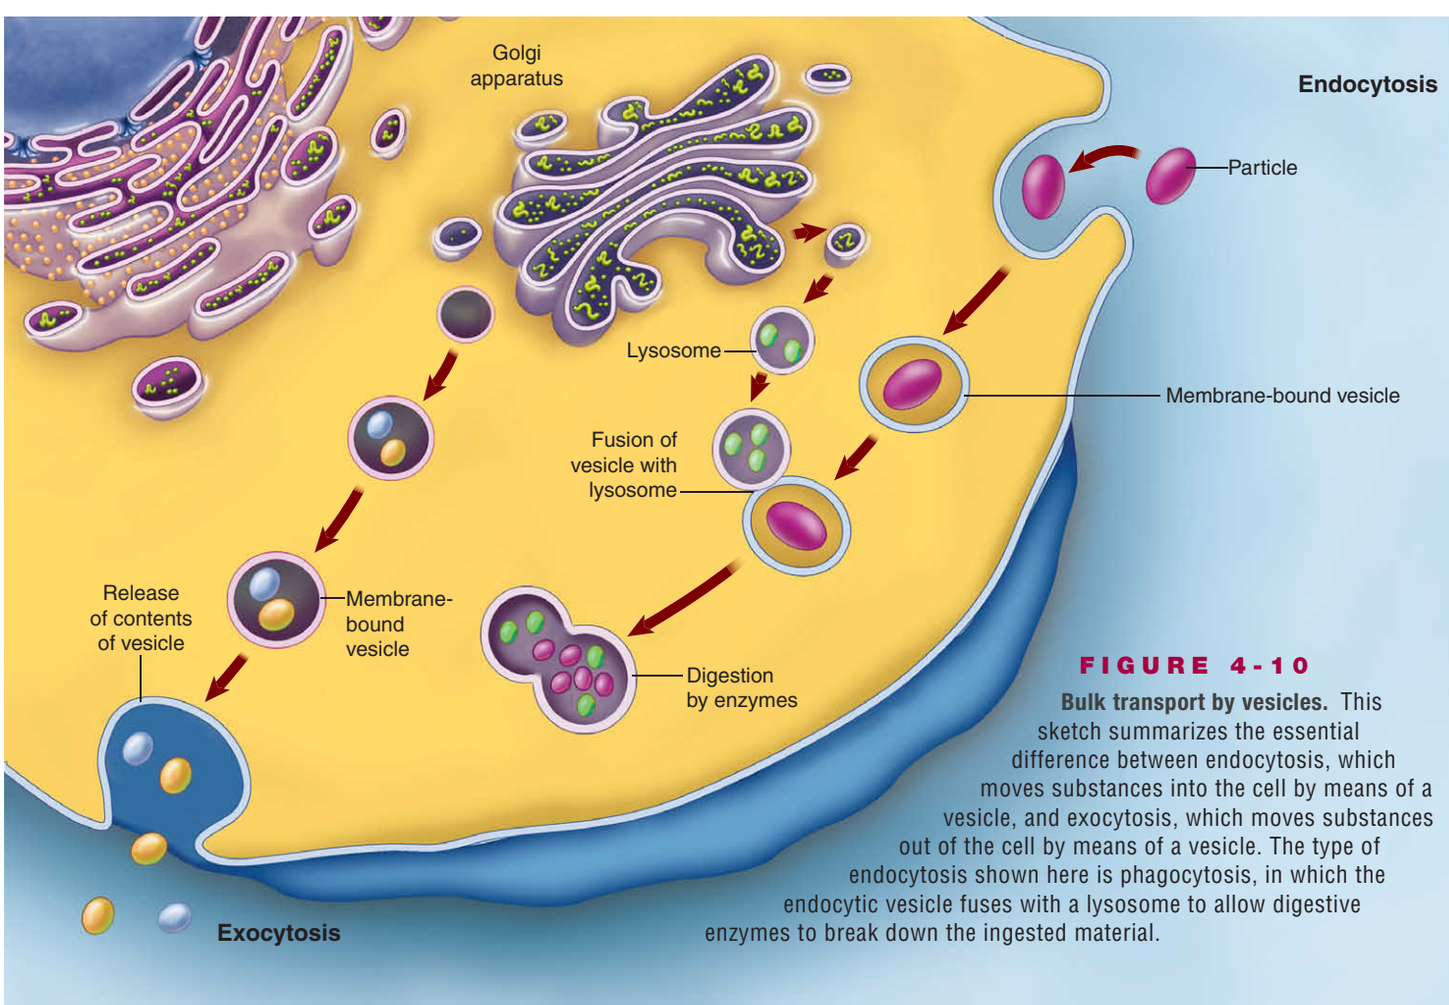

FIGURE 4-10

Bulk transport by vesicles. This sketch summarizes the essential difference between endocytosis, which moves substances into the cell by means of a vesicle, and exocytosis, which moves substances out of the cell by means of a vesicle. The type of endocytosis shown here is phagocytosis, in which the endocytic vesicle fuses with a lysosome to allow digestive enzymes to break down the ingested material.

extended edges of membrane fuse, a vesicle is formed. The cytoskeleton then pulls the vesicle containing extracellular material inward.

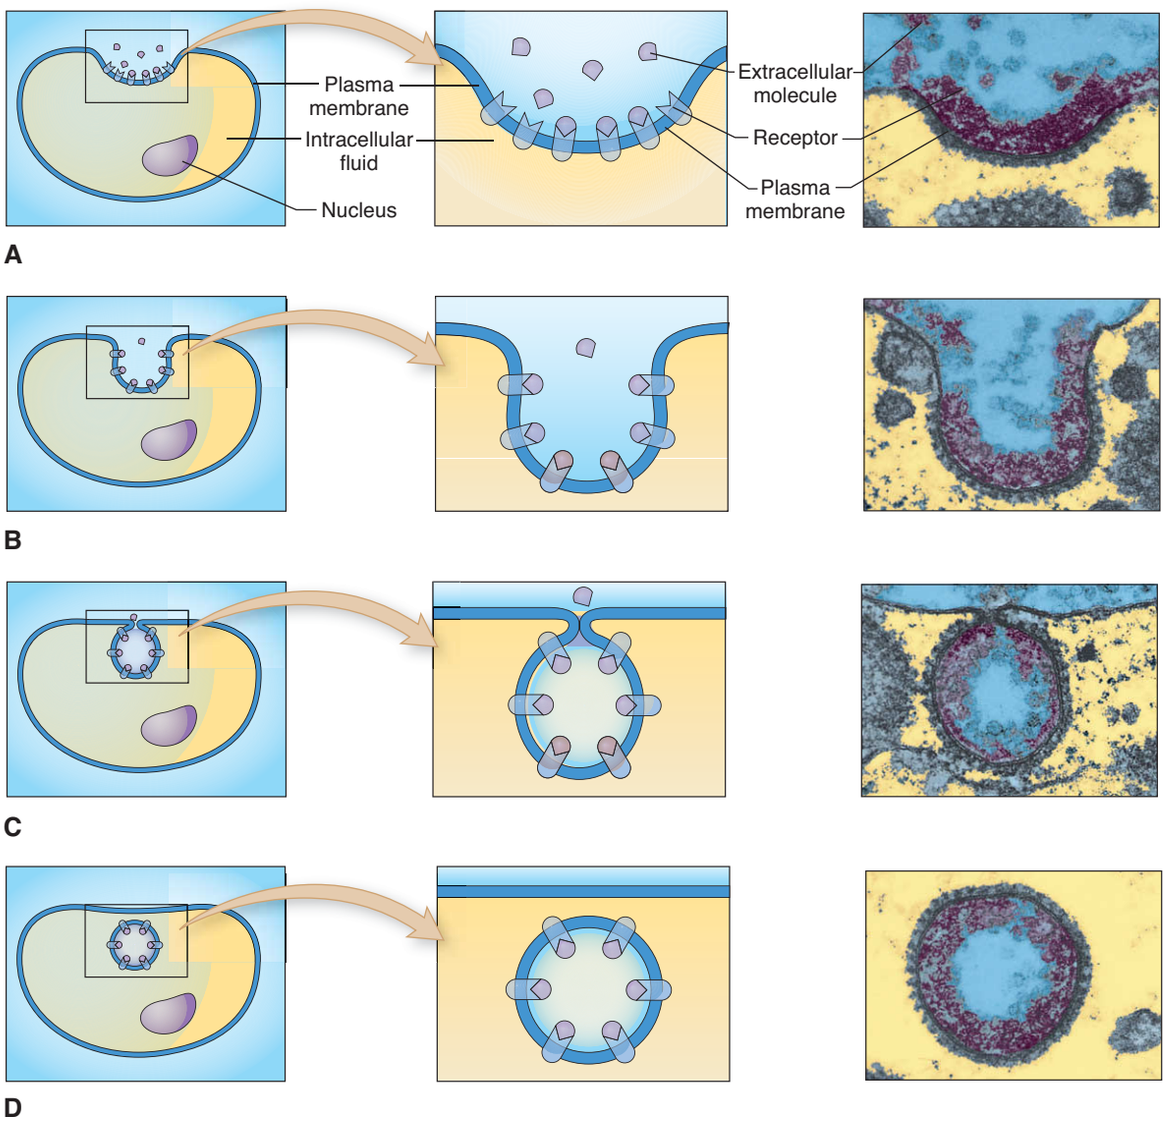
In a type of endocytosis called *receptor-mediated endocytosis*, receptors in the plasma membrane first bind to specific molecules in the extracellular fluid (Figure 4-11). This causes a portion of the plasma membrane to be pulled inward by the cytoskeleton and form a small pocket around the material to be moved into the cell. The edges of the membranous pocket extend and eventually fuse to form a vesicle. The vesicle is then pulled inward—away from the plasma membrane—by the cytoskeleton. Sometimes, endocytosis picks up various molecules and other particles along with receptor-bound molecules.

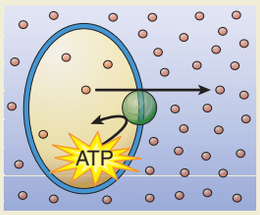
There are two basic forms of endocytosis: *phagocytosis* and *pinocytosis*. In **phagocytosis,** microorganisms or other large particles are engulfed by the plasma membrane and enter the cell in vesicles that have pinched off from the membrane. Once inside, they fuse with the membranous walls of lysosomes. Enzymes from the lysosomes then digest the particles into their component molecules. The products of digestion may subsequently diffuse through the membranous wall of the vesicle into the cytoplasm. The term *phagocytosis* means "condition of the cell eating" (from the word parts *phago-*, meaning "eat," *-cyto-*, meaning "cell," and *-osis*, meaning "condition").

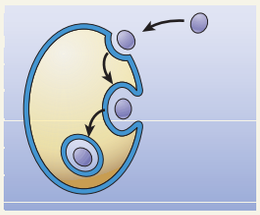
Pinocytosis, or "condition of the cell drinking," is a similar process in which fluid and the substances dissolved in it enter a cell. Besides providing a way for a cell to bring fluids and solutes into the interior of the cell, pinocytosis also provides a way for the cell to remove material, including membrane receptors and transporters, from the plasma membrane. A cell can thus regulate the function of its plasma membrane (Table 4-2).

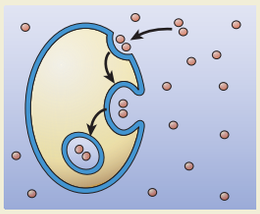
Exocytosis

Exocytosis is the process by which large molecules, notably proteins, can leave the cell even though they are too large to move out through the plasma membrane (see Figure 4-10 and Table 4-2). After first being enclosed in membranous vesicles by









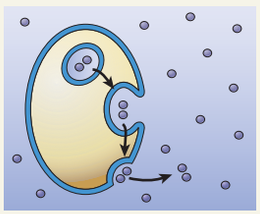


FIGURE 4-11

Receptor-mediated endocytosis. An artist's interpretation (left and center) and transmission electron micrographs (right) show the basic steps of receptor-mediated endocytosis. **A,** Membrane receptors bind to specific molecules in the extracellular fluid. **B,** A portion of the plasma membrane is pulled inward by the cytoskeleton and forms a small pocket around the material to be moved into the cell. **C,** The edges of the pocket eventually fuse and form a vesicle. **D,** The vesicle is then pulled inward—away from the plasma membrane—by the cytoskeleton. In this example, only the receptor-bound molecules enter the cell. In some cases, some free molecules or even entire cells may also be trapped within the vesicle and transported inward.

TABLE 4-2 Active Transport Processes

PROCESS		DESCRIPTION	EXAMPLES
Pumping		Movement of solute particles from an area of low concentration to an area of high concentration (up the concentration gradient) by means of an energy-consuming pump structure in the membrane	In muscle cells, pumping of nearly all calcium ions to special compartments—or out of the cell
Phagocytosis (endocytosis)		Movement of cells or other large particles into cell by trapping it in a section of plasma membrane that pinches off to form an intracellular vesicle; a type of *vesicle-mediated transport*	Trapping of bacterial cells by phagocytic white blood cells
Pinocytosis (endocytosis)		Movement of fluid and dissolved molecules into a cell by trapping them in a section of plasma membrane that pinches off to form an intracellular vesicle; a type of *vesicle-mediated transport*	Trapping of large protein molecules by some body cells
Exocytosis		Movement of proteins or other cell products out of the cell by fusing a secretory vesicle with the plasma membrane; a type of *vesicle-mediated transport*	Secretion of the hormone prolactin by pituitary cells

the Golgi apparatus, the vesicles are pulled out to the plasma membrane by the cytoskeleton. The vesicles then fuse with the plasma membrane and release their contents outside the cell. Some gland cells secrete their products by exocytosis. Besides providing a mechanism of transport, exocytosis also provides a way for new membrane material to be added to the plasma membrane.

ROLE OF ACTIVE TRANSPORT PROCESSES

Active transport processes include any mechanism that moves substances across a membrane using cellular energy—thus giving the membrane an active role in transport.

Major mechanisms of active transport in the body are ion pumps, which move ions against their concentration gradients and thus create a concentration of these ions on one side or the other. A cell can use ion pumps to keep a certain ion at an unusually high or low level, or concentrate them within an organelle. For example, the smooth ER (endoplasmic reticulum) membrane concentrates calcium ions inside the ER where they are stored for later use (as in muscle contraction).

Other active types of transport include endocytosis, exocytosis, and related vesicle-mediated processes within cells. Efforts of the cytoskeleton pull or push large volumes of material into or out of cells and organelles by wrapping them in (or unwrapping them from) bubbles of membrane (vesicles). In Chapter 3, we saw how these processes can be used to transport molecules from the ER to the Golgi apparatus, and eventually secreted out of the cell (see Figure 3-8). As you can imagine, this mechanism is used to secrete everything from hormones to neurotransmitters in the body.

| QUICK CHECK |

1. Name as many passive processes that transport substances across a cell membrane as you can. How are they alike? How are they different?
2. What causes osmotic pressure to develop in a cell?
3. Describe three different active processes that transport substances across a cell membrane. What distinguishes them from passive processes?

CELL METABOLISM

In Chapter 2 (pp. 33–65) we discovered the concept of **metabolism:** the chemical reactions that occur in the body. *Cell metabolism*, then, refers to the chemical reactions of the cell. This section of Chapter 4 picks up the important theme of human body chemistry and applies it to cell physiology. Later chapters also continue to bring up this theme because after all, body chemistry is the basis for all human functions.

Cell metabolism involves many different kinds of chemical reactions that often occur in a sequence of reactions called a **metabolic pathway.** A metabolic pathway can be described as being *catabolic* if its net effect is to break large molecules down into smaller ones. Recall that **catabolism** is the kind of metabolism that breaks down molecules, usually nutrient molecules, and thereby releases energy from the broken molecules. On the other hand, some metabolic pathways build larger molecules from smaller ones and are thus called *anabolic pathways.* Recall that **anabolism** is the kind of metabolism that builds large, complex molecules from smaller ones. Anabolic pathways usually require a net input of energy, whereas catabolic pathways usually produce a net output of energy.

Role of Enzymes

Enzymes, which are classified as *functional proteins*, were introduced on p. 61 in Chapter 2. We are now ready for a more comprehensive introduction to enzymes.

The series of chemical reactions that make up a metabolic pathway in a cell do not usually just happen on their own. At normal body temperatures, the *activation energy* needed to start a chemical reaction is too great for many molecules to react by themselves. What is needed to make essential chemical reactions happen is a **catalyst**—a chemical that reduces the amount of activation energy needed to start a chemical reaction (Figure 4-12). Catalysts participate in chemical reactions but are not themselves changed by the reaction. This is the role of enzymes in the cell—to act as chemical catalysts that allow metabolic reactions to occur. So important are they that life has been defined as the "orderly functioning of hundreds of enzymes" by one scientist.

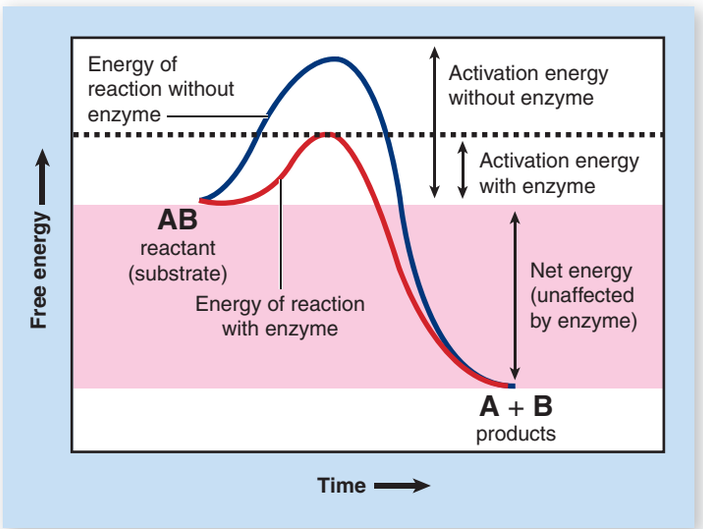

FIGURE 4-12

Enzymes as catalysts. A catalyst is a chemical that reduces the activation energy of a reaction—the energy needed to get a reaction started. Enzymes thus allow reactions to occur at the low level of free energy available at normal human body temperatures.

CHEMICAL STRUCTURE OF ENZYMES

Enzymes are proteins and have the chemical properties of proteins. Enzymes are usually tertiary or quaternary proteins of complex shape. Often, their molecules contain a nonprotein part called a *cofactor.* Inorganic ions or vitamins may make up part of a cofactor. If the cofactor is an organic nonprotein molecule, it is called a **coenzyme.**

A very important structural attribute of enzymes is the **active site.** The active site is the portion of the enzyme molecule that chemically "fits" the substrate molecule or molecules. Recall that a *substrate* is the molecule acted on by an enzyme molecule.

Since the enzyme acts on a substrate because the shape and electrochemical attractions of the active site complement some portion of the substrate or substrates, biochemists often use the **lock-and-key model** to describe the action of enzymes. As Figure 4-13 shows, the active site of an enzyme chemically fits a portion of the substrate just as a key fits into a lock. Like a key in a lock, the enzyme can

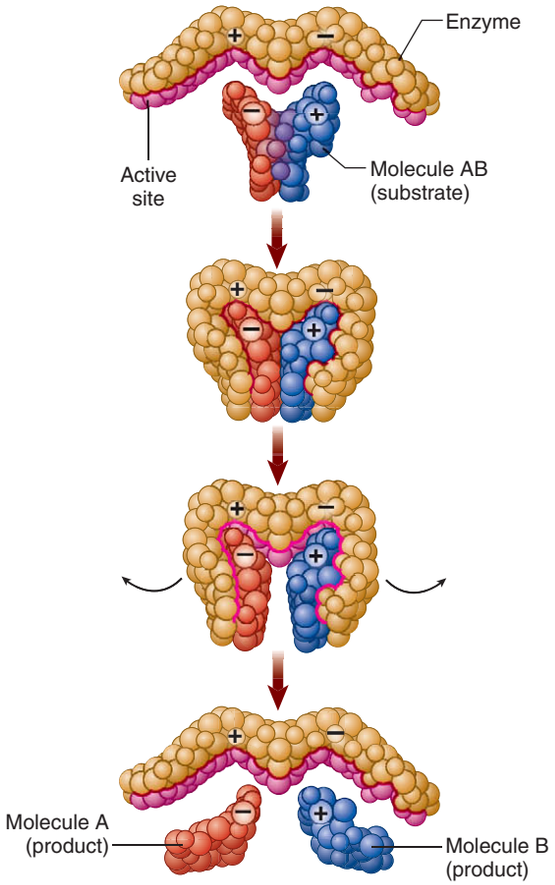

FIGURE 4-13

Model of enzyme action. Enzymes are functional proteins whose molecular shape allows them to catalyze chemical reactions. Substrate molecule AB is acted on by a digestive enzyme to yield simpler molecules A and B as products of the reaction. Notice how the active site of the enzyme chemically fits the substrate—the lock-and-key model of biochemical interaction. Notice also how the enzyme molecule bends its shape in performing its function.

bind substrates together ("locking" them together) or can unbind components of a substrate ("unlocking" them). And, as with a key, some movement of the enzyme shape is often required to "open the lock" or alter the substrate. As shown in Figure 4-13, such movements are critical to proper enzyme function.

CLASSIFICATION AND NAMING OF ENZYMES

Two systems used for naming enzymes are as follows: the suffix *-ase* is used with the root name of the substance whose chemical reaction is catalyzed (the substrate chemical, that is) or with the word that describes the kind of chemical reaction catalyzed. Thus, according to the first method, sucrase is an enzyme that catalyzes a chemical reaction in which sucrose takes part. According to the second method, sucrase might also be called a *hydrolase* because it catalyzes the hydrolysis of sucrose. Enzymes investigated before these methods of nomenclature were adopted are still called by older names, such as *pepsin* and *trypsin*.

Classified according to the kind of chemical reactions catalyzed, enzymes fall into several groups:

Oxidation-reduction enzymes. These are known as oxidases, hydrogenases, and dehydrogenases. Energy release for muscular contraction and all physiological work depends on these enzymes.

Hydrolyzing enzymes, or hydrolases. Digestive enzymes belong to this group. The hydrolyzing enzymes are named after the substrate acted on, for example, lipase, sucrase, and maltase.

Phosphorylating enzymes. These add or remove phosphate groups and are known as phosphorylases or phosphatases.

Enzymes that add or remove carbon dioxide. These are known as carboxylases or decarboxylases.

Enzymes that rearrange atoms within a molecule. These are known as mutases or isomerases.

Hydrases. These add water to a molecule without splitting it, as do hydrolases.

Enzymes are also classified as intracellular or extracellular, depending on whether they act within cells or outside them in the surrounding medium. Most enzymes act intracellularly in the body; an important exception is the digestive enzymes. All digestive enzymes are classified as hydrolases because they catalyze the hydrolysis of food molecules.

GENERAL FUNCTIONS OF ENZYMES

In general, enzymes regulate cell functions by regulating metabolic pathways (Figure 4-14). As stated earlier, each reaction of a metabolic pathway requires one or more types of enzymes to permit that reaction to occur. An entire metabolic pathway can be turned on or off by the activation or inactivation of any one of the enzymes that catalyze reactions in that particular pathway. A few general principles of enzyme function will help you understand their role in regulating cell metabolism more clearly.

Most enzymes are *specific in their action*; that is, they act only on a specific substrate. This is attributed to their "key-in-a-lock" kind of action, the configuration of the enzyme molecule fitting the configuration of some part of the substrate molecule (see Figure 4-13). This also means that every reaction that occurs in a metabolic pathway requires one or more specific enzymes—or else the reaction will not occur and the entire pathway will be disrupted.

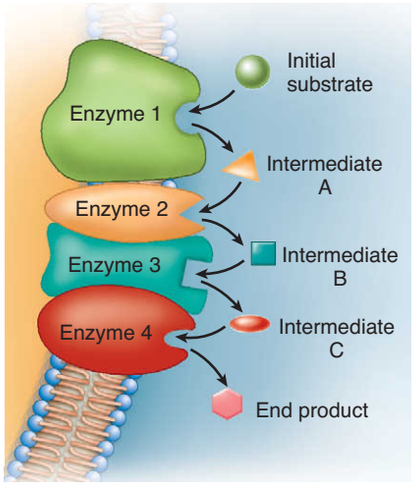

FIGURE 4-14

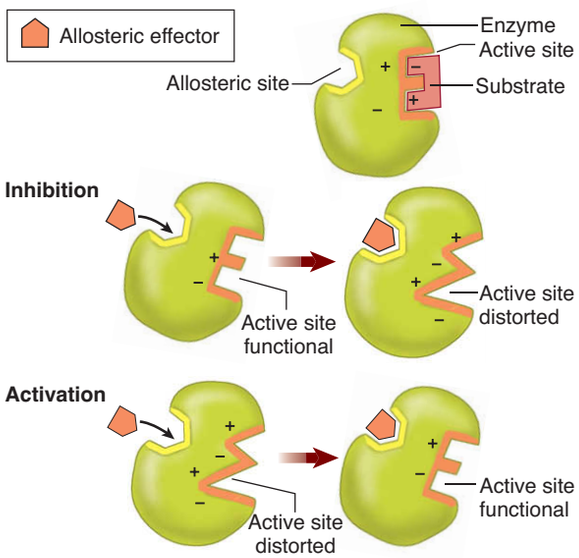
Enzyme regulation of a metabolic pathway. In a metabolic pathway, the product of one enzyme-regulated reaction becomes the substrate for the next reaction. Thus a whole series of enzymes is required to keep the pathway functioning. Notice that these enzymes are embedded in a cell membrane whereas other types of enzymes are mobile in the cytosol or extracellular in location.

Various physical and chemical agents activate or inhibit enzyme action by changing the shape of enzyme molecules. A molecule or other agent that alters enzyme function by changing its shape is called an **allosteric effector.** An *effector* is an agent that accomplishes something, and *allosteric* literally means "relating to a change in three-dimensional shape." Thus an allosteric effector is simply an agent that changes the shape of a molecule. Remember the principle you learned about the shape of proteins in Chapter 2: when the shape changes, so does the function. This certainly applies to enzymes. Some allosteric effectors are molecules that attach to an *allosteric site* on the enzyme molecule and thereby change the shape of the active site on a different part of the enzyme. As Figure 4-15 shows, allosteric effectors of this type may inhibit or



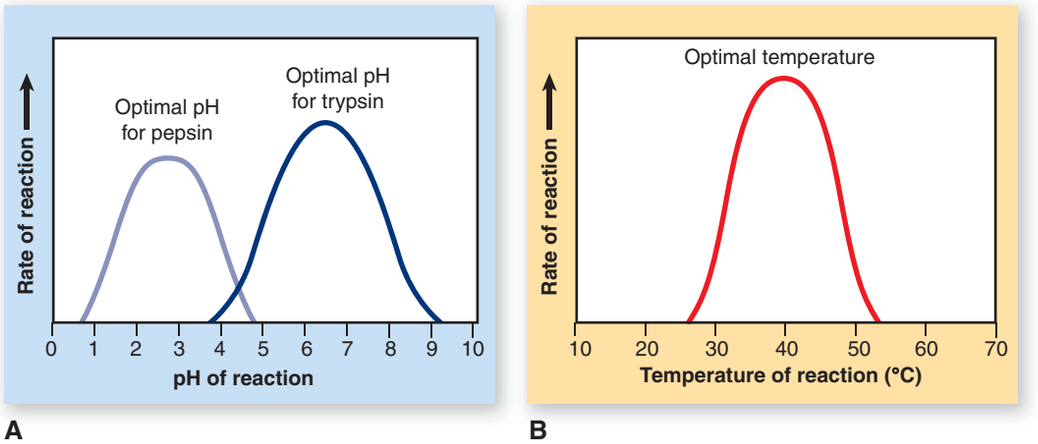


FIGURE 4-15

Allosteric effect. The allosteric effect occurs when some agent, in this case an allosteric effector molecule, binds to the enzyme at an allosteric site and thereby changes the shape of the enzyme's active site. Such an allosteric effect may inhibit enzyme action (by distorting the active site) or activate the enzyme (by giving the active site its functional shape).

FIGURE 4-16

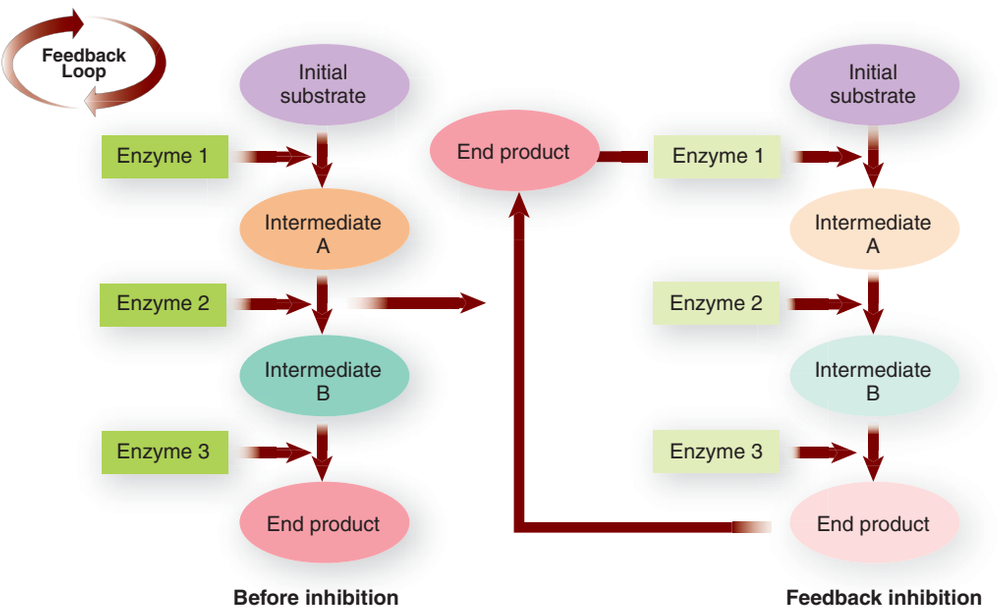
Effects of pH and temperature on enzyme function. The rate of reactions catalyzed can be affected by the allosteric effects of the chemical or physical properties of the surrounding medium. **A,** Enzymes catalyze chemical reactions with greatest efficiency within a narrow range of pH. For example, pepsin (a protein-digesting enzyme in gastric juice) operates within a low pH range, whereas trypsin (a protein-digesting enzyme in pancreatic juice) operates within a higher pH range. **B,** Most enzymes in the human body work best within a narrow range of temperatures near 40° C.

activate enzymes by altering the shape of the active site. Other types of allosteric effectors include certain antibiotic drugs, changes in pH, or changes in temperature. The allosteric effect of pH is produced by the fact that changes in the concentration of hydrogen ions (H^+) influence the chemical attractions that hold molecules—including enzymes—in their complex, multidimensional shapes. Temperature has a similar allosteric, or shape-changing, effect on enzymes. As Figure 4-16 shows, changing the pH or temperature alters the shape of the active sites of enzyme molecules enough to affect their function. Cofactors, when they are added to or removed from an enzyme molecule, also have an allosteric effect.

In a process known as **end-product inhibition,** a chemical product at the end of a metabolic pathway binds to the allosteric site of one or more enzymes along the pathway that produced it and thereby inhibits the synthesis of more product (Figure 4-17). This is a type of automatic negative feedback mechanism in the cell that prevents the accumulation of an extreme amount of a metabolic product.

Most enzymes catalyze a chemical reaction in both directions, the direction and rate of the reaction being governed by the law of mass action. An accumulation of a product slows the reaction and tends to reverse it.

Enzymes are continually being destroyed and therefore have to be continually synthesized, even though they are not used up in the reactions they catalyze.



Many enzymes are synthesized as inactive **proenzymes.** Substances that convert proenzymes to active enzymes are often called **kinases.** Kinases usually do their job of activating enzymes by means of an allosteric effect (see Figure 4-15). For example, enterokinase changes inactive trypsinogen into active trypsin by changing the shape of the molecule. Within cells, a type of kinase called simply *kinase* A has been shown to activate enzymes that regulate certain pathways after a hormonal signal is received by the cell.

| QUICK CHECK |

4. Describe the structure of an enzyme. How does its structure determine its function?
5. What is an allosteric effector? Give examples.

FIGURE 4-17

Feedback inhibition of enzymes. Formation of an excessive amount of end product can be inhibited by a negative feedback mechanism. In this example, the end product itself inhibits the function of an enzyme needed early in the pathway. Thus the entire pathway is inhibited—as long as there is an excess of the end product.

Catabolism

There are many catabolic pathways that operate inside human cells. Perhaps the most important for a basic understanding of cell catabolism is the pathway known as **cellular respiration.** This section briefly outlines the basic concepts of the cellular respiratory pathway. Details of this pathway are further outlined in Chapter 30.

OVERVIEW OF CELLULAR RESPIRATION

Cellular respiration is the process by which cells break down glucose ($C_6H_{12}O_6$), or a nutrient that has been converted to glucose or one of its simpler products, into carbon dioxide (CO_2) and water (H_2O). As the molecule breaks down, the potential energy that had been stored in its bonds is released. Much of the released energy is converted into heat, but a portion of it is transferred to the high-energy bonds of adenosine triphosphate (ATP). Figure 2-33 on p. 58 shows how ATP is synthesized from adenosine diphosphate (ADP) and inorganic phosphate with energy obtained from cellular respiration.

Three smaller pathways are chemically linked together to form the larger catabolic pathway known as *cellular respiration:*

1. Glycolysis
2. Citric acid cycle
3. Electron transport system

The paragraphs that follow briefly introduce these three basic processes.

GLYCOLYSIS

Glycolysis is a catabolic pathway that begins with glucose, which contains six carbon atoms per molecule, and ends with pyruvic acid, which contains only three carbon atoms per molecule. As Figure 4-18 shows, each glucose molecule that enters this pathway is eventually broken in half. In fact, the name *glycolysis* literally means "breaking glucose."

Glycolysis occurs in the cytosol of cells, outside any particular organelle. The cytosol, then, must contain all the enzymes necessary to catalyze each of the reactions that make up the glycolysis pathway. Because the reactions of glycolysis require no oxygen, glycolysis is said to be **anaerobic.**

Glycolysis releases a small portion of the potential energy stored in the glucose molecule. Some of this energy is transferred to ATP, a molecule that can then transfer the energy to any of a large number of energy-consuming reactions in the cell. Some of the energy is transferred to another energy transfer molecule, a form of nicotinamide adenine dinucleotide, (NADH). NADH may eventually transfer its energy to ATP in the electron transport system, a later step of cellular respiration that is discussed shortly.

Once pyruvic acid is formed by glycolysis, there is a fork in the metabolic pathway. That is, the molecule could enter one of two pathways linked to glycolysis (see Figure 4-18). If oxygen is available, the pyruvic acid molecule will follow the *aerobic pathway* and enter the citric acid cycle. This type of respiration is called **aerobic** respiration because oxygen (O_2) is required for this sequence of reactions to occur. If oxygen is unavailable for a particular pyruvic acid molecule to enter the aerobic pathway, it will continue along an anaerobic pathway to form a molecule called

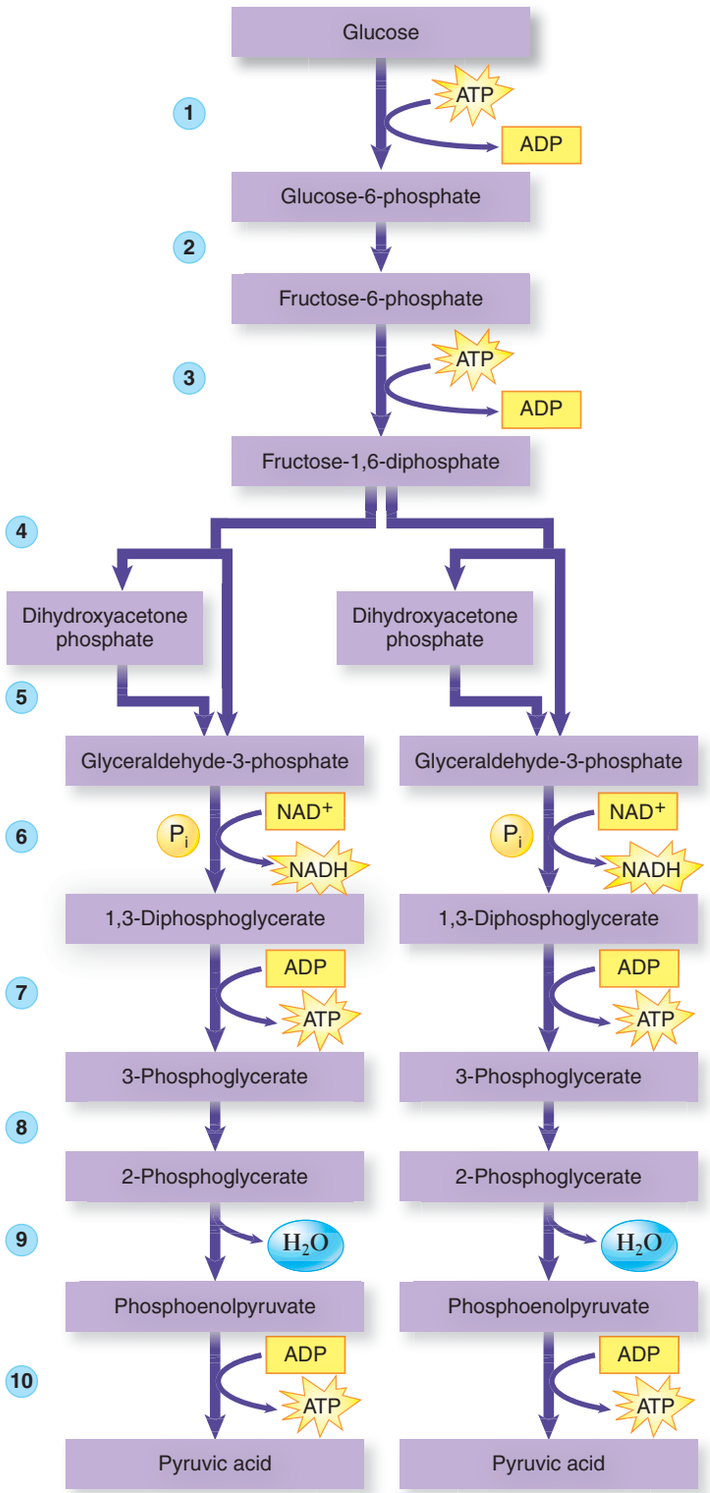


FIGURE 4-18

Glycolysis. This diagram of the reactions involved in glycolysis represents a classic example of a catabolic pathway. Note that each of the ten chemical reactions in this pathway cannot proceed until the previous step has occurred. Recall from our discussion that each step also requires the presence of one or more specific enzymes. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *NAD^+* and *NADH,* forms of nicotinamide adenine dinucleotide; *P_i,* inorganic phosphate.

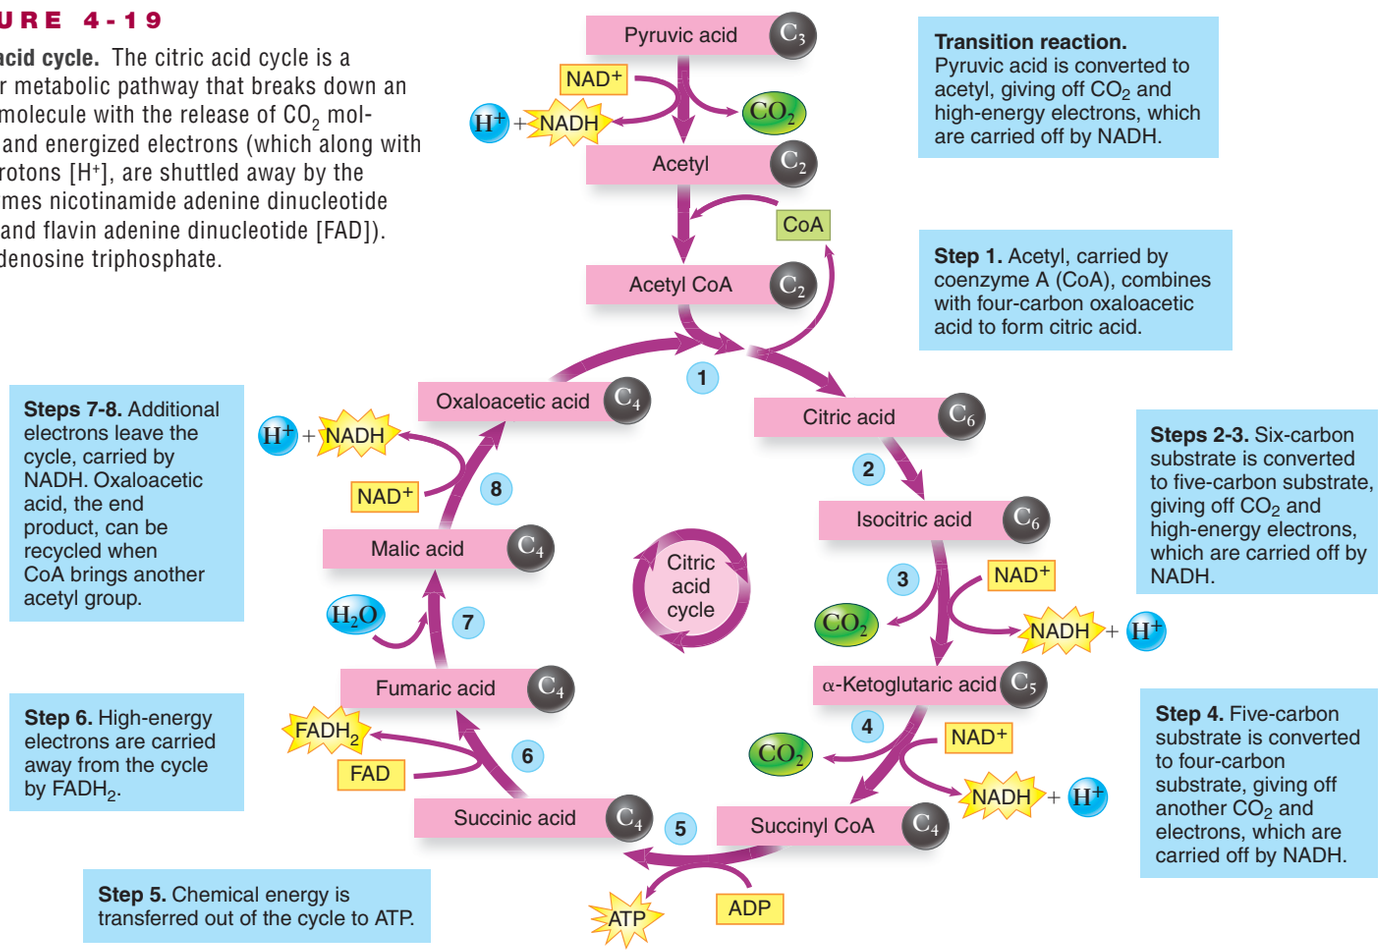
lactic acid. Lactic acid is later converted back to pyruvic acid or glucose in an energy- and oxygen-requiring pathway.

When the anaerobic pathway is followed, a small amount of the total energy stored in glucose is made available to the cell. However, if enough oxygen is not available to maintain a set point level of ATP by means of the aerobic pathway, the anaerobic pathway can help maintain adequate ATP levels for cellular functions to continue. Because oxygen is later used to process the lactic acid formed by anaerobic processes, biochemists say that an *oxygen debt* has been incurred. Much of the lactic acid diffuses out of the cell that formed it and is later processed in liver cells, which are adapted to perform this function efficiently.

CITRIC ACID CYCLE

If oxygen is available, the pyruvic acid molecules formed by glycolysis are prepared to enter the next major phase of aerobic cellular respiration—the **citric acid cycle.** This cyclic (repeating) sequence of reactions is still sometimes called the *Krebs cycle* after Sir Hans Krebs, who discovered this pathway in the first part of the twentieth century. Figure 4-19 shows that pyruvic acid is converted to acetyl coenzyme A (CoA) and moves into the citric acid cycle. During this transition into the citric acid cycle, the molecule loses one of its carbons, along with some oxygen, producing waste carbon dioxide (CO_2). This cycle also produces some available energy that is transferred to NADH and then to the electron transport system, as explained later.

The citric acid cycle, like glycolysis, is a sequence of many chemical reactions (see Figure 4-19). As in glycolysis, each reaction of the citric acid cycle requires one or more specific enzymes. These enzymes are located in the inner chamber of the mitochondrion, so that is the cell location in which the citric acid cycle occurs.



In the citric acid cycle, the two-carbon acetyl group that breaks away from its escort, CoA, is further broken down to yield its stored energy. A small amount of this energy is transferred directly to ATP molecules, but most of the available energy is transferred in the form of energized electrons (e^-) and their accompanying protons (H^+) to the coenzyme NAD or flavin adenine dinucleotide (FAD). NAD then becomes NADH and FAD becomes the reduced form of FAD ($FADH_2$). More information on how these coenzymes pick up energy released from a metabolic pathway is found in Chapter 30 on p. 933. The energized electrons (along with their protons) then move into the next phase of cellular respiration—the electron transport system.

ELECTRON TRANSPORT SYSTEM

As Figure 4-20 shows, NADH (and $FADH_2$) transfer the energized electrons to a set of special molecules embedded in the cristae of the inner mitochondrial membrane. These special electron-accepting molecules make up the **electron transport system (ETS).** As energized electrons leap from one of these molecules to the next, their energy is used to pump their accompanying protons (H^+) from the inner chamber of the mitochondrion to the outer chamber. As the

FIGURE 4-19

Citric acid cycle. The citric acid cycle is a circular metabolic pathway that breaks down an acetyl molecule with the release of CO_2 molecules and energized electrons (which along with their protons [H^+], are shuttled away by the coenzymes nicotinamide adenine dinucleotide [NAD] and flavin adenine dinucleotide [FAD]). *ATP,* Adenosine triphosphate.

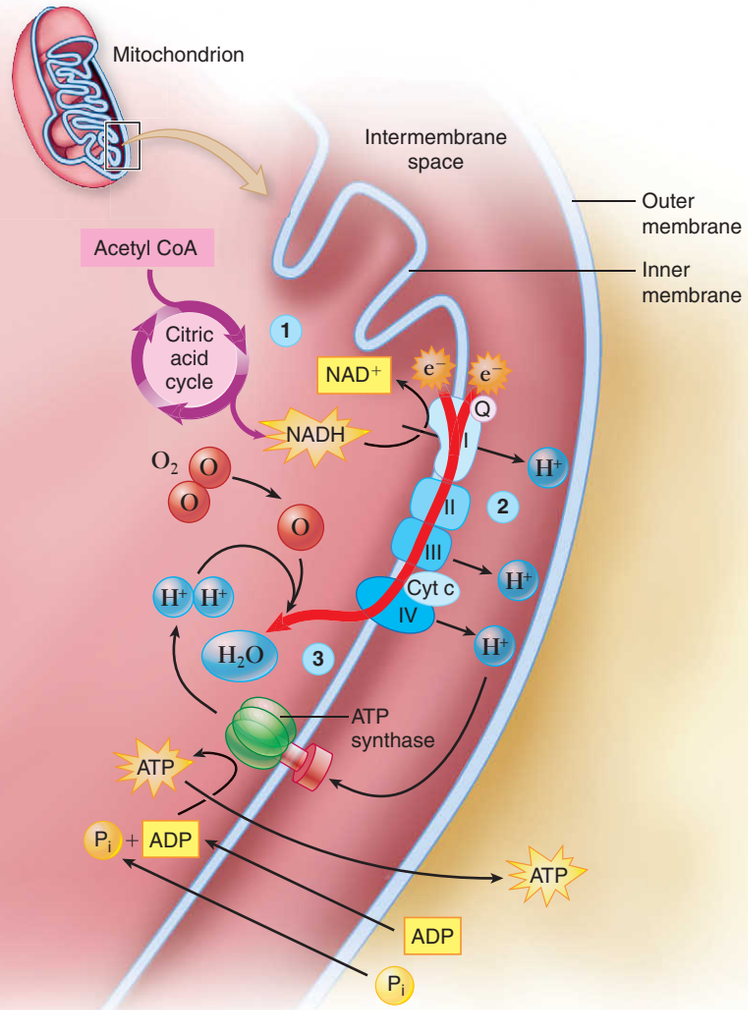


FIGURE 4-20

Electron transport system (ETS). 1, Pairs of high-energy electrons (e^-) and their protons (H^+) are shuttled from the citric acid cycle by coenzymes NAD and FAD to protein complexes (I, II, III, IV) embedded in the inner membrane of the mitochondrion. **2,** As the electrons are transported from molecule to molecule (*red path*), their energy is used to pump the protons (H^+) to the intermembrane space. **3,** As the proton gradient increases, passive movement of protons back across the membrane (through the ATP synthase carrier) provides the energy needed to "recharge" ADP and P to form ATP. Notice that oxygen (from O_2) is required as the final acceptor of the electrons and protons transported through the system, thus forming H_2O as a byproduct. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *FAD,* flavin adenine dinucleotide; *NAD,* nicotinamide adenine dinucleotide.

protons (H^+) build up in the outer chamber, a concentration gradient of protons develops. Protons then begin movement through the inner mitochondrial membrane into the inner chamber by way of "reverse pump" carriers (*ATP synthase*). These ATP synthase carriers convert the energy of proton flow into chemical energy, which is transferred to ATP molecules. In short, the energy transferred from the citric acid cycle is used to put protons behind a sort of dam, and then the energy of protons flowing back through "energy generators" from behind the dam is transferred to ATP. In most cells, aerobic respiration transfers enough energy from each glucose molecule to form 36 ATP molecules—2 directly from glycolysis and 34 from the rest of the pathway.

The deenergized electrons that come away from the electron transport system are accepted by oxygen molecules. This is why oxygen molecules are required for this metabolic pathway—to act as final electron acceptors. Once they combine with oxygen, the electrons are reunited with their accompanying protons (H^+) to form water (H_2O).

In summary, the aerobic respiratory pathway requires an input of glucose and oxygen and, by the action of specific enzymes, coenzymes, and other molecules, produces an output of carbon dioxide, water, and the real biochemical prize—energy in ATP. The major steps in cellular respiration are summarized in Figure 4-21. For an expanded discussion of cellular respiration, refer to Chapter 30, pp. 934–941.

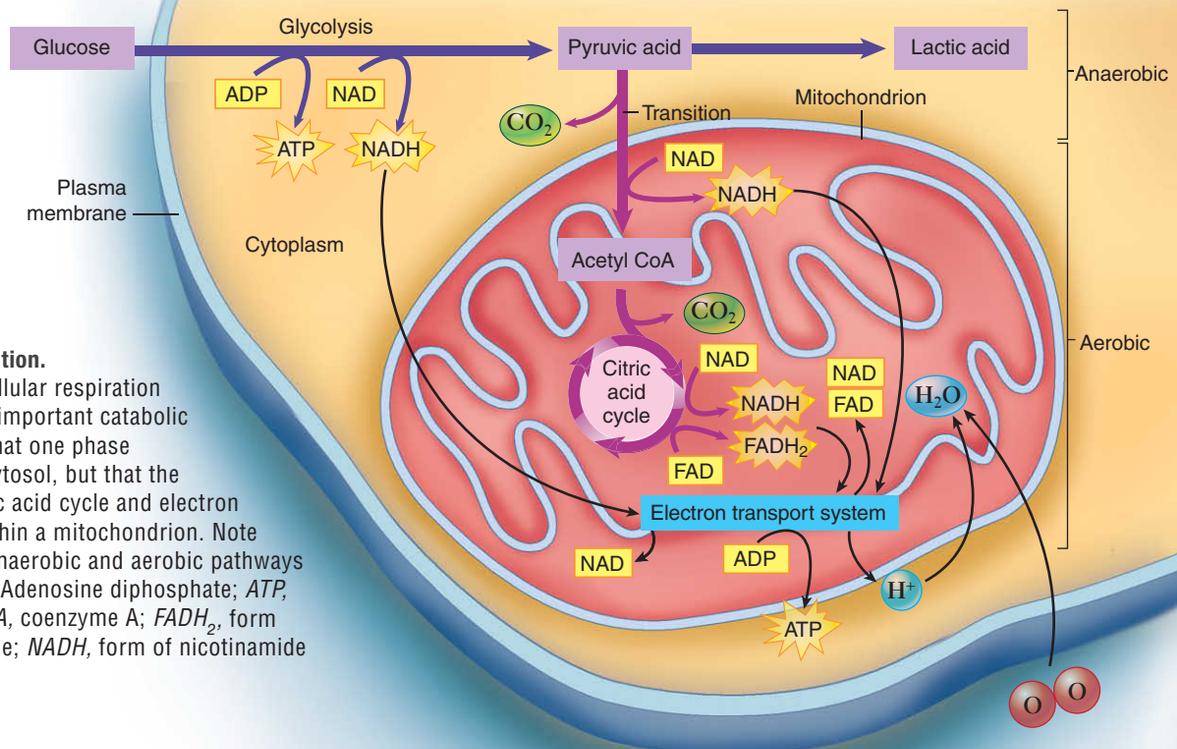

FIGURE 4-21

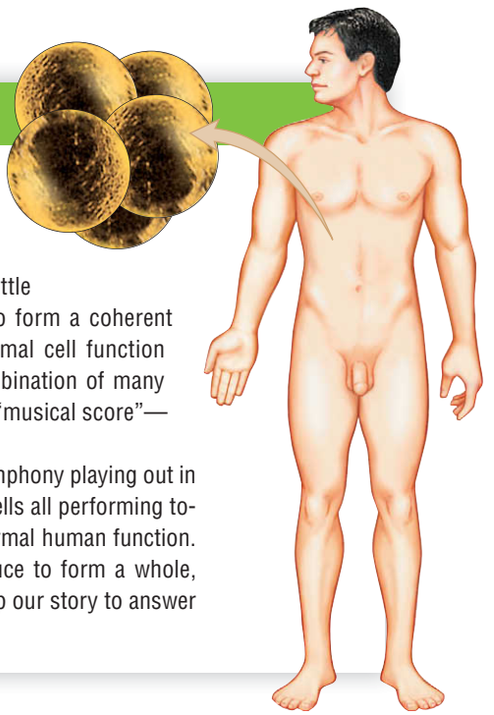
Summary of cellular respiration. This simplified outline of cellular respiration represents one of the most important catabolic pathways in the cell. Note that one phase (glycolysis) occurs in the cytosol, but that the two remaining phases (citric acid cycle and electron transport system) occur within a mitochondrion. Note also the divergence of the anaerobic and aerobic pathways of cellular respiration. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *CoA,* coenzyme A; *$FADH_2$,* form of flavin adenine dinucleotide; *NADH,* form of nicotinamide adenine dinucleotide.



| QUICK CHECK |

6. What are the three catabolic pathways that together make up the process of cellular respiration?
7. Which extracts more energy for cell use, the aerobic or anaerobic pathway?
8. To what molecule must energy be transferred before it can be used by most cell processes?
9. Briefly outline each of the major steps of cellular respiration.

Anabolism

Many anabolic or "building" pathways occur in human cells. Perhaps the most important for the beginning student to understand is the process of protein synthesis. Why is protein synthesis considered the central anabolic process of the cell? How is protein synthesis accomplished? These questions are answered as the story of cell function continues in the next chapter.

the BIG picture

Cell Physiology and the Whole Body

When exploring the microscopic world of cells, it is easy to get caught up in the intricate mechanisms that operate in each specific organelle. Once you feel comfortable with these mechanisms, try to put them together into a bigger picture of cell function. For example, most of the processes that we explored in this chapter are going on at about the same time within each and every cell of your body. Each cell is transcribing genes and synthesizing polypeptides, which are then dumped into the ER and transported to the Golgi apparatus for processing and packaging before being sent off to become a lysosome or being secreted by exocytosis. At the same time, energy for this and other cell work is being transferred from nutrient molecules to ATP molecules, which act as energy storage batteries for the cell. The cytoskeleton and the cell membrane are transporting materials into, out of, and around the cytoplasm. Studying cell structure and function is like looking at the score of a symphony for the first time. All the individual parts look unrelated and somewhat confusing, but with a little effort you can combine them to form a coherent whole. The "symphony" of normal cell function results from a coordinated combination of many processes dictated by the cell's "musical score"—the genetic code.

However, there is a larger symphony playing out in the body. There are trillions of cells all performing together in concert to produce normal human function. How do cells grow and reproduce to form a whole, healthy body? Chapter 5 picks up our story to answer that question.

MECHANISMS of DISEASE

DISORDERS OF CELL TRANSPORT

Several very severe diseases result from damage to cell transport mechanisms. **Cystic fibrosis (CF),** for example, is an inherited condition in which chloride ion (Cl^-) channels in the plasma membrane called *CTFRs (cystic fibrosis transmembrane conductance regulators)* are defective. In the most common form of CF, this happens when abnormal CTFR channel proteins become misfolded in the ER and are thus not sent to the plasma membrane. Because Cl^- transport is altered, secretions such as sweat, mucus, and pancreatic juice are very salty—and often very thick. Abnormally thick mucus in the lungs impairs normal breathing and often leads to recurring lung infections. Thick pancreatic secretions can plug ducts that carry important enzymes to the digestive tract. Figure 4-22 shows a child with CF next to a healthy child of the same age. Because of the breathing, digestive, and other problems caused by the disease, the affected child has not developed normally.

Cholera (KAHL-er-ah) is a bacterial infection that causes cells lining the intestines to leak chloride ions (Cl^-). Water follows Cl^- out of the cells by osmosis, causing severe diarrhea and the resulting loss of water by the body. Death can occur in a few hours if

treatment is not received. Interestingly, carriers of the defective CTFR gene that produces CF are resistant to cholera infections. Having defective Cl^- transport mechanisms apparently protects a person from an infection that disrupts normal Cl^- transport. This is one of many examples where so-called "disease genes" have turned out to have beneficial effects.

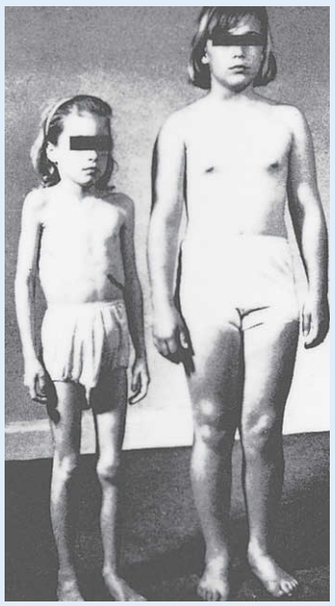


FIGURE 4-22

Cystic fibrosis (CF). The child on the left, who has CF, has failed to develop as normally as the child of the same age on the right.

CASE study

Tobie was visiting New York City for the first time. Being from a small town, he was fascinated by all the tall buildings and crowds of people. On his first day in the city, he took the subway across town. When the train finally arrived at its destination, Tobie was surprised to see a mob of people waiting on the subway platform; only a few people were already on the train. As the doors opened, the crowd surged forward through the doors and into the subway cars.

1. The movement of the crowd through the doors could be thought of as an example of what type of movement pertaining to a cell?
   a. Active transport by vesicles
   b. Facilitated diffusion
   c. Simple diffusion
   d. Active transport by pumps

With the crush of people flooding onto the train, Tobie found himself being pushed into the middle of the train car and was left with nothing to hold onto, making it difficult to keep his balance when the subway car was in motion. He kept shifting his weight from one leg to the other as the train sped along, rounding curves, lurching to a stop at one station, and then quickly accelerating on to the next. In order for Tobie to keep contracting the muscles in his legs, his muscle cells have to move sodium residing inside the cells back out of the cells—against their normal sodium concentration gradient.

2. The movement of sodium from a low concentration to a higher concentration is an example of _____.
   a. Active transport by vesicles
   b. Facilitated diffusion
   c. Simple diffusion
   d. Active transport by pumps

After rushing around most of the day on his whirlwind tour of the city, Tobie was so thirsty, he felt that he could drink gallons of water.

3. If he did indeed drink several gallons of water in a short time, what effect might that have on his blood?
   a. His blood would become hypertonic.
   b. His blood would become hypotonic.
   c. His blood would become isotonic.
   d. The water would have no effect on his blood.

MOVEMENT OF SUBSTANCES THROUGH CELL MEMBRANES

A. Passive transport processes—do not require any energy expenditure of the cell membrane (Table 4-1)
   1. Diffusion—a passive process (Figure 4-1)
      a. Molecules spread through the membranes
      b Molecules move from an area of high concentration to an area of low concentration, down a concentration gradient (Figure 4-2)
      c. As molecules diffuse, a state of equilibrium will occur
   2. Simple diffusion (Figure 4-3)
      a. Molecules cross through the phospholipid bilayer
      b Solutes permeate the membrane; therefore we call the membrane permeable
   3. Osmosis (Figure 4-4)
      a. Diffusion of water through a selectively permeable membrane; limits diffusion of at least some of the solute particles
      b. Water pressure that develops as a result of osmosis is called *osmotic pressure*
      c. Potential osmotic pressure is the maximum pressure that could develop in a solution when it is separated from pure water by a selectively permeable membrane; knowledge of potential osmotic pressure allows prediction of the direction of osmosis and the resulting change in pressure:
         (1) Isotonic—describes a fluid having the same potential osmotic pressure as cytosol (Figure 4-5)
         (2) Hypertonic—"higher pressure"; cells placed in solutions that are hypertonic always shrivel as water flows out of them; this has great medical importance: if medical treatment causes the extracellular fluid to become hypertonic, serious damage may occur
         (3) Hypotonic—"lower pressure"; cells placed in a hypotonic solution may swell as water flows into them; water always osmoses from the hypotonic solution into the cytosol
      d. Osmosis results in gain of volume on one side of the membrane and loss of volume on the other side of the membrane
   4. Facilitated diffusion (mediated passive transport)
      a. A special kind of diffusion in which movement of molecules is made more efficient by the action of transporters embedded in a cell membrane
      b. Transports substances down a concentration gradient
      c. Energy required comes from the collision energy of the solute

d. Channel-mediated passive transport (Figure 4-6)
(1) Channels are specific—allow only one type of solute to pass through
(2) Gated channels may be open or closed (or inactive)—may be triggered by any of a variety of stimuli
(3) Channels allow membranes to be selectively permeable
(4) Aquaporins are water channels that permit rapid osmosis
e. Carrier-mediated passive transport (Figure 4-7)
(1) Carriers attract and bind to the solute, change shape, and release the solute out the other side of the carrier
(2) Carriers are usually reversible, depending on the direction of the concentration gradient

5. Role of passive transport processes
a. Move substances down their concentration gradient, thus maintaining equilibrium—and homeostatic balance
b. Types of passive transport—simple and facilitated diffusion (channels and carriers); osmosis is a special example of channel-mediated passive transport of water

B. Active transport processes—require the expenditure of metabolic energy by the cell (Table 4-2)
1. Transport by pumps
a. Pumps are membrane transporters that move a substance against their concentration gradient—opposite of diffusion
b. Examples: calcium pumps (Figure 4-8) and sodium-potassium pumps (Figure 4-9)
2. Transport by vesicles—allow substances to enter or leave the interior of a cell without actually moving through its plasma membrane
a. Endocytosis—the plasma membrane "traps" some extracellular material and brings it into the cell in a vesicle
(1) Two basic types of endocytosis (Figure 4-10)
(a) Phagocytosis—"condition of cell eating"; large particles are engulfed by the plasma membrane and enter the cell in vesicles; the vesicles fuse with lysosomes, which digest the particles
(b) Pinocytosis—"condition of cell drinking"; fluid and the substances dissolved in it enter the cell
(2) Receptor-mediated endocytosis—membrane receptor molecules recognize substances to be brought into the cell (Figure 4-11)
b. Exocytosis
(1) Process by which large molecules, notably proteins, can leave the cell even though they are too large to move out through the plasma membrane
(2) Large molecules are enclosed in membranous vesicles and then pulled to the plasma membrane by the cytoskeleton, where the contents are released
(3) Exocytosis also provides a way for new material to be added to the plasma membrane

3. Role of active transport processes
a. Active transport requires energy use by the membrane
b. Pumps—concentrate substances on one side of membrane, as when storing an ion inside an organelle
c. Vesicle-mediated (endocytosis, exocytosis)—move large volumes of substances at once, as in secretion of hormones and neurotransmitters

CELL METABOLISM

A. Metabolism is the set of chemical reactions in a cell
1. Catabolism—breaks large molecules into smaller ones; usually releases energy
2. Anabolism—builds large molecules from smaller ones; usually consumes energy

B. Role of enzymes
1. Enzymes are chemical catalysts that reduce the activation energy needed for a reaction (Figure 4-12)
2. Enzymes regulate cell metabolism
3. Chemical structure of enzymes
a. Proteins of a complex shape
b. The active site is where the enzyme molecule fits the substrate molecule—the lock-and-key model (Figure 4-13)
4. Classification and naming of enzymes
a. Enzymes usually have an *–ase* ending, with the first part of the word signifying the substrate or the type of reaction catalyzed
b. Oxidation-reduction enzymes—known as oxidases, hydrogenases, and dehydrogenases; energy release depends on these enzymes
c. Hydrolyzing enzymes—hydrolases; digestive enzymes belong to this group
d. Phosphorylating enzymes—phosphorylases or phosphatases; add or remove phosphate groups
e. Enzymes that add or remove carbon dioxide—carboxylases or decarboxylases
f. Enzymes that rearrange atoms within a molecule—mutases or isomerases
g. Hydrases add water to a molecule without splitting it
5. General functions of enzymes
a. Enzymes regulate cell functions by regulating metabolic pathways (Figure 4-14)
b. Enzymes are specific in their actions
c. Various chemical and physical agents known as allosteric effectors affect enzyme action by changing the shape of the enzyme molecule; examples of allosteric effectors include (Figure 4-15):
(1) Temperature (Figure 4-16, B)
(2) Hydrogen ion (H^+) concentration (pH) (Figure 4-16, A)
(3) Ionizing radiation
(4) Cofactors
(5) End products of certain metabolic pathways (Figure 4-17)
d. Most enzymes catalyze a chemical reaction in both directions

e. Enzymes are continually being destroyed and continually being replaced
f. Many enzymes are first synthesized as inactive proenzymes

C. Catabolism
1. Cellular respiration, the pathway by which glucose is broken down to yield its stored energy, is an important example of cell catabolism; cellular respiration has three pathways that are chemically linked (Figure 4-21):
a. Glycolysis (Figure 4-18)
b. Citric acid cycle (Figure 4-19)
c. Electron transport system (ETS) (Figure 4-20)
2. Glycolysis (Figure 4-18)
a. Pathway in which glucose is broken apart into two pyruvic acid molecules to yield a small amount of energy (which is transferred to ATP and NADH)
b. Includes many chemical steps (reactions that follow one another), each regulated by specific enzymes
c. Is anaerobic (requires no oxygen)
d. Occurs within cytosol (outside the mitochondria)
3. Citric acid cycle (Krebs cycle) (Figure 4-19)
a. Pyruvic acid (from glycolysis) is converted into acetyl CoA and enters the citric acid cycle after losing CO_2 and transferring some energy to NADH
b. Citric acid cycle is a repeating (cyclic) sequence of reactions that occur inside the inner chamber of a mitochondrion; acetyl splits from CoA and is broken down to yield waste CO_2 and energy (in the form of energized electrons), which is transferred to ATP, NADH, and $FADH_2$
4. Electron transport system (ETS) (Figure 4-20)
a. Energized electrons are carried by NADH and $FADH_2$ from glycolysis and the citric acid cycle to electron acceptors embedded in the cristae of the mitochondrion
b. As electrons are shuttled along a chain of electron-accepting molecules in the cristae, their energy is used to pump accompanying protons (H^+) into the space between mitochondrial membranes
c. Protons flow back into the inner chamber through pump molecules in the cristae, and their energy of movement is transferred to ATP
d. Low-energy electrons coming off the ETS bind to oxygen and rejoin their protons to form water (H_2O)

D. Anabolism
1. Protein synthesis is a central anabolic pathway in cells, to be covered in more detail in Chapter 5

THE BIG PICTURE: CELL PHYSIOLOGY AND THE WHOLE BODY

A. Most cell processes are occurring at the same time in all of the cells throughout the body
B. Functions of individual cells are understood in the context of the trillions of cells of the body, to be explored further in Chapter 5

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the terms *diffusion*, *dialysis*, *facilitated diffusion*, *osmosis*, and *filtration*.
2. Explain how a concentration gradient relates to the process of diffusion.
3. Describe and give an example of a membrane channel.
4. Explain the terms *isotonic*, *hypotonic*, and *hypertonic*.
5. State the principle about a solution in which osmotic pressure develops, given appropriate conditions.
6. State the principle about the direction of active transport.
7. Name and describe the active transport pump that operates in the plasma membrane of all human cells.
8. Explain the processes of endocytosis and exocytosis.
9. Describe the classification of enzymes.
10. Discuss three general principles of enzyme function.
11. What is metabolism? Catabolism? Anabolism?
12. Describe briefly each of the three pathways that make up the process of cellular respiration.

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. The process of peritoneal dialysis and the process of a white blood cell trapping bacteria by phagocytosis are both transport processes. Compare and contrast these processes and identify them as active or passive.
2. Which type of osmotic pressure can be more easily measured? Explain your answer.
3. Intravenous solutions can be isotonic to blood cells. Therefore, it is very important to know whether sugar, a nonelectrolyte, or salt (NaCl), an electrolyte, is being given in the solution so that the proper amount can be added. What would result if the tonicity of the solution is not isotonic to the blood cells?
4. White blood cells engulf bacteria and solutions that contain dissolved proteins. How would you summarize the processes that allow them to ingest both solids and liquids?
5. Explain how the shape of an enzyme determines its function. What would result if an allosteric effector changed the shape of the enzyme?
6. Compare and contrast aerobic and anaerobic pathways.
7. Why is the mitochondrion such an important organelle for survival of the cell? Explain why some cells, such as skeletal muscle cells, have more mitochondria than others do.

Cell growth and reproduction are the most fundamental of all living functions. These two processes together constitute the cell life cycle. *On these processes depend the continued survival of all organisms already living and the creation of all new organisms. Cell growth depends on using genetic information in DNA to make the structural and functional proteins needed for cell survival. Cell reproduction ensures that the genetic information is passed from one generation of cells to the next and from one generation of organisms to the next. Mistakes in these processes can cause lethal genetic disorders, cancer, and other conditions. Advances in our ability to manipulate the genetic code, and thus cell growth and reproduction, now present us with ethical implications more far-reaching than those accompanying the birth of the atomic age. All this makes the cell life cycle a worthy and fascinating topic of study.*

PROTEIN SYNTHESIS

As stated in the previous chapter, the most important anabolic pathway for the student beginning the study of anatomy and physiology to understand is the process of protein synthesis. Protein synthesis is important for several reasons. First of all, protein synthesis is required for cell growth and maintenance. Protein synthesis begins with reading of the genetic "master code" in the cell's DNA. The genetic code dictates the structure of each protein produced during the growth process of each cell. A basic understanding of how the genetic code is used by the cell is essential for understanding modern concepts of human biology, including the study of disease processes.

Protein synthesis is also an important process because it influences all cell structures and functions. Proteins synthesized by the cell either are structural elements themselves or are enzymes or other functional proteins that direct the synthesis of other structural and functional molecules such as carbohydrates, lipids, and nucleic acids. In short, protein synthesis is the central building process for cell growth and maintenance.

Deoxyribonucleic Acid (DNA)

In 1953, American scientist James Watson, and three British scientists, Francis Crick, Maurice Wilkins, and Rosalind Franklin, won the race to solve the puzzle of DNA's molecular structure (Figure 5-1). Nine years later, Watson, Crick, and Wilkins received the Nobel Prize for their brilliant and significant work—hailed as the greatest biological discovery of our time. (Franklin died before the Nobel Prize was awarded.)

Since the original discovery of DNA's structure, we have seen a new branch of biology called *molecular genetics* emerge from our rapidly growing knowledge of DNA and how it works. Indeed, we have seen a revolution in human biology as we witness the continuing application of molecular genetics transform every single aspect of anatomy, physiology, and medicine. We begin our outline of protein synthesis with a discussion of DNA because it truly is, as Watson called it, "the most golden of all molecules."

The **deoxyribonucleic acid** molecule is a giant among molecules. Its size and the complexity of its shape exceed those of most molecules. The importance of its function—in a word, information—surpasses that of any other molecule in the world. To visualize the shape of the DNA molecule, picture an extremely long, narrow ladder made of a pliable material (see Figure 5-1). Now see it twisting round and round on its axis and taking on the shape of a steep spiral staircase millions of turns long. This is the shape of the DNA molecule—a double spiral or *double helix*.

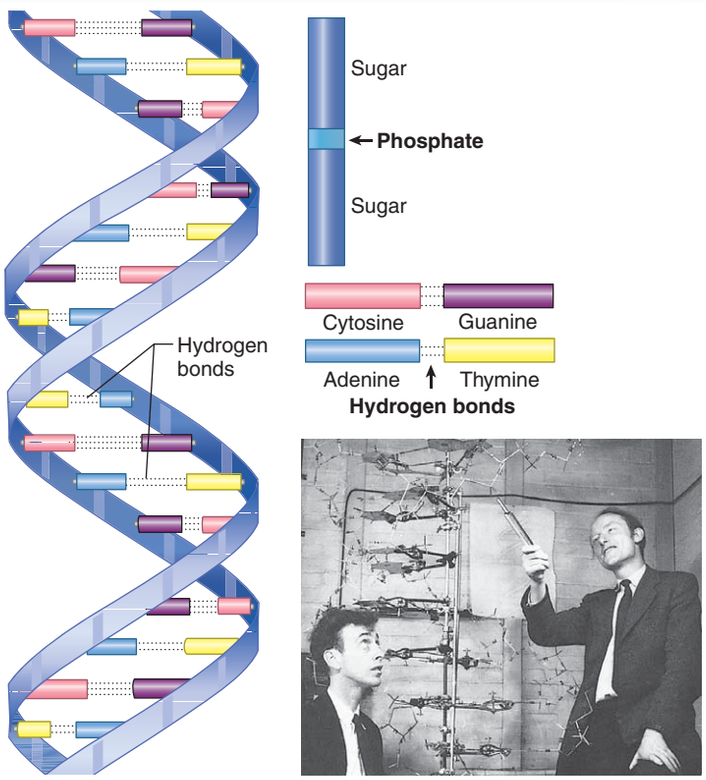

FIGURE 5-1

Watson-Crick model of the DNA molecule. The DNA structure illustrated here is based on that published by James Watson (photograph, left) and Francis Crick (photograph, right) in 1953. Note that each side of the DNA molecule consists of alternating sugar and phosphate groups. Each sugar group is united to the sugar group opposite it by a pair of nitrogenous bases (adenine-thymine or cytosine-guanine). The sequence of these pairs constitutes a genetic code that determines the structure and function of a cell.

The DNA molecule is a *polymer*, which means that it is a large molecule made up of many smaller molecules joined together in sequence. DNA is a polymer of millions of pairs of nucleotides. A nucleotide is a compound formed by combining phosphoric acid with a sugar and a nitrogenous base. The DNA molecule has four different kinds of nucleotides. Each consists of a phosphate group that attaches to the sugar deoxyribose, which attaches to one of four bases. Nucleotides differ, therefore, in their nitrogenous base component—containing either adenine or guanine (purine bases) or cytosine or thymine (pyrimidine bases). (Deoxyribose is a sugar that is not sweet and one whose molecules contain only five carbon atoms.) Notice what

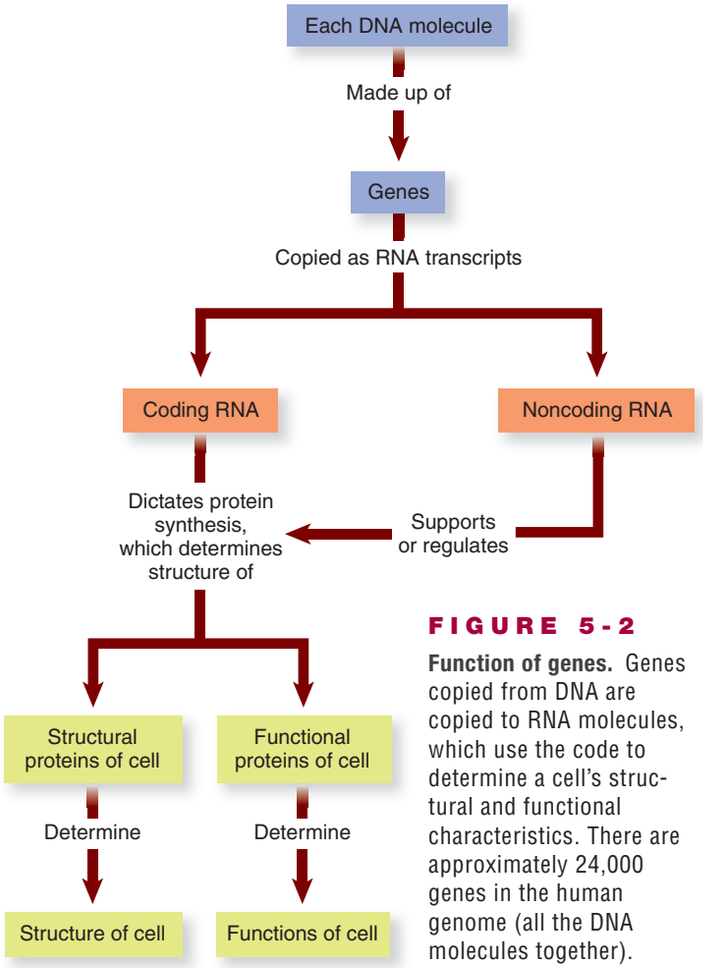

FIGURE 5-2

Function of genes. Genes copied from DNA are copied to RNA molecules, which use the code to determine a cell's structural and functional characteristics. There are approximately 24,000 genes in the human genome (all the DNA molecules together).

the name *deoxyribonucleic acid* tells you—that this compound contains deoxyribose, that it occurs in the nucleus, and that it is an acid.

Figure 5-1 reveals additional and highly significant facts about DNA's molecular structure. First, observe which compounds form the sides of the DNA spiral staircase—a long line of phosphate and deoxyribose units joined alternately one after the other. Look next at the stair steps. Notice two facts about them: two bases join (loosely bound by hydrogen bonds) to form each step, and only two combinations of bases occur. The same two bases invariably pair off with each other in a DNA molecule. Adenine always goes with thymine (or vice versa, thymine with adenine), and guanine always goes with cytosine (or vice versa). This aspect of DNA molecular structure is called **obligatory base pairing.** Pay particular attention to it, for it is the key to understanding how a DNA molecule is able to duplicate itself. DNA duplication, or *replication* as it is usually called, is one of the most important of all biological phenomena because it is an essential and crucial part of the mechanism of genetics.

Another aspect of DNA's molecular structure that has great functional importance is the sequence of its base pairs. Although the kinds of base pairs possible in all DNA molecules are the same, the *sequence* of these base pairs is not the same in all DNA molecules. For instance, the sequence of the base pairs composing the seventh, eighth, and ninth steps of one DNA molecule might be cytosine-guanine, adenine-thymine, and thymine-adenine. Such a sequence of three bases forms a code word or "triplet" called a *codon.* In another DNA molecule the coding sequence of the base pairs making up these same steps might be entirely different, perhaps thymine-adenine, guanine-cytosine, and cytosine-guanine. Perhaps these seem to be minor details, but nothing could be further from the truth, because it is the sequence of the base pairs in the nucleotides that make up the DNA molecules that identifies each gene. Therefore, it is the sequence of base pairs that determines all hereditary traits.

A human *gene* is a segment of a DNA molecule. One gene consists of a chain of approximately 1000 pairs of nucleotides joined one after the other in a precise sequence. Each gene in DNA is a code. As Figure 5-2 shows, a gene is the code for building a short strand of RNA (ribonucleic acid).

Ribonucleic Acid (RNA)

To make a protein, the gene code in DNA is first copied to a messenger ribonucleic acid (mRNA) molecule, or transcript. Each mRNA transcript of a gene may then be translated by the cell and used to build one polypeptide chain. Because it is a copy of a gene's code, we call mRNA *coding RNA.* A few RNA transcripts are instead used to support or regulate polypeptide production. We call such RNA molecules *noncoding RNAs.* Examples of noncoding RNAs are rRNA (ribosomal RNA) and tRNA (transfer RNA). Table 5-1 summarizes the major types of RNA.

TABLE 5-1 Major Types of RNA

ACRONYM	NAME	DESCRIPTION	ROLE IN CELL FUNCTION
RNA Involved in Protein Synthesis			
mRNA	Messenger RNA	Single, unfolded strand of nucleotides	Serves as working copy of one protein-coding gene
rRNA	Ribosomal RNA	Single, folded strand of nucleotides	Component of the ribosome (along with proteins); attaches to mRNA and participates in translation
tRNA	Transfer RNA	Single, folded strand of nucleotides; has an anticodon at one end and an amino acid–binding site at the other end	Carries a specific amino acid to a specific codon of mRNA at the ribosome during translation
snRNP	Small nuclear ribonucleo-protein	Single, folded strand of RNA (combined with polypeptide chains)	Component of the spliceosome (see Box 5-1); attaches to an mRNA transcript to facilitate editing (removal of introns; splicing of exons) into the final version of mRNA
RNA Involved in Gene Silencing (see Box 5-2)			
dsRNA	Double-strand RNA	Double strand of nucleotides (may be up to several hundred nucleotides long)	Involved in RNA interference; *see* siRNA, which is a type of dsRNA
siRNA	Short interfering RNA	Short segment of double-strand RNA (only 20-25 nucleotides long)	Forms part of the RNA-induced silencing complex (RISC) during RNA interference

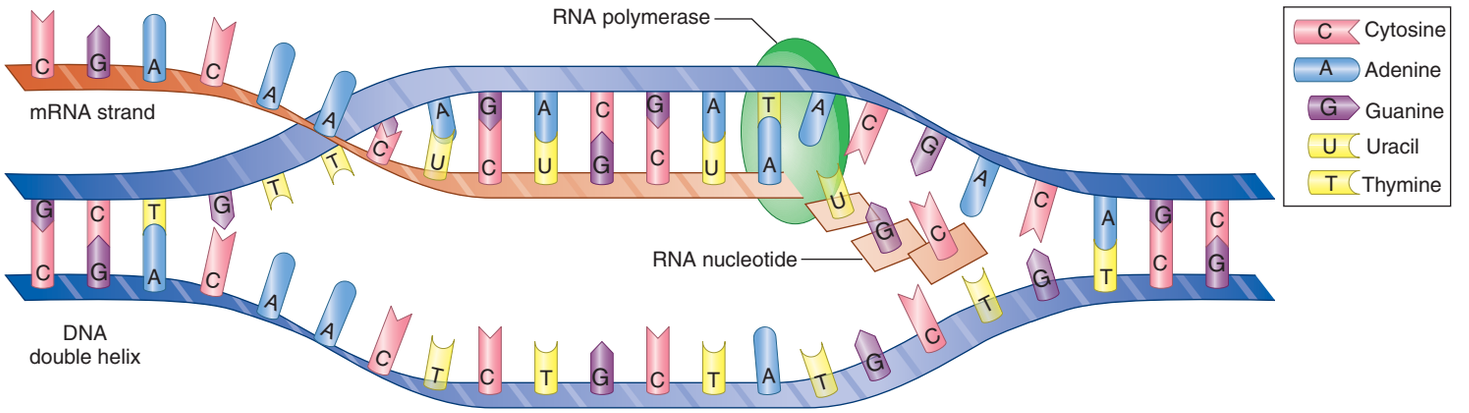

FIGURE 5-3

Transcription of messenger RNA (mRNA). A DNA molecule "unzips" in the region of the gene to be transcribed. RNA nucleotides already present in the nucleus temporarily attach themselves to exposed DNA bases along one strand of the unzipped DNA molecule according to the principle of complementary pairing. As the RNA nucleotides attach to the exposed DNA, they bind to each other and form a chainlike RNA strand called a *messenger RNA (mRNA)* molecule. Notice that the new mRNA strand is an exact copy of the base sequence on the opposite side of the DNA molecule. As in all metabolic processes, the formation of mRNA is controlled by an enzyme—in this case, the enzyme is called *RNA polymerase.*

One or more polypeptides made using RNA are used by the cell to make up each of a cell's structural proteins and the many functional proteins that regulate cellular processes. Therefore, as Figure 5-2 shows, the nearly 24,000 protein-coding genes that make up a cell's genome (DNA set) determine the cell's structure and its functions.

Transcription

Protein synthesis begins when a single strand of RNA (ribonucleic acid) forms along a segment of one strand of a DNA molecule. Figure 5-3 summarizes how this process happens. Recall from Chapter 2 that RNA differs from DNA in certain respects (see Table 2-6, p. 37). Its molecules are smaller than those of DNA, and RNA contains ribose instead of deoxyribose. In addition, one of the four bases in RNA is uracil instead of thymine. As a strand of RNA is forming along a strand of DNA, uracil attaches to adenine, and guanine attaches to cytosine. The process is known as **complementary pairing.** Thus a single-strand molecule of *messenger RNA (mRNA)* is formed.

The name "messenger RNA" describes its function. As soon as it is formed, it separates from the DNA strand, is edited, moves out of the nucleus, and carries a "message" to a ribosome in the cell's cytoplasm to direct the synthesis of a specific polypeptide. Synthesis of any RNA molecule is often called **transcription** because it actually copies or "transcribes" a portion of the DNA code—just like you "transcribe" your class notes when you make a copy of them.

Editing The Transcript

After the preliminary version of the mRNA molecule is formed, its message is "edited" into a final version before it reaches a ribosome (Figure 5-4). Just as you may edit your class notes by rearranging them for clarity after you transcribe them, the editing process allows the cell to arrange the code so that it will work in making a specific, needed polypeptide.

To begin editing, a modified guanine (G) nucleotide caps one end of the mRNA strand. At about the same time, a string of 50 to 200 adenine (A) nucleotides attaches to the opposite end of the mRNA strand. This string of A nucleotides is sometimes called the *poly A tail.* The cap and poly A tail both assist in the next step of mRNA editing. The cap and poly A tail also eventually help transport the mRNA strand out of the nucleus and assist in starting and stopping the translation process described in the next section.

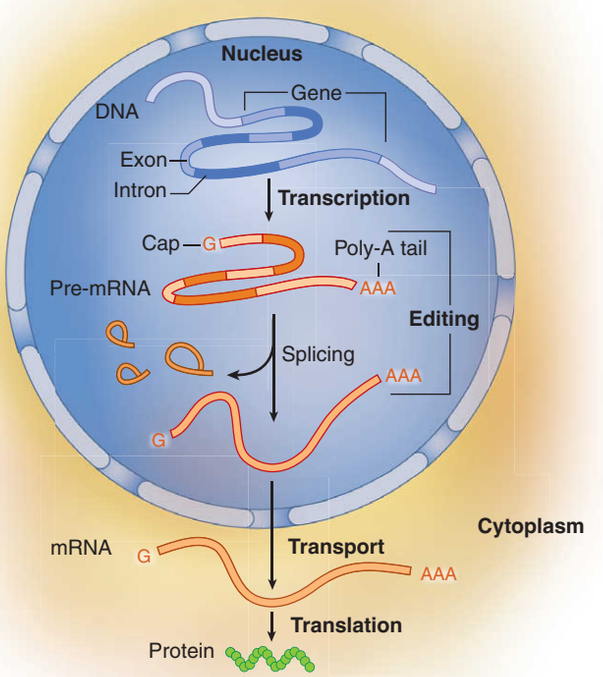

FIGURE 5-4

Editing of an mRNA transcript. After the preliminary mRNA strand is transcribed from a gene in DNA, it is capped with a modified G nucleotide at one end. At the same time, a poly A string is attached at the other end. The intron sections of the transcript are then removed and the remaining exons joined, or spliced, together to form the final version of mRNA. The edited mRNA transcript then moves out of the nucleus to participate in translation (see Figure 5-3).

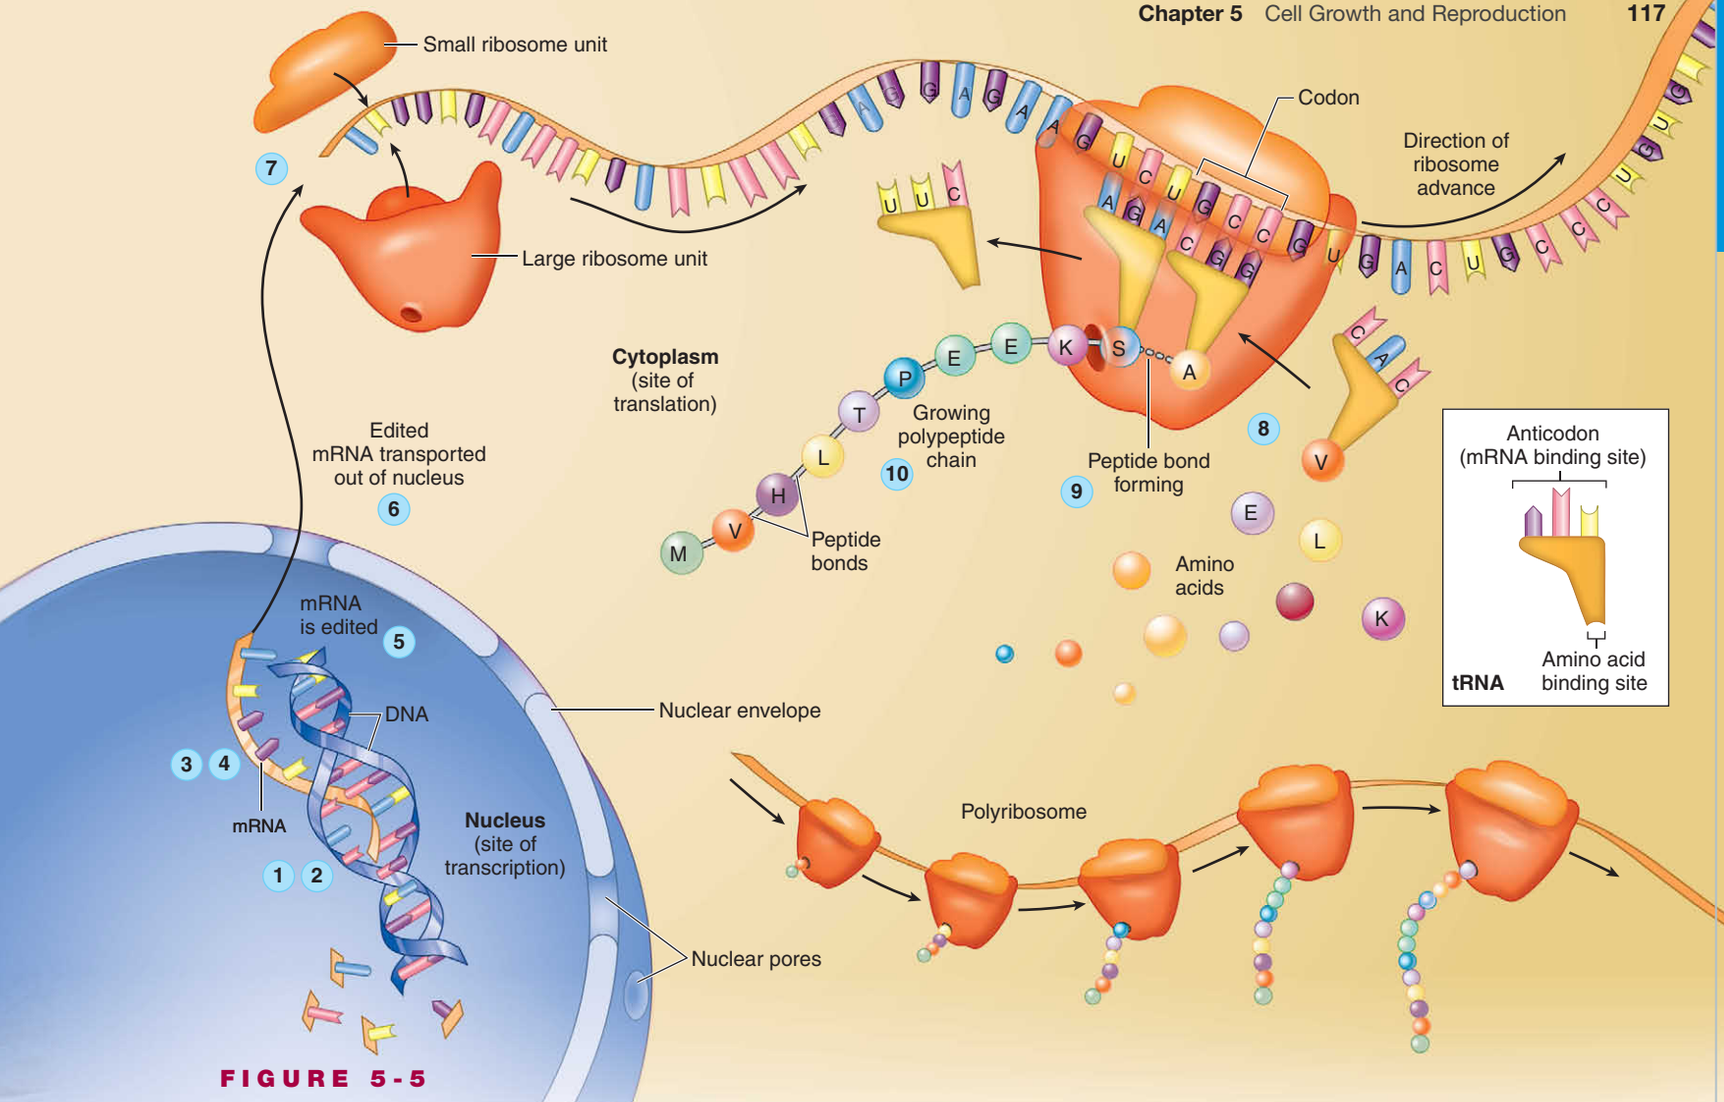

FIGURE 5-5

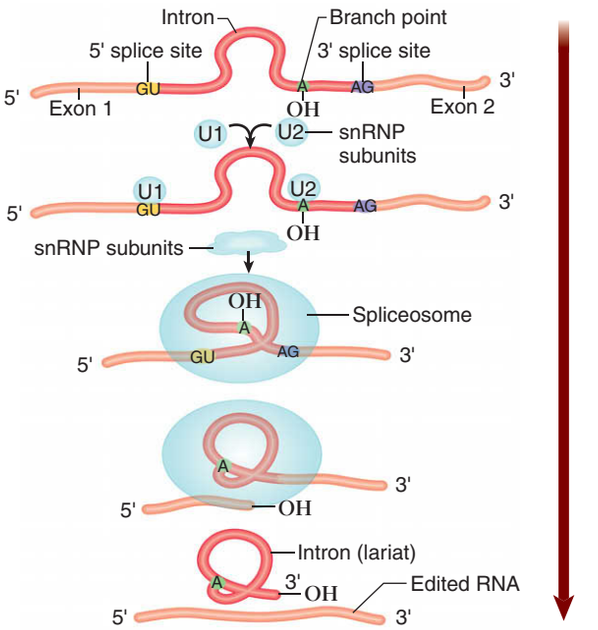
Protein synthesis. Each of the numbered steps in the figure is further summarized in Table 5-2. Protein synthesis begins with transcription, a process in which an mRNA molecule forms along one gene sequence of a DNA molecule within the cell's nucleus *(1-3)*. As it is formed, the mRNA molecule separates from the DNA molecule *(4)*, is edited *(5)*, and leaves the nucleus through the large nuclear pores *(6)*. Outside the nucleus, ribosome subunits attach to the beginning of the mRNA molecule and begin the process of translation *(7)*. In translation, transfer RNA (tRNA) molecules bring specific amino acids—encoded by each mRNA codon—into place at the ribosome site *(8)*. As the amino acids are brought into the proper sequence, they are joined together by peptide bonds *(9)* to form long strands called polypeptides *(10)*. Several polypeptide chains may be needed to make a complete protein molecule. Amino acids are identified by color codes and abbreviations (see Figure 2-26 on p. 55). See Table 5-2 for further clarification of protein synthesis.

Some segments of the RNA transcript represent noncoding parts of DNA called **introns.** These intron segments are removed by a complicated process involving small nuclear structures called *spliceosomes* (Box 5-1). This leaves behind segments that are copies of the DNA's **exons.** Many of these exons encode the functional domains within protein molecules. Only these exon copies will be used in the final recipe for the protein. All the RNA segments representing exons are then *spliced* (joined) together by enzymes to form the final edited form of mRNA. It is this edited version of RNA that leaves the nucleus and participates in the next step of protein synthesis.

Translation

In the cytoplasm, the edited mRNA molecule attracts first a small ribosome subunit and then a large subunit (see Figure 3-6). As the subunits come together, they form an "mRNA sandwich" with the mRNA molecule in the middle. Recall that the two subunits of the now-complete ribosome are composed largely of *ribosomal RNA* (rRNA). The cell is now ready to interpret or "translate" the genetic code and form a specific sequence of amino acids in a process called **translation.**



In translation, yet another type of RNA—*transfer RNA* (tRNA)—becomes involved in protein synthesis (Figure 5-5). As the name implies, tRNA molecules carry or "transfer" amino acids to the ribosome for placement in the prescribed sequence. This function is determined by a unique molecular structure: a binding site for a specific amino acid at one end and a binding site for a specific mRNA codon (base triplet) at the other end (see Figure 2-32 on p. 58). Because tRNA's binding site for mRNA contains the three bases that exactly complement one mRNA codon, this binding site is often called the *anticodon.*

Box 5-1 | Spliceosome

The noncoding *intron* segments of the mRNA initially transcribed from a DNA gene are removed by a complicated process involving small structures called **spliceosomes.** Found inside the nucleus, spliceosomes are about the size of a ribosome. Spliceosomes are made up of subunits consisting of *small nuclear ribonucleoprotein particles* (*snRNPs,* pronounced "snurps").

During mRNA editing, a snRNP subunit will attach at the beginning of an intron and another snRNP will attach at a spot in the intron called the "branch point." Eventually, several different subunits will all assemble on the intron in this manner to form a complete spliceosome. As the Figure shows, the assembled spliceosome then breaks the strand as it bends the intron into a loop called a *lariat.* The intron lariat breaks completely away from the strand, and the spliceosome splices the ends of the remaining coding *exon* segments together. Only the spliced exons remain in the final, edited version of mRNA, which is later translated into the polypeptide encoded by the gene.

The intron may later break down into individual nucleotides, which are then recycled by the cell and used again for transcription. The intron may instead be processed to form a noncoding RNA strand with regulatory functions (see Box 5-2). After splicing is accomplished, the snRNP subunits of the spliceosome are free to reassemble on another intron and repeat the process.

Editing of mRNA by the spliceosome. A simplified view of the complex splicing process.

After picking up its amino acid from a pool of different types of amino acids floating free in the cytoplasm, a tRNA molecule moves to the ribosome. There, its anticodon attaches to a complementary mRNA codon—the codon that signifies the specific amino acid carried by that tRNA molecule (Figure 5-6). After the next tRNA brings its amino acid into place, the two amino acids form a peptide bond. The ribosome then moves down the mRNA strand, making the next mRNA codon available for a complementary tRNA molecule bearing the appropriate amino acid. More tRNA molecules, one after the other in rapid sequence, bring more amino acids to the ribosome and fit them into their proper position in the growing chain of amino acids. As Figure 5-5 shows, the ribosome is all the while moving down the mRNA strand—until it reaches the end, where the ribosome subunits fall away.

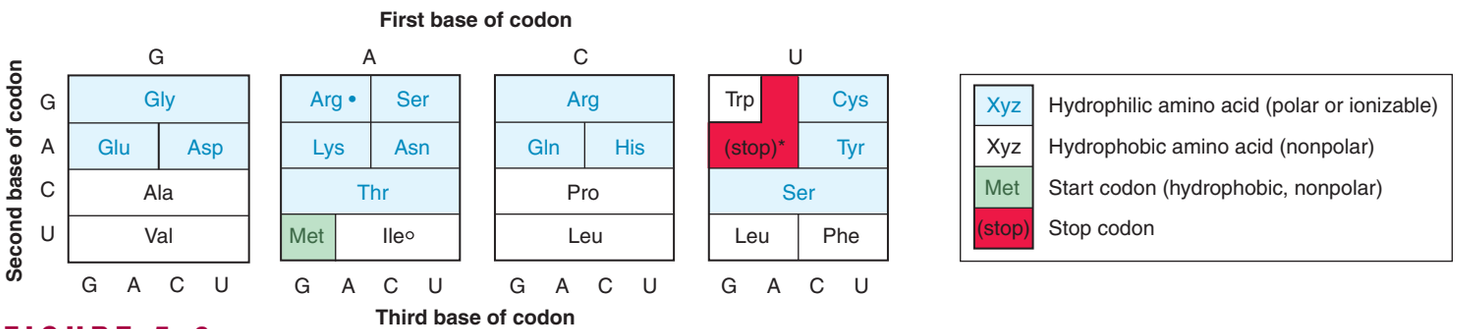

FIGURE 5-6

The genetic code. The first graphic "phrasebook" or "decoder" of the genetic language of the cell was developed in 1966 to summarize the amino acids encoded by various codons (three-base sequences of nucleotides) in RNA. To read this more recent decoder adapted for human biology, start with any codon (for example, CGA). Find the first base along the top of the decoder to find the correct box to use (*C* is the third box). The second base is found in each row of that box, labeled on the left (*G* is the first row). Then use the third base to find the correct column, labeled at the bottom of each box (*A* is the second column, showing that arginine [Arg] is the amino acid encoded by CGA; the bluish color tells us that arginine is a hydrophilic amino acid). •AGG, AGA act as stop codons in mitochondria ◦AUA codes for methionine (Met) in mitochondria * UGA, a stop codon, instead encodes selenocysteine (Sec) in the cytoplasm when a certain pattern appears in the surrounding codons; in mitochondria UGA instead encodes tryptophan.

Each of the tools needed for translation—mRNA, tRNA, and ribosome subunits—can be reused again and again to form copies of the same polypeptide. As a matter of fact, one ribosome can follow another along the same mRNA strand, each making its own polypeptide. Cell biologists often observe a whole train of ribosomes positioned along a single mRNA strand, each making an identical copy of the encoded polypeptide. Such a **polyribosome** is pictured in Figure 5-5.

Translation can be inhibited or prevented by a process called **RNA interference (RNAi).** Box 5-2 details the concept of silencing genes by interfering with the process of translating the genes. RNAi may be used by cells to protect against virus infections.

As specific polypeptides are formed, chaperone proteins and other enzymes in the endoplasmic reticulum (ER), Golgi apparatus, or cytosol assist them in folding and linking to form secondary, tertiary, and perhaps quaternary protein molecules (see Figure 3-8, p. 74). In some polypeptides, enzymes remove or insert additional amino acids or other chemical groups. Enzymes may also catalyze the formation of hybrid molecules such as lipoproteins or glycoproteins.

If any of the proteins formed during this process fail to fold or are misfolded, they will not function properly. Chaperone molecules may be able to refold them into the proper shape. But if not, then the cell risks serious problems. Recall from Chapter 3 that proteasomes break down unfolded and misfolded proteins, allowing the cell to recycle the amino acids and "start over again" (Figure 3-10, p. 76). If this "quality control" program fails to take care of all the defective proteins, they may clump together and form dense masses called *plaques* that could damage or kill the cell. Several degenerative diseases such as Alzheimer disease (AD) and Parkinson disease (PD) involve such a mechanism.

Protein anabolism is one of the major kinds of cellular work. One human cell is estimated to synthesize thousands of different enzymes! In addition to this staggering workload, the cell produces many different protein compounds that help form its own structures, and many cells also synthesize special functional proteins for use in other parts of the body. Liver cells are an example; they synthesize proteins such as prothrombin, fibrinogen, albumin, and globulin for blood plasma.

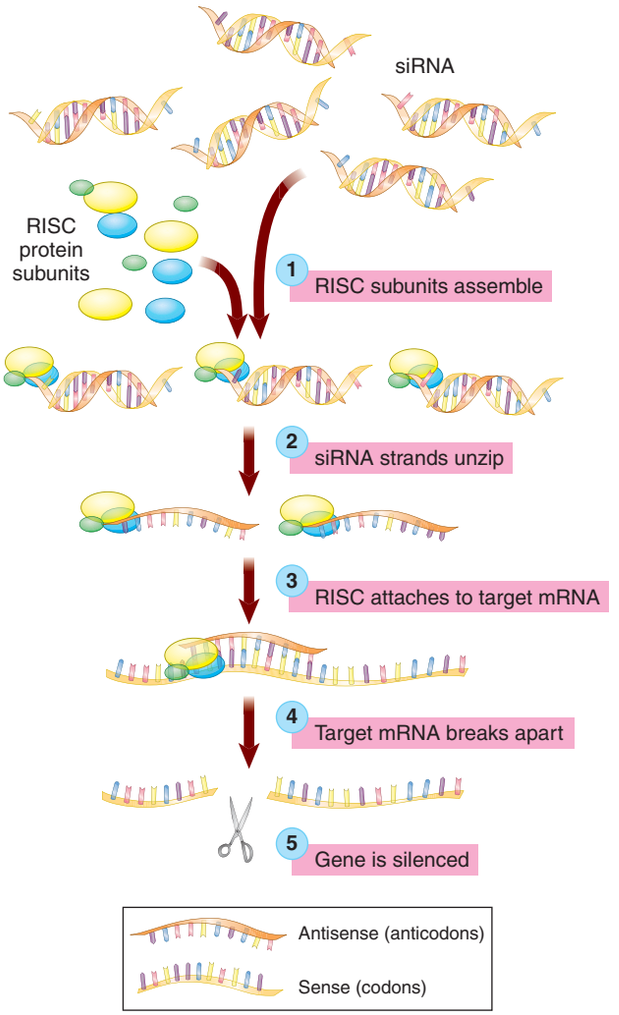
The complete set of proteins synthesized by a cell is called the **proteome** of the cell. The human proteome is the complete set of proteins synthesized by all the cells of the human body. The human proteome is much larger than the human genome (entire set of genes). How can that be, if genes are codes for the polypeptides that make up proteins? It is because each polypeptide may be used in a variety of different combinations with other polypeptides, enabling the production of a huge variety of different proteins.

For your convenience, Table 5-2 gives a detailed, step-by-step outline of this important process of protein synthesis.

TABLE 5-2 Summary of Protein Synthesis

STEP	LOCATION IN THE CELL	DESCRIPTION
Transcription		
1	Nucleus	One region, or gene, of a DNA molecule "unzips" to expose its bases
2	Nucleus	According to the principles of complementary base pairing, RNA nucleotides already present in the nucleoplasm temporarily attach themselves to the exposed bases along one side of the DNA molecule
3	Nucleus	As RNA nucleotides align themselves along the DNA strand, they bind to each other and thus form a chainlike strand called *messenger RNA* (mRNA) This binding of RNA nucleotides is controlled by the enzyme RNA polymerase
Preparation of mRNA		
4	Nucleus	As the preliminary mRNA strand is formed, it peels away from the DNA strand This mRNA strand is a copy, or *transcript,* of a gene
5	Nucleus	The spliceosome edits the mRNA molecule by removing noncoding portions of the strand (introns) and splicing the remaining pieces (exons)
6	Nuclear pores	The edited mRNA strand is transported out of the nucleus through pores in the nuclear envelope
Translation		
7	Cytoplasm	Two subunits sandwich the end of the mRNA molecule to form a ribosome
8	Cytoplasm	Specific transfer RNA (tRNA) molecules bring specific amino acids into place at the ribosome, which acts as a sort of "holder" for the mRNA strand and tRNA molecules The kind of tRNA (and thus the kind of amino acid) that moves into position is determined by complementary base pairing: each mRNA codon exposed at the ribosome site will permit only a tRNA with a complementary *anticodon* to attach
9	Cytoplasm	As each amino acid is brought into place at the ribosome, an enzyme in the ribosome binds it to the amino acid that arrived just before it The chemical bonds formed, called *peptide bonds,* link the amino acids together to form a long chain called a *polypeptide*
10	Cytoplasm	As the ribosome moves along the mRNA strand, more and more amino acids are added to the growing polypeptide chain in the sequence dictated by the mRNA codons (Each codon represents a specific amino acid to be placed in the polypeptide chain) When the ribosome reaches the end of the mRNA molecule, it drops off the end and separates into large and small subunits again; often, enzymes later link two or more polypeptides together to form a whole protein molecule

Box 5-2 | The RNA Revolution



For nearly a half century after the discovery of DNA and its central role in heredity in 1953, scientific understanding of cellular physiology focused primarily on DNA—that "most golden of molecules." RNA was seen as the "go between" molecule, acting mainly as a temporary working copy of a segment of DNA code (gene). However, we soon learned that tRNA (transfer RNA) and rRNA (ribosomal RNA) play a functional role other than direct coding for proteins. This discovery sparked some interest in looking for possible additional regulatory or supportive roles of RNA. Soon, catalytic forms of *noncoding RNA* were shown to be involved in editing mRNA (messenger RNA) transcripts before translation (see Box 5-1). The dawn of the twenty-first century saw an explosion of new discoveries regarding additional roles of RNA in regulating the function of the genome—a scientific revolution that still continues.

One aspect of the RNA revolution involves the surprising treasure trove of noncoding RNA molecules transcribed from the roughly 98% of the DNA genome that does not code for proteins. This includes introns (noncoding segments) that are removed from transcribed (mRNA) protein-coding genes during the editing process before translation. Current scientific databases are chock full of thousands of such regulatory RNA sequences. To cell scientists, it is becoming clear that an extensive RNA regulatory system manages the human genome.

One of the more interesting and useful recent discoveries of the current RNA revolution involves a cellular process of "gene silencing" called **RNA interference (RNAi).** Stated simply, RNAi is a process in which certain genes are silenced and thus synthesis of a particular protein is halted. RNAi occurs naturally in every cell, and scientists are still working to discover the mechanisms that govern the process and the purposes it serves in the cell. In human cells, RNAi is thought to be part of a complex scheme of "fine-tuning" protein synthesis. RNAi plays a variety of roles in the normal regulation of gene expression—what proteins we make and when we make them. For example, the cell could use RNAi to inhibit replication of virus components within the cell during a viral infection—thus protecting the cell. When the RNAi systems fails, it may lead to disease.

How does RNAi work? A special form of RNA with two strands—double-strand RNA (dsRNA)—seems to be the key, as the Figure shows. A small segment of dsRNA, only about 20 or so nucleotides long, called *short interfering RNA (siRNA),* begins the process by combining with protein subunits to form an *RNA-induced silencing complex (RISC).* The siRNA within the RISC unwinds and exposes anticodons that allow the RISC to attach to a particular mRNA transcript. After the RISC attaches to its target mRNA, the mRNA breaks apart and therefore fails to translate its encoded protein. Of course, this effectively silences the gene encoded in the target mRNA. RNAi has also been shown to remodel chromatin, thus changing the "master code" in the DNA molecule!

Scientists are especially excited about using RNAi as a research tool. Researchers can synthesize a particular siRNA double strand and insert it into a cell that they want to study. The siRNA will induce the silencing of a particular gene so that researchers can see what happens to the cell. Knocking out the activity of just one gene at a time allows scientists to test hypotheses regarding how particular genes or particular proteins function in the cell.

RNA interference. 1, Short, double-stranded siRNA (short interfering RNA) segments combine with protein subunits to form an RNA-induced silencing complex (RISC). **2,** The siRNA within the RISC unwinds to expose anticodons. **3,** The activated RISC attaches to target mRNA possessing complementary codons. **4,** The RISC causes the mRNA molecule to break apart. **5,** The mRNA can no longer code for a polypeptide, and thus the gene is effectively silenced. Eventually, the mRNA is broken down into its component nucleotides, which can be reused by the cell to build other RNA molecules.

The therapeutic possibilities of RNAi are also very exciting. Work is already under way to find an effective means of using RNAi for creating antiviral creams containing siRNA to protect against HIV and other viruses. Some researchers are using RNAi to knock out genes that permit permanent tissue damage during heart attacks, kidney failure, and stroke. Researchers are also attempting to harness the power of RNAi to treat cancer and many types of infection.

| QUICK CHECK |

1. How does DNA act as a "master molecule" of a cell?
2. Where in the cell does transcription occur? Editing (splicing)? Translation?
3. What determines the primary sequence in which amino acids are assembled to form a specific polypeptide?

CELL GROWTH

As stated earlier, one of the two major phases of the cell life cycle is the growth phase (Figure 5-7 and Table 5-3). It is during this phase that a newly formed cell produces new molecules, from which it constructs the additional cell membrane, cell fibers, and other structures necessary for growth. And as just stated, all the structural proteins, plus the enzymes needed to make lipids, carbohydrates, and other substances, are made by the cell with information contained in the genes of DNA molecules. First, we will review a simplified account of how these proteins are made and how additional organelles are produced. Later, we explore how the cell replicates its DNA molecules in anticipation of reproduction.

Production of Cytoplasm

As a cell grows, it must produce additional cytoplasm and the plasma membrane necessary to contain it. One mechanism by which additional cytoplasm is produced is protein synthesis. Recall from the previous section that protein synthesis is an anabolic process, which means that small molecules are joined together to form large molecules. Amino acids are strung together in a specific sequence to form polypeptide chains. Two or more folded polypeptide chains may then be linked to form larger, more

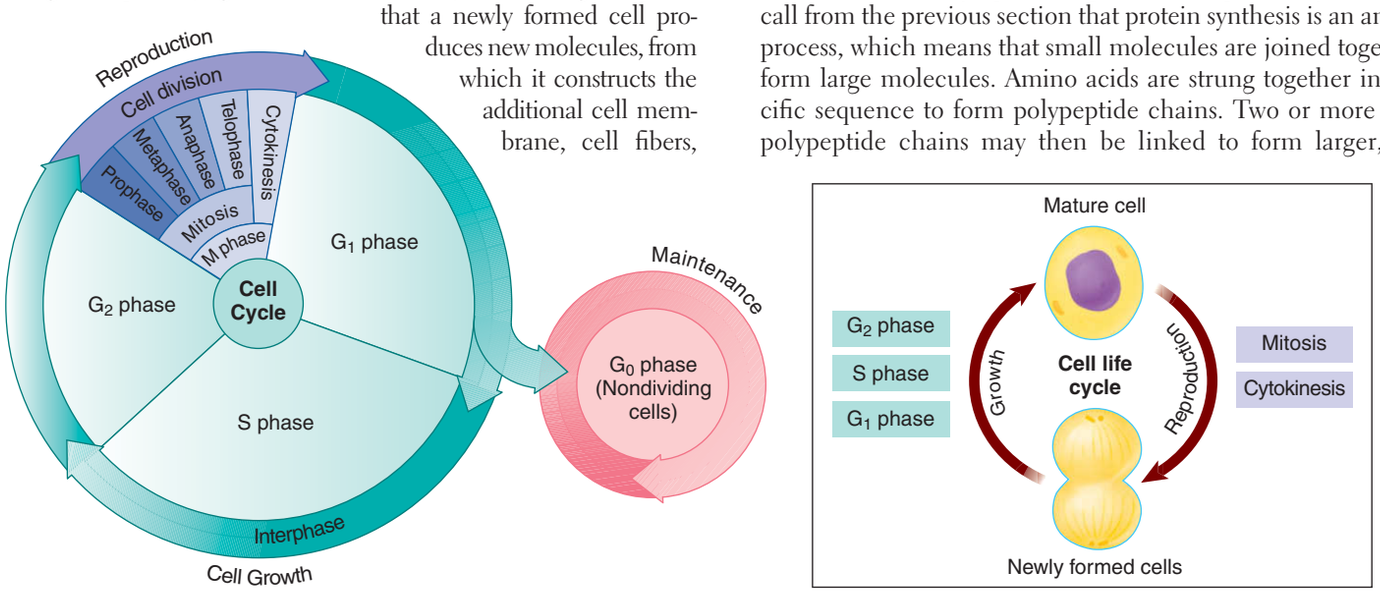


FIGURE 5-7

Life cycle of the cell. The processes of growth and reproduction of successive generations of cells exhibit a cyclic pattern. Newly formed cells grow to maturity by synthesizing new molecules and organelles (*G_1* and *G_2 phases*), including the replication of an extra set of DNA molecules (*S phase*) in anticipation of reproduction. Mature cells reproduce (*M phase*) by first distributing the two identical sets of DNA (produced during the S phase) in the orderly process of mitosis, then by splitting the plasma membrane, cytoplasm, and organelles of the parent cell into two distinct daughter cells (cytokinesis). Daughter cells that do not go on to reproduce are in a maintenance phase (*G_0*).

TABLE 5-3 Summary of the Cell Life Cycle

PHASE OF CELL LIFE CYCLE	DESCRIPTION
Cell Growth	***Interphase***
Protein synthesis	Proteins are manufactured according to the cell's genetic code; functional proteins, the enzymes, direct the synthesis of other molecules in the cells and thus the production of more and larger organelles and plasma membrane; sometimes called the *first growth phase* or *G_1 phase* of interphase
DNA replication	Nucleotides, influenced by newly synthesized enzymes, arrange themselves along the open sides of an "unzippered" DNA molecule, thereby creating two identical daughter DNA molecules; produces two identical sets of the cell's genetic code, which enables the cell to later split into two different cells, each with its own complete set of DNA; sometimes called the *(DNA) synthesis* stage or *S phase* of interphase
Protein synthesis	After DNA is replicated, the cell continues to grow by means of protein synthesis and the resulting synthesis of other molecules and various organelles; this *second growth phase* is also called the *G_2 phase*
Cell Reproduction	***M Phase***
Mitosis or meiosis	The parent cell's replicated set of DNA is divided into two sets and separated by an orderly process into distinct cell nuclei; mitosis is subdivided into at least four phases: *prophase, metaphase, anaphase,* and *telophase*
Cytokinesis	The plasma membrane of the parent cell "pinches in" and eventually separates the cytoplasm and two daughter nuclei into two genetically identical daughter cells

complex protein molecules. In the previous paragraphs, we briefly described how the cell "copies" information from genes and interprets it to form specific polypeptides. Refer again to Table 5-2 to review the process of protein synthesis.

Production of additional proteins means not only that more structural proteins are available to contribute to growth of the cytoplasm but also that more enzymes are available to catalyze the production of other organic compounds. Enzymes produced by protein synthesis are used to make additional carbohydrates, lipids, and nucleic acids—as well as more protein molecules.

Products of cell anabolism during the growth phase of the cell life cycle may be used in the production of additional organelles and plasma membrane. This is a good opportunity to go back to Chapter 3 and review the process by which the cell membrane—and thus membranous organelles and plasma membrane—is made by the ER and Golgi apparatus.

Most of the membranous organelles and plasma membrane increase in size or number (or both) by the membrane-producing processes referred to in Chapter 3. One notable exception is the mitochondrion. Each mitochondrion is capable of replicating itself in a process similar to that used by some one-celled organisms such as bacteria. Mitochondria often replicate themselves during the cell growth phase so that their total number is very large by the time the cell is ready to reproduce. Nonmembranous organelles grow by anabolic processes associated with the centrosome, or microtubule-organizing center, and other cell components, such as ribosomes, that manufacture elements of the cytoskeleton.

DNA Replication

As you may have noticed by now, nucleic acids such as RNA are synthesized directly on the DNA molecule with the help of enzymes. In Chapter 3, we discussed that rRNA is made and formed into ribosome subunits in the nucleolus. In a previous section, we described how mRNA molecules form during transcription by the complementary pairing of RNA bases with DNA bases. Transfer RNA is formed on DNA molecules in a similar fashion and then remains in the cytoplasm to be used over and over. As a cell becomes larger, mechanisms that are just now beginning to be understood trigger the synthesis of a complete copy of the nucleus' set of DNA molecules. Replication of the entire set of DNA molecules, or genome, prepares the cell for reproduction, when one set will go to one daughter cell and the other set to the other daughter cell. The mechanics of DNA replication resemble those of RNA synthesis—as we shall see.

In the first step of DNA replication, the tightly coiled DNA molecules uncoil except for small segments. (Because these remaining tight little coils are denser than the thin, elongated sections, they absorb more stain and appear as chromatin granules under the microscope. The thin, uncoiled sections, in contrast, are invisible because they absorb so little stain.) As the DNA molecule uncoils, its two strands come apart. Then, along each of the two separated strands of nucleotides, a complementary strand forms. Intracellular fluid contains many DNA nucleotides. By the mechanism of obligatory base pairing and with the work of specific enzymes, nucleotides become attached at their correct places along each DNA strand (Figure 5-8). This means that new thymine, that is, from the intracellular fluid, attaches to the "old" adenine in the original DNA strand. Conversely, new adenine attaches to old thymine. Also, new guanine joins old cytosine, and new cytosine joins old guanine.

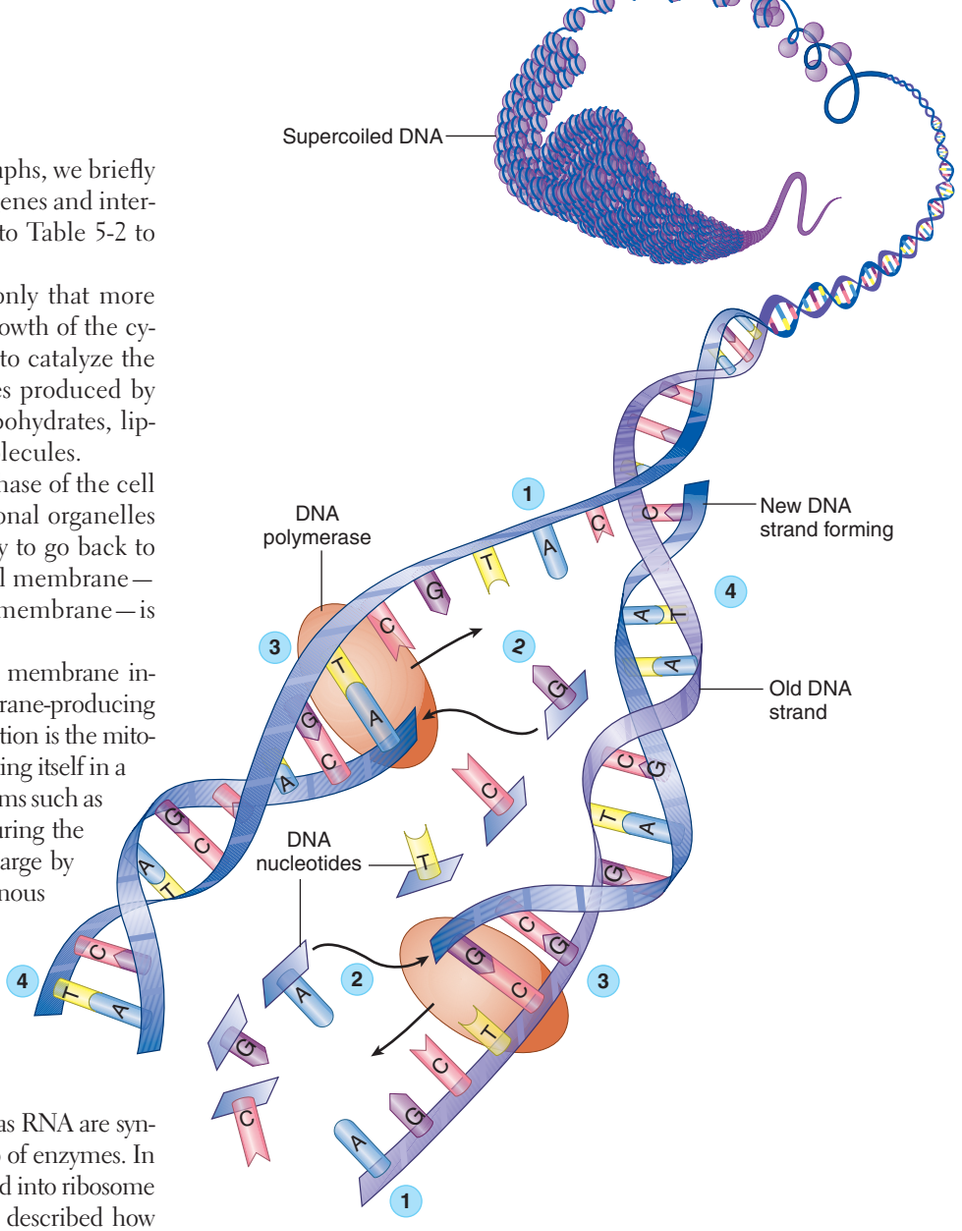

FIGURE 5-8

DNA replication When a DNA molecule makes a copy of itself, it "unzips" to expose its nucleotide bases. Through the mechanism of obligatory base pairing, coordinated by the enzyme DNA polymerase, new DNA nucleotides bind to the exposed bases (in an opposite direction on each strand). This forms a new "other half" to each half of the original molecule. After all the bases have new nucleotides bound to them, two identical DNA molecules will be ready for distribution to the two daughter cells. Numbers refer to steps described in Table 5-4.

Notice in Figure 5-8 that the DNA nucleotides are added in different directions in each of the two strands of the mother DNA molecule. This results in the end of one mother strand not being copied. The loss of useful code is prevented by the presence of **telomeres** (literally, "end roots"), which are strands of "extra" nucleotides that can be lost without affecting the coding part of the chromosome. As telomeres shorten, they eventually disappear unless rebuilt by the enzyme *telomerase*. Telomerase contains a bit of RNA that provides the code for rebuilding the telomere sequence.

TABLE 5-4 Summary of DNA Replication

STEP	DESCRIPTION
1	DNA molecules uncoil and "unzip" to expose their bases
2	Nucleotides already present in the intracellular fluid of the nucleus attach to the exposed bases according to the principle of obligatory base pairing
3	As nucleotides attach to complementary bases along each DNA strand, the enzyme *DNA polymerase* causes them to bind to each other
4	As new nucleotides fill in the spaces left open on each DNA strand, two identical *daughter molecules* are formed; as the parent DNA molecule completely unzips, the two daughter molecules coil to become distinct, but genetically identical, DNA double helices called *chromatids*

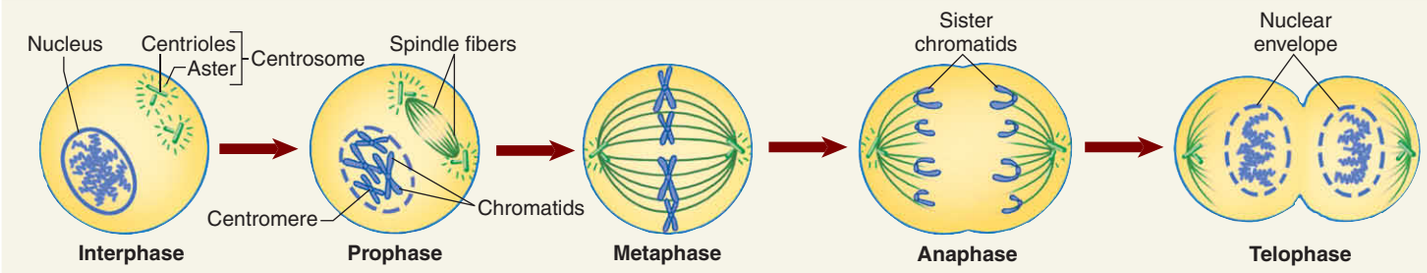
These steps are illustrated in Figure 5-8

By the end of this part of the growth phase, each of the two DNA strands of the original DNA molecule has a complete new complementary strand attached to it. Each half of the DNA molecule, or strand, in other words, has duplicated itself to create a whole new DNA molecule. Thus two new chromosomes now replace each original chromosome. However, at this stage (before cell reproduction has actually begun), they are called *chromatids* instead of chromosomes. The two chromatids formed from each original chromosome contain duplicate copies of DNA and, therefore, the same genes as the chromosome from which they were formed. Chromatids are present as attached pairs. Their point of attachment is called the *centromere*. Table 5-4 gives a detailed, step-by-step account of the process of DNA replication.

Because DNA replication is really the synthesis of new DNA, this part of a cell's growth phase is sometimes called the *synthesis phase* or, simply, the *S phase*. The portions of the growth phase before and after the S phase are simply called the *first growth* (G_1) *phase* and the *second growth* (G_2) *phase*. The first and second growth phases are characterized by a great deal of cytoplasm growth caused by a general increase in the anabolism of protein and other substances, as well as the production of new organelles and plasma membrane. The growth phases are also called *gap phases* because they represent a gap between major reproductive events.

CELL REPRODUCTION

Now that we have briefly looked at the growth phase, it is time to turn to the other major phase of the cell life cycle: cell reproduction (sometimes called the *M phase*). Simply put, cells reproduce by splitting themselves into two separate cells. One *parent cell* thus becomes two smaller *daughter cells*. Splitting of the plasma membrane and cytoplasm into two is called **cytokinesis** (meaning "cell movement"). This name is apt because the cell's cytoskeleton moves the plasma membrane and internal structures in a way that pinches it in half, thereby forming two equivalent daughter cells. Of course, each daughter cell must possess all the resources necessary for survival if the cycle of life is to remain unbroken. That means that besides sufficient cytoplasm, including mitochondria and other organelles, each cell must also have a complete set of genetic information (DNA) needed to run a cell properly. This aspect of cell reproduction or *cell division* is accomplished by a process called **mitosis.** During mitosis, the cell organizes replicated DNA into two identical sets and then distributes one complete set to each daughter cell.



Mitosis

Mitosis, the process of organizing and distributing nuclear DNA during cell division, is a continuous process (Table 5-5) consisting of four distinct phases:

1. Prophase
2. Metaphase
3. Anaphase
4. Telophase

TABLE 5-5 The Major Events of Mitosis

PROPHASE	METAPHASE	ANAPHASE	TELOPHASE
1. Chromosomes shorten and thicken (from coiling of the DNA molecules that compose them); each chromosome consists of two chromatids attached at the centromere	1. Chromosomes align across the equator of the spindle fiber at its centromere	1. Each centromere splits, thereby detaching two chromatids that compose each chromosome from each other, elongating in the process (DNA molecules start uncoiling)	1. Changes occurring during telophase essentially reverse those taking place during prophase; new chromosomes start elongating (DNA molecules start uncoiling)
2. Centrosomes move to opposite poles of the cell; spindle fibers appear and begin to orient between opposing poles		2. Sister chromatids (now called *chromosomes*) move to opposite poles; there are now twice as many chromosomes as there were before mitosis started	2. A nuclear envelope forms again to enclose each new set of chromosomes
3. Nucleoli and the nuclear membrane disappear			3. Spindle fibers disappear

When the cell is not experiencing mitosis—during the growth phase between cell divisions—it is said to be in **interphase** (meaning "between phase"). A cell is not actively reproducing during interphase, but it is actively *preparing for* reproduction. Not just the DNA molecules replicate; the centrosomes replicate as well. The centriole pairs in the parent centrosome split, and each single centriole produces a daughter centriole to produce a new pair of centrioles surrounded by a starlike formation of microtubules called an *aster* radiating outward. Go back to p. 81 and look at Figure 3-16 to review the details of centrosome structure. Additional cytoplasm, membrane, and other cell structures are likewise being constructed in anticipation of cell division.

The cell enters **prophase** when it begins to divide, usually before cytokinesis, or "pinching in half," becomes apparent. During prophase, which literally means "before phase," the nuclear envelope falls apart as the paired chromatids coil up to form dense, compact *chromosomes* (Figure 5-9). By the end of prophase, each chromosome consists of a pair of short, thick bodies joined together at a centromere. At the same time that chromosomes are forming, the replicated centrosomes move away from each other and toward opposite ends, or "poles," of the parent cell. As the centrosomes move apart, a parallel arrangement of microtubules, or *spindle fibers*, is constructed between them. Aster fibers radiating from each centrosome anchor the spindle at each pole of the cell.

The term **metaphase** literally means "position-changing phase." This name is appropriate because during this phase the chromosomes, no longer trapped within a nucleus, are moved by the cytoskeleton into an orderly pattern. The chromosomes are aligned along a plane at the "equator" of the cell about midway between the centriole pairs at opposite poles of the cell (the *equatorial plate*). One chromatid of each chromosome faces one pole of the cell, and its identical sister chromatid faces the opposite pole. Each chromatid then attaches to a spindle fiber.

Anaphase, or the "apart phase," begins as soon as all the chromosomes have aligned along the cell's equator. During this phase of mitosis, the centromere of each chromosome splits to form two chromosomes, each consisting of a single DNA molecule. Each chromosome is pulled toward the nearest pole (that is, toward the nearest centrosome) by a spindle fiber. The effect of this movement is that one set of DNA molecules reaches one end of the cell and another set reaches the other end of the cell—forming two separate, but identical pools of genetic information. By the time a dividing cell has reached anaphase, cytokinesis has usually become apparent. The cell has not completely split yet, but cleavage along the equator may be visible.

Telophase is the "end phase," or "completion phase," of mitosis. It is during this phase that the DNA is returned to its original form and location within the cell. The cell rebuilds the nuclear envelope, and the DNA molecules are trapped within a membranous basket once again. At the same time, the chromosomes elongate back into the chromatin form. Recall that DNA cannot participate in protein synthesis unless at least some of its length is uncoiled. Spindle fibers, which are no longer needed, disappear during telophase. Cytokinesis is usually completed during or just after the telophase portion of mitosis. Each genetically identical daughter cell thus formed is now in interphase. It will grow and develop into a mature cell, perhaps becoming a parent itself.

A series of photographs summarizing the events of mitotic cell division (mitosis and cytokinesis) are shown in Figure 5-10.

See an image of how chromosomes unwind during telophase to form specific areas of chromatin called *chromosome territories* in ***Chromosome Territories*** online at ***A&P Connect.***

evolve

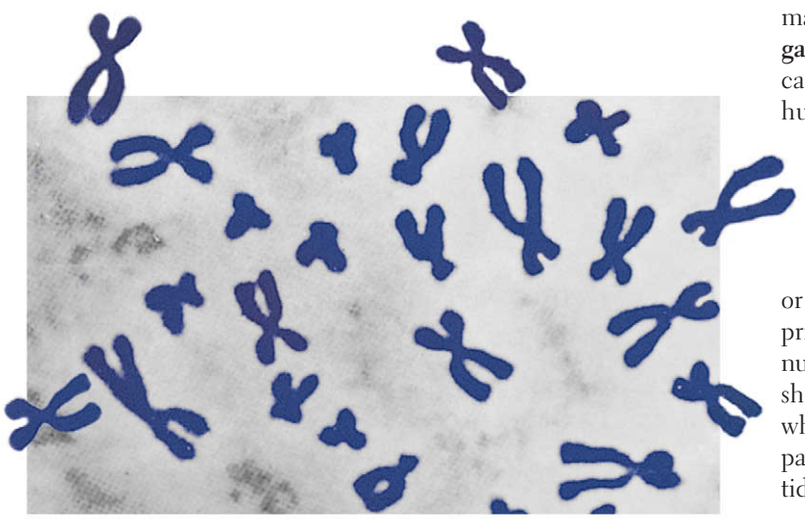

FIGURE 5-9

Chromosomes. Light micrograph showing chromosomes of a normal human cell before cell division is complete (metaphase). Additional detailed views of chromosome structure are found in Chapter 37.

Meiosis

Meiosis is the type of cell division that occurs only in primitive sex cells during the process of becoming mature sex cells. As a result of meiosis, the primitive sex cells (*spermatogonia* in the male and *oogonia* in the female) become mature sex cells called **gametes.** Male gametes are named *spermatozoa* but are usually called *sperm.* Female gametes are named *ova* (singular, *ovum*). In humans, all somatic cells contain 46 chromosomes. This total of 46 chromosomes per cell is known as the **diploid** number of chromosomes. *Diploid* comes from the Greek *diploos*, meaning "two" or "pair." In somatic cells the 46 chromosomes are present in 22 homologous pairs—the remaining 2 being the sex chromosomes XY (male) or XX (female). During meiosis, or *reduction division*, the diploid chromosome number (46) of the primitive spermatogonium or oogonium is reduced to the **haploid** number of 23 found in mature sex cells, or gametes. Figure 5-11 shows that meiotic division occurs in two steps: *meiosis I*, during which the number of chromosomes is halved but the chromatid pairs remain together, and *meiosis II*, during which the chromatids finally split apart.

The end result of fertilization is the fusion of two gametes, each containing the haploid number (23) of chromosomes. Fertilization results in formation of a zygote, which is a diploid cell having 46 chromosomes, 23 chromosomes being contributed by each parent. The zygote is the first cell of the human offspring. It will

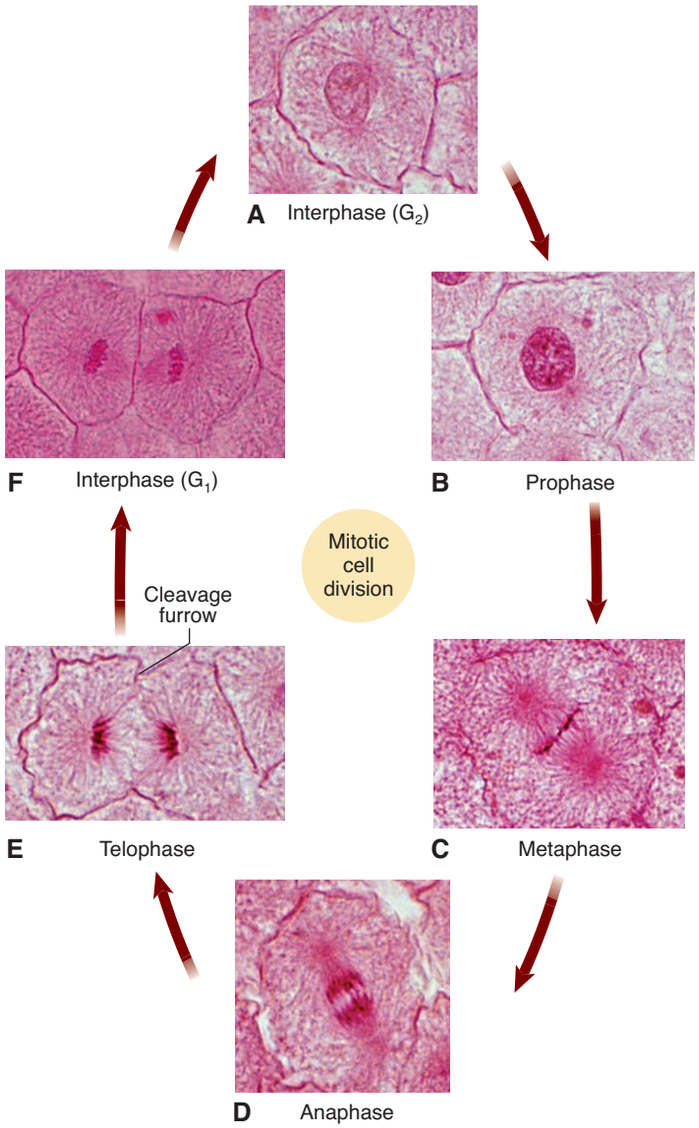

FIGURE 5-10

Mitotic cell division. Series of photomicrographs showing animal cells undergoing a cycle of mitotic cell division. **A,** Interphase—division begins at the end of interphase (G_2), after the cell has already replicated the DNA in its nucleus and increased its cytoplasm sufficiently for division. **B,** Prophase—chromosomes form from the nuclear chromatin material as the nuclear envelope disappears. **C,** Metaphase—chromosomes line up along the cell's equatorial plate, with spindle fibers distinctly visible on either side. **D,** Anaphase—spindle fibers pull each of the two chromatids (now called chromosomes) toward opposite poles of the cell. **E,** Telophase—chromosomes are now at opposite poles, nuclear envelopes begin forming around each group, and the cleavage furrow of cytokinesis becomes apparent. **F,** Interphase—after mitosis and cytokinesis are complete, the two daughter cells begin the first growth (G_1) of interphase. When they are ready, each daughter cell may continue the life cycle by undergoing mitotic division.

then undergo mitotic division to form 2 cells, then 4, and so on until 100 trillion cells are eventually formed.

During development, the new daughter cells will specialize, or **differentiate,** to become specific cell types, which in turn will form specific organs. In mature tissues, some cells may opt out of the cycle and remain in a growth and maintenance phase called the G_0 *phase*. We will have a little more to say about the development and maintenance of different tissue types in Chapter 6. More detailed information about meiosis and the formation of sex cells, fertilization, and development is explored in Chapters 34 through 37.

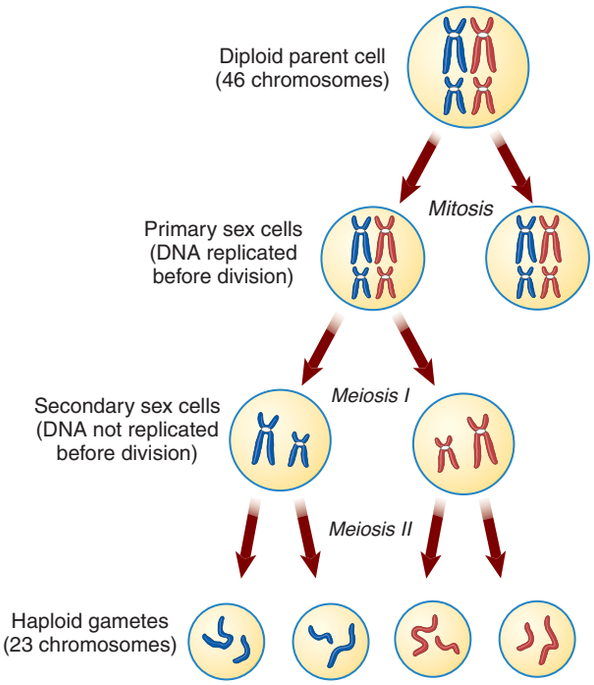

FIGURE 5-11

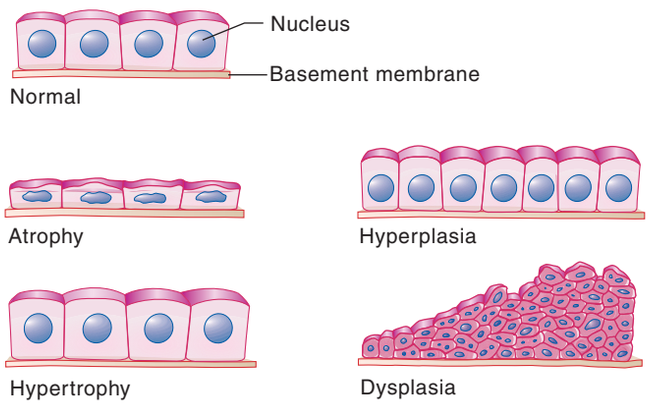
Meiosis. Meiotic cell division takes place in two steps: meiosis I and meiosis II. Meiosis I is called *reduction division* because the number of chromosomes is reduced by half (from the diploid number to the haploid number). A more detailed diagram of meiosis is presented in Figure 36-1 on p. 1098.

REGULATING THE CELL LIFE CYCLE

Table 5-3 summarizes the main phases of the cell life cycle, including the growth and reproductive phases. You may wonder what mechanisms control when and how a cell moves from one stage to another in its cycle of growth and reproduction. A series of independent experiments by Leland Hartwell, Tim Hunt, and Paul Nurse paved the way for understanding the molecular mechanisms that regulate the cell's life cycle. This achievement won the three scientists a Nobel Prize in 2001. Their experiments revealed the activity of regulatory proteins known as *cyclins* and *cyclin-dependent kinases* (CDKs) and the genes that produce them. The number of CDK enzyme molecules stays about the same throughout the cell's life cycle, but the number of cyclin molecules varies widely. Scientists often compare the CDK molecules with an engine that drives the cell forward through the phases of its life cycle. Cyclins act like a gear box that "shifts" the CDK into "drive" and thus moves the cell into the next phase of the cycle. Discoveries about how these molecules and their genes work have already helped us better understand the mechanisms of cancer and other cellular disorders (Box 5-3).

Box 5-3 | Changes in Cell Growth, Reproduction, and Survival



Cells have the ability to adapt to changing conditions. Cells may alter their size, reproductive rate, or other characteristics to adapt to changes in the internal environment. Such adaptations usually allow cells to work more efficiently. However, sometimes cells alter their characteristics abnormally—thereby decreasing their efficiency and threatening the health of the body. Common types of changes in cell growth and reproduction are summarized below.

Cells may respond to changes in function, hormone signals, or the availability of nutrients by increasing or decreasing in size. The term **hypertrophy** (hye-PER-tro-fee) refers to an increase in cell size, and the term **atrophy** (AT-ro-fee) refers to a decrease in cell size. Either type of adaptive change can occur easily in muscle tissue. When a person continually uses muscle cells to pull against heavy resistance, as in weight training, for example, the cells respond by increasing in size. Body builders thus increase the size of their muscles by hypertrophy—increasing the size of muscle cells. Atrophy often occurs in underused muscle cells. For example, when a broken arm is immobilized in a cast for a long period, muscles that move the arm often atrophy. Because the muscles are temporarily out of use, muscle cells decrease in size. Atrophy may also occur in tissues whose nutrient or oxygen supply is diminished. Sometimes cells respond to changes in the internal environment by increasing their rate of reproduction—a process called **hyperplasia** (hye-per-PLAY-zha). The ending *–plasia* comes from a Greek word that means "shape" or "formation"—referring to the formation of new cells. Because *hyper-* means "excessive," *hyperplasia* means excessive cell reproduction. Like hypertrophy, hyperplasia causes an increase in the size of a tissue or organ. However, hyperplasia is an increase in the *number of cells* rather than an increase in the size of each cell. A common example of hyperplasia occurs in the milk-producing glands of the female breast during pregnancy. In response to hormone signals, the glandular cells reproduce rapidly to prepare the breast for milk production and nursing.

If the body loses its ability to control mitosis normally, abnormal hyperplasia may occur. The new mass of cells thus formed is a tumor or **neoplasm** (NEE-o-plazm). Neoplasms may be relatively harmless growths called **benign** (be-NYNE) tumors. If tumor cells can break away and travel through the blood or lymphatic vessels to other parts of the body, the neoplasm is a **malignant tumor,** or cancer. Cells in malignant neoplasms often exhibit a characteristic called **anaplasia** (an-ah-PLAY-zha). Anaplasia is a condition in which cells fail to *differentiate* into a specialized cell type. **Dysplasia** (diss-PLAY-zha) is an abnormal change in shape, size, or organization of cells in a tissue and is often associated with neoplasms.

Part *A* of the Figure summarizes a few of the changes that can occur in cell growth and reproduction.

Cells also die sometimes. In **necrosis** (ne-KROH-sis), cells die because of an injury or pathological condition, often causing nearby cells to die and triggering an immune response called *inflammation,* which removes the debris if possible. Nonpathological cell death, often called **apoptosis** (ap-po-TOH-sis *or* ap-op-TOH-sis), occurs frequently in the cells of your body. Apoptosis is a type of programmed cell death in which organized biochemical steps within the cell lead to fragmentation of the cell and removal of the pieces by phagocytic cells. Apoptosis occurs when cells are no longer needed or when they have certain malfunctions that could lead to cancer or some other potential problem. Apoptosis is the normal process by which our tissues and other groups of cells remodel themselves throughout the life span. Although apoptosis is a normal cell function, it can be abnormally triggered in some conditions.

A, Alterations in cell growth and reproduction. **B,** Apoptosis. *1,* Early in apoptosis, the cell begins making the enzymes needed to break down the cell, but no structural changes yet occur. *2,* As apoptosis proceeds, surface features such as microvilli and cell junctions are lost, and nuclear DNA condenses and is broken into fragments. *3,* The cell then rapidly splits into apoptotic bodies. Notice that the nucleus has also fragmented. *4,* Apoptotic bodies may then be digested by adjacent cells, by extracellular enzymes, or (not shown) by nearby phagocytic cells.

| QUICK CHECK |

4. What are the two major phases of the cell life cycle? During which of these phases does mitosis occur?
5. How does the cytoplasm of a cell grow?
6. What is the difference between mitotic cell division and meiotic cell division?

Cycle of LIFE
Cells

Different types of cells have highly variable life cycles. The active life span of a single cell may vary from a few minutes to years, depending on its function and level of activity. Some cells may remain dormant or inactive for years. Then, when they are "activated" by some biological need and become functional, their life span may be shortened dramatically.

One example involves cells in the immune system that are programmed to produce antibodies against a specific disease. Other examples include the female sex cells, or ova, which are present from birth. They mature throughout the reproductive life span of the individual so that each month at least one cell will become fully developed and provide an opportunity for fertilization to occur.

Structure follows function at every level of organization in the body. Frequently, function decreases with advancing age, and resulting changes occur in cell numbers and their ability to function effectively. As a result, we lose functional capacity in every body organ system. Our muscles may atrophy, the skin will lose its elasticity, and our respiratory, cardiovascular, and skeletal systems will become affected because of cellular changes that accompany aging.

the BIG picture

Cell Growth, Reproduction, and the Whole Body

In previous chapters, we considered the cell as a whole living unit in which many dynamic processes keep an individual cell alive and functioning. Let's take another step back from our mental image of a cell. Picture a huge "society" of trillions of cells—the human body. We now understand more fully how we develop from a single cell to that huge society of cells. We have seen that the growth of cytoplasm, the accurate replication of the genetic code, and cell division are all necessary to the growth and maintenance of the entire human body.

Looking back on the last few chapters, we can now better appreciate that each cell contributes to the survival of its society (the body)—and itself—by specializing in functions that help maintain the relative constancy of the internal environment. When we think of that relative constancy, homeostasis, we should appreciate that it is all accomplished by the action of many individual cells. How are individual cells grouped together? How do they function as groups to promote homeostasis? These questions are answered, at least in part, in Chapter 6.

MECHANISMS of DISEASE

CELL GROWTH AND REPRODUCTION DISORDERS

Disorders Involving DNA and Protein Synthesis

Genetic disorders are pathological conditions caused by mistakes, or **mutations,** in a cell's genetic code. Abnormal genes cause the production of abnormal enzymes or other proteins. Abnormal proteins, in turn, cause abnormalities in cellular function—producing a specific disease. Many diseases are known to be caused by this mechanism, including some diseases such as infections or cancer that also involve other pathological mechanisms. Another example is **sickle cell anemia,** a blood disease caused by the production of abnormal hemoglobin (the protein in red blood cells that carries oxygen). Mistakes in enzyme production can cause a whole group of metabolic disorders called **inborn errors of metabolism.**

Disorders Involving Cell Reproduction

As mentioned earlier in this chapter (see p.126), abnormalities in mitotic division can cause tumors to arise. **Cancers** are tumors that tend to spread, often disrupting vital functions and eventually killing those with the disease. Even noncancerous tumors can cause significant health impairment—or death—depending on their size and location.

Infections

Bacteria and *viruses* can infect cells and thus damage them in ways that produce disease. Bacteria, tiny one-celled organisms, may parasitize cells directly and thus destroy them by stealing the cells' proteins and other substances needed for cell survival. The bacteria may produce toxins that damage cells

or interrupt cell functions. These toxins may also elicit violent reactions of the immune system. Viruses are microscopic particles that contain DNA or RNA. Viruses cause disease by taking over the genetic apparatus of a cell to force a cell to produce viral DNA or RNA and synthesize viral proteins. Thus, viral infections use the cell's resources to produce viral products—or even new viruses. If enough cells are damaged during a bacterial or viral infection to disrupt vital functions, death may result (Figure 5-12).

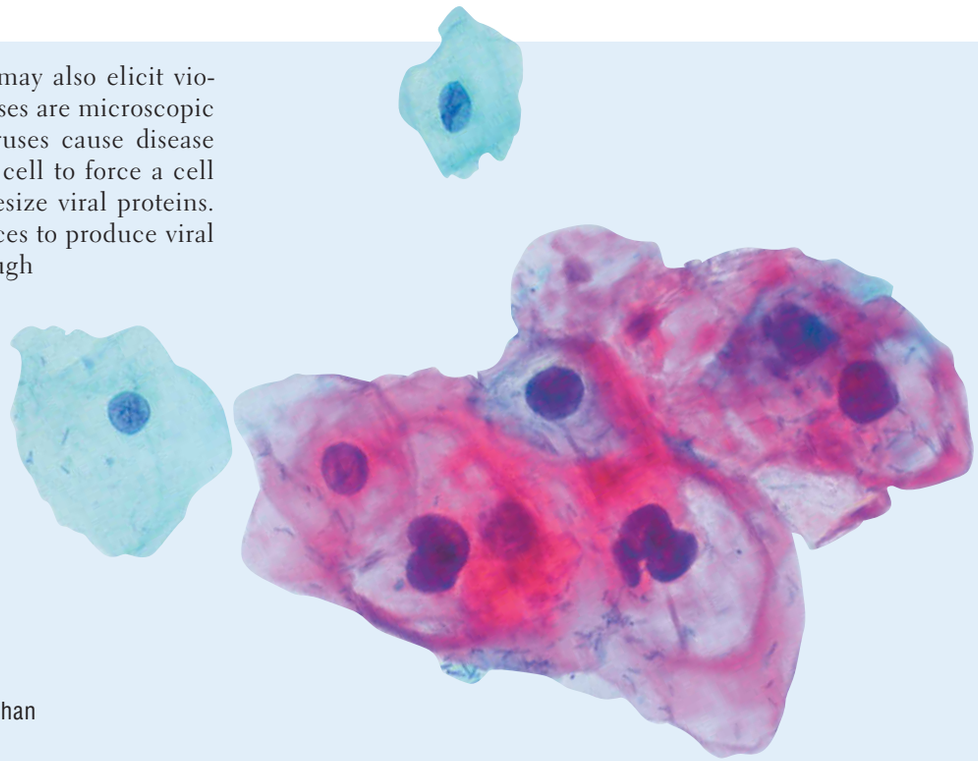


FIGURE 5-12

Viral infection. The pink cells have been infected by human papilloma virus (HPV) and show abnormal structure that is quite different than normal cells (blue).

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

GROWTH AND REPRODUCTION OF CELLS

A. Cell growth and reproduction of cells are the most fundamental of all living functions and together constitute the cell life cycle
   1. Cell growth—depends on using genetic information in DNA to make the structural and functional proteins needed for cell survival
   2. Cell reproduction—ensures that genetic information is passed from one generation to the next

PROTEIN SYNTHESIS

A. Protein synthesis is a central anabolic pathway in cells (Table 5-2)
B. Deoxyribonucleic acid (DNA)
   1. A double-helix polymer (composed of nucleotides) that functions to transfer information, encoded in genes, to direct the synthesis of proteins (Figure 5-1)
   2. Gene—a segment of a DNA molecule that consists of approximately 1000 pairs of nucleotides and contains the code for synthesizing one RNA molecule, which then may be translated into one polypeptide (Figure 5-2)
C. Ribonucleic acid (RNA) (Table 5-1)
   1. Coding RNA—mRNA, which is a transcript of a code for one polypeptide
   2. Noncoding RNA—rRNA and tRNA, which are each copies of a DNA gene but regulate processes rather than code for a polypeptide
D. Transcription—mRNA forms along a segment of one strand of DNA (Figure 5-3)
E. Editing the transcript (Figure 5-4)
   1. Noncoding introns are removed and the remaining exons are spliced together to form the final, edited version of the mRNA copy of the DNA segment
   2. Spliceosomes are ribosome-sized structures in the nucleus that splice mRNA transcripts (Box 5-1)
F. Translation (Figure 5-5)
   1. After leaving the nucleus and being edited, mRNA associates with a ribosome in the cytoplasm
   2. tRNA molecules bring specific amino acids to the mRNA at the ribosome; the type of amino acid is determined by the fit of a specific tRNA's anticodon with mRNA's codon (Figure 5-6)
   3. As amino acids are brought into place, peptide bonds join them—eventually producing an entire polypeptide chain
   4. Translation of genes can be inhibited by RNA interference (RNAi), which protects the cell against viral infection (Box 5-2)
G. Processing—chaperone molecules and other enzymes in the cytosol, ER, and Golgi apparatus help polypeptides fold and then possibly combine into larger protein molecules or hybrid molecules
H. Proteome
   a. All the proteins synthesized by a cell make up the cell's proteome
   b. All the proteins synthesized in the whole body is called the *human proteome*

CELL GROWTH

A. Newly formed cells produce a variety of molecules and other structures necessary for growth by using the information contained in the genes of DNA molecules; this stage is known as *interphase* (Figure 5-7)
B. Production of cytoplasm
   1. More cell material is made, a largely anabolic process
   2. Growth and/or replication of organelles and plasma membrane
   3. Replication of centrosomes and DNA in anticipation of cell division
C. DNA replication (Table 5-4)
   1. Replication of the genome prepares the cell for reproduction; the mechanics are similar to RNA synthesis
   2. DNA base pairing (Figure 5-8)
      a. The DNA strand uncoils and the strands come apart
      b. Along each separate strand, a complementary strand forms
         (1) Because the strands are rebuilt in opposite directions, one strand is not completely rebuilt
         (2) Telomeres are noncoding, protective segments of DNA at the ends of a chromosome; they are used up during DNA replication to prevent loss of needed DNA code; telomeres can be rebuilt by the enzyme telomerase
      c. The two new strands are called *chromatids* instead of chromosomes
      d. Chromatids are attached pairs; the point of attachment is called the centromere
D. The growth phase of the cell life cycle can be subdivided into the first growth phase (G_1), the [DNA] synthesis phase (S), and the second growth phase (G_2)

CELL REPRODUCTION

A. Cells reproduce by splitting themselves into two smaller daughter cells (Table 5-5)
B. Mitotic cell division—the process of organizing and distributing nuclear DNA during cell division has four distinct phases (Figure 5-10)
   1. Prophase—"before phase"
      a. After the cell has prepared for reproduction during interphase, the nuclear envelope falls apart as the chromatids coil up to form chromosomes that are joined at the centromere (Figure 5-9)
      b. As chromosomes form, centrosomes (centrioles/aster) move away from each other toward the poles of the

parent cell and spindle fibers are constructed between them
2. Metaphase—"position-changing phase"
   a. Chromosomes move so that one chromatid of each chromosome faces its respective pole
   b. Each chromatid attaches to a spindle fiber
3. Anaphase—"apart phase"
   a. The centromere of each chromosome splits to form two chromosomes, each consisting of a single DNA molecule
   b. Each chromosome is pulled toward the nearest pole to form two separate, but identical, pools of genetic information
4. Telophase—"end phase"
   a. DNA returns to its original form and location within the cell
   b. After completion of telophase, each daughter cell begins interphase to develop into a mature cell

C. Meiosis (Figure 5-11; see also Figure 36-1)

REGULATING THE CELL LIFE CYCLE

A. Cyclin-dependent kinases (CDKs) are activating enzymes that drive the cell through the phases of its life cycle
B. Cyclins are regulatory proteins that control the CDKs and "shift" them to start the next phase

CYCLE OF LIFE: CELLS

A. Different types of cells have different life cycles
B. Advancing age creates changes in cell numbers and in their ability to function effectively
   1. Examples of decreased functional ability include muscle atrophy, loss of elasticity of the skin, and changes in the cardiovascular, respiratory, and skeletal systems

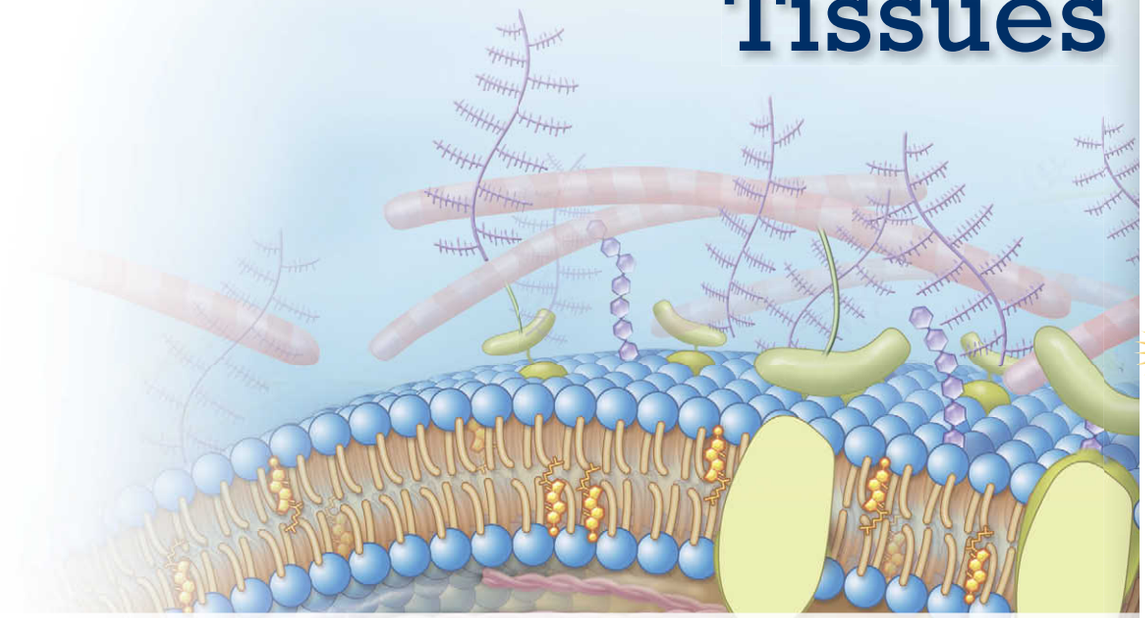
THE BIG PICTURE: CELL PHYSIOLOGY AND THE WHOLE BODY

A. Most cell processes are occurring at the same time in all of the cells throughout the body
B. The processes of normal cell function result from the coordination dictated by the genetic code

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Describe the size and shape of a DNA molecule.
2. Where is DNA located?
3. Briefly outline the steps of protein synthesis.
4. As a cell grows, how is additional cell material added?
5. What are the steps involved in DNA replication and when does it occur?
6. Define mitosis.
7. Briefly describe the four distinct phases of mitosis.
8. Define meiosis and discuss its four distinct stages.
9. When does the reduction of chromosomes from the diploid to the haploid number take place?
10. Give examples of normal and abnormal hyperplasia.



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Certain antibiotics can damage ribosomes in normal human body cells. People taking these antibiotics need to be carefully monitored. Summarize the result of fewer ribosomes on the process of transcription and translation.
2. DNA is often called the "blueprint of life." However, DNA is composed of only four nitrogen bases as part of its nucleotide structure. Explain how these four nitrogen bases can influence the genetic makeup of an individual.
3. Watson called DNA "the most golden of all molecules" primarily because of its role in protein synthesis. How would you describe the importance of the process of protein synthesis in the functioning of a cell?
4. A cast is frequently used to immobilize a broken bone. When the cast is removed, the muscles on that limb are usually smaller and weaker than the muscles on the other limb. How would you explain the difference between the two limbs?
5. Compare and contrast hypertrophy and hyperplasia.
6. The nucleus has been called the "brain" or the "control center" of the cell. By applying what you have learned, describe how the nucleus can control growth, development, and day-to-day functions of a cell.

continued on p. 160

A tissue is a group of similar cells that perform a common function. Tissues can be thought of as the fabric of the body, which is "sewn together" to form the organs of the body and to hold all the organs together as a whole.

To understand the fabric of the body, we begin with an overview of the general organization and development of tissues. We then outline the chief characteristics of the various tissue types that you will encounter later in your study of human anatomy and physiology.

INTRODUCTION TO TISSUES

Each tissue specializes in performing at least one unique function that helps maintain homeostasis, ensuring the survival of the whole body. The arrangement of cells in one tissue may form a thin sheet only one cell deep, whereas the cells of another tissue may form huge masses containing millions of cells. Regardless of the size, shape, or arrangement of cells in a tissue, they all are surrounded by or embedded in a complex extracellular material that often is called simply **matrix.**

The four major types of human tissue that were introduced in Chapter 1 are described in more detail in this chapter. An understanding of the major tissue types will help you understand the next higher levels of organization in the body—organs and organ systems. Eventually, your knowledge of **histology** (the biology of tissues) will give you a better appreciation for the nature of the whole body.

| A&P CONNECT |

This brief introduction to histology involves many images made with microscopes of various types. Refer to ***Tools of Microscopic Anatomy*** online at ***A&P Connect*** for an overview of the types of microscopy used in this chapter.

evolve

PRINCIPAL TYPES OF TISSUE

Although a number of subtypes are present in the body, all tissues can be classified by their structure and function into four principal types:

1. **Epithelial tissue** covers and protects the body surface, lines body cavities, specializes in moving substances into and out of the body or particular organs (secretion, excretion, and absorption), and forms many glands. The cells in epithelial tissue are usually very close together, with very little extracellular matrix.
2. **Connective tissue** functions to support the body and its parts, connect and hold them together, transport substances through the body, and protect it from foreign invaders. The cells in connective tissue are often relatively far apart and separated by large quantities of matrix.
3. **Muscle tissue** produces movement; it moves the body and its parts. Muscle cells are adapted for contractility and produce movement by shortening or lengthening the contractile units found in cytoplasm. Muscle tissue also produces most of the heat of the body.
4. **Nervous tissue** may be the most complex tissue in the body. It specializes in communication between the various parts of the body and in integration of their activities. This tissue's major function is the generation of complex messages that coordinate the body functions.

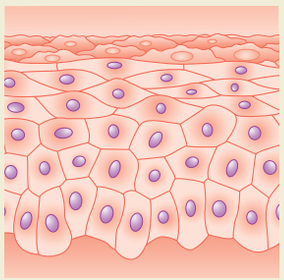
The major tissue types are also summarized in Table 6-1.

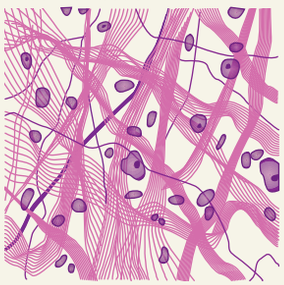
The four major tissues of the body appear early in the embryonic period of development. Within the first 2 weeks after conception, cells of the offspring move and regroup in an orderly way into three **primary germ layers** called **endoderm, mesoderm,** and **ectoderm.** During this process the cells in each germ layer become increasingly more differentiated to form specific tissues—a process called **histogenesis** (Box 6-1). Remodeling themselves by a combination of new growth, differentiation, and apoptosis, these early layers eventually give rise to the various organs of the body.

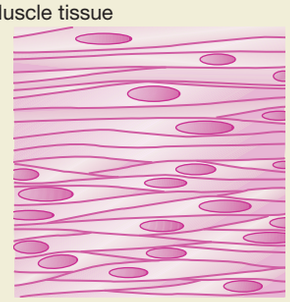
| A&P CONNECT |

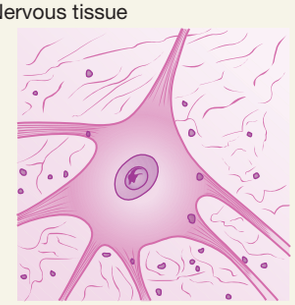
Embryonic development is discussed more thoroughly in Chapter 36. For now, take a look at a diagram illustrating the concept of primary germ layers in ***Embryonic Development of Tissues*** online at ***A&P Connect.***

evolve









Box 6-1 | Stem Cells

During embryonic development, new kinds of cells can be formed from a special kind of undifferentiated cell called a **stem cell.**

Embryonic stem cells have the potential to reproduce many different kinds of daughter cells, including more stem cells—thus populating the body with all the different cells and tissues needed for body function. Sometimes controversial research is now under way to learn the secrets of embryonic stems cells and develop therapies in which embryonic stem cells might be used to repair or replace damaged tissue in adults.

Adult stem cells are undifferentiated cells found scattered within a differentiated, mature tissue. Many different tissues contain adult stem cells—we may soon find that all adult tissues have some stem cells. Adult stem cells can usually produce any of the specialized cell types within its particular tissue. However, recent research shows that some adult stem cells can be coaxed into producing a variety of different types of cells. For example, blood cell–producing stem cells from bone marrow have been used to help repair damaged muscle tissue in laboratory animals. Already, therapies for treating degenerative diseases of muscles, the heart, and the brain—even baldness—are being proposed by medical scientists.

TABLE 6-1 Major Tissues of the Body

TISSUE TYPE	STRUCTURE	FUNCTION	EXAMPLES IN THE BODY
Epithelial tissue 	One or more layers of densely arranged cells with very little extracellular matrix May form either sheets or glands	Covers and protects the body surface Lines body cavities Transport of substances (absorption, secretion, excretion) Glandular activity	Outer layer of skin Lining of the respiratory, digestive, urinary, reproductive tracts Glands of the body
Connective tissue 	Sparsely arranged cells surrounded by a large proportion of extracellular matrix often containing structural fibers (and sometimes mineral crystals)	Supports body structures Transports substances throughout the body	Bones Joint cartilage Tendons and ligaments Blood Fat
Muscle tissue 	Long fiberlike cells, sometimes branched, capable of pulling loads; extracellular fibers sometimes hold muscle fiber together	Produces body movements Produces movements of organs such as the stomach, heart Produces heat	Heart muscle Muscles of the head/neck, arms, legs, trunk Muscles in the walls of hollow organs such as the stomach, intestines
Nervous tissue 	Mixture of many cell types, including several types of neurons (conducting cells) and neuroglia (support cells)	Communication between body parts Integration/regulation of body functions	Tissue of brain and spinal cord Nerves of the body Sensory organs of the body

EXTRACELLULAR MATRIX

Tissues differ in the amount and kind of material between the cells—the **extracellular matrix (ECM).** Figure 6-1 hints at the complex nature of the ECM. The particular makeup of the extracellular matrix in bone and cartilage, for example, contributes to the strength and resiliency of the body. Some tissues have very little ECM. Other tissues are almost entirely extracellular matrix—with only a few cells present. Some types of ECM contain large numbers of structural protein fibers that make them flexible or elastic, some contain many mineral crystals that make them rigid, and others are very fluid.

It is only recently that scientists have discovered the complexities of the ECM and its important role in human biology. Besides water, the ECM is made up mostly of proteins and **proteoglycans** (Table 6-2).

Proteins in the extracellular matrix include various types of structural protein fibers such as *collagen* and *elastin*, both of which are discussed frequently throughout this book. The ECM also contains many *glycoproteins*, which are mainly protein molecules with attached carbohydrate subunits. For example, *fibronectin* and *laminin* both help connect collagen and proteoglycans to cells by attaching to *integrin* molecules embedded in the plasma membrane of cells (see Figure 6-1). This arrangement thus unites the cells and their surroundings into an integral structure. It also provides a communication mechanism between the ECM and the cell that allows coordination of cell and tissue development, as well as guidance of cell movement and shape changes.

Proteoglycans are hybrid molecules made up mostly of carbohydrates attached to a protein backbone, as you can see in Figure 6-1, B. Many of the sugars attached to the protein backbone of a proteoglycan molecule are *N-acetylglucosamine* (NAG). Examples of proteoglycans are *chondroitin sulfate*, *heparin*, and *hyaluronate* (see Table 6-2).

In some tissues, such as bone, there may also be calcium-containing mineral crystals that make the ECM rigid. Considering the makeup of ECM, it's no wonder that many dietary supplements that claim to improve the health of bones and joints include calcium, glucosamine, and/or chondroitin sulfate—all are important components of the ECM of cartilage and bone tissues.

In some tissues, it is the ECM that holds the tissue in a single mass. For example, in skeletal muscles, it is mostly a network of structural protein fibers in the ECM that holds skeletal muscle tissue together. In such cases, components of the ECM bind to the integrins in the outer membranes of the cells, and the integrins bind to components of the internal cytoskeleton.

In other tissues, it is primarily the intercellular junctions, such as the desmosomes and tight junctions described in a previous

FIGURE 6-1

Extracellular matrix (ECM). A, The extracellular matrix is made up of water, proteins/glycoproteins, and proteoglycans that often form large bundles or complexes that bind together and to the cells of the tissue. Although the makeup of ECM varies from tissue to tissue, it usually includes some connections to integrins in the plasma membranes, thereby allowing for structural integrity, as well as communication and coordination within the tissue. **B,** A detailed view of a proteoglycan complex shows many proteoglycans, each with a protein backbone and attached carbohydrate subunits—all held together by a polysaccharide chain. **C,** Detailed view of a collagen bundle showing the individual collagen fibers within it.

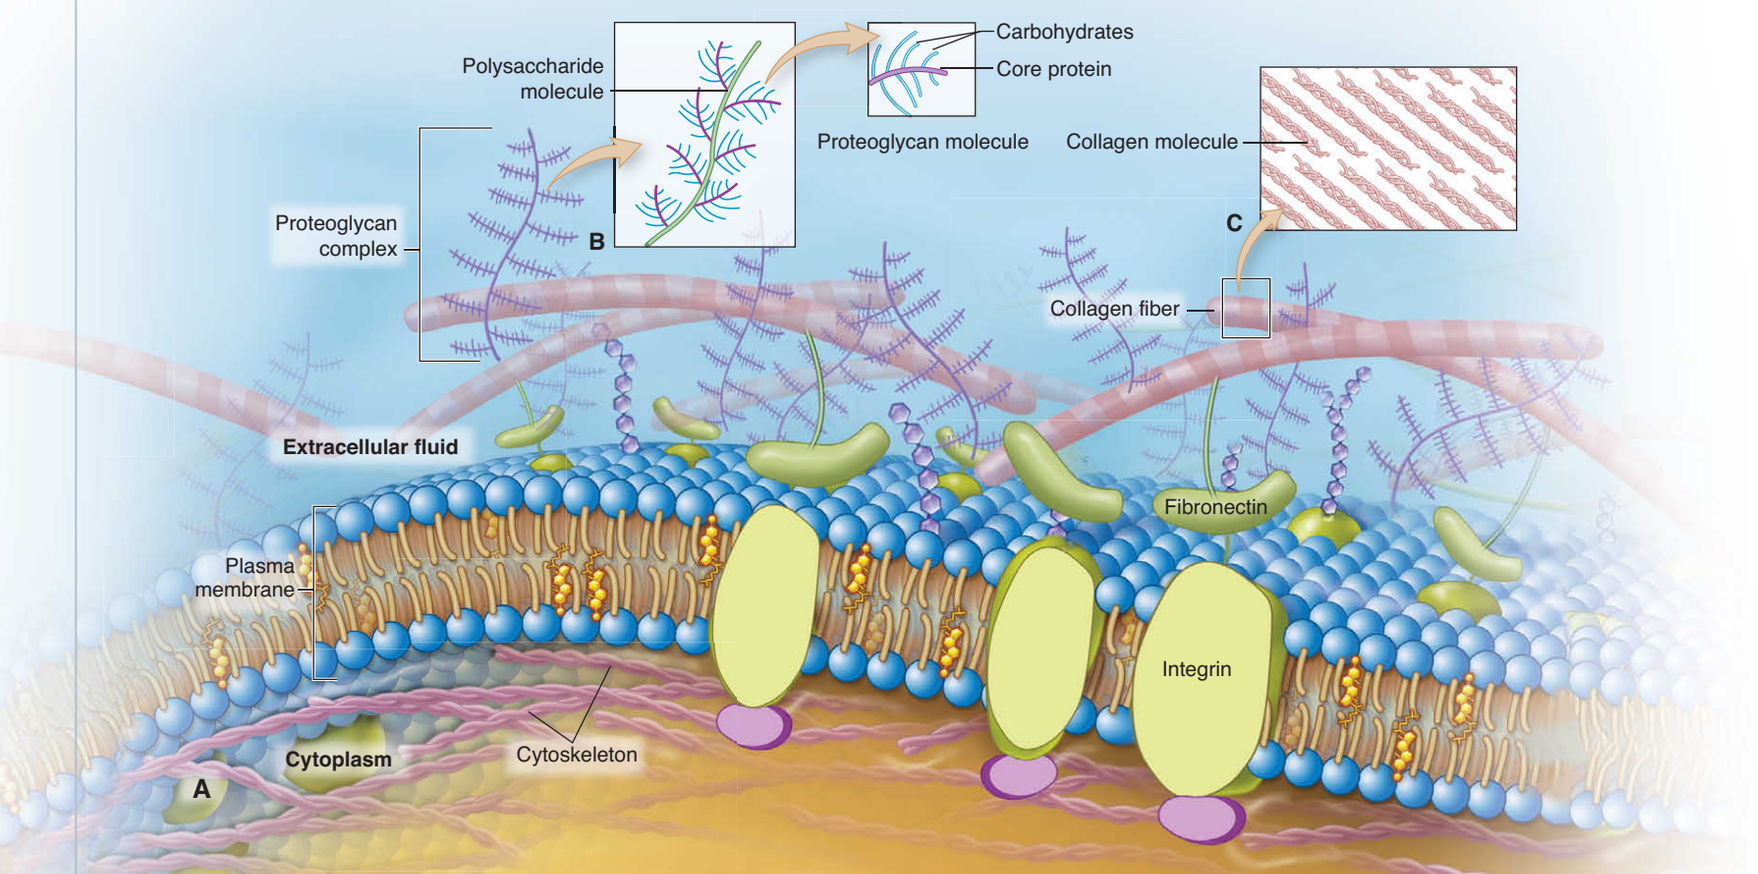


TABLE 6-2 Components of the Extracellular Matrix (ECM)*

COMPONENT	EXAMPLE	DESCRIPTION	FUNCTION	EXAMPLE OF LOCATION
Water		Water molecules along with a small number of ions (mostly Na^+ and Cl^-)	Solvent for dissolved ECM components; provides fluidity of ECM	All tissues of the body
Proteins and glycoproteins	Collagen	Strong, flexible structural protein fiber	Provides flexible strength to tissues	Tendons, ligaments, bones, cartilage, many tissues
	Elastin	Flexible, elastic structural protein fiber	Allows flexibility and elastic recoil of tissues	Skin, cartilage of ear, walls of arteries
	Fibronectin	Rodlike glycoprotein	Binds ECM to cells; communicates with cells through integrins	Many tissues of the body, for example, connective tissues
	Laminin	Glycoproteins arranged as a three-pronged fork	Binds ECM components together and to cells; communicates with cells through integrins	In basal lamina (basement membrane) of epithelial tissues
Proteoglycans	Various types	Protein backbone with attached chains of various polysaccharides:		
		Chondroitin sulfate	Shock absorber	Cartilage, bone, heart valves
		Heparin	Reduces blood clotting	Lining of some arteries
		Hyaluronate	Thickens fluid; lubricates	Loose fibrous connective tissue, joint fluids

*Not all components are present in all ECM; examples of only some of the many major ECM components are provided.

chapter (see Chapter 3, pp. 83–84), that hold groups of cells together to form tissues found in sheets or other continuous masses of cells. The tissue that forms the outer layer of skin is held together this way. In some tissues, the ECM does not bind to tissue cells. For example, the fluid nature of the blood's matrix (plasma) does not hold blood tissue in a solid mass at all.

| QUICK CHECK |

1. Name the four basic tissue types and give the major function of each.
2. What is the ECM? What is it made of?
3. What is a primary germ layer?

EPITHELIAL TISSUE

Types and Locations of Epithelial Tissue

Epithelial tissue, or **epithelium,** often is subdivided into two types: (1) **membranous** (covering or lining) epithelium and (2) **glandular** epithelium. Membranous epithelium covers the body and some of its parts and lines the serous cavities (pleural, pericardial, and peritoneal), the blood and lymphatic vessels, and the respiratory, digestive, and genitourinary tracts. Glandular epithelium is grouped in solid cords or hollow follicles that form the secretory units of endocrine and exocrine glands.

Functions of Epithelial Tissue

Epithelial tissues have a widespread distribution throughout the body and serve several important functions:

Protection. Generalized protection is the most important function of membranous epithelium. It is the relatively tough and impermeable epithelial covering of the skin that protects the body from mechanical and chemical injury and also from invading bacteria and other disease-causing microorganisms.

Sensory functions. Epithelial structures adapted for sensory functions are found in the skin, nose, eye, and ear.

Secretion. Glandular epithelium is adapted for secretory activity. Secretory products include hormones, mucus, digestive juices, and sweat.

Absorption. The lining epithelium of the gut and respiratory tract allows for the absorption of nutrients from the gut and the exchange of respiratory gases between air in the lungs and the blood.

Excretion. The unique epithelial lining of kidney tubules makes the excretion and concentration of excretory products in the urine possible.

Generalizations About Epithelial Tissue

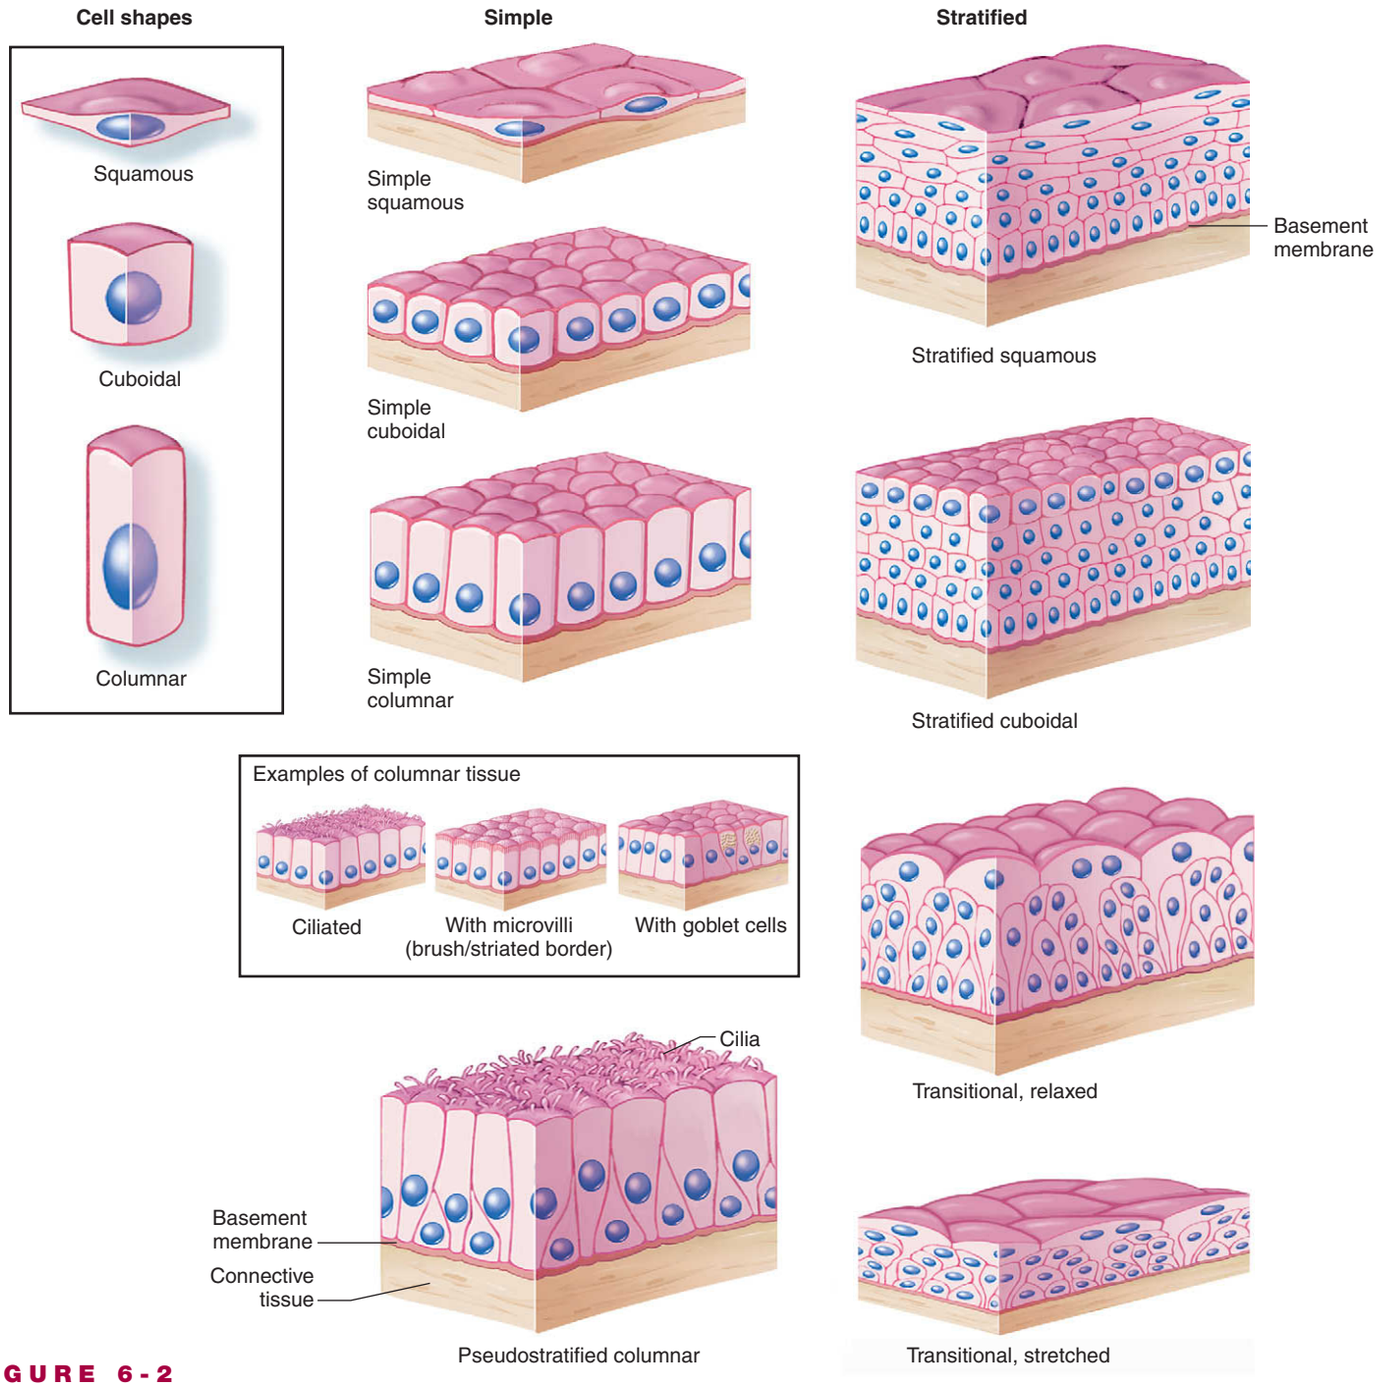
Most epithelial tissues are characterized by extremely limited amounts of intercellular, or matrix, material. This explains their characteristic appearance, when viewed under a light microscope, of a continuous sheet of cells packed tightly together. With the electron microscope, however, narrow spaces—about 20 nanometers (one millionth of an inch) wide—can be seen around the cells. These spaces, like other intercellular spaces, contain **interstitial fluid (IF).**

Epithelial tissues generally renew themselves throughout life. The presence of stem cells in most epithelial tissues allows epithelium to continuously produce new cells of various types.

Sheets of epithelial cells compose the surface layer of skin and mucous and serous membranes. The epithelial tissue attaches to an underlying layer of connective tissue by means of a thin noncellular layer of adhesive, permeable material called the **basement membrane (BM)** (Figure 6-2). Both epithelial and

connective tissue cells synthesize the basement membrane, which is a highly complex structure made up partly of glycoprotein material secreted by the epithelial components and a fine mesh of fibers produced by the connective tissue cells. Histologists refer to the glycoprotein material secreted by epithelial cells as the *basal lamina* and to the connective tissue fibers as the *fibroreticular lamina*. The union of basal and fibroreticular lamina forms the basement membrane. *Integrins* embedded in each plasma membrane help bind the cytoskeletons of the epithelial cells to the fibers of the basement membrane so that a strong connection forms between them.

Epithelial tissues contain no blood vessels. As a result, epithelium is said to be **avascular** (*a*, "without"; *vascular*, "vessels"). Hence oxygen and nutrients must diffuse from capillaries in the underlying connective tissue through the permeable basement membrane to reach living epithelial cells.



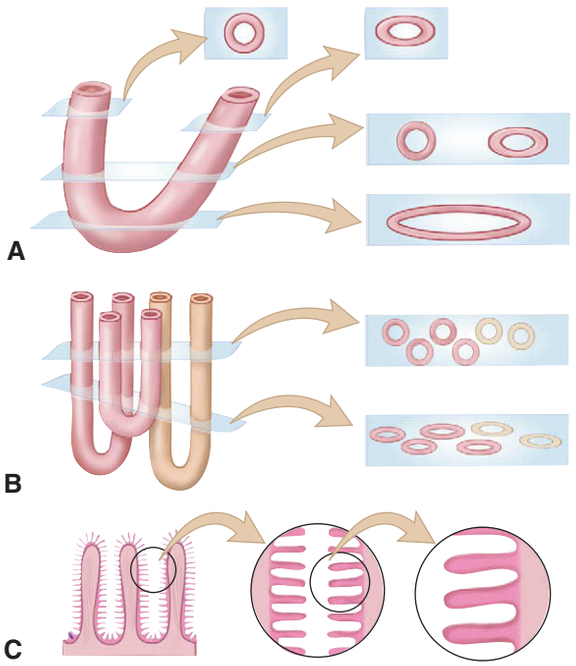


FIGURE 6-2

Classification of epithelial tissues. The tissues are classified according to the shape and arrangement of cells. The color scheme of these drawings is based on a common staining technique used by histologists called *hematoxylin and eosin (H&E)* staining. H&E staining usually renders the cytoplasm pink and the chromatin inside the nucleus a purplish color. The cellular membranes, including the plasma membrane and nuclear envelope, do not usually pick up any stain and thus may be transparent. (See Box 6-2 for information on cross sections of membranous tissues.)

Box 6-2 | Imagining Cross Sections

When you look at photomicrographs of epithelial tissues or other structures that are tubelike, saclike, or folded into complex shapes, it is sometimes hard to imagine what you are really looking at. As diagram A shows, when you cut a tube on a cross section, the slice looks like a ring (if cut at a right angle) or oval (if cut at an oblique, or slanted, angle). Diagram A also shows that if the tube is bent where the cut is made, it can also look like an oval on your slide. Diagram B shows what happens when you have many tubes next to one another—your slice has many round or oval rings (depending on the angle of the cut). Compare Diagram A to Figure 6-5. Can you imagine the type of tissue that produced this slice? Diagram C shows what can happen when a membrane such as the intestinal lining is folded into complex shapes. The slice may look like a sort of zigzag line of cells, or if it is at a high magnification, it may just look like a series of parallel rows. Look at Figure 6-6. Can you imagine what the original tissue must have looked like? Look ahead to Figures 28-9 through 28-21. Can you "see" the context or "situation" of the various tissue slices found in many of these figures? Try sketching out the "big picture" of the context of various tissue samples shown in the photomicrographs of this chapter, and then keep them in your notebook. By doing so, you'll be preparing yourself for later chapters (and later courses) by learning to identify the context of a tissue "on sight."

Cross sections.

At intervals between adjacent epithelial cells, their plasma membranes are modified to hold the cells together. These complex intercellular structures, such as **desmosomes** and **tight junctions,** are described in Chapter 3. Epithelial cells can reproduce themselves. They frequently go through the process of cell division. Because epithelial cells in many locations meet considerable wear and tear, this fact has practical importance. It means, for example, that new cells can replace old or destroyed epithelial cells in the skin or in the lining of the gut or respiratory tract.

Cross sections of epithelial tissues are described in Box 6-2.

Classification of Epithelial Tissue

MEMBRANOUS EPITHELIUM

Classification Based on Cell Shape

The shape of membranous epithelial cells may be used for classification purposes. Four cell shapes, called **squamous, cuboidal, columnar,** and **pseudostratified columnar,** are used in this classification scheme (see Figure 6-2). Squamous (Latin, "scaly") cells are flat and platelike. Cuboidal cells, as the name implies, are cube-shaped and have more cytoplasm than the scalelike squamous cells do. Columnar epithelial cells have more height than width and thus appear narrow and cylindrical. Pseudostratified columnar epithelium has only one layer of oddly shaped columnar cells. Although each cell touches the basement membrane, the tops of some pseudostratified cells do not fully extend to the surface of the membrane. Also, some nuclei are near the "top" of the cell and some near the "bottom" of the cell—rather than all nuclei being near the bottom. The result is a false *(pseudo)* appearance of layering, or stratification, when only a single layer of cells is present.

Classification Based on Layers of Cells

In most cases the location and function of membranous epithelium determine whether its cells will be stacked and layered or arranged in a sheet one cell layer thick. An arrangement of epithelial cells in a single layer is called **simple epithelium.** If epithelial cells are layered one on another, the tissue is called **stratified epithelium. Transitional epithelium** (described later) is a unique arrangement of differing cell shapes in a stratified, or layered, epithelial sheet.

If membranous or covering epithelium is classified by the shape and layering of its cells, the specific types listed in Table 6-3 are

TABLE 6-3 Classification Scheme for Membranous Epithelial Tissues

SHAPE OF CELLS*	TISSUE TYPE
One Layer	
Squamous	Simple squamous
Cuboidal	Simple cuboidal
Columnar	Simple columnar
Pseudostratified columnar	Pseudostratified columnar
Several Layers	
Squamous	Stratified squamous
Cuboidal	Stratified cuboidal
Columnar	Stratified columnar
(Varies)	Transitional

*In the top layer (if more than one layer is present in the tissue).

possible. Notice that stratified tissue types are named for the shape of cells in their top layer only. Each type is described in the paragraphs that follow, and selected examples are illustrated in Figures 6-3 to 6-10.

Simple Epithelium

Simple squamous epithelium consists of only one layer of flat, scalelike cells (Figure 6-3). Consequently, substances can readily diffuse or filter through this type of tissue. The microscopic air sacs (alveoli) of the lungs, for example, are composed of this kind of tissue, as are the linings of blood and lymphatic vessels and the surfaces of the pleura, pericardium, and peritoneum (Figure 6-4). (Blood and lymphatic vessel linings are called **endothelium,** and the surfaces of the pleura, pericardium, and peritoneum are called **mesothelium.** Some histologists classify these linings as connective tissue because of their embryological origin.)

Simple cuboidal epithelium is composed of one layer of cuboidal cells resting on a basement membrane (Figure 6-5). This type of epithelium is seen in many types of glands and their ducts. It is also found in the ducts and tubules of other organs, such as the kidney.

Simple columnar epithelium composes the surface of the mucous membrane that lines the stomach, intestine, uterus, uterine tubes, and parts of the respiratory tract (Figure 6-6). It consists of a single layer of cells, many of which have a modified structure. Three common modifications are goblet cells, cilia, and microvilli. Goblet cells have large, secretory vesicles that give them the appearance of a goblet. The vesicles contain mucus, which goblet cells produce in great quantity and secrete onto the surface of the epithelial membrane. Mucus is a solution of water, electrolytes, and proteoglycans. In the intestine, the plasma membranes of many columnar cells extend out in hundreds and hundreds of microscopic fingerlike projections called **microvilli.** By greatly increasing the surface area of the intestinal mucosa, microvilli make it especially well suited for absorbing nutrients and fluids from the intestine.

Pseudostratified columnar epithelium is found lining the air passages of the respiratory system and certain segments of the male reproductive system such as the urethra (Figure 6-7). Although appearing to be stratified, only a single layer of irregularly shaped columnar cells touches the basement membrane. The cells are of differing heights,

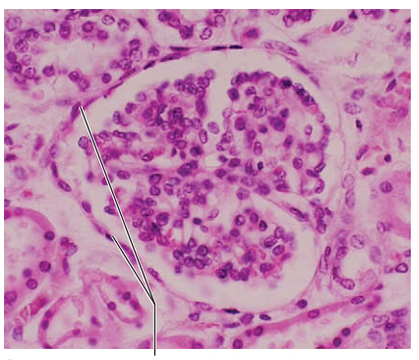

FIGURE 6-3

Simple squamous epithelium. Photomicrograph of the Bowman capsule of the kidney showing thin simple squamous epithelium. Notice how the H&E staining (see Figure 6-2) renders the cytoplasm of each cell pink and each nucleus a purplish color. The outlines of cellular membranes are transparent in the photomicrograph.

FIGURE 6-4

Simple squamous lining of the lung. The tiny air sacs of the lung, which are called *alveoli,* are lined with a thin layer of simple squamous epithelium. This thin epithelium, shown clearly in the scanning electron micrograph in the inset, allows for easy diffusion of oxygen and carbon dioxide across the walls of the alveoli. *Arrowheads* indicate pores that allow air to pass from one alveolus to another.

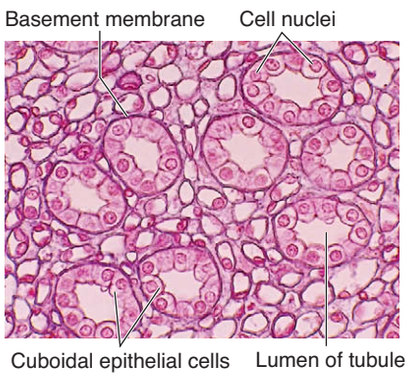

FIGURE 6-5

Simple cuboidal epithelium. Photomicrograph of kidney tubules showing the single layer of cuboidal cells touching a basement membrane. Note the cuboidal cells that enclose the tubule opening (lumen).

and many are not tall enough to reach the upper surface of the epithelial sheet. This fact, coupled with placement of cell nuclei at odd and irregular levels in the cells, gives a false (pseudo) impression of stratification. Mucus-secreting goblet cells are numerous and cilia are present. In the respiratory system air passages, uniform motion of the cilia causes a thin layer of tacky mucus to move in one direction only over the free surface of the epithelium. As a result, dust particles and other contaminants in the inspired air are trapped and moved toward the mouth and away from the delicate lung tissues.

Stratified Epithelium

Stratified squamous epithelium is characterized by multiple layers of cells with typically flattened squamous cells at the free, or outer, surface of the epithelial sheet (Figure 6-8).

In *keratinized* stratified squamous epithelium, the presence of tough keratin fibers in the squamous cells contributes to the protective qualities of skin covering the body surface. Details of the histology of this type of epithelium are presented in Chapter 7.

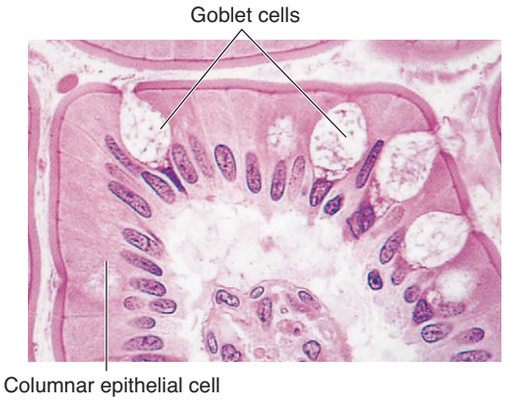

FIGURE 6-6

Simple columnar epithelium. Photomicrograph of simple columnar epithelium. Note the goblet, or mucus-producing, cells present.

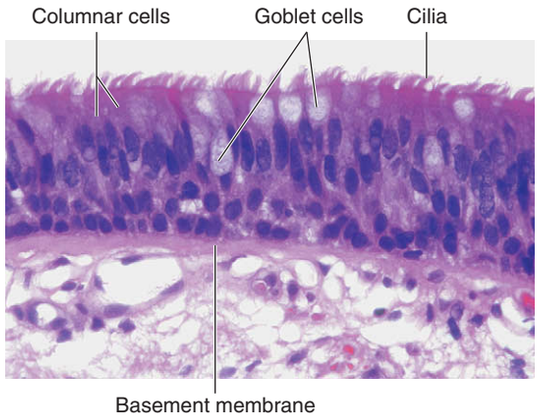

FIGURE 6-7

Pseudostratified columnar epithelium. This photomicrograph from the respiratory system shows that each irregularly shaped columnar cell touches the underlying basement membrane. Placement of cell nuclei at irregular levels in the cells gives a false (pseudo) impression of stratification. This tissue is ciliated—note the "fuzz" along the outer edge of the cells.

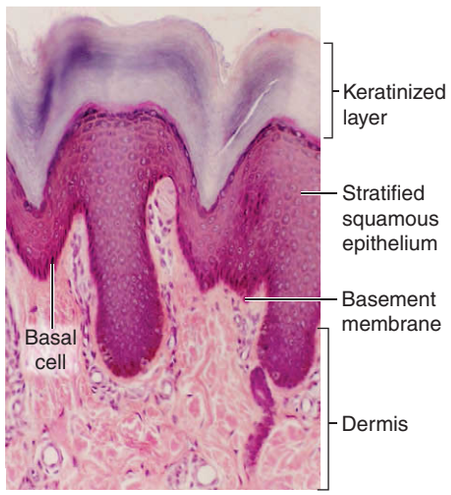

FIGURE 6-8

Keratinized stratified squamous epithelium. Photomicrograph of the thick skin showing cells becoming progressively flattened and scalelike as they approach the surface and are lost. The outer surface of this epithelial sheet contains many flattened cells that have lost their nuclei.

Nonkeratinized stratified squamous epithelium is found lining the vagina, mouth, and esophagus (Figure 6-9). Its free surface is moist, and the outer epithelial cells, unlike those found in the skin, do not contain keratin. This type of epithelium serves a protective function.

Stratified cuboidal epithelium also serves a protective function. Typically, two or more rows of low cuboidal cells are arranged randomly over a basement membrane. Stratified cuboidal epithelium can be located in the sweat gland ducts, in the pharynx, and over parts of the epiglottis.

Stratified columnar epithelium has multiple layers of columnar cells, with only the most superficial cells are truly columnar in appearance. It is a protective type of epithelium found in few places in the human body. It is located in segments of the male urethra and in the mucous layer near the anus.

Transitional epithelium is a stratified tissue typically found in body areas that are subjected to stress and tension changes, such as the wall of the urinary bladder (Figure 6-10). Because it lines part of the urinary

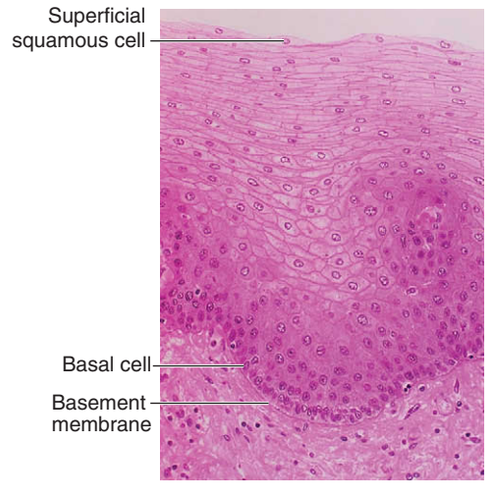

FIGURE 6-9

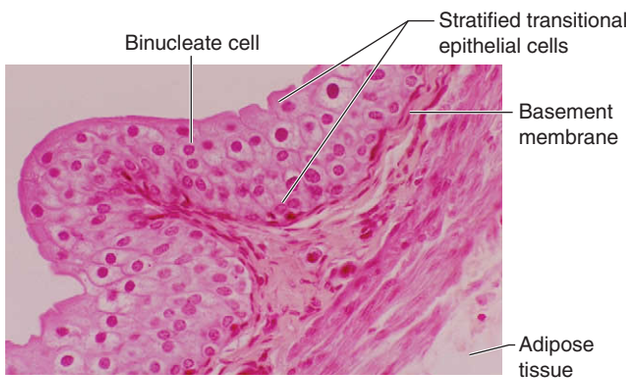
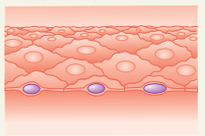
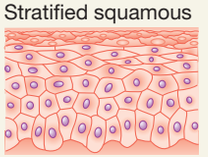
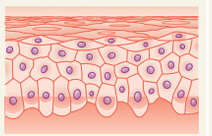
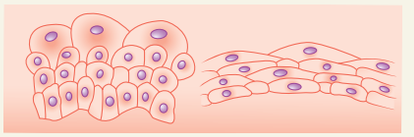
Nonkeratinized stratified squamous epithelium. Photomicrograph of the lining of the esophagus. Each cell in the layer is flattened near the surface and attached to the sheet. No flaking of dead cells from the surface occurs. All cells have nuclei. Compare with Figure 6-8.

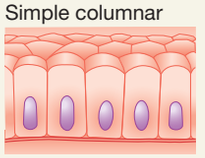


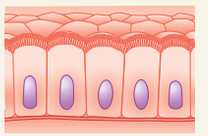


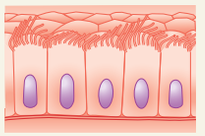


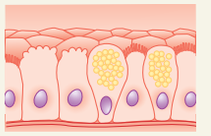


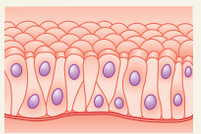


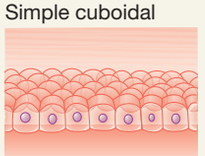


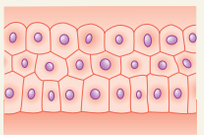












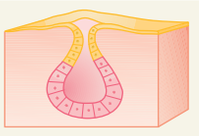


FIGURE 6-10

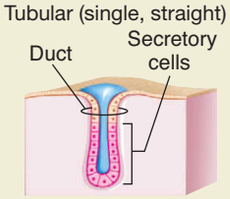

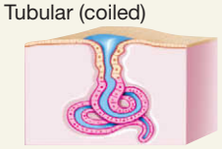

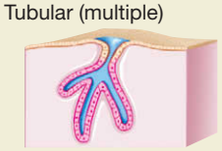

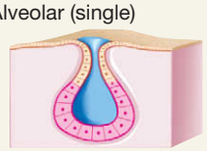

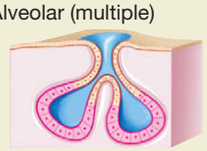

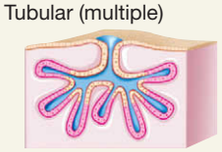

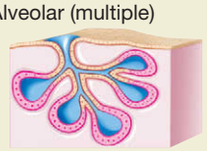

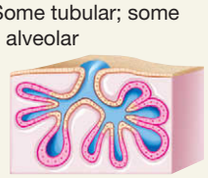

Transitional epithelium. Photomicrograph from the urethra showing that its cell shape is variable from cuboidal to squamous. Several layers of cells are present. Intermediate and surface cells do not touch the basement membrane.

TABLE 6-4 Epithelial Tissues

TISSUE	LOCATION	FUNCTION
Membranous		
Simple squamous 	Alveoli of lungs Lining of blood and lymphatic vessels (called endothelium; classified as connective tissue by some histologists) Surface layer of the pleura, pericardium, and peritoneum (called *mesothelium;* classified as connective tissue by some histologists)	Absorption by diffusion of respiratory gases between alveolar air and blood Absorption by diffusion, filtration, and osmosis Absorption by diffusion and osmosis; also, secretion
Stratified squamous  Nonkeratinized  Keratinized	Surface of the mucous membrane lining the mouth, esophagus, and vagina Surface of the skin (epidermis)	Protection Protection
Transitional  Relaxed Stretched	Surface of the mucous membrane lining the urinary bladder and ureters	Permits stretching Protection
Simple columnar  Without surface specialization  With microvilli (brush/striated border)  Ciliated  With goblet cells	Surface layer of the mucous lining of the stomach, intestines, and part of the respiratory tract	Protection Secretion Absorption Moving of mucus (by ciliated columnar epithelium)
Pseudostratified columnar 	Surface of the mucous membrane lining the trachea, large bronchi, nasal mucosa, and parts of the male reproductive tract (epididymis and vas deferens); lines the large ducts of some glands (e.g., parotid)	Protection
Simple cuboidal 	Ducts and tubules of many organs, including the exocrine glands and kidneys	Secretion Absorption
Stratified cuboidal/columnar 	Ducts of the sweat glands and mammary glands; lining of the pharynx; covering some of the epiglottis; lining portions of the male urethra	Protection
Glandular		
	Glands	Secretion

tract, it is also called *urothelium.* In many instances, 10 or more layers of cuboidal cells of varying shapes are present in the absence of stretching or tension. As tension increases, the epithelial sheet is expanded, the number of observable cell layers decreases, and cell shape changes from cuboidal to squamous in appearance. This ability of transitional epithelium to stretch protects the bladder wall and other distensible structures that it lines from tearing when stretched with great force.

TABLE 6-5 Structural Classification of Multicellular Exocrine Glands

SHAPE*	COMPLEXITY†	TYPE	EXAMPLE
Tubular (single, straight) 	Simple	Simple tubular	Intestinal glands
Tubular (coiled) 	Simple	Simple coiled tubular	Sweat glands
Tubular (multiple) 	Simple	Simple branched tubular	Gastric (stomach) glands
Alveolar (single) 	Simple	Simple alveolar	Sebaceous (skin oil) glands
Alveolar (multiple) 	Simple	Simple branched alveolar	Sebaceous glands
Tubular (multiple) 	Compound	Compound tubular	Mammary glands
Alveolar (multiple) 	Compound	Compound alveolar	Mammary glands
Some tubular; some alveolar 	Compound	Compound tubulo-alveolar	Salivary glands

*Shape of the distal secreting units of the gland.
†Number of ducts reaching the surface.

The major types of epithelium are summarized in Table 6-4.

GLANDULAR EPITHELIUM

Epithelium of the glandular type is adapted for secretory activity. Regardless of the secretory product produced, glandular activity depends on complex and highly regulated cellular activities requiring the expenditure of stored energy.

Unlike the single or layered cells of membranous epithelium typically found in protective coverings or linings, glandular epithelial cells may function singly as **unicellular glands,** or they may function in clusters, solid cords, or hollow follicles as **multicellular glands.** Glandular secretions may be discharged into ducts, into the lumen of hollow visceral structures, onto the body surface, or directly into the blood.

All **glands** in the body can be classified as either exocrine or endocrine glands. **Exocrine glands,** by definition, discharge their secretion products into ducts. The salivary glands are typical exocrine glands. The secretion product (saliva) is produced in the gland and then discharged into a duct that transports it to the mouth. **Endocrine glands** are often called *ductless glands* because they discharge their secretion products (hormones) directly into blood or interstitial fluid. The pituitary, thyroid, and adrenal glands are typical endocrine glands.

Structural Classification of Exocrine Glands

Multicellular exocrine glands are most often classified by structure, with the shape of their ducts and the complexity (branching) of their duct systems used as distinguishing characteristics. Shapes include **tubular** and **alveolar** (saclike). Simple exocrine glands have only one duct leading to the surface, and **compound** exocrine glands have two or more ducts. Table 6-5 describes some of the major structural types of exocrine glands. Figure 6-11 shows examples of exocrine glands in the lining of the stomach.

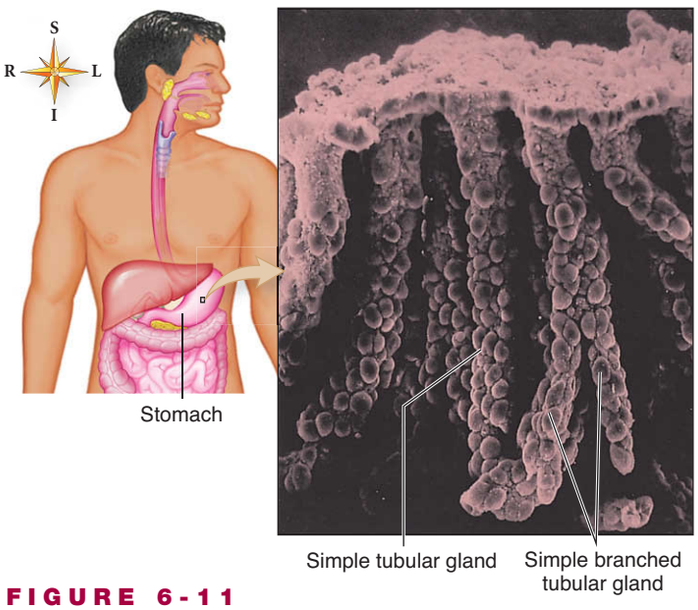

FIGURE 6-11

Exocrine glands in the stomach. The inset shows a scanning electron micrograph of exocrine glands, called *gastric glands,* in the lining of the stomach. These glands produce gastric juice—a mixture of water, mucus, enzymes, acid, and other substances.

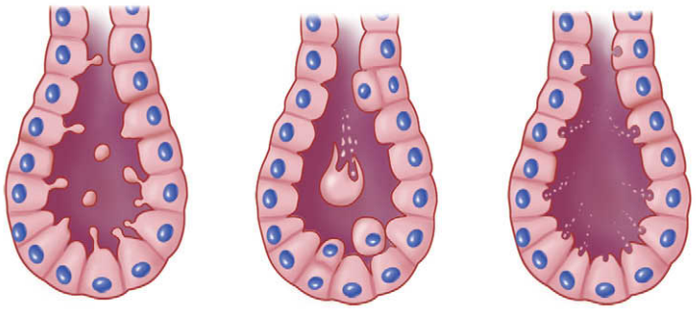

FIGURE 6-12

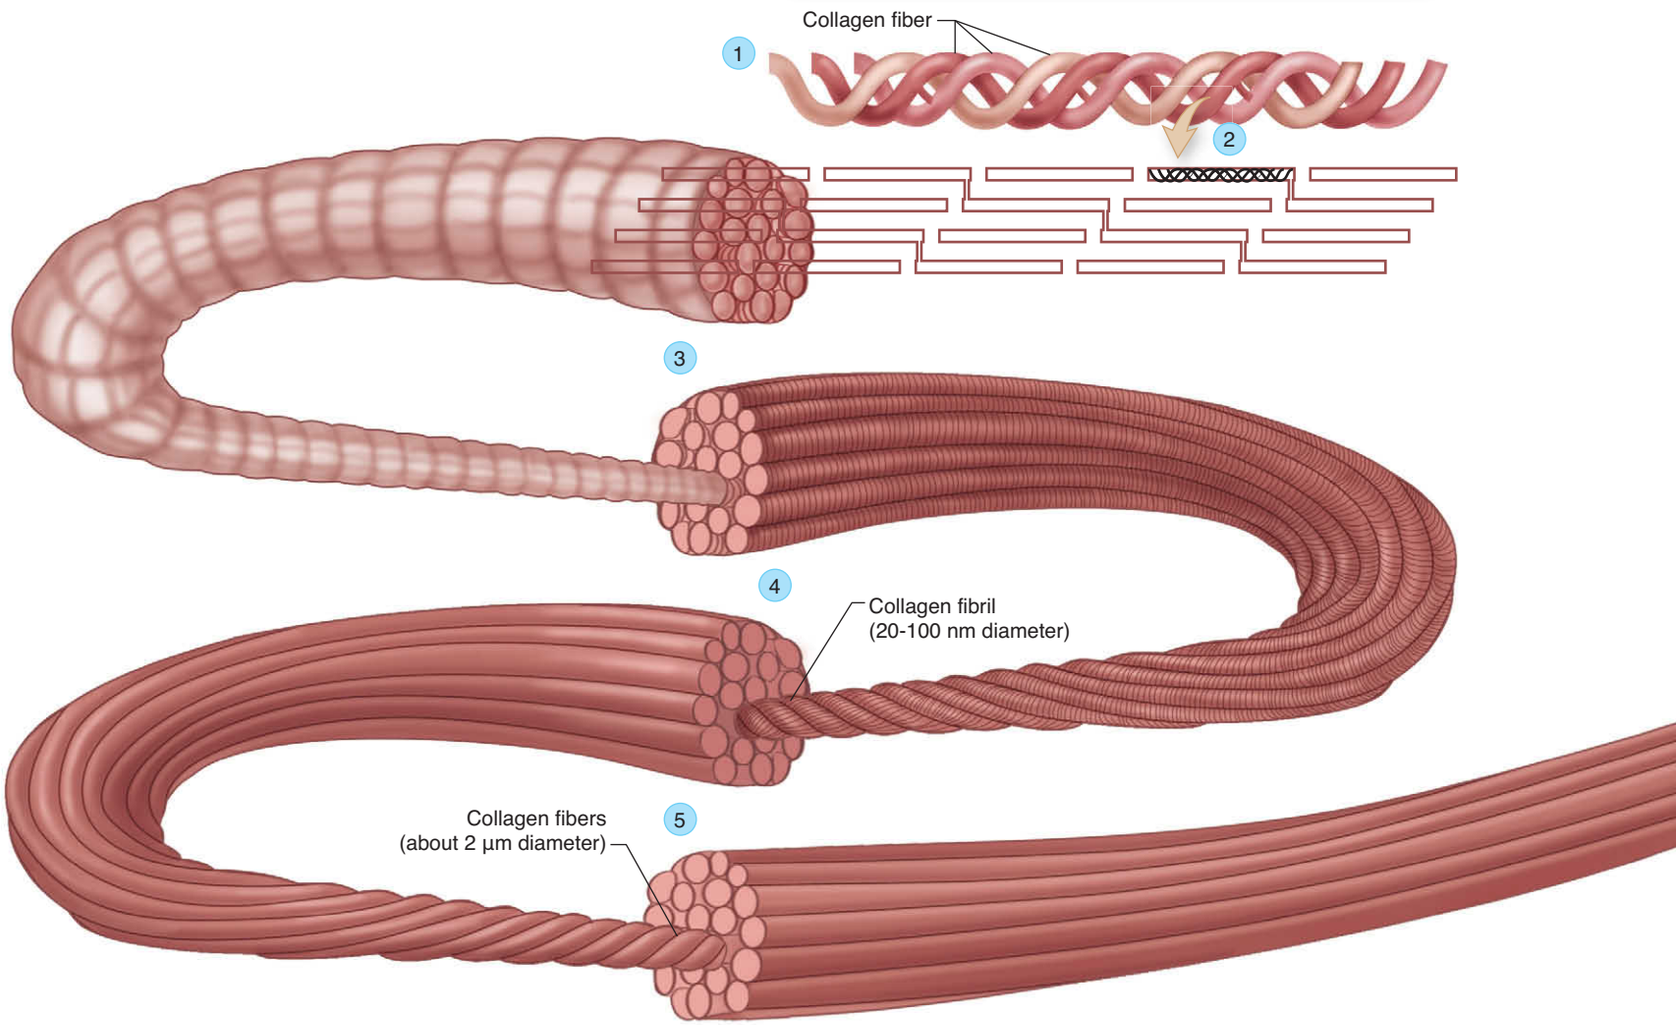
Three types of exocrine glands. Exocrine glands may be classified by the method of secretion.

Functional Classification of Exocrine Glands

In addition to structural differences, exocrine glands also differ in the method by which they discharge their secretion products from the cell. Using these functional criteria, three types of exocrine glands may be identified (Figure 6-12):

1. Apocrine
2. Holocrine
3. Merocrine



Apocrine glands collect their secretory products near the apex, or tip, of the cell and then release them into a duct by pinching off the distended end. This process results in some loss of cytoplasm and damage to the cell. Recovery and repair of cells are rapid, however, and continued secretion occurs. The milk-producing mammary glands are examples of apocrine-type glands.

Holocrine glands—such as the sebaceous glands that produce oil to lubricate the skin—collect their secretory product inside the cell and then rupture completely to release it. These cells literally self-destruct to complete their function.

Merocrine glands discharge their secretion product directly through the cell or plasma membrane. This discharge process is completed without injury to the plasma membrane and without loss of cytoplasm. Only the secretion product passes from the glandular cell into the duct. Most secretory cells are of this type. The salivary glands are examples of merocrine-type exocrine glands.

| QUICK CHECK |

4. List at least three functions of epithelial tissue.
5. What are the three basic shapes of epithelial cells?
6. Distinguish between a simple epithelial tissue and a stratified epithelial tissue.
7. How do exocrine glands secrete their products?

CONNECTIVE TISSUE

Connective tissue is one of the most widespread and diverse tissues in the body and is found in or around nearly every organ of the body. Connective tissue arises during embryonic development from stem cell tissue called *mesenchyme*, most of which originates in the mesoderm (primary germ layer). Connective tissue exists in more varied forms than the other three basic tissues do. Among the types that we will discuss are delicate tissue paper webs, tough resilient cords, rubbery elastic sheets, rigid bones, and a fluid (blood).

Functions of Connective Tissue

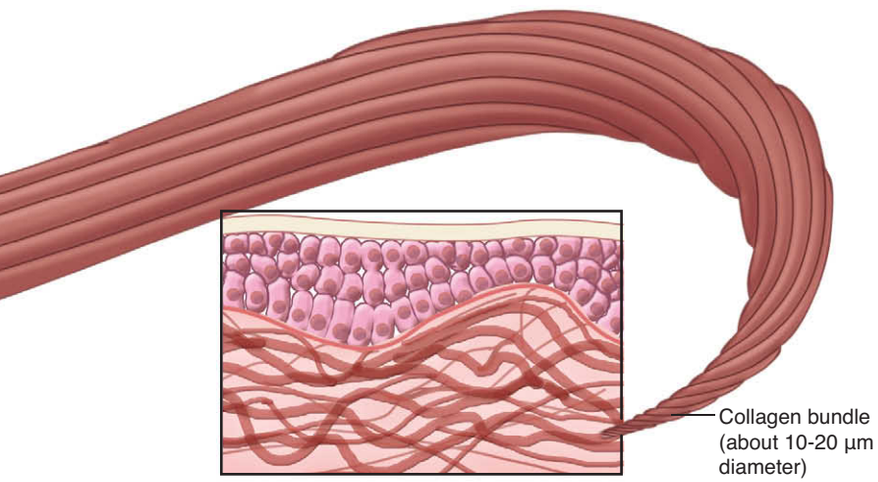
Connective tissue connects, supports, transports, and defends. It connects tissues to each other, for example. It also connects muscles to muscles, muscles to bones, and bones to bones. It forms a supporting framework for the body as a whole and for its organs individually. One kind of connective tissue—blood—transports a large array of substances between parts of the body. And finally, several kinds of connective tissue cells even defend us against microorganisms and other invaders.

Characteristics of Connective Tissue

Connective tissue consists predominantly of extracellular matrix. Embedded in the matrix are relatively few cells. The ECM of connective tissues is made up of varying numbers and kinds of fibers, fluid, and perhaps other material sometimes called *ground substance*. The qualities of the ECM's fibers and other components largely determine the structural characteristics of each type of connective tissue. The matrix of blood, for example, is a fluid (plasma). It contains numerous blood cells but no fibers, except when it coagulates. Some connective tissues have the consistency of a soft gel, some are firm but flexible, some hard and rigid, some tough, others delicate—and in each case it is their matrix and extracellular fibers that make them so.

A connective tissue's extracellular matrix contains one or more of the following kinds of fibers: collagenous (or white), reticular, or elastic (or yellow). Fibroblasts and some other cells produce these protein fibers. Collagenous fibers are tough and strong, reticular fibers are delicate, and elastic fibers are extensible and elastic.

Collagenous fibers are made of **collagen** and often occur in twisted bundles—an arrangement that provides great tensile strength (Figure 6-13). Because collagenous fibers look white in living tissue, they are sometimes called *white fibers*. However, they often appear pink in stained microscopic specimens.



Of all the hundreds of different protein compounds in the body, collagen is the most abundant. Biologists estimate that it constitutes somewhat more than one fourth of all the protein in the body. And interestingly, one of the most basic factors in the aging process, according to some researchers, is the change in the molecular structure of collagen that occurs gradually with the passage of years. In its hydrated form, collagen is also known as *gelatin*. Perhaps you have eaten some flavored gelatin made from animal collagen.

Reticular fibers, in contrast to collagenous fibers, occur in networks and, although delicate, support small structures such as capillaries and nerve fibers. Reticular fibers are made of a special type of collagen called *reticulin*.

Elastic fibers are made of a protein called **elastin**, which returns to its original length after being stretched (Figure 6-14).

FIGURE 6-13

Collagen bundles. 1, Collagen forms when quaternary proteins made up of three tertiary protein chains twist into a fibrous molecule. **2,** Collagen molecules then assemble into a staggered strand of collagen. **3,** Bundles of collagen strands twist together to form collagen fibrils, which in turn twist together with additional fibrils (**4**) to form collagen fibers. **5,** The collagen fibers then twist together in groups to form rope-like collagen bundles having flexibility and great strength.

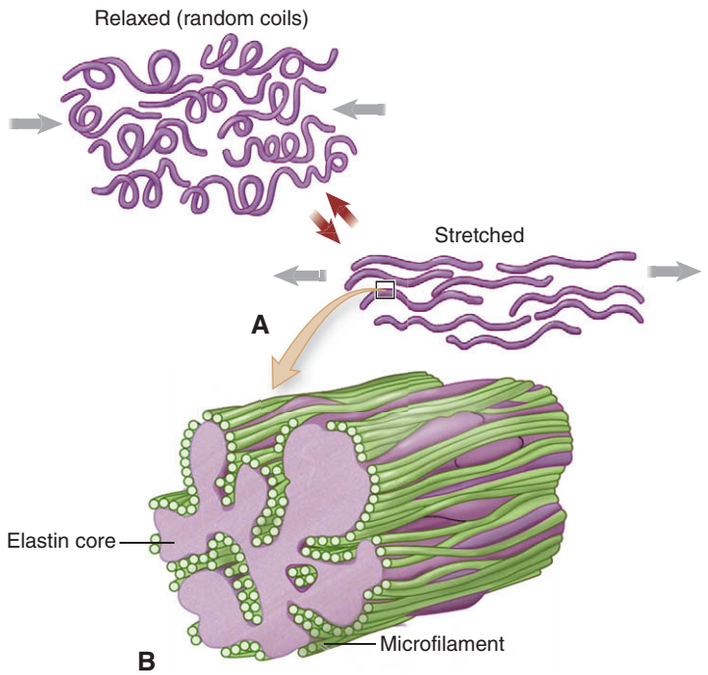


FIGURE 6-14

Elastin fibers. A, Elastin fibers form random coils within the extracellular matrix *(ECM)* that may easily be stretched. When released, the elastin fibers will recoil to a relaxed formation. **B,** Each elastin fiber is made of stretchy, formless elastin that is held in a fibrous shape by an arrangement of microfibrils.

Elastin is a rubbery substance that is held in a fibrous shape by long, thin microfilaments—as you can see in Figure 6-14, *B*. Elastic fibers are found in "stretchy" tissues, such as the cartilage of the external ear and the walls of arteries. Because elastin fibers look yellowish in living tissue, they are sometimes called *yellow fibers*.

In addition to protein fibers, the matrix of connective tissues contains a number of *proteoglycans* made up of polysaccharide chains often containing *glucosamine* and bound to a protein core (see Figure 6-1). These chemicals make the matrix fluid thick enough to be a barrier to bacteria and other microbes. They also form transparent lubricant and help hold the tissue together. Among the more notable of these compounds are *hyaluronic acid* and *chondroitin sulfate*.

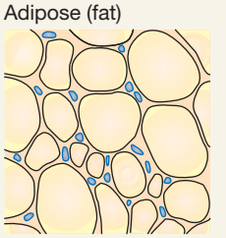
Classification of Connective Tissue

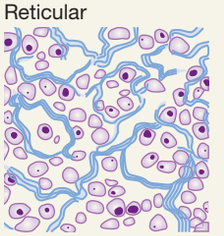
Connective tissues have been classified by histologists in several different ways. Usually they are placed in different categories or types according to the structural characteristics of the intercellular material. The classification scheme we have adopted here is widely used and includes most of the major types:

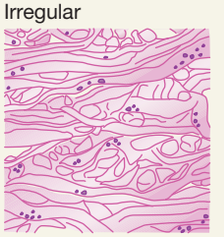
1. Fibrous (connective tissue proper)
   a. Loose fibrous (areolar)
   b. Adipose
   c. Reticular
   d. Dense
      (1) Irregular
      (2) Regular
         (a) Collagenous
         (b) Elastic
2. Bone
   a. Compact
   b. Cancellous (spongy)
3. Cartilage
   a. Hyaline
   b. Fibrocartilage
   c. Elastic
4. Blood

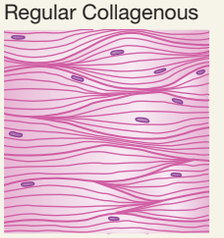
Fibrous tissues, also called *connective tissue proper*, such as loose fibrous connective, adipose, reticular, and dense fibrous tissues have many fibers in the ECM as their predominant feature. The type and arrangement of extracellular fibers are what distinguish members of the group from each other. Bone is considered a separate category of connective tissue because it has fibers and a hard mineralized ECM. Cartilage is yet another category because besides fibers, it has a type of ECM that traps water to form a firm gel. Blood, the last category listed, is characterized by the lack of fibers in its matrix. These major types of connective tissues are described further in the following pages and in Table 6-6.

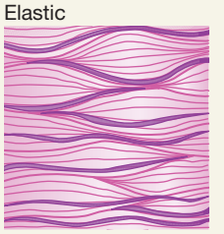
TABLE 6-6 Connective Tissues

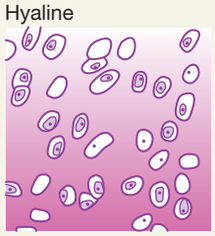


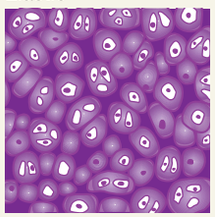


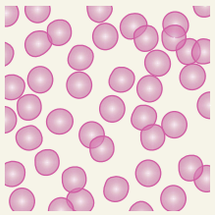












TISSUE	LOCATION	FUNCTION
Fibrous		
Loose fibrous (areolar) 	Between other tissues and organs Superficial fascia	Connection
Adipose (fat) 	Under skin Padding at various points	Protection Insulation Support Reserve food Regulation of other tissues
Reticular 	Inner framework of spleen, lymph nodes, bone marrow	Support Filtration Blood production Immunity
Dense Fibrous		
Irregular 	Deep fascia Dermis Scars Capsule of kidney, spleen, lymph nodes, etc.	Connection Support
Regular Collagenous 	Tendons Ligaments Aponeuroses	Flexible but strong connection
Elastic 	Walls of some arteries	Flexible, elastic support

TABLE 6-6 Connective Tissues *(continued)*

TISSUE	LOCATION	FUNCTION
Bone		
Compact bone 	Skeleton (outer shell of bones)	Support Protection Calcium reservoir
Cancellous (spongy) bone 	Skeleton (inside bones)	Support Provides framework for blood production
Cartilage		
Hyaline 	Part of nasal septum Covering articular surfaces of bones Larynx Rings in trachea and bronchi	Firm but flexible support; connection between structures
Fibrocartilage 	Disks between vertebrae Pubic symphysis	
Elastic 	External ear Eustachian or auditory tube	
Blood		
	In the blood vessels	Transportation Protection

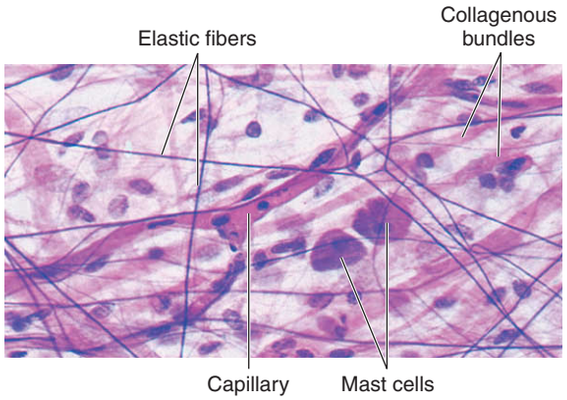


FIGURE 6-15

Loose fibrous (areolar) connective tissue. Notice how the H&E staining (see Figure 6-2) renders the bundles of collagen fibers a pinkish color and the elastin fibers and cell nuclei a darker, purplish color. Compare the loose arrangement of fibers here with fibers in Figures 6-20, 6-21, and 6-23.

Fibrous Connective Tissue

LOOSE FIBROUS CONNECTIVE TISSUE (AREOLAR)

Loose fibrous connective tissue, shown in Figure 6-15, is sometimes called *areolar tissue*. It is loose because it is stretchable and ordinary because it is one of the most widely distributed of all tissues. It is common and ordinary, not special like some kinds of connective tissue (e.g., bone and cartilage) that help form comparatively few structures. *Areolar* was the early name for the loose fibrous connective tissue that connects many adjacent structures of the body. It acts like a glue spread between them—but an elastic glue that permits movement. The word **areolar** means "like a small space" and refers to the bubbles that appear as areolar tissue is pulled apart during dissection. The matrix of loose fibrous connective tissue is a soft, thick gel mainly because it contains hyaluronic acid. An enzyme, hyaluronidase, can change the matrix from its thick gel state to a watery consistency. Physicians have made use of this knowledge for many years. They frequently inject a commercial preparation of hyaluronidase with drugs or fluids. By decreasing the viscosity (thickness) of intercellular material, the enzyme hastens diffusion and absorption of the injected material and lessens tissue tension and pain. Some bacteria, notably *pneumococci* and *streptococci*, spread through connective tissues by secreting hyaluronidase.

The matrix of loose fibrous connective tissue contains numerous fibers and cells, typically many interwoven collagenous and elastic fibers and about a half dozen kinds of cells

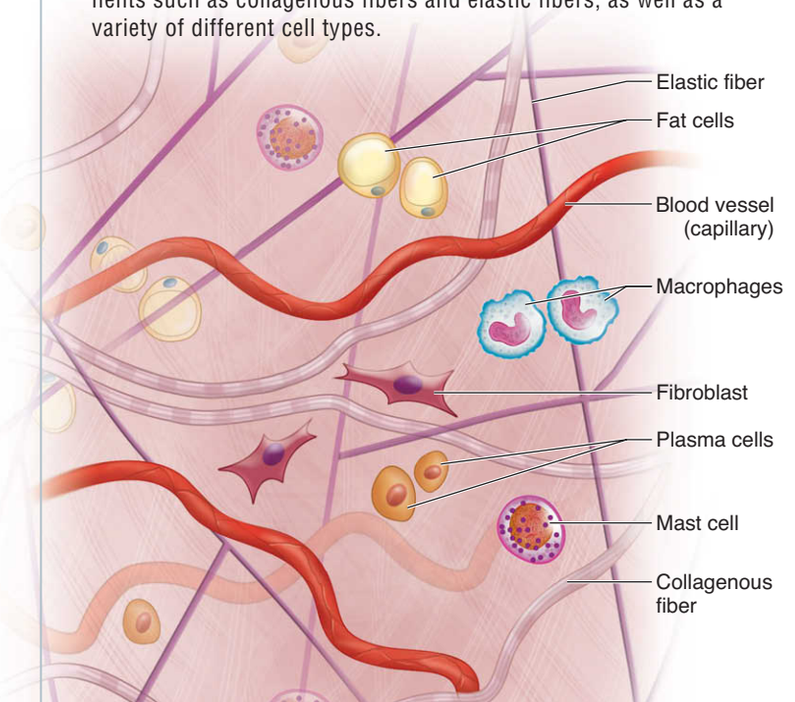
Box 6-3 | HEALTH matters

Hay Fever and Asthma

Mast cells in loose fibrous connective tissues are often involved in *allergy,* or *hypersensitivity,* reactions in local tissues. This is a type of inflammation (see ***A&P Connect: Inflammation*** online) in response to *allergens,* which are substances that trigger such allergic responses. For example, the inflammation that you experience after a bee sting or when your skin is exposed to poison ivy are both examples of allergic or hypersensitivity reactions. Such reactions are triggered when mast cells encounter an allergen and release any of a group of chemical mediators.

For example, in hay fever (allergies to grasses and other plants), mast cells release the chemical **histamine.** Histamine increases the permeability of blood vessels in the nasal membranes, which in turn causes swelling in the lining of the nose. This gives us a "stuffy feeling" because the swelling makes it difficult to breathe easily. Histamine can also cause itchiness of the nose and eyes (see figure). The stuffiness and itchy eyes of hay fever can be relieved by antihistamines such as diphenhydramine (Benadryl) and fexofenadine (Allegra), which block histamine's action.

On the other hand, a different mast cell product is responsible for the breathing difficulties in an asthma attack. In asthma, chemicals called *leukotrienes* trigger muscles in the walls of the respiratory tract to contract—thereby constricting the airways. Thus, leukotriene-blocking drugs such as montelukast (Singulair) and zileuton (Zyflo) are often used along with other drugs that prevent or reduce contraction of airway muscles.



Allergic eyes. Some allergies cause itchiness and watering of the eyes, which may trigger frequent rubbing of the eyes, that produces these reddened features.

(Figure 6-16). **Fibroblasts** are usually present in the greatest numbers in loose fibrous connective tissue, and **macrophages** are second. Fibroblasts synthesize the gel-like ground substance and the fibers present in it. Macrophages carry on *phagocytosis,* hence their name, which means "large eater." Phagocytosis is part of the body's vital collection of defense mechanisms. **Mast cells,** also found in loose fibrous connective tissue, are capable of releasing a variety of molecules such as *histamine*, *heparin*, *leukotrienes*, and *prostaglandins*. These chemical mediators are released in response to exposure to substances from outside the body and produce a type of inflammation response (Box 6-3). Other kinds of cells found in loose fibrous connective tissue are various forms of white blood cells (leukocytes) and some fat cells.

FIGURE 6-16

Diagram of loose fibrous (areolar) connective tissue. This artist's sketch illustrates the fact that loose fibrous connective tissue includes a number of different extracellular matrix (ECM) components such as collagenous fibers and elastic fibers, as well as a variety of different cell types.

ADIPOSE TISSUE

Adipose tissue differs from loose fibrous connective tissue mainly in that it contains predominantly fat cells, also called **adipocytes,** and many fewer fibroblasts, macrophages, and mast cells (Figure 6-17). Each adipocyte typically has one large vesicle filled with stored triglycerides. This fat vesicle is so large that it pushes the cytoplasm of the cell outward against the plasma membrane as it stores more and more fat. This expands the entire cell to a

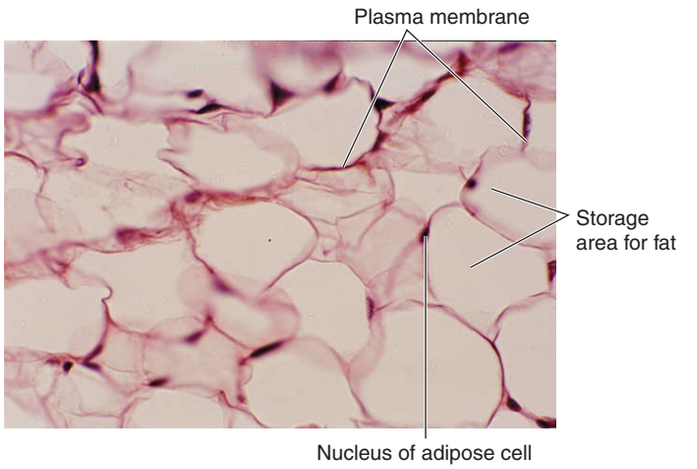


FIGURE 6-17

Adipose tissue. Note the large storage spaces for fat inside the adipose tissue cells.

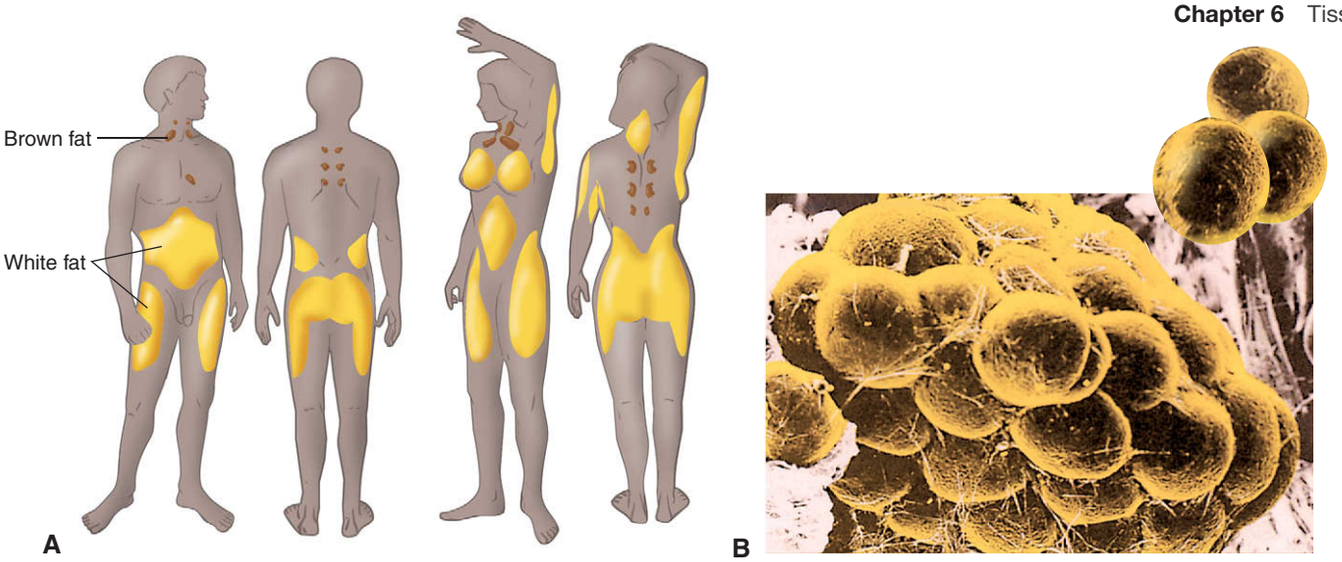

FIGURE 6-18

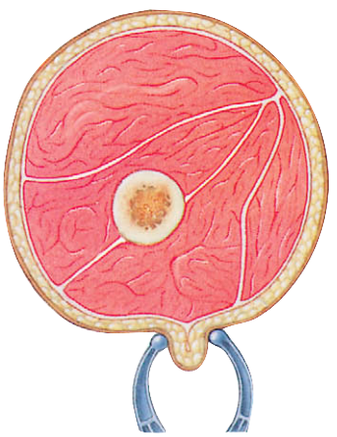
Fat distribution. A, The different distribution of fat in adult male and female bodies. **B,** Electron micrograph of a cluster of adipose cells in white fat held together by a network of fine reticular fibers (×150).

huge size. The hormone *leptin* is released from adipocytes as they expand, signaling the brain and other tissues regarding how much fat is stored and ready to use for energy. The role of leptin is described further in Chapters 19 and 30.

The predominant form of adipose tissue is *white fat*, which serves mainly as a storage depot for excess food. White fat also acts as an insulating material to conserve body heat. It also forms supporting, protective pads around the kidneys and various other structures.

Brown fat is a less abundant form of adipose tissue. Adipocytes in brown fat are able to use stored fat to generate heat with their numerous mitochondria. This function is vital to the survival of newborns, which do not have enough muscle to generate enough heat by shivering. In adults, this fat-burning function may help regulate overall fat content of the body.

Figure 6-18 shows the location of the main fat storage areas in adults and how fat distribution varies between males and females. Box 6-4 discusses body composition.



Box 6-4 | SPORTS and FITNESS

Tissues and Fitness

Achieving and maintaining ideal body weight is a health-conscious goal. However, a better indicator of health and fitness is **body composition.** Exercise physiologists assess body composition to identify the percentage of the body made of lean tissue and the percentage made of fat. Body fat percentage is often determined by using calipers to measure the thickness of skin folds at certain locations on the body (see figures). The thickness measurements, which reflect the volume of adipose tissue under the skin, are then used to estimate the percentage of fat in the entire body. A much more accurate method is to weigh a subject totally immersed in a tank of water. Fat has very low density and therefore increases the buoyancy of the body. When in water, a person's measured weight is relatively low if the body fat percentage is high and the measured weight is high if the body fat percentage is low.

A person with low body weight may still have a high ratio of fat to muscle, an unhealthy condition. In this case the individual is "underweight" but "overfat." In other words, fitness depends more on the percentage and ratio of specific tissue types than on the overall amount of tissue present. Therefore, one goal of a good fitness program is a desirable body fat percentage. For men, the ideal is 15% to 18%, and for women, the ideal is 20% to 22%.

Because fat contains stored energy (measured in calories), a low fat percentage means a low energy reserve. High body fat percentages are associated with several life-threatening conditions, including cardiovascular disease. A balanced diet and an exercise program ensure that the ratio of fat to muscle tissue stays at a level appropriate for maintaining homeostasis.

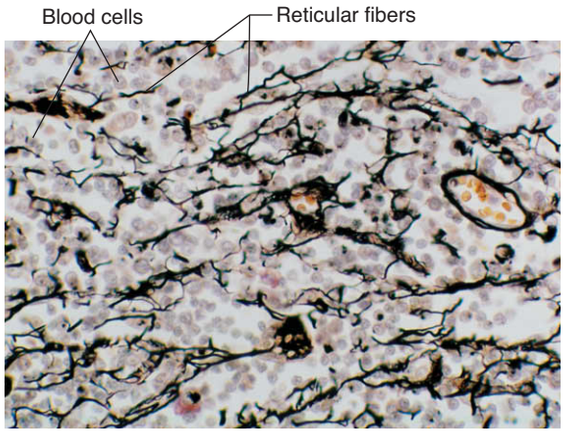


FIGURE 6-19

Reticular connective tissue. The supporting framework of reticular fibers are stained black in this section of lymph node.

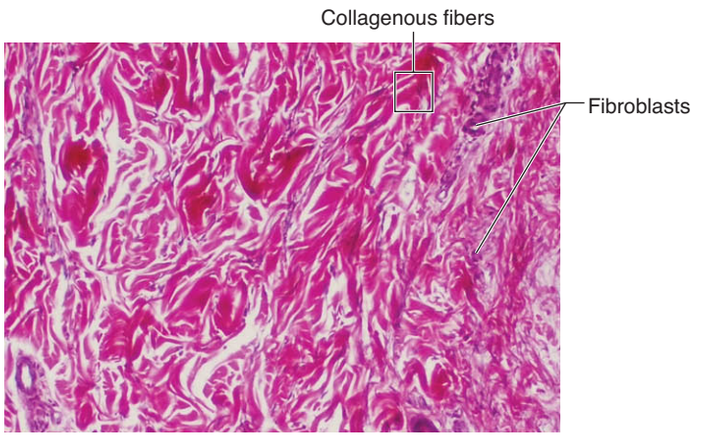

FIGURE 6-20

Dense irregular fibrous connective tissue. Section of skin (dermis) showing arrangements of collagenous fibers (pink) and purple-staining fibroblast cell nuclei.

RETICULAR TISSUE

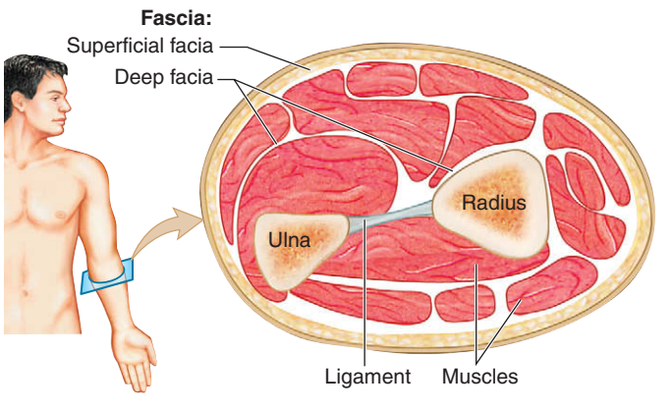
A three-dimensional web, that is, a reticular network, identifies **reticular tissue** (Figure 6-19). The word *reticular* means "like a net." Slender, branching reticulin fibers with reticular cells overlying them compose the reticular meshwork. Branches of the cytoplasm of reticular cells follow the branching reticular fibers.

Reticular tissue forms the framework of the spleen, lymph nodes, and bone marrow. It is often called *marrow tissue* or *lymphoid tissue* in these locations. Reticular tissue functions as part of the body's complex mechanisms for producing blood cells and for defending itself against microorganisms and injurious substances. The reticular meshwork filters injurious substances out of the blood and lymph. Various types of reticular cells then phagocytose (engulf and destroy) the trapped substances. Another function of some reticular cells is to make reticular fibers.

DENSE FIBROUS TISSUE

Dense fibrous tissue consists mainly of fibers packed densely in the matrix. It contains relatively few fibroblast cells. Some dense fibrous tissues are designated as *regular* and others are designated as *irregular*, depending on the arrangement of fibers.

Dense Irregular Fibrous Tissue



In dense irregular fibrous tissues, the bundles of collagenous fibers intertwine in irregular, swirling arrangements (Figure 6-20). This irregular pattern forms a thick mat of strong connective tissue that can withstand stresses applied from any direction. Dense irregular fibrous tissue forms the strong inner skin layer called the *dermis*. It also forms the outer capsule of such organs as the kidney and the spleen, as well as much of the fascia that surrounds muscles (Box 6-5).

Box 6-5 | Fascia

The term **fascia** (FASH-ee-ah) is a general name for the fibrous connective tissue masses that can be seen by the unaided eye in many locations throughout the body. The word *fascia* is Latin for "band." This literal translation is helpful because it summarizes the general structure and function of fascia: fibrous tissue that binds together the structures of the body.

Fascia is always some form of fibrous connective tissue and almost always features many collagenous fibers that are interwoven in an irregular arrangement. In some areas of the body, for example under the skin, fascia is mostly adipose tissue. In other areas, such as around some of the muscles, it is dense irregular fibrous tissue. Often, some of the fibers of fascia extend into the tissue of nearby organs, thus strongly binding to them.

For convenience, anatomists often distinguish between *superficial fascia,* which is just under the skin, and *deep fascia,* which extends well into the body and surrounds muscles, blood vessels, and other organs (see the figure).

Fascia. Horizontal section of the forearm showing the superficial fascia under the skin and deep fascia below that, extending to surround the individual muscles.

Inflammation is an important defensive reaction in the body's tissues. Check out ***Inflammation*** online at ***A&P Connect*** for a brief overview of the inflammatory response and its effects on the tissues of your body.

evolve

Dense Regular Fibrous Tissue

In dense regular fibrous tissues, the bundles of fibers are arranged in regular, parallel rows. One form of dense regular fibrous tissue is predominantly bundles of collagenous fibers and may be called **collagenous dense regular fibrous tissue** (Figure 6-21). This type of fibrous tissue is flexible but possesses great tensile strength when pulled from either or both ends. These characteristics are desirable in structures that anchor muscle to bone, such as tendons (Figure 6-22). Ligaments (which connect bone to bone) instead have a predominance of elastic fibers. Hence ligaments exhibit some degree of elasticity.

Another form of dense (regular) fibrous tissue contains mostly elastic fibers and may be called **elastic dense regular fibrous tissue.** As you can see in Figure 6-23, elastic fibers in this type of tissue are in a parallel arrangement. In the walls of arteries, this arrangement permits the walls to be pushed out by blood pressure without breaking and then recoil to a smaller diameter when the blood pressure decreases.

Bone Tissue

Bone, or *osseous tissue*, is a rather unique form of very hard connective tissue. The mature cells of bone, **osteocytes,** are embedded in a unique matrix material containing both collagen fibers and mineral salt crystals. The inorganic mineral crystals make up about 66% of the total extracellular matrix. These mineral crystals are responsible for the hardness of bone.

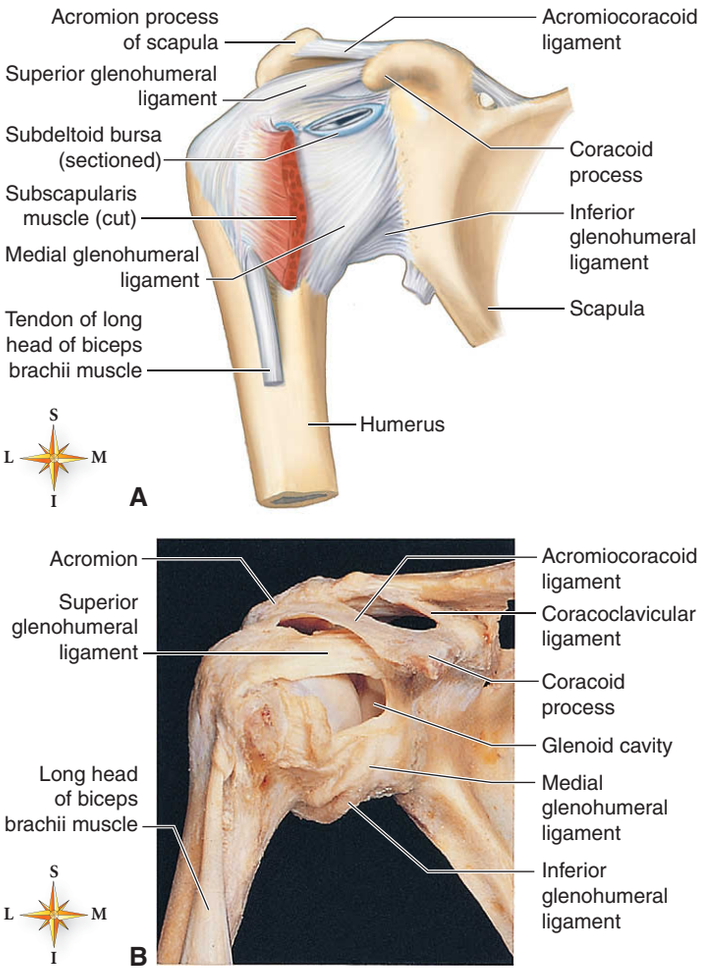

FIGURE 6-22

Tendons and ligaments. A, Tendons and ligaments of the shoulder are examples of dense fibrous connective tissue. **B,** Photo of cadaver dissection. Note the many strong connections needed to keep this important joint functioning properly.

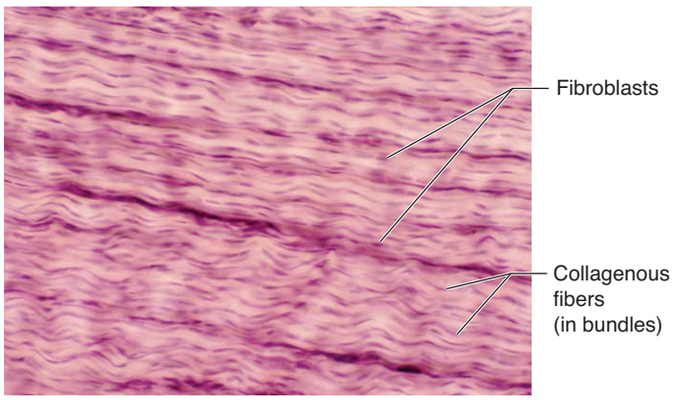

FIGURE 6-21

Collagenous dense regular fibrous connective tissue. Photomicrograph of tissue in a tendon. Note the multiple (regular) bundles of collagenous fibers arranged in parallel rows.

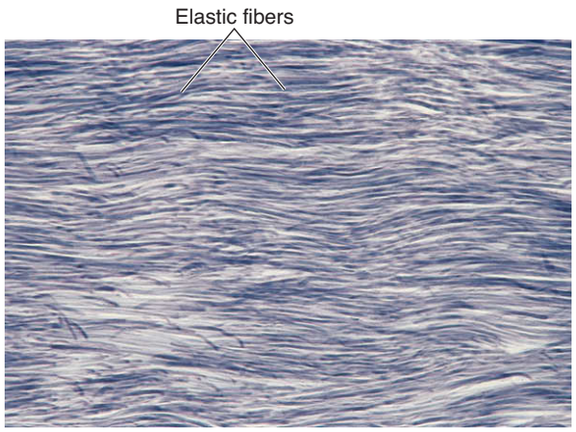

FIGURE 6-23

Elastic dense regular fibrous connective tissue. Note the roughly parallel arrangement of short, darkly stained elastic fibers.

Bones are the organs of the skeletal system. They provide support and protection for the body and serve as points of attachment for muscles. In addition, the calcified matrix of bones serves as a mineral reservoir for the body. A lattice made of bone also serves as the support for red bone marrow, which produces new blood cells.

Certain bones called **membrane bones** (e.g., flat bones of the skull) are formed within membranous tissue, whereas others (e.g., long bones such as the humerus) are formed indirectly through replacement of cartilage in a process called **endochondral ossification** (Figure 6-24). The details of bone formation are presented in Chapter 8.

COMPACT BONE TISSUE

The type of bone tissue that forms the hard shell of a bone is called **compact bone tissue** (Figure 6-25). The basic organizational or structural unit of compact bone is the microscopic **osteon,** or *Haversian system* (Figure 6-26). Osteocytes, or bone cells, are located in small spaces, or **lacunae,** which are arranged in concentric layers of bone matrix called **lamellae.** Small canals called **canaliculi** connect each lacuna and osteocyte with nutrient blood vessels found in the central, or Haversian, canal.

Mature osteocytes are actually trapped in hard bone matrix. At one time they were active, bone-forming cells called **osteoblasts.** However, as they surround themselves with bone, they become trapped and cease making new bone matrix. Another type of bone cell, the **osteoclast,** or bone-destroying cell, may dissolve the bone away from the mature osteocyte and release it to again become an active osteoblast. Mature bone can thus grow and be reshaped by the simultaneous activity of osteoclasts breaking down and removing existing bone tissue as osteoblasts lay down new bone.

CANCELLOUS (SPONGY) BONE TISSUE

Inside many bones is a lattice of thin beams of **cancellous bone tissue** (Figure 6-27). These thin beams, or **trabeculae,** form a framework that supports a softer tissue—*red bone marrow.* Red bone marrow is also called *myeloid tissue* (the term *myeloid* literally means "of marrow"). Myeloid tissue is a type of reticular tissue that contains the stem cells responsible for producing the various types of blood cells. It also contains fat-storing *adipocytes.*

The lattice of trabeculae also give internal support to the bone, much as the crisscrossing pattern of the roof trusses of a building help support the weight of a roof. Because cancellous bone looks somewhat like a sponge at first glance, it is sometimes called *spongy bone tissue.* This type of bone is also called *trabecular bone* because of its many trabeculae.

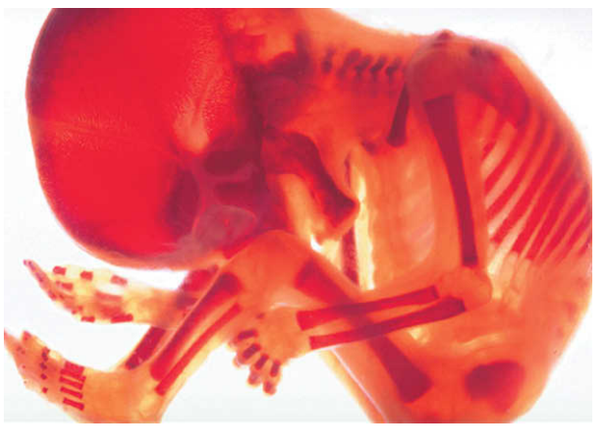

FIGURE 6-24

Ossification of the skeleton. The darkly stained areas of mineralization seen in this 14-week-old fetus show how the cartilage and membrane skeleton is beginning to develop into bone.

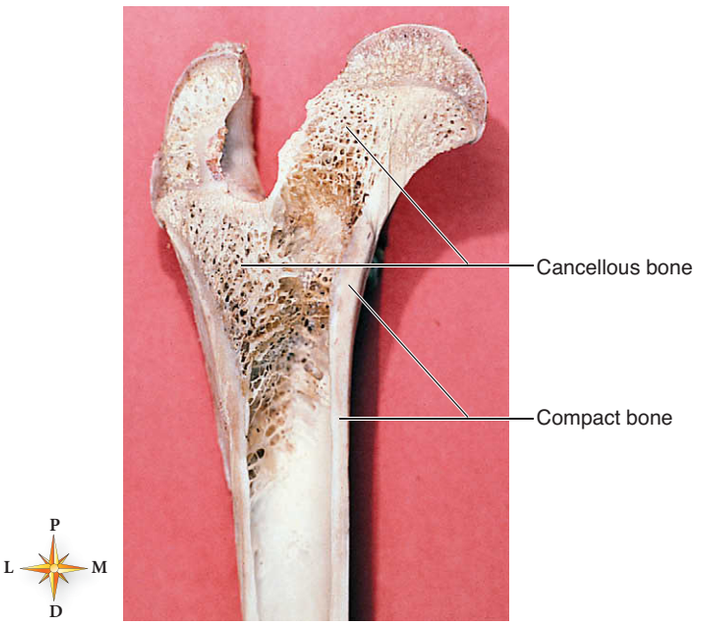

FIGURE 6-25

Types of bone tissue. Compact bone is found forming most of the hard shell of a bone. Cancellous (spongy) bone forms a network of hard beams of bone tissue inside many bones.

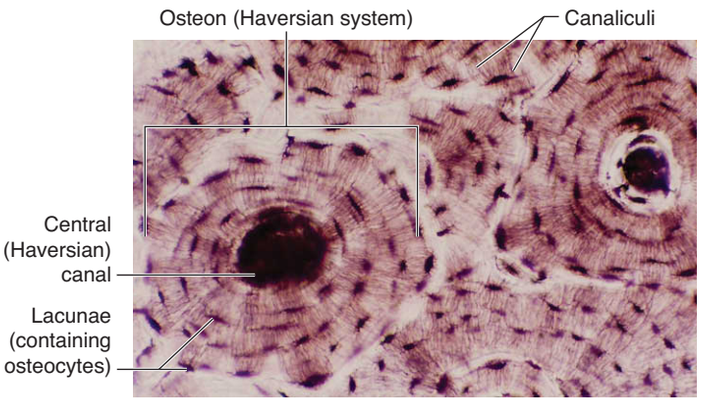

FIGURE 6-26

Compact bone tissue. Photomicrograph of ground compact bone. Many wheel-like structural units of bone, known as *osteons* or *Haversian systems,* are apparent in this section.

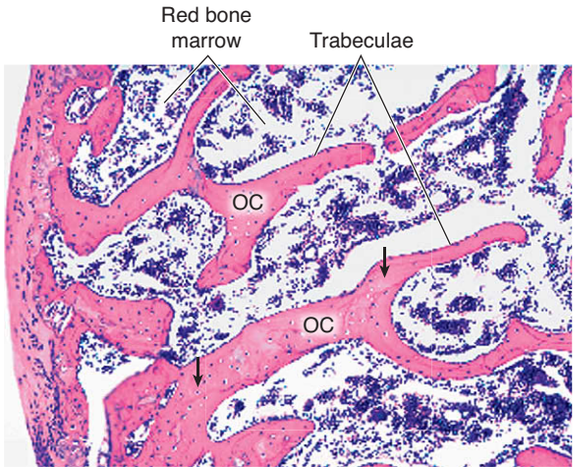

FIGURE 6-27

Cancellous bone tissue. Photomicrograph of cancellous (*spongy* or *trabecular*) bone. The pink-stained mineralized bone tissue forms a lattice of irregular beams, or *trabeculae,* that support the softer reticular tissue of the bone marrow. The darkly stained nuclei of osteocytes *(OC)* are visible, as well as the dark boundaries *(arrows)* of mineralized bone layers or lamellae.

Cartilage Tissue

Cartilage differs from other connective tissues in that only one cell type, the **chondrocyte,** is present. Chondrocytes produce the fibers and the tough, rubbery ground substance of cartilage. Chondrocytes, like bone cells, are found in small openings called *lacunae.* Cartilage is avascular (lacking blood vessels), so nutrients must reach the cells by diffusion. Movement is through the matrix from blood vessels located in a connective tissue membrane called the **perichondrium,** which surrounds the cartilage mass. Injuries to cartilage heal slowly, if at all, because of this inefficient method of nutrient delivery.

HYALINE CARTILAGE TISSUE

Hyaline cartilage takes its name from the Greek word *hyalos* or "glass." The name is appropriate because the low amount of collagen in the matrix gives hyaline cartilage a shiny and translucent appearance. This is the most prevalent type of cartilage and is found in the support rings of the respiratory tubes and covering the ends of bones that articulate at joints (Figure 6-28).

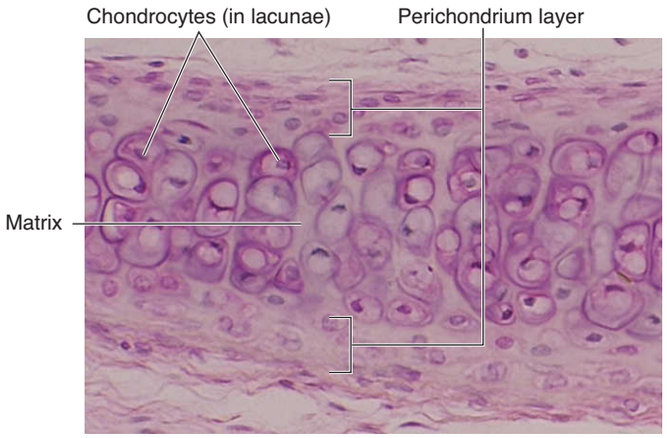

FIGURE 6-28

Hyaline cartilage. Photomicrograph of the trachea. Note the many spaces, or lacunae, in the gel-like matrix.

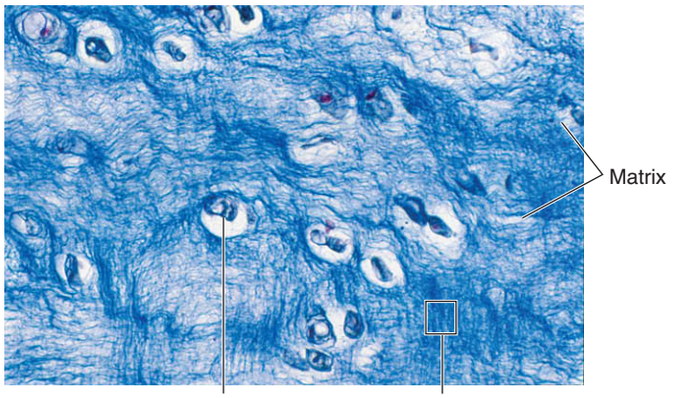

FIGURE 6-29

Fibrocartilage. Photomicrograph of the pubic symphysis joint. The strong dense fibers that fill the matrix convey shock-absorbing qualities.

FIBROCARTILAGE TISSUE

Fibrocartilage is the strongest and most durable type of cartilage (Figure 6-29). The matrix is rigid and filled with a dense packing of strong white collagen fibers. Fibrocartilage disks serve as shock absorbers between adjacent vertebrae (intervertebral disks) and in the knee joint. Damage to the fibrocartilage pads or joint menisci (curved pads) in the knee occurs frequently as a result of sports-related injuries.

ELASTIC CARTILAGE TISSUE

Elastic cartilage contains few collagen fibers, but large numbers of very fine elastic fibers that give the matrix material a high degree of flexibility (Figure 6-30). This type of cartilage is found in the external ear and in the voice box, or larynx.

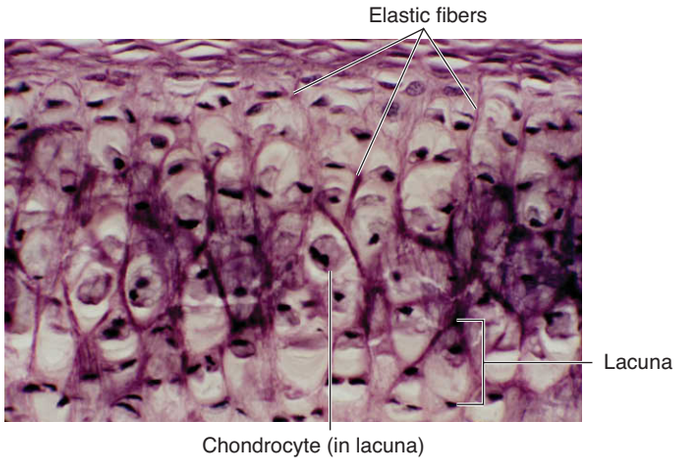

FIGURE 6-30

Elastic cartilage. Photomicrograph of the voice box (larynx). Note the cartilage cells in the lacunae surrounded by matrix and dark-staining elastic fibers.

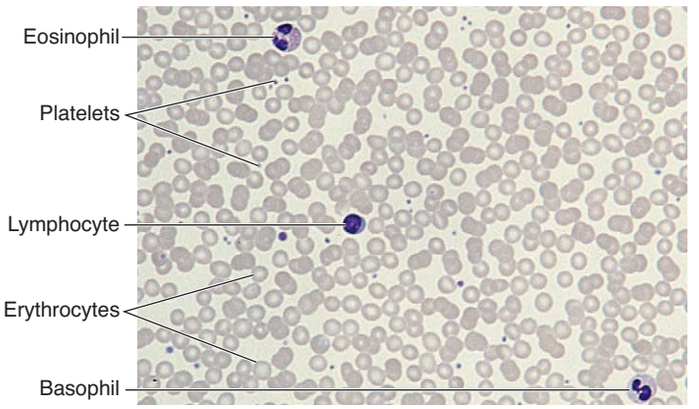

FIGURE 6-31

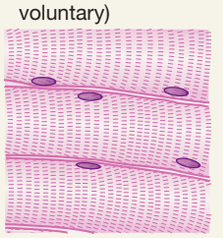
Blood. Photomicrograph of a human blood smear (×270) showing three white blood cells, or leukocytes, surrounded by numerous smaller red blood cells and platelets.

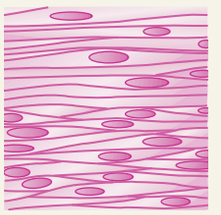
Blood Tissue

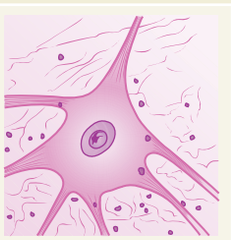
Blood is perhaps the most unusual connective tissue because it exists in a liquid state and contains neither ground substance nor fibers (Figure 6-31).

Whole blood is often divided into a matrix, or *liquid fraction*, called **plasma** and **formed elements,** or blood cells. Blood cells may be divided into three classes: red blood cells, or **erythrocytes;** white blood cells, or **leukocytes;** and **thrombocytes,** or platelets. The liquid fraction makes up about 55% of whole blood, and the formed elements compose about 45%.

Blood performs many body transport functions, including movement of respiratory gases (oxygen and carbon dioxide), nutrients, and waste products. In addition, blood plays a critical role in maintaining a constant body temperature and regulating the pH of body fluids. White blood cells function in destroying harmful microorganisms.







Circulating blood tissue is formed in the *red marrow* of bones and in other tissues by a process of differentiation called *hematopoiesis.* This blood-forming tissue is sometimes given the status of a separate connective tissue type: **hematopoietic tissue.**

Blood and its formation are described in detail in Chapter 20.

TABLE 6-7 Muscle and Nervous Tissues

TISSUE	LOCATION	FUNCTION
Muscle		
Skeletal (striated voluntary) 	Muscles that attach to bones Extrinsic eyeball muscles Upper third of the esophagus	Movement of bones Eye movements First part of swallowing
Smooth (nonstriated, involuntary, or visceral) 	In the walls of tubular viscera of the digestive, respiratory, and genitourinary tracts In the walls of blood vessels and large lymphatic vessels In the ducts of glands Intrinsic eye muscles (iris and ciliary body) Arrector muscles of hairs	Movement of substances along the respective tracts Change diameter of blood vessels, thereby aiding in regulation of blood pressure Movement of substances along ducts Change diameter of pupils and shape of the lens Erection of hairs (gooseflesh)
Cardiac (striated involuntary) 	Wall of the heart	Contraction of the heart
Nervous		
	Brain Spinal cord Nerves	Excitability Conduction

MUSCLE TISSUE

Three types of **muscle tissue** are present in the body—skeletal muscle, smooth muscle, and cardiac muscle (Table 6-7). Their names suggest their locations. **Skeletal muscle tissue** (Figure 6-32) makes up most of the muscles attached to bones; these are the organs that we think of as our muscles. **Smooth muscle tissue,** also sometimes called *visceral muscle tissue* (Figure 6-33), is found in the walls of the viscera (hollow internal organs, e.g., the stomach, intestines, and blood vessels; Figure 6-34). **Cardiac muscle tissue** makes up the wall of the heart (Figure 6-35).

Another name for skeletal muscle is *striated voluntary* muscle. The term *striated* refers to cross striations (stripes) visible on

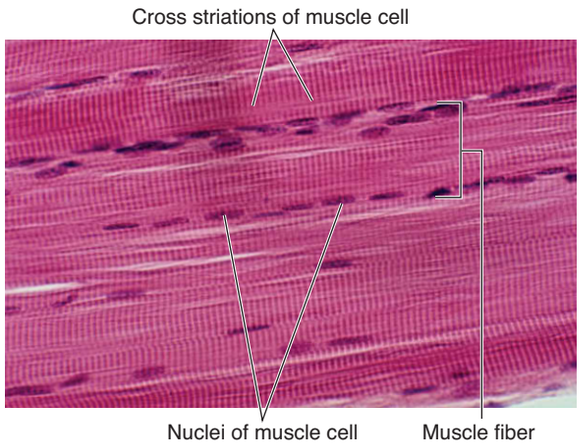

FIGURE 6-32

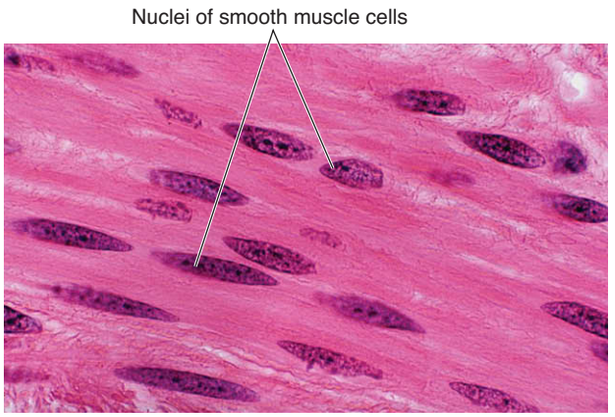
Skeletal muscle. Note the striations of the muscle cell fibers in longitudinal section.



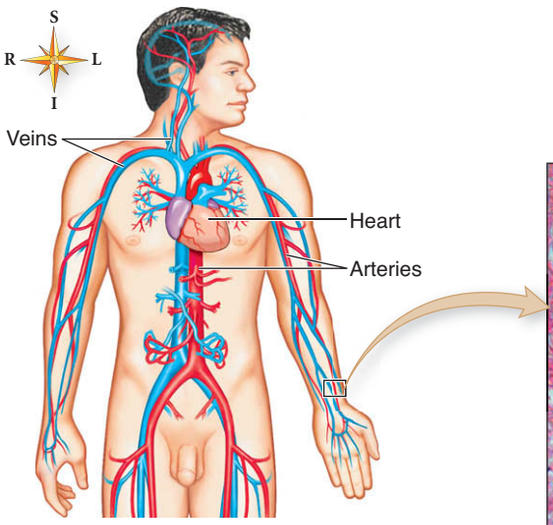


FIGURE 6-33

Smooth muscle. Photomicrograph, longitudinal section. Note the central placement of nuclei in the spindle-shaped smooth muscle fibers.

Cardiovascular system

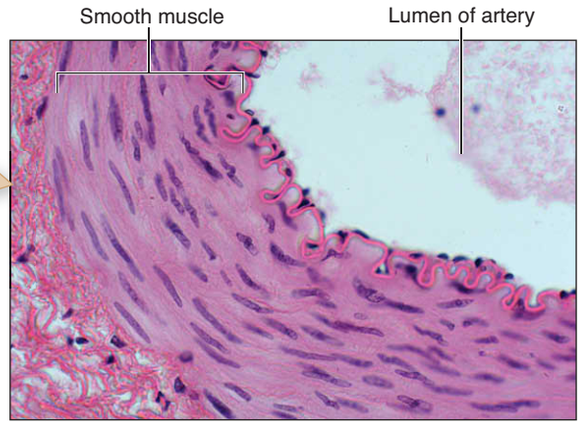

FIGURE 6-34

Location of smooth muscle. Smooth muscle is found in the walls of most internal hollow organs such as the stomach, intestines, and blood vessels. For example, the cross section of an artery shown in the inset reveals that the arterial wall has a thick layer of smooth muscle, which contracts or relaxes to control the diameter of the artery—thus controlling the flow of blood through this vessel.

microscopic slides of the tissue. The term *voluntary* indicates that voluntary or willed control of skeletal muscle contractions is possible. Another name for smooth muscle is *nonstriated involuntary*. Smooth muscle has no cross striations and cannot ordinarily be controlled by the will. Another name for cardiac muscle is *striated involuntary* muscle. Like skeletal muscle, cardiac muscle has cross striations, and like smooth muscle, its contractions cannot ordinarily be controlled by will.

Look now at Figure 6-32 and observe the following structural characteristics of skeletal muscle cells: many cross striations, many nuclei per cell, and long, narrow, threadlike shape of the cells. Skeletal muscle cells may have a length of more than 3.75 cm, but they have diameters of only 10 to 100 μm. Because this gives them a threadlike appearance, muscle cells are often called *muscle fibers*. Chapter 12 gives more detailed information about the structure of skeletal muscle tissue.

Smooth muscle cells are also long, narrow fibers, but not nearly as long as striated fibers. One can see the full length of a

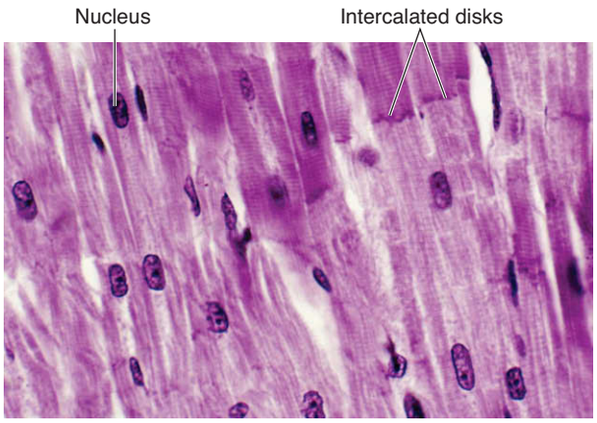

FIGURE 6-35

Cardiac muscle. The dark bands, called *intercalated disks,* which are characteristic of cardiac muscle, are easily identified in this tissue section.

smooth muscle fiber in a microscopic field, but only a small part of a striated fiber. According to one estimate, the longest smooth muscle fibers measure about 500 µm and the longest striated fibers about 40,000 µm. As Figure 6-33 shows, smooth muscle fibers have only one nucleus per fiber and are nonstriated or smooth in appearance. Smooth muscle fibers are shaped like a spindle—that is, they are cylinders that taper at both ends.

Under the light microscope, cardiac muscle fibers (see Figure 6-35) have cross striations and unique dark bands (intercalated disks) that join together the untapered ends of fibers. They also seem to be incomplete cells that branch into each other to form a big continuous mass of cytoplasm (a *syncytium*). The electron microscope, however, reveals that the intercalated disks are actually places where the plasma membranes of two cardiac fibers abut. Cardiac fibers branch in and out, but a complete plasma membrane encloses each cardiac fiber—around its end (at intercalated disks) and its sides.

Muscle cells are the movement specialists of the body. Because their cytoskeletons include bundles of microfilaments capable of movement, they have a higher degree of contractility (ability to shorten and lengthen with force) than cells of any other tissue.

NERVOUS TISSUE

The basic function of the nervous system is to rapidly regulate, and thereby integrate, the activities of the different parts of the body. Functionally, rapid communication is possible because **nervous tissue** has much more developed excitability and conductivity characteristics than any other type of tissue does.

The organs of the nervous system are the brain, the spinal cord, and the nerves. Actual nerve tissue is ectodermal in origin and consists of two basic kinds of cells: nerve cells, or **neurons,** which are the conducting units of the system, and special connecting, protective, and supporting cells called **neuroglia** (see Table 6-7 and Figure 6-36).

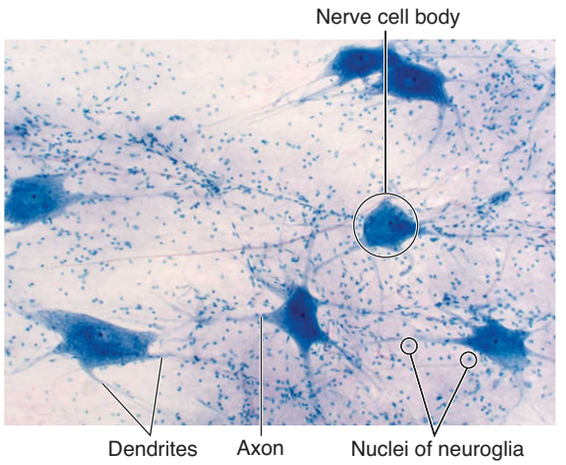

FIGURE 6-36

Nervous tissue. Photomicrograph showing multipolar neurons surrounded by smaller neuroglia in a smear of spinal cord tissue. All of the large neurons in this photomicrograph show characteristic soma, or cell bodies, and multiple cell processes.

All neurons are characterized by a cell body called the **soma** and, generally, at least two processes: one **axon,** which transmits nerve impulses away from the cell body, and one or more **dendrites,** which carry nerve signals toward the axon. Most neurons are located within the organs of the central nervous system.

There are many types of neuroglia, all with different structures and functions. For example, *astrocytes* form a blood-brain barrier that protects delicate brain tissue from potentially harmful substances in the blood. *Microglia* help destroy pathogens and damaged tissue cells in the brain. *Schwann cells* and *oligodendrocytes* electrically insulate axons to increase their speed of conduction. In addition to physically supporting neurons, neuroglia are known to have important coordinating roles in the nervous system—a concept that we explore further in Chapter 13.

The anatomy and physiology of the nervous system are presented in Chapters 13 through 17.

| QUICK CHECK |

12. Name the two types of involuntary muscle. Where is each found in the body?
13. What are the two principal types of cell in nervous tissue? What is the function of each?

TISSUE REPAIR

When damaged by mechanical or other injuries, tissues have varying capacity to repair themselves. Damaged tissue regenerates or is replaced by tissue we know as scars. Tissues usually repair themselves by allowing phagocytic cells to remove dead or injured cells and then filling in the gaps that are left. This growth of functional new tissue is called **regeneration.**

Epithelial and connective tissues have the greatest capacity to regenerate (Figure 6-37). When a break in an epithelial membrane occurs, as in a cut, cells quickly divide to form daughter cells that fill the wound. In connective tissues, cells that form collagen fibers become active after an injury and fill in a gap with an unusually dense mass of fibrous connective tissue. If this dense mass of fibrous tissue is small, it may be replaced by normal tissue later. If the mass is deep or large or if cell damage was extensive, it may remain as a dense fibrous mass, called a **scar.** An atypical and unusually thick scar that may develop in the lower layer of the skin, such as that shown in Figure 6-38, is called a **keloid.**

Muscle tissue, on the other hand, has a limited capacity to regenerate and thus heal itself. Scientists are just now learning about the abilities of muscle fibers to be replaced in adults. Damaged muscle is sometimes replaced with fibrous connective tissue instead of muscle tissue. When this happens, the organ involved loses some or all of its ability to function.

Like muscle tissue, nerve tissue also has a limited capacity to regenerate. Neurons can sometimes regenerate, but very slowly and only if certain neuroglia are present to "pave the way." In the normal adult brain and spinal cord, a few new neurons are regularly produced in certain regions. However, adult brain neurons do not often grow back when injured. Thus serious brain and spinal cord injuries often result in at least some permanent damage.

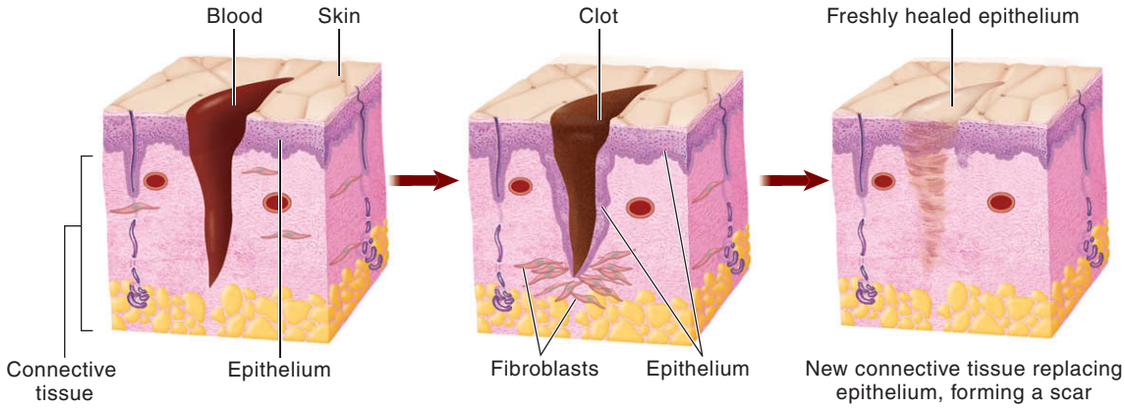

FIGURE 6-37

Healing of a minor wound. When a minor injury damages a layer of epithelium and the underlying connective tissue (as in a minor skin cut), the epithelial tissue and the connective tissue can self-repair.

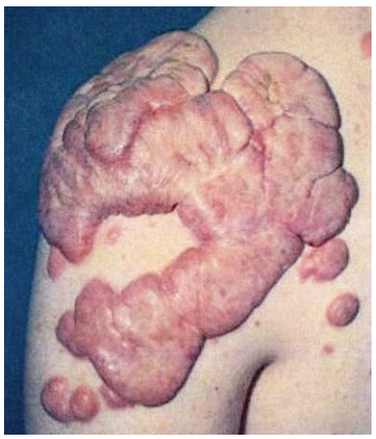

FIGURE 6-38

Keloid. Keloids are thick scars that form in the lower layer of the skin in predisposed individuals.

Fortunately, research on *nerve growth factors* produced by neuroglia offers the promise of treating brain damage. Research on adult stem cells present in both muscle and nerve tissue also holds hope for such therapies.

BODY MEMBRANES

The term **membrane** refers to a thin, sheetlike structure that may have many important functions in the body. Membranes cover and protect the body surface, line body cavities, and cover the inner surfaces of hollow organs such as the digestive, reproductive, and respiratory passageways. Some membranes anchor organs to each other or to bones, and others cover the internal organs. In certain areas of the body, membranes secrete lubricating fluids that reduce friction during organ movements such as beating of the heart or lung expansion and contraction. Membrane lubricants also decrease friction between bones and joints. Two major categories, or types, of body membranes exist (Figure 6-39):

1. **Epithelial membranes,** composed of epithelial tissue and an underlying layer of supportive connective tissue
2. **Connective tissue membranes,** composed exclusively of various types of connective tissue; no epithelial cells are present in this type of membrane

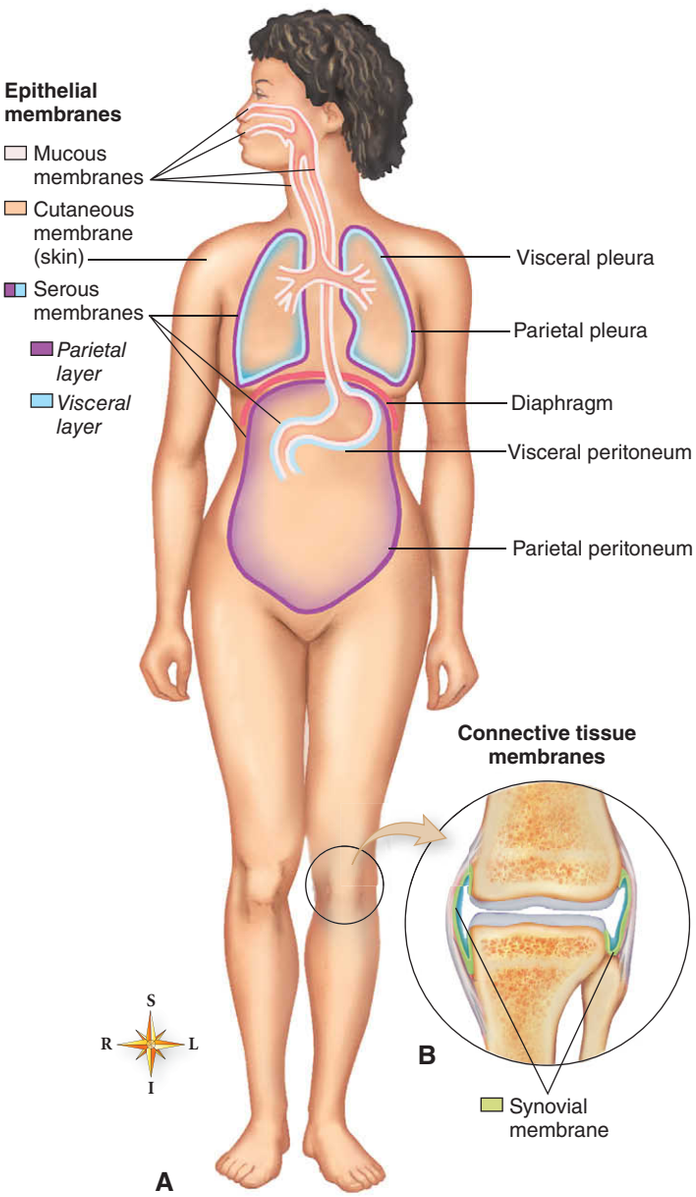

FIGURE 6-39

Types of body membranes. A, Epithelial membranes, including cutaneous membrane (skin), serous membranes (parietal and visceral pleura and peritoneum), and mucous membranes. **B,** Connective tissue membranes, including synovial membranes.

Epithelial Membranes

There are three types of epithelial tissue membranes in the body: (1) cutaneous membrane, (2) serous membranes, and (3) mucous membranes (Figure 6-40).

CUTANEOUS MEMBRANES

The **cutaneous membrane** covers body surfaces that are exposed to the external environment. The cutaneous membrane, or **skin,** is the primary organ of the integumentary system. It is one of the most important and certainly one of the largest and most visible organs of the body. In most individuals the skin composes approximately 16% of body weight. It fulfills the requirements necessary for an epithelial tissue membrane in that it has a superficial layer of epithelial cells and an underlying layer of supportive connective tissue. It also contains many sweat and oil glands that produce a *surface film* over the skin. The structure of the skin is uniquely suited to its many functions. The skin is discussed in depth in Chapter 7.

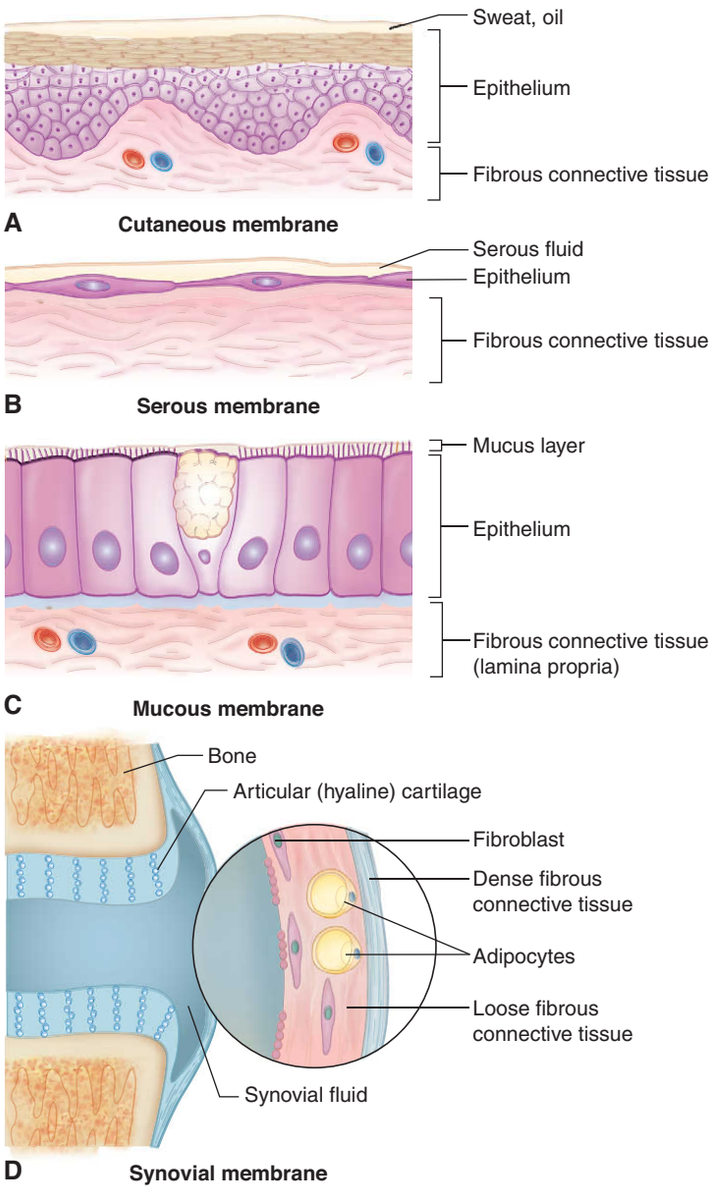

FIGURE 6-40
Structure of body membranes.

SEROUS MEMBRANES

Serous membrane lines cavities that are not open to the external environment and covers many of the organs inside these cavities. Serous membranes are sometimes called by their Latin name, *serosa*. Like all epithelial membranes, a serous membrane is composed of two distinct layers of tissue. One of the layers, the epithelial sheet, is a thin layer of simple squamous epithelium. The other layer, the connective tissue layer, forms a very thin sheet that holds and supports the epithelial cells.

The serous membrane that lines body cavities and covers the surfaces of organs in these cavities is in reality a single, continuous sheet covering two different surfaces. The *parietal membrane* is the portion that lines the wall of the cavity like wallpaper; the *visceral membrane* covers the surface of the viscera (organs within the cavity). Two important serous membranes are identified in Figure 6-39: the *pleura*, which surrounds a lung and lines the thoracic cavity, and the *peritoneum*, which covers the abdominal viscera and lines the abdominal cavity. Another example is the *pericardium*, which surrounds the heart (Box 6-6).

Serous membranes secrete a thin, watery fluid that lubricates organs as they rub against one another and against the walls of cavities.

MUCOUS MEMBRANES

Mucous membranes are epithelial membranes that line body surfaces opening directly to the exterior. Mucous membranes are sometimes called by their Latin name, *mucosa*. Examples of mucous membranes include those lining the respiratory, digestive, urinary, and reproductive tracts. The epithelial component of the mucous membrane varies, depending on its location and function. In the esophagus, for example, a tough, abrasion-resistant stratified squamous epithelium is found. A thin layer of simple columnar epithelium covers the walls of the lower segments of the digestive tract. The fibrous connective tissue underlying the epithelium in mucous membranes is called the **lamina propria.**

Box 6-6 | HEALTH matters

Inflammation of Serous Membranes

Pleurisy (PLOOR-i-see) (also called *pleuritis*) is a very painful pathological condition characterized by inflammation of the serous membranes (pleurae) that line the chest cavity and cover the lungs. Pain is caused by irritation and friction as the lungs rub against the walls of the chest cavity. In severe cases the inflamed surfaces of the pleura fuse, and permanent damage may develop. The term **peritonitis** (pair-i-toh-NYE-tis) is used to describe inflammation of the serous membranes in the abdominal cavity. Peritonitis is sometimes a serious complication of an infected appendix. See ***Inflammation*** online at ***A&P Connect*** for more about the inflammatory response.

Mucous membranes get their name from the fact that they produce a film of **mucus** that coats and protects the underlying cells. Besides protection, mucus also serves other purposes. For example, mucus acts as a lubricant for food as it moves along the digestive tract. In the respiratory tract, it serves as a sticky trap for contaminants.

Mucus is a watery secretion that contains a mixture of *mucins*, which are a group of about two dozen different proteoglycans. Different mucins are found in different locations in the body. Some mucins are attached directly to the plasma membranes of the epithelial cells to form a protective coat. Other mucins are released by goblet cells and form a protective, sometimes lubricating gel. Thus mucous membranes have two layers of protective coating.

The mucous membrane is clinically important because it is the place that our body will most likely interact with microorganisms from the external environment. In fact, a very active area of research is attempting to understand the microbial colonization of mucous membranes in the digestive tract, respiratory tract, urinary tract, and reproductive tract (Figure 6-41). As researchers learn more about how mucus defends our internal environment from attack, the better able they will be to develop new strategies to avoid life-threatening infections. Chapter 24 discusses the role of mucous membranes in immunity.

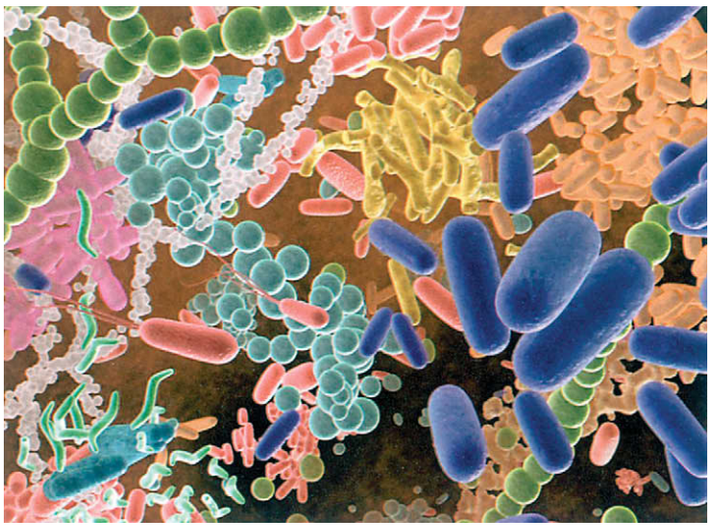

FIGURE 6-41

Colonization of mucous membranes by microbes. This colorized scanning electron micrograph shows many different types of bacteria that colonize the mucous membranes of the digestive tract and urinary tract within a short time after birth (*yellow,* bifidobacteria; *red,* coliform bacteria; *purple,* lactobacilli; *light blue,* streptococci; *green,* other coccal bacteria).

Connective Tissue Membranes

Unlike cutaneous, serous, and mucous membranes, connective tissue membranes do not contain epithelial components. The **synovial membranes** lining the spaces between bones and joints that move are classified as connective tissue membranes. These membranes are smooth and slick and secrete a thick and colorless lubricating fluid called **synovial fluid.** The membrane itself, with its specialized fluid, helps reduce friction between the opposing surfaces of bones in movable joints. Synovial membranes also line the small, cushionlike sacs called *bursae* found between some moving body parts.

Table 6-8 summarizes the main characteristics of the four major types of membranes in the body.

| QUICK CHECK |

14. Which two of the four major tissue types have the greatest capacity to regenerate after an injury?
15. Name the four principal types of body membranes. Which are epithelial membranes?

TABLE 6-8 Membranes of the Body

TYPE	SUPERFICIAL LAYER	DEEP LAYER	LOCATION	FLUID SECRETION	FUNCTION
Epithelial					
Cutaneous (skin)	Keratinized stratified squamous epithelium (epidermis)	Dense irregular fibrous connective tissue (dermis)	Directly exposed to external environment	Sweat; sebum (skin oil)	Protection, sensation, thermoregulation
Serous	Simple squamous epithelium	Fibrous connective tissue	Lines body cavities that are not open to the external environment	Serous fluid	Lubrication
Mucous	Various types of epithelium	Fibrous connective tissue (lamina propria)	Lines tracts that open to the external environment	Mucus	Protection, lubrication
Connective					
Synovial	Dense fibrous connective tissue	Loose fibrous connective tissue	Lines joint cavities (in movable joints)	Synovial fluid	Helps hold joint together, lubricates, cushions

the BIG picture

Tissues, Membranes, and the Whole Body

Tissues and body membranes are sometimes called "the fabric of the body." Like the pieces of fabric in a garment, tissues and body membranes are portions of a larger integrated structure. Just as each type of fabric in a complex garment has a different functional role determined by its structural characteristics, so does each type of tissue within the body. One of the ultimate functional goals of most tissues and membranes is maintenance of relative constancy in the body: homeostasis.

How do the major tissue types help maintain homeostasis? Epithelial tissues promote constancy of the body's internal environment in several ways. They form membranes that contain and protect the internal fluid environment, they absorb nutrients and other substances needed to maintain an optimum concentration in the body, and they secrete various products that regulate body functions involved in homeostasis. Connective tissues hold organs and systems together to form a whole, connected body. They also form structures that support the body and permit movement, such as the components of the skeleton.

Some connective tissues, such as blood, transport nutrients, wastes, and other substances within the internal environment. Some blood cells help protect the internal environment by participating in the body's immune system. Muscle tissues work in conjunction with connective tissues (bones, tendons, etc.) to permit movement (a function needed to avoid injury); to communicate; and to find food, shelter, and other requirements. Nervous tissue works with glandular epithelial tissue to regulate various body functions in a way that maintains homeostatic balance.

Now that you have a basic knowledge of the various types of body "fabric"—the tissues and body membranes—you are ready to study the structure and function of specific organs and systems. As you take this next step in your studies, pay close attention to the tissue types that make up each organ. If you do, you will find it easier to understand the characteristics of a particular organ, and you will also improve your understanding of the integrated nature of the whole body.

MECHANISMS of DISEASE

TUMORS AND CANCER

The concept of tumors and cancer was introduced in Chapter 1, then expanded in Box 5-3 on p. 126. Because tumors are tissue abnormalities, we resume our discussion here. Keep in mind that these and other tissue abnormalities continue to be important in later chapters as well.

Neoplasms

The term **neoplasm** literally means "new matter" and refers to any abnormal growth of cells: another name for a neoplasm is **tumor.** Neoplasms can be distinct lumps of abnormal cells or, in blood tissue, can be diffuse. Neoplasms are often classified as **benign** or **malignant.** Benign tumors are called that because they do not spread to other tissues and they usually grow very slowly. Their cells are often well differentiated, unlike the undifferentiated cells typical of malignant tumors. Cells in a benign tumor tend to stay together, and they are often surrounded by a capsule of dense tissue. Benign tumors are not usually life threatening, but can be if they disrupt the normal function of a vital organ. Malignant tumors, or **cancers,** on the other hand, are not encapsulated and tend to spread to other regions of the body. For example, cells from malignant breast tumors usually form new (secondary) tumors in bone, brain, and lung tissues. The cells migrate by way of lymphatic or blood vessels. This manner of spreading is called **metastasis.** Cells that do not metastasize can spread another way: they grow rapidly and extend the tumor into nearby tissues (Figure 6-42). Malignant tumors may replace part of a vital organ with abnormal, undifferentiated tissue—a life-threatening situation.

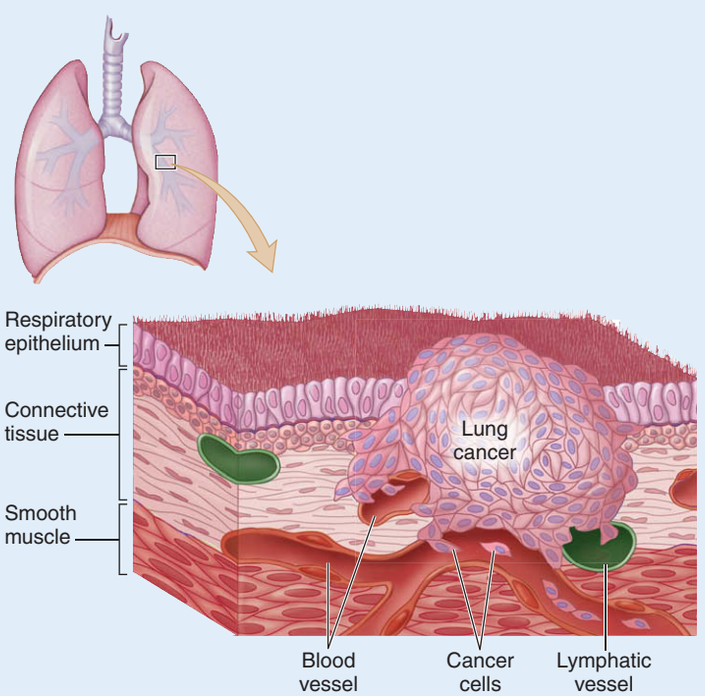

FIGURE 6-42

Cancer. This abnormal mass of proliferating cells in the lining of lung airways is a malignant tumor—lung cancer. Notice how some cancer cells are leaving the tumor and entering the blood and lymph vessels.

Neoplasms are classified further into subgroups, depending on the tissue in which they originate. Both benign and malignant tumors can be divided into three types: epithelial tumors, connective tissue tumors, and miscellaneous tumors. Benign tumor types that arise from epithelial tissues include *papilloma* (a finger-like projection), *adenoma* (glandular tumor), and *nevus* (small, pigmented skin tumors). Benign tumor types that arise from connective tissues include *lipoma* (adipose tumor), *osteoma* (bone tumor), and *chondroma* (cartilage tumor). Malignant tumors that arise from epithelial tissues are generally called **carcinomas.** Examples include *melanoma* (cancer of skin pigment cells) and *adenocarcinoma* (glandular cancer).

Malignant tumors that arise from connective tissues are generally called **sarcomas.** Examples include *lymphoma* (lymphatic cancer), *osteosarcoma* (bone cancer), and *fibrosarcoma* (cancer of fibrous connective tissue). Miscellaneous tumors are those that do not fit either of the previous categories. For example, an *adenofibroma* is a benign neoplasm formed by epithelial and connective tissues. Another example is *neuroblastoma*, a malignant tumor that arises from nerve tissue.

The etiologies (origins) of various forms of cancer puzzle medical science no less today than a hundred years ago. We do know that cancer involves uncontrolled cell division: **hyperplasia** (too many cells) and/or **anaplasia** (abnormal, undifferentiated cells). Thus the mechanism of all cancers is a mistake or problem in cell division. What we are uncertain of is the cause of the abnormal cell division. Currently, several factors are known to play a role.

Genetic Factors

Many forms of cancer are known to be inherited directly, perhaps involving abnormal "cancer genes" called **oncogenes.** Another type of gene, called a **tumor suppressor gene,** may fail to operate and thus allow cancer to develop. Exactly how these genes work is still being investigated. For example, a gene called *p53* springs into action at the first sign of cancer and initiates a chain reaction that causes the cell's death—before it can develop into full-blown cancer.

Presumably, many cancers involve a genetic predisposition (risk factor) coupled with other cancer-causing mechanisms. Cancers with known genetic risk factors include basal cell carcinoma (a type of skin cancer), breast cancer, and neuroblastoma (a cancer of nerve tissue).

Carcinogens

Carcinogens (cancer makers) are agents that affect genetic activity in some way and cause abnormal cell reproduction. Some carcinogens are **mutagens** (mutation makers) that cause changes or mutations in a cell's DNA structure. Although many industrial products are known to be carcinogens, various natural mineral, vegetable, and animal materials are also carcinogenic. Exposure to damaging types of radiation or other physical injuries can be carcinogenic. For example, sunburns or chronic exposure to sunlight can cause skin cancer. Even viruses have been known to cause cancer, perhaps by altering the genetic code of cells during an infection or by damaging the body's ability to suppress cancer. Papilloma (wart) viruses have been blamed for many cases of cervical cancer in women.

Age

Certain cancers are found primarily in young people (e.g., leukemia) and others primarily in older adults (e.g., colon cancer). The age factor may result from changes in the genetic activity of cells over time or from the accumulated effects of cell damage.

Detection and Treatment of Cancer

Signs of cancer are those one would expect of a malignant neoplasm: the appearance of abnormal, rapidly growing tissue. Cancer specialists, or *oncologists*, have stressed that early detection of cancer is important because it is in the early stages of development of primary tumors, before metastasis and the development of secondary tumors have begun, that cancer is most treatable. Some methods currently used to detect the presence of cancer include the following:

Self-examination for the early signs of cancer previously described is one method for detection of cancer. For example, women are encouraged to perform a monthly breast self-examination. Likewise, males are encouraged to perform a monthly testicular self-examination. If an abnormality is found, it can be further investigated with one of the following described methods.

Medical imaging techniques that visualize deep tissues for medical study are often used to detect cancers. Radiography (x-ray photography) often is used to detect the presence of tumors. *Mammography*, x-ray photography of a breast, is considered an important detection tool for this type of cancer. *Computed tomography (CT)* (x-ray scanning), *magnetic resonance imaging (MRI)* (electromagnetic scanning), and *ultrasonography* (ultrasound scanning) produce cross-sectional images of body regions suspected of having tumors.

| A&P CONNECT |

Check out ***Medical Imaging of the Body*** online at ***A&P Connect*** to see diagrams of medical imaging technology and examples of the images produced by them.

Blood tests to determine the concentration of ions, enzymes, or other blood components are useful in detecting cancer when the results show abnormalities associated with particular forms of cancer. Cancer cells may also produce or trigger the production of substances often referred to as *tumor markers*. For example, tests for a prostate cancer marker are now being used in conjunction with other diagnostic tests.

Biopsy is the removal and examination of living tissue. Microscopic examination of tumor tissue removed surgically or through a needle sometimes reveals whether it is malignant or benign.

The information gained from these techniques can be used to *stage* and *grade* malignant tumors. Staging involves classifying a tumor based on its size and the extent of its spread. Grading is an

assessment of what the tumor is likely to do based on the degree of abnormality of the cells—a useful basis for making a prognosis (statement of probable outcome).

Without treatment, cancer usually results in death. The progress of a particular type of cancer depends on the type of cancer and its location. Many cancer patients suffer from *cachexia*, a syndrome involving loss of appetite, weight loss, and general weakness. Various anatomical or functional abnormalities may arise as a result of damage to particular organs. The ultimate causes of death in cancer patients include secondary infection by pathogenic microorganisms, organ failure, hemorrhage (blood loss), and in some cases, undetermined factors.

Of course, once cancer has been identified, every effort is made to treat it and thus prevent or delay its development. Surgical removal of cancerous tumors is sometimes performed, but the probability that malignant cells have been left behind must be addressed. **Chemotherapy,** or "chemical therapy" with *cytotoxic* (cell-killing) compounds or antineoplastic drugs, can be used after surgery to destroy any remaining malignant cells. **Radiation therapy,** also called *radiotherapy*, involves the use of destructive x-ray or gamma radiation alone or with chemotherapy to destroy any remaining cancer cells. **Laser therapy,** in which an intense beam of light destroys a tumor, is also sometimes coupled with chemotherapy or radiation therapy. **Immunotherapy,** a newer type of cancer treatment, bolsters the body's own defenses against cancer cells. Because viruses cause some types of cancer, oncologists hope that vaccines against certain forms of cancer will greatly reduce cancer risk.

Perhaps the most promising research area in the battle against cancer is *molecular oncology*. This rapidly growing medical specialty attempts to use advances in molecular biology and genetics to develop so-called *rational drugs* that unlike conventional chemotherapy agents, target only those specific molecules, enzymes, receptors, or other features unique to cancer cells or tumor growth. Ideally, such treatments would affect only the cancer and spare normal cells and body functions, thus increasing efficiency and reducing side effects. Three of the most promising new classes of "rational" drugs used to treat various types of cancer include the following:

Monoclonal antibodies, for example, trastuzumab (Herceptin) for breast cancer and cetuximab (Erbitux) for colorectal cancer

Antiangiogenesis (anti–blood vessel formation) *agents*, for example, vascular endothelial growth factor (VEGF) for various solid tumors

Tyrosine kinase inhibitors (enzyme inhibitors), for example, imatinib mesylate (Gleevec) for chronic myeloid leukemia

Some oncologists believe that future advances in rational drug design could mean for cancer what antibiotics meant for infectious diseases.

CASE study

Nathan had been mountain biking for about 2 hours, winding his way up and down the familiar trails with a devil-may-care attitude. Pedaling at a break-neck speed, he swerved around a fallen branch as he headed down the last steep incline, and suddenly he lost control and went flying off his bike. After rolling over a couple of times, he stopped hard, jamming his right foot against a boulder. His friends helped him limp the rest of the way down the hill and back to their car; then they drove him to the urgent care center (which was almost as familiar to Nathan as the trails).

The physician's assistant ordered an x-ray film of Nathan's leg to confirm no break in the bones. She came back soon with the results and told Nathan that there was no break, just "soft tissue damage" (i.e., a sprained ankle). By "soft tissue," she meant the tendons and ligaments that hold all of the bones of the foot and ankle together.

1. What specific tissue type did Nathan injure?
   a. Dense irregular connective tissue
   b. Skeletal muscle
   c. Dense regular connective tissue
   d. Reticular connective tissue

The bones in Nathan's ankle and foot are connected by joints (discussed in Chapter 10).

2. The tips of these bones are covered with what type of tissue?
   a. Fibrocartilage
   b. Transitional epithelium
   c. Stratified cuboidal epithelium
   d. Hyaline cartilage

In addition to spraining his ankle, Nathan cut his arm in the fall. He had a deep gash that required five stitches to close.

3. What type of membrane did the stitches go through?
   a. Cutaneous
   b. Serous
   c. Mucous
   d. Epidermal

4. In the membrane through which the stitches passed, which layer connects the epithelial layer to the connective tissue layer?
   a. Membrane glue
   b. Basement membrane
   c. Intercellular membrane
   d. Epithelial-connective lamina

HINT *To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook,* ***A&P Connect,*** *and other resources.*

CAREER choices

Jean A. Proehl, RN, MN, CEN, CCRN

Emergency Clinical Nurse Specialist

As an emergency clinical nurse specialist at Dartmouth Hitchcock Medical Center in Lebanon, New Hampshire, my responsibilities involve the nursing care delivered to emergency patients. I teach classes, orient new nurses, evaluate supplies and equipment, troubleshoot patient care problems, set up systems to enhance care delivery, and help take care of patients.

I've wanted to be a nurse since I was 4 or 5 years old. I was drawn to the emergency care setting because I like action and variety. We see it all, cradle to grave, benign to life threatening. I've delivered babies in the parking lot; I've reassured parents that their child's "blue" hands are related to a new pair of jeans. I've seen teenagers with "lesions" that turned out to be pimples; I've held the hands of the dying as I administered blood to try to save their lives.

Change is a current trend in my field; new medications, new equipment, and new therapies are constantly being introduced. The reassuring thing about change in the twenty-first century is that it is more likely to be evidence based than in the past. In other words, we have scientific data to support doing things differently. We're questioning things we've always done and evaluating them in terms of their impact on the patient's outcome.

When I'm taking care of patients, the rewards are obvious: relief of pain and suffering (physical and emotional), saving lives, and helping people return to an optimum state of health. When I'm teaching other nurses, the reward is in promoting improved knowledge and skills so that the professional practice of the nurse is enhanced and the care that she or he delivers to patients is improved.

I use anatomy specifically for accurate and concise descriptions of my physical examination findings. Physiology is interwoven into the patient's overall care. In assessment, I relate the signs, symptoms, and laboratory results to potential underlying physiological causes. When implementing interventions such as medication administration or positioning, I must consider their intended effect on the patient and potential adverse affects. To evaluate the effectiveness of interventions, I rely on my understanding of physiology to gauge outcome. For example, if I am giving intravenous fluid to a patient in shock, I know that the glomerular filtration rate reflects perfusion to vital organs, so urine output is a valuable parameter to monitor.

One professor I had always emphasized that nurses needed to know anatomy because some day we might be the only one available who could identify something. I found an anatomy coloring book to be a great study aid. Mnemonics were also a lifesaver; I still recite "On Old Olympus' Tiny Tops A Friendly Viking Grew Vines And Hops" when naming cranial nerves.

INTRODUCTION

A. Tissue—group of similar cells that perform a common function
B. Matrix—nonliving intercellular material

PRINCIPAL TYPES OF TISSUE (TABLE 6-1)

A. Epithelial tissue
B. Connective tissue
C. Muscle tissue
D. Nervous tissue
E. Embryonic development of tissues
   1. Primary germ layers
      a. Endoderm
      b. Mesoderm
      c. Ectoderm
   2. Histogenesis—the process of the primary germ layers differentiating into different kinds of tissue

EXTRACELLULAR MATRIX (ECM)

A. Complex, nonliving material between cells in a tissue (Figure 6-1)
   1. Some tissues have a large amount of ECM; other tissues have hardly any ECM
   2. Different kinds of components give ECM in different tissues a variety of characteristics
B. Components (Table 6-2)
   1. Water
   2. Proteins
      a. Structural proteins
         (1) Collagen—strong, flexible protein fiber
         (2) Elastin—elastic fibers
      b. Includes glycoproteins—proteins with a few carbohydrate attachments
         (1) Fibronectin and laminin help connect the ECM components to cells by binding with integrins in plasma membranes
         (2) Glycoprotein attachments also allow local communication within a tissue

3. Proteoglycans
   a. Defined as hybrid molecules that are mostly carbohydrates attached to a protein backbone
   b. Examples: chondroitin sulfate, heparin, and hyaluronate
   c. Different proteoglycans give different characteristics to ECM, such as thickness, shock absorption (Table 6-2)

C. Functions
1. Help bind tissues together structurally
   a. ECM components bind to each other and to integrins in plasma membranes of cells
   b. In some tissues, it is primarily intercellular junctions that hold cells together
2. Allow local communication among ECM and various cells—through connection via integrins in plasma membranes

EPITHELIAL TISSUE

A. Types and locations
1. Epithelium is divided into two types:
   a. Membranous (covering or lining) epithelium
   b. Glandular epithelium
2. Locations
   a. Membranous epithelium—covers the body and some of its parts; lines the serous cavities, blood and lymphatic vessels, and respiratory, digestive, and genitourinary tracts
   b. Glandular epithelium—secretory units of endocrine and exocrine glands

B. Functions
1. Protection
2. Sensory functions
3. Secretion
4. Absorption
5. Excretion

C. Generalizations about epithelial tissue
1. Limited amount of matrix material
2. Membranous type attached to a basement membrane
3. Avascular
4. Cells are in close proximity, with many desmosomes and tight junctions
5. Capable of reproduction

D. Classification of epithelial tissue
1. Membranous (covering or lining) epithelium (Table 6-3)
   a. Classification based on cell shape (Figure 6-2)
      (1) Squamous
      (2) Cuboidal
      (3) Columnar
      (4) Pseudostratified columnar
   b. Classifications based on layers of cells (Table 6-4)
      (1) Simple epithelium
         (a) Simple squamous epithelium (Figures 6-3 and 6-4)
            (i) One-cell layer of flat cells
            (ii) Permeable to many substances
            (iii) Examples: endothelium—lines blood vessels; mesothelium—pleura
         (b) Simple cuboidal epithelium (Figure 6-5)
            (i) One-cell layer of cuboidal-shaped cells
            (ii) Found in many glands and ducts
         (c) Simple columnar epithelium (Figure 6-6)
            (i) Single layer of tall, column-shaped cells
            (ii) Cells often modified for certain functions such as goblet cells (secretion), cilia (movement), microvilli (absorption)
            (iii) Often lines hollow visceral structures
         (d) Pseudostratified columnar epithelium (Figure 6-7)
            (i) Columnar cells of differing heights
            (ii) All cells rest on basement membrane but may not reach the free surface above
            (iii) Cell nuclei at odd and irregular levels
            (iv) Line the air passages and segments of male reproductive system
            (v) Motile cilia and mucus are important modifications
      (2) Stratified epithelium
         (a) Keratinized stratified squamous epithelium
            (i) Multiple layers of flat, squamous cells (Figure 6-8)
            (ii) Cells filled with keratin
            (iii) Covering outer skin on body surface
         (b) Nonkeratinized stratified squamous epithelium (Figure 6-9)
            (i) Line the vagina, mouth, and esophagus
            (ii) Free surface is moist
            (iii) Primary function is protection
         (c) Stratified cuboidal epithelium
            (i) Two or more rows of cells are typical
            (ii) Basement membrane is indistinct
            (iii) Located in sweat gland ducts and pharynx
         (d) Stratified columnar epithelium
            (i) Multiple layers of columnar cells
            (ii) Only most superficial cells are typical in shape
            (iii) Rare
            (iv) Located in segments of male urethra and near anus
         (e) Transitional epithelium (Figure 6-10)
            (i) Located in lining of hollow viscera subjected to stress (e.g., urinary bladder)
            (ii) Stratified—often 10 or more layers thick
            (iii) Protects organ walls from tearing
2. Glandular epithelium
   a. Specialized for secretory activity
   b. Exocrine glands—discharge secretions into ducts
   c. Endocrine glands—"ductless" glands; discharge secretions directly into blood or interstitial fluid
   d. Structural classification of exocrine glands (Figure 6-11; Table 6-5)
      (1) Multicellular exocrine glands are classified by the shape of their ducts and the complexity of their duct system
      (2) Shapes include tubular and alveolar

(3) Simple exocrine glands—only one duct leads to the surface
(4) Compound exocrine glands—have two or more ducts
e. Functional classification of exocrine glands (Figure 6-12)
(1) Apocrine glands
(a) Secretory products collect near apex of cell and are secreted by pinching off the distended end
(b) Secretion process results in some damage to cell's plasma membrane and some loss of cytoplasm
(c) Mammary glands are good examples of this secretory type
(2) Holocrine glands
(a) Secretion products, when released, cause rupture and death of the cell
(b) Sebaceous glands are holocrine
(3) Merocrine glands
(a) Secrete directly through cell membrane
(b) Secretion proceeds with no damage to plasma membrane and no loss of cytoplasm
(c) Most numerous gland type

CONNECTIVE TISSUE

A. Functions, characteristics, and types
1. General function—connects, supports, transports, and protects
2. General structure
a. Extracellular matrix (ECM) predominates in most connective tissues and determines its physical characteristics; consists of fluid, gel, or solid matrix, with or without extracellular fibers (collagenous, reticular, and elastic) and proteoglycans or other compounds that thicken and hold together the tissue (Figures 6-1 and 6-15)
b. Collagenous fibers—twisted ropes that form strong, flexible bundles in many connective tissues (Figure 6-13)
c. Elastic fibers—stretchy fibers made of elastin that impart the ability to recoil in some connective tissues (Figure 6-14)
3. Four main types (Table 6-6)
a. Fibrous (connective tissue proper)
(1) Loose fibrous (areolar)
(2) Adipose
(3) Reticular
(4) Dense
(a) Irregular
(b) Regular (collagenous and elastic)
b. Bone
(1) Compact bone
(2) Cancellous bone
c. Cartilage
(1) Hyaline
(2) Fibrocartilage
(3) Elastic
d. Blood

B. Fibrous connective tissue
1. Loose fibrous (areolar) connective tissue (Figure 6-15)
a. One of the most widely distributed of all tissues
b. Intercellular substance is prominent and consists of collagenous and elastic fibers loosely interwoven and embedded in soft viscous ground substance
c. Several kinds of cells present, notably, fibroblasts and macrophages, also mast cells, plasma cells, fat cells, and some white blood cells (Figure 6-16)
d. Function—stretchy, flexible connection
2. Adipose tissue (Figures 6-17 and 6-18)
a. Similar to loose fibrous connective tissue but contains mainly fat cells
b. Functions
(1) Acts as food (energy) reserve, support, protection, insulation (white fat), and heat generation (brown fat)
(2) Produces the hormone leptin, which signals the brain how much fat is stored
3. Reticular tissue (Figure 6-19)
a. Forms framework of spleen, lymph nodes, and bone marrow
b. Consists of network of branching reticular fibers with reticular cells overlying them
c. Functions—defense against microorganisms and other injurious substances; reticular meshwork filters out injurious particles and reticular cells phagocytose them
4. Dense fibrous tissue
a. Matrix consists mainly of fibers packed densely and relatively few fibroblast cells
(1) Irregular—fibers intertwine irregularly to form a thick mat (Figure 6-20)
(2) Regular—bundles of fibers are arranged in regular parallel rows
(a) Collagenous—mostly collagenous fibers in ECM (Figures 6-21 and 6-22)
(b) Elastic—mostly elastic fibers in ECM (Figure 6-23)
b. Locations—composes structures that need great tensile strength, such as tendons and ligaments; also dermis and the outer capsule of the kidney and spleen
c. Function—furnishes flexible connections that are strong or stretchy

C. Bone tissue
1. Uniquely hard and strong connective tissue type
a. Cells—osteocytes—embedded in a calcified matrix
b. Inorganic component of matrix accounts for 65% of total bone tissue
2. Functions
a. Support
b. Protection
c. Point of attachment for muscles
d. Reservoir for minerals

e. Supports blood-forming tissue
3. Compact bone (Figures 6-25 and 6-26)
a. Osteon (Haversian system)
(1) Structural unity of bone
(2) Spaces for osteocytes called *lacunae*
(3) Matrix present in concentric rings called *lamellae*
(4) Canaliculi are canals that join lacunae with the central Haversian canal
b. Cell types
(1) Osteocyte—mature, inactive bone cell
(2) Osteoblast—active bone-forming cell
(3) Osteoclast—bone-destroying cell
c. Formation (ossification) (Figure 6-24)
(1) In membranes—e.g., flat bones of skull
(2) From cartilage (endochondral)—e.g., long bones, such as the humerus
4. Cancellous bone (Figures 6-25 and 6-27)
a. Trabeculae—thin beams of bone
b. Supports red bone marrow
(1) Myeloid tissue—a type of reticular tissue
(2) Produces blood cells
c. Called spongy bone because of its spongelike appearance

D. Cartilage
1. Chondrocyte is the only cell type present
2. Lacunae house cells as in bone
3. Avascular—therefore nutrition of cells depends on diffusion of nutrients through matrix
4. Heals slowly after injury because of slow nutrient transfer to cells
5. Perichondrium is membrane that surrounds cartilage
6. Types
a. Hyaline (Figure 6-28)
(1) Appearance is shiny and translucent
(2) Most prevalent type of cartilage
(3) Located on ends of articulating bones
b. Fibrocartilage (Figure 6-29)
(1) Strongest and most durable type of cartilage
(2) Matrix is semirigid and filled with strong white fibers
(3) Found in intervertebral disks and pubic symphysis
(4) Serves as shock-absorbing material between bones at the knee (menisci)
c. Elastic (Figure 6-30)
(1) Contains many fine elastic fibers
(2) Provides strength and flexibility
(3) Located in external ear and larynx

E. Blood
1. A liquid tissue (Figure 6-31)
2. Contains neither ground substance nor fibers
3. Composition of whole blood
a. Liquid fraction (plasma) is the matrix—55% of total blood volume
b. Formed elements contribute 45% of total blood volume
(1) Red blood cells, erythrocytes
(2) White blood cells, leukocytes
(3) Platelets, thrombocytes
4. Functions
a. Transportation
b. Regulation of body temperature
c. Regulation of body pH
d. White blood cells destroy bacteria
5. Circulating blood tissue is formed in the red bone marrow by a process called *hematopoiesis*; the blood-forming tissue is sometimes called *hematopoietic tissue*

MUSCLE TISSUE

A. Types (Table 6-7)
1. Skeletal, or striated voluntary (Figure 6-32)
2. Smooth, or nonstriated involuntary, or visceral (Figures 6-33 and 6-34)
3. Cardiac, or striated involuntary (Figure 6-35)

B. Microscopic characteristics
1. Skeletal muscle—threadlike cells with many cross striations and many nuclei per cell
2. Smooth muscle—elongated narrow cells, no cross striations, one nucleus per cell
3. Cardiac muscle—branching cells with intercalated disks (formed by abutment of plasma membranes of two cells)

NERVOUS TISSUE

A. Functions—rapid regulation and integration of body activities

B. Special characteristics
1. Excitability
2. Conductivity

C. Organs
1. Brain
2. Spinal cord
3. Nerves

D. Cell types (Table 6-7)
1. Neuron—conducting unit of system (Figure 6-36)
a. Cell body, or soma
b. Processes
(1) Axon (single process)—transmits nerve impulse away from the cell body
(2) Dendrite (one or more)—transmits nerve impulse toward the cell body and axon
2. Neuroglia—special connecting, supporting, coordinating cells that surround neurons

TISSUE REPAIR

A. Tissues have a varying capacity to repair themselves; damaged tissue regenerates or is replaced by scar tissue

B. Regeneration—growth of new tissue (Figure 6-37)

C. Scar—dense fibrous mass; unusually thick scar is a keloid (Figure 6-38)

D. Epithelial and connective tissues have the greatest ability to regenerate

E. Muscle and nervous tissues have limited capacity to regenerate

BODY MEMBRANES

A. Thin tissue layers that cover surfaces, line cavities, and divide spaces or organs (Figure 6-39, Table 6-8)
B. Epithelial membranes are most common type (Figure 6-40)
   1. Cutaneous membrane (skin)
      a. Primary organ of integumentary system
      b. One of the most important organs
      c. Composes approximately 16% of body weight
   2. Serous membrane (serosa)
   a. Parietal membranes—line closed body cavities
   b. Visceral membranes—cover visceral organs
   c. Pleura—surrounds a lung and lines the thoracic cavity
   d. Peritoneum—covers the abdominal viscera and lines the abdominal cavity
   3. Mucous membrane (mucosa)
      a. Lines and protects organs that open to the exterior of the body
      b. Found lining ducts and passageways of the respiratory, digestive, and other tracts
      c. Lamina propria—fibrous connective tissue underlying mucous epithelium
      d. Mucus is made up mostly of water and mucins—proteoglycans that form a double-layer protection against environmental microbes (Figure 6-41)
C. Connective tissue membranes
   1. Do not contain epithelial components
   2. Synovial membranes—line the spaces between bone in joints
   3. Have smooth and slick membranes that secrete synovial fluid
   4. Help reduce friction between opposing surfaces in a movable joint
   5. Synovial membranes also line bursae

THE BIG PICTURE: TISSUES, MEMBRANES, AND THE WHOLE BODY

A. Tissues and membranes maintain homeostasis
   1. Epithelial tissues
      a. Form membranes that contain and protect the internal fluid environment
      b. Absorb nutrients
      c. Secrete products that regulate functions involved in homeostasis
   2. Connective tissues
      a. Hold organs and systems together
      b. Form structures that support the body and permit movement
   3. Muscle tissues
      a. Work with connective tissues to permit movement
   4. Nervous tissues
      a. Work with glandular epithelial tissue to regulate body function

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the term *tissue* and identify the four principal tissue types.
2. What is the function of the primary germ layers? Name them.
3. What are the five most important functions of epithelial tissue?
4. Which of the following best describes the number of blood vessels in epithelial tissue: none, very few, very numerous?
5. Explain how the shape of epithelial cells is used for classification purposes. Identify the four types of epithelium described in this classification process.
6. Classify epithelium according to the layers of cells present.
7. List the types of simple and stratified epithelium and give examples of each.
8. What is glandular epithelium? Give examples.
9. Discuss the structural classification of exocrine glands. Give examples of each type.
10. Describe loose fibrous connective tissue.
11. How do the types of dense fibrous connective tissue differ from one another?
12. Discuss and compare the microscopic anatomy of bone and cartilage tissue.
13. Compare the structure of the three major types of cartilage tissue. Locate and give an example of each type.
14. List the components of whole blood and discuss the basic function of each fraction or cell type.
15. List the three major types of muscle tissue.
16. Identify the two basic types of cells in nervous tissue.
17. What are the four cardinal signs of inflammation? What causes each?
18. Describe the regenerative capacity of muscle and nerve tissues.
19. Name the two major categories or types of body membranes. Give examples of each.
20. What is a neoplasm?

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

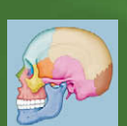
1. A baby was born with congenital problems in the skeleton and muscle systems. From what primary germ layers do these systems arise? What is the earliest possible developmental stage during which a problem could have affected just one primary germ layer? (Hint: Use ***A&P Connect.***)

2. Summarize the structural characteristics of epithelial tissues that enable them to perform their specific functions.
3. Does the production of saliva, milk, or oil cause the most damage to the cell that produces it? Explain.
4. Describe the role of the fiber types in the classification of connective tissue. What examples can you find of these various types?
5. Based on your knowledge of tissues, explain how sufficient dietary intake of calcium could ensure the normal development of bone.
6. Many athletes work to reduce their body fat to the lowest possible percentage. What would happen if too little body fat were present?
7. If a tendon is badly damaged, it may need to be replaced surgically. Based on what you know about the structural and functional differences, explain why a tendon rather than a ligament must replace it.
8. Develop a flowchart or other diagram to describe the process by which tissues respond to injury.
9. If a small, but deep cut involving skin and muscle occurs, predict which tissue will probably heal first and which will heal more completely. Explain your answer.
10. When a joint swells, sometimes it is necessary to remove a thick colorless liquid from the joint. What is it, where did it come from, and what is its normal function?

Unit Two

Support and Movement

The six chapters in Unit Two describe the outer covering of the body, as well as the bones, muscles, and articulations, or joints, of the body. The skin (and its appendages) is selected in Chapter 7 as the first organ system to be studied. Chapter 8—Skeletal Tissues—provides information on the types of skeletal tissues and how they are formed, grown, and repaired if injured and how they function. Skeletal tissues protect and support body structures and function as storage sites for important mineral elements vital to many body functions. Blood cell formation also occurs within the red marrow of bones.



The organs of the skeletal system, bones, are described and organized into major subdivisions in Chapter 9. Movement between bones occurs at joints, or articulations, which are classified in Chapter 10 according to both structure and potential for movement.

Anatomy of the major muscle groups and the basic concepts of muscle physiology are discussed in Chapters 11 and 12. The microscopic and molecular structure of muscle cells and tissues is related to function, as is the gross structure of individual muscles and muscle groups. Movement and heat production constitute the two most important functions of muscle. Discussion of muscle groups in Chapter 11 focuses on how muscles function and on how they attach to bones, how they are named, and how they are integrated functionally with other body organ systems.

Case Study, 195

Vital, diverse, complex, extensive—these adjectives describe the body's largest, thinnest, and one of its most important organs, the skin. It forms a self-repairing and protective boundary between the internal environment of the body and an often hostile external world.

The skin surface is as large as the body, an area in average-sized adults of roughly 1.6 to 1.9 m^2 (17 to 20 square feet). Its thickness varies from slightly less than 0.05 cm (1/50 inch) to slightly more than 0.3 cm (1/8 inch).

As you know, the body is characterized by a "nested," or hierarchical, type of organization. Complexity progresses from cells to tissues and then to organs and organ systems. This chapter discusses the skin and its appendages—hair, nails, and skin glands—as an organ system. Ideally, by studying the skin and its appendages before you proceed to the more complex organ systems in the chapters that follow, you will improve your understanding of how structure is related to function. Integument *is another name for the skin.* Integumentary system *is a term used to denote the skin and its appendages.*

STRUCTURE OF THE SKIN

The skin is a thin, relatively flat organ classified as a membrane—the **cutaneous membrane.** As Figure 7-1 shows, two primary layers compose the skin:

1. Epidermis—superficial, thinner layer
2. Dermis—the deep, thicker layer

| A&P CONNECT |

To briefly review the primary germ layers check out ***Embryonic Development of Tissues*** online at ***A&P Connect.***

evolve

The **epidermis** is an epithelial layer derived from the ectodermal germ layer of the embryo. By the seventeenth week of gestation, the epidermis of the developing baby has all the essential characteristics of the adult. The deeper dermis is derived from the mesoderm.

The **dermis** is a relatively dense and vascular connective tissue layer that may average more than 4 mm in thickness in some body areas. The area where the cells of the epidermis meet the connective tissue cells of the dermis is called the **dermoepidermal**

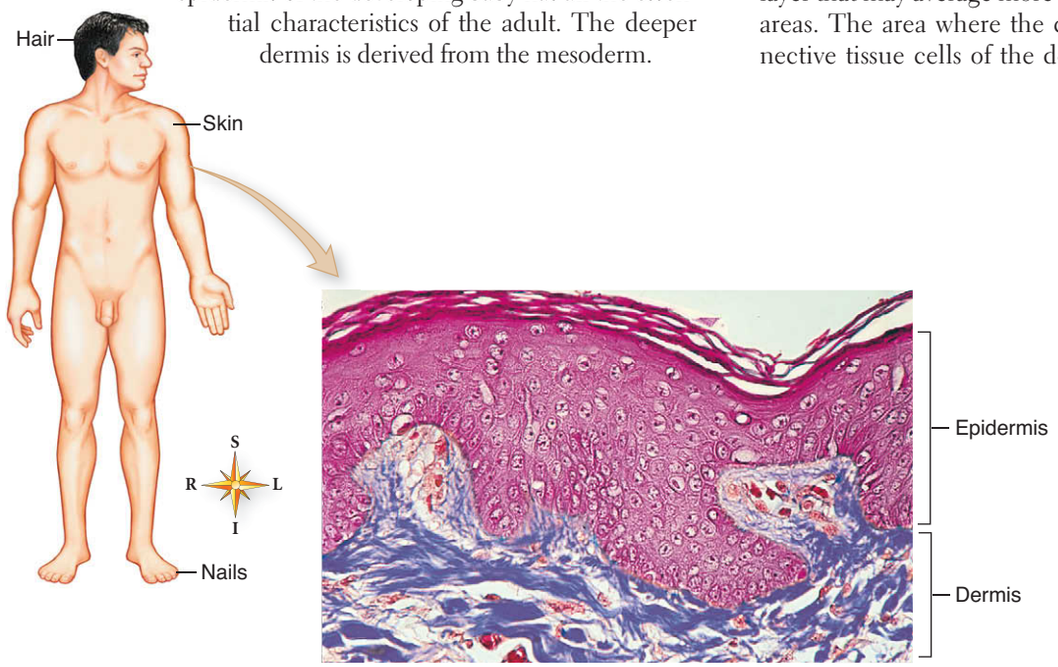

FIGURE 7-1

Photomicrograph of the skin. The staining of this cross section of skin clearly shows the red superficial epidermis and the bluish dermis below it. This photograph has been cropped; the dermis is actually quite thick in comparison to the epidermis.

junction (DEJ) (Figure 7-2). Beneath the dermis lies a loose **hypodermis** rich in fat and loose fibrous connective tissue.

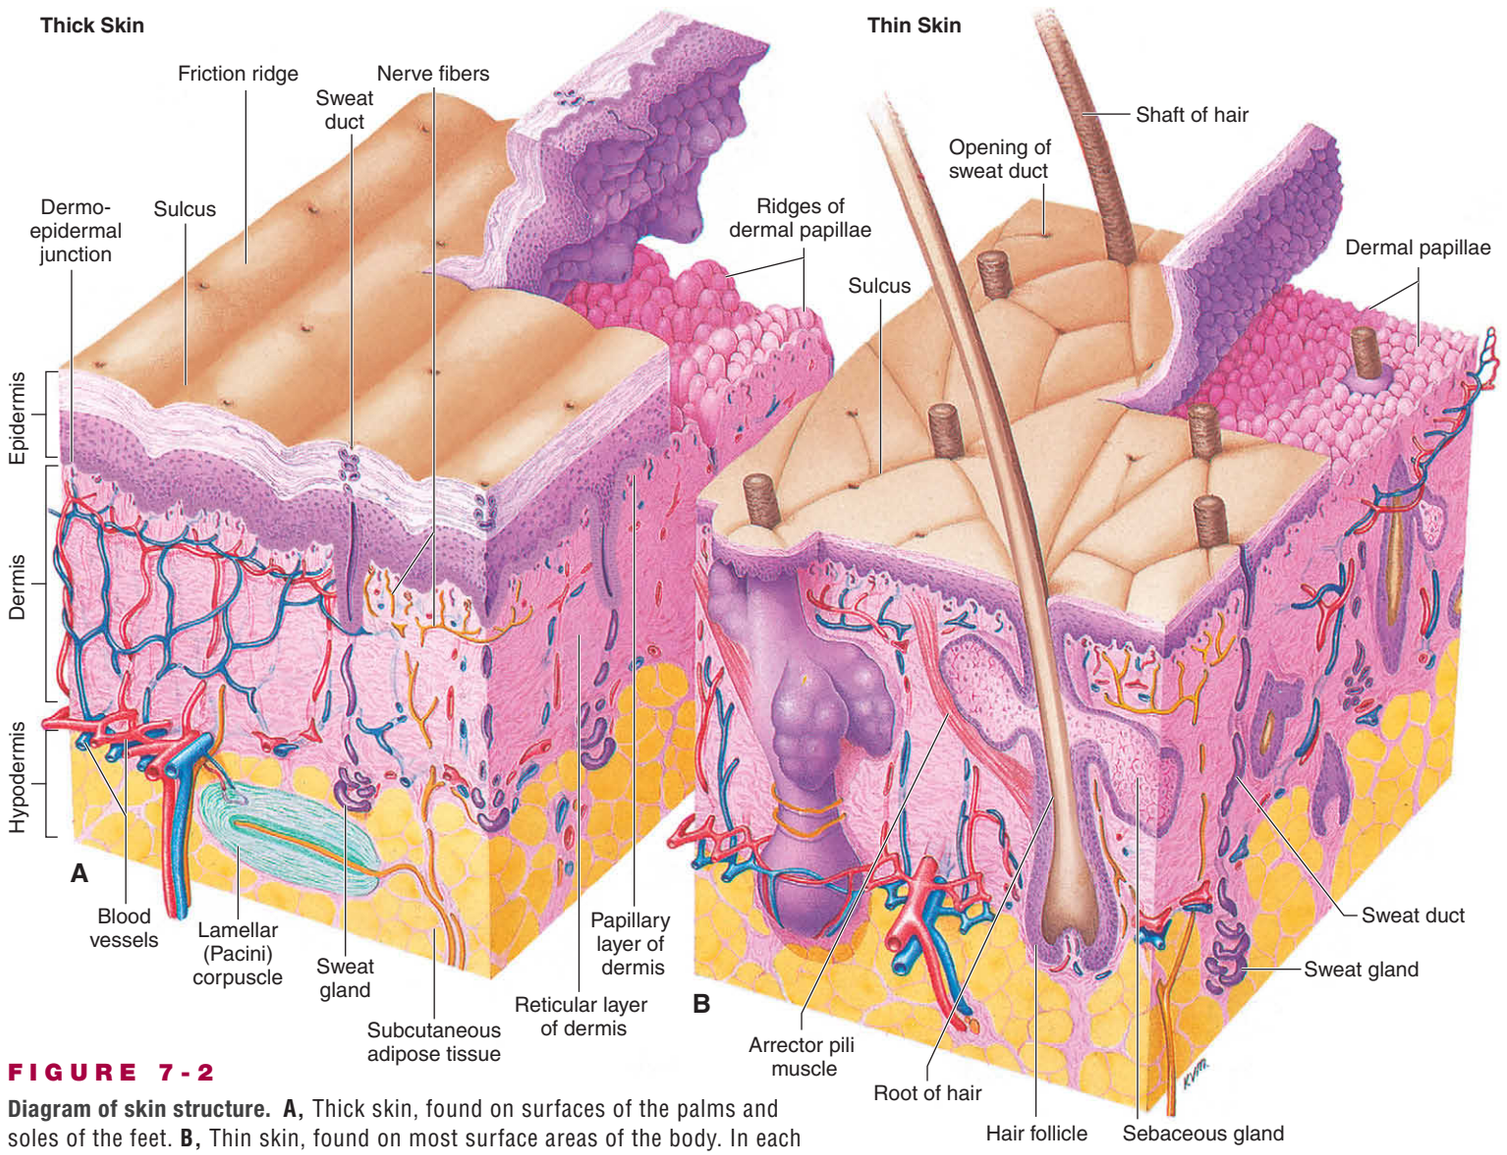
Thin and Thick Skin

Most of the body surface is covered by skin that is classified as *thin skin*. The hairless skin covering the palms of the hands (and fingertips), soles of the feet, and other body areas subject to friction is classified as *thick skin*. These terms refer only to the epidermal layer and not to overall or total skin thickness, which includes the epidermis and dermis. Total skin thickness varies from 0.5 mm in areas such as the eyelids to more than 5 mm over the back, with most of the difference accounted for by variation in depth of the dermis.

In thick skin, each of the five strata, or layers, of the epidermis described below are present, and each stratum is generally several cell layers thick. The outermost stratum—the stratum corneum—is especially noticeable in thick skin and is generally composed of many cell layers. Hair is not found in thick skin.

Furthermore, in thick skin the underlying dermal papillae are raised in curving parallel *epidermal ridges*—or **friction ridges**—to form fingerprints or footprints that are visible on the overlying epidermis. As their name implies, friction ridges increase friction—similar to the function of the ridges of tire treads. These ridges help us pick up and manipulate small objects with the hands and provide slip resistance to the soles of the feet. The epidermal ridges also act as sensory organs, amplifying vibrations as we lightly swipe across a textured surface. The surface of thick skin is seen in Figure 7-3, A.

In thin skin, the number of cell layers in each epidermal stratum is less than in thick skin, and one or more strata may be absent entirely. Raised parallel ridges are not present in the dermis of thin skin (Figure 7-3, B). Instead, the dermal papillae project upward individually and therefore no "fingerprints" are formed on the more superficial epidermis above.



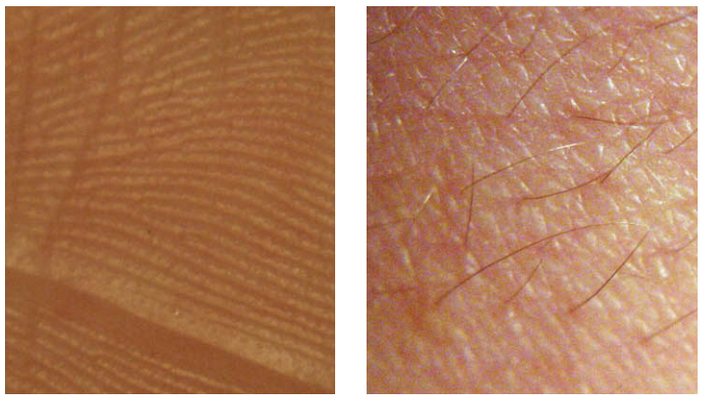


FIGURE 7-2

Diagram of skin structure. A, Thick skin, found on surfaces of the palms and soles of the feet. **B,** Thin skin, found on most surface areas of the body. In each diagram, the epidermis is raised at one corner to reveal the papillae of the dermis.

FIGURE 7-3

Thick and thin skin. A, The surface of thick skin is hairless and features regular, deep sulci and friction ridges, which form the "prints" of the palmar and plantar surfaces of the hands and feet. **B,** The surface of thin skin features irregular sulci (grooves) and hairs.

Box 7-1 | HEALTH matters

Vitiligo

An acquired condition called **vitiligo** results in loss of pigment in certain areas of the skin. The patches of depigmented white skin that characterize this condition contain melanocytes, but for unknown reasons they no longer produce pigment.

Epidermis

CELL TYPES

The epidermis is composed of several types of epithelial cells (Figure 7-4).

Keratinocytes eventually become filled with a tough, fibrous protein called **keratin.** These cells, arranged in distinct *strata*, or layers, are by far the most important cells in the epidermis. They make up more than 90% of the epidermal cells and form the principal structural element of the outer skin. After they are dead and fully keratinized, the flattened keratinocytes are sometimes called *corneocytes.*

Melanocytes contribute colored pigments to the skin and serve to decrease the amount of ultraviolet (UV) light that can penetrate into the deeper layers of the skin. Although they often compose more than 5% of the epidermal cells, melanocytes may also be completely absent from the skin in certain nonlethal conditions (Box 7-1).

Epidermal **dendritic cells (DCs)** of the skin, also called *Langerhans cells*, are branched cells that play a role in immunity. As a type of *antigen-presenting cell (APC)*, each dendritic cell finds markers (antigens) on bacteria and other invaders and presents them to other immune system cells for recognition and destruction—an important defensive function. These cells originate in the bone marrow but migrate to the deep cell layers of the epidermis early in life. Dendritic cells and other APCs are discussed further in Chapter 24.

Tactile epithelial cells, also called *Merkel cells*, are located in the deepest layer of the epidermis. As Figure 7-4 shows, they connect to sensory nerve endings to form structures that serve as light touch receptors.

CELL LAYERS

The cells of the epidermis are found in up to five distinct layers, or **strata.** Each stratum (meaning "layer") is named for its structural

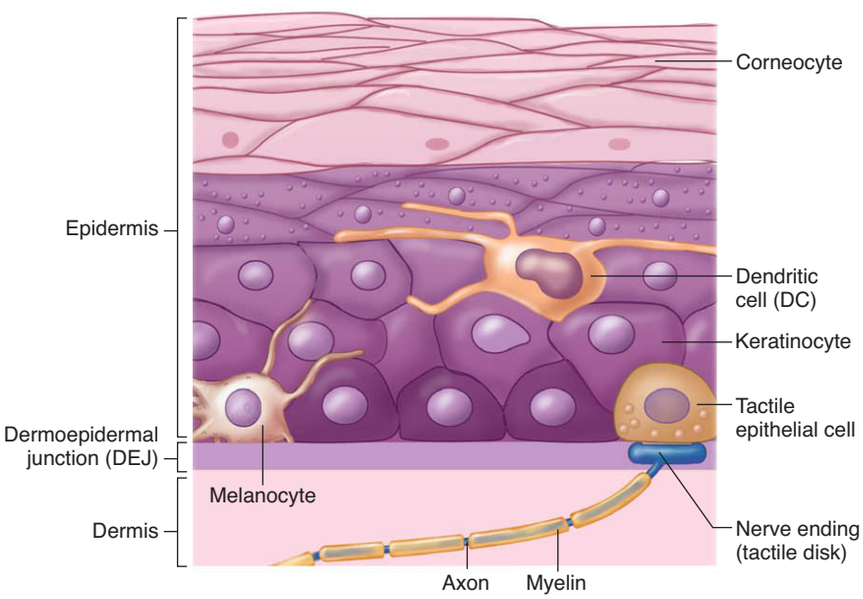

FIGURE 7-4

Epidermal cell types. Keratinocytes, most of the cells seen here, begin their life in the deepest layer of the epidermis and are pushed upward as more keratinocytes are formed. Melanocytes produce pigments. Epidermal dendritic cells *(DCs)* have a function in immunity. Tactile epithelial cells (Merkel cells) attach to sensory nerve endings to form "light touch" receptors.

or functional characteristics. The strata of the epidermis are listed here in order from deepest to most superficial.

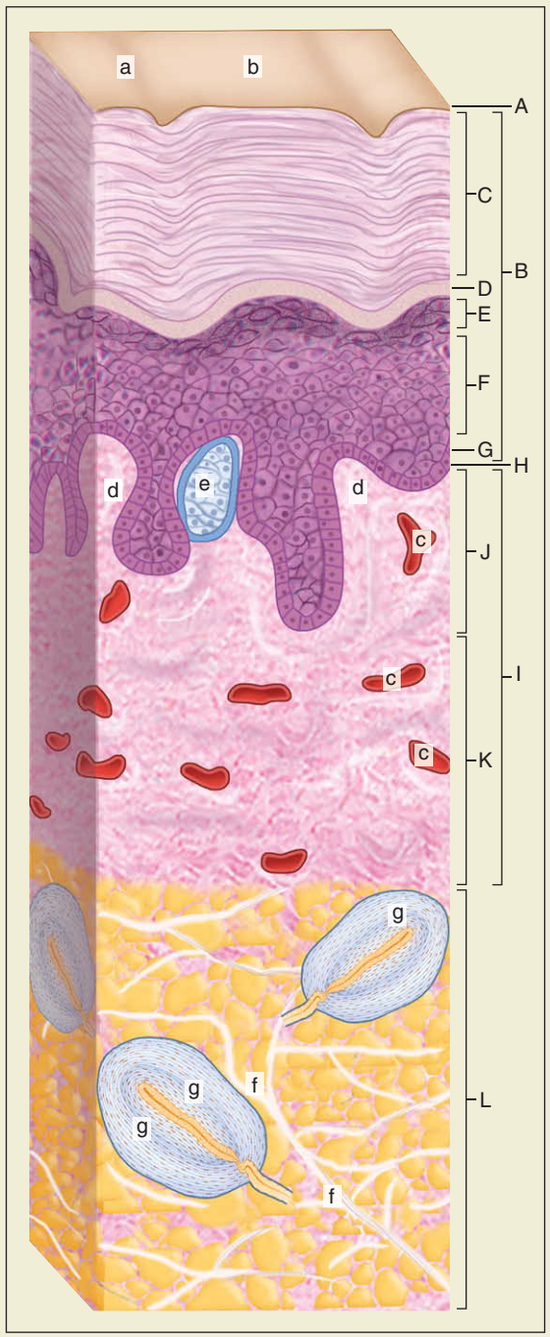
1. **Stratum basale** (base layer). The stratum basale is a single layer of columnar cells. Only the cells in this deepest stratum of the epithelium undergo mitosis. As a result of this regenerative activity, cells transfer or migrate from the basal layer through the other layers until they are shed from the skin surface. The term *stratum germinativum* (growth layer) is often used to designate stratum basale (or sometimes, stratum basale and stratum spinosum together).
2. **Stratum spinosum** (spiny layer). The stratum spinosum layer of the epidermis is formed from 8 to 10 layers of irregularly shaped cells with very prominent intercellular bridges, or desmosomes. When viewed under a microscope, the desmosomes appear to pull points of the plasma membranes of adjoining cells toward one another. This gives cells of this layer a spiny or prickly appearance. Cells in this epidermal layer are rich in ribonucleic acid (RNA) and are therefore well equipped to initiate the protein synthesis required for the production of keratin.
3. **Stratum granulosum** (granular layer). The process of surface keratin formation begins in the stratum granulosum of the epidermis. Cells are arranged in a sheet two to four layers deep and are filled with intensely staining granules called **keratohyalin,** which is required for surface keratin formation. At this stage, the keratinocytes also form small bodies of *glycophospholipids* (part sugar, part phospholipid) built up in multiple layers. Even though there is some important biochemical activity at this stage, cells in the stratum granulosum have started to degenerate. As a result, high levels of lysosomal enzymes are present in the cytoplasm, and the nuclei are in the process of breaking down. In thin skin, not many cells at this stage are present, so this layer of the epidermis may not be visible.
4. **Stratum lucidum** (clear layer). The keratinocytes in the stratum lucidum are very flat, closely packed, and clear. Typically, nuclei are absent, and the cell outlines are now indistinct. These dying cells are filled with a substance called **eleidin,** which will eventually be transformed to keratin. This layer is absent in thin skin but is apparent in sections of thick skin from the soles of the feet and the palms of the hands.
5. **Stratum corneum** (horny layer). The stratum corneum is the most superficial layer of the epidermis. It is composed of very thin squamous (flat) cells, which at the skin surface are dead and continually being shed and replaced. Much of the cytoplasm in these cells has been replaced by a dense network of keratin fibers. The glycophospholipids from the multilayer bodies cement the keratin fibers into a strong, waterproof barrier. The desmosomes that hold adjacent keratinocytes together strengthen this layer even more and permit it to withstand considerable wear and tear. The process by which cells in this layer are formed from cells in deeper layers of the epidermis and then filled with keratin and moved to the surface is called **keratinization.**

   The stratum corneum is sometimes called the *barrier area* of the skin because it functions as a barrier to water loss and to many environmental threats ranging from microorganisms and harmful chemicals to physical trauma. Once this barrier layer is damaged, the effectiveness of the skin as a protective covering is greatly reduced, and most contaminants can easily pass through the lower layers of the cellular epidermis. If the glycophospholipid barrier is washed away by prolonged soaking in water (especially if the water contains lipid-dissolving detergents), the keratin may absorb water and make the skin appear puffy and wrinkled—most easily seen in thick skin because of its high water content. Certain diseases of the skin cause the stratum corneum layer of the epidermis to thicken far beyond normal limits—a condition called **hyperkeratosis.** The result is a thick, dry, scaly skin that is inelastic and subject to painful fissures.

Table 7-1 clearly shows each of these layers of the epidermis.

EPIDERMAL GROWTH AND REPAIR

The most important function of the integument—protection—largely depends on the special structural features of the epidermis and its ability to create and repair itself after injury or disease.



Turnover time and *regeneration* time are terms used to describe the period required for a population of cells to mature and reproduce. Obviously, as the surface cells of the stratum corneum are lost, replacement of keratinocytes by mitotic activity must occur. New cells must be formed at the same rate that old keratinized cells flake off from the stratum corneum to maintain a constant thickness of the epidermis. Cells push upward from the stratum basale into each successive layer, die, become keratinized, and eventually desquamate (fall away), as did their predecessors. This fact illustrates a physiological principle: while life continues, the body's work is never done. Even at rest it is producing millions upon millions of new cells to replace old ones.

A cell-signaling protein called *epidermal growth factor (EGF)* plays a role in regulating the regeneration and repair of the epidermis, as its name suggests. Discovery of EGF has led to its use as a therapy to stimulate skin repairs in diabetic and pressure ulcers and other conditions. EGF requires the hormone *insulin-like growth factor 1 (EGF-1)* to have its full effect in stimulating skin growth and repair. *Growth hormone (GH)* also has a growth-promoting effect on epidermal cells. The cooperative actions of hormones are explored further in Chapters 18 and 19.

Research suggests that the regeneration time required for completion of mitosis, differentiation, and movement of new keratinocytes from the stratum basale to the surface of the epidermis is about 35 days. The process can be accelerated by abrasion of the skin surface, which tends to peel off a few of the cell layers of the stratum corneum. The result is an intense stimulation of mitotic activity in the stratum basale and a shortened turnover period. If abrasion continues over a prolonged period, the increase in mitotic activity and shortened turnover time will result in an abnormally thick stratum corneum and the development of **calluses** at the point of friction or irritation. Although callus formation is a normal and protective response of the skin to friction, several skin diseases are also characterized by abnormally high mitotic activity in the epidermis. In such conditions, the thickness of the corneum is dramatically increased. As a result, scales accumulate and skin lesions often develop.

Normally, about 10% to 12% of all cells in the stratum basale enter mitosis each day. Cells migrating to the surface proceed

TABLE 7-1 Structure of the Skin

	STRUCTURE	DESCRIPTION
A	**Surface film**	Thin film coating the skin; made up of a mixture of sweat, sebum, desquamated cells/fragments, various chemicals; protects the skin
B	**Epidermis**	Superficial primary layer of the skin; made up entirely of keratinized stratified squamous epithelium; derived from the ectoderm; also includes hairs, sweat glands, sebaceous glands
C	Stratum corneum (horny layer)	Several layers of flakelike dead cells (or *corneocytes*) mostly made up of dense networks of *keratin* fibers cemented by *glycophospholipids* and forming a tough, waterproof barrier; the keratinized layer *a,* sulcus (groove) *b,* friction ridge
D	Stratum lucidum (clear layer)	A few layers of squamous cells filled with *eleidin*—a keratin precursor that gives this layer a translucent quality (not visible in thin skin)
E	Stratum granulosum (granular layer)	2-5 layers of dying, somewhat flattened cells filled with darkly staining keratohyalin granules and multilayered bodies of glycophospholipids; nuclei disappear in this layer
F	Stratum spinosum (spiny layer)	8-10 layers of cells pulled by desmosomes into a spiny appearance
G	Stratum basale (base layer)	Single layer of mostly columnar cells capable of mitotic cell division; it is from this layer that all cells of superficial layers are derived; includes keratinocytes and some melanocytes
H	**Dermoepidermal junction (DEJ)**	The basement membrane, a unique and complex arrangement of adhesive components that glue the epidermis and dermis together
I	**Dermis**	Deep primary layer of the skin; made up of fibrous tissue; also includes some blood vessels *(c),* muscles, and nerves; derived from mesoderm
J	Papillary layer	Loose fibrous tissue with collagenous and elastic fibers; forms nipplelike bumps (papillae, *d*); includes tactile corpuscles (touch receptors, *e*) and other sensory receptors
K	Reticular layer	Tough network (reticulum) of collagenous dense irregular fibrous tissue (with some elastic fibers); forms most of the dermis
L	**Hypodermis** (subcutaneous layer; superficial fascia)	Loose fibrous (areolar) connective tissue and adipose tissue; under the skin (not part of the skin); includes fibrous bands or *skin ligaments (f)* that connect the skin strongly to underlying structures; includes lamellar corpuscles (pressure receptors, *g*) and other sensory receptors

upward in vertical columns from discrete groups of 8 to 10 of these basal cells undergoing mitosis. Each group of active basal cells, together with its vertical columns of migrating keratinocytes, is called an *epidermal proliferating unit*, or EPU. Keratinization proceeds as the cells migrate toward the stratum corneum. As mitosis continues and new basal cells enter the column and migrate upward, fully keratinized "dead" cells are sloughed off at the skin surface. Numerous skin diseases are characterized by an abnormally high rate of keratinization.

| QUICK CHECK |

1. Identify the two main or primary layers of skin. What tissue type dominates each layer?
2. The terms *thin* and *thick* skin refer to which primary layer of skin? How do thin and thick skin differ?
3. Identify the two main cell types found in the epidermis.
4. List the five layers, or strata, of the epidermis.

Dermoepidermal Junction

Electron microscopy and histochemical studies have demonstrated the existence of a rather unique area between the epidermis and dermis called the *dermoepidermal junction (DEJ)*.

The DEJ is a unique kind of basement membrane (BM) that includes special fibrous elements and a unique polysaccharide gel that strongly cement the superficial epidermis to the dermis below. The junction "glues" the two layers together and provides mechanical support for the epidermis, which is attached to its upper surface. Box 7-2 shows what happens when this "skin glue" fails.

In addition, the DEJ serves as a partial barrier to the passage of some cells and large molecules. Certain dyes, for example, if injected into the dermis cannot passively diffuse upward into the epidermis unless the junctional barrier is damaged by heat, enzymes, or other chemicals that change its permeability characteristics. Although the junction is remarkably effective in preventing separation of the two skin layers, even when they are subjected to relatively high shear force, this barrier is thought to have only a limited role in preventing passage of harmful chemicals or disease-causing organisms through the skin from the external environment. Any widespread detachment of a large area of epidermis from the dermis is an extremely serious condition that may result in overwhelming infection and death.

Dermis

The dermis, or *corium*, is sometimes called the "true skin." It is composed of two layers—a thin **papillary** layer and a thicker **reticular** layer. The dermis is much thicker than the epidermis and may exceed 4 mm on the soles and palms. It is thinnest on the eyelids and penis, where it seldom exceeds 0.5 mm. As a rule of thumb, the dermis on the ventral surface of the body and over the appendages is generally thinner than on the dorsal surface. The mechanical strength of the skin is in the dermis. In addition to serving a protective function against mechanical injury and compression, this layer of the skin provides a reservoir storage area for water and important electrolytes. A widespread network of nerves and nerve endings in the dermis called *somatic sensory receptors* also process sensory information such as pain, pressure, touch, and temperature. Sensory receptors are discussed in detail in Chapter 17. At various levels of the dermis extend a variety of muscle fibers, hair follicles, sweat and sebaceous glands, and many blood vessels. It is the rich vascular supply of the dermis that plays a critical role in regulation of body temperature—a function described later in the chapter.

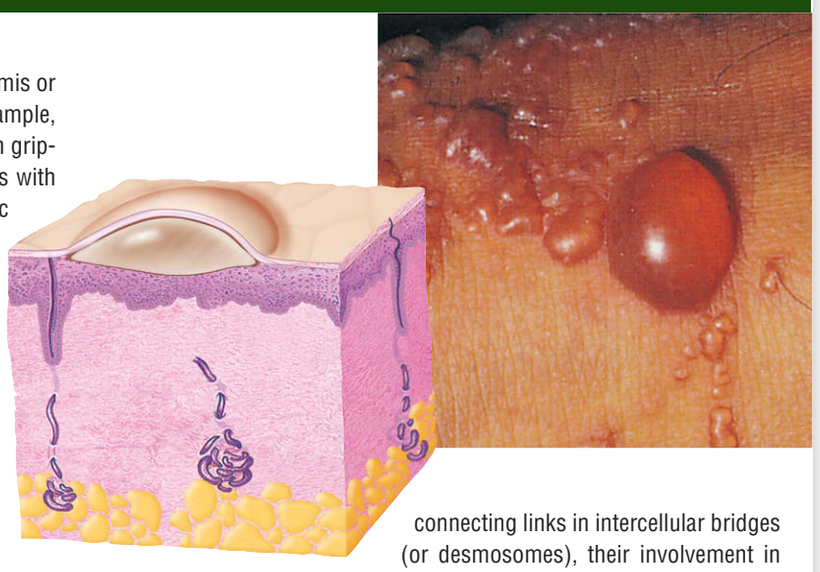
PAPILLARY LAYER

Note in Figure 7-2 that the thin superficial layer of the dermis forms bumps, called **dermal papillae,** that project into the epidermis. *Papilla* (plural, *papillae*) is the Latin word for "nipple" and is used often in anatomy to name any small, nipplelike bump. The papillary layer takes its name from the papillae on its surface. Between the sculptured surface of the papillary layer and the stratum basale lies the important dermoepidermal junction.

The papillary layer and its papillae are composed essentially of loose fibrous connective tissue elements and a fine network of thin collagenous and elastic fibers. The thin epidermal layer of the skin conforms tightly to the ridges of dermal papillae. As a result, the epidermis also has characteristic ridges on its surface. Epidermal ridges are especially well defined on the tips of the fingers and toes. In each of us they form a unique pattern—an anatomical fact made famous by the art of fingerprinting. These ridges perform a function that is very important to human survival: they allow us to grip surfaces well enough to walk upright on slippery surfaces and to grasp and use tools. For that reason, they are usually called *friction ridges*.

RETICULAR LAYER

The thick reticular layer of the dermis consists of a much more dense *reticulum*, or network of fibers, than is seen in the papillary



Box 7-2 | HEALTH matters

Blisters

Blisters (see figures) may result from injury to cells in the epidermis or from separation of the dermoepidermal junction (DEJ). For example, repeated rubbing of the skin against the inside of a shoe or when gripping a tool can pull cells or the DEJ and create a space that fills with interstitial fluid. Regardless of cause, blisters represent a basic reaction of skin to injury. Any irritant that damages the physical or chemical bonds that hold adjacent skin cells or layers together, such as poison ivy, initiates blister formation.

The cell-to-cell junctions (desmosomes) that hold adjacent cells in the epidermis together are essential for integrity of the skin. If these intercellular bridges, sometimes described as "spot welds" between adjacent cells, are weakened or destroyed, the skin literally falls apart and away from the body. Damage to the DEJ produces similar results.

Blister formation follows burns, friction injuries, exposure to primary irritants, or accumulation of toxic breakdown products after cell injury or death in the layers of the skin. Typically, chemical agents that break disulfide linkages or hydrogen bonds cause blisters. Because both types of these chemical bonds are the functional

connecting links in intercellular bridges (or desmosomes), their involvement in blister formation serves as a good example of the relationship between structure and function at the chemical level of organization.

layer above it. It is this dense layer of tough and interlacing white collagenous fibers that when commercially processed from animal skin, results in leather. Although most of the fibers in this layer are of the collagenous type, which gives toughness to the skin, elastic fibers are also present. These fibers make the skin stretchable and elastic (able to rebound).

The dermis serves as a point of attachment for numerous skeletal (voluntary) and smooth (involuntary) muscle fibers. Several skeletal muscles are located in the skin of the face and scalp. These muscles permit a variety of facial expressions and are also responsible for voluntary movement of the scalp. The distribution of smooth muscle fibers in the dermis is much more extensive than the skeletal variety. Each hair follicle has a small bundle of involuntary muscles attached to it. These are the **arrector pili muscles.** Contraction of these muscles makes the hair "stand on end"—as in extreme fright, for example, or from cold. As the hair is pulled into an upright position, shown in Figure 7-5, it raises the skin around it into what we commonly call "goose bumps." In the dermis of the skin of the scrotum and in the pigmented skin called the *areolae* surrounding the nipples, smooth muscle cells form a loose network. Contraction of these smooth muscle cells wrinkles the skin and causes elevation of the testes or erection of the nipples.

Millions of somatic sensory receptors are located in the dermis of all skin areas (Figure 7-6; see also Figure 7-2). They permit the skin to serve as a sense organ transmitting sensations of pain, pressure, touch, and temperature to the brain.

Hair follicles and various skin glands, made up of epithelial tissues that extend from the surface of the epidermis, have most of their structures within the reticular layer of the dermis.

DERMAL GROWTH AND REPAIR

Unlike the epidermis, the dermis does not continually shed and regenerate. It does maintain itself, but rapid regeneration of connective tissue in the dermis occurs only during unusual circumstances, as in the healing of wounds (see Figure 6-37, p. 155). In the healing of a wound such as a surgical incision, fibroblasts in the dermis quickly reproduce and begin forming an unusually dense mass of new connective tissue fibers. If this dense mass is not replaced by normal tissue, it remains as a *scar.*

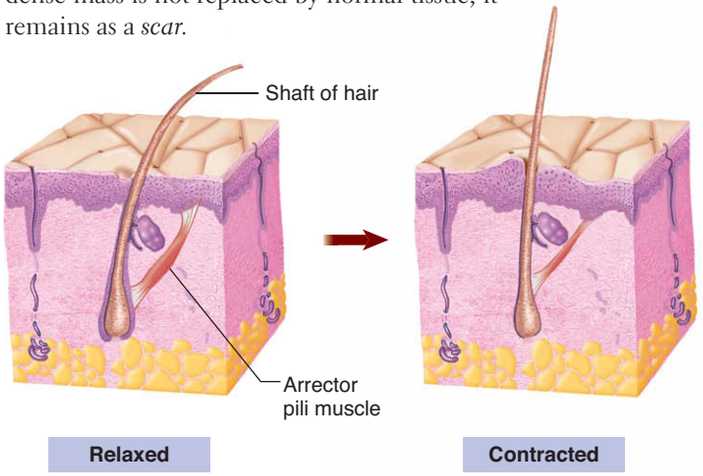


FIGURE 7-5

Arrector pili muscle. When the arrector pili muscle contracts, it pulls the follicle and hair into a more perpendicular position, thus "fluffing up" the hair. Notice how a "goose bump" is raised around the hair shaft.

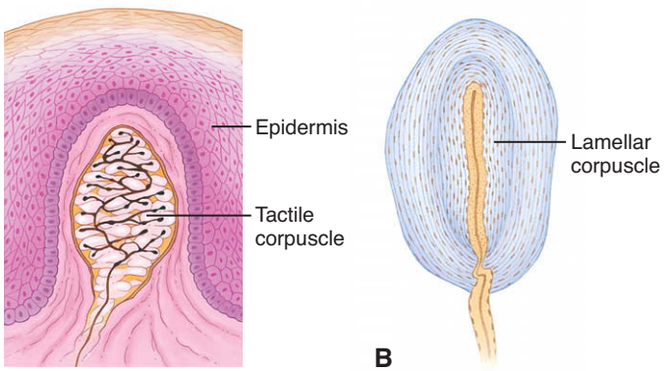

FIGURE 7-6

Skin receptors. Receptors are sensitive nerve endings that make it possible for the skin to act as a sense organ. **A,** This *tactile (Meissner) corpuscle* is capable of detecting light touch (slight pressure). **B,** Another skin receptor is the *lamellar corpuscle,* also called a *Pacini corpuscle,* which detects sensations of deep pressure.

The dense bundles of white collagenous fibers that characterize the reticular layer of the dermis tend to orient themselves in patterns that differ in appearance from one body area to another. The result is formation of patterns called **cleavage lines** (Figure 7-7). If surgical incisions are made parallel to the cleavage lines, or *Langer lines,* the resulting wound will have less tendency to gape open and will tend to heal with a thin and less noticeable scar.

If the elastic fibers in the dermis are stretched too much—for example, by a rapid increase in the size of the abdomen during pregnancy or as a result of great obesity—these fibers will weaken and tear. The initial result is the formation of pinkish or slightly bluish depressed furrows with jagged edges. These tiny linear markings *(stretch marks)* are really tiny tears. When they heal and lose their color, the *striae* (Latin, "furrows") that remain appear as glistening silver-white scar lines.

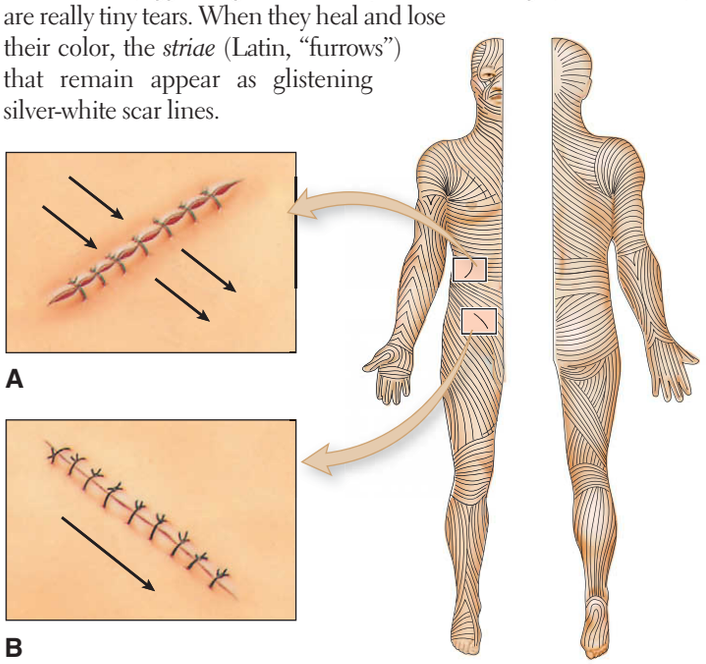

FIGURE 7-7

Cleavage lines. A, If an incision "cuts across" cleavage lines (Langer lines), stress tends to pull the cut edges apart and may retard healing. **B,** Surgical incisions parallel to cleavage lines are subjected to less stress and tend to heal more rapidly.

HYPODERMIS

The hypodermis is sometimes called the **subcutaneous layer,** or **superficial fascia** (see Box 6-5, p. 148). It is not part of the skin, but lies deep to the dermis and thus forms a connection between the skin and the underlying structures of the body. Thus the hypodermis is often discussed along with the skin because of the close structural and functional association of these two superficial body structures. Box 7-3 discusses one reason why it is important to know about the structure hypodermis.

The hypodermis is mostly loose fibrous and adipose tissue. The fat content of the hypodermis varies with the state of nutrition and in obese individuals may exceed 10 cm in thickness in certain areas. The density and arrangement of fat cells and collagen fibers in this area determine the relative mobility of the skin. Bands of fibers called *skin ligaments* running through the hypodermis help hold the skin to underlying structures such as deep fascia and muscles (Table 7-1, *f*). When skin is removed from an animal by blunt dissection, separation occurs in the "cleavage plane" that exists between the superficial fascia and the underlying structures.

| QUICK CHECK |

5. What is the name of the gluelike layer separating the dermis from the epidermis?
6. Which layer of the dermis forms the bumps that produce ridges on the palms and soles?
7. Which layer is vascular: the epidermis or dermis?
8. What is the main function of the hypodermis?

SKIN COLOR

Melanin

Human skin ranges widely in color. The main determinant of skin color is the quantity of **melanin** deposited in the cells of the epidermis by melanocytes. The number of pigment-producing melanocytes scattered throughout the stratum basale of the epidermis in most body areas is about the same in all humans. It is the amount and type of melanin pigment actually produced by these cells that account for the majority of skin color variations among families.

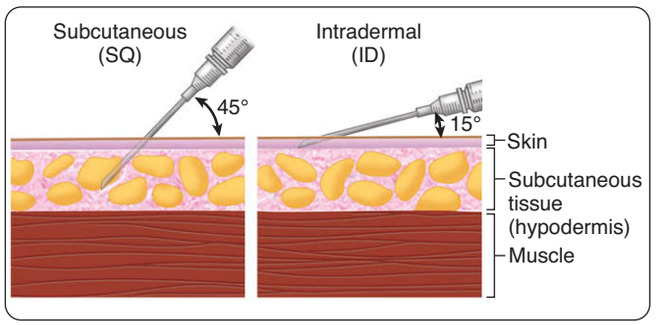
Two groups of melanin are made by the melanocytes of the body. One group of these pigments is called **eumelanin** (yoo-MEL-ah-nin) and the other group is called **pheomelanin** (fee-oh-MEL-ah-nin). The word *eumelanin* literally means "true black substance" because it is very dark brown, sometimes nearly black. *Pheomelanin* means "dusky black substance"—which hints at its lighter reddish or orange color. Dark-skinned and dark-haired people produce large quantities of eumelanin. On the other hand, people with very light skin with red-orange freckles and red hair produce pheomelanin—and little if any eumelanin—in the skin.

Of all body cells, only melanocytes have the ability to routinely convert the amino acid *tyrosine* into melanin pigments. The pigment granules are then released in tiny **melanosomes** and transferred to surrounding keratinocytes, where they form a sort of protective cap over the nucleus (Figure 7-8). The pigment-producing process is

Box 7-3 | HEALTH matters

Subcutaneous and Intradermal Injections

Although the hypodermis, or subcutaneous layer, is not part of the skin itself, it carries the major blood vessels and nerves to the skin above. The rich blood supply and loose spongy texture of this area make it an ideal site for the rapid and relatively pain-free absorption of injected material. Liquid medicines, such as insulin, and pelleted implant materials are often administered by *subcutaneous (SQ) injection* with a *hypodermic needle* into this spongy and porous layer beneath the skin. *Intradermal (ID) injections,* on the other hand, place the medication in the skin proper. ID injections, which are ideal for some vaccines, are hard to administer with a typical needle because it is so easy to punch through to the hypodermis. Therefore, this type of injection is sometimes given with special needle-free injectors.



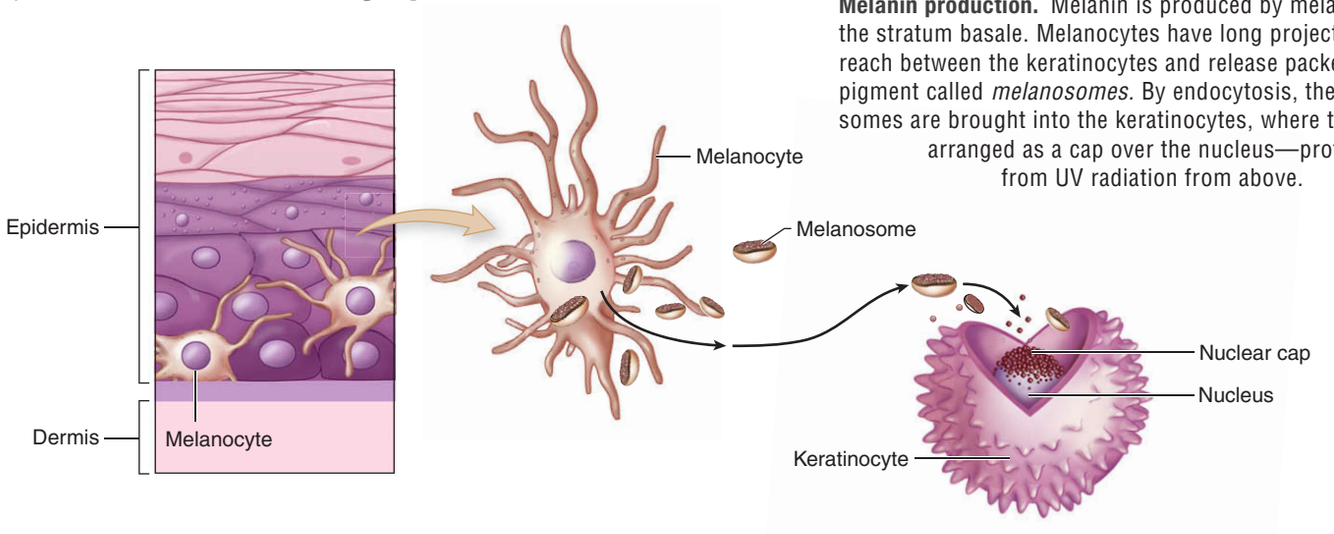


FIGURE 7-8

Melanin production. Melanin is produced by melanocytes in the stratum basale. Melanocytes have long projections that reach between the keratinocytes and release packets of pigment called *melanosomes.* By endocytosis, the melanosomes are brought into the keratinocytes, where they are arranged as a cap over the nucleus—protecting it from UV radiation from above.

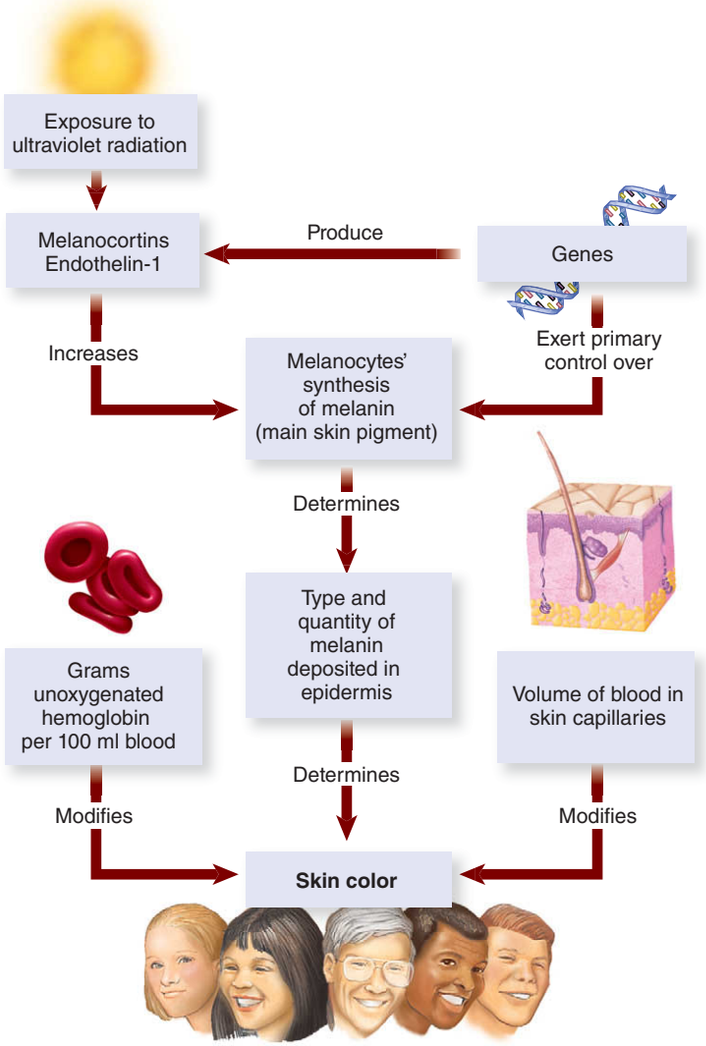

FIGURE 7-9

How genes affect skin color. Genes determine an individual's basic skin color by controlling the amount and type of melanin synthesized and deposited in the epidermis. However, as the diagram shows, other factors may modify the basic skin color.

regulated in the cell by the enzyme *tyrosinase*. But this conversion process depends on several factors (Figure 7-9).

Heredity is a major factor in melanin production. Geneticists tell us that several genes exert primary control over the amount of melanin formed by melanocytes. These genes may affect any part of the chemical pathway that produces the two types of melanin. For example, if the enzyme tyrosinase is absent from birth because of a genetic mutation, the melanocytes cannot form melanin and a condition called **albinism** results. Albino individuals have a characteristic absence of pigment in their hair, skin, and eyes. Thus heredity determines how dark or light one's skin color will be (see Chapter 37).

Other factors can influence the expression of the genes for melanin production. Sunlight is an obvious example. Prolonged exposure to the ultraviolet (UV) radiation in sunlight causes melanocytes to increase melanin production and darken skin color (Figure 7-10). Notice in Figure 7-8 that the melanosomes form a cap over the top of the nucleus in each keratinocyte. The melanin in this nuclear cap absorbs UV radiation before it can reach the DNA inside the nucleus, where it can cause severe damage that can lead to skin cancer and other problems. Unless the cells are protected by melanin, UV radiation can also break down other

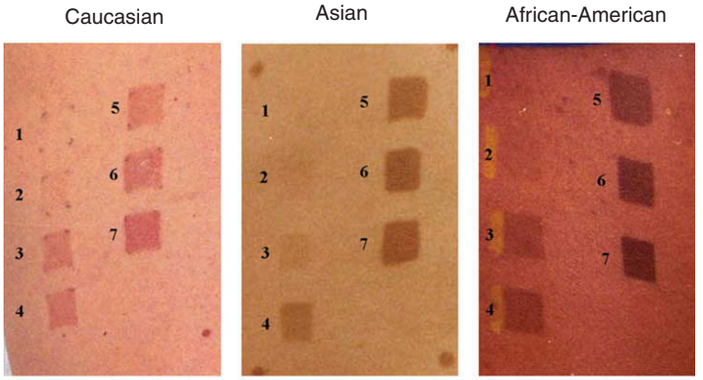

FIGURE 7-10

Tanning effects in skin. Photos showing skin effects of ultraviolet (UV) radiation on day 8 after exposure to increasing doses (1 through 7) in three skin types. Notice that the Caucasian skin involves more redness (from burning) than the darker skin types, which become even darker in response to higher doses of UV radiation.

important molecules, such as the vitamin *folic acid* (B_9). Eumelanin absorbs more UV radiation than pheomelanin does—which explains why very dark-skinned individuals have less risk of developing skin cancer than very light-skinned, reddish freckled individuals do.

Research shows that dark skin pigmentation also facilitates apoptosis (programmed cell death) of any cells that do suffer damage to their DNA structure. Removal of DNA-damaged cells prevents them from becoming cancerous.

Melanin production is stimulated when *melanocortin* receptors are triggered at the surface of a melanocyte. Melanocortins are a family of hormones produced from a single gene that codes for a large polypeptide that breaks into distinct hormones. One product of the gene is adrenocorticotropic hormone (ACTH), some of which breaks down further to form *alpha melanocyte-stimulating hormone* (*α-MSH*). Although tiny amounts of melanocortins are released by the anterior pituitary gland, they can also be made by keratinocytes in response to UV radiation—thus triggering nearby melanocytes to produce more melanin. Other local regulatory proteins, such as *endothelin-1 (ET-1)*, act with melanocortins to produce this "tanning" effect. Some people with light skin, red hair, and freckles inherit malfunctioning melanocyte receptors or melanocortin genes and thus fail to produce melanin in response to UV exposure.

Increasing age may also influence melanocyte activity. In many individuals, apoptosis of melanocyte stem cells in hair follicles produces the graying of the hair often associated with age. Cumulative exposure to UV radiation over the years can also trigger excess production of melanin. This may result in a collection of dark "age spots" on the skin (Figure 7-11).

FIGURE 7-11

Age spots. Hyperpigmentations from the cumulative effects of UV exposure over the years can produce a dark type of "age spots" that are also called "liver spots."

Other Pigments

In addition to melanin, other pigments such as the yellow pigment *beta-carotene (β-carotene)* found in many vegetables and roots (for example, carrots) also contribute to skin color. Because β-carotenes can be converted by the body into vitamin A—a critically important nutrient for skin growth—they are stored in skin tissue. Extremely high consumption of carrot juice or sweet potatoes, in infants especially, may cause an orange or yellow coloration of the skin. Yellowish discoloration can also be caused by jaundice (Box 7-4) or can be seen after a bruise begins to heal (see Figure 7-13).

As epidermal cells age and stop undergoing mitosis, they often accumulate a brown-yellow pigment called *lipofuscin*. Aged skin often shows a mottling of brown-yellow age spots as a result.

An individual's basic skin color can also change temporarily when the volume of blood flowing through skin capillaries increases or decreases. The reason is that blood contains the reddish pigment hemoglobin (Hb) that carries oxygen or carbon dioxide. If blood vessels in the skin dilate, as they do during blushing, the skin appears to be redder than usual because of additional hemoglobin flowing through the dermis. If skin blood vessels constrict, on the other hand, skin blood volume decreases, and the skin may turn paler (less red) than usual.

In general, the sparser the pigments in the epidermis, the more transparent the skin and therefore the more vivid the change in skin color with a change in skin blood volume. Conversely, the richer the pigmentation, the more opaque the skin and therefore the less the change in skin color with a change in skin blood volume.

In some abnormal conditions, skin color changes because of an excess amount of hemoglobin that is low in oxygen and high in carbon dioxide. If skin contains relatively little melanin, it will appear bluish, that is, *cyanotic*, when its blood has a high proportion of unoxygenated hemoglobin. The blue coloration results from the fact that hemoglobin changes from a bright red color to a deep maroon-red color when it loses oxygen and gains carbon dioxide. Light reflecting from the dark red hemoglobin and diffused by fibers in the skin may appear blue—as you can see in Figure 7-12. In general, the darker the skin pigmentation, the greater the amount of unoxygenated hemoglobin that must be present before **cyanosis** ("condition of blueness") becomes visible.

FIGURE 7-12

Cyanosis. The blue discoloration of the fingers of this light-skinned individual is caused by the diffusion of light reflected off dark, unoxygenated hemoglobin in the blood vessels of the skin. The fingertips have an especially high volume of blood and thus look bluer than other regions of the skin.

Bruising can cause a variety of different skin colors to appear in light-skinned individuals, as you can see in Figure 7-13. When damage to blood vessels in the skin permits the release of red blood cells, their reddish color begins to darken and produce the bluish colors described previously when hemoglobin loses oxygen and gains carbon dioxide. As the blood clots, it may begin to appear darker blue or even black. Macrophages remove the hemoglobin and break it down into iron-containing *hemosiderin* (a brownish pigment) and several iron-free *bile pigments* that are greenish and yellowish.

Pigments from cosmetics or from tattoos can also change the coloring of the skin. Most cosmetics simply add layers of pigment on top of the skin. Some temporary tattoos also add layers of pigment on top of the skin. Henna tattoos stain epidermal cells, which are later shed—making their brown color temporary. Permanent tattoos (see the photo in Box 7-4) are made by using

Box 7-4 | HEALTH matters

Jaundice

Yellowish discoloration of the skin and other tissues, such as the "white" or sclera of the eye, can be caused by bile pigments. Bile pigments are a natural breakdown product when old red blood cells are destroyed. Ordinarily, bile pigments are excreted from the liver into the digestive tract, where they become part of the feces and are eliminated by the body. However, in some cases the liver is unable to remove bile from the blood efficiently—thus allowing the bile to stain the tissues of the body. An example of a condition that can cause jaundice is a liver infection, as illustrated in the photograph.

Jaundice also often occurs just after birth. In about half of all full-term newborns, jaundice occurs when old red blood cells containing an immature fetal form of hemoglobin are rapidly replaced with red blood cells containing the mature form of hemoglobin. Often, a baby's liver is simply too immature to handle the removal of such a large amount of bile pigment all at once. This form of jaundice is temporary and usually disappears without treatment. UV light breaks down bile pigments in the skin and can help speed recovery in infants with moderate to severe cases of jaundice.

Jaundice. Yellowish discoloration of the skin and other tissues by bile pigments was, in the case seen here, caused by a liver infection. The patient was infected with hepatitis B by a contaminated tattoo needle. The yellow tinge of the skin can be best seen by comparing the patient's skin color with that of the physician's hand.

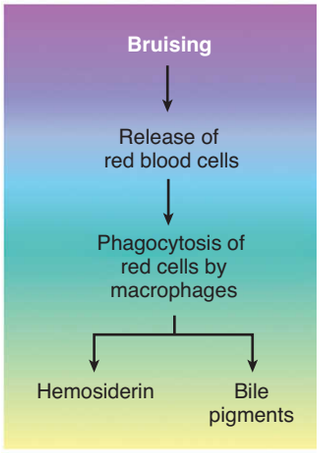

FIGURE 7-13

Color changes in a bruise. In this light-skinned individual, different colors appear in the skin as hemoglobin becomes unoxygenated and turns bluish (see Figure 7-12) and perhaps even black as the blood clots. As macrophages consume the hemoglobin, it is broken down into brownish, greenish, and yellowish pigments—sometimes producing a rainbow of skin colors.

a needle to insert pigments into the dermis of the skin. Because these pigments eventually diffuse to deeper layers of the dermis, such a tattoo may fade or become less distinct after several decades. Some permanent tattoos are made by cutting the skin and rubbing in pigments, producing colored scar tissue.

FUNCTIONS OF THE SKIN

Skin functions are crucial to maintenance of homeostasis and thus to survival itself. They are also diverse and include such different processes as protection, sensation, growth, synthesis of important chemicals and hormones (such as vitamin D), excretion, temperature regulation, and immunity. Because of its structural flexibility, the skin permits body growth and movement to occur without injury. We also know that certain substances can be absorbed through the skin, including the fat-soluble vitamins (A, D, E, and K), estrogens and other sex hormones, corticoid hormones, and certain drugs such as nicotine and nitroglycerin.

The skin also produces melanin—the pigment that serves as an extremely effective screen to potentially harmful ultraviolet light—and keratin—one of nature's most flexible, yet enduring protective proteins. Refer to Table 7-2 as you read about the seven functions of the skin described in the paragraphs that follow.

Protection

The keratinized stratified squamous epithelial cells that cover the epidermis makes the skin a formidable barrier. It protects underlying tissues against invasion by hordes of microorganisms, bars entry of most harmful chemicals, and minimizes mechanical injury to underlying structures that might otherwise be harmed by even the relatively minor types of trauma experienced on a regular basis.

In addition to protection from microbiological entry, chemical hazards, and mechanical trauma, the skin also protects us from dehydration caused by loss of internal body fluids and from unwanted entry of fluids from the external environment. The ability of the pigment melanin to protect us from the harmful effects of overexposure to ultraviolet light is yet another protective function of the skin.

SURFACE FILM

The ability of the skin to act as a protective barrier against an array of potentially damaging assaults from the environment begins with the proper functioning of a thin film of emulsified material spread over its surface. The **surface film** is produced by the mixing of residue and

TABLE 7-2 Functions of the Skin

FUNCTION	EXAMPLE	MECHANISM
Protection	Against microorganisms Against dehydration Against ultraviolet radiation Against mechanical trauma	Surface file/ mechanical barrier Keratin Melanin Tissue strength
Sensation	Pain Heat and cold Pressure Touch	Somatic sensory receptors
Permits movement and growth without injury	Body growth and change in body contours during movement	Elastic and recoil properties of skin and subcutaneous tissue
Endocrine	Vitamin D production	Activation of precursor compound in skin cells by ultraviolet light
Excretion	Water Urea Ammonia Uric acid	Regulation of sweat volume and content
Immunity	Destruction of microorganisms and interaction with immune system cells (helper T cells)	Phagocytic cells and epidermal dendritic cells
Temperature regulation	Heat loss or retention	Regulation of blood flow to the skin and evaporation of sweat

secretions from sweat and sebaceous glands with epithelial cells constantly being cast off from the epidermis. The shedding of epithelial elements from the skin surface is called **desquamation.** A variety of microbial cells are another important part of the mixture (Box 7-5).

Functions of surface film include the following:

- Antibacterial and antifungal activity
- Lubrication
- Hydration of the skin surface
- Buffering of caustic irritants
- Blockade of many toxic agents

The chemical composition of surface film includes (1) amino acids, sterols, and complex phospholipids from the breakdown of sloughed epithelial cells; (2) fatty acids, triglycerides, and waxes from sebum; and (3) water, ammonia, lactic acid, urea, and uric acid from sweat. The specific chemical composition of surface film is variable, and samples taken from skin covering one body area often have a different "mix" of chemical components than film covering skin in another area does. This difference helps explain the unique and localized distribution patterns of certain skin diseases and also explains why the skin covering a particular area of the body is sometimes more susceptible to attack by certain bacteria or fungi.

Sensation

The widespread placement of the millions of different somatic sensory receptors found in the skin enables it to function as a sophisticated sense organ covering the entire body surface (see Figures 7-1 and 7-3).The receptors serve as antennas that detect stimuli, which eventually produce the general, or somatic, senses, including pressure, touch, temperature, pain, and vibration. When these receptors are activated by their respective stimuli, they make it possible for the body to respond to changes occurring in both the external and internal environments. A full discussion of the anatomy and physiology of the somatic sense receptors is provided in Chapter 17.

Flexibility

Contraction of our muscles produces the purposeful movement that serves as one of the most easily observed "Characteristics of Life" discussed in Chapter 1. For movement of the body to occur without injury, the skin must be supple and elastic. It grows as we grow and exhibits stretch and recoil characteristics that permit changes in body contours to occur without tearing or laceration.

Excretion

By regulating the volume and chemical content of sweat, the body, through a function of the skin, can influence both its total fluid volume and the amounts of certain waste products, such as uric acid, ammonia, and urea that are excreted. In most circumstances the skin plays only a minor role in the overall excretion of body wastes. However, it can become a more important function in certain disease states or pathological conditions.

Hormone (Vitamin D) Production

The first step in the production of vitamin D in the body occurs when the skin is exposed to ultraviolet light. When this occurs, molecules of a chemical called *7-dehydrocholesterol*, which is normally found in skin cells, are converted into a precursor substance called *cholecalciferol* (Figure 7-14). This chemical is then transported in the blood to the liver and kidneys where it is converted into an active form of vitamin D—a compound that influences several important chemical reactions in the body. In this respect, vitamin D fulfills the requirements required for a substance to be classified as a *hormone*. In general, any chemical substance produced in one body area and then transported in the blood to another location where it has its effect is called a *hormone*. Hormones are critically important regulators of homeostasis and are discussed in detail in Chapters 18 and 19.

Box 7-5 | FYI

Microbes of the Skin

Surface film of the skin contains more than just the mixed secretions of various glands and the sloughed-off keratinized cells of stratum corneum. It is teaming with a variety of microbes—microscopic organisms such as bacteria and fungi (see Figure 6-41 on p. 157). There are up to ten times as many microbial cells on your body's skin and mucous membranes as there are human cells in your body! These microbes act as a set of interactive ecosystems—a microbiome.

There are always some pathogenic bacteria in the body's microbiome, but when you are healthy they are kept in check by a majority of nonpathogenic bacteria. If the healthy ecological balance is upset, however, the pathogenic bacteria can take over in local areas and cause disease. Scientists have been mapping out the widely varied microbial communities that inhabit different locations of our skin in hopes of preventing or curing skin disorders. They have already discovered that the microbiome of each person has unique characteristics. We may soon be able to identify individuals by their microbiome as easily as we do by using fingerprints!

Melanin in the skin must be dark enough to protect the skin from damage from UV radiation, destruction of folic acid, and other adverse health effects. However, if there is too much melanin, the body cannot synthesize enough vitamin D for normal function. In such a case, vitamin D from outside the body is necessary to compensate for the failure of skin to make enough vitamin D. Research shows that various ethnic groups often have just enough melanin to protect them from harm by the UV radiation levels in their native region—and not so much that it prevents vitamin D production.

Immunity

Important defensive cells that attach to and destroy pathogenic microorganisms are found in the skin and play an important role in immunity. In addition, epidermal dendritic cells function with helper T cells to trigger helpful immune reactions in certain diseases.

Homeostasis of Body Temperature

Despite sizable variations in environmental temperature, humans maintain a remarkably constant core body temperature. The functioning of the skin in homeostasis of body temperature is critical to survival and is examined in some detail.

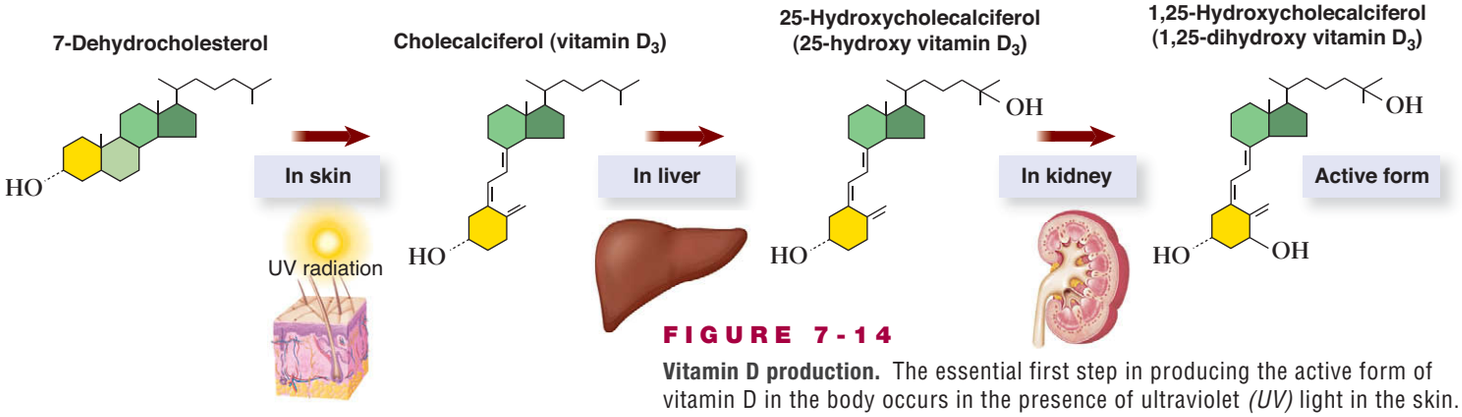

FIGURE 7-14

Vitamin D production. The essential first step in producing the active form of vitamin D in the body occurs in the presence of ultraviolet *(UV)* light in the skin.

In most people, body temperature moves up and down very little in the course of a day. It hovers close to a set point of about 37° C, perhaps increasing to 37.6° C by late afternoon and decreasing to around 36.2° C by early morning. This homeostasis of body temperature is of the utmost importance. Why? Because healthy survival depends on biochemical reactions taking place at certain rates—and these rates depend on normal enzyme functioning, which depends on body temperature staying within the narrow range of normal.

To maintain an even temperature, the body must balance the amount of heat it produces with the amount it loses. This means that if extra heat is produced in the body, this same amount of heat must be lost from it. Obviously, if this does not occur, if increased heat loss does not closely follow increased heat production, body temperature climbs steadily upward. If body temperature increases above normal for any reason, the skin plays a critical role in heat loss by the physical phenomena of evaporation, radiation, conduction, and convection.

HEAT PRODUCTION

Heat is produced by one means—metabolism of foods. Because the muscles and glands (especially the liver) are the most active tissues, they carry on more metabolism and therefore produce more heat than any of the other tissues. So the chief determinant of how much heat the body produces is the amount of muscular work it does. During exercise and shivering, for example, metabolism and heat production increase greatly. But during sleep, when very little muscular work is being done, metabolism and heat production decrease. The skin does not produce heat, but it plays a big role in retaining and dissipating heat to maintain homeostasis of body temperature.

HEAT LOSS

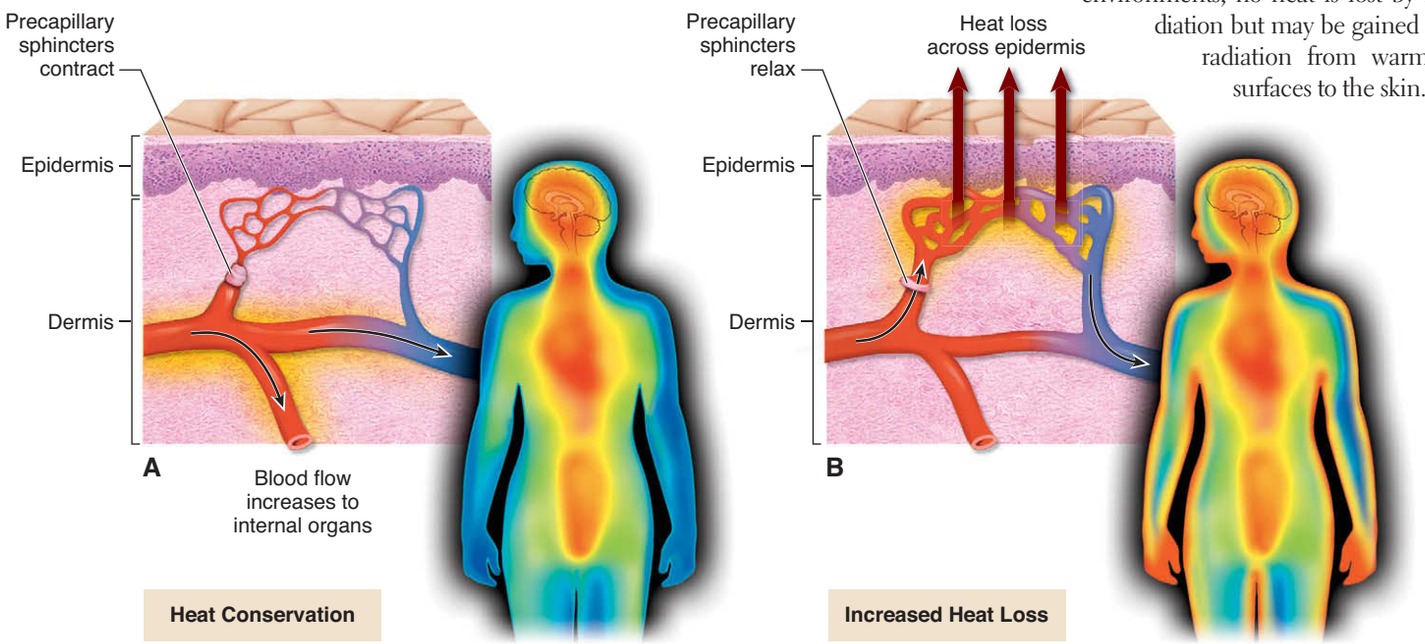
As already stated, one mechanism the body uses to maintain relative constancy of internal temperature is to regulate the amount of heat loss. Some 80% or more of this transfer of heat occurs through the skin; the remainder takes place in mucous membranes. As Figure 7-15 shows, heat loss can be regulated by altering the flow of blood in the skin. If heat must be conserved to maintain a constant body temperature, dermal blood vessels constrict (vasoconstriction) to keep most of the warm blood circulating deeper in the body. If heat loss must be increased to maintain a constant temperature, dermal blood vessels widen (vasodilation) to increase the skin's supply of warm blood from deeper tissues. Heat transferred from the warm blood to the epidermis can then be lost to the external environment through the physical processes of evaporation, radiation, conduction, and convection.

Evaporation

Heat energy must be expended to evaporate any fluid. Evaporation of water constitutes one method by which heat is lost from the body, especially from the skin. Evaporation is especially important in high environmental temperatures, when it is the only method by which heat can be lost from the skin. A humid atmosphere necessarily retards evaporation and therefore lessens the cooling effect derived from it—the explanation for the fact that the same degree of temperature seems hotter in humid climates than in dry ones. At moderate temperatures, evaporation accounts for about half as much heat loss as radiation does.

Radiation

Radiation is the transfer of heat from the surface of one object to that of another without actual contact between the two. Heat radiates from the body surface to nearby objects that are cooler than the skin and radiates to the skin from those that are warmer than the skin. This is the principle of heating and cooling systems. In cool environmental temperatures, radiation accounts for a greater percentage of heat loss from the skin than conduction and evaporation combined do. In hot environments, no heat is lost by radiation but may be gained by radiation from warmer surfaces to the skin.



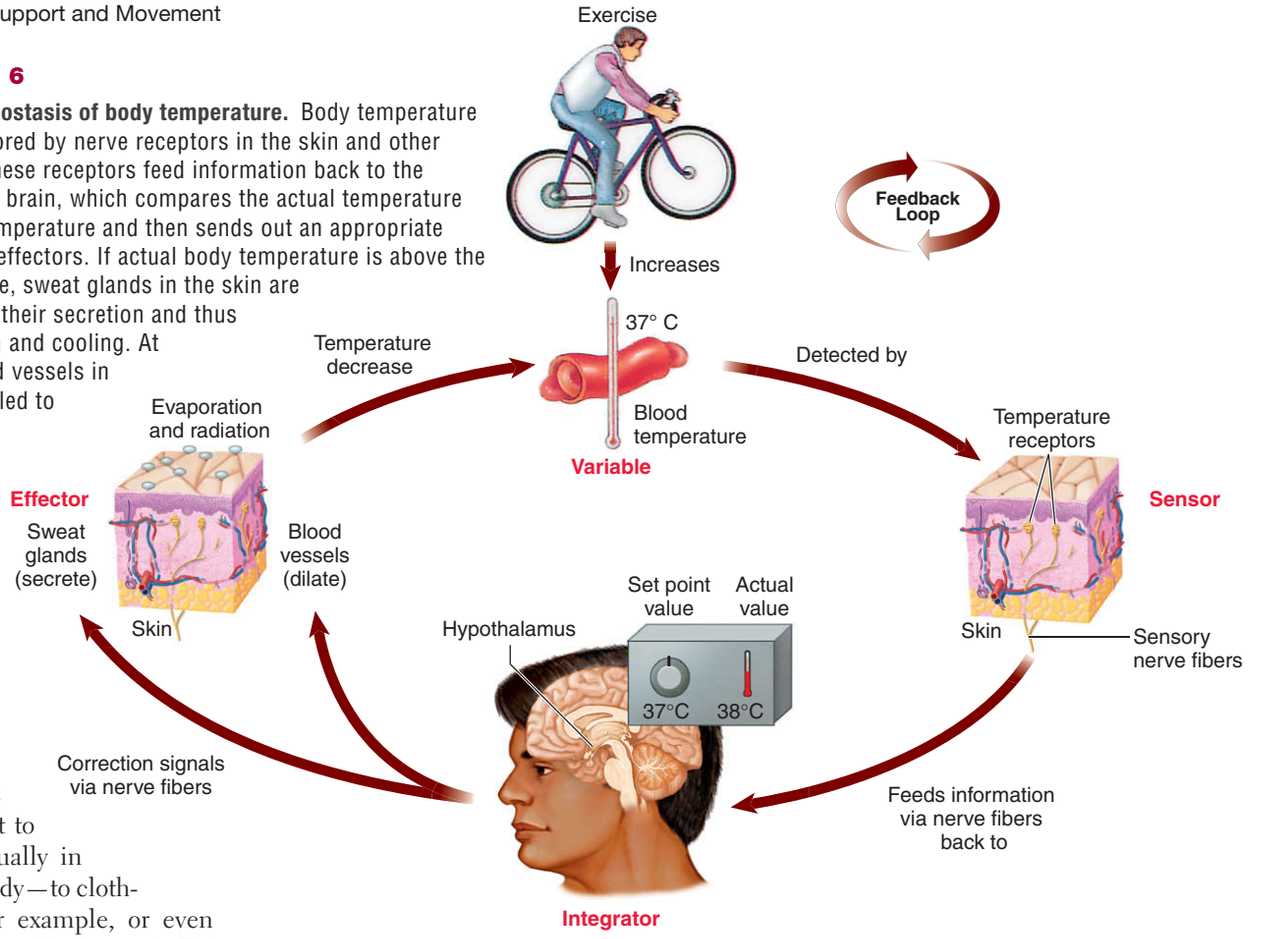


FIGURE 7-15

The skin as a thermoregulatory organ. When homeostasis requires that the body conserve heat, blood flow in the warm organs of the body's core increases. **A,** When heat must be lost to maintain stability of the internal environment, flow of warm blood to the skin increases. **B,** Heat can be lost from the blood and skin by means of radiation, conduction, convection, and evaporation. The head, hands, and feet are major areas of heat loss.

FIGURE 7-16

Role of skin in homeostasis of body temperature. Body temperature is continually monitored by nerve receptors in the skin and other parts of the body. These receptors feed information back to the hypothalamus of the brain, which compares the actual temperature with the set point temperature and then sends out an appropriate correction signal to effectors. If actual body temperature is above the set point temperature, sweat glands in the skin are signaled to increase their secretion and thus promote evaporation and cooling. At the same time, blood vessels in the dermis are signaled to dilate and thus promote radiation of heat away from the skin's surface.

Conduction

Conduction means the transfer of heat to any substance actually in contact with the body—to clothing or jewelry, for example, or even to cold foods or liquids ingested. This process accounts for a relatively small amount of heat loss.

Convection

Convection is the transfer of heat away from a surface by movement of heated air or fluid particles. Usually, convection causes very little heat loss from the body's surface. However, under certain conditions, it can account for considerable heat loss, as you know if you have ever stepped from your shower into even slightly moving air from an open window.

Box 7-6 | SPORTS and FITNESS

Exercise and the Skin

Excess heat produced by the skeletal muscles during exercise increases the core body temperature far beyond the normal range. Because blood in vessels near the skin's surface dissipates heat well, the body's control centers adjust blood flow so that more warm blood from the body's core is sent to the skin for cooling. During exercise, blood flow in the skin can be so high that the skin takes on a redder coloration.

To help dissipate even more heat, sweat production increases to as high as 3 L per hour during exercise. Although each sweat gland produces very little of this total, more than 3 million individual sweat glands are found throughout the skin. Sweat evaporation is essential to keeping body temperature in balance, but excessive sweating can lead to a dangerous loss of fluid. Because the usual intake of fluids may not replace the water lost through sweating, it is important to increase fluid consumption during and after any type of exercise to avoid *dehydration.*

HOMEOSTATIC REGULATION OF HEAT LOSS

The operation of the skin's blood vessels and sweat glands must be coordinated carefully and must take into account moment-by-moment fluctuations in body temperature. Like most homeostatic mechanisms, heat loss by the skin is controlled by a negative feedback loop (Figure 7-16). Temperature receptors in a part of the brain, called the *hypothalamus*, detect changes in the body's internal temperature. If some disturbance, such as exercise, increases body temperature above the set point value of 37° C, the hypothalamus acts as an integrator and sends a nervous signal to the sweat glands and blood vessels of the skin. The sweat glands and blood vessels (the effectors) respond to the signal by acting in ways that promote heat loss. That is, sweat glands increase their output of sweat (increasing heat loss by evaporation), and blood vessels increase their diameter (increasing heat loss by radiation and other means). This process continues until the homeostatic set point for normal body temperature is reached (Box 7-6).

9. What is the one means of heat production in the body? In what type of organs does most heat production occur?
10. Name three of the four physical processes by which heat is lost from the body.

APPENDAGES OF THE SKIN

Appendages of the skin consist of *hair, nails,* and *skin glands.*

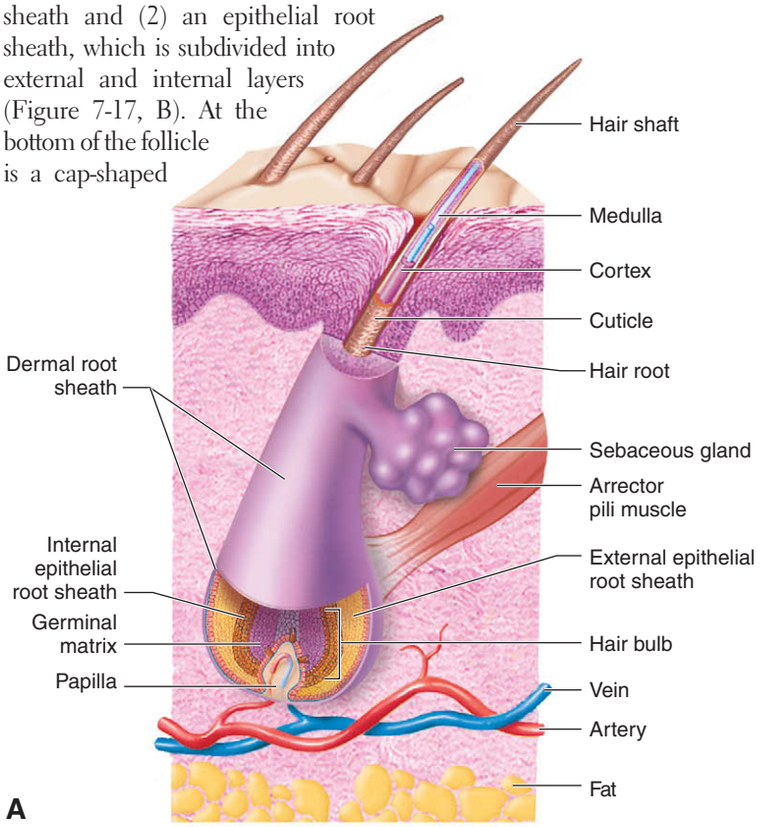
Hair

We have about 5 million hairs on the skin of our body. About 150,000 hairs are on our heads, with the rest scattered all over the skin. Only a few areas of the skin are hairless—notably the palms of the hands and the soles of the feet. Hair is also absent from the lips, nipples, and some areas of the genitals.

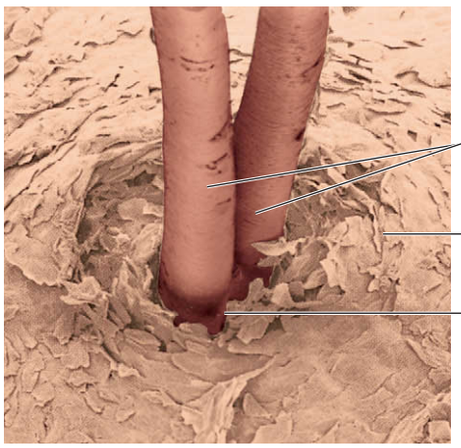
DEVELOPMENT OF HAIR

Many months before birth, tiny tubular pockets called **hair follicles** begin to develop in most parts of the skin. By about the sixth month of pregnancy the developing fetus is all but covered by an extremely fine and soft hair coat, called **lanugo.** Most of the lanugo hair is lost before birth. Soon after birth, any lanugo hair that remains is lost and then replaced by **vellus** hair, which is stronger, fine, and usually less pigmented (see Figure 7-3, B).

The replacement hair growth after birth first appears on the scalp, eyelids, and eyebrows, and the coarse pubic and axillary hair that develops at puberty is called **terminal hair.** In the adult male, terminal hair replaces 80% to 90% of the vellus hair on the chest and extremities and also makes up the beard. In the female, far less vellus hair is replaced with the more coarse terminal variety except in the pubic and axillary areas.



Hair growth begins at the base of the follicle (Figure 7-17). The follicle wall consists of two primary layers: (1) an outer dermal root sheath and (2) an epithelial root sheath, which is subdivided into external and internal layers (Figure 7-17, B). At the bottom of the follicle is a cap-shaped cluster of cells known as the **germinal matrix.** Protruding into the germinal matrix is a small mound of the dermis, called the **hair papilla,** which is an important structure because it contains the blood capillaries that nourish the germinal matrix (see Figure 7-17). Cells of the germinal matrix are responsible for forming hairs. They undergo repeated mitosis, push upward in the follicle, and become keratinized to form a hair. As long as cells of the germinal matrix remain alive, hair regenerates even though it is cut, plucked, or otherwise removed.



Part of the hair, namely, the root, lies hidden in the follicle. The visible part of a hair is called the **shaft.** The inner core of a hair is known as the **medulla,** the more superficial portion around it is called the **cortex,** and the covering layer is called the *cuticle.* If hair is plucked from the follicle, the internal epithelial root sheath will be torn free as well and appears as a whitish layer adherent to the hair cuticle. Layers of keratinized cells make up the cortex.

Besides being a structure to grow and support hair, the hair follicle wall also serves as a primary location of adult stem cells for various types of skin cells such as melanocytes and keratinocytes.

APPEARANCE OF HAIR

Deposited in the cells of the hair are varying amounts of melanins, the pigments responsible for hair color. Although reflections of light can affect hair color somewhat, it is largely the amount, type,

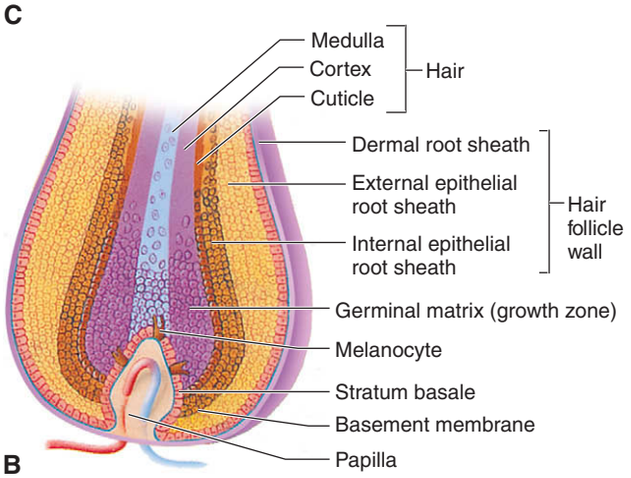


FIGURE 7-17

Hair follicle. A, Relationship of a hair follicle and related structures to the epidermal and dermal layers of the skin. **B,** Enlargement of a hair follicle wall and hair bulb. **C,** Scanning electron micrograph showing shafts of hair extending from their follicles.

FIGURE 7-18

Gray hair. Gray hair results from a scattered arrangement of both white (pigmentless) hairs and darker (pigmented) hairs.

and distribution of melanin that determine the color of hair. Varying amounts of eumelanins in the cortex and/or medulla can produce many shades of blonde and brunette hair. Pheomelanins give hair a reddish tint. Advancing age often produces an increasing smattering of white hairs—the proverbial "crown of glory." White hairs have no pigments at all but appear white because of the diffusion of light through the translucent hair shaft. White hair results from the accumulation of oxygen *free radicals*—highly reactive forms of oxygen that increase as we age. The free radicals damage stem cells in the hair follicle. We fail to maintain the production of new melanocytes and thus lose the ability to produce pigment in the hair. Gray hair, seen in Figure 7-18, is usually a "salt-and-pepper" mixed arrangement of white and dark hairs. Besides adding color, melanin also imparts strength to the hair shaft.

Whether hair is straight or wavy depends mainly on the shape of the shaft. Straight hair has a round, cylindrical shaft. Wavy hair, in contrast, has a flat shaft that is not as strong. As a result, it is more easily broken or damaged than is straight hair. Two or more small **sebaceous glands** secrete **sebum,** an oily substance, into each hair follicle (see Figure 7-17). The sebaceous gland secretions lubricate and condition the hair and surrounding skin to keep it from becoming dry, brittle, and easily damaged. Lipid-containing hair and skin conditioners can add to this damage-reducing effect.

Hair alternates between periods of growth and rest. On average, hair on the head grows a little less than 12 mm (1/2 inch) per month, or about 11 cm (5 inches) a year. Body hair grows more slowly. Head hairs reportedly live between 2 and 6 years, then die and are shed. Normally, however, new hairs replace those lost. But baldness, also called *alopecia*, can develop.

A common type of baldness occurs only when two requirements are met: genes for baldness must be inherited and the male sex hormones (*androgens*) must be present. When the right combination of these causative factors exist, *androgenic alopecia* or **male pattern baldness** (Figure 7-19) inevitably results. An available treatment that may slow or stop the development of male pattern baldness is the drug minoxidil (Rogaine). Unfortunately, the treatment is expensive, must be continued for life if new hair growth is to be retained, and does not always produce as dramatic an effect as hoped.

FIGURE 7-19

Male pattern baldness.

Contrary to what many people believe, hair growth is not stimulated by frequent cutting or shaving. In addition, stories about hair or beard growth continuing after death are also false. What may appear to be continuing beard growth after death is in reality only a more visible beard in a skin surface dehydrated by environmental conditions or the embalming process.

Nails

Heavily keratinized epidermal cells compose fingernails and toenails. The visible part of each nail is called the **nail body.** The rest of the nail, namely, the **root,** lies in a flat sinus hidden by a fold of skin bordered by the **cuticle.** The nail body nearest the root has a crescent-shaped white area known as the **lunula,** or "little moon." Under the nail lies a layer of epithelium called the **nail bed** (Figure 7-20). Because it contains abundant blood vessels, it normally appears pink through the translucent part of the nail bodies. Clinically, this is useful to know. Cyanosis (blueness) often appears under the nails first (see Figure 7-12), and thus nail beds are often monitored closely during surgery or other procedures in which oxygenation of the blood may suddenly drop. Sometimes, lightly pigmented streaks appear in the nail beds of dark-skinned individuals (Figure 7-21).

Nails grow by mitosis of cells in the stratum basale beneath the lunula. On average, nails grow about 0.5 mm a week. Fingernails, however, as you may have noticed, grow faster than toenails, and both grow faster in the summer than in the winter. Even minor trauma to long fingernails can sometimes result in loosening of the nail from the nail bed with a resulting separation that starts at the distal or free edge of the affected nail (Figure 7-22). The condition, called **onycholysis** (ahn-ik-oh-LYE-sis), is common.

Bruising under a nail can cause discoloration as the bruise forms, then heals. Fungal infections can also cause discoloration of nails, often turning them yellow or even black. Fungal

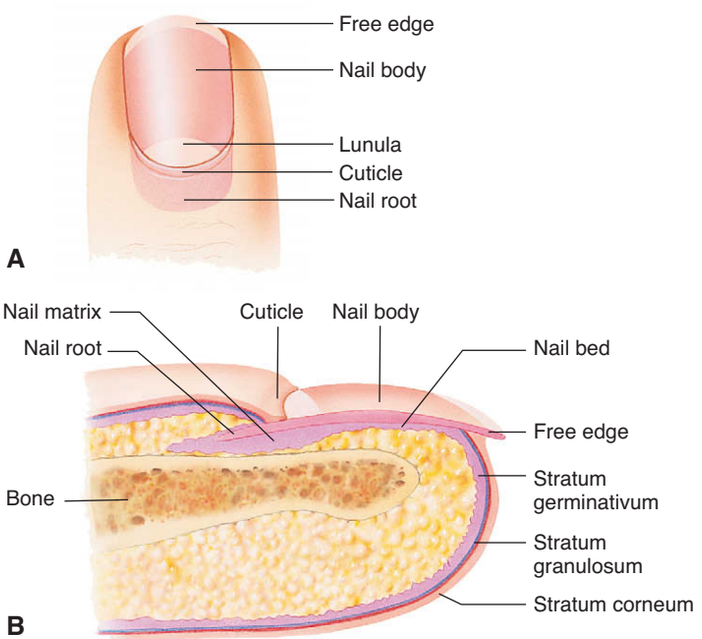

FIGURE 7-20

Structure of nails. A, Fingernail viewed from above. **B,** Sagittal section of a fingernail and associated structures.

FIGURE 7-21

Pigmented nails. In light-skinned individuals, the nail bed is usually free of pigmentation. In very dark-skinned individuals, yellowish or brown pigmented bands (seen in the photograph) are common.

FIGURE 7-22

Onycholysis. In the photo, note that separation of the nails from the nail bed begins at the free edge. Minor trauma to long fingernails is the most common cause.

infections also frequently weaken the nail structure, causing a nail to flake, split, or break more easily.

Artificial nails made of plastic can be used to help repair broken nails or simply to enhance the nails' appearance. However, health care workers are discouraged from using artificial nails because they tend to transmit bacterial infection more easily. In surgery patients, artificial nails obscure signs of cyanosis, which is a helpful clinical sign of oxygen deficiency.

| QUICK CHECK |

11. Identify the pigment that determines hair color.
12. List seven functions of the skin.
13. How does surface film contribute to the protective function of the skin?
14. List the appendages of the skin.

Skin Glands

The skin glands include three kinds of microscopic glands: sweat, sebaceous, and ceruminous (Figure 7-23).

SWEAT GLANDS

Sweat or **sudoriferous** (soo-doh-RIF-er-us) **glands** are the most numerous of the skin glands. They can be classified into two groups—*eccrine* and *apocrine*—based on the type of secretion, location, and nervous system connections.

Eccrine sweat glands are by far the most numerous, important, and widespread sweat glands in the body. They are small, with a secretory portion less than 0.4 mm in diameter, and are distributed over the total body surface with the exception of the lips, ear canal, glans penis, and nail beds. Eccrine sweat glands are a simple, coiled, tubular

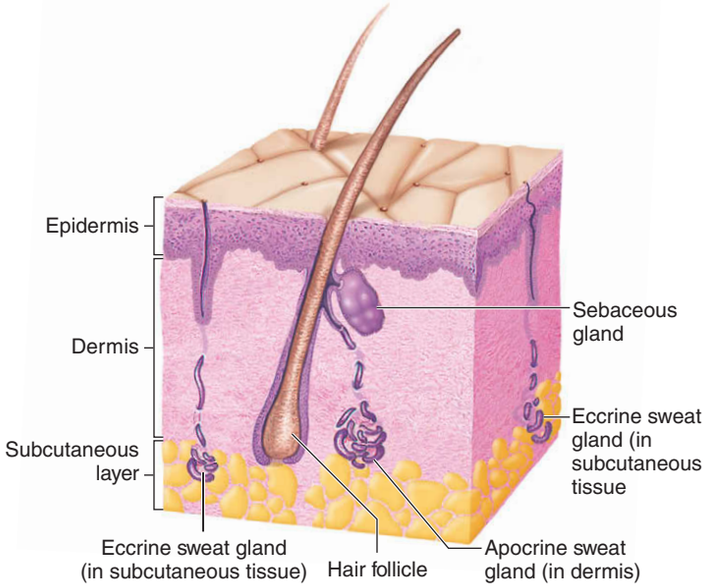

FIGURE 7-23

Skin glands. Several types of exocrine glands occur in the skin.

type of gland. They function throughout life to produce a transparent watery liquid (*perspiration*, or *sweat*) rich in salts, ammonia, uric acid, urea, and other wastes. In addition to elimination of waste, sweat plays a critical role in helping the body maintain a constant core temperature. Histologists estimate that a single square inch of skin on the palms of the hands contains about 3000 sweat glands. Eccrine sweat glands are also numerous on the soles of the feet, forehead, and upper part of the torso. With a good magnifying glass you can locate the openings of these sweat gland ducts on the skin ridges of the palms and on the skin of the palmar surfaces of the fingers. Although the ducts of eccrine glands travel through both the dermis and epidermis to open on the skin surface, the actual secretory portion is located in the subcutaneous tissue.

Apocrine sweat glands are located deep in the subcutaneous layer of the skin in the armpit (axilla), the areola of the breast, and the pigmented skin areas around the anus. They are much larger than eccrine glands and often have secretory units that reach 5 mm or more in diameter. They are connected to hair follicles and are classified as simple, branched tubular glands. Apocrine glands enlarge and begin to function at puberty; they produce a more viscous and colored secretion than eccrine glands do. In the female, apocrine gland secretions show cyclic changes linked to the menstrual cycle. The odor often associated with apocrine gland secretion is not caused by the secretion itself. Instead, it is caused by decomposition of the secretion by skin bacteria.

| A&P CONNECT |

Apocrine sweat contains a class of molecules called **pheromones,** which are signaling molecules detected by other individuals. They may be used as a territorial marker, but in humans they seem to serve mainly as social or sexual signals. Want to know more about these "sex molecules?" Check out ***Pheromones and the Vomeronasal Organ*** online at ***A&P Connect.***

evolve

SEBACEOUS GLANDS

Sebaceous glands secrete oil for the hair and skin. Wherever hairs grow from the skin, there are sebaceous glands, at least two for each hair. The oil, or **sebum,** keeps the hair supple and the skin soft and pliant. It is nature's own protective skin cream that prevents excessive water loss from the epidermis. Because sebum is rich in chemicals that have an antifungal effect, such as triglycerides, waxes, fatty acids, and cholesterol, it also contributes to reducing fungal activity on the skin surface. This property of sebum increases the effectiveness of the skin's surface film and helps protect the skin from numerous types of fungal infections. Sebaceous glands are simple branched glands of varying size that are found in the dermis, except in the skin of the palms and soles. Although almost always associated with hair follicles, some sebaceous glands do open directly onto the skin surface in such areas as the glans penis, lips, and eyelids. Sebum secretion increases during adolescence because it is stimulated by increased blood levels of sex hormones. Frequently, sebum accumulates in and enlarges some of the ducts of the sebaceous glands, thereby forming white pimples. With oxidation, this accumulated sebum darkens and forms a **blackhead.**

CERUMINOUS GLANDS

Ceruminous glands are a special variety or modification of apocrine sweat glands. Histologically, they appear as simple coiled tubular glands with excretory ducts that open onto the free surface of the skin in the external ear canal or with sebaceous glands into the necks of hair follicles in this area. The mixed secretions of sebaceous and ceruminous glands form a brown waxy substance called **cerumen.** Although it serves a useful purpose in protecting the skin of the ear canal from dehydration, excess cerumen can harden and cause blockage in the ear, resulting in loss of hearing.

| QUICK CHECK |

15. What are the two types of sweat glands? How do they differ?
16. List two functions of sebum.
17. What substances make up the skin's surface film?

Cycle of LIFE

Skin

Everyone is aware of the dramatic changes in skin that each person experiences from birth through the mature years. Infants and young children have relatively smooth and unwrinkled skin characterized by the elasticity and flexibility associated with extreme youth. Because the skin tissues are in an active phase of new growth, healing of skin injuries is often rapid and efficient. Young children have fewer sweat glands than adults do, so their bodies rely more on increased blood flow to maintain normal body temperature. This explains why preschoolers often become "red-faced" while playing outdoors on a warm day.

As adulthood begins, at puberty, hormones stimulate the development and activation of sebaceous glands and sweat glands.

Box 7-7 | HEALTH matters

Acne

Common *acne,* or *acne vulgaris,* occurs most frequently in the adolescent years as a result of overactive secretion by the sebaceous glands, with blockage and inflammation of their ducts. The rate of sebum secretion increases more than fivefold between 10 and 19 years of age. As a result, sebaceous gland ducts may become plugged with sloughed skin cells and sebum contaminated with bacteria. The inflamed plug is called a *comedo* and is the most characteristic sign of acne. Pus-filled *pimples* or *pustules* result from secondary infections within or beneath the epidermis, often in a hair follicle or sweat pore.

After the sebaceous glands become active, especially during the initial years, they often overproduce sebum and thus give the skin an unusually oily appearance. Sebaceous ducts may become clogged or infected and form acne pimples or other blemishes on the skin (Box 7-7). Activation of apocrine sweat glands during puberty causes increased sweat production—an ability needed to maintain an adult body properly—and also the possibility of increased "body odor." Body odor is caused by wastes produced by bacteria that feed on the organic compounds found in apocrine sweat and on the surface of the skin.

As one continues past early adulthood, the sebaceous and sweat glands become less active. Although this can provide a welcome relief to those who suffer from acne or other problems associated with over-activity of these glands, it can affect normal function of the body. For example, the reduction of sebum production can cause the skin and hair to become less resilient and therefore more likely to wrinkle or crack. Wrinkling can also be caused by an overall degeneration in the skin's ability to maintain itself as efficiently as it did during the early years of development (Figure 7-24). Loss of function in sweat glands as adulthood advances adversely affects the body's ability to cool itself during exercise or when the external temperature is high. Thus elderly individuals are more likely to suffer severe problems during hot weather than are young adults. Figure 7-11 shows the hyperpigmented "age spots" seen in the elderly after years of sun exposure.

FIGURE 7-24

Aged skin. In late adulthood, wrinkles in the skin often develop—especially in areas of frequent movement such as on the hands, around the mouth, and around the eyelids.

the BIG picture

Skin and the Whole Body

The skin is one of the major components of the body's structural framework. It is continuous with the connective tissues that hold the body together, including the fascia, bones, tendons, and ligaments. The integumentary, skeletal, and muscular systems work together to protect and support the whole body.

As stated several times in this chapter, the skin is a barrier that separates the internal environment from the external environment. Put another way, the skin *defines* the internal environment of the body. The barrier formed by the skin is a formidable one indeed; the skin possesses numerous mechanisms for protecting internal structures from the sometimes harsh external environment. Without these protective mechanisms, the internal environment could not maintain a relative constancy that is independent of the external environment.

First, the dermis and epidermis work together to form a tough, waterproof envelope that protects us from drying out and from the dangers of chemical or microbial contamination. The sebaceous secretions of the skin, along with other components of the skin's surface film, enhance the skin's ability to protect the internal environment. Protection against mechanical injuries is provided by hair, calluses, and the layers of the skin itself. Pigmentation in the skin and our ability to regulate its concentration protect us from the harmful effects of solar radiation.

Although its primary functions are support and protection, the skin has other important roles in maintaining homeostasis. For example, the skin is also an important agent in the regulation of body temperature—it serves as a sort of "radiator" that can be activated or deactivated as needed. It helps maintain a constant level of calcium in the body by producing vitamin D, which is necessary for normal absorption of calcium in the digestive tract. Ridges on the palms and fingers allow us to make and use tools for getting food, building shelters, and conducting other survival tasks. The skin's flexibility and elasticity permit the free movement required to perform such tasks. Sensory nerve receptors in the dermis allow the skin to be a "window on the world." Information about the external environment is relayed from skin receptors to nervous control (integration) centers, where it is used to coordinate the function of other organs.

As you continue your study of the various organ systems of the body, keep in mind that none of them could operate properly without the structural and functional assistance of the integumentary system.

MECHANISMS of DISEASE

SKIN DISORDERS

Any disorder of the skin can be called a **dermatosis,** which means "skin condition." Many dermatoses involve inflammation of the skin, or **dermatitis.** Various disorders involving the skin have already been discussed in this chapter. A few more representative disorders are described here.

Skin Infections

The skin is the first line of defense against microorganisms that might invade the body's internal environment. It is no wonder that the skin is a common site of infection. In adults, the antimicrobial characteristics of sebum in the skin's surface film often inhibit skin infections. In children, the lack of sebum in surface film makes the skin less resistant to infection.

Many different viruses, bacteria, and fungi cause skin conditions. Here are a few examples of skin infections caused by different types of pathogenic (disease-causing) organisms:

1. **Impetigo.** This highly contagious bacterial condition results from *Staphylococcus* or *Streptococcus* infection and occurs most often in young children. Impetigo starts as a reddish discoloration, or *erythema*, but soon develops into vesicles (blisters) and yellowish crusts. Occasionally, the infection becomes systemic (bodywide) and thus is life threatening.
2. **Tinea.** Tinea is the general name for many different *mycoses* (fungal infections) of the skin. Ringworm, jock itch, and athlete's foot are all classified as tinea. Signs of tinea include erythema, scaling, and crusting. Occasionally, fissures, or cracks, in the epidermis develop at creases in the epidermis. Figure 7-25 shows a case of ringworm, a tinea infection that typically forms a round rash that heals in the center to form a ring. Antifungal agents usually stop the acute infection but

FIGURE 7-25

Tinea infection (ringworm). Note that the lesions heal in the center, with inflamed rings left on the skin's surface.

are unable to completely destroy the fungus. Recurrence of tinea can be avoided by keeping the skin dry because fungi require a moist environment to grow.

3. **Warts.** Caused by papillomaviruses, warts are nipplelike neoplasms of the skin. Although they are usually benign, some warts transform to become malignant. Transmission of warts generally occurs through direct contact with warts on the skin of an infected person. Warts can be removed by freezing, drying, laser therapy, or the application of chemicals.
4. **Boils.** Also called *furuncles*, boils are local *Staphylococcus* infections of hair follicles characterized by large, inflamed, pus-filled lesions. A group of untreated boils may fuse into even larger lesions called *carbuncles.*

Vascular and Inflammatory Skin Disorders

Everyone who might ever be called on to provide care to a bedridden or otherwise immobilized individual should be aware of the causes and nature of pressure sores, or **decubitus ulcers** (Figure 7-26). *Decubitus* means "lying down," a name that hints at a common cause of pressure sores: lying in one position for long periods. Also called *bedsores*, these lesions appear after blood flow to a local area of skin slows because of pressure on skin covering bony prominences such as the ankles. Ulcers form and infections develop as lack of blood flow causes tissue damage. Frequent changes in body position and soft support cushions help prevent decubitus ulcers.

A common type of skin disorder that involves blood vessels is **urticaria,** or *hives.* This condition is characterized by raised red lesions, called *wheals*, caused by leakage of fluid from the skin's blood vessels. Urticaria is often associated with severe itching. Hypersensitivity or allergic reactions, physical irritants, and systemic diseases are common causes.

Scleroderma is an autoimmune disease that affects the blood vessels and connective tissues of the skin. The name *scleroderma* comes from the word parts *sclera-*, which means "hard," and *derma*, which means "skin." Hard skin is a good description of the lesions characteristic of scleroderma. Scleroderma begins as a mild inflammation that later develops into a patch of yellowish, hardened skin. Scleroderma most commonly remains a mild, localized condition. Very rarely, localized scleroderma progresses to a systemic form that affects large areas of the skin and other organs. Persons with advanced systemic scleroderma seem to be wearing a mask because skin hardening prevents them from moving their mouths freely. Both forms of scleroderma occur more commonly in women than in men.

FIGURE 7-26

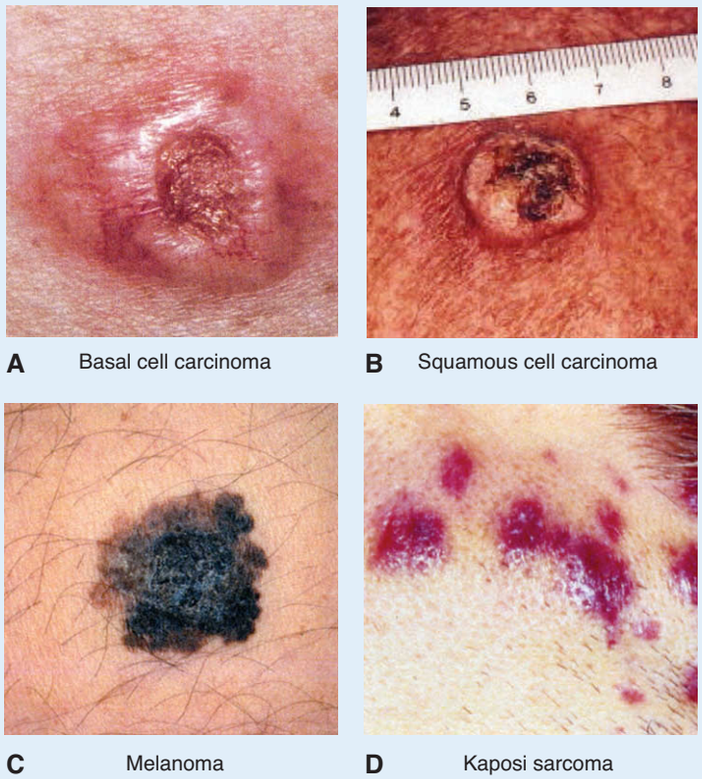
Decubitus ulcer. The skin forms crater-like lesions when the blood supply is diminished and skin tissue cannot be maintained in the area of reduced blood flow.

FIGURE 7-27

Psoriasis. Inflammation and scaling are characteristic of this skin disorder.

Psoriasis is a chronic inflammatory disorder of the skin thought to have a genetic basis. This common skin problem is characterized by cutaneous inflammation accompanied by silver-colored, scaly lesions that develop from an excessive rate of epithelial cell growth (Figure 7-27).

Eczema is the most common inflammatory disorder of the skin. This condition is characterized by inflammation often accompanied by papules (bumps), vesicles (blisters), and crusts. Eczema is not a distinct disease but rather a sign or symptom of an underlying condition. For example, an allergic reaction called *contact dermatitis* can progress to become eczematous. Poison ivy is a form of contact dermatitis—occurring on *contact* with chemicals produced by the poison ivy plant.



Skin Cancer

Each year in the United States more than 800,000 new cases of skin cancer are diagnosed. These *neoplasms*, or abnormal growths, result from cell changes in the epidermis and are the most common form of cancer in humans. They account for nearly 25% of all cancer in men and 14% of reported cases in women.

Two forms of the disease, called **basal cell carcinoma** and **squamous cell carcinoma,** account for more than 95% of all reported cases of skin cancer (Figure 7-28, *A* and *B*). Both types are very responsive to treatment and seldom *metastasize* (meh-TAS-tah-size), or spread to other body areas. However, if left untreated, these cancers can cause significant damage to adjacent tissues that results in disfigurement and loss of function.

A third type of skin cancer called **malignant melanoma** has a tendency to spread to other body areas and is a much more serious form of the disease than either the basal cell or squamous cell varieties (Figure 7-28, *C*). About 35,000 new cases of malignant melanoma are reported each year, and of that number more than 7000 die of the disease.

Kaposi (KAH-poh-see) **sarcoma** appears in immune deficiencies such as AIDS. It produces purple papules on the skin (Figure 7-28, *D*) and quickly spreads to the lymph nodes and internal organs.

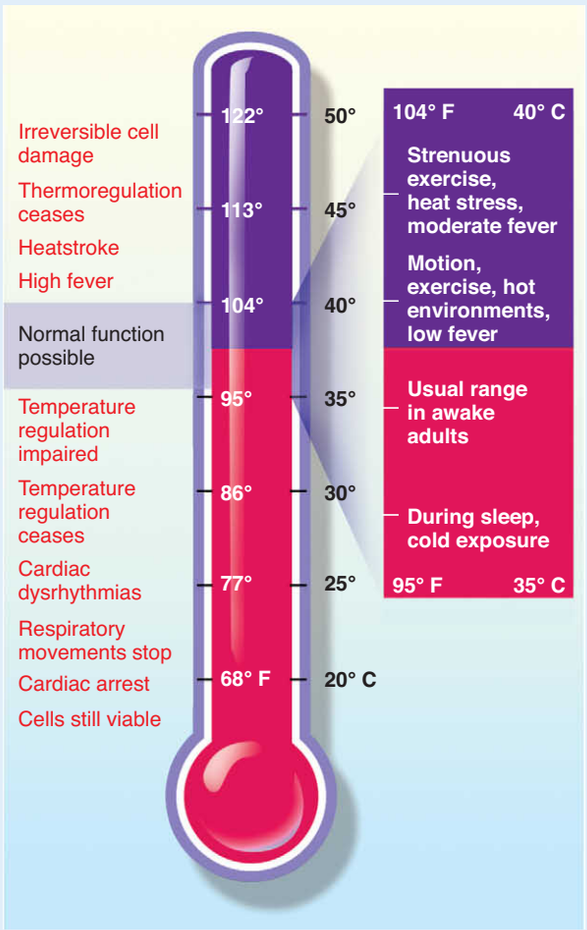

FIGURE 7-29

Body temperature. This diagram, modeled after a thermometer, shows some physiological consequences of abnormal body temperature. The inset shows a range of body temperatures at which normal function is possible. Ideally, body temperature should be near 37° C (98.6° F), but the body can operate normally within the range shown if conditions are not ideal.

How can you tell the difference between a normal mole and skin cancer? Find out at ***Skin Cancer*** online at ***A&P Connect.***

evolve

Abnormal Body Temperature

Maintenance of body temperature within a narrow range is necessary for normal functioning of the body. Figure 7-29 shows that straying too far out of the normal range of body temperatures can have very serious physiological consequences. A few important conditions related to body temperature follow:

1. **Fever,** or a *febrile* state, is an unusually high body temperature associated with a systemic inflammatory response. In the case of infections, chemicals called **pyrogens** (literally "fire makers") cause the thermostatic control centers of the hypothalamus to produce a fever. Because the body's "thermostat" is reset to a higher setting, a person feels a need to warm up to this new temperature and often experiences "chills" as the febrile state begins. The high body temperature associated with infectious fever is thought to enhance the body's immune responses to eliminate the pathogen. Strategies aimed at reducing the temperature of a febrile person are normally counteracted by the body's heat-generating mechanisms and have the effect of further weakening the infected person. Under ordinary circumstances, it is best to let the fever "break" on its own after the pathogen is destroyed.
2. **Malignant hyperthermia (MH),** an inherited condition, is characterized by abnormally increased body temperature (hyperthermia) and muscle rigidity when exposed to certain anesthetics or muscle relaxants (succinylcholine, for example). The drug *dantrolene (Dantrium)*, which inhibits heat-producing muscle contractions, has been used to prevent or relieve the effects of this condition.
3. **Heat exhaustion** occurs when the body loses a large amount of fluid from heat loss mechanisms. This usually happens when environmental temperatures are high. Although normal body temperature is maintained, the loss of water and electrolytes can cause weakness, dizziness, nausea, and possibly loss of consciousness. Heat exhaustion may also be accompanied by skeletal muscle cramps often called *heat cramps*. Heat exhaustion is treated with rest (in a cool environment) accompanied by fluid replacement.

4. **Heat stroke,** or *sunstroke,* is a severe, sometimes fatal condition resulting from the inability of the body to maintain normal temperature in an extremely warm environment. Such thermoregulatory failure may result from factors such as old age, disease, drugs that impair thermoregulation, or simply overwhelming elevated environmental temperatures. Heat stroke is characterized by body temperatures of 41° C (105° F) or higher, tachycardia (rapid heart rate), headache, and hot, dry skin. Confusion, convulsions, or loss of consciousness may occur. Unless the body is cooled and body fluids are replaced immediately, death may result.
5. **Hypothermia** is the inability to maintain normal body temperature in extremely cold environments. Hypothermia is characterized by body temperatures lower than 35° C (95° F), shallow and slow respirations, and a faint, slow pulse. Hypothermia is usually treated by slowly warming the affected person's body.
6. **Frostbite** is local damage to tissues caused by extremely low temperature. Damage to tissues results from the formation of ice crystals accompanied by a reduction in local blood flow. **Necrosis** (tissue death) and even **gangrene** (decay of dead tissue) can result from frostbite.

Burns

Typically we think of a burn as a thermal injury or lesion caused by contact of the skin with some hot object or fire. In addition, overexposure to ultraviolet light (sunburn) (Box 7-8) or contact with an electric current or corrosive chemicals causes injury or death to skin cells. The injuries that result can all be classified as *burns.*

| A&P CONNECT |

You recall from the article ***Radioactivity*** online at ***A&P Connect*** that ionizing radiation can also cause burns of the skin.

evolve

Box 7-8 | HEALTH matters

Sunburn and Skin

Burns caused by exposure to harmful UV radiation in sunlight are commonly called *sunburns.* As with any burn, serious sunburns can cause tissue damage and lead to secondary infections and fluid loss. Cancer researchers have theorized that blistering (second-degree) sunburns during childhood may trigger the development of malignant melanoma later in life. Some epidemiological studies show that adults who had more than two blistering sunburns before the age of 20 years have a greater risk for melanoma than someone who experienced no such burns. If this theory is true, it could explain the dramatic increase in skin cancer rates in the United States in recent decades. Those who grew up as sunbathing and "suntans" became popular in the 1950s, 1960s and 1970s are now, as adults, exhibiting melanoma at a much higher rate than in previous generations.

Estimating Body Surface Area

When burns involve large areas of the skin, treatment and the prognosis for recovery depend in large part on the total area involved and the severity of the burn. The severity of a burn is determined by the depth and extent (percentage of body surface burned) of the lesion. There are several ways to estimate the extent of body surface area burned. One method is called the "**rule of palms**" and is based on the assumption that the palm size of a burn victim is about 1% of the total body surface area. Therefore, estimating the number of "palms" that are burned approximates the percentage of body surface area involved.

The "**rule of nines**" (Figure 7-30) is another and more accurate method of determining the extent of a burn injury. In this technique the body is divided into 11 areas of 9% each, with the area around the genitals, called the *perineum,* representing the additional 1% of body surface area. As Figure 7-30 shows, 9% of the skin covers the head and each upper extremity, including the front and back surfaces. Twice as much, or 18%, of the total skin area covers the front and back of the trunk and each lower extremity, including the front and back surfaces. The rule of nines works well with adults but does not reflect the differences in body surface area in small children. Special tables called *Lund-Browder charts,* which take the large surface area of certain body areas (such as the head) in a growing child into account, are used by physicians to estimate burn percentages in children.

The depth of a burn injury depends on the tissue layers of the skin that are involved (Figure 7-31). A **first-degree burn** (typical sunburn) causes minor discomfort and some reddening of the skin. Although the surface layers of the burned area may peel in

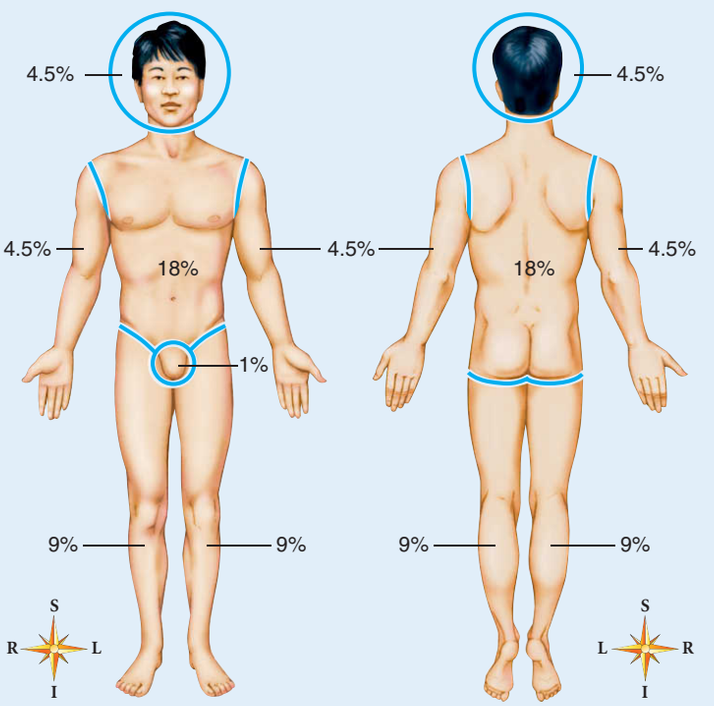

FIGURE 7-30

"Rule of nines." The "rule of nines" is one method used to estimate amount of skin surface burned in an adult.

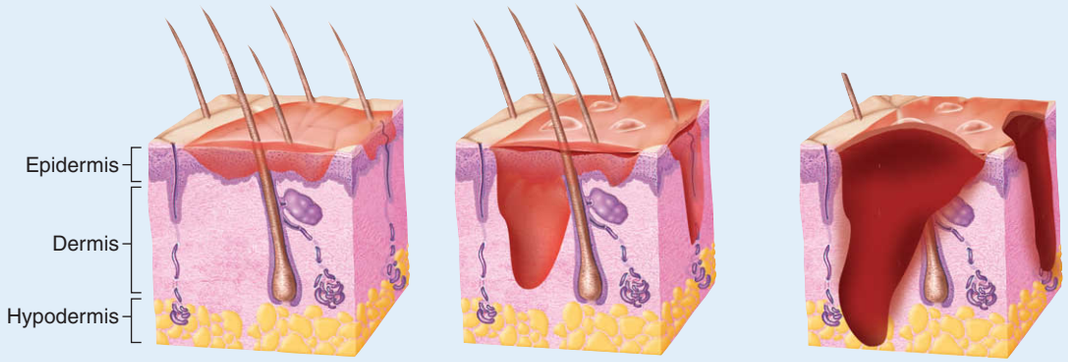

FIGURE 7-31
Classification of burns. Partial-thickness burns include first- and second-degree burns. Full-thickness burns include third-degree burns. Fourth-degree burns involve tissues under the skin, such as muscle or bone.

1 or 2 days, no blistering occurs and the actual tissue destruction is minimal. First- and second-degree burns are called **partial-thickness burns.**

Second-degree burns involve the deep epidermal layers and always cause injury to the upper layers of the dermis. In deep second-degree burns, damage to sweat glands, hair follicles, and sebaceous glands may occur, but tissue death is not complete. Blisters, severe pain, generalized swelling, and edema characterize this type of burn. Scarring is common.

Third-degree, or **full-thickness, burns** are characterized by destruction of both the epidermis and dermis. Tissue death extends below the hair follicles and sweat glands. If burning involves underlying muscles, fasciae, or bone, it may be called a **fourth-degree burn.** A distinction between second- and third- or fourth-degree burning is the fact that a third- or fourth-degree lesion is insensitive to pain immediately after injury because of the destruction of nerve endings. Scarring is a serious problem.

CASE study

One afternoon, Aidan (12 years old) was playing in his tree house. While running his fingers along the railing, he suddenly yelled, snatching his hand back off the rail. When he looked down, he saw a small sliver of wood sticking out of his middle finger. The splinter hurt, but his finger wasn't bleeding.

1. What primary layer or layers of the cutaneous membrane has the splinter gone through? (HINT: There's no bleeding.)
   a. Epidermis only
   b. Dermis only
   c. Both epidermis and dermis
   d. Stratum basale only
2. If the splinter went into Aidan's arm instead of his finger, which of these layers would the splinter NOT have pierced?
   a. Stratum corneum
   b. Stratum granulosum
   c. Stratum spinosum
   d. Stratum lucidum

This puncture has broken Aidan's intact skin barrier and now may allow bacteria or other pathogens to enter.

3. What cells will help identify these pathogens and mark them for destruction?
   a. Keratinocytes
   b. Melanocytes
   c. Dendritic cells (Langerhans cells)
   d. Lamellar (Pacinian) corpuscles

INTRODUCTION

A. Skin (integument) is body's largest organ
B. Skin measures approximately 1.6 to 1.9 m^2 in average-sized adult
C. Integumentary system describes the skin and its appendages—the hair, nails, and skin glands

STRUCTURE OF THE SKIN

A. Skin classified as a cutaneous membrane
B. Two primary layers—epidermis and dermis; joined by dermoepidermal junction (Figures 7-1 and 7-2)
C. Hypodermis lies beneath dermis
D. Thin and thick skin (Figure 7-3)
   1. "Thin skin"—covers most of body surface (1 to 3 mm thick); has hair and smooth surface
   2. "Thick skin"—soles and palms (4 to 5 mm thick); ridged surface with no hair
E. Epidermis
   1. Cell types (Figure 7-4)
      a. Keratinocytes—constitute over 90% of cells present; principal structural element of the outer skin; sometimes called *corneocytes* after they are fully keratinized
      b. Melanocytes—pigment-producing cells (5% of the total); contribute to skin color; filter ultraviolet light
      c. Epidermal dendritic cells—branched antigen-presenting cells (APCs); they play a role in immune response; also called *Langerhans cells*
      d. Tactile epithelial cells (Merkel cells)—attach to sensory nerve endings to form "light touch" receptors
   2. Cell layers
      a. Stratum basale (base layer)—single layer of columnar cells; only these cells undergo mitosis and then migrate through the other layers until they are shed; *stratum germinativum* (growth layer) is another name for stratum basale (or stratum spinosum and stratum basale together)
      b. Stratum spinosum (spiny layer)—cells arranged in 8 to 10 layers with desmosomes that pull cells into spiny shapes; cells rich in RNA
      c. Stratum granulosum (granular layer)—cells arranged in two to four layers and filled with keratohyalin granules; contain high levels of lysosomal enzymes
      d. Stratum lucidum (clear layer)—cells filled with keratin precursor called *eleidin*; absent in thin skin
      e. Stratum corneum (horny layer)—most superficial layer; dead cells filled with keratin (barrier area)
   3. Epidermal growth and repair
      a. Turnover or regeneration time refers to time required for epidermal cells to form in the stratum basale and migrate to the skin surface—about 35 days
      b. Several hormones support normal growth and repair of the epidermis: epidermal growth factor (EGF), insulin-like growth factor 1 (EGF-1), and growth hormone (GH)
      c. Shortened turnover time will increase the thickness of the stratum corneum and result in callus formation

d. Normally 10% to 12% of all cells in stratum basale enter mitosis daily
e. Each group of 8 to 10 basal cells in mitosis with their vertical columns of migrating keratinocytes is called an *epidermal proliferating unit*, or *EPU*

F. Dermoepidermal junction (DEJ)
1. A basement membrane, with unique fibrous elements, and a polysaccharide gel serve to "glue" the epidermis to the dermis below
2. The junction serves as a partial barrier to the passage of some cells and large molecules

G. Dermis
1. Sometimes called "true skin"—much thicker than the epidermis and lies beneath it
2. Gives strength to the skin
3. Serves as a reservoir storage area for water and electrolytes
4. Contains various structures
a. Arrector pili muscles and hair follicles (Figure 7-5)
b. Sensory receptors (Figure 7-6)
c. Sweat and sebaceous glands
d. Blood vessels
5. Rich vascular supply plays a critical role in temperature regulation
6. Layers of dermis
a. Papillary layer—composed of dermal papillae that project into the epidermis; contains fine collagenous and elastic fibers; contains the dermoepidermal junction; forms a unique pattern that gives individual fingerprints
b. Reticular layer—contains dense, interlacing white collagenous fibers and elastic fibers to make the skin tough yet stretchable; when processed from animal skin, produces leather
7. Dermal growth and repair
a. The dermis does not continually shed and regenerate itself as does the epidermis
b. During wound healing, fibroblasts begin forming an unusually dense mass of new connective fibers; if not replaced by normal tissue, this mass remains a scar
c. Cleavage lines (Figure 7-7)—patterns formed by the collagenous fibers of the reticular layer of the dermis; also called *Langer lines*

H. Hypodermis
1. Also called the *subcutaneous layer* or *superficial fascia*
2. Located deep to the dermis; forms connection between skin and other structures
3. Not part of the skin

SKIN COLOR

A. Melanin
1. Basic determinant is quantity, type, distribution of melanin
2. Types of melanin
a. Eumelanin—group of dark brown (almost black) melanins
b. Pheomelanin—group of reddish and orange melanins
3. Melanin formed from tyrosine by melanocytes (Figure 7-8)
a. Melanocytes release melanin in packets called *melanosomes*
b. Melanosomes are ingested by surrounding keratinocytes and form a cap over the nucleus
4. Albinism—congenital absence of melanin
5. Process regulated by tyrosinase, exposure to sunlight (UV radiation), and certain hormones, including melanocortins (ACTH, α-MSH) and ET-1 (Figures 7-9 and 7-10)
6. Cumulative effects of UV exposure may produce age spots (Figure 7-11)

B. Other pigments
1. Beta-carotene (group of yellowish pigments from food) can also contribute to skin color
2. Lipofuscin—accumulates in cells that have ceased mitosis in aging skin, producing brown-yellow age spots
3. Hemoglobin—color changes also occur as a result of changes in blood flow
a. Redder skin color when blood flow to skin increases
b. Cyanosis—bluish color caused by darkening of hemoglobin when it loses oxygen and gains carbon dioxide (Figure 7-12)
c. Bruising can cause a rainbow of different colors to appear in the skin (Figure 7-13)
4. Other pigments—from cosmetics, tattoos, bile pigments in jaundice (Box 7-4)

FUNCTIONS OF THE SKIN (TABLE 7-2)

A. Protection
1. Physical barrier to microorganisms
2. Barrier to chemical hazards
3. Reduces potential for mechanical trauma
4. Prevents dehydration
5. Protects against excess UV exposure (melanin function)

B. Surface film
1. Emulsified protective barrier formed by mixing of residue and secretions of sweat and sebaceous glands with sloughed epithelial cells from skin surface; shedding of epithelial elements is called *desquamation*
2. Functions
(1) Antibacterial, antifungal activity
(2) Lubrication
(3) Hydration of skin surface
(4) Buffer of caustic irritants
(5) Blockade of toxic agents
3. Chemical composition
(1) From epithelial elements—amino acids, sterols, and complex phospholipids
(2) From sebum—fatty acids, triglycerides, and waxes
(3) From sweat—water, ammonia, urea, and lactic and uric acid

C. Sensation
1. Skin acts as a sophisticated sense organ
2. Somatic sensory receptors detect stimuli that permit us to detect pressure, touch, temperature, pain, and other general senses

D. Flexibility
1. Skin is supple and elastic, thus permitting change in body contours without injury

E. Excretion
   1. Water
   2. Urea/ammonia/uric acid

F. Hormone (vitamin D) production (Figure 7-14)
   1. Exposure of skin to UV light converts 7-dehydrocholesterol to cholecalciferol—a precursor to vitamin D
   2. Blood transports precursor to liver and kidneys where vitamin D is produced

G. Immunity
   1. Phagocytic cells destroy bacteria
   2. Epidermal dendritic cells trigger helpful immune reaction working with "helper T cells"

H. Homeostasis of body temperature
   1. To maintain homeostasis of body temperature, heat production must equal heat loss; skin plays a critical role in this process
   2. Heat production
      a. By metabolism of foods in skeletal muscles and liver
      b. Chief determinant of heat production is the amount of muscular work being performed
   3. Heat loss—approximately 80% of heat loss occurs through the skin; remaining 20% occurs through the mucosa of the respiratory, digestive, and urinary tracts (Figure 7-15)
      a. Evaporation—to evaporate any fluid, heat energy must be expended; this method of heat loss is especially important at high environmental temperatures when it is the only method by which heat can be lost from the skin
      b. Radiation—transfer of heat from one object to another without actual contact; important method of heat loss in cool environmental temperatures
      c. Conduction—transfer of heat to any substance actually in contact with the body; accounts for relatively small amounts of heat loss
      d. Convection—transfer of heat away from a surface by movement of air; usually accounts for a small amount of heat loss
   4. Homeostatic regulation of heat loss (Figure 7-16)
      a. Heat loss by the skin is controlled by a negative feedback loop
      b. Receptors in the hypothalamus monitor the body's internal temperature
      c. If body temperature is increased, the hypothalamus sends a nervous signal to the sweat glands and blood vessels of the skin
      d. The hypothalamus continues to act until the body's temperature returns to normal

APPENDAGES OF THE SKIN

A. Hair (Figure 7-17)
   1. Development of hair
      a. Distribution—over entire body except palms of hands and soles of feet and a few other small areas
      b. Fine and soft hair coat existing before birth called *lanugo*
      c. Coarse pubic and axillary hair that develops at puberty called *terminal hair*
      d. Hair follicles and hair develop from epidermis; mitosis of cells of germinal matrix forms hairs
      e. Papilla—cluster of capillaries under germinal matrix
      f. Root—part of hair embedded in follicle in dermis
      g. Shaft—visible part of hair
      h. Medulla—inner core of hair; cortex—outer portion
   2. Appearance of hair
      a. Color—result of different amounts, distribution, types of melanin in cortex of hair (Figure 7-18)
      b. Growth—hair growth and rest periods alternate; hair on head averages 5 inches of growth per year
      c. Sebaceous glands—attach to and secrete sebum (skin oil) into follicle
      d. Male pattern baldness (androgenic alopecia) results from combination of genetic tendency and male sex hormones (Figure 7-19)

B. Nails (Figure 7-20)
   1. Consist of epidermal cells converted to hard keratin
   2. Nail body—visible part of each nail
   3. Root—part of nail in groove hidden by fold of skin, the cuticle
   4. Lunula—moon-shaped white area nearest root
   5. Nail bed—layer of epithelium under nail body; contains abundant blood vessels
      a. Appears pink under translucent nails
      b. Nails may have pigmented streaks (Figure 7-21)
      c. Separation of a nail from the nail bed is called *onycholysis* (Figure 7-22)
   6. Growth—nails grow by mitosis of cells in stratum basale beneath the lunula; average growth about 0.5 mm per week, or slightly over 1 inch per year

C. Skin glands (Figure 7-23)
   1. Two types of sweat glands
      a. Eccrine glands
         (1) Most numerous sweat glands; quite small
         (2) Distributed over total body surface with exception of a few small areas
         (3) Simple, coiled, tubular glands
         (4) Function throughout life
         (5) Secrete perspiration or sweat; eliminate wastes and help maintain a constant core temperature
      b. Apocrine glands
         (1) Located deep in subcutaneous layer
         (2) Limited distribution—axilla, areola of breast, and around anus
         (3) Large (often more than 5 mm in diameter)
         (4) Simple, branched, tubular glands
         (5) Begin to function at puberty
         (6) Secretion shows cyclic changes in female with menstrual cycle
   2. Sebaceous glands
      a. Secrete sebum—oily substance that keeps hair and skin soft and pliant; prevents excessive water loss from skin
      b. Lipid components have antifungal activity

c. Simple, branched glands
d. Found in dermis except in palms and soles
e. Secretion increases in adolescence; may lead to formation of pimples and blackheads

3. Ceruminous glands
a. Modified apocrine sweat glands
b. Simple, coiled, tubular glands
c. Empty contents into external ear canal alone or with sebaceous glands
d. Mixed secretions of sebaceous and ceruminous glands called *cerumen* (wax)
e. Function of cerumen to protect area from dehydration; excess secretion can cause blockage of ear canal and loss of hearing

CYCLE OF LIFE: SKIN

A. Children
1. Skin is smooth, unwrinkled, and characterized by elasticity and flexibility
2. Few sweat glands
3. Rapid healing

B. Adults
1. Development and activation of sebaceous and sweat glands
2. Increased sweat production; can result in body odor
3. Increased sebum production; can result in acne

C. Old age
1. Decreased sebaceous and sweat gland activity
a. Wrinkling (Figure 7-24)
b. Decrease in body's ability to cool itself

THE BIG PICTURE: SKIN AND THE WHOLE BODY

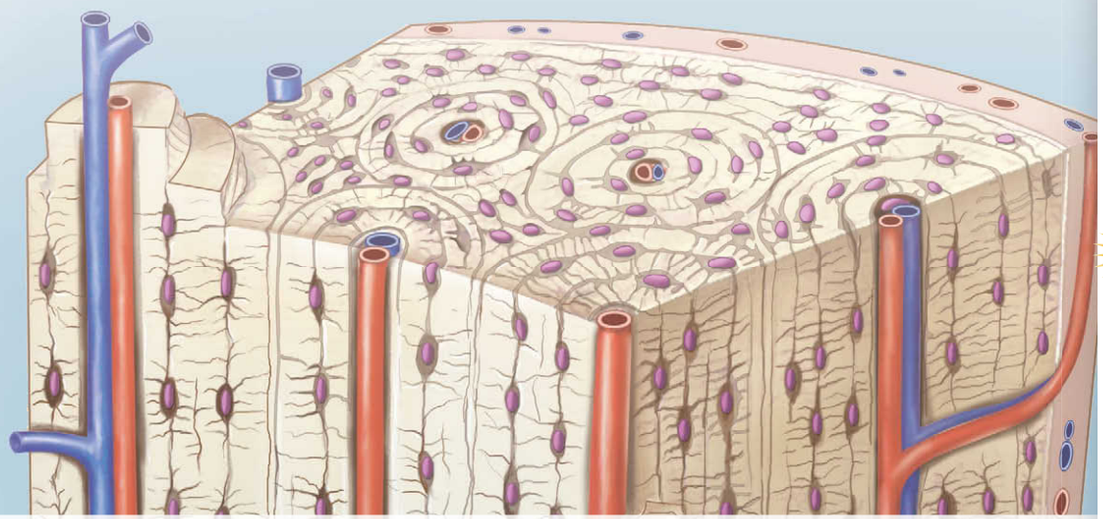
A. Skin is a major component of the body's structural framework
B. Skin defines the internal environment of the body
C. Primary functions are support and protection

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. List and briefly discuss several of the different functions of the skin.
2. List three cell types found in the epidermis.
3. List and describe the cell layers of the epidermis from superficial to deep.
4. What layer of the epidermis is sometimes called the *barrier area?*
5. Discuss the process of epidermal growth and repair.
6. What is keratin? Where is it found and how is it formed?
7. What part of the skin contains blood vessels?
8. Why is the process of blister formation a good example of the relationship between the skin's structure and function?
9. List the two layers of the dermis. Which layer helps make the skin stretchable and able to rebound?
10. What are arrector pili muscles?
11. List the appendages of the skin.
12. Identify each of the following: hair papilla, germinal matrix, hair root, hair shaft, follicle.
13. List the three primary types of skin glands.
14. What is the difference between eccrine and apocrine sweat glands?
15. Discuss the importance of the surface film of the skin.
16. How is the "rule of nines" used in determining the extent of a burn injury?
17. What are the differences between first-, second-, and third-degree burns?

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. The stratum corneum, hair follicle, nails, sweat glands, oil glands, and stratum basale are all discussed in this chapter. Can you make a distinction regarding whether these structures are part of the integumentary system only or both the integumentary system and the integument?
2. Identify what affects the thickness of the skin (dermis and epidermis). What is the relationship between what affects the thickness of the skin and the thickness of the hypodermis?
3. What is the dermoepidermal junction (DEJ)? By analyzing its anatomical components, what inference can you make regarding how it functions?
4. In terms of leaving a less noticeable scar, why should an incision on the front of the thigh be made at a different angle than an incision on the back of the thigh?
5. Concern about skin cancer is causing people to reduce the amount of time they spend in the sun. If this caution is carried to the extreme, explain how it would impact skin function?
6. Explain why a light-skinned individual would be more susceptible to malignant melanoma?
7. An individual running a marathon expends a great deal of energy. Much of this energy generates heat, which increases core body temperature. What is the role of sweat glands in balancing body temperature during this strenuous exercise? With this loss of fluid, what suggestions do you have for avoiding dehydration?

continued on p. 218

*This is the first of three chapters on the skeletal system, or more simply, the skeleton (Figure 8-1). This chapter focuses mainly on two highly adapted types of connective tissues that make up the skeleton—*bone *and* cartilage. *We also briefly discuss the fibrous connective, blood, nervous, epithelial, lymphatic, marrow, and fatty tissues found in the skeleton.*

Chapter 9 then goes on to discuss the overall organization of the skeleton. Individual bones, which are considered separate, discrete organs, are also discussed in Chapter 9. Then Chapter 10 outlines the articulations, *or joints. Articulations are the points of contact between bones that either stabilize the parts of the skeleton or make movement possible.*

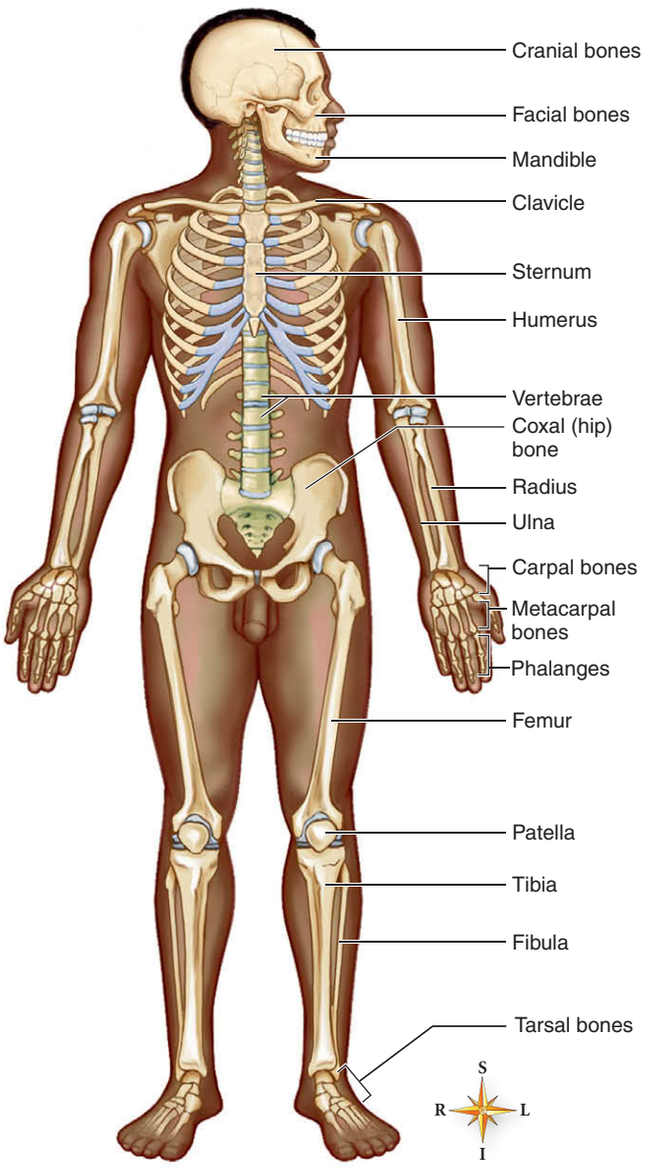

FIGURE 8-1
The skeleton.

FUNCTIONS OF BONE

A good place to begin a study of the skeletal system is with the overall functions of its organs, the bones and ligaments. **Ligaments** are fibrous bands that help hold the various bones together into an organized skeleton. **Bones** are rigid, mineralized structures that help perform five major roles in the body. Each is important for maintaining overall stability of the body's internal environment, or homeostasis.

1. **Support.** Bones serve as the supporting framework of the body, much as steel girders are the supporting framework of our modern buildings. They contribute to the shape, alignment, and positioning of the body parts. Bones are held in place by ligaments, muscles, and other structures.
2. **Protection.** Hard, bony "boxes" serve to protect the delicate structures they enclose. For example, the skull protects the brain, and the rib cage protects the lungs and heart. You can also use the bones of your arm to help defend against injuries to the face or abdomen.
3. **Movement.** Bones along with their joints constitute levers. Muscles are anchored firmly to bones. As muscles contract and shorten, they pull on bones, thereby producing movement at a joint. This process is discussed further in Chapter 10.
4. **Mineral storage.** Bones serve as the major reservoir for calcium, phosphorus, and certain other minerals. Homeostasis of the blood calcium concentration—essential for healthy survival—depends largely on changes in the rate of calcium movement between blood and bones. If, for example, the blood calcium concentration increases above normal, calcium moves more rapidly out of blood into bones and more slowly in the opposite direction. The result? Blood calcium concentration decreases—usually to its homeostatic level. Hormonal control of blood calcium is discussed further in Chapter 19.
5. **Hematopoiesis.** *Hematopoiesis*, or blood cell formation, is a vital process carried on by red bone marrow, or *myeloid tissue*. Myeloid tissue, in the adult, is located primarily in the ends, or epiphyses, of certain long bones, in the flat bones of the skull, in the pelvis, and in the sternum and ribs. The process of hematopoiesis is discussed further in Chapter 20.

TYPES OF BONES

Structurally, a simple way to categorize the 206 or more bones of the skeleton is by shape. Usually they are divided into five categories: long bones, short bones, flat bones, irregular bones, and sesamoid bones. Figure 8-2 shows an example of each type. The size,

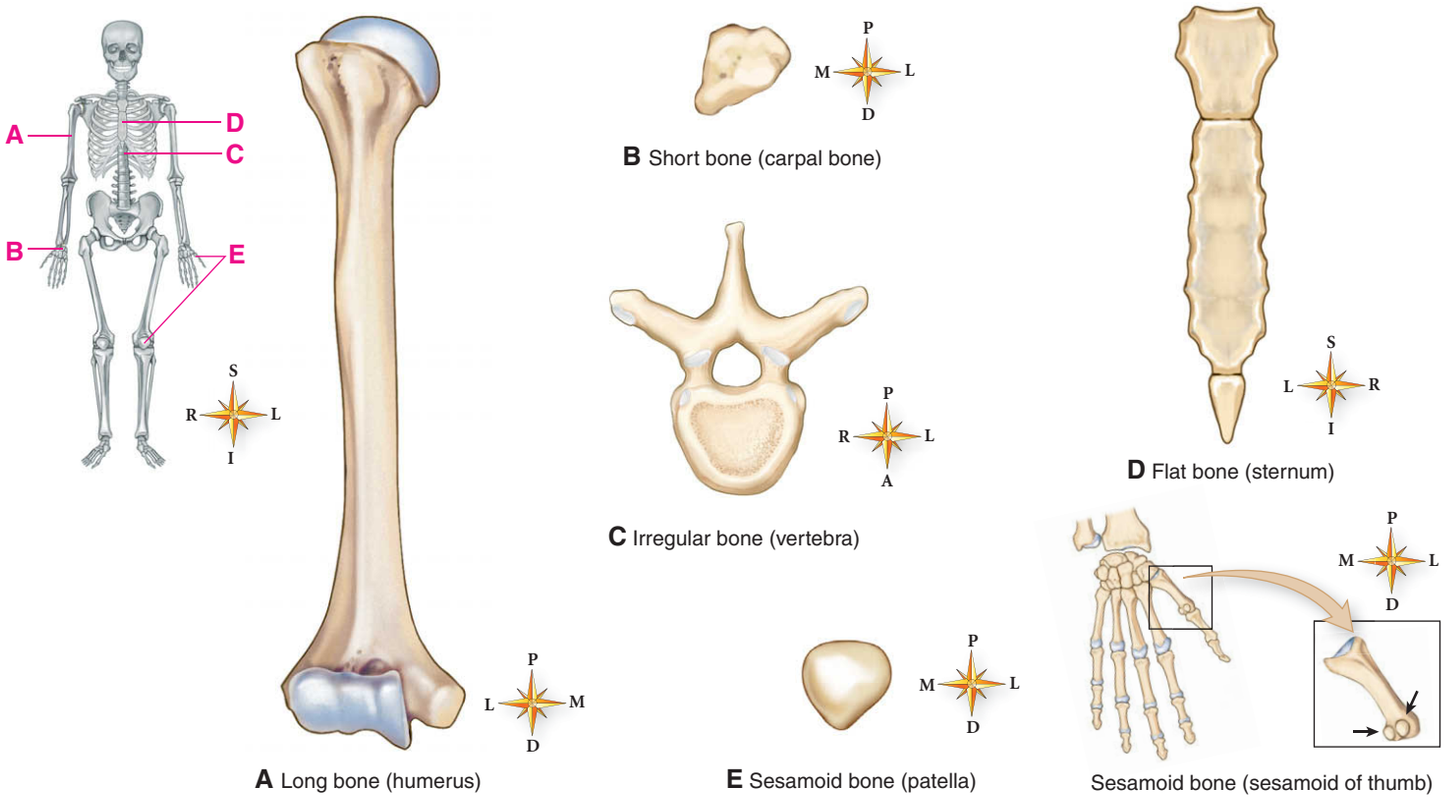

FIGURE 8-2

Types of bones. Examples of bone types include **A,** long bones (humerus); **B,** short bones (carpal bone); **C,** irregular bones (vertebra); **D,** flat bones (sternum); and **E,** sesamoid bones (patella and sesamoid of thumb).

shape, and appearance of bones vary according to the role of each bone in the skeleton. Some bones must bear great weight; others serve a protective function or serve as delicate support structures, such as for the fingers and toes.

Bones differ in size and shape and also in the amount and proportion of the two different types of bone tissue that compose them. **Compact bone** is dense and "solid" in appearance. **Cancellous bone,** on the other hand, is characterized by open space with a network of thin, branched crossbeams. Recall from Chapter 6 that cancellous bone is also called *spongy bone* or *trabecular bone*. Both compact and cancellous bone types are discussed when the microscopic structure of bone is described later in the chapter.

All five shape categories of bone discussed below have varying amounts of cancellous and compact bone in their structure.

Long bones are easily identified by their roughly cylindrical shape that is longer than it is wide. They also have enlarged and often uniquely shaped ends that articulate with other bones. The femur of the thigh and humerus of the arm are examples. Other examples include the radius, ulna, tibia, fibula, metacarpal bones, metatarsal bones, and phalanges.

Short bones are often described as cube- or box-shaped structures that are about as broad as they are long. Examples include each of the wrist (carpal) and ankle (tarsal) bones.

Flat bones are generally broad and thin with a flattened and often curved surface. Certain bones of the skull, the shoulder blades (scapulae), ribs, and breastbone (sternum) are typical flat bones.

Irregular bones are often clustered in groups and come in various sizes and shapes. The vertebral bones that form the spine and the facial bones of the skull are good examples.

Sesamoid bones, which are sometimes grouped with the irregular bones, often appear singly rather than in groups. The name comes from "sesame seed" because these bones often resemble sesame seeds in size and shape. The number of sesamoid bones in the body can be many or only a few—the number and size vary from one person to the next. Sesamoid bones usually develop in the tendons close to the joints. The patella (kneecap) is the largest sesamoid bone—one of the few that consistently appear in the human skeleton.

| QUICK CHECK |

1. Name the two major types of connective tissue found in the skeletal system.
2. Name the two different types of bone tissue.

Parts of a Long Bone

A long bone consists of the following structures visible to the naked eye: diaphysis, epiphyses, articular cartilage, periosteum, medullary (marrow) cavity, and endosteum. Identify each of these structures in the tibia shown in Figure 8-3, *A*. The tibia is the longer, stronger, and more medially located of the two leg bones.

1. **Diaphysis** (dye-AF-i-sis)—main shaftlike portion. Its hollow, cylindrical shape and the thick compact bone that composes it adapt the diaphysis well to its function of providing strong support without adding cumbersome weight.
2. **Epiphyses** (eh-PIF-i-seez)—the proximal and distal ends of a long bone. Epiphyses have a bulbous shape that provides generous space near joints for muscle attachments and also gives stability to joints. Look at Figure 8-3 to note the innumerable small spaces in the bone of the epiphysis. They make this kind of bone look a little like a sponge—hence its name spongy, or cancellous, bone. A soft connective tissue called *red marrow* fills the spaces within this spongy bone. Early in development, epiphyses are separated from the diaphysis by a layer of cartilage, the *epiphyseal plate*. The cartilage layer is eventually replaced by bone, forming an *epiphyseal line*. The region between the epiphyses and diaphysis (in a mature bone) or the epiphyseal plate region (in a growing bone) is called the *metaphysis* (meh-TAF-i-sis).
3. **Articular cartilage**—thin layer of hyaline cartilage that covers the articular or joint surfaces of epiphyses. The resiliency of this material cushions jolts and blows.
4. **Periosteum** (pair-ee-OS-tee-um)—dense, white fibrous membrane that covers bone except at joint surfaces, where articular cartilage forms the covering. Many of the periosteum fibers penetrate the underlying bone and weld these two structures to each other. In addition, muscle tendon fibers interlace with periosteal fibers, thereby anchoring muscles firmly to bone. The periosteum is a critically important membrane that, depending on its location, also contains

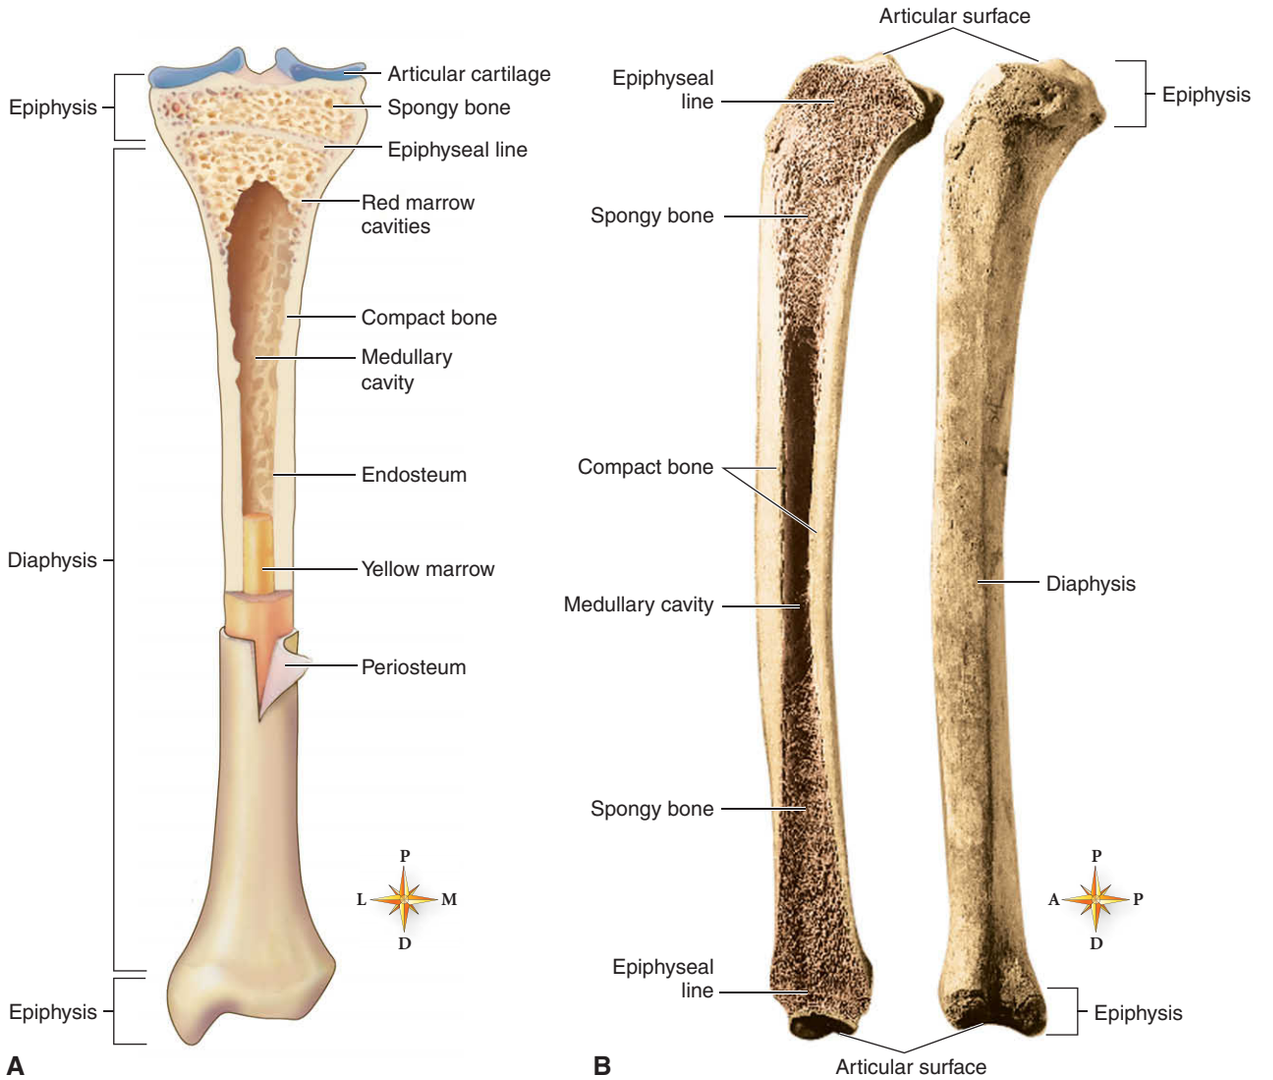

FIGURE 8-3

Long bone. A, Partial frontal section of a long bone (tibia) showing cancellous and compact bone. **B,** Sagittal section of a long bone with a whole long bone (tibia) in lateral view.

bone-forming and bone-destroying cells and blood vessels that become incorporated into bones during their initial growth or subsequent remodeling and repair. This important membrane is essential for bone cell survival and for bone formation, a process that continues throughout life.

5. **Medullary cavity**—a tubelike hollow space in the diaphysis of a long bone, also called a *marrow cavity*. In the adult the medullary cavity is filled with connective tissue rich in fat—a substance called *yellow marrow*.
6. **Endosteum** (en-DOS-tee-um)—a thin fibrous membrane that lines the medullary cavity of long bones. The endosteum lines the spaces of spongy bone as well. Like the periosteum, the endosteum has various types of bone cells and the stem cells that produce them.

Parts of Flat Bones and Other Bones

The structure of the flat bone is very similar to that of a long bone, but simpler. As you can see in Figure 8-4, a flat bone of the cranium has outer and inner walls made of compact bone. These hard walls are called the **internal table** and **external table.** Between is a region called the **diploe,** which is made up of cancellous bone. Other flat bones, such as the ribs and sternum, have a similar overall structure. Like long bones, flat bones are covered in a periosteum and the inner spaces are lined with endosteum.

Red marrow fills the spaces of the cancellous bone inside many flat bones. The sternum, which contains red marrow even in adulthood, is one example. To help in the diagnosis of leukemia and certain other diseases, a physician may decide to perform a needle puncture of one of these bones. In this type of diagnostic procedure, a needle is inserted through the skin and compact bone into the red marrow, and a small amount of the marrow is then aspirated and examined under the microscope for evidence of normal or abnormal blood cells. The procedure, called *aspiration biopsy cytology (ABC)*, is discussed on p. 619.

Short bones, irregular bones, and sesamoid bones all have features similar to those of flat bones.

BONE TISSUE

Bone tissue, sometimes called *osseous tissue*, is perhaps the most distinctive form of connective tissue in the body. It is typical of other connective tissues in that it consists of cells, fibers, and extracellular material, or *matrix*. However, its extracellular components are hard and *calcified*. In bone the extracellular material, or matrix, predominates. It is much more abundant than the bone cells, and it contains many fibers of collagen (the body's most abundant protein). The rigidity of bone enables it to serve supportive and protective functions.

As a tissue, bone is ideally suited to its functions. You can easily see the concept that structure and function are interrelated in bone tissue! It has a tensile strength nearly equal to that of cast iron but at less than one third the weight. Bone is organized so that its great strength and minimal weight result from the interrelationships of its structural components. The relationship of structure to function is seen all the way through the chemical, cellular, tissue, and organ levels of organization.

Composition of Bone Matrix

The extracellular matrix (ECM) of bone, or **bone matrix,** can be subdivided into two principal chemical components: *inorganic salts* and *organic matrix*. About two thirds of the matrix by dry weight analysis consists of inorganic salts and one third, organic material. You may find it helpful to review the section describing the unique characteristics of ECM in Chapter 6 on p. 134 and illustrated in Figure 6-1 on the same page.

INORGANIC SALTS

The calcified nature and thus the hardness of bone result from the deposition of rocklike crystals of calcium and phosphate. Chemists call them *hydroxyapatite* crystals. The process of forming these crystals within a softer tissue is called *calcification*. The tiny, needlelike hydroxyapatite crystals make up about 85% of

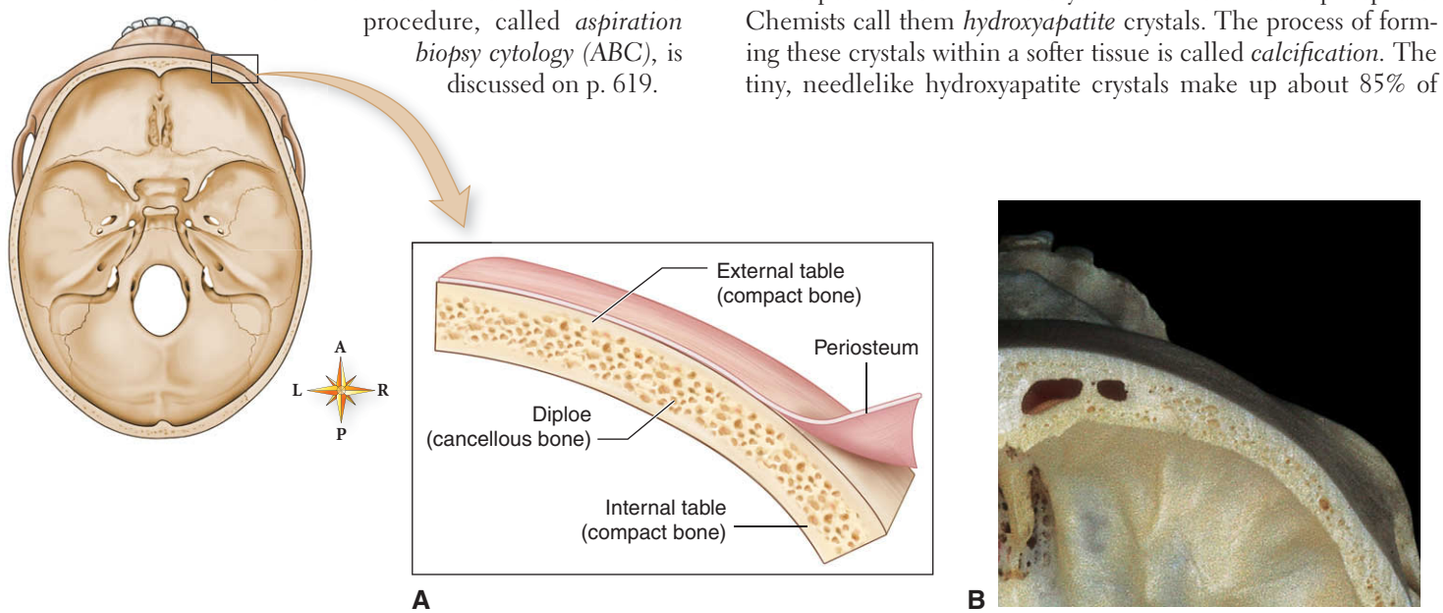

FIGURE 8-4

Flat bone. A, Horizontal section of a flat bone of the skull (frontal bone) showing cancellous and compact bone. **B,** Photograph of a frontal bone cut in horizontal section.

the total inorganic matrix and are found oriented in the microscopic spaces between collagen fibers so that they can most effectively resist stress and mechanical deformation. In addition to hydroxyapatite and about 10% calcium carbonate, other mineral constituents such as magnesium, sodium, sulfate, and fluoride are also found in bone. Unfortunately, harmful elements can become incorporated into bone matrix as well and result in loss of normal function or active disease. For example, radioactive elements such as radium, strontium-90, uranium, or plutonium can become concentrated in bone and continue to emit radiation, which can lead to various types of cancer and other serious disease.

evolve

ORGANIC MATRIX

The organic matrix of bone and other connective tissues is a composite of collagenous fibers and a mixture of protein and polysaccharides called *ground substance*. Connective tissue cells secrete the gel-like ground substance. The ground substance of bone provides support and adhesion between cellular and fibrous elements and also serves an active role in many cellular metabolic functions necessary for growth, repair, and remodeling.

Chondroitin sulfate and **glucosamine** are the names of chemical substances that many people recognize as components of over-the-counter dietary supplements. Taken alone or together they are widely thought to facilitate healing and reduce the "wear and tear" pain of osteoarthritis. However, research has yet to fully support that claim. Chondroitin sulfate and glucosamine are found naturally in the body and are important constituents of the ground substance in both bone and cartilage. Chemically, chondroitin sulfate is a large protein molecule that helps cartilage remain compressible and elastic and may slow its destruction. Glucosamine is an amino sugar important in cartilage formation, maintenance, and repair. Go back to Figure 6-1 (p. 134) to see how such molecules are incorporated into the ECM of a tissue.

Components of the organic matrix help cartilage maintain a smooth surface and springy consistency. They add to overall strength and also give bone some degree of plasticlike resilience so that applied stress—within reasonable limits—does not result in frequent crush or fracture injuries.

| QUICK CHECK |

3. List the six structural components of a typical long bone that are visible to the naked eye.
4. Identify the two principal chemical components of bone matrix.
5. Why is it important that cartilage in the skeleton have some "give" or spring to it?

MICROSCOPIC STRUCTURE OF BONE

The basic structural components and cell types of bone were described briefly in Chapter 6. In the paragraphs that follow, additional information about bone structure and cell types will serve as a basis for learning the functional characteristics of this important tissue. Understanding how a bone forms and grows, how it repairs itself after injury, and how it interacts with other tissues and organs in maintaining various important homeostatic mechanisms is based on a knowledge of its basic structure—a structure as unique as its chemical composition.

Compact Bone

Compact bone constitutes about 80% of the total bone mass in the adult human body. It contains many cylinder-shaped structural units called **osteons** (AHS-tee-onz), or *Haversian systems*. Note in Figure 8-5 that each osteon surrounds a **central canal** that runs lengthwise through the bone. Living bone cells in these units are literally cemented together to constitute the structural framework of compact bone. The unique structure of the osteon permits delivery of nutrients and removal of waste products from metabolically active, but imprisoned, bone cells.

Several simple structures make up each osteon: lamellae, lacunae, canaliculi, and a central canal. As you read the following descriptions, identify each structure in Figure 8-5.

Lamellae *(lah-MEL-ee)*. *Concentric lamellae* are cylinder-shaped layers of calcified matrix in the osteon. Lamellae (layers) of hard bone matrix are also present outside the osteon. *Interstitial lamellae* are layers of calcified matrix between osteons. They are the remnants of older osteons that have been altered by bone growth or remodeling. A few layers of bone matrix also run around the outer boundary of compact bone, encircling all the osteons. These layers that run along the inner circumference (along the endosteum) and outer circumference (along the periosteum) of a bone are called *circumferential lamellae*.

Lacunae *(lah-KOO-nay)*. These are small spaces in bone matrix that contain tissue fluid and in which bone cells lie imprisoned between the hard layers of the lamellae.

Canaliculi *(kan-ah-LIK-yoo-lye)*. These ultra-small canals radiate in all directions from the lacunae and connect them to each other and to a larger canal, the central canal.

Central canal. Also called an *osteonal canal* or *Haversian canal*, the central canal extends lengthwise through the center of each osteon. The central canal is lined with endosteum and contains blood vessels, lymphatic vessels, and nerves. Nutrients and oxygen move from the central canal through canaliculi to the lacunae and their bone cells—a short distance of about 0.1 mm or less.

Parallel central canals are connected to each other by **transverse canals** (*Volkmann canals*). These communicating canals contain nerves and vessels that carry blood and lymph from the exterior surface of the bone to the osteons.

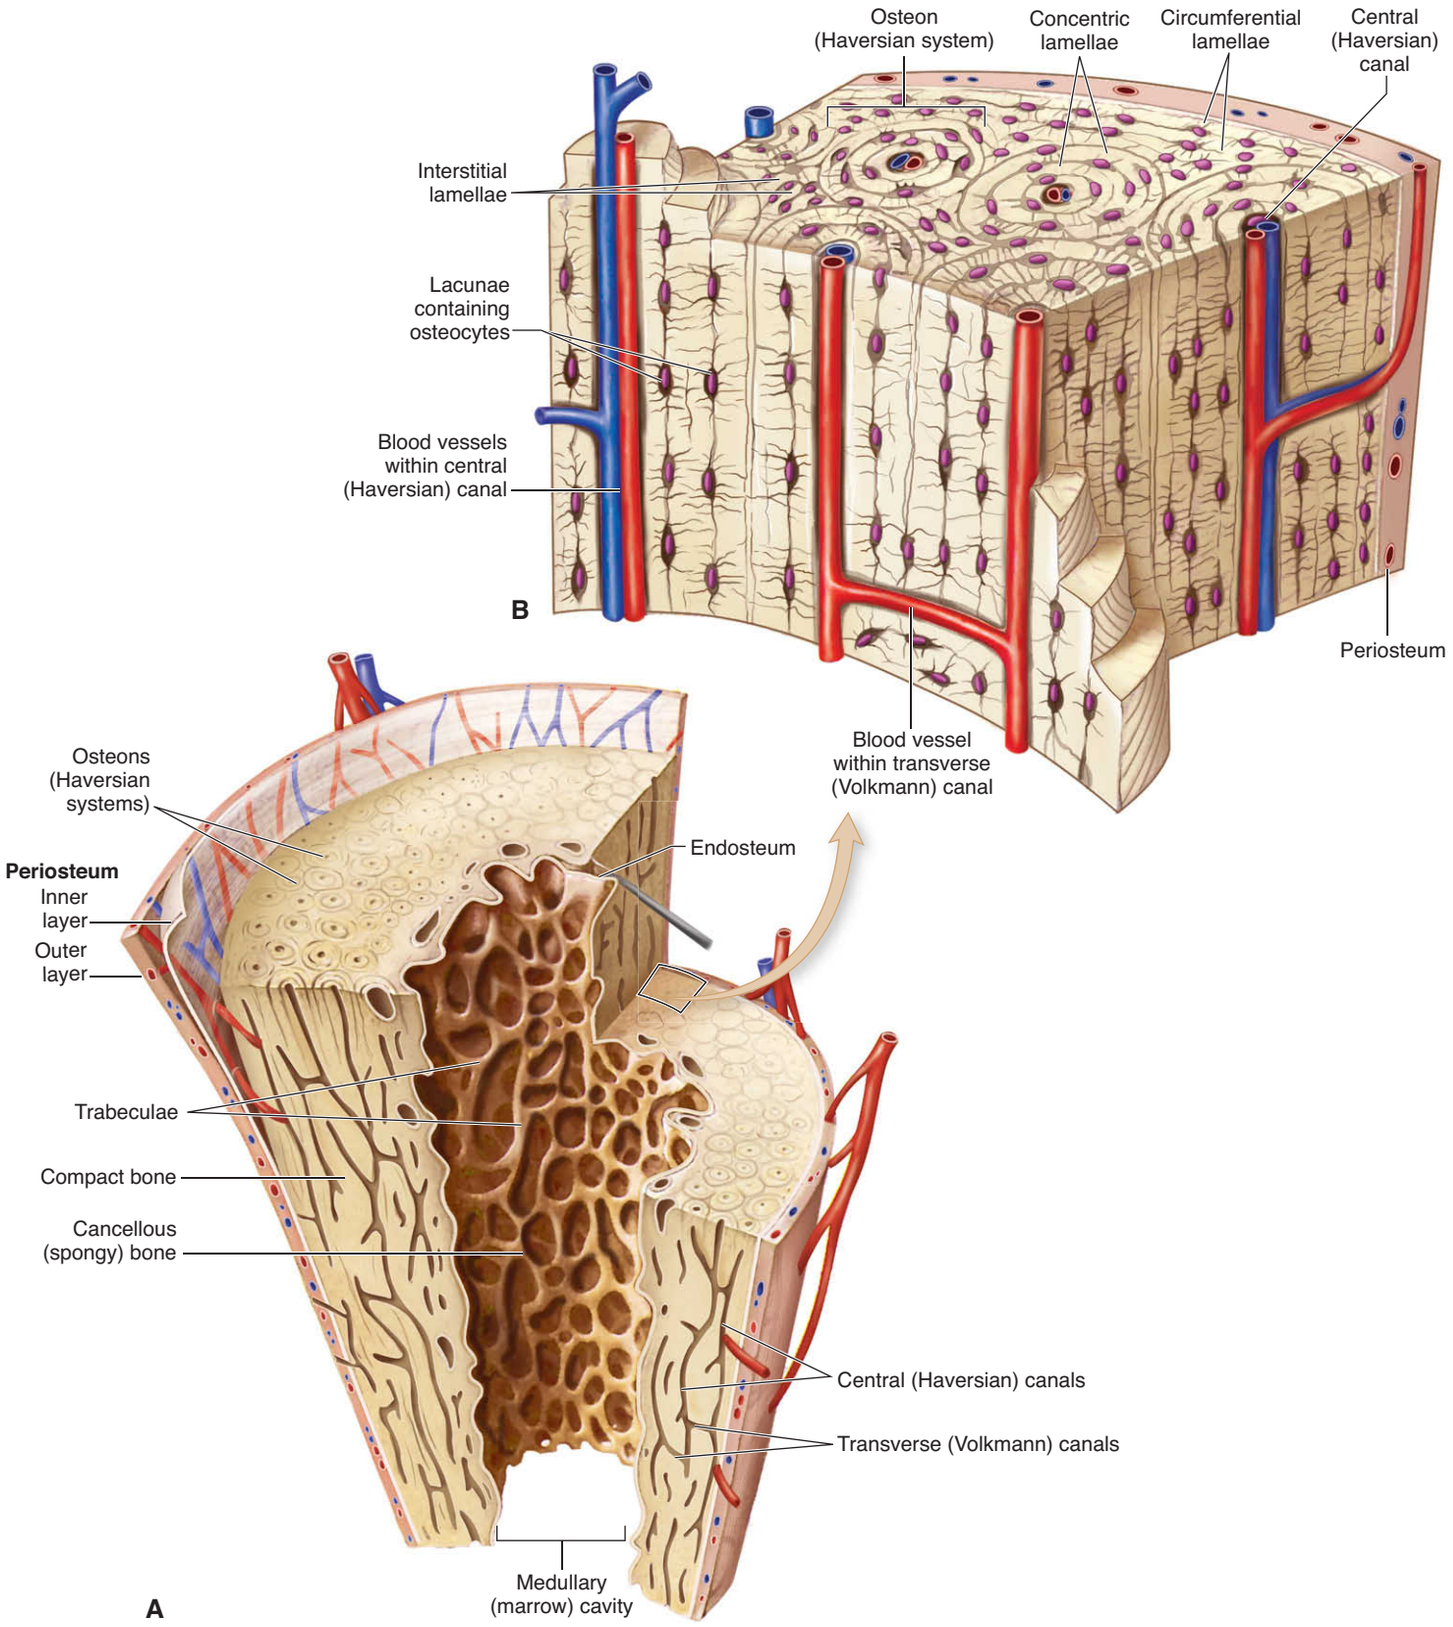

FIGURE 8-5

Compact and cancellous bone in a long bone. A, Longitudinal section of a long bone showing both cancellous and compact bone. **B,** Magnified view of compact bone.

Cancellous Bone

Cancellous, or spongy, bone constitutes about 20% of the total bone mass and differs in microscopic structure from compact bone. As you recall, the structural unit of compact bone is the highly organized osteon. There are no osteons in cancellous bone. Instead, it consists of crisscrossing bony branches called **trabeculae.** Bone cells are found within the trabeculae. Nutrients are delivered to the cells and waste products are removed by diffusion through tiny canaliculi that extend to the surface of the very thin bony branches. Cancellous bone is often called **trabecular bone.**

Note that the cancellous bone shown in Figure 8-6 lies between two layers of compact bone, much like the filling in a sandwich. Recall that the middle layer of spongy bone is called the *diploe*. This layered organization is typical of flat bones such as those found in the skull. Cancellous bone is also found inside short and irregular bones, as well as inside the epiphyses (see Figure 8-3) and lining the medullary cavities of long bones (see Figure 8-5, A).

The placement of trabeculae in spongy bone is not as random and unorganized as it might first appear. They are *fractal* in nature, meaning that they appear random, but there is really an underlying, complex organization to them. The bony branches are actually arranged along lines of stress, and their size and orientation will therefore differ between individual bones according to the nature and magnitude of the applied load (Figure 8-7). This feature greatly enhances a bone's strength and is yet another example of the relationship between structure and function.

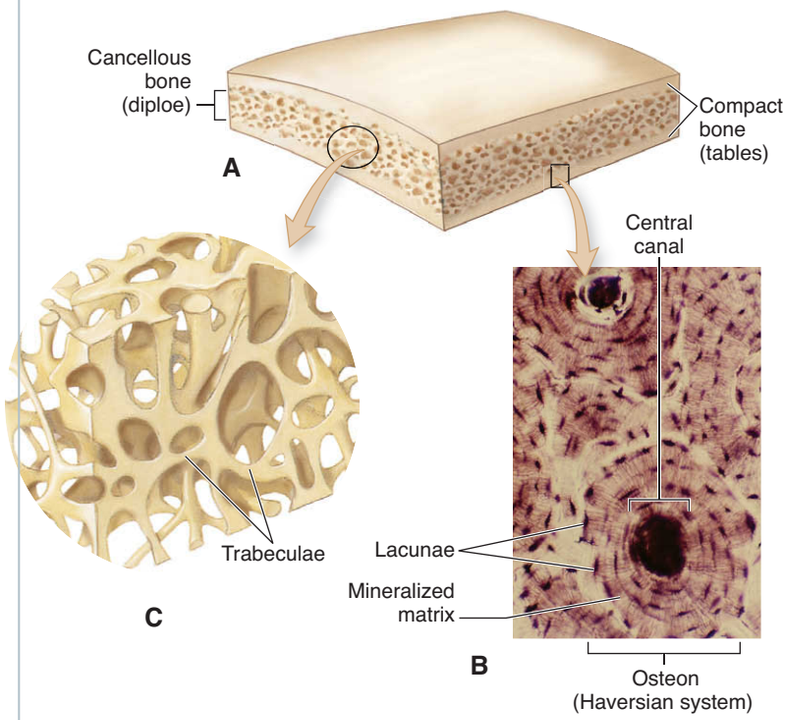

FIGURE 8-6

Compact and cancellous bone in a flat bone. A, Section of a flat bone. (See also Figure 8-4.) Outer layers of compact bone surround cancellous bone. Note the fine structure of compact **(B)** and cancellous **(C)** bone.

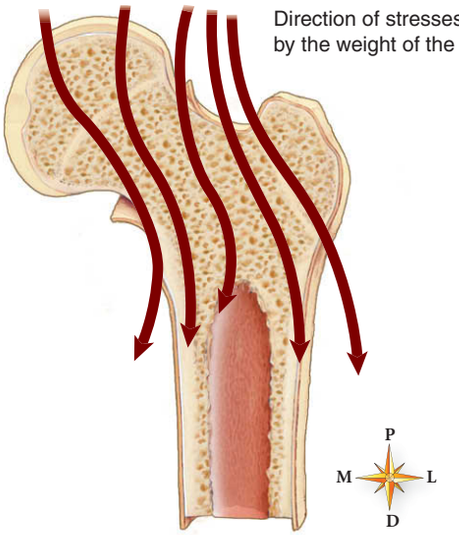

FIGURE 8-7

Orientation of trabeculae. Longitudinal section of a long bone showing trabeculae oriented along lines of stress.

Locked within a seemingly lifeless calcified matrix, bone cells are active metabolically. They must, like all living cells, continually receive food and oxygen and excrete their wastes, so blood supply to bone is both important and abundant. One or more arteries supply the bone marrow in the internal medullary cavity and provide nutrients to areas of cancellous bone. In addition, blood vessels from the periosteum, when they eventually become covered by new bone in the development process, become incorporated into the bone itself and then, by way of the transverse canals and by connections with other vessels in adjacent osteons, ultimately serve the nutrient needs of cells that, because of their own secretions, have become surrounded by calcified matrix in compact bone. The mechanism by which periosteal blood vessels become "imprisoned" by the deposition of new bone during growth and remodeling is described later in this chapter.

| QUICK CHECK |

6. Identify the main structures that form the osteon.
7. Name the canals that connect blood vessels between adjacent, parallel osteons.
8. Name the tiny branches of hard bone present in cancellous bone.

Types of Bone Cells

Three major types of cells are found in bone: *osteoblasts* (bone-forming cells), *osteoclasts* (bone-reabsorbing cells), and *osteocytes* (mature bone cells). All bone surfaces are covered with a continuous layer of cells that is critical to the survival of bone. This layer is composed of relatively large numbers of osteoblasts interspersed with a much smaller population of osteoclasts.

Osteoblasts (OS-tee-oh-blasts) are small cells that synthesize and secrete an organic matrix called *osteoid*. Collagen strands in the osteoid serve as a framework for the formation of hydroxyapatite

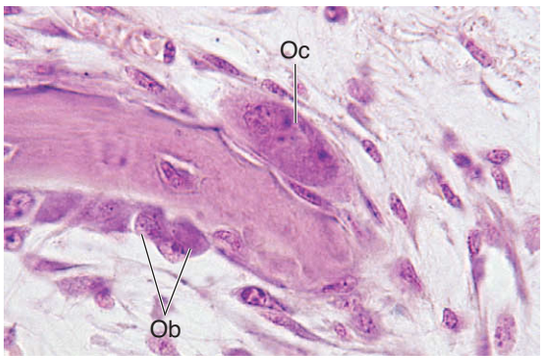

FIGURE 8-8

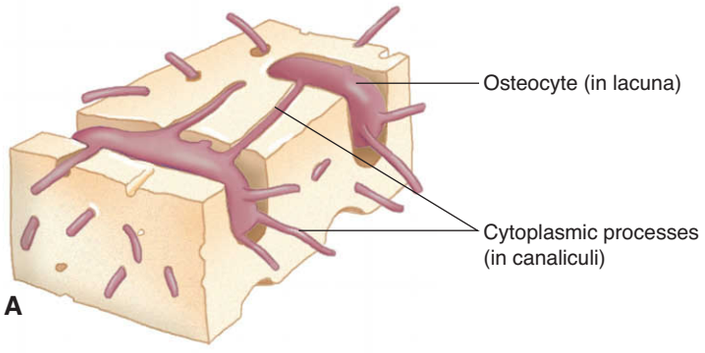
Bone-forming and bone-eroding cells. Note the large multinucleate osteoclast cell *(Oc)* dissolving bone on the upper surface of a developing branch of bone while smaller osteoblast cells *(Ob)* on the undersurface of the bone are secreting new osteoid.

crystals, which mineralizes the bone tissue. *Osteogenic* (os-tee-oh-JEN-ik) *stem cells*, found in the endosteum and lining the central canals, undergo cell division to form osteoblasts.

Osteoclasts (OS-tee-oh-klasts) are giant multinucleate cells (Figure 8-8) that are responsible for the active erosion of bone minerals. They are formed by the fusion of several precursor cells and contain large numbers of mitochondria and lysosomes. Each 24-hour period sees an alternation of primarily osteoblast, then osteoclast activity. Note in Figure 8-8 how a branchlike piece of bone is being "sculpted" by an osteoclast eroding existing bone mineral from its upper surface while osteoblasts are simultaneously depositing new osteoid on its under surface. As minerals are dissolved during bone erosion, they are reabsorbed back into the blood, their original source.

The process of bone formation and reabsorption characterizes bone as a dynamic tissue that undergoes continuous change and remodeling.



Osteocytes (OS-tee-oh-sytes) are mature, nondividing osteoblasts that have become surrounded by matrix and now lie within lacunae. Figure 8-9 includes an illustration and a scanning electron micrograph showing a mature osteocyte within a lacuna. Note that a cytoplasmic process from the cell is extending into a canaliculus below. Cytoplasmic processes from neighboring cells are connected by gap junctions, which allow the cells to share water and nutrients. Numerous collagen fibers are seen in the ground substance and mineralized bone surrounding the osteocyte.

The way in which these cell types work together to produce bone is described in detail when the development of bone is discussed later in this chapter.

BONE MARROW

Bone marrow is a type of soft, diffuse connective tissue called **myeloid tissue.** It serves as the site for production of blood cells and is found in the medullary cavities of certain long bones and in the spaces of spongy bone in some areas (Figure 8-10).

During the lifetime of an individual, two types of marrow exist. In an infant's or child's body, virtually all of the bones contain *red marrow*. This is named for its function in the production of red blood cells. As an individual ages, the red marrow is gradually replaced

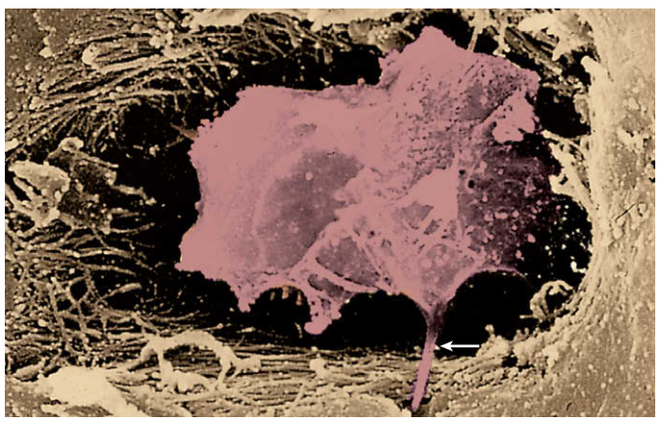


FIGURE 8-9

Osteocyte. A, Sketch showing osteocytes trapped inside hollow lacunae within hard bone matrix. **B,** Scanning electron micrograph showing an osteocyte within a lacuna. Note the cytoplasmic process *(arrow)* extending into a canaliculus below. The cell is surrounded by collagen fibers and mineralized bone.

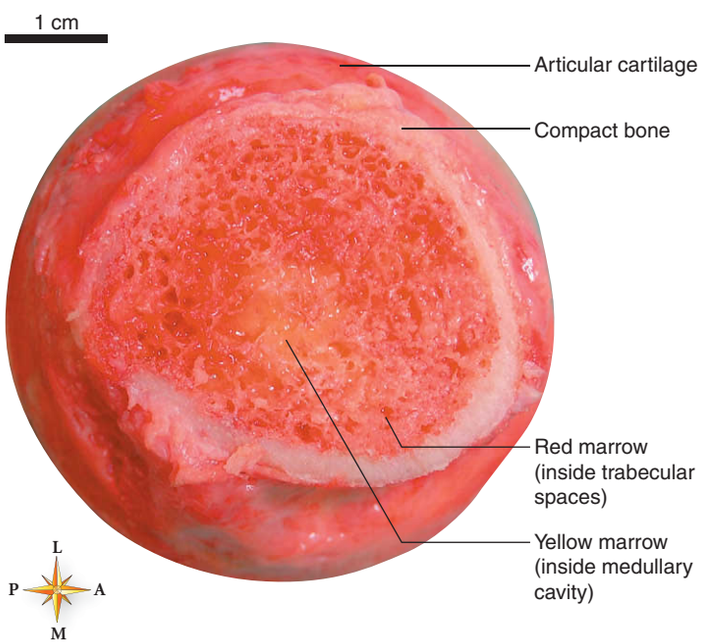

FIGURE 8-10

by *yellow marrow*. In yellow marrow, the increasing population of *adipocytes* (fat cells) begins to replace hemopoietic stem cells. The adipocytes also signal the remaining stem cells to reduce blood cell production. With advancing age, yellow marrow becomes almost rust-colored, less fatty, and more gelatinous in consistency.

The main bones in an adult that still contain red marrow include the ribs, bodies of the vertebrae, and ends of the humerus in the upper part of the arm, the pelvis, and the femur, or thigh bone. During times of decreased blood supply, yellow marrow in an adult can alter to become red marrow. Such a transition may occur during periods of prolonged anemia caused by chronic blood loss, exposure to radiation or toxic chemicals, and certain diseases.

If the bone marrow is severely diseased or damaged, a **bone marrow transplant** can be a lifesaving treatment. In this procedure, red marrow from a compatible donor is introduced into the recipient intravenously. If the recipient's immune system does not reject the new tissue, which is always a danger in tissue transplants, the donor cells may establish a colony of new, healthy tissue in the bone marrow.

REGULATION OF BLOOD CALCIUM LEVELS

The bones of the skeletal system serve as a storehouse for about 98% of the body calcium reserves. As the major reservoir for this physiologically important body mineral, bones play a key role in maintaining the constancy of blood calcium levels. To maintain homeostasis of blood calcium levels within a very narrow range, calcium is mobilized and moves into and out of blood during the continuous remodeling of bone. It is the balance between deposition of bone by osteoblasts and breakdown and reabsorption of bone matrix by osteoclasts that helps regulate blood calcium levels. During bone formation, osteoblasts serve to remove calcium from blood, thus lowering its circulating levels. However, when osteoclasts are active and breakdown of bone predominates, calcium is released into blood and circulating levels will increase.

Homeostasis of the calcium ion concentration is essential not only for bone formation, which is described below, but also for normal blood clotting, transmission of nerve impulses, and maintenance of skeletal and cardiac muscle contraction. The primary homeostatic mechanisms involved in the regulation of blood calcium levels involve the secretion of two hormones: (1) *parathyroid hormone (PTH)* by the parathyroid glands and (2) *calcitonin (CT)* by the thyroid gland.

Mechanisms of Calcium Homeostasis

PARATHYROID HORMONE

The actions of parathyroid hormone are fully discussed in Chapter 19. However, the importance of this hormone as the primary regulator of calcium homeostasis and its effect on bone remodeling call for a brief description here. When the level of calcium in blood passing through the parathyroid glands decreases below its normal homeostatic "set point" level, osteoclasts are stimulated to initiate increased breakdown of bone matrix, which results in the release of calcium into blood and the return of calcium levels to normal (Figure 8-11). In addition, parathyroid hormone also increases renal absorption of calcium from urine, thus reducing its loss from the body.

Another effect of parathyroid hormone is to stimulate vitamin D synthesis, which increases the efficiency of absorption of calcium from the intestine. If blood passing through the parathyroid glands has an elevated calcium level, osteoclast activity will be suppressed, thus reducing the breakdown of bone matrix and the level of calcium circulating in blood. The multiple effects of this type of hormonal control permit the body to precisely regulate a number of homeostatic mechanisms that have an effect both directly and indirectly on the blood levels of this important mineral.

Parathyroid hormone is the most critical factor in homeostasis of blood calcium levels. As a result of its actions and the ability of the body to regulate its formation and release, bones remain strong and calcium levels are maintained within normal limits during both bone formation and bone reabsorption.

CALCITONIN

Calcitonin, also discussed in Chapter 19, is a protein hormone produced by endocrine cells in the thyroid gland. It is produced in response to high blood calcium levels and functions to stimulate bone deposition by osteoblasts and inhibit osteoclast activity. As a result, calcium will move into the bones from the blood and circulating levels will decrease. Nasal spray containing calcitonin is available to treat postmenopausal osteoporosis.

Although calcitonin does play a role in the homeostasis of blood calcium levels, it is far less important than parathyroid hormone.

OTHER MECHANISMS

Additional regulatory mechanisms also play a role in calcium homeostasis by affecting mineral storage in the bone. For example, *growth hormone (GH)* secreted from the anterior pituitary gland stimulates the development of new bone and can thus reduce calcium in the blood. On the other hand, the neurotransmitter *serotonin* produced in the nerves of the gut may act as a

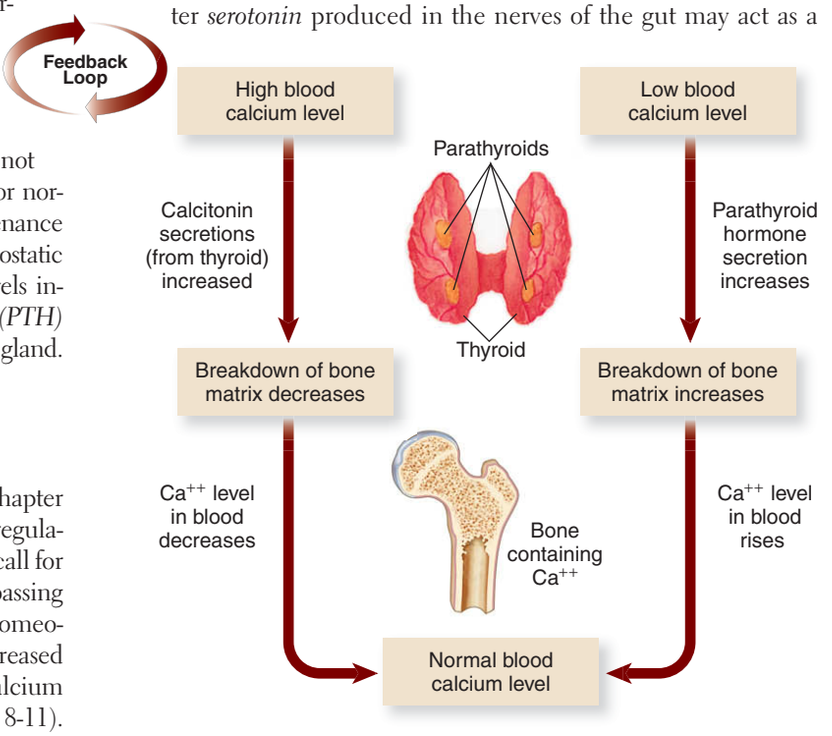

FIGURE 8-11

Calcium homeostasis. Calcitonin and parathyroid hormones have antagonistic (opposing) effects that help to maintain a homeostatic balance of calcium in the blood.

hormone to inhibit osteoblast activity and thus raise blood calcium level. Research also shows that osteoblasts themselves are able to monitor extracellular calcium levels and react to changes.

DEVELOPMENT OF BONE

When the skeleton begins to form in an infant before birth, it consists not of bones but of cartilage and fibrous structures shaped like bones. Gradually, these cartilage "models" become transformed into real bones when the cartilage is replaced with calcified bone matrix. This process of constantly "remodeling" a growing bone as it changes from a small cartilage model to the characteristic shape and proportion of the adult bone requires continuous activity by the bone-forming osteoblasts and bone-resorbing osteoclasts. The laying down of calcium salts in the gel-like matrix of the forming bones is an ongoing process. This calcification process is what makes bones as "hard as bone." The combined action of osteoblasts and osteoclasts sculpts bones into their adult shape. The term **osteogenesis** is used to describe this process.

"Sculpting" by the bone-forming and bone-resorbing cells allows bones to respond to stress or injury by changing size, shape, and density. The stress placed on certain bones during exercise increases the rate of bone deposition. For this reason, athletes or dancers may have denser, stronger bones than less active people.

Most bones of the body are formed from cartilage models in a process called **endochondral ossification,** meaning "bone formation in cartilage." A few flat bones are formed within fibrous membrane, rather than cartilage, in the process of **intramembranous ossification.** Figure 8-12 illustrates osseous development of an infant at birth.

| A&P CONNECT |

Patterns of bone-forming activity in the skeleton often can be visualized with a *bone scan.* To see a bone scan image and learn how it is produced, check out ***Bone Scans*** online at ***A&P Connect.***

evolve

Intramembranous Ossification

Intramembranous ossification takes place, as its name implies, within a connective tissue membrane. The flat bones of the skull, for example, begin to take shape when groups of osteogenic stem cells within the membrane differentiate into osteoblasts. These clusters of osteoblasts are called **ossification centers.** They secrete matrix material and collagenous fibrils. The Golgi apparatus in an osteoblast specializes in synthesizing and secreting carbohydrate compounds of the type called *mucopolysaccharides,* and its endoplasmic reticulum makes and secretes collagen, a protein. In time, relatively large amounts of the mucopolysaccharide substance, or *ground substance,* accumulate around each osteoblast. Numerous bundles of collagenous fibers then become embedded in the ground substance. Together, the ground substance and collagenous fibers constitute the organic bone matrix. Calcification of the organic bone matrix occurs when complex calcium salts are deposited in it.

As calcification of bone matrix continues, the trabeculae appear and join in a network to form spongy bone (Figure 8-13).

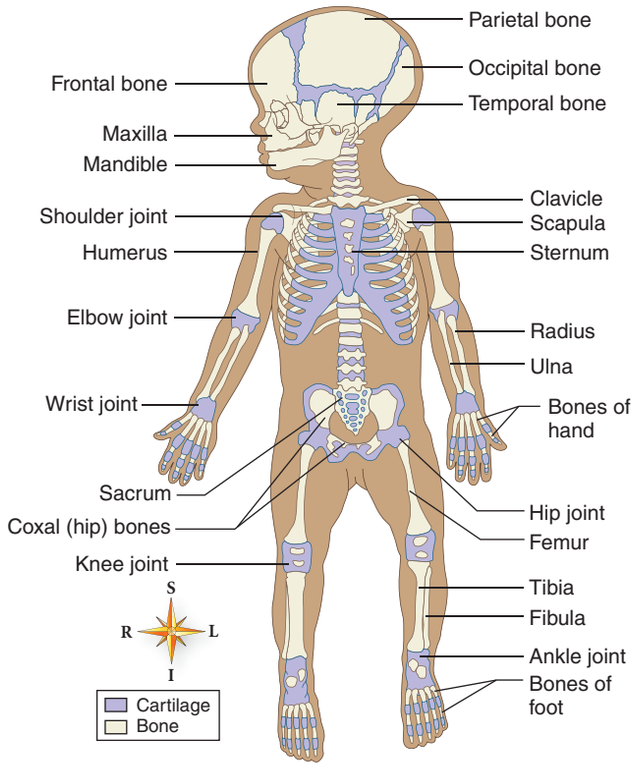

FIGURE 8-12

Bone development. Diagram showing osseous development at birth.

In time the core layer of spongy bone (diploe) will be covered on each side by plates of compact, or dense, bone. Once formed, a flat bone grows in size by the addition of osseous tissue to its outer surface. The process is called **appositional growth.** Flat bones cannot grow by interior expansion as is the case with endochondral bone growth described in the following section.

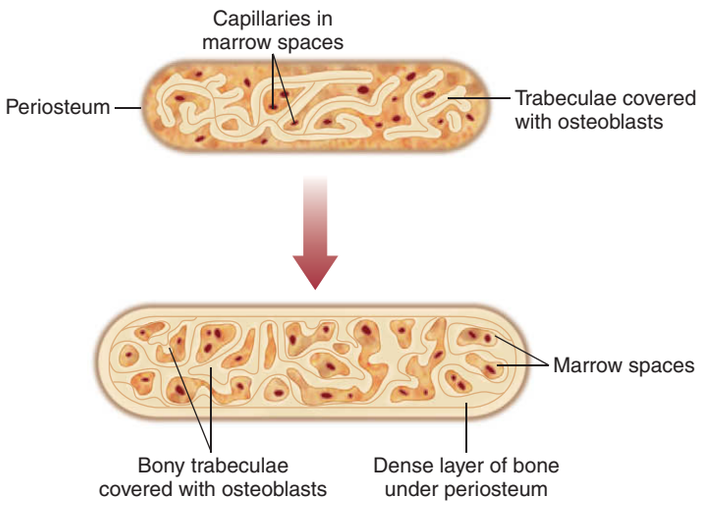

FIGURE 8-13

Intramembranous bone formation. Layers of bone matrix build up to form a lattice of branched trabeculae forming the diploe of a flat bone. Eventually, a layer of compact bone forms under the periosteum to form the tables of a flat bone. Compare to Figure 8-6.

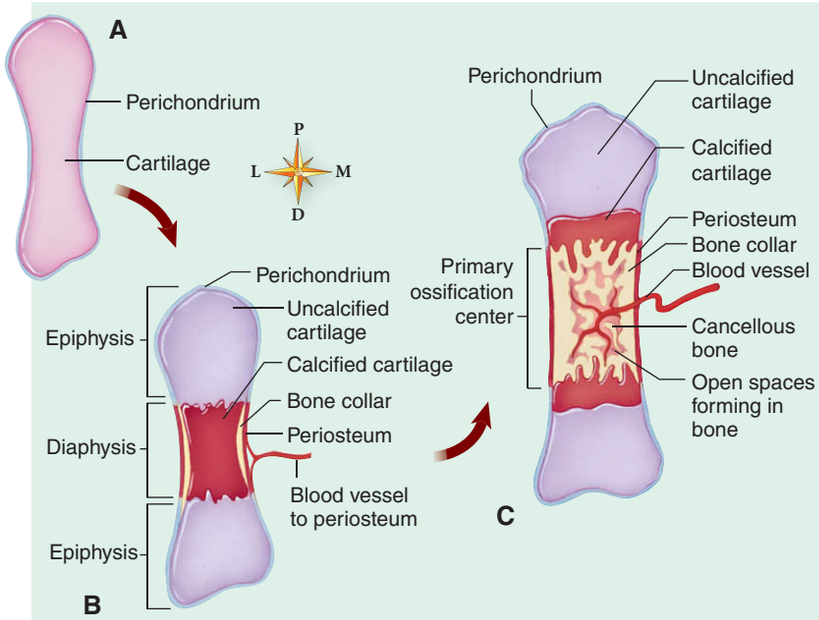

FIGURE 8-14

Endochondral bone formation. A, Cartilage model. **B,** Bone collar formation under the periosteum. **C,** Development of the primary ossification center and entrance of a blood vessel. **D,** Prominent medullary cavity with thickening and lengthening of the collar. **E,** Development of secondary ossification centers in epiphyseal cartilage. **F,** Enlargement of secondary ossification centers, with bone growth proceeding toward the diaphysis from each end. **G,** With cessation of bone growth, the lower, then upper epiphyseal plates disappear (only the epiphyseal lines remain).

Endochondral Ossification

Most bones of the body are formed from cartilage models, with bone formation spreading essentially from the center to the ends. The steps of endochondral ossification are illustrated in Figure 8-14. The cartilage model of a typical long bone, such as the tibia, can be identified early in embryonic life (Figure 8-14, *A*). The cartilage model then develops a periosteum (Figure 8-14, *B*) that soon enlarges and produces a ring, or collar, of bone. Bone is deposited by osteoblasts, which differentiate from cells on the inner surface of the covering periosteum. Soon after appearance of the ring of bone, the cartilage begins to calcify (Figure 8-14, *C*), and a **primary ossification center** forms when a blood vessel enters the rapidly changing cartilage model at the midpoint of the diaphysis. Endochondral ossification progresses from the diaphysis toward each epiphysis (Figure 8-14, *D*), and the bone grows in length. The process is called *interstitial growth.* Eventually, **secondary ossification centers** appear in the epiphyses (Figure 8-14, *E*), and bone growth proceeds toward the diaphysis from each end (Figure 8-14, *F*).

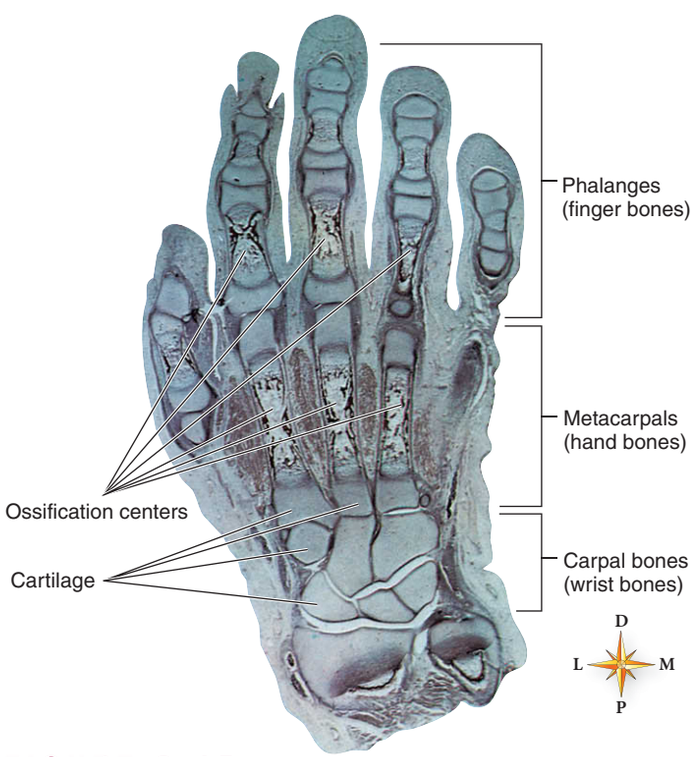
Until bone growth in length is complete, a layer of the cartilage, known as the **epiphyseal plate,** remains between each epiphysis and the diaphysis. During periods of growth, proliferation of epiphyseal cartilage cells brings about a thickening of this layer. Ossification of the additional cartilage nearest the diaphysis follows—that is, osteoblasts synthesize organic bone matrix, and the matrix undergoes calcification (Figure 8-15). As a result, the bone becomes longer (Figure 8-16). It is the epiphyseal plate that allows the diaphysis of a long bone to increase in length.

The epiphyseal plate shown in Figure 8-17 is composed of four layers of cells. The top layer of cells closest to the epiphysis is composed of "resting" cartilage cells. These cells are not proliferating or undergoing change. This layer serves as a point of attachment firmly joining the outer end, or epiphysis, of a bone to the shaft.

The second layer of cells shown in Figure 8-17 is called the *proliferating zone.* It is composed of cartilage cells that are undergoing active mitosis. As a result of mitotic division and increased cellular activity, the layer thickens and the plate as a whole increases in length (Figure 8-18).

The third layer of cells, called the *zone of hypertrophy*, is composed of older, enlarged cells that are undergoing degenerative changes associated with calcium deposition.

The layer closest to the diaphysis is a thin layer composed of dead or dying cartilage cells undergoing rapid calcification. As the process of calcification progresses, this layer becomes fragile and disintegrates. The resulting space is soon filled with new bone tissue, and the bone as a whole grows in length.



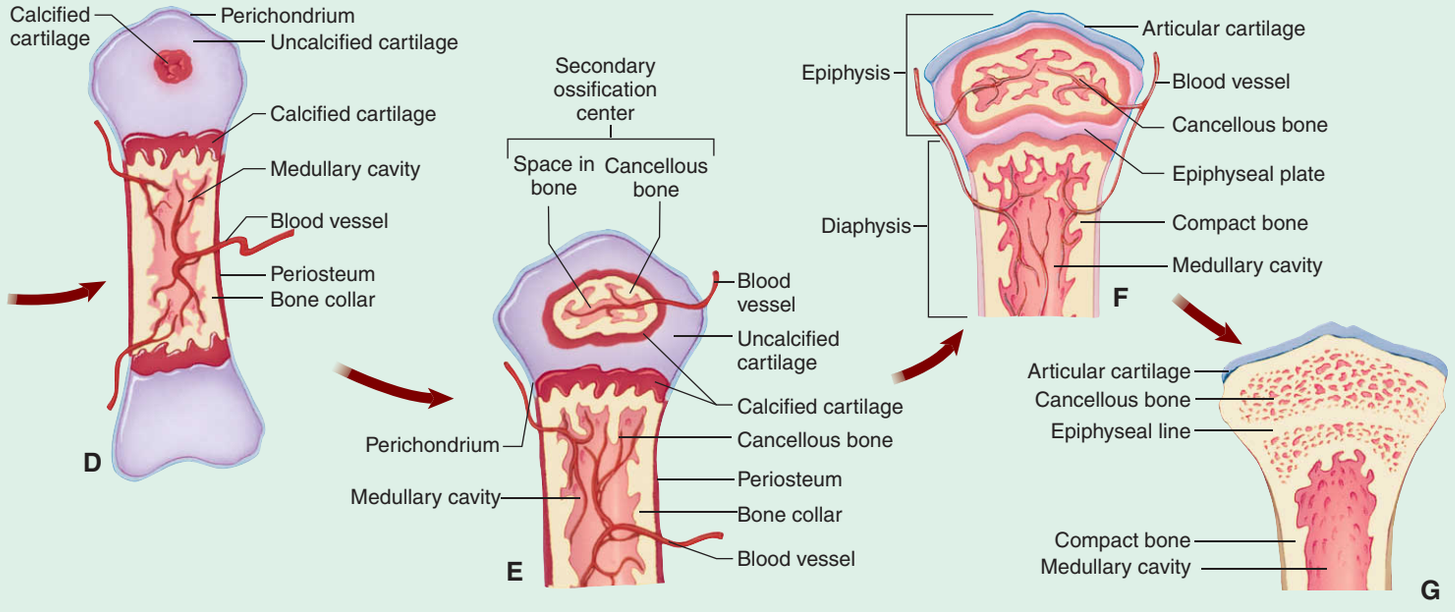


FIGURE 8-15

Fetal ossification centers. Photograph of a specially prepared fetal hand specimen showing primary ossification centers in the bones of the hand (metacarpal bones) and fingers (phalanges). Note that none of the wrist (carpal) bones show any evidence of ossification.

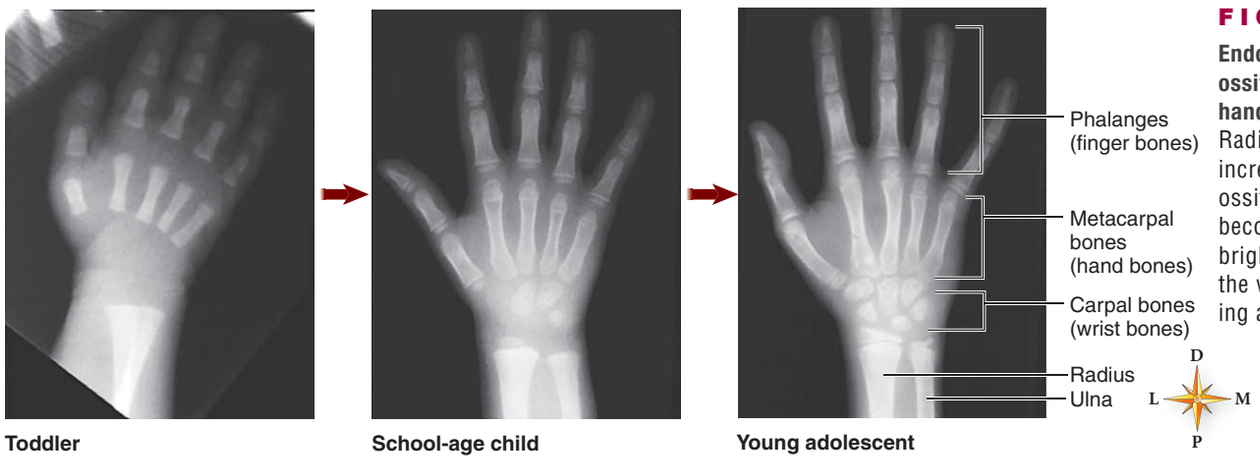

FIGURE 8-16

Endochondral ossification of the hand and wrist. Radiographs showing increasing numbers of ossification centers becoming visible as bright white areas in the wrist with increasing age.

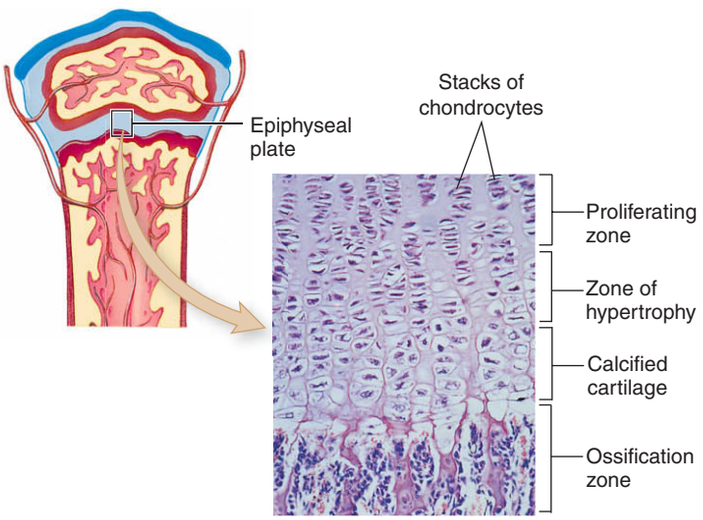

FIGURE 8-17

Epiphyseal plate structure. An epiphyseal plate between the epiphysis and diaphysis of a long bone. Photograph shows the zones of the epiphyseal plate.

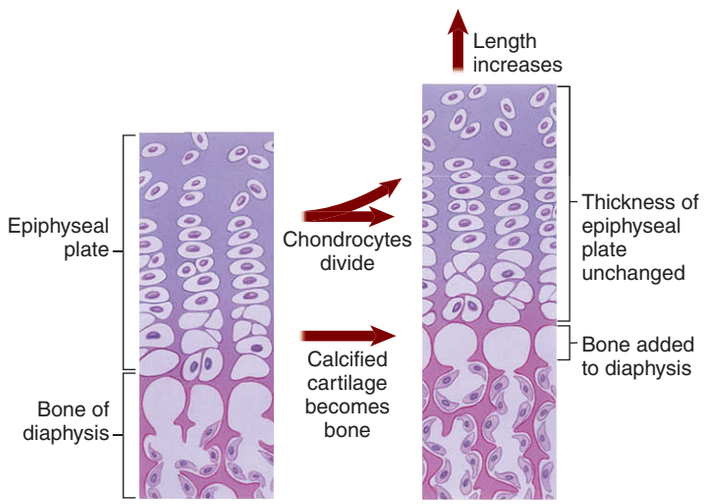

FIGURE 8-18

Growth of epiphyseal plate. Diagrams showing steps in ossification on either side of the epiphyseal plate.

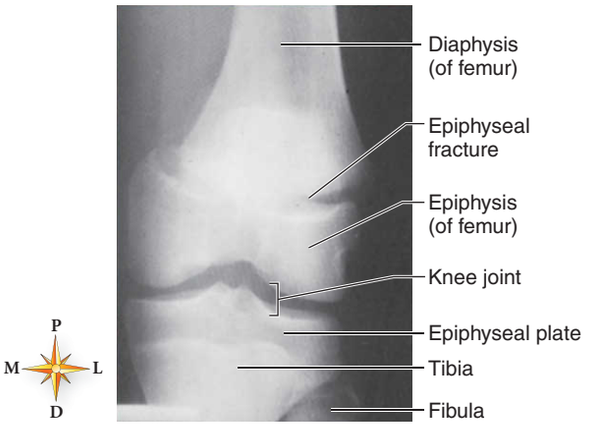

FIGURE 8-19

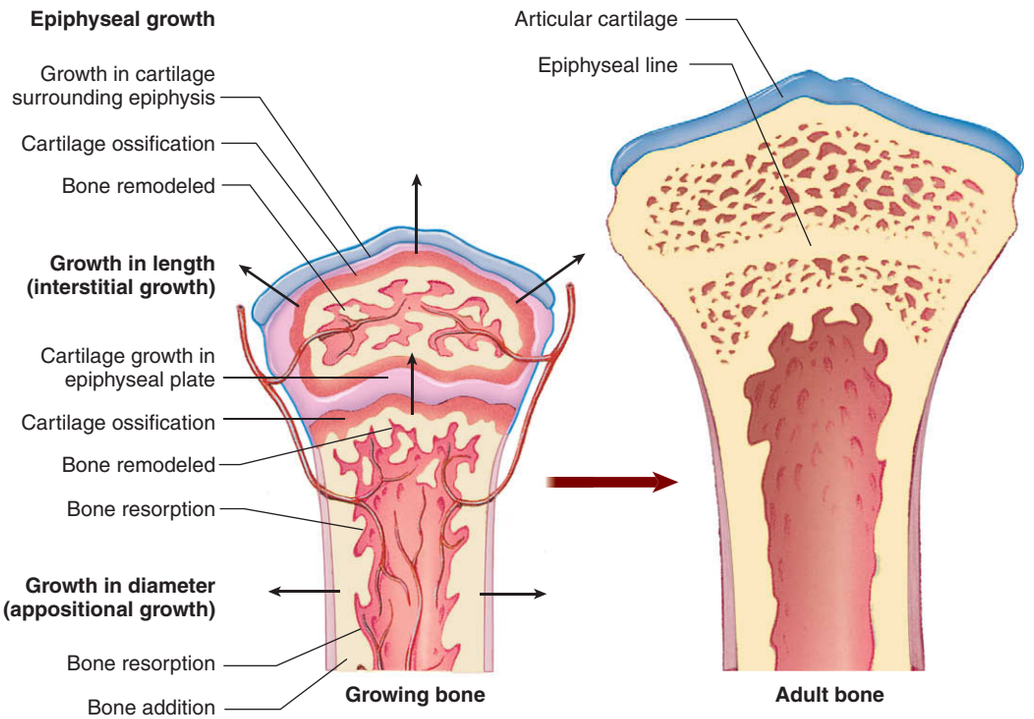
Epiphyseal fracture. Radiograph showing an epiphyseal fracture of the distal end of the femur in a young athlete. Note the separation of the diaphysis and epiphysis at the level of the growth plate.

When epiphyseal cartilage cells stop multiplying and the cartilage has become completely ossified, bone growth ends. Radiographs can reveal any epiphyseal cartilage still present. When bones have grown their full length, the epiphyseal cartilage disappears—bone has replaced it and is then continuous between epiphysis and diaphysis. The point of articulation between the epiphysis and diaphysis of a growing long bone, however, is susceptible to injury if overstressed—especially in a young child or preadolescent athlete. In these individuals the epiphyseal plate can be separated from the diaphysis or epiphysis and result in **epiphyseal fracture** (Figure 8-19). The relationship between interstitial growth (growth in length) and appositional growth (growth in diameter) during endochondral ossification of a long bone is shown in Figure 8-20.

| QUICK CHECK |

9. Name the three major types of bone cells.
10. Name the two types of bone marrow.
11. What are the five functions of bone?
12. Identify the two types of bone formation.



BONE REMODELING

In the early stages of ossification, bone tissue develops in a chaotic pattern of mineralized layers. Its crisscross appearance gives this new bone tissue the name *woven bone*. However, the woven bone is soon replaced by stronger, layered bone called *lamellar bone*, which is characterized by the presence of many osteons. The first osteons formed in lamellar bone are called *primary osteons*. To form a primary osteon, osteoclasts in the endosteum that surrounds a blood vessel first demineralize a cone or tube around a blood vessel. This leaves a cavelike hollow filled with collagenous fibers and lined with endosteum. Figure 8-21 shows how osteoblasts in the endosteum then form layer upon layer (lamellae) along the inside wall of the tube, trapping osteocytes between the lamellae. Eventually, the concentric lamella run out of space to mineralize—leaving only the central canal with its tightly packed blood vessels, nerves, and lymphatic vessels. As the bone develops, primary osteons are later replaced through the same process with *secondary osteons*.

Bones grow at their outer margins by the ossification of fibrous tissue by osteoblasts. Long bones grow in diameter by the combined action of osteoblasts and osteoclasts. Osteoclasts enlarge the diameter of the medullary cavity by eating away the bone of its walls. At the same time, osteoblasts from the periosteum build new bone around the outside of the bone. By this dual process, a bone with a larger diameter and larger medullary cavity is produced from a smaller bone with a smaller medullary cavity.

FIGURE 8-20

Bone remodeling. Bone formation on the outside of the shaft coupled with bone reabsorption on the inside increases the bone's diameter. Endochondral growth during bone remodeling increases the length of the diaphyses and causes the epiphysis to enlarge.

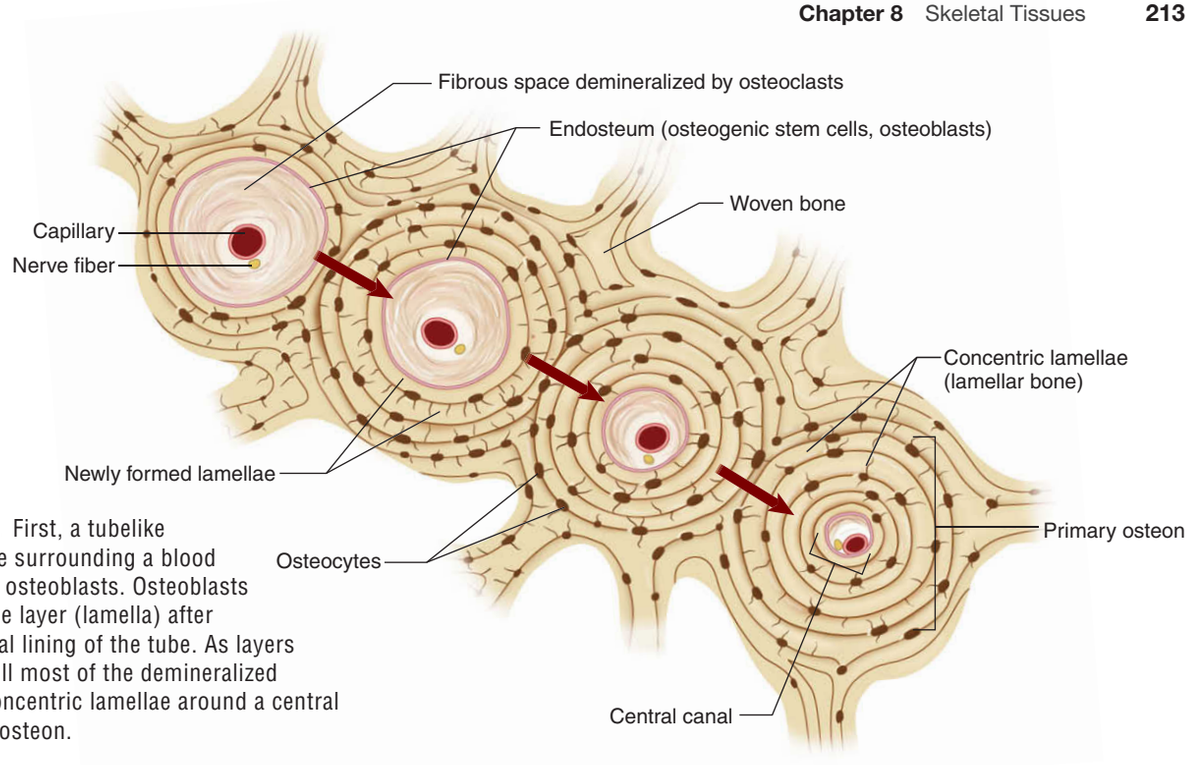


FIGURE 8-21

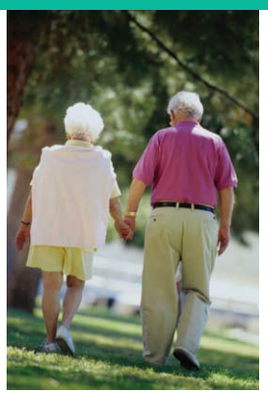
Primary osteon formation. First, a tubelike passage in the woven bone surrounding a blood vessel is demineralized by osteoblasts. Osteoblasts then begin laying down one layer (lamella) after another along the endosteal lining of the tube. As layers build up, they eventually fill most of the demineralized tube—thus forming the concentric lamellae around a central canal that characterize an osteon.

The remodeling activity of osteoclasts (removal of old bone) and osteoblasts (deposition of new bone) is important in homeostasis of blood calcium levels. It also permits bones to grow in length and diameter and to change their overall shape and the size of the marrow cavity (see Figure 8-20).



The formation of bone tissue continues long after bones have stopped growing. Throughout life, bone formation (ossification) and bone destruction (reabsorption) proceed concurrently. These opposing processes balance each other during the early to middle years of adulthood. The rate of bone formation equals the rate of bone destruction. Bones, therefore, neither grow nor shrink. They stay constant in size. Not so in the earlier years. During childhood and adolescence, ossification occurs at a faster rate than bone reabsorption does. Bone gain outstrips bone loss, and bones grow larger. But between the ages of 35 and 40 years, the process reverses, and from that time on, bone loss exceeds bone gain. Bone gain occurs slowly at the outer, or periosteal, surfaces of bones. Bone loss, on the other hand, occurs at the inner, or endosteal, surfaces and takes place at a somewhat faster pace. More bone is lost on the inside than gained on the outside, and inevitably bones become remodeled as the years go by.

Recall that under mechanical stress cancellous bone remodels its trabecula in different directions and thicker diameters to better withstand the stress (see Figure 8-7). Remodeling in compact bone involves the formation of new (secondary) osteons when bones are stressed. The higher the mechanical load on a bone, the narrower the tube hollowed out by osteoclasts as they prepare for the new osteon. Thus bones that bear the greatest weight have the narrowest osteons. These narrower osteons also have denser mineralization. The dense mineralization along with more numerous, narrower osteons gives the bone great strength to resist the stress. It is clear then why physical activity, which increases the various loads on bones throughout the body, tends to increase the density and strength of the skeleton (Box 8-1).

Box 8-1 | SPORTS and FITNESS

Exercise and Bone Density

Walking, jogging, and other forms of exercise subject bones to stress. They respond by laying down more collagen fibers and mineral salts in the bone matrix. This, in turn, makes bones stronger. But inactivity and lack of exercise tend to weaken bones because of decreased collagen formation and excessive calcium withdrawal. To prevent these changes, as well as many others, astronauts regularly perform special exercises in space because of the lack of gravity. Regular weight-bearing exercise is also an important part of the prevention and treatment of osteoporosis.

Physical activity increases bone density.

REPAIR OF BONE FRACTURES

The term *fracture* is defined as a break in the continuity of a bone. *Fracture healing* is the process that results in bone repair. The complex bone tissue repair process that follows a fracture is apparently initiated by bone death or by damage to periosteal and osteon blood vessels.

A bone fracture invariably tears and destroys blood vessels that carry nutrients to osteocytes. It is this vascular damage that initiates the highly regulated and generally very successful repair

process described below. When uncomplicated fractures occur in healthy children and young adults, the healing process often results in a repair that is all but impossible to detect 6 months after injury. Healing thus becomes a simple matter of adjusting normal bone remodeling processes to repair the injury. However, especially in older age groups, fracture repair may be complicated by underlying disease or other health problems, such as osteoporosis, diabetes, infection, or diminished blood supply to the injured area. In these cases, delayed healing, instability, deformity, or even nonunion of the fractured bone can result in very serious medical complications.

The process of fracture healing is shown in Figure 8-22, A to D. Vascular damage occurring immediately after a fracture results in hemorrhage and the pooling of blood at the point of injury. The resulting blood clot is called a *fracture hematoma* (Figure 8-22, *B*). The fracture hematoma quickly becomes "organized," develops a fibrin mesh, and transforms into a soft mass of *granulation tissue* containing inflammatory cells, fibroblasts, bone- and cartilage-forming cells, and new capillaries. Soon, islands of cartilaginous tissue called *procallus* form, and although they offer no structural rigidity for weight bearing, they help anchor the ends of the fractured bone more firmly. Growing numbers of osteoblasts continue the healing process with the formation of bony *callus* tissue. It serves to bind the broken ends of the fracture on both the outside surface and along the marrow cavity internally. The rapidly growing callus tissue effectively "collars" or "splints" the broken ends and stabilizes the fracture so that healing can proceed (Figure 8-22, C). If the fracture is properly aligned and immobilized and if complications do not develop, callus tissue will be actively "modeled" and eventually replaced with normal bone as the injury heals completely (Figure 8-22, D).

What are the types of bone fractures? How are they treated? Learn more about bone fractures in Chapter 9, p. 264, and in ***Bone Fractures*** online at ***A&P Connect.***

evolve

CARTILAGE

Types of Cartilage

Cartilage is classified as connective tissue and is classified into three types called **hyaline** (HYE-ah-lin) **cartilage, elastic cartilage,** and **fibrocartilage.** As a tissue, cartilage resembles bone in some ways but differs from bone in other ways. Innumerable collagenous fibers reinforce the matrix of both tissues, and as with bone, cartilage consists more of extracellular substance than cells. However, in cartilage the fibers are embedded in a firm gel instead of a calcified cement substance. Hence cartilage has the flexibility of a firm plastic material, whereas bone has the rigidity of cast iron. Another difference is that no canal system and no blood vessels penetrate the cartilage matrix. Cartilage is avascular and bone is abundantly vascular. Nevertheless, cartilage cells, as with bone cells, lie in lacunae. However, because no canals and blood vessels interlace cartilage matrix, nutrients and oxygen can reach the scattered, isolated **chondrocytes** (cartilage cells) only by diffusion. They diffuse through the matrix gel from capillaries in the fibrous covering of the cartilage—the **perichondrium**—or from synovial fluid in the case of articular cartilage.

The three cartilage types differ from one another largely by the relative amounts of elastic and collagenous fibers that are embedded in the matrix material. *Hyaline* is the most abundant type, and both elastic cartilage and fibrocartilage are considered modifications of the hyaline type. Collagenous fibers are present in all three types, but are most numerous in *fibrocartilage.* Hence it has the greatest tensile strength. *Elastic cartilage* matrix contains elastic fibers, as well as collagenous fibers, and thus has elasticity, as well as firmness.

Cartilage is an excellent skeletal support tissue in the developing embryo. It forms rapidly and yet retains a significant degree of rigidity, or stiffness. A majority of the bones that eventually form the axial and the appendicular skeleton described in Chapter 9 first appear as cartilage models. Skeletal maturation involves replacement of the cartilage models with bone.

After birth there is a decrease in the total amount of cartilage tissue present in the body. However, it continues to play an important role in the growth of long bones until skeletal maturity and is found throughout life as the material that covers the articular surfaces of bones in joints. The three types of cartilage also serve other important functions throughout the body.

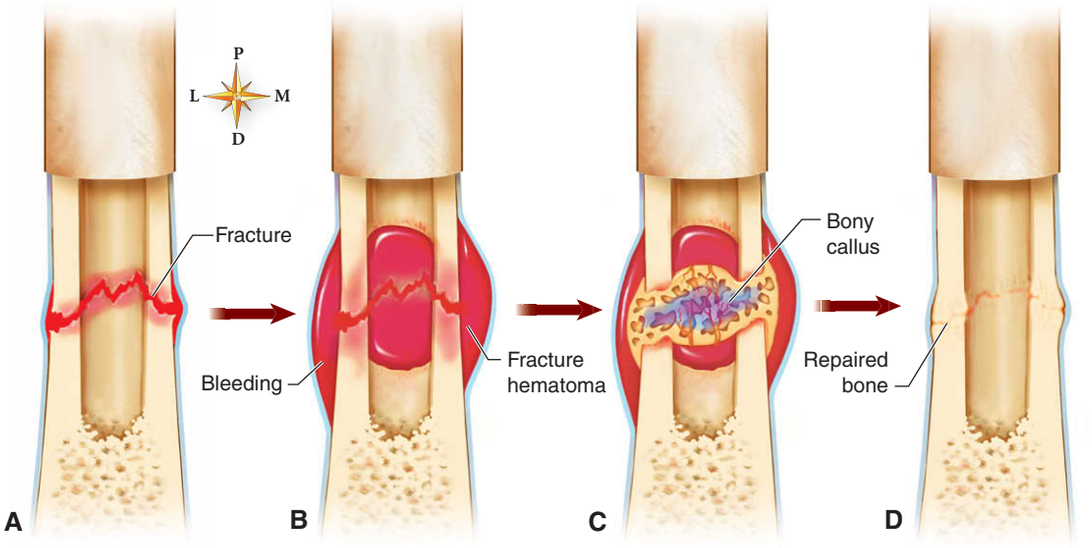

FIGURE 8-22

HYALINE CARTILAGE

Hyaline, in addition to being the most common type of cartilage, serves many functions. It resembles milk glass in appearance (Figure 8-23, A). In fact, its name is derived from the Greek word meaning "glassy." Sometimes called *gristle*, it is semitransparent and often has a bluish, opalescent cast.

In the embryo, hyaline cartilage forms from differentiation of mesenchymal cells that become crowded together in so-called **chondrification centers.** As the cells enlarge, they secrete matrix material that surrounds the delicate collagen fibrils. Eventually, the continued production of matrix separates and isolates the cells, or chondrocytes, into compartments, which as in bone, are called *lacunae*. Like bone, the organic matrix of hyaline cartilage is a mixture of ground substance and collagenous fibers. The ground substance is rich in both chondroitin sulfate and a unique gel-like polysaccharide. Both substances are secreted from chondrocytes in much the same way protein and carbohydrates are secreted from glandular cells.

In addition to covering the articular surfaces of bones, hyaline cartilage forms the costal cartilages that connect the anterior ends of the ribs with the sternum, or breastbone. It also forms the cartilage rings in the trachea, bronchi of the lungs, and tip of the nose.

ELASTIC CARTILAGE

Elastic cartilage gives form to the external ear, the epiglottis that covers the opening of the respiratory tract when swallowing, and the eustachian, or auditory, tubes that connect the middle ear and nasal cavity. The collagenous fibers of hyaline cartilage are also present—but in fewer numbers—in elastic cartilage. Large numbers of darkly stained elastic fibers confer the elasticity and resiliency typical of this form of cartilage (Figure 8-23, B).

FIBROCARTILAGE

Fibrocartilage—or *fibrous cartilage*—is characterized by abundant fibrous elements within the matrix (Figure 8-23, C). It is strong, rigid, and most often associated with regions of dense connective tissue in the body. It occurs in the pubic symphysis, in intervertebral disks, and near the points of attachment of some large tendons to bones.

Function of Cartilage

The tough, rubberlike nature of cartilage permits it to sustain great weight when covering the articulating surfaces of bones. It also may serve as a shock-absorbing pad between articulating bones in the spine. In other areas, such as the external ear, nose, or respiratory passages, cartilage provides a strong, yet pliable support structure that resists deformation or collapse of tubular passageways. Cartilage permits growth in the length of long bones and is largely responsible for their adult shape and size.

Growth of Cartilage

Growth of cartilage occurs in two ways:

1. Interstitial growth
2. Appositional growth

During interstitial growth, cartilage cells within the substance of the tissue mass divide and begin to secrete additional matrix. Internal division of chondrocytes is possible because of the soft, pliable nature of cartilage tissue. This form of growth is most often seen during childhood and early adolescence, when a majority of cartilage is still soft and capable of expansion from within. Interstitial growth may be referred to as *endogenous growth* because it occurs *within* the cartilage tissue.

Appositional growth occurs when chondrocytes in the deep layer of the perichondrium begin to divide and secrete additional matrix. The new matrix is then deposited on the surface of the cartilage, which causes it to increase in size. Appositional growth is unusual in early childhood but, once initiated, continues beyond adolescence and throughout an individual's life. Appositional growth may be referred to as *exogenous growth* because it occurs on the *outer* surfaces of cartilage tissue.

| QUICK CHECK |

Cycle of LIFE

Skeletal Tissues

This chapter focused on the changes that occur in bone and cartilage tissue from the time before birth to advanced old age. For instance, we have outlined in some detail the process by which the soft cartilage and membranous skeleton become ossified over a period of years. By the time a person is a young adult in the mid-twenties, the skeleton has become fully ossified. A few areas of soft tissue—the cartilaginous areas of the nose and ears, for example—may continue to grow and ossify very slowly throughout adulthood so that by advanced old age, some structural changes are apparent.

Changes in skeletal tissue that occur during adulthood usually result from specific conditions. For example, the mechanical stress of weight-bearing exercise can trigger dramatic increases in the density and strength of bone tissue. Pregnancy, nutritional deficiencies, and illness can all cause loss of bone density accompanied by loss of structural strength.

In advanced adulthood, degeneration of bone and cartilage tissue becomes apparent. Replacement of hard bone matrix by softer connective tissue results in a loss of strength that increases susceptibility to injury. This is especially true in older women who suffer from osteoporosis. Fortunately, even very light exercise by elderly individuals can counteract some of the skeletal tissue degeneration associated with old age.

the BIG picture

Skeletal Tissues

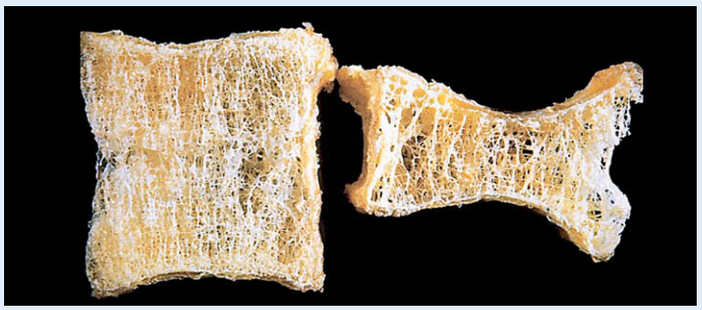
Skeletal tissues influence many important body functions that are crucial to the "big picture" of overall health and survival of the individual. The pervasive importance of the protective and support functions of skeletal tissues is immediately apparent. Bone and cartilage tissues are organized and grouped to protect the body and its internal organs from injury. In addition to providing a supporting and protective framework, these tissues also contribute to the shape, alignment, and positioning of the body and its myriad parts. Also, because of the organization of skeletal tissues into bones and the articulation of these bones in joints, we are able to engage in purposeful and coordinated movement. Bone remodeling permits ongoing change to occur in both structure and related functions throughout the cycle of life.

The homeostatic function of skeletal tissues is beautifully illustrated by the role they play in mineral storage and release. For example, regulation of blood calcium levels is important in such diverse areas as nerve transmission, muscle contraction, and normal clotting of blood. Because they contain red marrow, the bones also serve in the important role of hematopoiesis, or blood cell formation. This function ties skeletal tissues to such diverse homeostatic functions as regulation of body pH and the transport of respiratory gases and vital nutrients. By viewing skeletal tissues in such a broad and interrelated functional context, you can more readily sense the "connectedness" that unites these otherwise seemingly isolated body structures to the "big picture" of overall health and survival.

MECHANISMS of DISEASE

DISEASES OF SKELETAL TISSUES

Malignant Tumors of Bone and Cartilage



Osteosarcoma (osteogenic sarcoma) is the most common primary malignant tumor of skeletal tissue and is often the most fatal. It appears more frequently in males, with a peak age of incidence between 10 and 25 years. Common sites of involvement are the tibia, femur, and humerus. Roughly 10% of patients experience metastases to the lungs, and if left untreated, the course can involve widespread metastases and death within 1 year. Therapy commonly involves surgery followed by chemotherapy.

Chondrosarcoma is a malignant tumor of hyaline cartilage that arises from chondroblasts. It is a large, bulky, slow-growing tumor occurring most frequently in middle-aged persons. Common sites of involvement include the humerus, femur, spine, pelvis, ribs, and scapula. Large excisions or amputation of the affected extremity can improve survival rates. Chemotherapy has not been proven to be effective.

Metabolic Bone Diseases

Metabolic bone diseases are disorders of bone remodeling.

As a serious and very common bone disease, especially in older age groups, **osteoporosis** (os-tee-oh-poh-ROH-sis) has been the subject of intense scientific research and widespread public interest and concern. Characterized by increased bone porosity and reduced mineral density and mass, osteoporotic bones fracture easily. Some bones, such as the vertebral bodies in the spinal column, are particularly susceptible to damage. These bones have a large percentage of cancellous bone with trabeculae that become less numerous and weak in osteoporosis. The result is extensive and progressive microfracture of many of the remaining trabeculae and eventual vertebral collapse (Figure 8-24). Over time, increasing numbers of vertebral compression fractures result in a shortened stature and cause an abnormal backward curvature of the spine called "dowager's hump." The condition is, unfortunately, a common sign of long-standing

FIGURE 8-24

Osteoporosis. A, Compare the normal vertebral body (left) with the osteoporotic specimen (right). Note that the osteoporotic vertebral body has been shortened by compression fractures. **B,** Scanning electron micrograph (SEM) of normal bone. **C,** SEM of osteoporotic bone. Note the loss of trabeculae and appearance of enlarged pores caused by osteoporosis.

osteoporosis in many untreated older women. Although osteoporosis can occur in both men and women, one of every two women who survive 40 years after menopause will suffer an osteoporosis-related fracture, in contrast to one in 40 men of similar age.

In most women, a majority of the bone loss characteristic of osteoporosis occurs during the decade after menopause and beyond. However, significant loss can occur much earlier—even during adolescence. Therefore, health care providers are suggesting earlier screening for the disease and lifestyle changes that include weight-bearing exercise and a diet adequate in calcium and vitamin D.

evolve

Rickets and Osteomalacia

Rickets in young children and **osteomalacia** (os-tee-oh-mah-LAY-shah) in adults are metabolic skeletal diseases that affect significant numbers of individuals worldwide. Both diseases are characterized by demineralization or loss of minerals from bone related to vitamin D deficiency. The loss of minerals is coupled with increased production of unmineralized matrix. Rickets involves demineralization of developing bones in infants and young children before skeletal maturity. In osteomalacia, mineral content is lost from bones that have already matured. In rickets, the lack of rigidity caused by the demineralization of developing bones results in gross skeletal changes, including the classic "bowing of the legs" symptom (Figure 8-25). The demineralization of bones in osteomalacia does not generally affect overall skeletal contours but does result in increased susceptibility to fractures, especially in the vertebral bodies and femoral necks. Box 8-2 discusses how nutritional deficiencies affect cartilage as well as bone tissue.

FIGURE 8-25

Rickets. Bowing of legs in this toddler is due to poorly mineralized bones from rickets.

Box 8-2 | HEALTH matters

Cartilage and Nutritional Deficiencies

Certain nutritional deficiencies and other metabolic disturbances have an immediate and very visible effect on cartilage. It is for this reason that changes in cartilage often serve as indicators of inadequate vitamin, mineral, or protein intake. Vitamin A and protein deficiency, for example, will decrease the thickness of epiphyseal plates in the growing long bones of young children—an effect immediately apparent on x-ray examination. The opposite effect occurs in vitamin D deficiencies. As the epiphyseal cartilage increases in thickness but fails to calcify, the growing bones become deformed and bend under weight bearing. The bent long bones are a sign of rickets (see Figure 8-25).

Osteitis deformans, also known as *Paget disease*, is a disorder affecting older adults. It is characterized by proliferation of osteoclasts and compensatory increased osteoblastic activity. The result is rapid and disorganized bone remodeling. The bones formed are poorly constructed and weakened. It commonly affects the skull, humerus, femur, vertebra, and pelvic bones. Clinical manifestations may include bone pain, tenderness, and fractures. However, the majority of patients experience minimal changes and never know they have the disease. No treatment is recommended in an asymptomatic patient.

Osteomyelitis is a bacterial infection of the bone and marrow tissue. Infections of bone are often more difficult to treat than soft tissue infections because of the decreased blood supply and density of the bone. Bacteria, viruses, fungi, and other pathogens may cause osteomyelitis. *Staphylococcus* bacteria are the most common pathogens. Osteomyelitis is associated with extension of another infection (e.g., bacteremia, urinary tract infection, vascular ulcer) or direct bone contamination (e.g., gunshot wound, open fracture). Patients who are elderly, poorly nourished, or diabetic are also at risk. Thrombosis of blood vessels in osteomyelitis often results in ischemia and bone necrosis. As a result, infection can extend under the periosteum and spread to adjacent soft tissues and joints. Signs and symptoms may include an area swollen, warm, tender to touch, and painful. Early recognition of infection and aggressive antimicrobial management are required. Sometimes patients may require many weeks of antibiotic therapy.

CASE study

Eleanor stepped off the curb by her mailbox, just as she had done thousands of times before. But this time, her hip gave way, and she suddenly found herself on the ground, unable to get back up. An x-ray film at the hospital showed a fracture in the neck of her femur. Eleanor wondered how she could have broken a bone by simply stepping off a curb. The doctor was talking about surgery and a 6-month recovery time. She would definitely have to reschedule the cruise she had booked to celebrate retirement.

1. Which of the following conditions likely caused Eleanor's broken hip?
   a. Osteosarcoma
   b. Rickets
   c. Osteoporosis
   d. Osteomyelitis
2. What type of bone did Eleanor fracture?
   a. Long bone
   b. Short bone
   c. Flat bone
   d. Irregular bone
3. What type of cartilage would you find covering the ends of that bone?
   a. Elastic cartilage
   b. Hylophil cartilage
   c. Fibrocartilage
   d. Hyaline cartilage

After her surgery, Eleanor gets a prescription from her doctor for calcitonin nasal spray.

4. What is the primary effect of that medication?
   a. Stimulates osteoclasts
   b. Stimulates osteoblasts
   c. Stimulates osteocytes
   d. All of the above

FUNCTIONS OF BONE

A. Support—bones form the framework of the body and contribute to the shape, alignment, and positioning of body parts; ligaments help hold bones together (Figure 8-1)
B. Protection—bony "boxes" protect the delicate structures they enclose
C. Movement—bones with their joints constitute levers that move as muscles contract
D. Mineral storage—bones are the major reservoir for calcium, phosphorus, and other minerals
E. Hematopoiesis—blood cell formation is carried out by myeloid tissue

TYPES OF BONES

A. Structurally, there are five major types of bones (Figure 8-2)
   1. Long bones—cylindrical
   2. Short bones—boxlike
   3. Flat bones—broad, sheetlike
   4. Irregular bones—various shapes
   5. Sesamoid bones—seedlike

B. Size, shape, and appearance of bones vary to meet the various needs served
C. Bones vary in the proportion of compact and cancellous (spongy) bone
   1. Compact bone—dense and solid in appearance
   2. Cancellous bone—characterized by open space partially filled with a lattice of thin branched structures supporting soft tissue
D. Parts of a long bone (Figure 8-3)
   1. Diaphysis
      a. Main shaft of a long bone
      b. Hollow, cylindrical shape and thick compact bone
      c. Function—to provide strong support without cumbersome weight
   2. Epiphyses
      a. Both ends of a long bone; made of cancellous bone filled with marrow
      b. Bulbous shape
      c. Function—to provide attachments for muscles and give stability to joints
   3. Articular cartilage
      a. Layer of hyaline cartilage that covers the articular surface of epiphyses
      b. Function—to cushion jolts and blows
   4. Periosteum
      a. Dense, white fibrous membrane that covers bone
      b. Attaches tendons firmly to bones
      c. Contains cells that form and destroy bone
      d. Contains blood vessels important in growth and repair

e. Contains blood vessels that send branches into bone
f. Essential for bone cell survival and bone formation

5. Medullary (or marrow) cavity
   a. Tubelike, hollow space in the diaphysis
   b. Filled with yellow marrow in adults
6. Endosteum—thin fibrous membrane that lines the medullary cavity

E. Parts of a flat bone
1. Inner portion is cancellous bone covered on the outside with compact bone
   a. Cranial flat bones have an internal and external table of compact bone and an inner cancellous region called the *diploe* (Figure 8-4)
   b. Bones are covered with periosteum and lined with endosteum, as in a long bone
   c. Other flat bones, short bones, and irregular bones have features similar to the cranial bones
2. Spaces inside the cancellous bone of short, flat, irregular and sesamoid bones are filled with red marrow

BONE TISSUE

A. Most distinctive form of connective tissue
B. Extracellular components are hard and calcified
C. Rigidity of bone allows it to serve its supportive and protective functions
D. Tensile strength nearly equal to that of cast iron at less than one third the weight
E. Composition of bone matrix
1. Inorganic salts
   a. Hydroxyapatite—crystals of calcium and phosphate contribute to bone hardness
   b. Slender needlelike crystals are oriented to most effectively resist stress and mechanical deformation
   c. Magnesium, sodium, sulfate, and fluoride are also found in bone
2. Organic matrix
   a. Composite of collagenous fibers and an amorphous mixture of protein and polysaccharides called *ground substance*
   b. Ground substance—secreted by connective tissue cells
   c. Adds to overall strength of bone and gives some degree of resilience to bone

MICROSCOPIC STRUCTURE OF BONE

A. Compact bone (Figure 8-5)
1. Contains many cylinder-shaped structural units called *osteons*, or *Haversian systems* (Figure 8-6)
2. Osteons surround central (osteonal or Haversian) canals that run lengthwise through bone and are connected by transverse (Volkmann) canals
   a. Living bone cells located in these units
   b. Constitute the structural framework of compact bone
3. Osteons permit delivery of nutrients and removal of waste products
4. Structures make up each osteon
   a. Lamellae
      (1) Concentric—cylinder-shaped layers of calcified matrix around the central canal
      (2) Interstitial—layers of bone matrix *between* the osteons; leftover from previous osteons
      (3) Circumferential—few layers of bone matrix that surround all the osteons; run along the outer circumference of a bone and inner circumference (boundary of medullary cavity) of a bone
   b. Lacunae—small spaces containing tissue fluid in which bone cells are located between hard layers of the lamella
   c. Canaliculi—ultra-small canals radiating in all directions from the lacunae and connecting them to each other and to the central canal
   d. Central (osteonal or Haversian) canal—extends lengthwise through the center of each osteon and contains blood vessels and lymphatic vessels

B. Cancellous bone—also called *spongy bone* or *trabecular bone* (Figure 8-6)
1. No osteons in cancellous bone; instead, it has trabeculae
2. Nutrients are delivered and waste products removed by diffusion through tiny canaliculi
3. Lattice of bony branches (trabeculae) are arranged along lines of stress to enhance the bone's strength (Figure 8-7)
4. Blood supply
   a. Bone cells receive blood supply from the bone marrow in the internal medullary cavity of cancellous bone
   b. Blood vessels from the periosteum become incorporated into the bone and serve nutrient needs of cells by way of transverse (Volkmann) canals, connected with vessels in the central canals of osteons

C. Types of bone cells
1. Osteoblasts (Figure 8-8)
   a. Bone-forming cells found in all bone surfaces
   b. Small cells synthesize and secrete osteoid, an important part of the ground substance
   c. Collagen fibrils line up in osteoid and serve as a framework for the deposition of calcium and phosphate
2. Osteoclasts (Figure 8-8)
   a. Giant multinucleated cells
   b. Responsible for the active erosion of bone minerals
   c. Contain large numbers of mitochondria and lysosomes
3. Osteocytes—mature, nondividing osteoblasts surrounded by matrix and lying within lacunae (Figure 8-9)

BONE MARROW

A. Type of soft, diffuse connective tissue; called *myeloid tissue*
B. Site for the production of blood cells
C. Found in the medullary cavities of long bones and in the spaces of spongy bone
D. Two types of marrow occur during a person's lifetime (Figure 8-10)
1. Red marrow
   a. Found in virtually all bones in an infant's or child's body
   b. Functions to produce red blood cells
2. Yellow marrow
   a. As an individual ages, red marrow is replaced by yellow marrow

b. Marrow cells become saturated with fat and are no longer active in blood cell production

E. Main bones in an adult that still contain red marrow include the ribs, bodies of the vertebrae, humerus, pelvis, and femur

F. Yellow marrow can change to red marrow during times of decreased blood supply, such as anemia, exposure to radiation, and certain diseases

REGULATION OF BLOOD CALCIUM LEVELS

A. Skeletal system serves as a storehouse for about 98% of body calcium reserves
   1. Helps maintain constancy of blood calcium levels
      a. Calcium is mobilized and moves into and out of blood during bone remodeling
      b. During bone formation, osteoblasts remove calcium from blood and lower circulating levels
      c. During breakdown of bone, osteoclasts release calcium into blood and increase circulating levels
   2. Homeostasis of calcium ion concentration essential for the following:
      a. Bone formation, remodeling, and repair
      b. Blood clotting
      c. Transmission of nerve impulses
      d. Maintenance of skeletal and cardiac muscle contraction

B. Mechanisms of calcium homeostasis (Figure 8-11)
   1. Parathyroid hormone
      a. Primary regulator of calcium homeostasis
      b. Stimulates osteoclasts to initiate breakdown of bone matrix and increase blood calcium levels
      c. Increases renal absorption of calcium from urine
      d. Stimulates vitamin D synthesis
   2. Calcitonin
      a. Protein hormone produced in the thyroid gland
      b. Produced in response to high blood calcium levels
      c. Stimulates bone deposition by osteoblasts
      d. Inhibits osteoclast activity
      e. Far less important in homeostasis of blood calcium levels than is parathyroid hormone
   3. Other mechanisms
      a. Growth hormone (GH)—increases bone growth, thus reducing blood calcium
      b. Serotonin—inhibits osteoblast activity, thus increases blood calcium

DEVELOPMENT OF BONE

A. Osteogenesis—development of bone from small cartilage or membrane model to adult bone

B. Intramembranous ossification (Figure 8-13)
   1. Occurs within a connective tissue membrane
   2. Flat bones begin when groups of cells differentiate into osteoblasts
   3. Osteoblasts are clustered together in ossification center
   4. Osteoblasts secrete matrix material and collagenous fibrils
   5. Large amounts of ground substance accumulate around each osteoblast
   6. Collagenous fibers become embedded in the ground substance and constitute the bone matrix
   7. Bone matrix calcifies when calcium salts are deposited
   8. Trabeculae appear and join in a network to form spongy bone
   9. Appositional growth occurs by adding osseous tissue

C. Endochondral ossification (Figure 8-14)
   1. Most bones begin as a cartilage model with bone formation spreading essentially from the center to the ends
   2. Periosteum develops and enlarges to produce a collar of bone
   3. Primary ossification center forms (Figure 8-15)
   4. Blood vessel enters the cartilage model at the midpoint of the diaphysis
   5. Bone grows in length as endochondral ossification progresses from the diaphysis toward each epiphysis (Figure 8-16)
   6. Secondary ossification centers appear in the epiphysis, and bone growth proceeds toward the diaphysis
   7. Epiphyseal plate remains between the diaphysis and each epiphysis until bone growth in length is complete
   8. Epiphyseal plate is composed of four layers (Figures 8-17 and 8-18)
      a. "Resting" cartilage cells—point of attachment joining the epiphysis to the shaft
      b. Zone of proliferation—cartilage cells undergoing active mitosis, which causes the layer to thicken and the plate to increase in length
      c. Zone of hypertrophy—older, enlarged cells undergoing degenerative changes associated with calcium deposition
      d. Zone of calcification—dead or dying cartilage cells undergoing rapid calcification
   9. Epiphyseal plate can be a site for bone fractures in young people (Figure 8-19)
   10. Long bones grow in both length and diameter (Figure 8-20)

BONE REMODELING

A. Primary osteons develop within early woven bone (Figure 8-21)
   1. Conelike or tubelike space is hollowed out by osteoclasts
   2. Osteoblasts in the endosteum that lines the tube begin forming layers (lamellae) that trap osteocytes between layers.
   3. A central canal is left for the blood and lymphatic vessels and nerves
   4. Primary osteons can be replaced later by secondary osteons in a similar manner

B. Bones grow in length and diameter by the combined action of osteoclasts and osteoblasts
   1. Osteoclasts enlarge the diameter of the medullary cavity
   2. Osteoblasts from the periosteum build new bone around the outside of the bone

C. Mechanical stress, as from physical activity, strengthens bone

REPAIR OF BONE FRACTURES

A. Fracture—break in the continuity of a bone

B. Fracture healing (Figure 8-22)
   1. Fracture tears and destroys blood vessels that carry nutrients to osteocytes
   2. Vascular damage initiates repair sequence
   3. Callus—special repair tissue that binds the broken ends of the fracture together
   4. Fracture hematoma—blood clot occurring immediately after the fracture, which is then resorbed and replaced by callus

CARTILAGE

A. Characteristics
   1. Avascular connective tissue
   2. Fibers of cartilage are embedded in a firm gel
   3. Has the flexibility of firm plastic
   4. No canal system or blood vessels
   5. Chondrocytes receive oxygen and nutrients by diffusion
   6. Perichondrium—fibrous covering of the cartilage
   7. Cartilage types differ because of the amount of matrix present and the amounts of elastic and collagenous fibers

B. Types of cartilage (Figure 8-23)
   1. Hyaline cartilage
      a. Most common type
      b. Covers the articular surfaces of bones
      c. Forms the costal cartilages, cartilage rings in the trachea, bronchi of the lungs, and the tip of the nose
      d. Forms from special cells in chondrification centers, which secrete matrix material
      e. Chondrocytes are isolated into lacunae
   2. Elastic cartilage
      a. Forms external ear, epiglottis, and eustachian tubes
      b. Large number of elastic fibers confers elasticity and resiliency
   3. Fibrocartilage (fibrous cartilage)
      a. Occurs in pubic symphysis and intervertebral disks
      b. Small quantities of matrix and abundant fibrous elements
      c. Strong and rigid

C. Function of cartilage
   1. Tough, rubberlike nature permits cartilage to sustain great weight or serve as a shock absorber
   2. Strong yet pliable support structure
   3. Permits growth in length of long bones

D. Growth of cartilage
   1. Interstitial or endogenous growth
      a. Cartilage cells divide and secrete additional matrix
      b. Seen during childhood and early adolescence while cartilage is still soft and capable of expansion from within
   2. Appositional or exogenous growth
      a. Chondrocytes in the deep layer of the perichondrium divide and secrete matrix
      b. New matrix is deposited on the surface, thereby increasing its size
      c. Unusual in early childhood, but once initiated, continues throughout life

CYCLE OF LIFE: SKELETAL TISSUES

A. Skeleton fully ossified by mid-twenties
   1. Soft tissue may continue to grow—ossifies more slowly

B. Adults—changes occur from specific conditions
   1. Increased density and strength from exercise
   2. Decreased density and strength from pregnancy, nutritional deficiencies, and illness

C. Advanced adulthood—apparent degeneration
   1. Hard bone matrix replaced by softer connective tissue
   2. Exercise can counteract degeneration

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Describe the microscopic structure of bone and cartilage.
2. Describe the structure of a long bone.
3. Explain the functions of the periosteum.
4. Describe the two principal chemical components of extracellular bone.
5. List and discuss each of the major anatomical components that together constitute an osteon.
6. Compare and contrast the three major types of cells found in bone.
7. Discuss and discriminate between the sequence of steps characteristic of fracture healing.
8. Compare and contrast the basic structural elements of bone and cartilage.
9. Compare the structure and function of the three types of cartilage.

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Cancer treatment may precipitate the need for a bone marrow transplant. Osteoporosis is a condition characterized by an excessive loss of calcium in bone. These two conditions are disruptions or failures of two bone functions. Identify these two functions and explain what their normal functioning should be.
2. Compare and contrast bone formation in intramembranous and endochondral ossification.
3. Can you make a distinction between the growth processes of cartilage and bone? Explain.
4. Explain why a bone fracture along the epiphyseal plate may have serious implications in children and young adults.
5. During the aging process, adults face the issue of a changing skeletal framework. Describe these changes and explain how these skeletal framework changes affect the health of older adults.

Skeletal System

continued on p. 266

Just as skeletal tissues are organized to form bones, the bones are organized or grouped to form the skeletal system. The rigid bones lie buried within soft tissues, providing support and shape to the body. Understanding the relationship of bones to each other and to other body structures provides a basis for understanding the function of many other organ systems. Coordinated movement, for example, is possible only because of the way bones are joined in joints and the way muscles are attached to those bones.

The adult skeleton is composed of 206 named bones. Variations in the total number of bones in the body occur as a result of certain anomalies, such as extra ribs, or from failure of certain small bones to fuse in the course of development.

In Chapter 8 the basic types of skeletal tissue, including bone and cartilage, were discussed providing the background for study in this chapter of individual bones and their interrelationships in the skeleton. Chapter 10 explores articulations—that is, how the bones form joints.

DIVISIONS OF THE SKELETON

The human skeleton consists of two main divisions—the axial skeleton and the appendicular skeleton (Figure 9-1). Eighty bones make up the **axial skeleton.** This includes 74 bones that form the upright axis of the body and 6 tiny middle ear bones. The **appendicular skeleton** consists of 126 bones—more than half again as many as in the axial skeleton. Bones of the appendicular skeleton form the appendages to the axial skeleton: the shoulder girdles, arms, wrists, and hands and the hip girdles, legs, ankles, and feet.

One of the first things you should do in studying the skeleton is to familiarize yourself with the names of the individual bones listed in Table 9-1. Next, look at Table 9-2, which lists some terms often used to name or describe bone markings—specific features on an individual bone. After this preparation, begin a step-by-step exploration of the skeletal system by studying the illustrations, text, and tables that constitute the rest of this chapter. To help you learn to distinguish between the names of bones and the names of their markings, the bone names are highlighted in a boldface font and the markings are shown in a normal font in illustrations and tables throughout this chapter.

A picture is worth a thousand words. The illustrations and tables contained in this chapter were carefully selected and compiled to assist you in visualizing and organizing the material discussed. If in addition to your textbook, you have access to individual bones or an articulated skeleton in a laboratory setting, frequent reference to chapter illustrations and tabular material will prove immensely helpful in your study efforts.

TABLE 9-1 Bones of the Skeleton (206 Total)*

PART OF BODY	NAME OF BONE
Axial Skeleton (80 Bones Total)	
Skull (28 bones total)	
Cranium (8 bones)	Frontal (1) Parietal (2) Temporal (2) Occipital (1) Sphenoid (1) Ethmoid (1)
Face (14 bones)	Nasal (2) Maxillary (2) Zygomatic (malar) (2) Mandible (1) Lacrimal (2) Palatine (2) Inferior nasal conchae (turbinates) (2) Vomer (1)
Ear bones (6 bones)	Malleus (hammer) (2) Incus (anvil) (2) Stapes (stirrup) (2)
Hyoid bone (1)	
Spinal column (26 bones)	Cervical vertebrae (7) Thoracic vertebrae (12) Lumbar vertebrae (5) Sacrum (1) Coccyx (1)
Sternum and ribs (25 bones)	Sternum (1) True ribs (14) False ribs (10)
Appendicular Skeleton (126 Bones Total)	
Upper extremities (including shoulder girdle) (64 bones)	Clavicle (2) Scapula (2) Humerus (2) Radius (2) Ulna (2) Carpal bones (16) Metacarpal bones (10) Phalanges (28)
Lower extremities (including hip girdle) (62 bones)	Innominate (2) Fibula (2) Femur (2) Patella (2) Tibia (2) Tarsal bones (14) Metatarsal bones (10) Phalanges (28)

*An inconstant number of small, flat, round bones known as *sesamoid bones* (because of their resemblance to sesame seeds) are found in various tendons in which considerable pressure develops. Because the number of these bones varies greatly between individuals, only two of them, the patellae, have been counted among the 206 bones of the body. Generally, two of them can be found in each thumb (in the flexor tendon near the metacarpophalangeal and interphalangeal joints) and great toe, plus several others in the upper and lower extremities. *Sutural bones (wormian bones),* the small islets of bone frequently found in some of the cranial sutures, have not been counted in this list of 206 bones because of their variable occurrence.
The numeral following each bone name is the typical number of bones found in the adult skeleton.

TABLE 9-2 Terms Used to Describe Bone Markings

TERM	MEANING
Angle	A corner
Body	The main portion of a bone
Border	Edge of a bone
Condyle	Rounded bump; usually fits into a fossa on another bone to form a joint
Crest	Moderately raised ridge; generally a site for muscle attachment
Epicondyle	Bump near a condyle; often gives the appearance of a "bump on a bump"; for muscle attachment
Facet	Flat surface that forms a joint with another facet or flat bone
Fissure	Long, cracklike hole for blood vessels and nerves
Foramen	Round hole for vessels and nerves (*pl.,* foramina)
Fossa	Depression; often receives an articulating bone (*pl.,* fossae)
Head	Distinct epiphysis on a long bone, separated from the shaft by a narrowed portion (or neck)
Line	Similar to a crest but not raised as much (is often rather faint)
Margin	Edge of a flat bone or flat portion of the edge of a flat area
Meatus	Tubelike opening or channel (*pl.,* meatus or meatuses)
Neck	A narrowed portion, usually at the base of a head
Notch	A V-like depression in the margin or edge of a flat area
Process	A raised area or projection
Ramus	Curved portion of a bone, like a ram's horn (*pl.,* rami)
Sinus	Cavity within a bone
Spine	Similar to a crest but raised more; a sharp, pointed process; for muscle attachment
Sulcus	Groove or elongated depression (*pl.,* sulci)
Trochanter	Large bump for muscle attachment (larger than a tubercle or tuberosity)
Tuberosity	Oblong, raised bump, usually for muscle attachment; also called a *tuber*; a small tuberosity is called a *tubercle*

AXIAL SKELETON

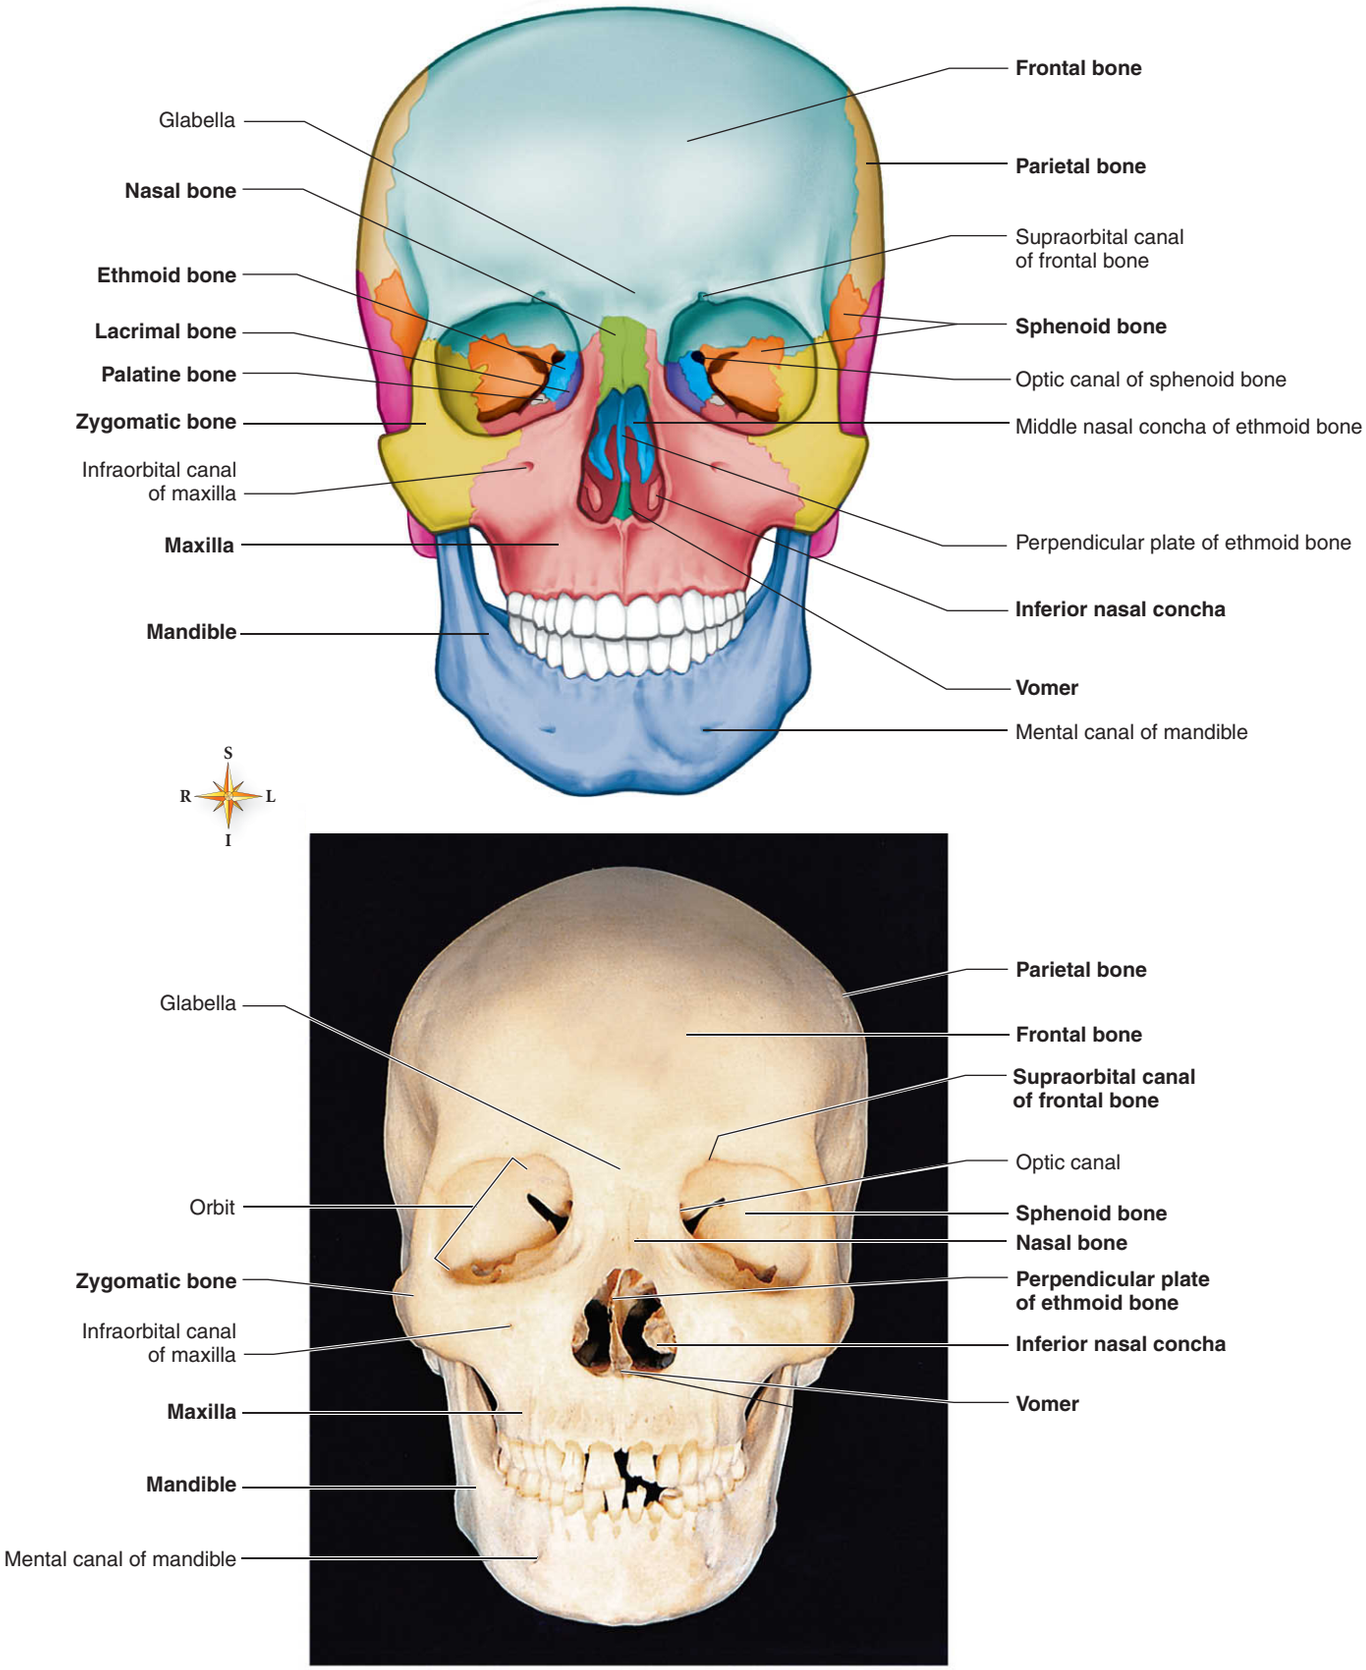
Skull

Twenty-eight irregularly shaped bones form the skull (Figures 9-2 to 9-8). Figures 9-2 through 9-7 show the articulated bones of the skull in full or sectioned views.

Figure 9-8 is a multipart series highlighting the individual bones and shows their relationship to the skull as a whole. As you study the skull, refer often to the illustrations and the descriptive information contained in Tables 9-3 to 9-5.

The skull consists of two major divisions: the **cranium,** or brain case, and the **face.** The cranium is formed by eight bones, namely, the frontal, two parietal, two temporal, the occipital, the sphenoid,

(continued on page 232)



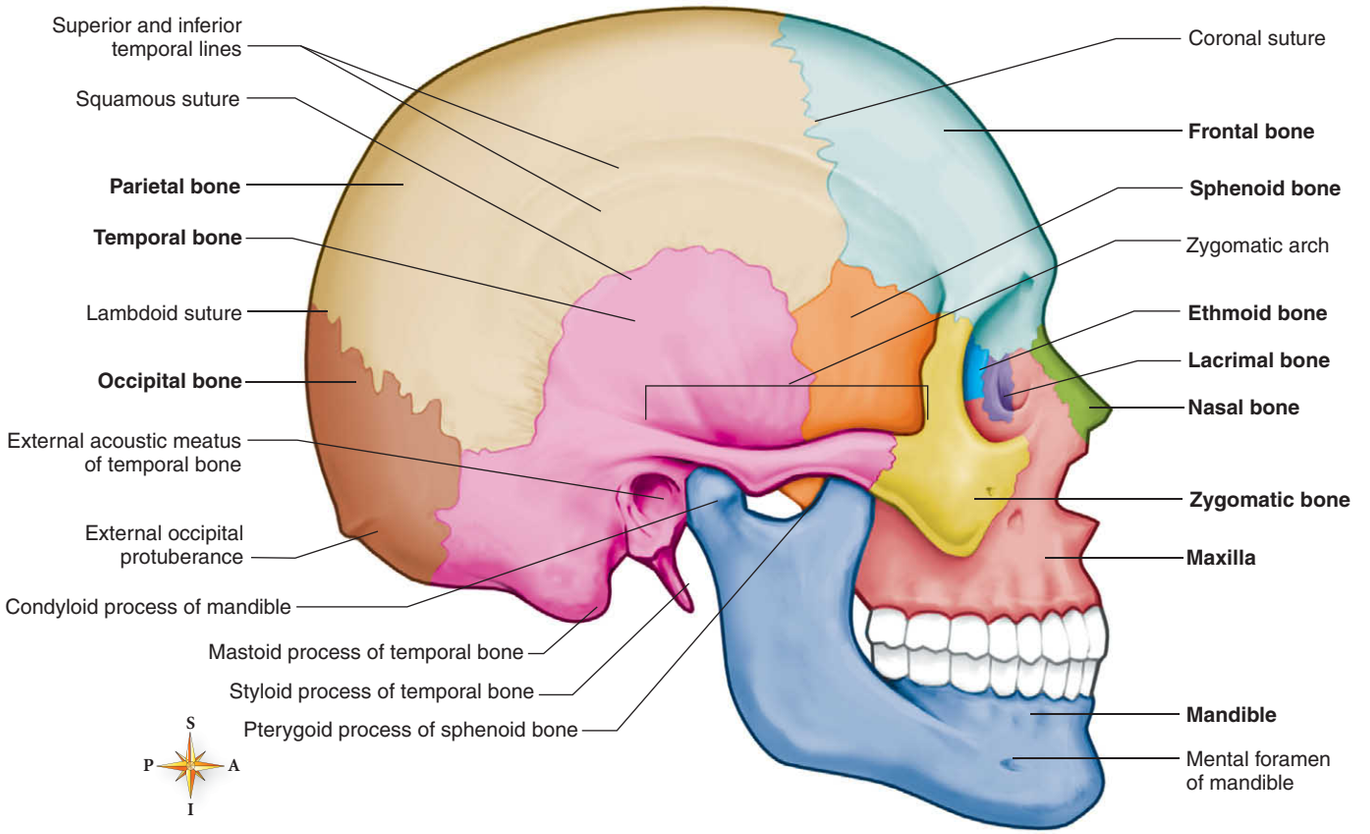


FIGURE 9-2

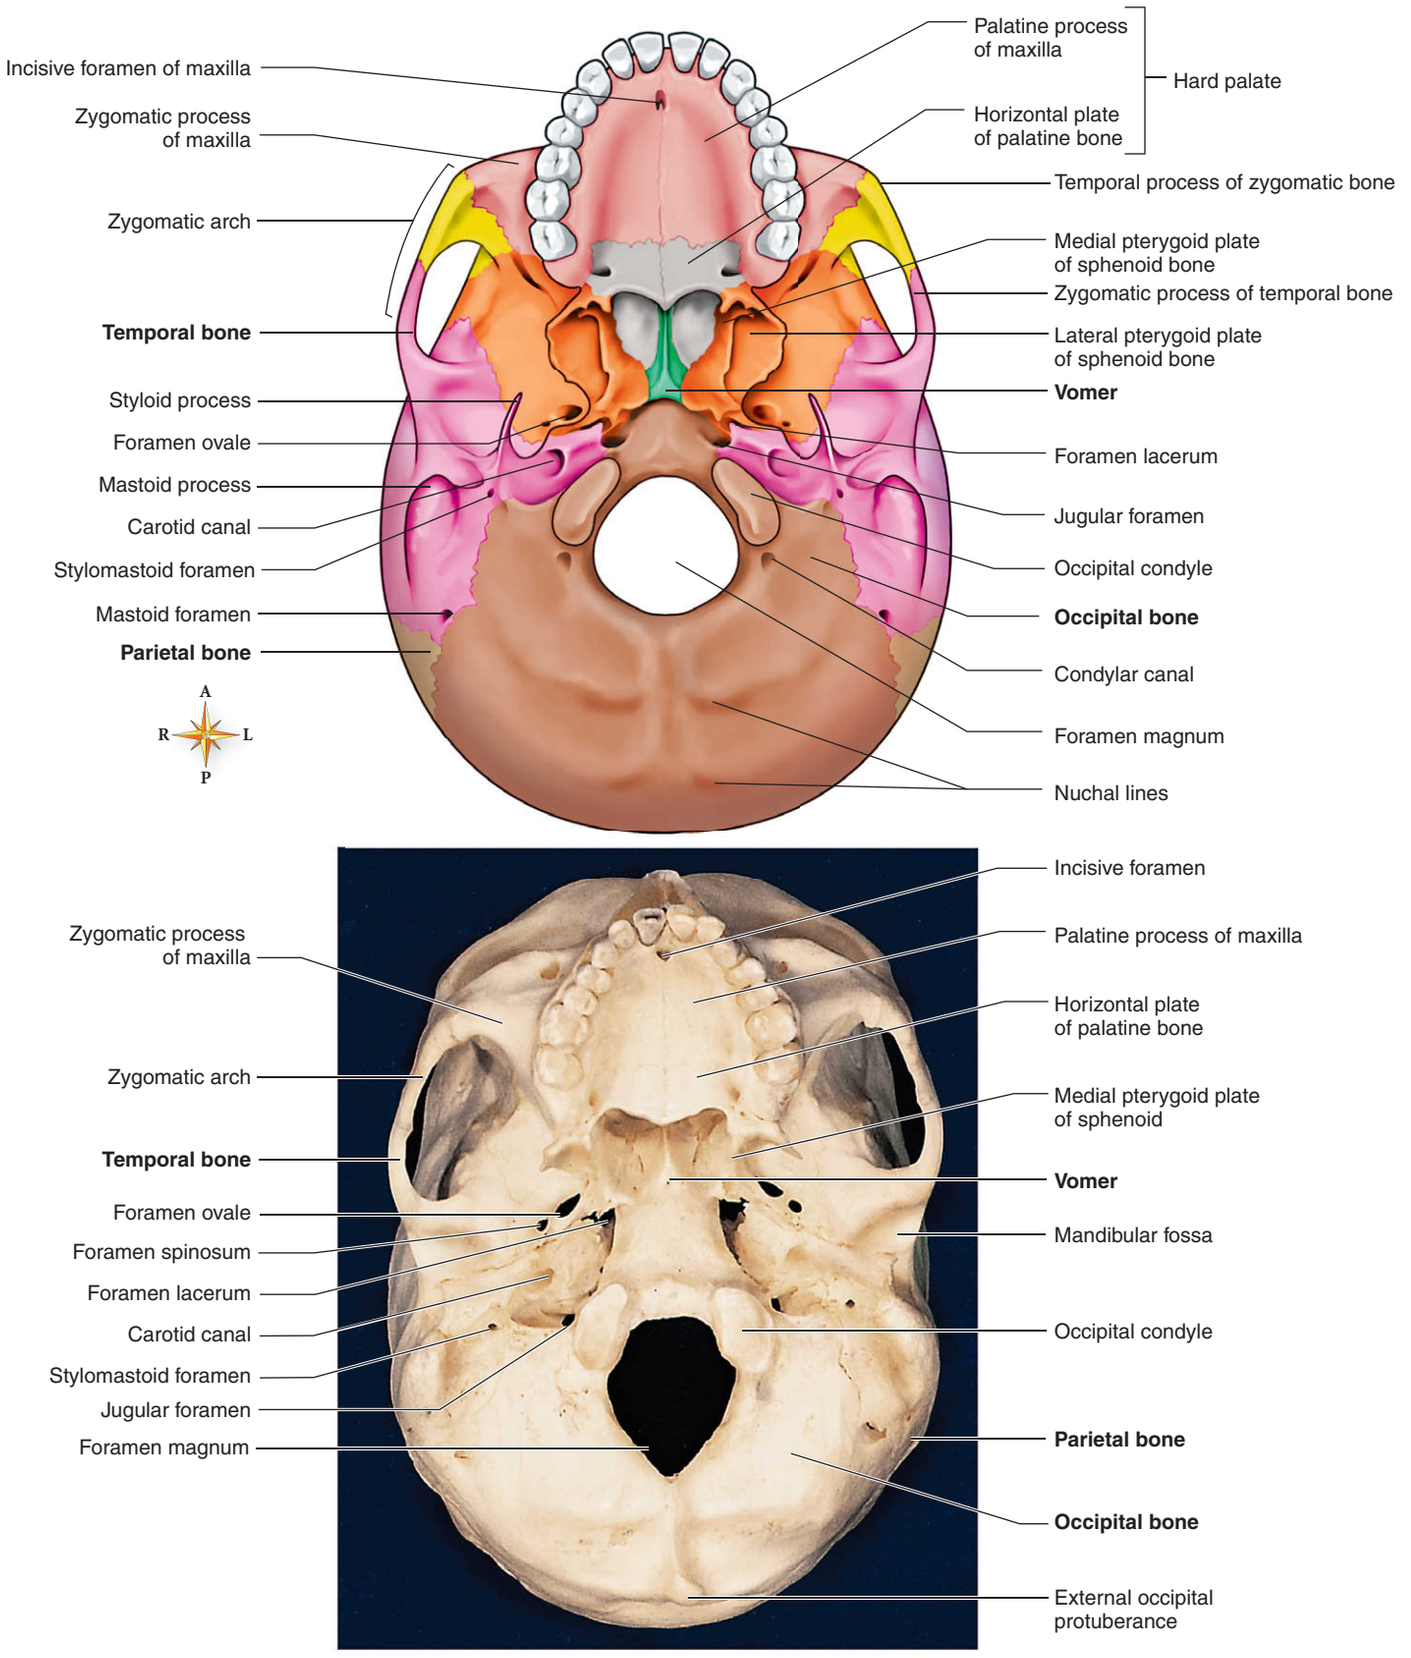

FIGURE 9-5

Skull viewed from below.

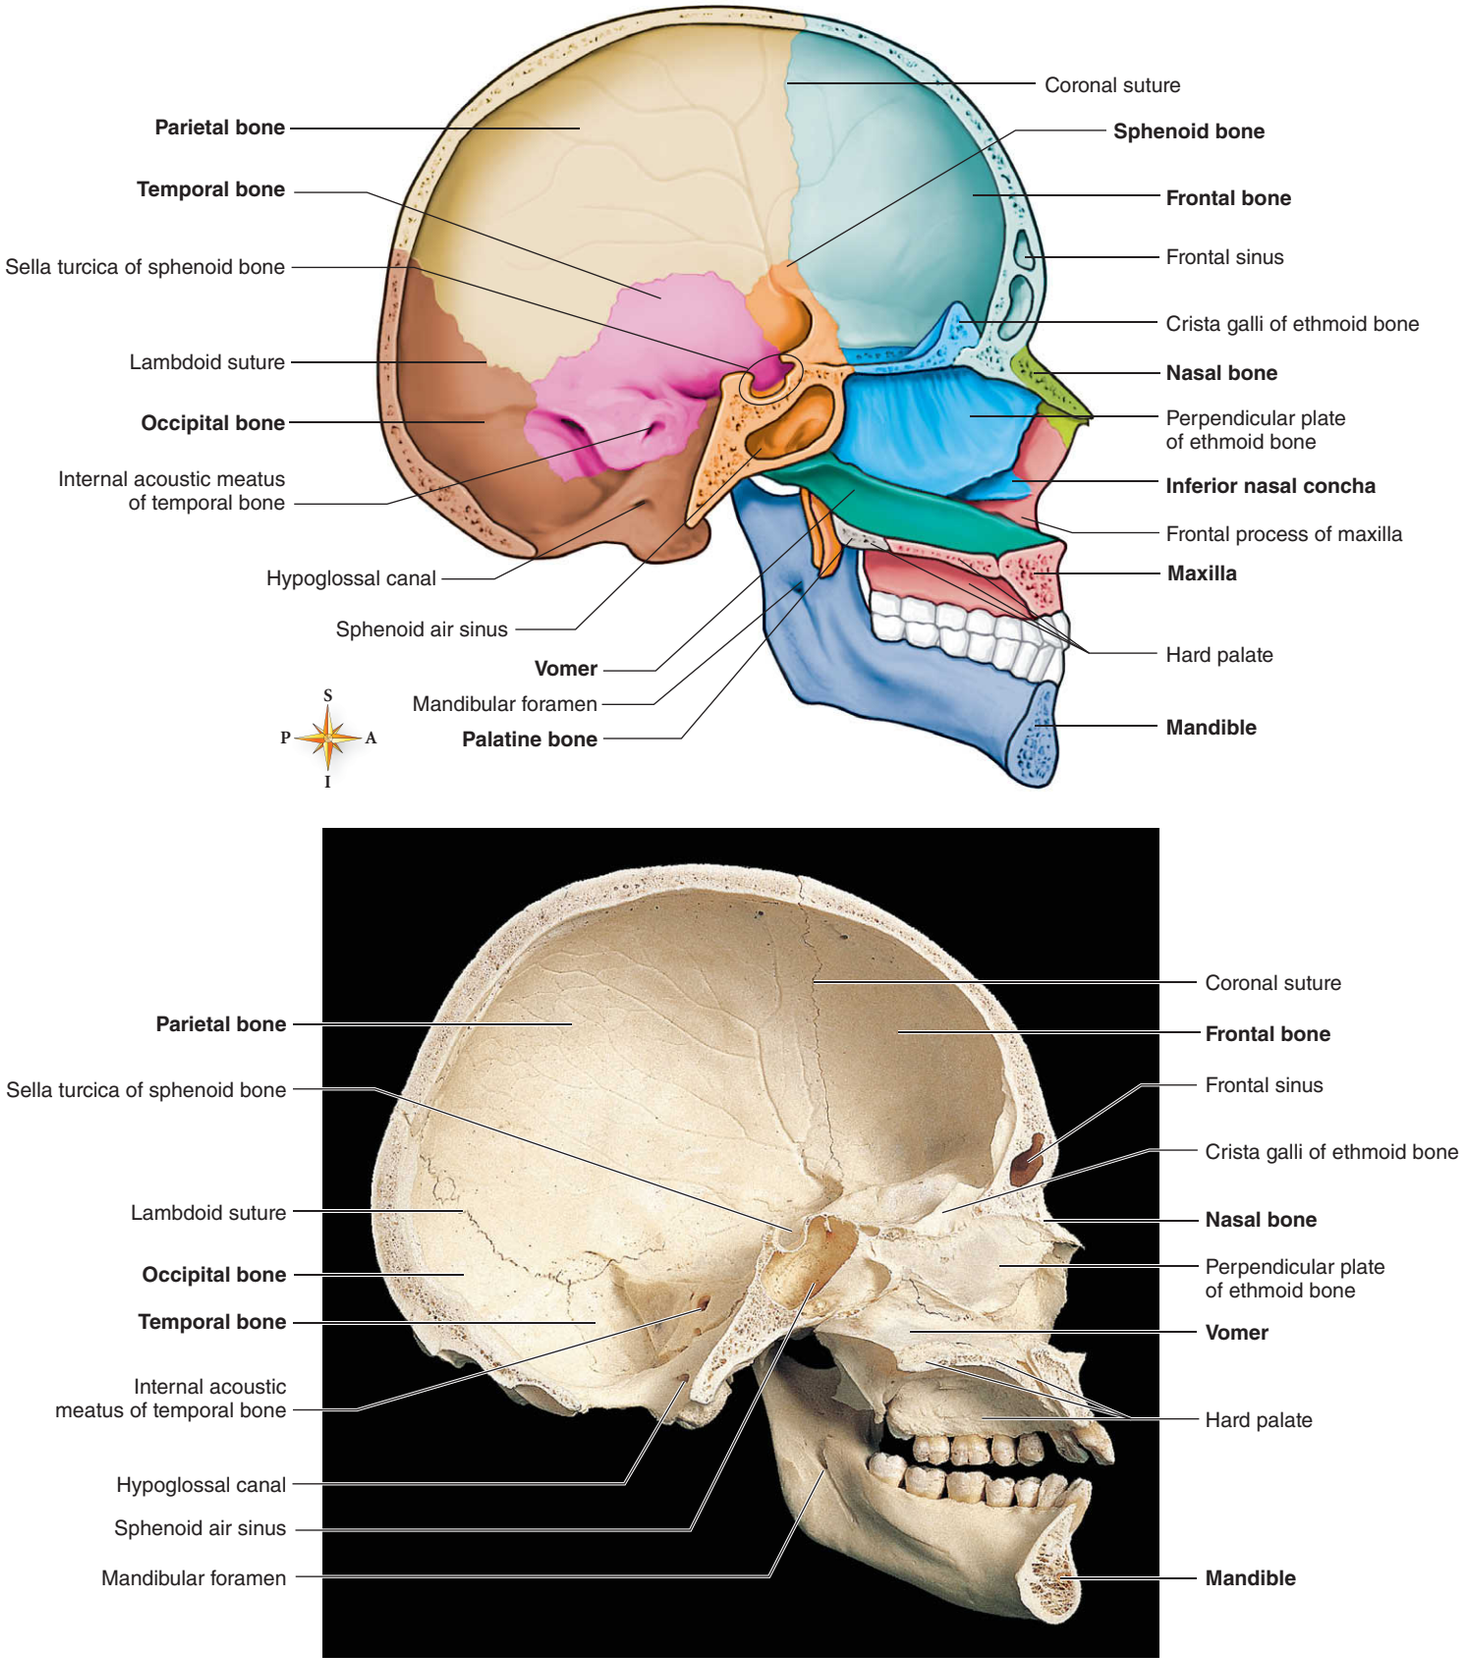

FIGURE 9-6

Left half of the skull viewed from within.

and the ethmoid (Table 9-3). The 14 bones that form the face are the two maxillae, two zygomatic (malar), two nasal, the mandible, two lacrimal, two palatine, two inferior nasal conchae (turbinates), and the vomer (Table 9-4). Note that all the facial bones are paired except for the mandible and vomer. All the cranial bones, on the other hand, are single (unpaired) except for the parietal and temporal bones, which are paired. The frontal and ethmoid bones of the skull help shape the face but are not numbered among the facial bones.

TABLE 9-3 Cranial Bones and Their Markings

BONES AND MARKINGS	DESCRIPTION
Parietal	Prominent, bulging bones behind the frontal bone; forms the top sides of the cranial cavity
Temporal	Form the lower sides of the cranium and part of the cranial floor; contain the middle and inner ear structures
Squamous portion	Thin, flaring upper part of the bone
Mastoid portion	Rough-surfaced lower part of the bone posterior to the external acoustic meatus
Petrous portion	Wedge-shaped process that forms part of the center section of the cranial floor between the sphenoid and occipital bones; name derived from the Greek word for stone because of the extreme hardness of this process; houses the middle and inner ear structures
Mastoid process	Protuberance just behind the ear
Mastoid air cells	Mucosa-lined, air-filled spaces within the mastoid process
External acoustic meatus (or canal)	Tube extending into the temporal bone from the external ear opening to the tympanic membrane

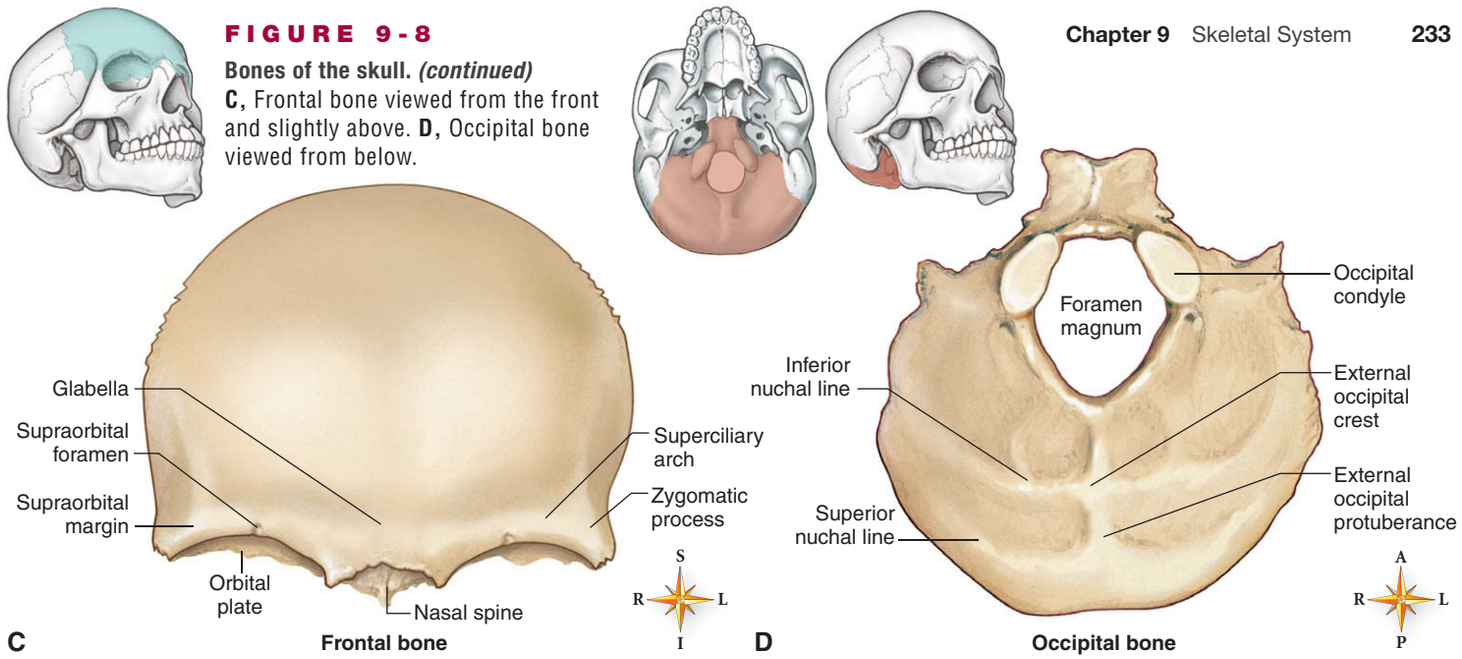

FIGURE 9-8

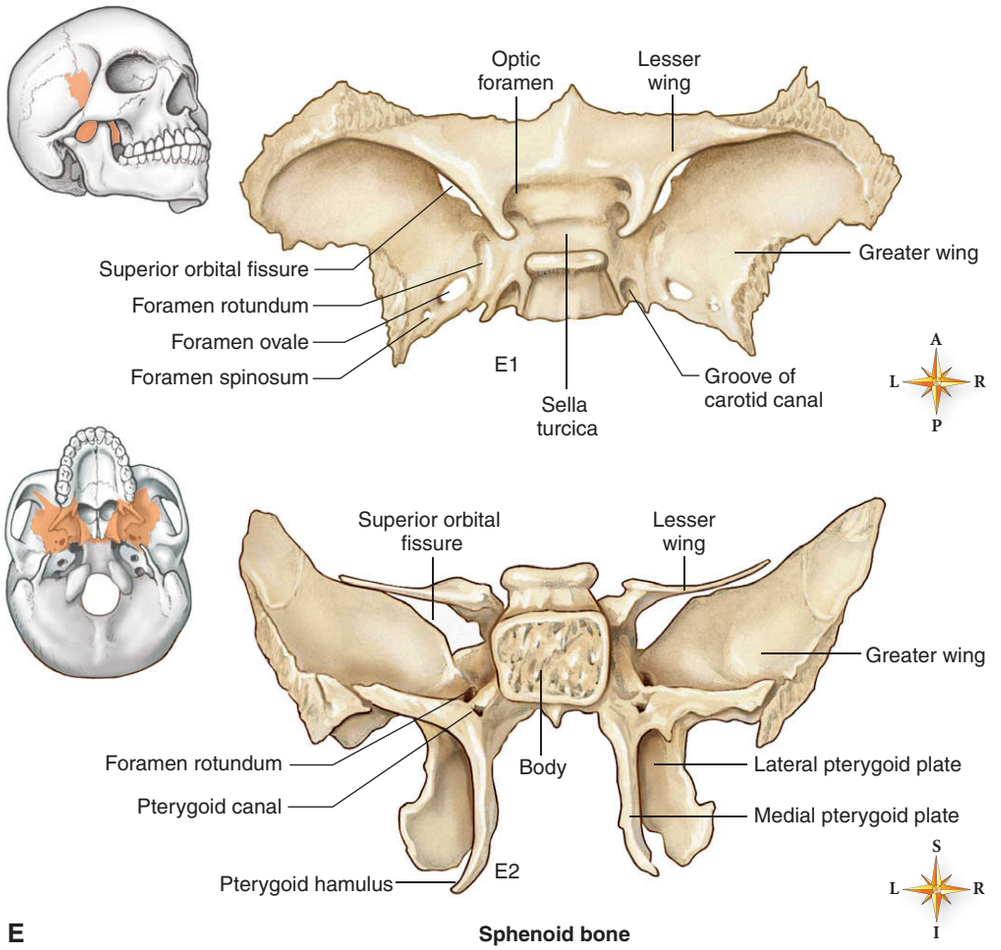
Bones of the skull. ***(continued)***
C, Frontal bone viewed from the front and slightly above. **D**, Occipital bone viewed from below.

(continued)

TABLE 9-3 Cranial Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Zygomatic process	Projection that articulates with the zygomatic (or malar) bone
Internal acoustic meatus	Fairly large opening on the posterior surface of the petrous part of the bone; transmits the eighth cranial nerve to the inner ear and the seventh cranial nerve on its way to the facial structures
Mandibular fossa	Oval-shaped depression anterior to the external acoustic meatus; forms the socket for the condyle of the mandible
Styloid process	Slender spike of bone extending downward and forward from the undersurface of the bone anterior to the mastoid process; often broken off in a dry skull; several neck muscles and ligaments attach to the styloid process
Stylomastoid foramen	Opening between the styloid and mastoid processes where the facial nerve emerges from the cranial cavity
Jugular fossa	Depression on the undersurface of the petrous part; dilated beginning of the internal jugular vein lodged here
Jugular foramen	Opening in the suture between the petrous part and occipital bone; transmits the lateral sinus and ninth, tenth, and eleventh cranial nerves
Carotid canal (or foramen)	Channel in the petrous part; best seen from the undersurface of the skull; transmits the internal carotid artery
Frontal	Forehead bone; also forms most of the roof of the orbits (eye sockets) and the anterior part of the cranial floor
Supraorbital margin	Arched ridge just below eyebrow; forms the upper edge of the orbit
Frontal sinuses	Cavities inside the bone just above supraorbital margin; lined with mucosa; contain air
Frontal tuberosities (tubers or eminences)	Bulge above each orbit; most prominent part of forehead
Superciliary arches (ridges)	Curved ridges caused by projection of the frontal sinuses; eyebrows lie superficial to these ridges
Supraorbital foramen (sometimes notch)	Foramen or notch in the supraorbital margin slightly medial to its midpoint; transmits supraorbital nerve and blood vessels
Glabella	Smooth area between the superciliary ridges and above the nose
Occipital	Forms the posterior part of the cranial floor and walls
Foramen magnum	Hole through which the spinal cord enters the cranial cavity
Occipital condyles	Convex, oval processes on either side of the foramen magnum; articulate with depressions on the first cervical vertebra
External occipital protuberance	Prominent projection on the posterior surface in the midline a short distance above the foramen magnum; can be felt as a definite bump
Superior nuchal line	Curved ridge extending laterally from the external occipital protuberance
Inferior nuchal line	Less well defined ridge paralleling the superior nuchal line a short distance below it
Internal occipital protuberance	Projection in the midline on the inner surface of the bone; grooves for the lateral sinuses extend laterally from this process and one for sagittal sinus extends upward from it

(continued)



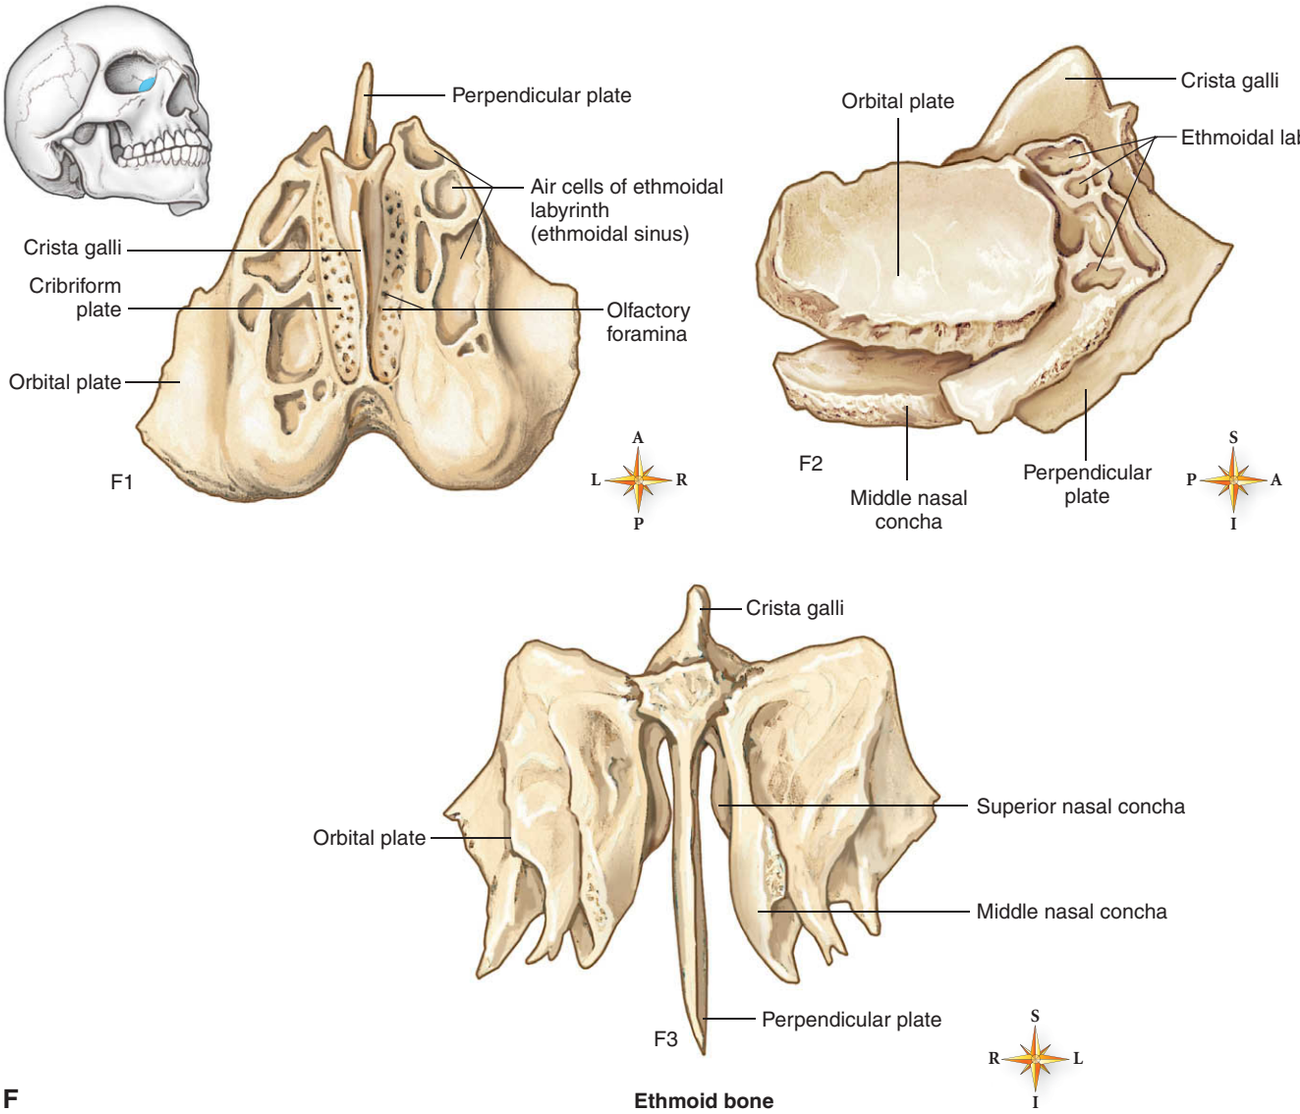


FIGURE 9-8

Bones of the skull. ***(continued)***
E, Sphenoid bone. **E1**, Superior view; **E2,** posterior view.

TABLE 9-3 **Cranial Bones and Their Markings** ***(continued)***

BONES AND MARKINGS	DESCRIPTION
Sphenoid	Keystone of the cranial floor; forms its midportion; resembles a bat with wings outstretched and legs extended downward posteriorly; lies behind and slightly above the nose and throat; forms part of the floor and sidewalls of the orbit
Body	Hollow, cubelike central portion
Greater wings	Lateral projections from the body; form part of the outer wall of the orbit
Lesser wings	Thin, triangular projections from the upper part of the sphenoid body; form the posterior part of the roof of the orbit
Sella turcica	Saddle-shaped depression on the upper surface of the sphenoid body; contains the pituitary gland; literally "Turkish saddle"
Sphenoid sinuses	Irregular mucosa-lined, air-filled spaces within the central part of the sphenoid
Pterygoid processes	Downward projections on either side where the body and greater wing unite; comparable to the extended legs of a bat if the entire bone is likened to this animal; form part of the lateral nasal wall
Optic canal	Opening into the orbit at the root of the lesser wing; transmits the optic nerve
Superior orbital fissure	Slitlike opening into the orbit; lateral to the optic foramen; transmits the third, fourth, and part of the fifth cranial nerves
Foramen rotundum	Opening in the greater wing that transmits the maxillary division of the fifth cranial nerve
Foramen ovale	Opening in the greater wing that transmits the mandibular division of the fifth cranial nerve
Foramen lacerum	Opening at the junction of the sphenoid, temporal, and occipital bones; transmits a branch of the ascending pharyngeal artery
Foramen spinosum	Opening in the greater wing that transmits the middle meningeal artery to supply the meninges

(continued)

F **Ethmoid bone**

FIGURE 9-8

Bones of the skull. ***(continued)*** **F,** Ethmoid bone. **F1,** Superior view; **F2,** lateral view; **F3,** anterior view.

(continued)

TABLE 9-3 Cranial Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Ethmoid	Complex irregular bone that helps make up the anterior portion of the cranial floor, medial wall of the orbits, upper parts of the nasal septum, and sidewalls and part of the nasal roof; lies anterior to the sphenoid and posterior to the nasal bones
Cribriform plate	Olfactory nerves pass through numerous holes in this horizontal plate
Crista galli	Meninges (membranes around the brain) attach to this process
Perpendicular plate	Forms the upper part of the nasal septum
Ethmoid sinuses	Honeycombed, mucosa-lined air spaces within the lateral masses of the bone
Superior and middle nasal conchae (turbinates)	Help form the lateral walls of the nose
Ethmoidal labyrinth	Hollow lateral masses of the ethmoid; contain many air spaces (ethmoid cells or sinuses); the inner surface forms the superior and middle conchae

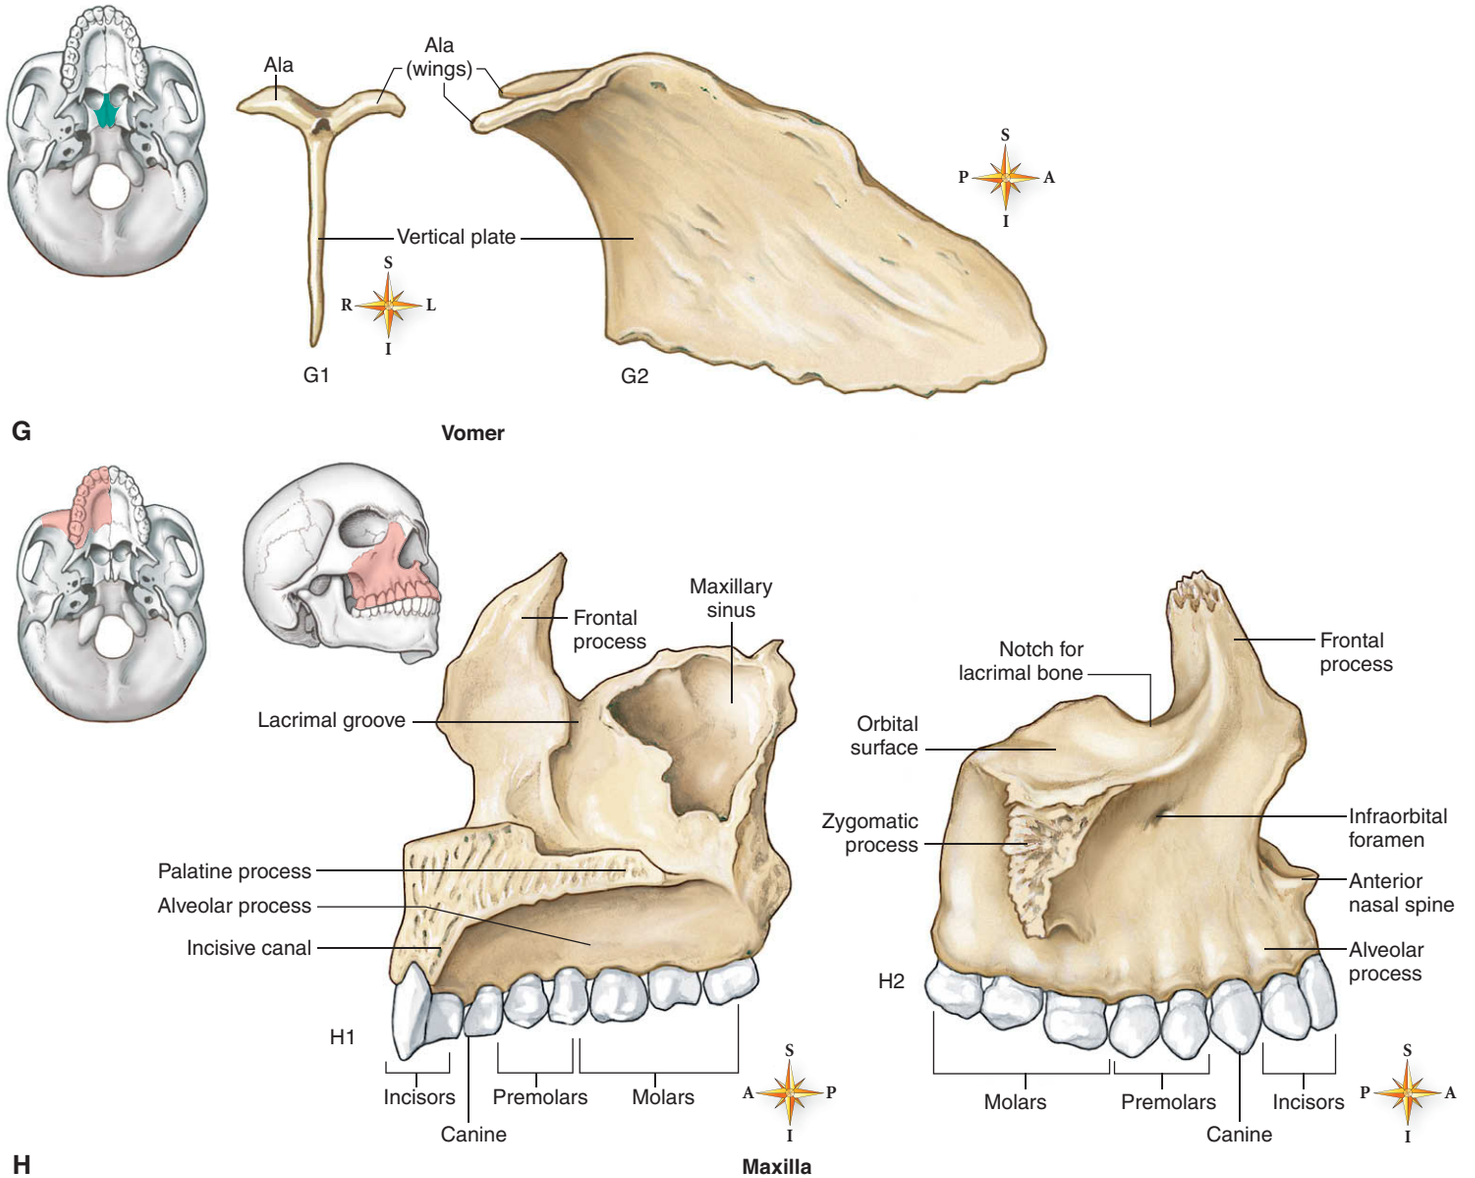

FIGURE 9-8

Bones of the skull. ***(continued)*** **G,** Vomer. **G1,** Anterior view; **G2,** lateral view. **H,** Right maxilla. **H1,** Medial view; **H2,** lateral view.

TABLE 9-4 Facial Bones and Their Markings

BONES AND MARKINGS	DESCRIPTION
Vomer	Forms lower and posterior part of nasal septum; shaped like the blade of a plough
Maxilla	Upper jaw bones; form part of the floor of the orbit, anterior part of the roof of the mouth, and floor of the nose and part of the sidewalls of the nose
Alveolar process	Archlike process that holds the tooth sockets
Maxillary sinus	Large, air-filled cavity within body of maxilla; lined with mucous membrane; largest of paranasal sinuses
Palatine process	Horizontal plate that projects inward from the alveolar process; forms anterior and larger part of hard palate
Infraorbital foramen	Hole on external surface orbit; transmits vessels and nerves
Lacrimal groove	Groove on inner surface; joined by similar groove on lacrimal bone to form bony space for the nasolacrimal duct

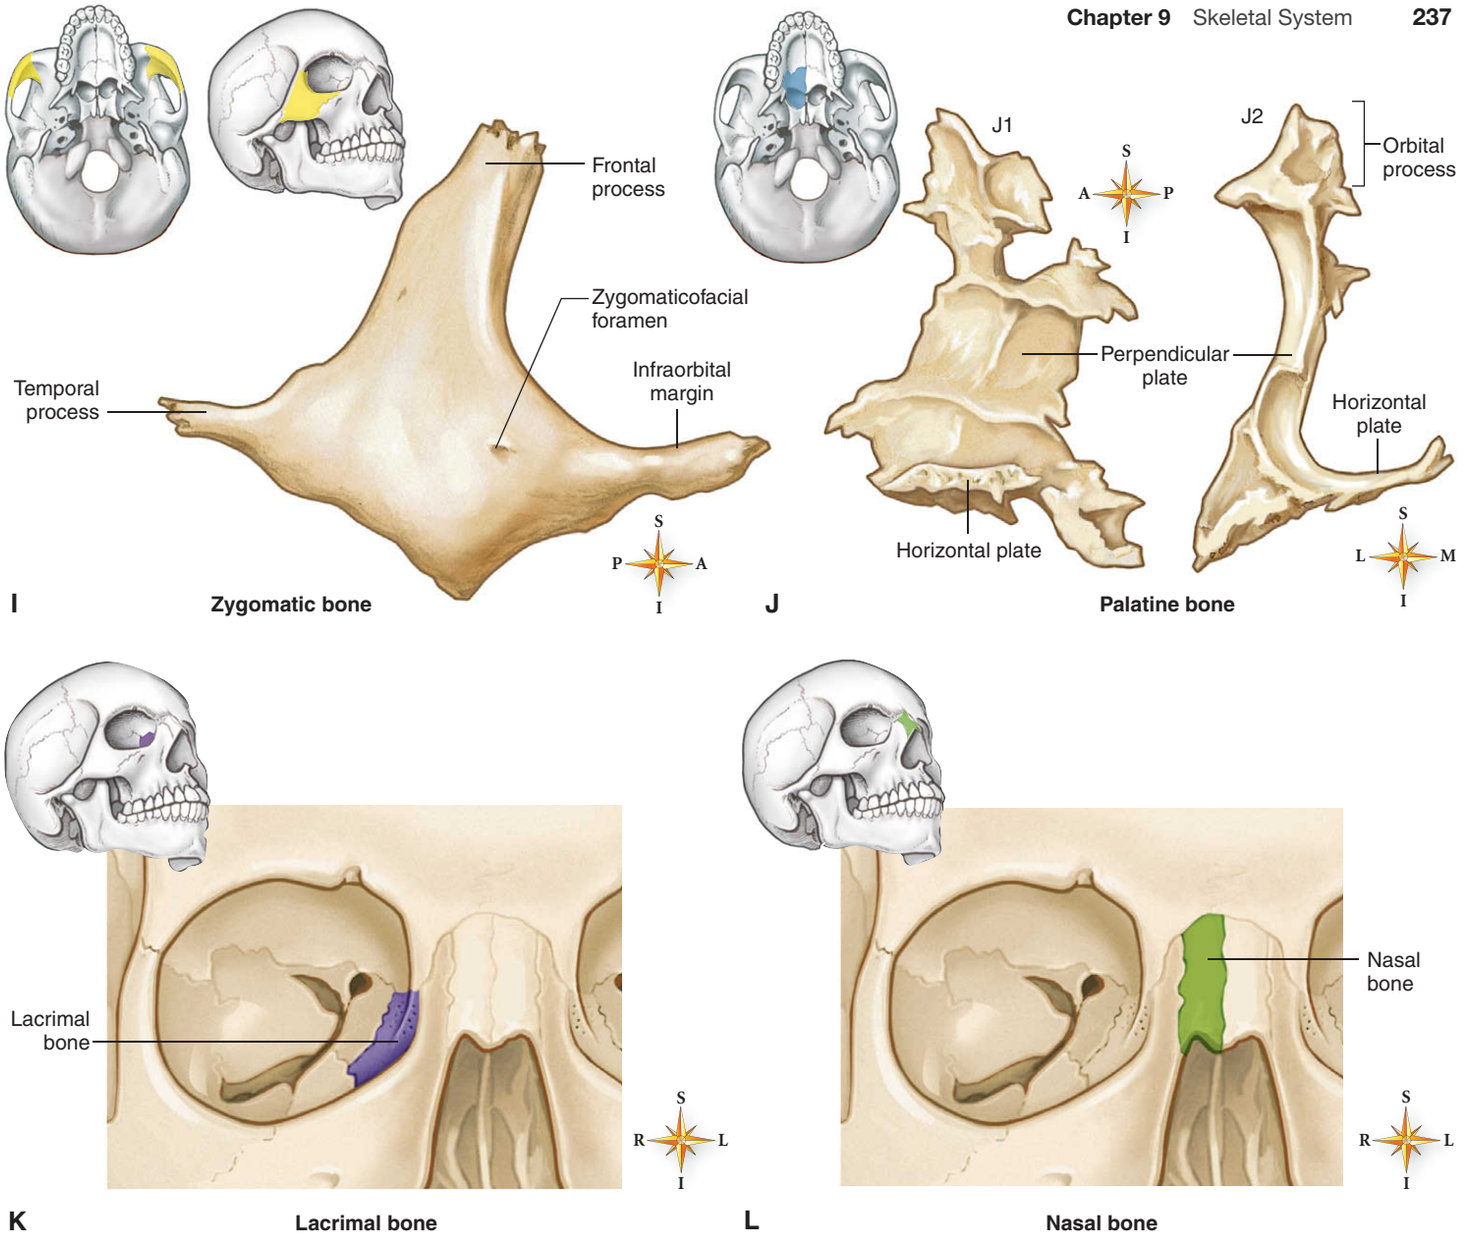

FIGURE 9-8

Bones of the skull. ***(continued)*** **I,** Right zygomatic bone viewed from the lateral side. **J,** Right palatine bone. **J1,** Medial view; **J2,** anterior view. **K,** Right lacrimal bone viewed from the lateral side. **L,** Right nasal bone viewed from the lateral side.

(continued)

TABLE 9-4 Facial Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Zygomatic	Cheekbones; form part of floor and sidewall of eye orbit
Palatine	Form the posterior part of the hard palate, floor, and part of the sidewalls of the nasal cavity and floor of orbit
Horizontal plate	Joined to the palatine processes of the maxillae to complete part of the hard palate
Lacrimal	Thin platelike bones; posterior and lateral to nasal bones in medial wall of eye orbit; help form sidewall of nasal cavity (often missing in dry skull specimen)
Nasal	Pair of small bones that form the upper part of bridge of nose
Inferior nasal conchae (turbinates)	Thin scroll of bone forming shelf along inner surface of sidewall of nasal cavity; lies above roof of mouth

(continued)

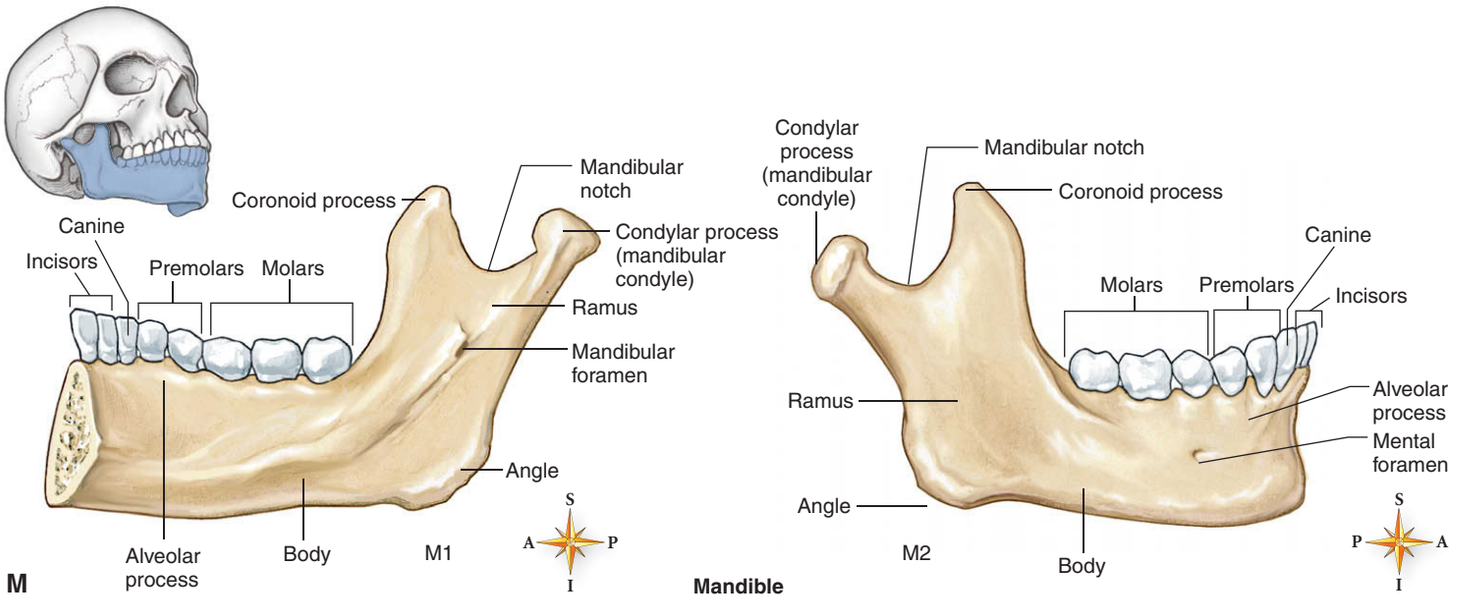

FIGURE 9-8

Bones of the skull. ***(continued)*** **M,** Right half of the mandible. **M1,** Medial view; **M2,** lateral view.

TABLE 9-4 Facial Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Mandible	Lower jawbone; largest, strongest bone of the face
Body	Main part of the bone; forms the chin
Ramus	Process, one on either side, that projects upward from the posterior part of the body
Condylar process	Part of each ramus that articulates with the mandibular fossa of the temporal bone
Neck	Constricted part just below the condyles
Alveolar process	Teeth set into this arch
Mandibular foramen	Opening on the inner surface of the ramus; transmits nerves and vessels to the lower teeth
Mental foramen	Opening on the outer surface below the space between the two bicuspids; transmits the terminal branches of the nerves and vessels that enter the bone through the mandibular foramen; dentists inject anesthetics through these foramina
Coronoid process	Projection upward from the anterior part of each ramus; the temporal muscle inserts here
Angle	Juncture of posterior and inferior margins of ramus

CRANIAL BONES

The **frontal bone** forms the forehead and the anterior part of the calvaria or top of the cranium (see Figure 9-8, *C*). It contains mucosa-lined, air-filled spaces, or **sinuses**—the *frontal sinuses.* The frontal sinuses, with similar sinuses in the sphenoid, ethmoid, and maxillae, are often called *paranasal sinuses* because they have narrow channels that open into the nasal cavity (Figure 9-9). The paranasal sinuses are also discussed in Chapter 26, p.802. A portion of the frontal bone forms the upper part of the orbits. It unites with the two parietal bones posteriorly in an immovable joint, or **suture**—the *coronal suture.* Several of the more prominent frontal bone markings are described in Table 9-3.

The two **parietal bones** give shape to the bulging topside of the cranium (see Figure 9-8, *A*). They form immovable joints with several bones: the *lambdoid suture* with the occipital bone, the *squamous suture* with the temporal bone and part of the sphenoid, and the *coronal suture* with the frontal bone.

The lower sides of the cranium and part of its floor are fashioned from two **temporal bones** (see Figure 9-8, *B*). They house the middle and inner ear structures and contain the *mastoid sinuses,* notable because of the occurrence of *mastoiditis,* an inflammation of the mucous lining of these spaces (see Mechanisms of Disease, pp. 264–265). For a description of several other temporal bone markings, see Table 9-3.

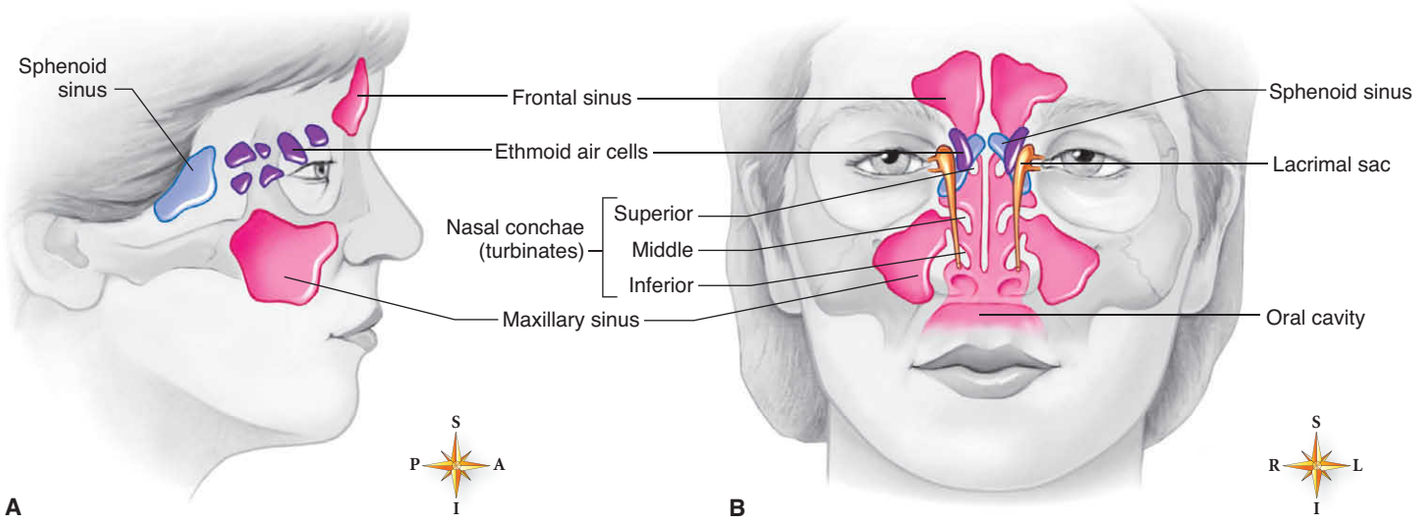

FIGURE 9-9

The paranasal sinuses. A, Lateral view. **B,** Frontal view.

The **occipital bone** creates the framework of the lower, posterior part of the skull (see Figure 9-8, *D*). It forms immovable joints with three other cranial bones—the parietal, temporal, and sphenoid—and a movable joint with the first cervical vertebra. Table 9-3 lists a description of some of its markings.

The shape of the **sphenoid bone** resembles a bat with its wings outstretched and legs extended down and back. Note in Figures 9-4 and 9-8, *E*, the location of the sphenoid bone in the central portion of the cranial floor. Here it serves as the keystone in the architecture of the cranium and anchors the frontal, parietal, occipital, and ethmoid bones. The sphenoid bone also forms part of the lateral wall of the cranium and part of the floor of each orbit (see Figures 9-2 and 9-3). The sphenoid bone contains fairly large mucosa-lined, air-filled spaces—the sphenoid sinuses (see Figure 9-6). Several prominent sphenoid markings are described in Table 9-3.

The **ethmoid,** a complex, irregular bone, lies anterior to the sphenoid but posterior to the nasal bones. It helps fashion the anterior part of the cranial floor (see Figures 9-4 and 9-8, *F*), the medial walls of the orbits (see Figures 9-2 and 9-7), the upper parts of the nasal septum (see Figure 9-2) and the sidewalls of the nasal cavity (Figure 9-10), and the part of the nasal roof (the cribriform plate) perforated by small foramina through which olfactory nerve branches reach the

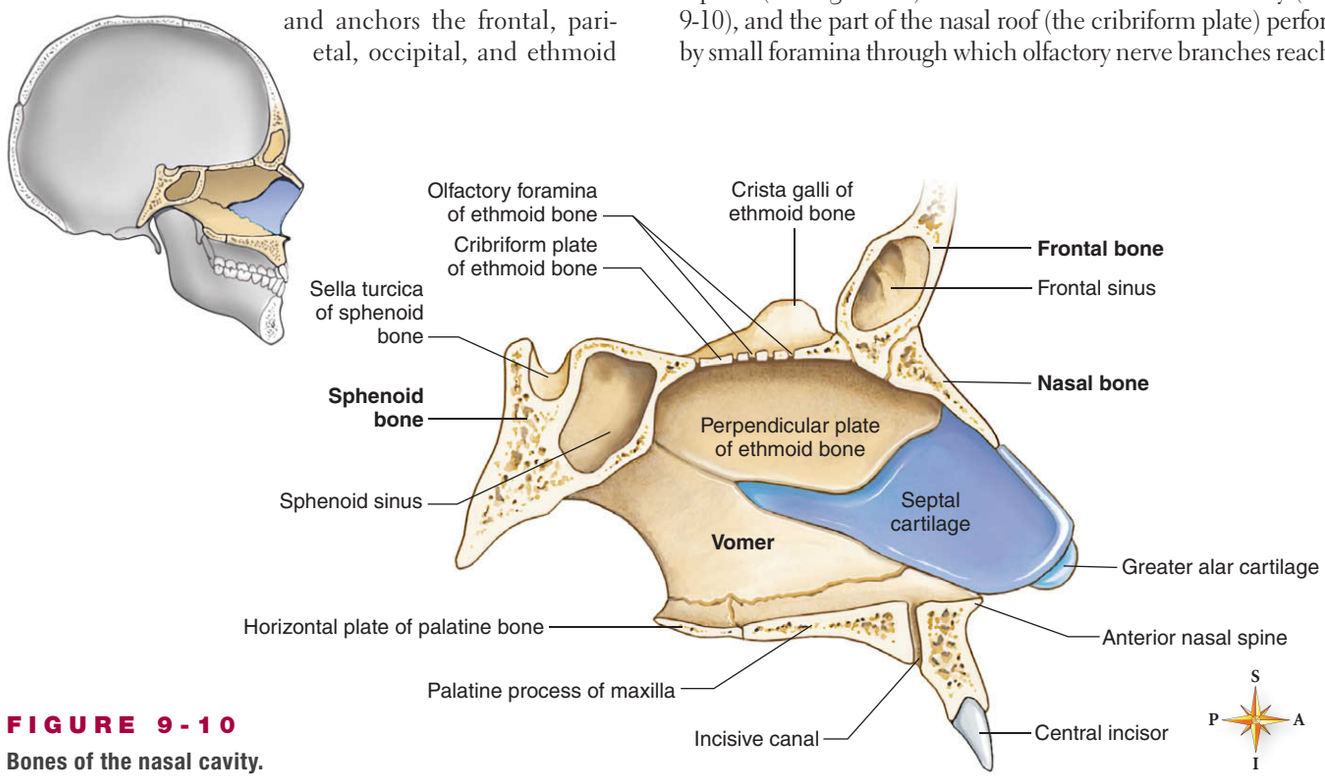

FIGURE 9-10

Bones of the nasal cavity.

brain (Box 9-1). The lateral masses of the ethmoid bone are honeycombed with sinus spaces called *ethmoid air cells* (see Figure 9-9). For more ethmoid bone markings, see Table 9-3.

FACIAL BONES

The two **maxillae** serve as the keystone in the architecture of the face, just as the sphenoid bone acts as the keystone of the cranium. Each maxilla articulates with the other maxilla and also with a nasal, a zygomatic, an inferior concha, and a palatine bone (see Figure 9-8, *H*). Of all the facial bones, only the mandible does not articulate with the maxillae. The maxillae form part of the floor of the orbits, part of the roof of the mouth, and part of the floor and sidewalls of the nose. Each maxilla contains a mucosa-lined space, the *maxillary sinus* (see Figure 9-9). This sinus is the largest of the paranasal sinuses, that is, sinuses connected by channels to the nasal cavity. For other markings of the maxillae, see Table 9-4.

Unlike the upper jaw, which is formed by the articulation of the two maxillae, the lower jaw, because of fusion of its halves during infancy, consists of a single bone, the **mandible** (see Figure 9-8, *M*). It is the largest, strongest bone of the face. It articulates with the temporal bone in the only movable joint of the skull. Its major markings are identified in Table 9-4.

The cheek is shaped by the underlying **zygomatic,** or malar, **bone** (see Figure 9-8, *I*). This bone also forms the outer margin of the orbit and, with the zygomatic process of the temporal bone, makes the zygomatic arch. It articulates with four other facial bones: the maxillary, temporal, frontal, and sphenoid bones.

Shape is given to the nose by the two **nasal bones,** which form the upper part of the bridge of the nose (see Figure 9-8, *L*), and by the *septal cartilage*, which forms the lower part (see Figure 9-10). Although small, the nasal bones enter into several articulations: with the perpendicular plate of the ethmoid bone, the cartilaginous part of the nasal septum, the frontal bone, the maxillae, and each other.

Box 9-1 | HEALTH matters

The Cribriform Plate

Separation of the nasal and cranial cavities by the cribriform plate of the ethmoid bone has great clinical significance. The cribriform plate is perforated by many small openings that permit branches of the olfactory nerve responsible for the special sense of smell to enter the cranial cavity and reach the brain. Separation of these two cavities by a thin, perforated plate of bone presents real hazards. If the cribriform plate is damaged as a result of trauma to the nose, it is possible for potentially infectious material to pass directly from the nasal cavity into the cranial fossa. If fragments of a fractured nasal bone are pushed through the cribriform plate, they may tear the coverings of the brain or enter the substance of the brain itself.

An almost paper-thin bone, shaped and sized about like a fingernail, lies just posterior and lateral to each nasal bone. It helps form the sidewall of the nasal cavity and the medial wall of the orbit. Because it contains a groove for the nasolacrimal (tear) duct, this bone is called the **lacrimal bone** (see Figure 9-8, *K*). It joins the maxilla, frontal bone, and ethmoid bone.

| A&P CONNECT |

The sinuses of the skull are often visible in x-ray images and other radiographs, as you can see in ***Skeletal Radiography*** online at ***A&P Connect.***

The two **palatine bones** join to each other in the midline like two L's facing each other. Their united horizontal portions form the posterior part of the hard palate (see Figure 9-8, *J*). The vertical portion of each palatine bone forms the lateral wall of the posterior part of each nasal cavity. The tip of the vertical portion is the *orbital process*, which forms part of the eye orbit (see Figure 9-7). The palatine bones articulate with the maxillae and the sphenoid bone.

There are two **inferior nasal conchae** (turbinates). Each concha is scroll shaped and forms a kind of ledge projecting into the nasal cavity from its lateral wall. Each nasal cavity has three such ledges. The superior and middle conchae (which are projections of the ethmoid bone) form the upper and middle ledges. The inferior concha (which is a separate bone) forms the lower ledge. They are covered by mucosa and divide each nasal cavity into three narrow, irregular channels, the nasal meatus. The inferior nasal conchae form immovable joints with the ethmoid, lacrimal, maxilla, and palatine bones.

Two structures that are involved in the formation of the nasal septum have already been mentioned—the perpendicular plate of the ethmoid bone and the septal cartilage. One other structure, the **vomer bone,** completes the septum posteriorly (see Figures 9-8, *G*, and 9-10 and Table 9-5). It forms immovable joints with four bones: the sphenoid, ethmoid, palatine, and maxillae.

EYE ORBITS

The right and left orbital cavities of the skull contain not only the eyes and associated muscles but also the lacrimal apparatus and important blood vessels and nerves. These structures are separated from the cranial cavity, nose, paranasal sinuses, and mouth by the often very thin and fragile orbital walls (see Figures 9-2 and 9-7).

| A&P CONNECT |

The fragile bones of the eye orbit can fracture easily, causing a dramatic condition called ***raccoon eyes.*** See for yourself in ***Bone Fractures*** online at ***A&P Connect.***

TABLE 9-5 Special Features of the Skull

FEATURE	DESCRIPTION
Sutures	Immovable joints between skull bones
Squamous	Line of articulation along the top curved edge of the temporal bone
Coronal	Joint between the parietal bones and frontal bone
Lambdoid	Joint between the parietal bones and occipital bone
Sagittal	Joint between the right and left parietal bones
Fontanels	"Soft spots" where ossification is incomplete at birth; allow some compression of the skull during birth; also important in determining the position of the head before delivery; six such areas located at angles of the parietal bones
Anterior (or frontal)	At the intersection of the sagittal and coronal sutures (juncture of the parietal bones and frontal bone); diamond shaped; largest of the fontanels; usually closed by 11.2 years of age
Posterior (or occipital)	At the intersection of the sagittal and lambdoid sutures (juncture of the parietal bones and occipital bone); triangular; usually closed by the second month
Sphenoid (or anterolateral)	At the juncture of the frontal, parietal, temporal, and sphenoid bones
Mastoid (or posterolateral)	At the juncture of the parietal, occipital, and temporal bones; usually closed by the second year
Air sinuses	Spaces, or cavities, within bones; those that communicate with the nose are called *paranasal sinuses* (frontal, sphenoidal, ethmoidal, and maxillary); mastoid cells communicate with the middle ear rather than the nose, so not included among the paranasal sinuses
Orbits formed by	
Frontal bone	Roof of the orbit
Ethmoid bone	Medial wall
Lacrimal bone	Medial wall
Sphenoid bone	Lateral wall
Zygomatic bone	Lateral wall
Maxilla	Floor
Palatine bone	Floor
Nasal septum formed by	Partition in the midline of the nasal cavity; separates the cavity into right and left halves
Perpendicular plate of the ethmoid bone	Forms the upper part of the septum
Vomer	Forms the lower, posterior part of the septum
Cartilage	Forms the anterior part of the septum
Sutural (wormian) bones	Small islets of bone in sutures; vary greatly from person to person
Malleus, incus, stapes	Tiny bones, referred to as *auditory ossicles,* in the middle ear cavity in the temporal bones; resemble, respectively, a miniature hammer, anvil, and stirrup

FETAL SKULL

The skulls of both a fetus and a newborn infant have unique anatomical features not seen in an adult. For example, placement of the cranial bones in the fetal skull allows it to change shape during the birth process. During infancy and childhood, differential growth and development of certain areas of the skull produce changing proportions of the cranium and face. As you will learn in Chapter 36, the face at birth forms a relatively smaller proportion of the cranium (about one eighth) than in the adult (about one half). Also, whereas an infant's head is approximately one fourth the total height of the body, an adult's head is only about one eighth the total height (see Figure 36-22 on p. 1116).

The **fontanels,** visible in Figure 9-11 and described in Table 9-5, are perhaps the best known of the unique features

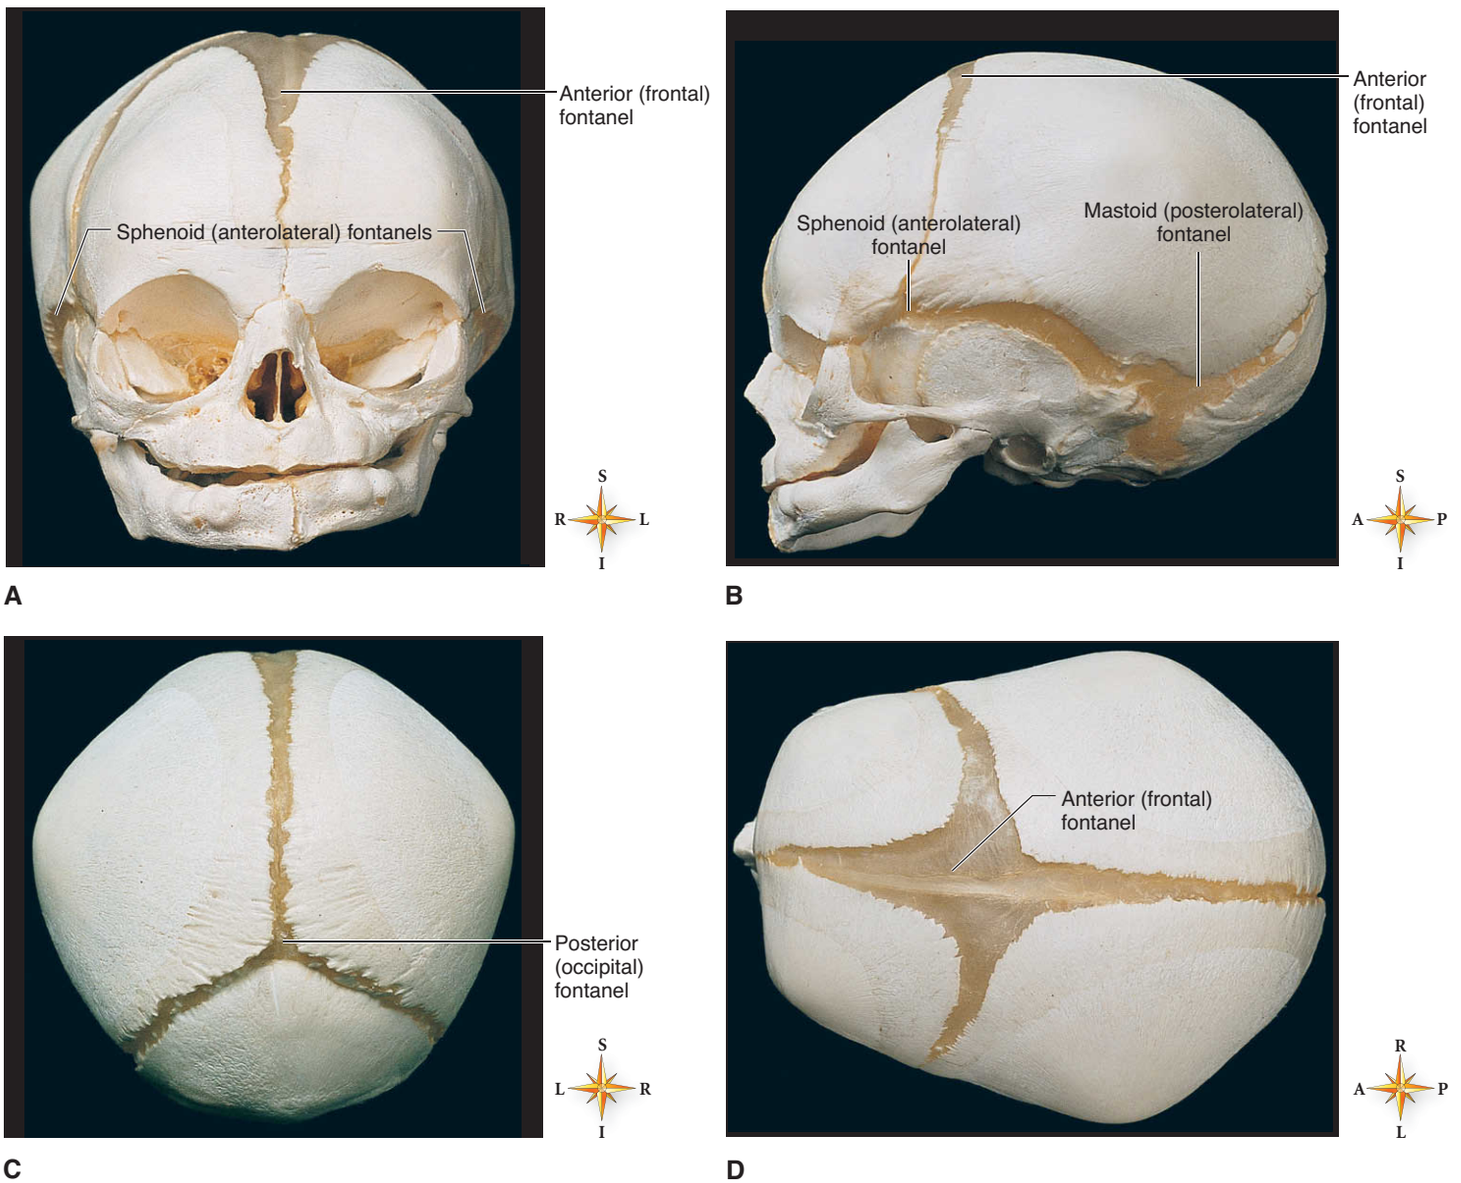

FIGURE 9-11

Skull at birth. A, Viewed from the front. **B,** Viewed from the left and slightly below. **C,** Viewed from behind. **D,** Viewed from above.

in the infant skull. Without the additional space between skull bones provided by the fontanels, molding of head shape as the baby passes through the birth canal could result in fracture of one or more cranial bones. Fontanels also allow rapid brain growth to occur in infancy without causing damaging increases in intracranial pressure. When the fontanels close and the cranial bones grow together as they reach adult size and shape, they fuse together and form the adult suture lines that remain visible throughout life (see Table 9-5).

Numerous other changes occur as the skull of the newborn undergoes skeletal aging processes that prepare it for adult functions. For example, the paranasal sinuses, shown in Figure 9-6 and described in detail in Chapter 26, undergo dramatic changes in size and placement during the time between birth and skeletal maturity. They are listed as special features of the skull in Table 9-5. In Figure 9-11, elevations that cover the developing deciduous, or baby, teeth can be seen in the body of the mandible. Over time these teeth will erupt and eventually be replaced by the adult dentition. These and other anatomical changes in the skull are possible because of the orderly sequence of aging processes that occur between fetal life and skeletal maturity.

Special features of the skull including the eye orbits, nasal septum, sutures, fontanels, sutural (wormian) bones, and the auditory ossicles, are briefly described in Table 9-5.

| A&P CONNECT |

The skull changes quite a bit over the life span, a fact that helps anthropologists and forensic scientists determine the age of a person simply by examining the skeleton or skeletal remains. You can see examples of these changes in ***Skeletal Variations*** online at ***A&P Connect.***

evolve

Hyoid Bone

The hyoid bone is a single bone in the neck—a part of the axial skeleton (Table 9-6). Its U shape may be felt just above the larynx (voice box) and below the mandible, where it is suspended from the styloid processes of the temporal bones (Figure 9-12). Several muscles attach to the hyoid bone. Among them are an extrinsic tongue muscle and certain muscles of the floor of the mouth. The hyoid claims the distinction of being the only bone in the body that articulates with no other bones.

| QUICK CHECK |

1. Name the eight bones of the cranium and describe how they fit together.
2. Name the 14 bones of the face and describe how they fit together.
3. Which bone is the only bone that normally does not form a joint with any other bone of the skeleton?

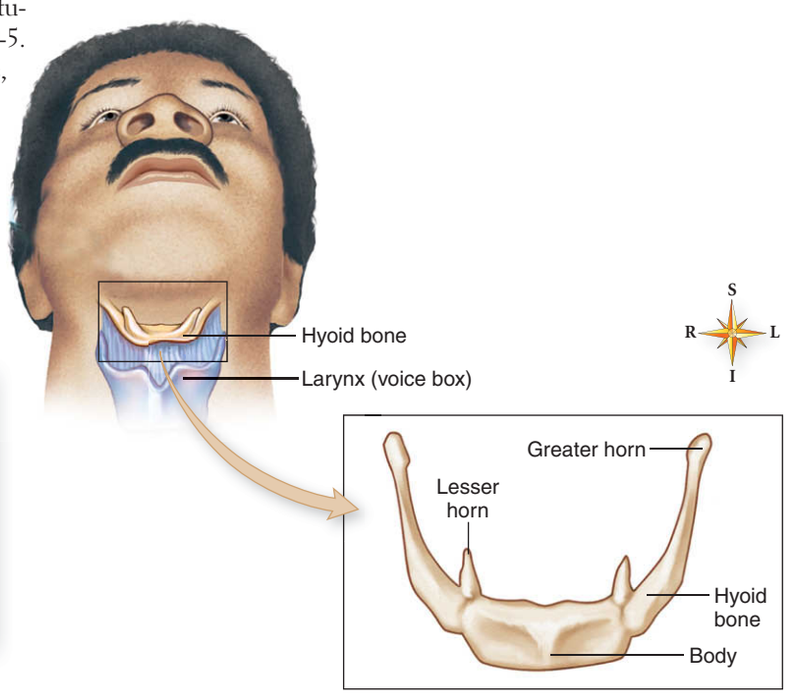

FIGURE 9-12

Hyoid bone. The insert shows the relationship of the hyoid bone in the neck below the skull and above the voice box (larynx). Note that the hyoid does not articulate with any other bony structure.

TABLE 9-6 Hyoid, Vertebrae, and Thoracic Bones and Their Markings

BONES AND MARKINGS	DESCRIPTION
Hyoid	U-shaped bone in the neck between the mandible and upper part of the larynx; distinctive as the only bone in the body not forming a joint with any other bone; suspended by ligaments from the styloid processes of the temporal bones

(continued)

TABLE 9-6 Hyoid, Vertebrae, and Thoracic Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Vertebral column	Not actually a column, but a flexible, segmented curved rod; forms the axis of the body; head balanced above, ribs and viscera suspended in front, and lower extremities attached below; encloses the spinal cord *General features:* Anterior part of each vertebra (except the first two cervical) consists of the body; posterior part of the vertebrae consists of the neural arch, which in turn consists of two pedicles, two laminae, and seven processes projecting from the laminae
Body	Main part; flat, round mass located anteriorly; supporting or weight-bearing part of the vertebra
Pedicles	Short projections extending posteriorly from the body
Lamina	Posterior part of the vertebra to which pedicles join and from which processes project
Neural arch	Formed by the pedicles and laminae; protects the spinal cord posteriorly; congenital absence of one or more neural arches is known as *spina bifida* (the cord may protrude right through the skin)
Spinous process	Sharp process projecting inferiorly from laminae in the midline
Transverse processes	Right and left lateral projections from laminae
Superior articulating processes	Project upward from laminae; have smooth *superior articular facets*
Inferior articulating processes	Project downward from laminae; articulate with the superior articulating processes of vertebrae below; have smooth *inferior articular facets*
Spinal foramen	Hole in the center of the vertebra formed by union of the body, pedicles, and laminae; spinal foramina, when vertebrae are superimposed on one another, form the spinal cavity that houses the spinal cord
Intervertebral foramina	Opening between the vertebrae through which the spinal nerves emerge
Cervical vertebrae	First or upper seven vertebrae; the foramen in each transverse process for transmission of the vertebral artery, vein, and plexus of nerves; short bifurcated spinous processes except on the seventh vertebra, where it is extra long and may be felt as a protrusion when head is bent forward; the bodies of these vertebrae are small, whereas spinal foramina are large and triangular
Atlas	First cervical vertebra; lacks a body and spinous process; superior articulating processes are concave ovals that act as rockerlike cradles for the condyles of the occipital bone; named *atlas* because it supports the head as Atlas supports the world in Greek mythology
Axis (epistropheus)	Second cervical vertebra, so named because the atlas rotates about this bone in rotating movements of the head; the *dens,* or odontoid process, is a peglike projection extending upward from the body of the axis that forms a pivot for rotation of the atlas
Thoracic vertebrae	Next 12 vertebrae; 12 pairs of ribs attached to these vertebrae; stronger, with more massive bodies than the cervical vertebrae; no transverse foramina; two sets of facets for articulations with the corresponding rib: one on the body, the second on the transverse process; the upper thoracic vertebrae have elongated spinous processes
Lumbar vertebrae	Next five vertebrae; strong, massive; superior articulating processes directed medially instead of upward; inferior articulating processes, laterally instead of downward; short, blunt spinous processes
Sacrum	Five separate vertebrae until about 25 years of age; then fused to form one wedge-shaped bone
Sacral promontory	Protuberance from the anterior, upper border of the sacrum into the pelvis; of obstetrical importance because its size limits the anteroposterior diameter of the pelvic inlet
Coccyx	Four or five separate vertebrae in a child but fused into one in an adult
Curves	Curves have great structural importance because they increase the carrying strength of the vertebral column, make balance possible in an upright position (if the column was straight, the weight of the viscera would pull the body forward), absorb jolts from walking (a straight column would transmit jolts straight to the head), and protect the column from fracture
Primary curves Thoracic curve Sacral curve	Column curves at birth from the head to the sacrum with the convexity posteriorly; after the child stands, the convexity persists only in the *thoracic* and *sacral* regions, which are therefore called *primary curves*
Secondary curves Cervical curve Lumbar curve	Concavities in the *cervical* and *lumbar* regions; the cervical concavity results from the infant's attempts to hold the head erect (2 to 4 months); the lumbar concavity, from balancing efforts in learning to walk (10 to 18 months)

(continued on page 248)

Vertebral Column

The vertebral, or spinal, column forms the longitudinal axis of the skeleton. It is a flexible rather than a rigid column because it is segmented. As Figure 9-13 shows, the vertebral column consists of 24 **vertebrae** plus the sacrum and coccyx. Joints between the vertebrae permit forward, backward, and sideways movement of the column. Consider too these additional facts about the vertebral column. The head is balanced on top, the ribs are suspended in front, the lower extremities are attached below, and the spinal cord is enclosed within. It is indeed the "backbone" of the body.

The seven **cervical vertebrae** constitute the skeletal framework of the neck (see Figure 9-13). The next 12 vertebrae are called **thoracic vertebrae** because of their location in the posterior part of the chest, or the thoracic region. The next five, the **lumbar vertebrae,** support the small of the back. Below the lumbar vertebrae lie the sacrum and coccyx. In an adult the sacrum is a single bone that has formed from the fusion of five separate vertebrae, and the coccyx is a single bone that has formed from the fusion of four or five vertebrae.

All the vertebrae resemble each other in certain features and differ in others. For example, all except the first cervical vertebra have a flat, rounded body placed anteriorly and centrally, plus a sharp or blunt *spinous process* projecting inferiorly in the posterior midline and two transverse processes projecting laterally (Figure 9-14). All but the sacrum and coccyx have a central opening, the *vertebral foramen*. An upward projection (the *dens*) from the body of the second cervical vertebra furnishes an axis for rotating the head. A long, blunt spinous process, which can be felt at the back of the base of the neck, characterizes the seventh cervical vertebra. Each thoracic vertebra has articular facets for the ribs. More detailed descriptions of separate vertebrae are given in Table 9-6. The vertebral column, as a whole, articulates with the head, ribs, and iliac bones. Individual vertebrae articulate with each other in joints between their bodies and between their articular processes.

To increase the carrying strength of the vertebral column and to make balance possible in the upright position, the vertebral column is curved. At birth there is a continuous posterior convexity from the head to the coccyx. Later, as the child learns to sit and stand, secondary posterior concavities necessary for balance develop in the cervical and lumbar regions (see Figures 36-23 and 36-24, p. 1117).

Sternum

The medial part of the anterior chest wall is supported by the **sternum,** a somewhat dagger-shaped bone consisting of three parts: the upper handle part, the *manubrium*; the middle blade part, the *body*; and a blunt cartilaginous lower tip, the *xiphoid process*. The last ossifies during adult life. The manubrium articulates with the clavicle and first rib, whereas the next nine ribs join the body of the sternum, either directly or indirectly, by means of the *costal cartilages* (Figure 9-15).

Ribs

Twelve pairs of ribs, together with the vertebral column and sternum, form the bony cage known as the *thoracic cage* or, simply, the **thorax.** Each rib articulates with both the body and the transverse process of its corresponding thoracic vertebra. The head of each rib articulates with the body of the corresponding thoracic vertebra, and the tubercle of each rib articulates with the vertebra's transverse process (Figure 9-16). In addition, the second through ninth ribs articulate with the body of the vertebra above. From its vertebral attachment, each rib curves outward, then forward and downward (see Figures 9-1 and 9-16), a mechanical fact important for breathing.

Anteriorly, each rib of the first seven pairs joins a costal cartilage that attaches to the sternum. For this reason, these ribs are often called the *true ribs*. Ribs of the remaining five pairs, the *false ribs*, do not attach directly to the sternum. Instead, each costal cartilage of pairs 8, 9, and 10 attaches to the costal cartilage of the rib above it—indirectly attaching it to the sternum. Ribs of the last two pairs of false ribs are designated *floating ribs* because they do not attach even indirectly to the sternum (see Figure 9-15).

| QUICK CHECK |

4. Name the three types of vertebrae and how many of each type are found in the vertebral column.
5. What bones make up the bony cage known as the thorax? How do these bones fit together to form this structure?
6. What is a floating rib?

TABLE 9-6 Hyoid, Vertebrae, and Thoracic Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Sternum	Breastbone; flat dagger-shaped bone; the sternum, ribs, and thoracic vertebrae together form a bony cage known as the *thorax*
Body	Main central part of the bone
Manubrium	Flaring, upper part
Xiphoid process	Projection of cartilage at the lower border of the bone
Ribs	
Types	
True ribs	Upper seven pairs; fasten to the sternum by costal cartilages
False ribs	False ribs do not attach to the sternum directly; the upper three pairs of false ribs attach by means of the costal cartilage of the seventh ribs
Floating ribs	The last two pairs of false ribs do not attach to the sternum at all and are therefore called "floating" ribs
Parts	
Head	Projection at the posterior end of a rib; articulates with the corresponding thoracic vertebra and one above, except the last three pairs, which join the corresponding vertebrae only
Neck	Constricted portion just below the head
Tubercle	Small knob just below the neck; articulates with the transverse process of the corresponding thoracic vertebra; missing in the lowest three ribs
Body or shaft	Main part of a rib
Costal cartilage	Cartilage at the sternal end of true ribs; attaches ribs (except floating ribs) to the sternum

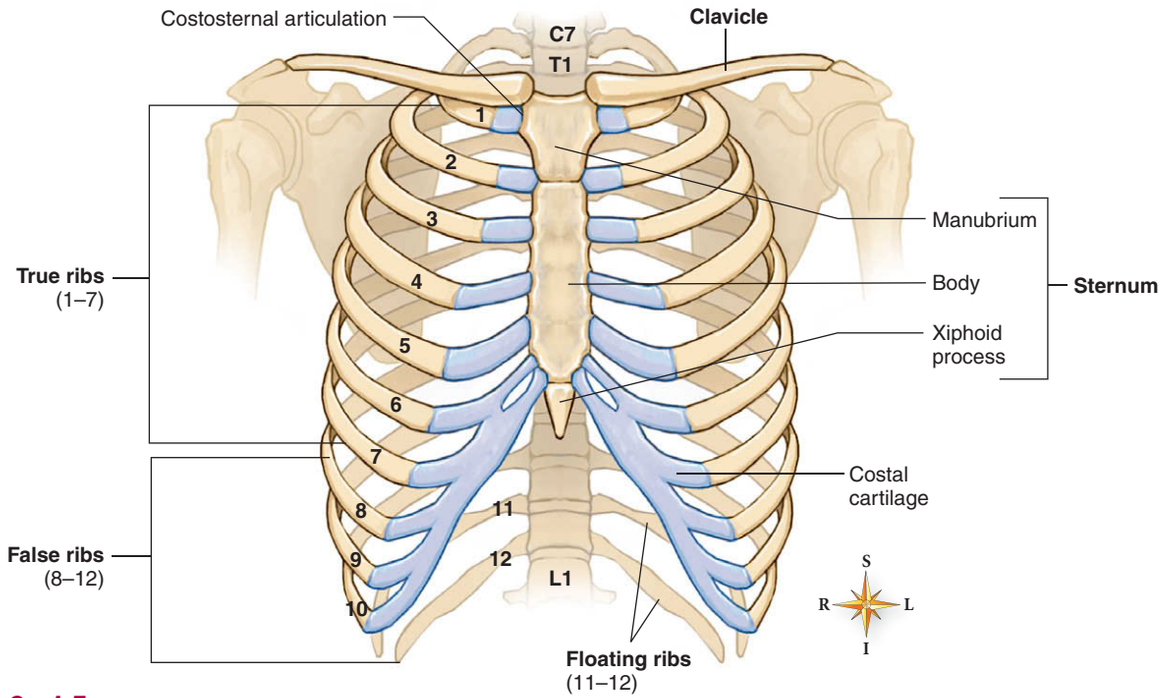

FIGURE 9-15

Thoracic cage. Note the costal cartilages and their articulations with the body of the sternum.

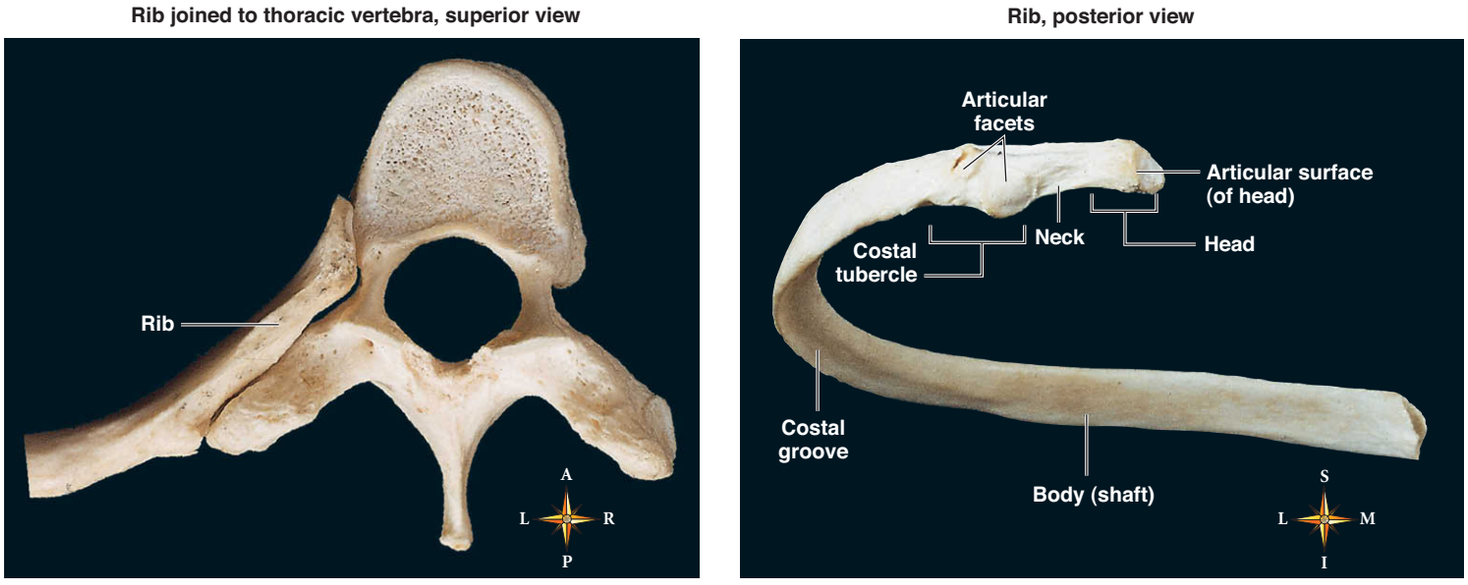

FIGURE 9-16

Articulation of a rib and vertebra. A, Note the head of the rib articulating with the vertebral body and the tubercle of the rib articulating with the transverse process of the vertebra. **B,** Anatomical components of a typical rib (fifth rib) viewed from behind.

APPENDICULAR SKELETON

Upper Extremity

The upper extremity consists of the bones of the shoulder girdle, upper part of the arm, forearm, wrist, and hand. Two bones, the **clavicle** and **scapula,** compose the **shoulder girdle** or *pectoral girdle.* Contrary to appearances, this belt or girdle of bone forms only one bony joint with the trunk: the sternoclavicular joint between the sternum and clavicle. At its outer end, the clavicle articulates with the scapula, which attaches to the ribs by muscles and tendons, not by a joint. All shoulder movements therefore

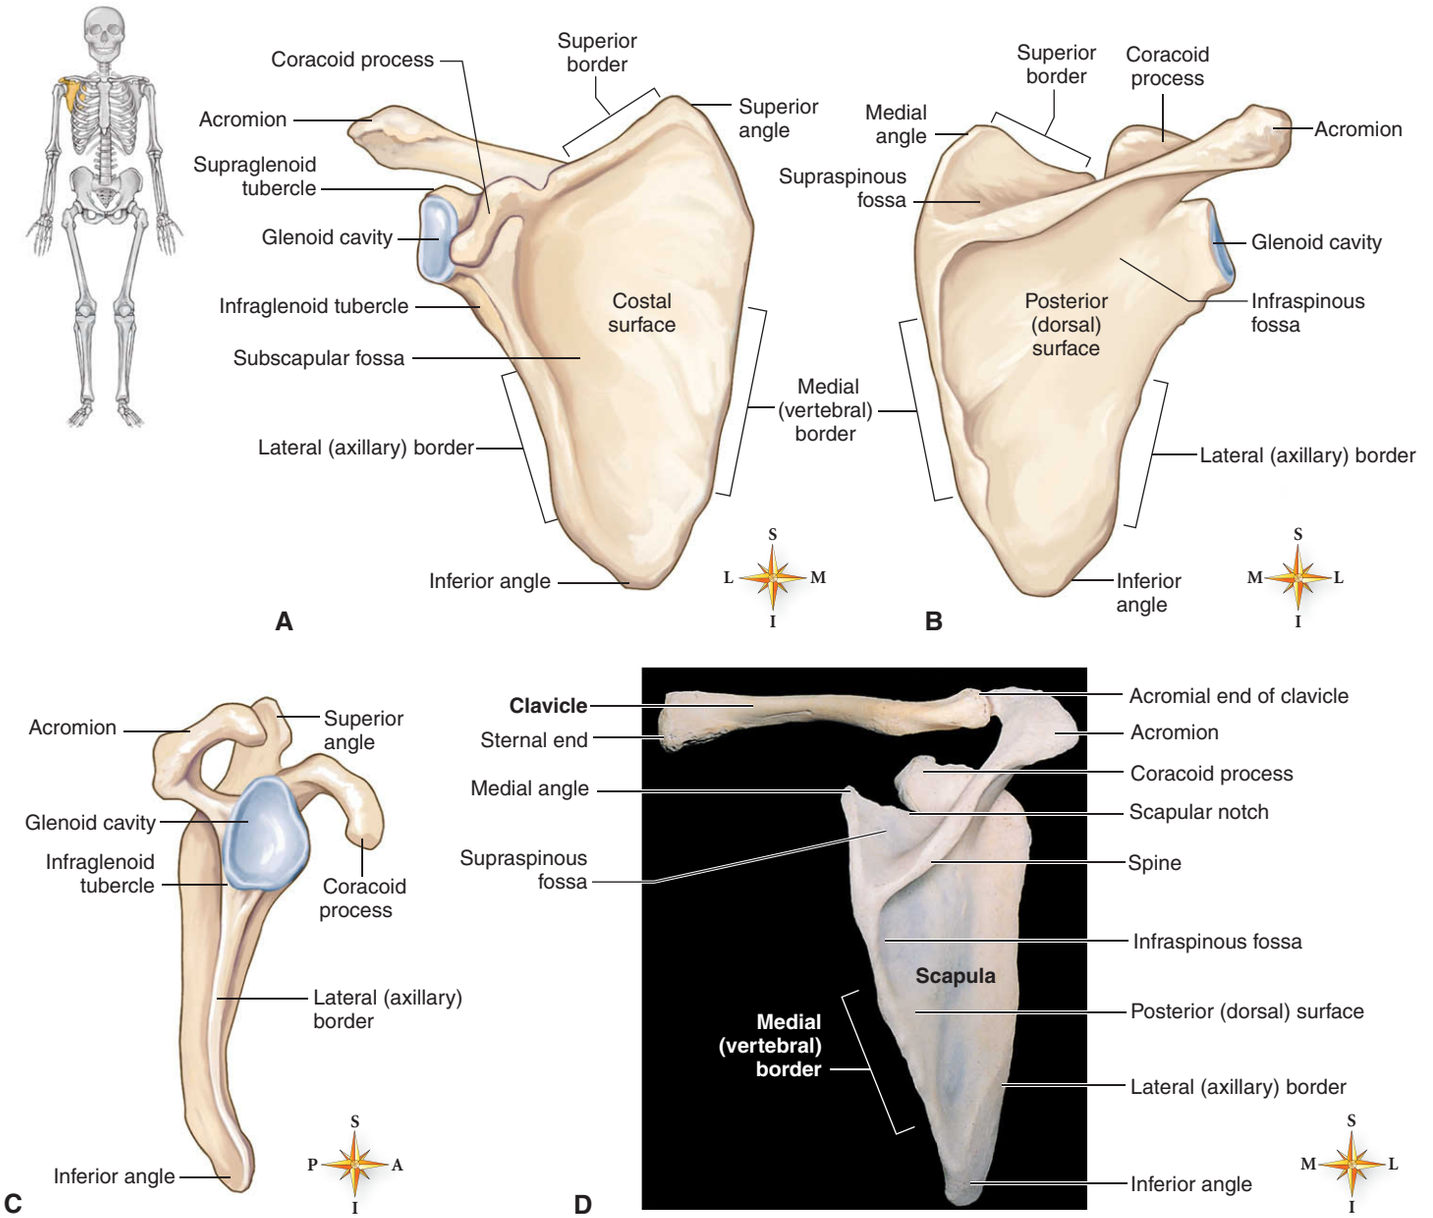

FIGURE 9-17

Right scapula. A, Anterior view. **B,** Posterior view. **C,** Lateral view. **D,** Posterior view showing articulation of the right scapula with the clavicle. (The skeleton inset shows the relative position of the right scapula within the entire skeleton.)

TABLE 9-7 Upper Extremity Bones and Their Markings

BONES AND MARKINGS	DESCRIPTION
Clavicle	Collar bones; the shoulder girdle is joined to the axial skeleton by articulation of the clavicles with the sternum (the scapula does not form a joint with the axial skeleton)
Scapula	Shoulder blades; the scapulae and clavicles together make up the shoulder girdle
Borders	
Superior	Upper margin
Medial (vertebral)	Margin toward the vertebral column
Lateral (axillary)	Lateral margin, toward axilla
Spine	Sharp ridge running diagonally across the posterior surface of the shoulder blade
Acromion	Slightly flaring projection at the lateral end of the scapular spine; may be felt at the tip of the shoulder; articulates with the clavicle
Coracoid process	Projection on the anterior surface from the upper border of the bone; may be felt in the groove between the deltoid and pectoralis major muscles, about 1 inch below the clavicle
Glenoid cavity	Arm socket

(continued)

involve the sternoclavicular joint. Various markings of the scapula are described in Table 9-7 (see also Figure 9-17).

The **humerus,** or arm bone, like other long bones, consists of a shaft, or diaphysis, and two ends, or epiphyses (Figures 9-18 and 9-19). The upper epiphysis bears several identifying structures: the head, anatomical neck, greater and lesser tubercles, intertubercular groove, and surgical neck. On the diaphysis are found the deltoid tuberosity and the radial groove. The distal epiphysis has four projections—the medial and lateral epicondyles, the capitulum, and the trochlea—and two depressions—the olecranon and coronoid fossae. For descriptions of all of these markings, see Table 9-7. The humerus articulates proximally with the scapula and distally with the radius and the ulna.

Two bones form the framework for the forearm: the **radius** on the thumb side and the **ulna** on the little finger side. At the proximal end of the ulna, the olecranon projects posteriorly and the coronoid process projects anteriorly. There are also two depressions: the semilunar notch on the anterior surface and the radial notch on the lateral surface. The distal end has two projections: a rounded head and a sharper styloid process. For more detailed identification of these markings, see Table 9-7. The ulna articulates proximally with the humerus and radius and distally with a fibrocartilaginous disk, but not with any of the carpal bones.

The radius has three projections: two at its proximal end, the head and radial tuberosity, and one at its distal end, the styloid process (see Figures 9-18 and 9-19). There are two proximal articulations: one with the capitulum of the humerus and the other with the radial notch of the ulna. The three distal articulations are with the scaphoid and lunate carpal bones and with the head of the ulna.

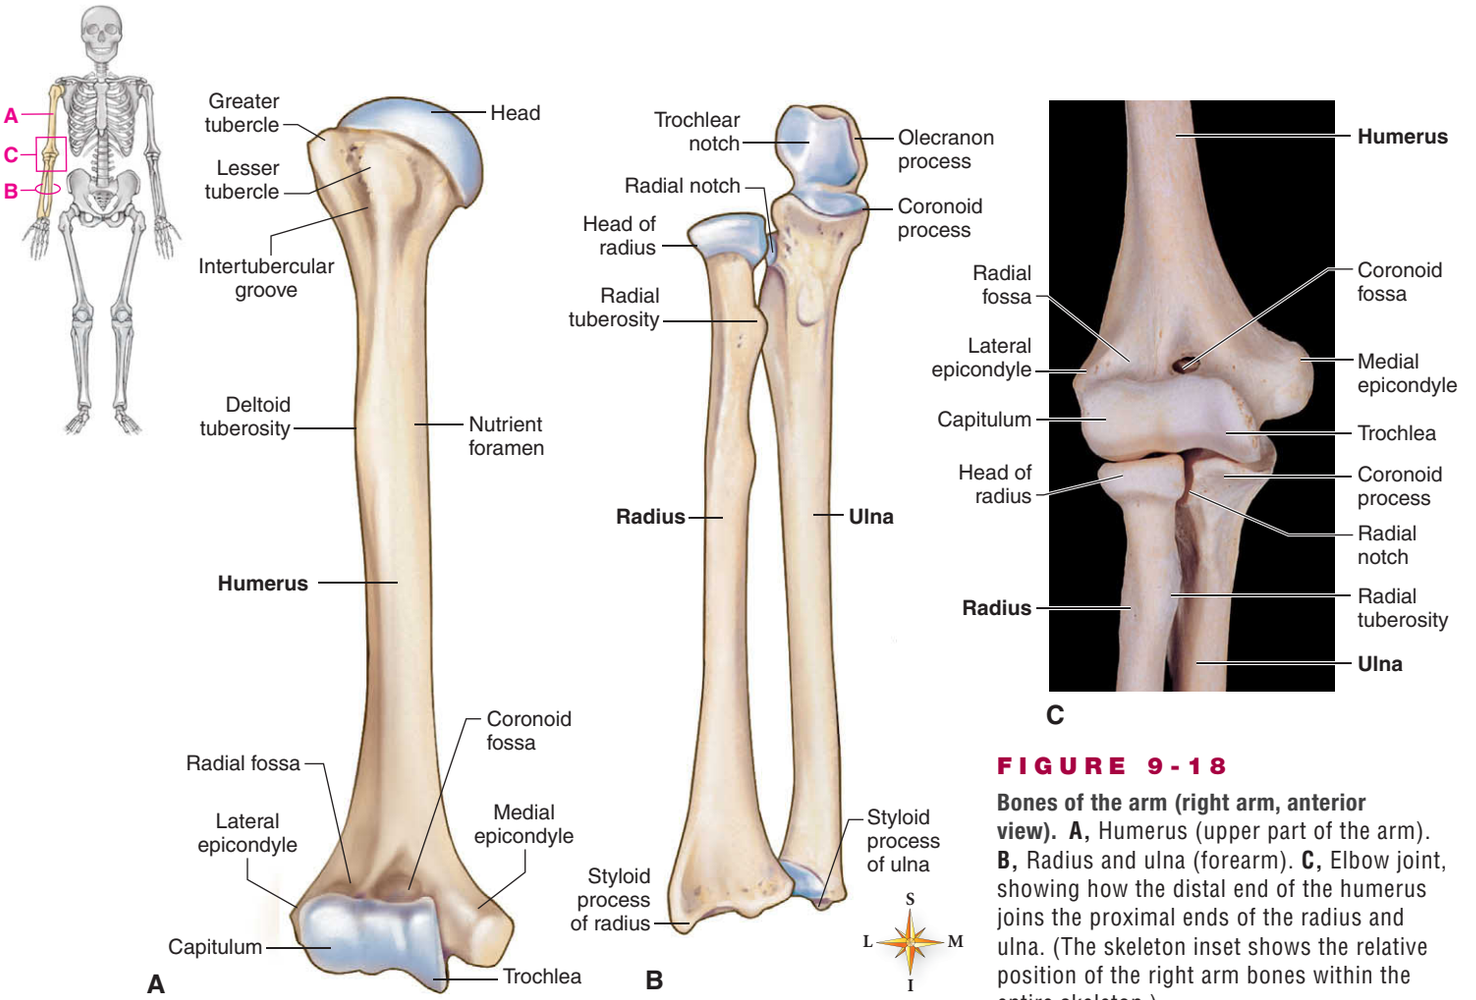

FIGURE 9-18

Bones of the arm (right arm, anterior view). A, Humerus (upper part of the arm). **B,** Radius and ulna (forearm). **C,** Elbow joint, showing how the distal end of the humerus joins the proximal ends of the radius and ulna. (The skeleton inset shows the relative position of the right arm bones within the entire skeleton.)

TABLE 9-7 Upper Extremity Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Humerus	Long bone of the arm
Head	Smooth, hemispherical enlargement at the proximal end of the humerus
Anatomical neck	Oblique groove just below the head
Greater tubercle	Rounded projection lateral to the head on the anterior surface
Lesser tubercle	Prominent projection on the anterior surface just below the anatomical neck
Intertubercular groove	Deep groove between the greater and lesser tubercles; the long tendon of the biceps muscle lodges here
Surgical neck	Region just below the tubercles; so named because of its liability to fracture
Deltoid tuberosity	V-shaped, rough area about midway down the shaft where the deltoid muscle inserts
Radial groove	Groove running obliquely downward from the deltoid tuberosity; lodges the radial nerve
Epicondyles (medial and lateral)	Rough projections at both sides of the distal end
Capitulum	Rounded knob below the lateral epicondyle; articulates with the radius; sometimes called the *radial* head of the humerus
Trochlea	Projection with a deep depression through the center similar to the shape of a pulley; articulates with the ulna
Olecranon fossa	Depression on the posterior surface just above the trochlea; receives the olecranon of the ulna when the forearm extends
Coronoid fossa	Depression on the anterior surface above the trochlea; receives the coronoid process of the ulna in flexion of the forearm

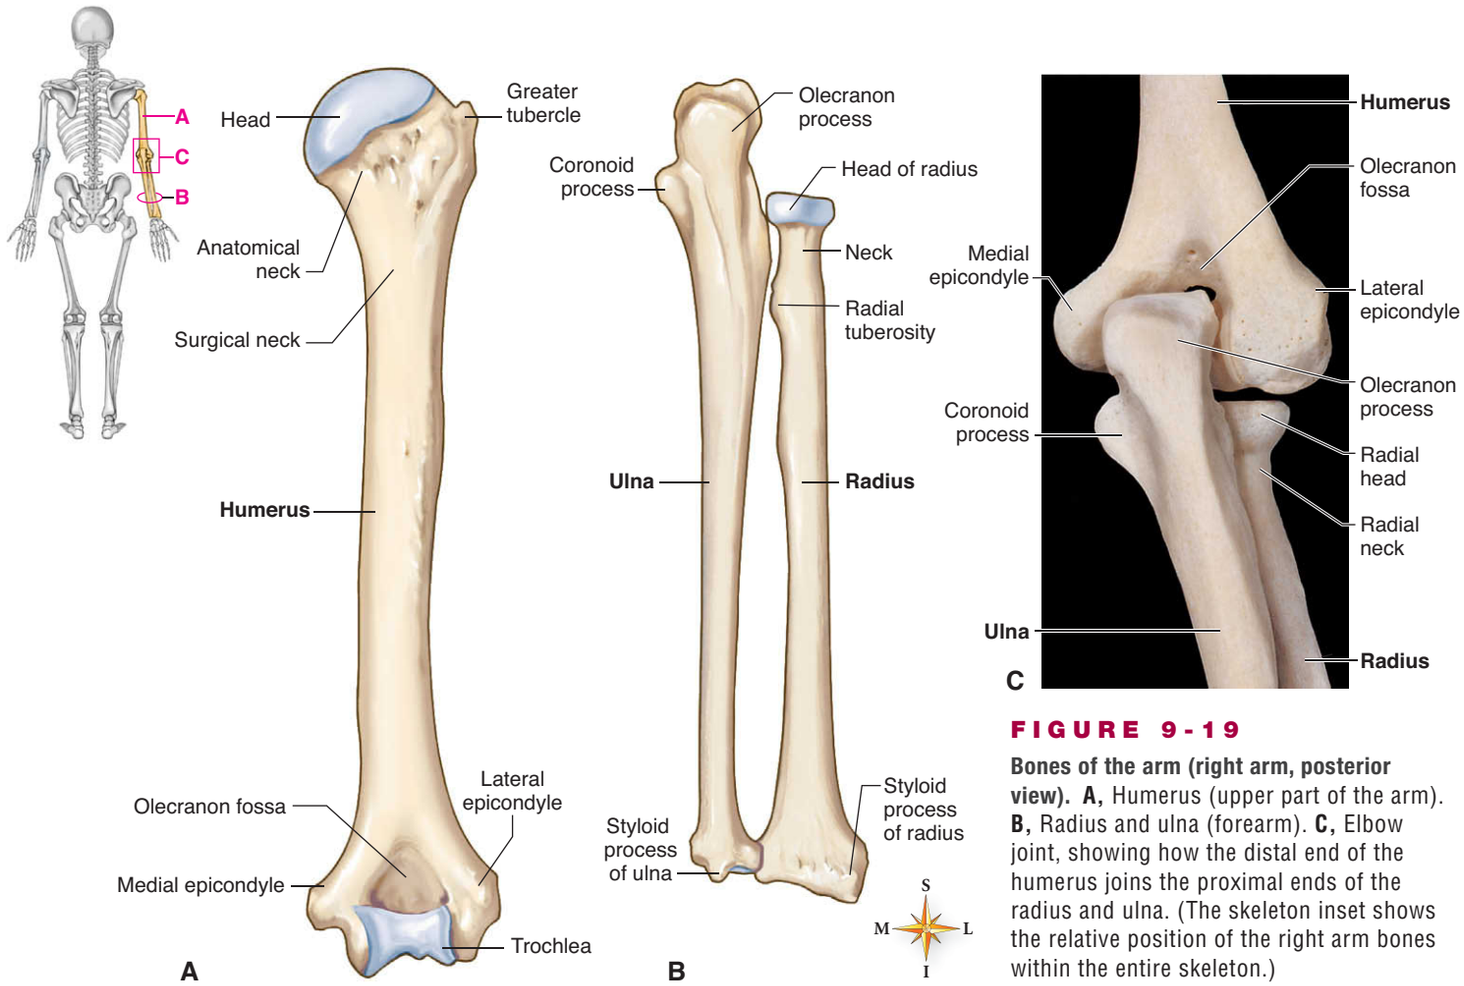

FIGURE 9-19

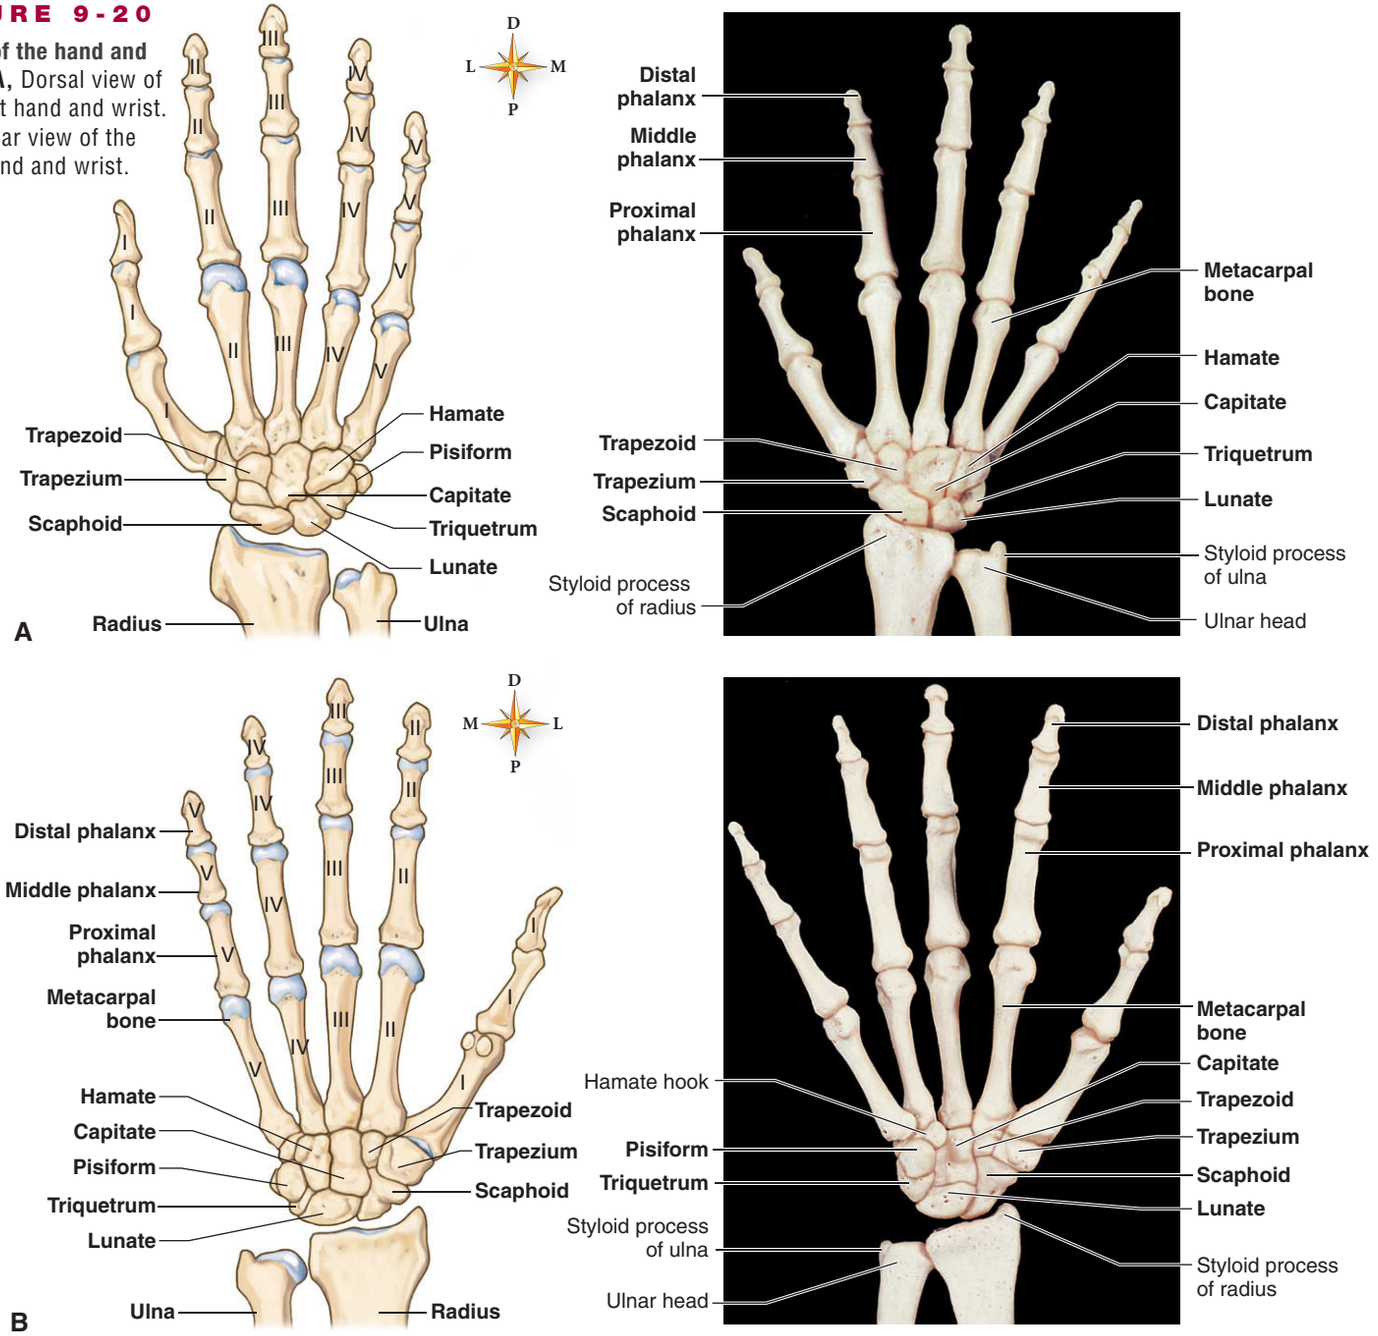
Bones of the arm (right arm, posterior view). A, Humerus (upper part of the arm). **B,** Radius and ulna (forearm). **C,** Elbow joint, showing how the distal end of the humerus joins the proximal ends of the radius and ulna. (The skeleton inset shows the relative position of the right arm bones within the entire skeleton.)

TABLE 9-7 Upper Extremity Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Radius	Bone of the thumb side of the forearm
Head	Disk-shaped process forming the proximal end of the radius; articulates with the capitulum of the humerus and with the radial notch of the ulna
Radial tuberosity	Roughened projection on the ulnar side, a short distance below the head; the biceps muscle inserts here
Styloid process	Protuberance at the distal end on the lateral surface (with the forearm in the anatomical position)
Ulna	Bone of the little finger side of the forearm; longer than the radius
Olecranon	Scooplike process that joins the trochlea of the humerus at the elbow
Coronoid process	Projection on the anterior surface of the proximal end of the ulna; the trochlea of the humerus fits snugly between the olecranon and coronoid processes
Trochlear notch	Curved notch between the olecranon and coronoid process into which the trochlea fits; also called *semilunar notch*
Radial notch	Curved notch lateral and inferior to the semilunar notch; the head of the radius fits into this concavity
Head	Rounded process at the distal end; does not articulate with the wrist bones but with the fibrocartilaginous disk
Styloid process	Sharp protuberance at the distal end; can be seen from outside on the posterior surface
Carpal bones	Wrist bones; arranged in two rows at the proximal end of the hand; proximal row (from the little finger toward the thumb)—*pisiform, triquetrum, lunate,* and *scaphoid;* distal row—*hamate, capitate, trapezoid,* and *trapezium*
Metacarpal bones	Long bones forming the framework of the palm of the hand; numbered (from medial side) I, II, III, IV, V
Phalanges	Miniature long bones of the fingers, three (proximal, middle, distal) in each finger, two (proximal, distal) in each thumb; numbered (from medial side) I (except first middle), II, III, IV, V

The eight **carpal bones** (Figure 9-20) form what most people think of as the upper part of the hand but what, anatomically speaking, is the wrist. Only one of these bones is evident from the outside, the pisiform bone, which projects posteriorly on the little finger side as a small rounded elevation. The pisiform bone is an example of a sesamoid bone. Ligaments bind the carpal bones closely and firmly together in two rows of four each: proximal row (from the little finger toward the thumb)—pisiform, triquetrum, lunate, and scaphoid bones; distal row—hamate, capitate, trapezoid, and trapezium bones. The joints between the carpal bones and radius permit wrist and hand movements.



Of the five **metacarpal bones** that form the framework of the hand, the thumb metacarpal forms the most freely movable joint with the carpal bones. This fact has great significance. Because of the wide range of movement possible between the thumb metacarpal and the trapezium, particularly the ability to oppose the thumb to the fingers, the human hand has much greater dexterity than the forepaw of any animal, which has enabled humans to manipulate even small objects in their environment effectively. The heads of the metacarpal bones, prominent as the proximal knuckles of the hand, articulate with the phalanges.

| QUICK CHECK |

7. What bones make up the shoulder girdle? Where does the shoulder girdle form a joint with the axial skeleton?
8. What are the two bones of the forearm? In the anatomical position, which one is lateral?
9. Name the bones of the hand and wrist.

FIGURE 9-20

Bones of the hand and wrist. A, Dorsal view of the right hand and wrist. **B,** Palmar view of the right hand and wrist.

Lower Extremity

Bones of the hip, thigh, leg, ankle, and foot constitute the lower extremity (Table 9-8). Strong ligaments bind each **coxal bone** (*pelvic* or *hip bone*) to the sacrum posteriorly and to each other anteriorly to form the **pelvic girdle** (see Figures 9-21 and 9-26). The pelvic girdle serves as a stable, circular base that supports the trunk and attaches the lower extremities to it. In early life, each coxal bone is made up of three separate bones. Later, they fuse into a single, massive irregular bone that is broader than any other bone in the body. The largest and uppermost of the three bones is the **ilium,** the strongest and lowermost is the **ischium,** and the most anteriorly placed is the **pubis.** Numerous markings are present on the three bones (see Table 9-8 and Figures 9-21 and 9-22). (The coxal bone was formerly called the os coxae or innominate bone.)

The pelvis can be divided into two parts by an imaginary plane called the *pelvic inlet*. The edge of this plane, outlined in Figure 9-21, is called the *pelvic brim*, or *brim of the true pelvis*. The structure above the pelvic inlet, termed the **false pelvis,** is bordered by muscle in the front and by bone along the sides and back. The structure below the pelvic inlet, the so-called *true pelvis*, creates the boundary of another imaginary plane called the *pelvic outlet*. It is through the pelvic outlet that the digestive tract empties. The female reproductive tract also passes through the pelvic outlet; this is a fact of great importance in childbirth. The pelvic outlet is just large enough for the passage of a baby during delivery; however, careful positioning of the baby's head is required. Measurements such as those shown in Figure 9-21 are routinely made by obstetricians to ensure successful delivery.

Despite its apparent rigidity, the joint between the pubic portions of each coxal bone, the *pubic symphysis*, softens before delivery. This softening allows the pelvic outlet to expand to accommodate the newborn's head as it passes out of the birth canal. The tiny coccyx bone, which protrudes into the pelvic outlet, sometimes breaks when the force of labor contractions pushes the newborn's head against it.

The two thigh bones, or **femurs,** have the distinction of being the longest and heaviest bones in the body. Several prominent markings characterize them. For example, three projections are

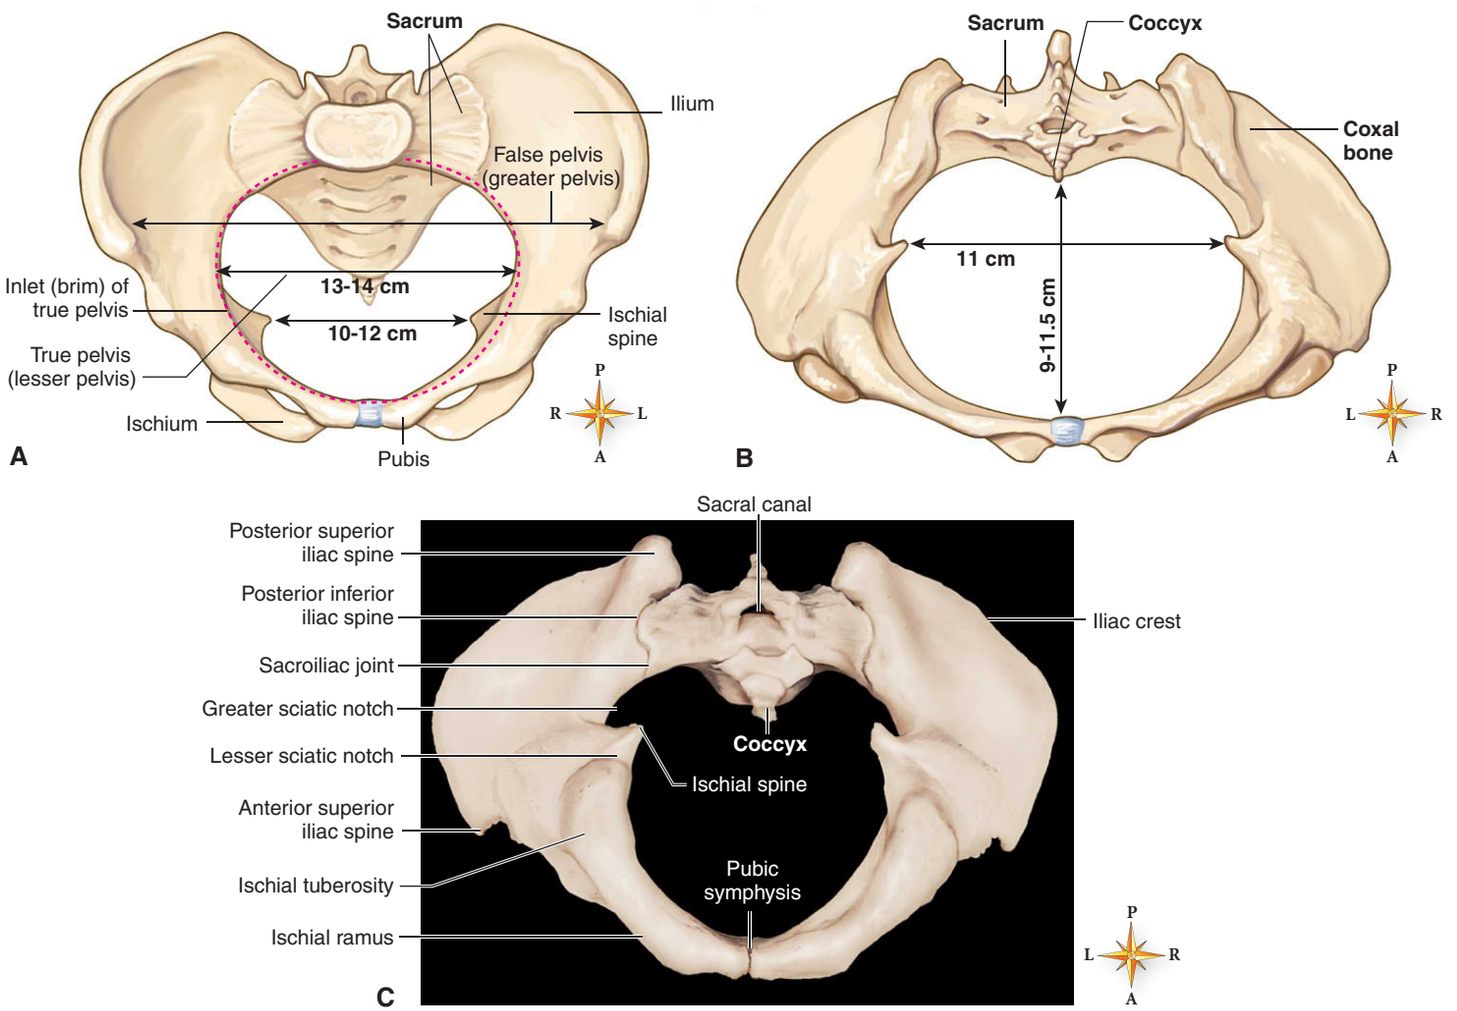


FIGURE 9-21

The female pelvis. A, Pelvis viewed from above. Note that the brim of the true pelvis (*dotted line*) marks the boundary between the superior false pelvis (*pelvis major*) and the inferior true pelvis (*pelvis minor*). **B** and **C,** Pelvis viewed from below. A comparison of the male pelvis and female pelvis is shown in Figure 9-26.

FIGURE 9-22

Left coxal (hip) bone. The left coxal bone is disarticulated from the bony pelvis and viewed from the side. Also see Figure 9-14, *H,* for a view of the right coxal bone outlining its three main regions.

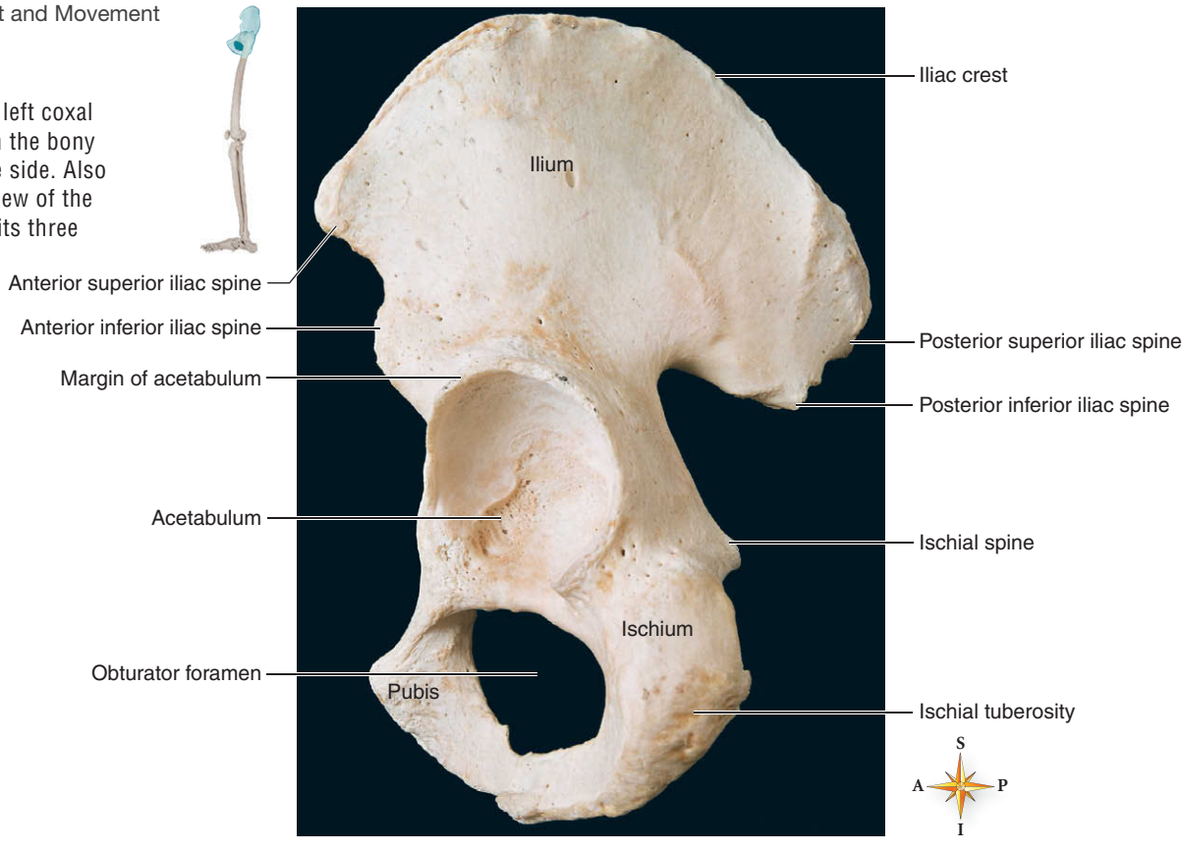

TABLE 9-8 Lower Extremity Bones and Their Markings

BONES AND MARKINGS	DESCRIPTION
Coxal	Large hip bone (pelvic bone); with the sacrum and coccyx, forms the basinlike pelvic cavity; lower extremities attached to the axial skeleton by the coxal bones
Ilium	Upper, flaring portion
Ischium	Lower, posterior portion
Pubis	Medial, anterior section
Acetabulum	Hip socket; formed by union of the ilium, ischium, and pubis
Iliac crests	Upper, curving boundary of the ilium
Iliac spines	
Anterior superior	Prominent projection at the anterior end of the iliac crest; can be felt externally as the “point” of the hip
Anterior inferior	Less prominent projection short distance below anterior superior spine
Posterior superior	At the posterior end of the iliac crest
Posterior inferior	Just below the posterior superior spine
Greater sciatic notch	Large notch on the posterior surface of the ilium just below the posterior inferior spine
Ischial tuberosity	Large, rough, quadrilateral process forming the inferior part of the ischium; in an erect sitting position the body rests on these tuberosities
Ischial spine	Pointed projection just above the tuberosity
Pubic symphysis	Cartilaginous, amphiarthrotic joint between the pubic bones
Superior pubic ramus	Part of the pubis lying between the symphysis and acetabulum; forms the upper part of the obturator foramen
Inferior pubic ramus	Part extending down from the symphysis; unites with the ischium
Pubic arch	Curve formed by the two inferior rami
Subpubic angle	Angle formed under the inferior pubic rami; generally larger in women than in men
Pubic crest	Upper margin of the superior ramus
Pubic tubercle	Rounded process at the end of the crest
Obturator foramen	Large hole in the anterior surface of the coxal bone; formed by the pubis and ischium; largest foramen in the body

TABLE 9-8 Lower Extremity Bones and Their Markings *(continued)*

BONES AND MARKINGS	DESCRIPTION
Pelvic inlet (or brim)	Boundary of the aperture leading into the true pelvis; formed by the pubic crests, iliopectineal lines, and sacral promontory; the size and shape of this inlet have obstetrical importance because if any of its diameters are too small, the infant's skull cannot enter the true pelvis for natural birth(or lesser pelvis)
True pelvis (or greater pelvis)	Space below the pelvic brim; true "basin" with bone and muscle walls and a muscle floor; pelvic organs located in this space
False pelvis (or lesser pelvis)	Broad, shallow space above the pelvic brim, or the pelvic inlet; name "false pelvis" is misleading because this space is actually part of the abdominal cavity, not the pelvic cavity
Pelvic outlet	Irregular circumference marking the lower limits of the true pelvis; bounded by the tip of the coccyx and two ischial tuberosities
Pelvic girdle (or bony pelvis)	Complete bony ring; composed of two hip bones (ossa coxae), the sacrum, and the coccyx; forms a firm base by which the trunk rests on the thighs and for attachment of the lower extremities to the axial skeleton
Femur	Thigh bone; largest, strongest bone of the body
Head	Rounded upper end of the bone; fits into the acetabulum
Neck	Constricted portion just below the head
Greater trochanter	Protuberance located inferiorly and laterally to the head
Lesser trochanter	Small protuberance located inferiorly and medially to the greater trochanter
Intertrochanteric line	Line extending between the greater and lesser trochanter
Linea aspera	Prominent ridge extending lengthwise along the concave posterior surface
Supracondylar ridges	Two ridges formed by division of the linea aspera at its lower end; the medial supracondylar ridge extends inward to the inner condyle, the lateral ridge to the outer condyle
Condyles	Large, rounded bulges at the distal end of the femur; one medial and one lateral
Epicondyles	Blunt projections from the sides of the condyles; one on the medial aspect and one on the lateral aspect
Adductor tubercle	Small projection just above the medial condyle; marks the termination of the medial supracondylar ridge
Trochlea	Smooth depression between the condyles on the anterior surface; articulates with the patella
Intercondylar fossa (notch)	Deep depression between the condyles on the posterior surface; the cruciate ligaments, which help bind the femur to the tibia, lodge in this notch
Patella	Kneecap; largest sesamoid bone of the body; embedded in the tendon of the quadriceps femoris muscle
Tibia	Shin bone
Condyles	Bulging prominences at the proximal end of the tibia; upper surfaces concave for articulation with the femur
Intercondylar eminence	Upward projection on the articular surface between the condyles
Crest	Sharp ridge on the anterior surface
Tibial tuberosity	Projection in the midline on the anterior surface
Medial malleolus	Rounded downward projection at the distal end of the tibia; forms the prominence on the medial surface of the ankle
Fibula	Long, slender bone of the lateral side of the leg
Lateral malleolus	Rounded prominence at the distal end of the fibula; forms the prominence on the lateral surface of the ankle

(continued on page 274)

conspicuous at each epiphysis: the head and greater and lesser trochanters proximally and the medial and lateral condyles and adductor tubercle distally (Figure 9-23). Both condyles and the greater trochanter may be felt externally. For a description of the various femur markings, see Table 9-8.

The largest sesamoid bone in the body, and one of the few that is almost universally present, is the **patella,** or kneecap, located in the tendon of the quadriceps femoris muscle as a projection to the underlying knee joint. Although some individuals have sesamoid bones in the tendons of other muscles, lists of bone names do not usually include them because they are not always present, are not found in any particular tendons, and are less important. (See the footnote in Table 9-1.) When the knee joint is extended, the patellar outline may be distinguished through the skin, but as the knee flexes, it sinks into the intercondylar notch of the femur and can no longer be easily distinguished.

The **tibia** is the larger and stronger and more medially and superficially located of the two leg bones. The **fibula** is smaller and more laterally and deeply placed. At its proximal end it articulates with the lateral condyle of the tibia. The proximal end of the tibia, in turn, articulates with the femur to form the knee joint, the largest and one of the most complex and frequently injured joints of the body. Distally, the tibia articulates with the fibula and also with the talus. The latter fits into a boxlike socket (ankle joint) formed by the medial and lateral malleoli, projections of the tibia and fibula, respectively. For other tibial markings, see

Box 9-2 | FYI

Palpable Bony Landmarks

Health professionals often identify externally palpable bony landmarks when dealing with the sick and injured. **Palpable** bony landmarks are bones that can be touched and identified through the skin. They serve as reference points in identifying other body structures.

Externally palpable bony landmarks are present throughout the body. Many skull bones, such as the zygomatic bone, can be palpated. The medial and lateral epicondyles of the humerus, the olecranon of the ulna, and the styloid process of the ulna and the radius at the wrist can be palpated on the upper extremity. The highest corner of the shoulder is the acromion process of the scapula.

When you put your hands on your hips, you can feel the superior edge of the ilium, called the iliac crest. The anterior end of the crest, called the anterior superior iliac spine, is a prominent landmark often used as a clinical reference. The sacral promontory is a prominent anteriorly projecting ridge or border on the superior aspect of the sacrum. Commonly, it serves as a palpable reference point when measuring the pelvis during obstetrical examinations. The medial malleolus of the tibia and the lateral malleolus of the fibula are prominent at the ankle. The calcaneus, or heel bone, is easily palpated on the posterior aspect of the foot. On the anterior aspect of the lower extremity, examples of palpable bony landmarks include the patella, or kneecap; the anterior border of the tibia, or shin bone; and the metatarsal bones and phalanges of the toes. Try to identify as many of the externally palpable bones of the skeleton as possible on your own body. Using these as points of reference will make it easier for you to visualize the placement of other bones that cannot be touched or palpated through the skin.

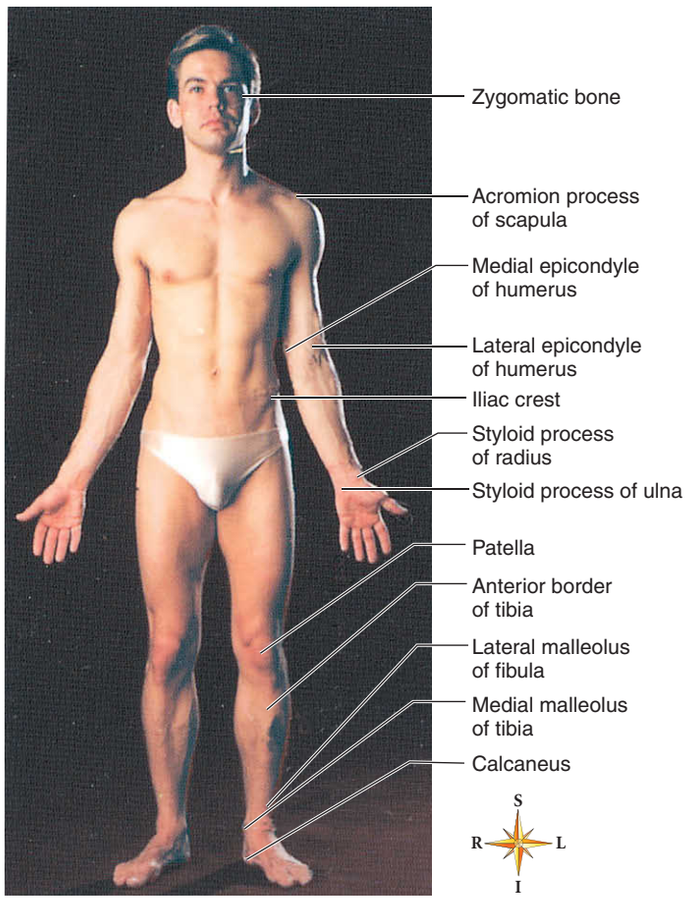

Table 9-8 and Figure 9-23. Box 9-2 explains how the malleoli and other bony prominences can be palpated through the skin.

The structure of the **foot** is similar to that of the hand, with certain differences that adapt it for supporting weight (Figure 9-24). One example is the much greater solidity and the more limited mobility of the great toe as compared to the thumb. Then, too, the foot bones are held together in such a way that they form springy lengthwise and crosswise arches (Figure 9-25). This arrangement is architecturally sound because arches furnish more supporting strength per given amount of structural material than does any other type of construction. Hence the two-way arch construction makes a highly stable base.

The **longitudinal arch** of the foot has an inner, or medial, portion and an outer, or lateral, portion. Both are formed by the placement of the tarsal and metatarsal bones. Specifically, some of the tarsal bones (calcaneus, talus, navicular, and cuneiforms) and the first three metatarsal bones (starting with the great toe) form the **medial longitudinal arch.** The calcaneus and cuboid tarsal bones plus the fourth and fifth metatarsal bones shape the **lateral longitudinal arch.** The **transverse arch** of the foot results from the relative placement of the distal row of tarsals and the five metatarsal bones. (See Table 9-8 for specific bones of different arches.)

Strong ligaments and leg muscle tendons normally hold the foot bones firmly in their arched positions. Not infrequently, however, these structures weaken and cause the arches to flatten—a condition aptly called **fallen arches,** or **flatfeet** (see Figure 9-25, *B*). Look at Figure 9-25, *D*, to see what shoes with high heels do to the position of the foot. They give a forward thrust to the body, which forces an undue amount of weight on the heads of the metatarsal bones. The resulting shift from the normal weight-bearing position of the feet may cause injury and chronic pain.

Normally, the tarsal and metatarsal bones have the major role in functioning of the foot as a supporting structure, with the phalanges being relatively unimportant. The reverse is true for the hand. Here, manipulation is the main function rather than support. Consequently, the phalanges of the fingers are all important, and the carpal and metacarpal bones are subsidiary.

In Chapter 8 the sesamoid bones were described as small rounded bones generally found embedded in the substance of tendons close to joints. The kneecap, or patella, is the largest of the sesamoid bones; other much smaller sesamoid bones are often found in tendons near the distal end (head) of the first metatarsal bone of the big toe (see Figure 9-24, *C*).

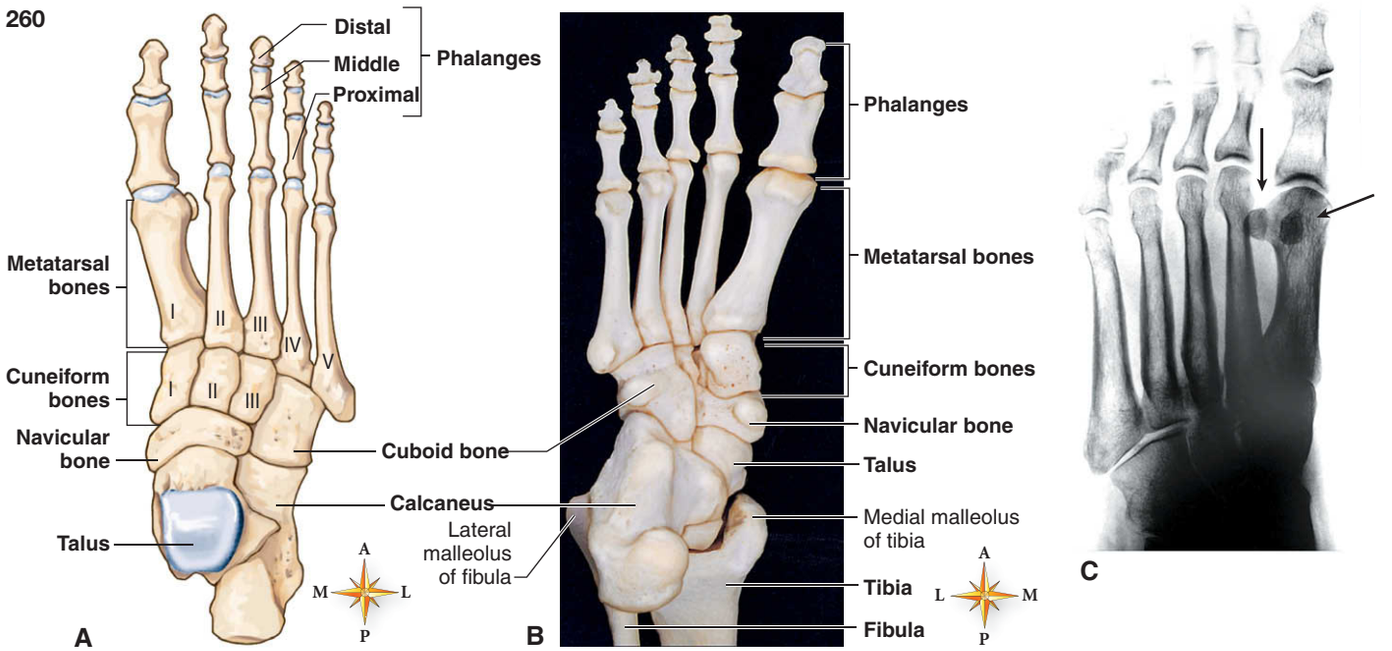

FIGURE 9-24 The foot. **A,** Bones of the right foot viewed from above. The tarsal bones consist of the cuneiforms, navicular, talus, cuboid, and calcaneus. **B,** Posterior aspect of the right ankle skeleton and inferior aspect of the right foot skeleton. **C,** X-ray film of the left foot showing prominent sesamoid bones (arrows) near the distal end (head) of the first metatarsal bone of the great toe.

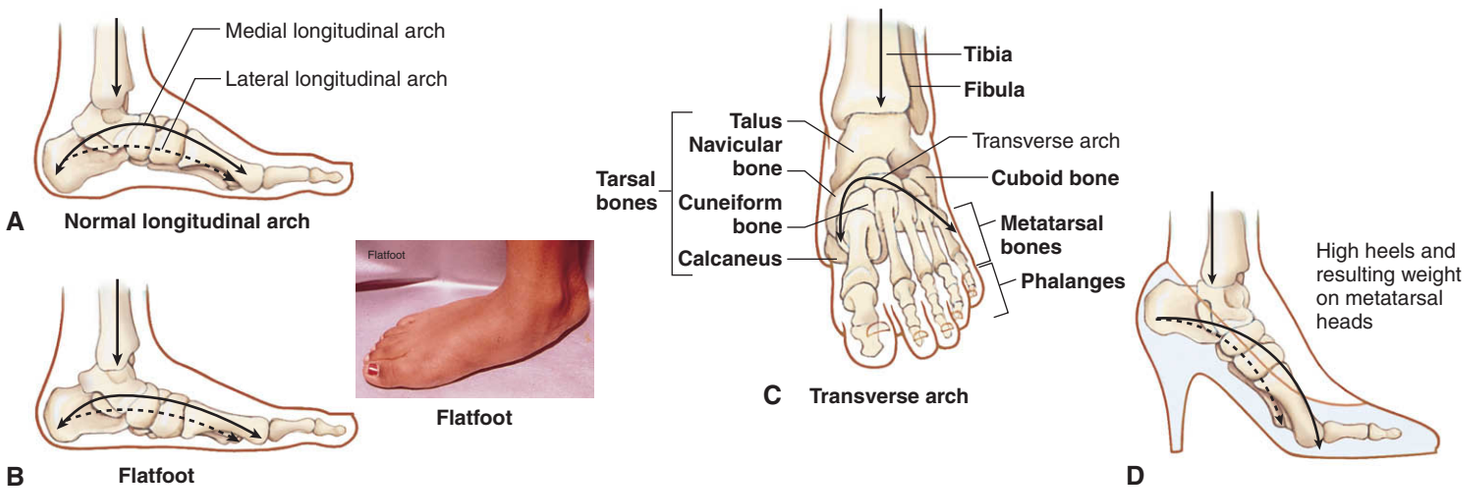

FIGURE 9-25 Arches of the foot. **A,** Longitudinal arch. The medial portion is formed by the calcaneus, talus, navicular, cuneiforms, and three metatarsal bones; the lateral portion is formed by the calcaneus, cuboid, and two lateral metatarsal bones. **B,** "Flatfoot" results when the tendons and ligaments attached to the tarsal bones are weakened. Downward pressure by the weight of the body gradually flattens out the normal arch of the bones. The photo shows the clinical appearance of a flatfoot. **C,** Transverse arch in the metatarsal region of the left foot. **D,** High heels throw the weight forward and cause the heads of the metatarsal bones to bear most of the body's weight. (*Arrows* show direction of force.)

TABLE 9-8 Lower Extremity Bones and Their Markings *(continued from p. 257)*

BONES AND MARKINGS	DESCRIPTION
Tarsal bones	Bones that form the heel and proximal or posterior half of the foot; include calcaneus, talus, navicular, cuboid, medial cuneiform (I), intermediate cuneiform (II), and lateral cuneiform (III)
Calcaneus	Heel bone
Talus	Uppermost of the tarsal bones; articulates with the tibia and fibula; boxed in the medial and lateral malleoli
Arches of foot	Curves of the bones of the foot and ankle that, along with muscles and other soft tissues, properly support the mass of the skeleton
Longitudinal arches	Tarsal and metatarsal bones so arranged as to form an arch from the front to the back of the foot
Medial	Formed by the calcaneus, talus, navicular, cuneiforms, and three medial metatarsal bones

BONES AND MARKINGS	DESCRIPTION
Lateral	Formed by the calcaneus, cuboid, and two lateral metatarsal bones
Transverse (or metatarsal) arch	Metatarsal and distal row of tarsal bones (cuneiforms and cuboid) articulated so as to form an arch across the foot; bones kept in two arched positions by means of powerful ligaments in the sole of the foot and by muscles and tendons
Metatarsal bones	Long bones of the feet; numbered (from medial side) I, II, III, IV, V
Phalanges	Miniature long bones of the toes; two in each great toe; three in the other toes; from metatarsal bone: proximal, middle (except first toe), distal; numbered (from medial side) I (except first toe), II, III, IV, V

SKELETAL DIFFERENCES BETWEEN MEN AND WOMEN

General and specific differences exist between male and female skeletons. The general difference is one of size and weight, the male skeleton being larger and heavier. The specific differences concern the shape of the pelvic bones and cavity. Whereas the male pelvis is deep and funnel shaped with a narrow subpubic angle (usually less than 90 degrees), the female pelvis, as Figure 9-26 shows, is shallow, broad, and flaring, with a wider subpubic angle (usually greater than 90 degrees). The childbearing

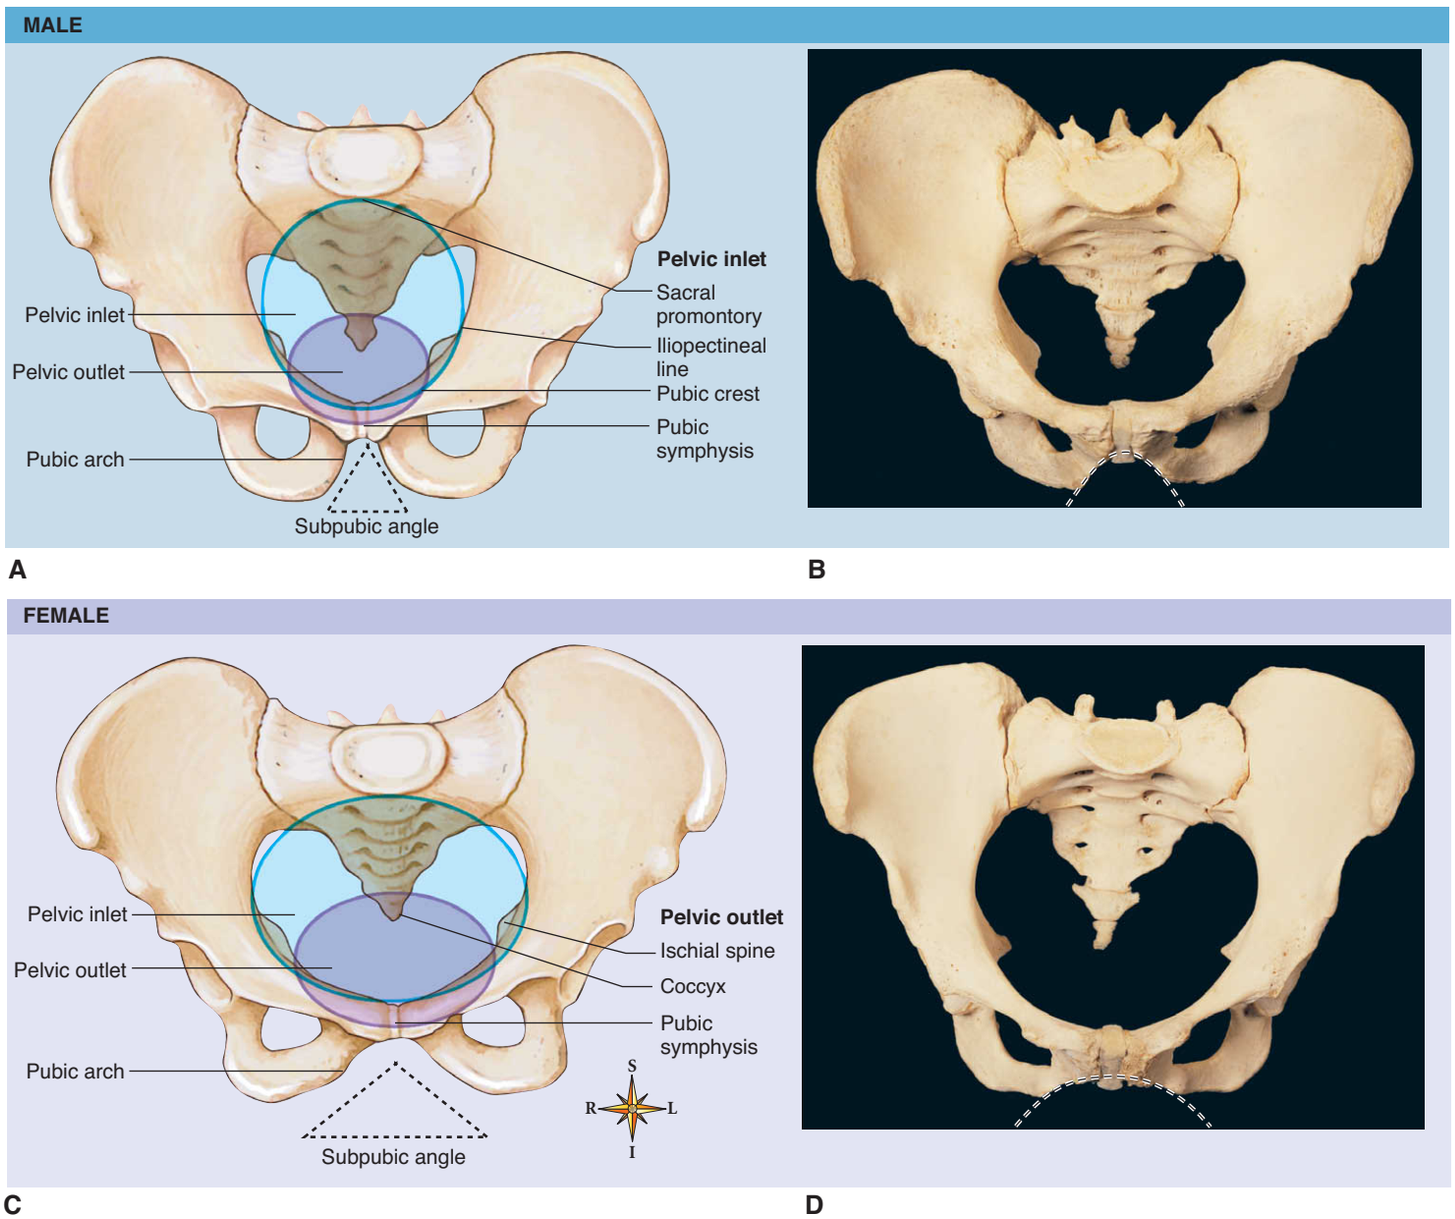

FIGURE 9-26

Comparison of the bony pelvis of the male and female skeletons. **A** and **C**, Diagrams showing components of the bony pelvis of the male and female. **B** and **D**, Photographs showing the bony pelvis of the male and female from in front and above.

TABLE 9-9 Comparison of Male and Female Skeletons

PORTION OF SKELETON	MALE	FEMALE
General form	Bones heavier and thicker Muscle attachment sites more massive Joint surfaces relatively large	Bones lighter and thinner Muscle attachment sites less distinct Joint surfaces relatively small
Skull	Forehead shorter vertically Mandible and maxillae relatively smaller Facial area rounder, with less pronounced features Processes less pronounced	Forehead more elongated vertically Mandible and maxillae relatively larger Facial area more pronounced Processes more prominent
Pelvis		
Pelvic cavity	Narrower in all dimensions Deeper Pelvic outlet relatively small	Wider in all dimensions Shorter and roomier Pelvic outlet relatively large
Sacrum	Long, narrow, with a smooth concavity (sacral curvature); sacral promontory more pronounced	Short, wide, flat concavity more pronounced in a posterior direction; sacral promontory less pronounced
Coccyx	Less movable	More movable and follows the posterior direction of the sacral curvature
Pubic arch	60- to 90-degree angle	90- to 120-degree angle
Pubic symphysis	Relatively deep	Relatively shallow
Ischial spine, ischial tuberosity, and anterior superior iliac spine	Turned more inward	Turned more outward and further apart
Greater sciatic notch	Narrow	Wide

function obviously explains the necessity for these and certain other modifications of the female pelvis. These and other differences between the skeletons of the male and female are summarized in Table 9-9.

12. What is the functional advantage of foot arches?
13. Name two differences between typical male and female skeletons.

Cycle of LIFE

Skeletal System

The changes that occur in the body's skeletal framework over the course of life result primarily from structural changes in bone, cartilage, and muscle tissues. For example, the resilience of incompletely ossified bone in young children allows their bones to withstand the mechanical stresses of childbirth and learning to walk with relatively little risk of fracturing. The density of bone and cartilage in a young to middle-aged adult permits the carrying of great loads. Loss of bone density in later adulthood can make a person so prone to fractures that simply walking or lifting with moderate force can cause bones to crack or break. Loss of skeletal tissue density may result in a compression of weight-bearing bones that causes a loss of height and perhaps an inability to maintain a standard posture. Degeneration of skeletal muscle tissue in late adulthood may also contribute to postural changes and loss of height. The effects of aging are discussed further in the Mechanisms of Disease section later in this chapter.

evolve

the BIG picture

Skeletal System

The skeletal system is a good example of increasing structural hierarchy or complexity in the body.

Recall from Chapter 1 that "levels of organization" characterize body structure so that all of our anatomical components logically fit together and function effectively (see Figure 1-3 on p. 7). In studying skeletal tissues in Chapter 8, we proceeded from the chemical level of organization (inorganic salts and organic matrix) to a discussion of the cells and tissues of bone and cartilage.

In this chapter, we have grouped skeletal tissues into discrete organs (bones) and then joined groups of individual bones together with varying numbers and kinds of other structures, such as blood vessels and nerves, to form a complex operational unit—the skeletal system. The "big picture" becomes more apparent when we integrate the skeletal system with other organ systems, which ultimately allows us to respond in a positive way to disruptions in homeostasis. The skeletal system, for example, plays a key role in purposeful movement, which in turn allows us to move away from potentially harmful stimuli. This organ system is much more than a collection of individual bones—it is a complex and interdependent functional unit essential for life.

MECHANISMS of DISEASE

SKELETAL CHANGES OVER THE LIFE SPAN

It is said that the body's aging processes begin at fertilization and continue until death. In the case of the skeletal system, a number of changes related to aging first become obvious early in uterine development. Other changes then occur at differing times and proceed at differing rates throughout life. Keep in mind that some of these changes are normal and produce positive outcomes whereas others are indicators of deterioration and disease.

Recall from Chapter 8 that flat bones enlarge during intramembranous ossification by appositional growth, which also permits the shafts of long bones to widen. It is endochondral ossification that replaces cartilaginous "models" of long bones present in the fetal skeleton with ossified matrix and then allows the new calcified bones to increase in length by interstitial growth until skeletal maturity occurs. The appearance and progression of these highly regulated skeletal aging processes is determined by genetic control factors, hormones, and other homeostatic control mechanisms.

Differing rates of bone deposition or reabsorption, including the nature and effectiveness of the remodeling process, often characterize aging-associated skeletal changes—both normal and pathological. For example, in the skull, fontanels close, sutures appear, teeth erupt, the paranasal sinuses enlarge and assume their adult placement, and the size of the cranium enlarges to accommodate a growing brain. All these changes occur in a predictable sequence over time and result from normal skeletal aging processes. In long bones, both the age of appearance of ossification centers and, later, the closure of epiphyseal growth plates are age-related skeletal changes important in clinical medicine (see Figure 8-9 on p. 207). Ossification centers (see Figure 8-8 and Figure 8-9 on p. 207) and epiphyseal growth plates appear, enlarge, mature, and close in an orderly fashion. Such orderly progression makes it possible to estimate a child's potential for growth and ultimate height from the number and location of ossification centers and the status of epiphyseal plate closures visible on radiographs. Once the epiphyseal plates in long bones ossify, they can no longer lengthen and growth in height ceases. Physicians often compare an individual's "**bone age**," which is determined by the number of ossification centers visible on a radiograph, with "**chronological age.**" This type of information can prove useful in the diagnosis or treatment of many genetic, metabolic, or inflammatory skeletal diseases characterized by abnormally rapid or delayed skeletal maturity.

In the absence of disease, new bone mass produced after puberty, and generally into the early thirties, is properly calcified but not brittle. It exhibits both the hardness and tensile strength required to resist fractures. During this period, osteoblastic activity results in the deposition of more bone than is resorbed in the remodeling process. Before puberty this process results in bones that continue to grow until they reach adult size and proportions. Instead of growth in bone size, the skeletal remodeling process in the immediate postpuberal years and, generally, into the second decade of life results in the replacement of younger and weaker bone with bone that is more dense and has higher-quality organic matrix. Thus the skeletal aging process in early adulthood produces a positive outcome—stronger bones. Unfortunately, the efficiency of the remodeling process during the next decade begins a progressive decline that can be slowed only by good nutrition and a healthy lifestyle, but never fully stopped. The negative outcomes of skeletal aging soon appear, and they continue over a lifetime.

Degenerative aging processes affect spongy bone before compact bone and generally begin between 30 and 40 years of age. In many cases, problems arise because of abnormalities in bone remodeling that result from both a decrease in osteoblasts and a gradual increase in osteoclast cell numbers and activity. In addition, the osteoblasts that are formed during late adulthood are less metabolically active and produce lower-quality bone matrix. Furthermore, in compact bone, older osteocytes tend to shrink and coalesce, resulting in the appearance of tiny, honeycomb-like open spaces. The result is bone thinning and loss of density. The

Box 9-3 | Balloon Kyphoplasty

Balloon kyphoplasty is an orthopedic procedure used to treat the vertebral compression fractures that occur in osteoporosis, as a result of certain tumors, or after prolonged use of steroid drugs. Fractured (collapsed) vertebrae (see Figure 8-22 on p. 214) result in shortened height and spinal deformity and may be the cause of chronic pain. The balloon kyphoplasty procedure involves the insertion of an inflatable balloonlike device called a **bone tamp** through a small incision in the skin and then through a channel drilled into the body of the fractured vertebra. Expansion of the balloon restores the vertebra to a normal height. The balloon is then deflated and removed, and the surgeon uses the needle to fill the cavity with a type of "super glue" bone cement that quickly hardens and thus stabilizes and seals the fracture. An earlier procedure, called **vertebroplasty,** also involves injecting bone cement, but without using a balloon. Both procedures are cost-effective, have short recovery periods, and in many cases may eliminate the need for difficult and expensive spinal surgery. However, as with all surgical procedures, both the physician and patient need to fully evaluate the risks and rewards beforehand. Specialized physician training and experience in performing the procedure are important, as is the availability of hospital spinal surgery service facilities and personnel if problems should occur.

skeleton as a whole loses strength, bones become brittle, and the risk for fracture increases.

It is the loss of trabeculae and resulting compression fractures in the spongy bone of vertebrae that cause the progressive decrease in height that is a typical consequence of aging. It's true—all of us "shrink with age." And the process begins earlier than you might think—about age 35. However, a regular weight-bearing exercise program coupled with good nutrition, especially adequate calcium and vitamin D intake, will help minimize the degenerative effects of skeletal aging.

The severe and repeated vertebral compression fractures common in osteoporosis cause not only a decrease in height but also spinal deformity and loss of mobility (Box 9-3). Recall that **osteoporosis** (see p. 216) is characterized by loss of bone mass, especially spongy bone, and demineralization of matrix. No discussion of skeletal aging is complete without emphasizing the importance of this very common and serious bone disease. You are encouraged to review the discussion of osteoporosis in Chapter 8. Unfortunately, advancing age is often accompanied by the appearance of other metabolic, genetic, or inflammatory disease conditions that affect skeletal tissues, bones, and joints.

evolve

Bone Fractures

A *bone fracture* is defined as a partial or complete break in the continuity of a bone that most often occurs under mechanical stress. The most common cause of a fracture is traumatic injury. However, bone cancer, cysts, or metabolic bone disorders such as osteoporosis can also cause what are described as **pathological** or **spontaneous fractures.** In these types of fractures, the bone is so weak that it fractures under very little stress and in the absence of any significant trauma. Most fractures can be identified visually during physical examination or on a standard radiograph. One exception is the so-called **stress fracture,** which often occurs in the absence of any clinically visible damage to bone or surrounding tissue. In addition, most x-ray images appear normal with this type of fracture. The microscopic bone damage typical of a stress fracture frequently appears in one or more bones of the leg or foot after repetitive trauma. Long-distance (marathon) runners and ballet dancers are notoriously "at risk." Often called hidden or occult fractures because they frequently remain unseen on regular radiographs, they are clearly visible on bone scans.

| A&P CONNECT |

Check out ***Bone Scans*** online at ***A&P Connect.***

evolve

A **displaced** or **open fracture,** also known as a *compound fracture* (Figure 9-27, *A*), is one in which broken bone projects through surrounding tissue and skin, thereby inviting the possibility of osteomyelitis (see p. 218) or other types of infection. A **nondisplaced** or **closed fracture,** also known as a simple fracture (Figure 9-27, *B*) does not produce a break in the skin and therefore does not pose an immediate danger of bone infection. A closed fracture that results in one end of the broken bone being driven into the marrow cavity or diaphysis of the other bone segment is called an **impacted fracture.** As Figure 9-27, *C*, shows, fractures also are classified as "complete" or "incomplete." A complete fracture involves a break across the entire section of bone, whereas an incomplete fracture involves only a partial break, with the bone fragments still being partially joined.

| A&P CONNECT |

The process of healing in a fractured bone is discussed in Chapter 8 (p. 213). Check out ***Bone Fractures*** online at ***A&P Connect*** for more on bone healing and types of bone fractures.

evolve

Mastoiditis

Mastoiditis (mass-toyd-EYE-tis) is inflammation of the air spaces within the mastoid portion of the temporal bone. Infectious material may find its way into the mastoid air cells from middle ear infections and, unless treated promptly and successfully, can produce very serious medical problems. The mastoid air cells do not drain into the nose, as do the paranasal sinuses. As a result,

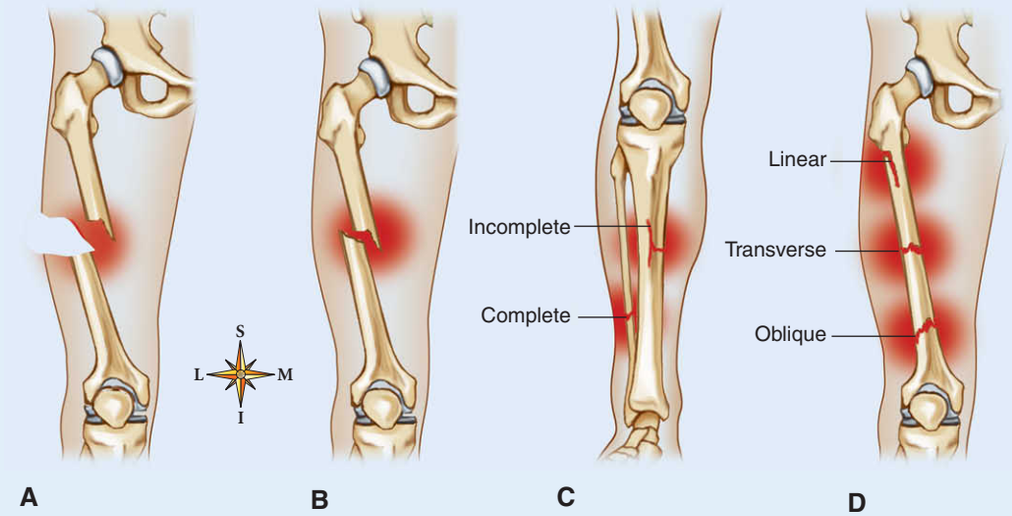

FIGURE 9-27

Bone fractures. A, Open. **B,** Closed. **C,** Incomplete and complete. **D,** Linear, transverse, and oblique.

infectious material that accumulates may erode the bony partition that separates the air cells from the cranial cavity. If such erosion develops, the inflammation may spread to the brain or its covering membranes. Infection and an accumulation of pus (abscess) may then develop in or on the surface of the brain. Should this occur, a localized infection within the middle ear and mastoid air cells in the substance of the temporal bone escalates into a life-threatening medical emergency involving the central nervous system. Externally, clinical signs of mastoiditis include redness and swelling of the external ear and the skin overlying the mastoid process. The area is very painful when touched. In severe cases, the external ear may be pushed forward and downward by the underlying swelling (Figure 9-28).

Prompt treatment of middle ear infection, or **otitis media,** with antibiotics has made life-threatening cases of mastoiditis rare. Exceptions occur in instances of antibiotic resistance or in cases of inadequate or untreated chronic middle ear infections. If intensive antibiotic therapy fails and the subsequent accumulation of infectious material that fills the middle ear and mastoid air cells threatens extension into the cranial cavity, surgical intervention may be required. A surgical incision of the eardrum is often performed to reduce pressure and release pus from the middle ear. Though rarely performed today, surgical removal of part of the diseased mastoid portion of the temporal bone, a procedure called **mastoidectomy,** may also be necessary to drain trapped infectious material from the air cells. Fortunately, modern antibiotics and prompt medical treatment have dramatically reduced the need for this procedure with its attendant scarring and hearing loss.

FIGURE 9-28

Mastoiditis. Note redness and swelling over the mastoid process of the temporal bone.

Abnormal Spinal Curvatures

The normal curvature of the spine is convex through the thoracic region and concave through the cervical and lumbar regions (see Figure 9-13). This gives the spine strength to support the weight of the rest of the body and makes it possible to also balance the weight of the body, which is necessary to stand and walk. A curved structure has more strength than does a straight one of the same size and material. Poor posture or disease may cause the lumbar curve to be abnormally accentuated—a condition known as "sway back," or **lordosis** (Figure 9-29, A). This condition is frequently

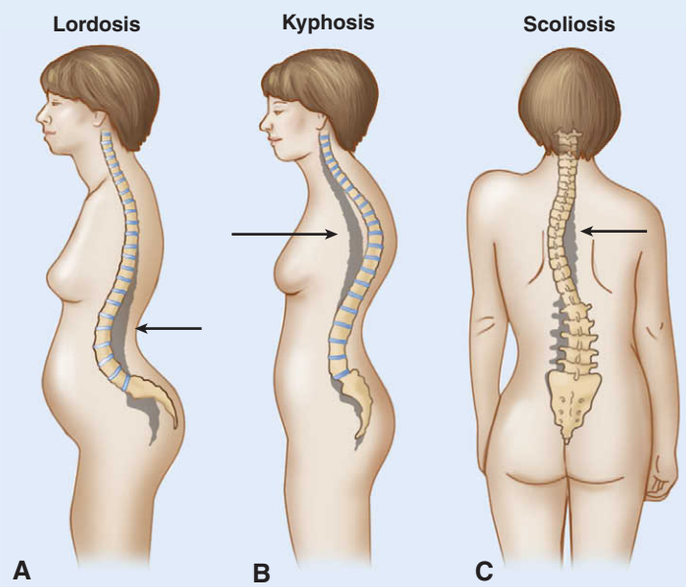

FIGURE 9-29

Abnormal spine curvatures. A, Lordosis. **B,** Kyphosis. **C,** Scoliosis. *Black arrows* highlight areas of abnormal curvature

seen during pregnancy as the woman adjusts to changes in her center of gravity. It may also be secondary to traumatic injury or a degenerative process of the vertebral bodies.

Kyphosis, or "hunchback," is an abnormally increased roundness in the thoracic curvature (Figure 9-29, *B*). It is frequently seen in elderly people with osteoporosis or chronic arthritis, those with neuromuscular diseases, or individuals with compression fractures of the thoracic vertebrae. In a condition called **Scheuermann disease,** kyphosis can develop in children at puberty.

Abnormal side-to-side curvature is called **scoliosis** (Figure 9-29, *C*). This too may be idiopathic or a result of damage to the supporting muscles along the spine. It is a relatively common condition that appears before adolescence.

All three abnormal curvatures can interfere with normal breathing, posture, and other vital functions. The degree of abnormal curvature and resulting deformity of the vertebral column determine the various treatments instituted. The traditional treatment of scoliosis is the use of a supportive brace, called the **Milwaukee brace,** that is worn on the upper part of the body 23 hours per day for up to several years. A newer approach to straightening abnormal curvature is **transcutaneous stimulation.** In this method, muscles on one side of the vertebral column are electrically stimulated to contract and pull the vertebrae into a more normal position. If these methods fail, correction may be achieved by surgical intervention in which pieces of bone from elsewhere in the skeleton, or metal rods, are grafted to the deformed vertebrae to hold them in proper alignment. If treated early enough, kyphosis resulting from poor posture can be corrected with special exercises and instructions for appropriate posture. Kyphosis resulting from pathological causes may also require special braces or surgical intervention.

Box 9-4 | SPORTS and FITNESS

Chondromalacia Patellae

Chondromalacia patellae is a degenerative process that results in softening (degeneration) of the articular surface of the patella. The symptoms associated with chondromalacia of the patella are a common cause of knee pain in many individuals—especially young athletes. The condition is usually caused by irritation of the patellar groove, with subsequent changes in the cartilage on the underside of the patella. The most common complaint is of pain arising from behind or beneath the kneecap, especially during activities that require flexion of the knee, such as climbing stairs, kneeling, jumping, or running.

UNIT 2

CASE study

No matter how much he turned the steering wheel, Robert's car just kept veering directly toward the guardrail as it slid across the black ice. The impact from the car slamming against an immovable object was horrendous. Even though he was wearing his seat belt, Robert was thrown violently forward and sideways as the car and railing collided. After the car came to a jolting stop, Robert's first thought was to unbuckle his seat belt so he could get out of the car, but a severe pain in his chest kept him from moving. Thankfully, the paramedics were on the scene in a matter of minutes. They gently moved Robert from his car to a backboard and strapped his head in place.

In the emergency department, a nurse gave Robert the news: his spine was fractured at "T6"; his fourth and fifth ribs were cracked; and he had a broken mandible and a shattered tibia.

1. Which bone in the spine was fractured?
   a. Thyroid vertebra
   b. Tibia
   c. Tarsal
   d. Thoracic vertebra
2. What is another name for the fourth and fifth ribs that were cracked in the accident?
   a. Floating ribs
   b. False ribs
   c. True ribs
   d. Costal ribs
3. What daily activity will be affected most by his broken mandible?
   a. Walking
   b. Eating
   c. Writing
   d. Sitting
4. What daily activity will be affected most by his shattered tibia?
   a. Walking
   b. Eating
   c. Writing
   d. Sitting

HINT *To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook,* ***A&P Connect,*** *and other resources.*

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

INTRODUCTION

A. Skeletal tissues form bones—the organs of the skeletal system
B. The relationship of bones to each other and to other body structures provides a basis for understanding the function of other organ systems
C. The adult skeleton is composed of 206 separate bones

DIVISIONS OF THE SKELETON (FIGURE 9-1; TABLE 9-1)

A. Axial skeleton—the 80 bones of the head, neck, and torso; composed of 74 bones that form the upright axis of the body and six tiny middle ear bones
B. Appendicular skeleton—the 126 bones that form the appendages to the axial skeleton; the upper and lower extremities

AXIAL SKELETON

A. Skull—made up of 28 bones in two major divisions: cranial bones and facial bones (Figures 9-2 to 9-7; Table 9-3)
   1. Cranial bones
      a. Frontal bone (Figure 9-8, *C*)
         (1) Forms the forehead and anterior part of the top of the cranium
         (2) Contains the frontal sinuses
         (3) Forms the upper portion of the orbits
         (4) Forms the coronal suture with the two parietal bones
      b. Parietal bones (Figure 9-8, *A*)
         (1) Form the bulging top of the cranium
         (2) Form several sutures: lambdoid suture with the occipital bone; squamous suture with the temporal bone and part of the sphenoid; and coronal suture with the frontal bone
      c. Temporal bones (Figure 9-8, *B*)
         (1) Form the lower sides of the cranium and part of the cranial floor
         (2) Contain the inner and middle ears
      d. Occipital bone (Figure 9-8, *D*)
         (1) Forms the lower, posterior part of the skull
         (2) Forms immovable joints with three other cranial bones and a movable joint with the first cervical vertebra
      e. Sphenoid bone (Figure 9-8, *E*)
         (1) A bat-shaped bone located in the central portion of the cranial floor
         (2) Anchors the frontal, parietal, occipital, and ethmoid bones and forms part of the lateral wall of the cranium and part of the floor of each orbit (Figure 9-7)
         (3) Contains the sphenoid sinuses
      f. Ethmoid bone (Figure 9-8, *F*)
         (1) A complex, irregular bone that lies anterior to the sphenoid and posterior to the nasal bones
         (2) Forms the anterior cranial floor, medial orbit walls, upper parts of the nasal septum, and sidewalls of the nasal cavity
         (3) The cribriform plate is located in the ethmoid
   2. Facial bones (Table 9-4)
      a. Maxilla (upper jaw) (Figure 9-8, *H*)
         (1) Two maxillae form the keystone of the face
         (2) Maxillae articulate with each other and with the nasal, zygomatic, inferior concha, and palatine bones
         (3) Forms parts of the orbital floors, roof of the mouth, and floor and sidewalls of the nose
         (4) Contains maxillary sinuses
      b. Mandible (lower jaw) (Figure 9-8, *M*)
         (1) Largest, strongest bone of the face
         (2) Forms the only movable joint of the skull with the temporal bone
      c. Zygomatic bone (Figure 9-8, *I*)
         (1) Shapes the cheek and forms the outer margin of the orbit
         (2) Forms the zygomatic arch with the zygomatic process of the temporal bones
      d. Nasal bone (Figures 9-8, *L* and 9-10)
         (1) Both nasal bones form the upper part of the bridge of the nose, whereas cartilage forms the lower part
         (2) Articulates with the ethmoid, nasal septum, frontal bone, maxillae, and the other nasal bone
      e. Lacrimal bone (Figure 9-8, *K*)
         (1) Paper-thin bone that lies just posterior and lateral to each nasal bone
         (2) Forms the nasal cavity and medial wall of the orbit
         (3) Contains a groove for the nasolacrimal (tear) duct
         (4) Articulates with the maxilla, frontal, and ethmoid bones
      f. Palatine bone (Figure 9-8, *J*)
         (1) Two bones form the posterior part of the hard palate
         (2) Vertical portion forms the lateral wall of the posterior part of each nasal cavity
         (3) Articulates with the maxillae and the sphenoid bone
      g. Inferior nasal conchae (turbinates)
         (1) Form the lower edge projecting into the nasal cavity and form the nasal meatus
         (2) Articulate with ethmoid, lacrimal, maxillary, and palatine bones
      h. Vomer bone (Figure 9-8, *G*)
         (1) Forms the posterior portion of the nasal septum
         (2) Articulates with the sphenoid, ethmoid, palatine, and maxillae
B. Eye orbits (Figure 9-7)
   1. Right and left eye orbits
      a. Contain eyes, associated eye muscles, lacrimal apparatus, blood vessels, and nerves
      b. Thin and fragile orbital walls separate orbital structures from the cranial and nasal cavities and paranasal sinuses
C. Fetal skull (Figure 9-11)

1. Characterized by unique anatomical features not seen in adult skull
2. Fontanels or "soft spots" (4) allow the skull to "mold" during the birth process and also allow for rapid growth of the brain (Table 9-5)
3. Permits differential growth or appearance of skull components over time
   a. Face—smaller proportion of total cranium at birth (⅛) than in adult (½)
   b. Head at birth is ¼ the total height; at maturity about ⅛ body height
   c. Sutures appear with skeletal maturity (Table 9-5)
   d. Paranasal sinuses—change in size and placement with skeletal maturity (Figure 9-9)
   e. Appearance of deciduous and, later, permanent teeth

D. Hyoid bone (Figure 9-12)
1. U-shaped bone located just above the larynx and below the mandible
2. Suspended from the styloid processes of the temporal bone
3. Only bone in the body that articulates with no other bones

E. Vertebral column (Figure 9-13)
1. Forms the flexible longitudinal axis of the skeleton
2. Consists of 24 vertebrae plus the sacrum and coccyx
3. Segments of the vertebral column:
   a. Cervical vertebrae, 7
   b. Thoracic vertebrae, 12
   c. Lumbar vertebrae, 5
   d. Sacrum—in adults, results from the fusion of five separate vertebrae
   e. Coccyx—in adults, results from the fusion of four or five separate vertebrae
4. Characteristics of the vertebrae (Figures 9-14; Table 9-6)
   a. All vertebrae, except the first, have a flat, rounded body anteriorly and centrally, a spinous process posteriorly, and two transverse processes laterally
   b. All but the sacrum and coccyx have a vertebral foramen
   c. Second cervical vertebrae has an upward projection, the dens, to allow rotation of the head
   d. Seventh cervical vertebra has a long, blunt spinous process
   e. Each thoracic vertebra has articular facets for the ribs
5. Vertebral column as a whole articulated with the head, ribs, and iliac bones
6. Individual vertebrae articulate with each other in joints between their bodies and between their articular processes

F. Sternum (Figure 9-15)
1. Dagger-shaped bone in the middle of the anterior chest wall made up of three parts:
   a. Manubrium—the upper handle part
   b. Body—middle blade part
   c. Xiphoid process—blunt cartilaginous lower tip, which ossifies during adult life
2. Manubrium articulates with the clavicle and first rib
3. Next nine ribs join the body of the sternum, either directly or indirectly, by means of the costal cartilages

G. Ribs (Figures 9-15 and 9-16)
1. Twelve pairs of ribs, with the vertebral column and sternum, form the thorax
2. Each rib articulates with the body and transverse process of its corresponding thoracic vertebra
3. Ribs 2 through 9 articulate with the body of the vertebra above
4. From its vertebral attachment, each rib curves outward, then forward and downward
5. Rib attachment to the sternum:
   a. Ribs 1 through 8 join a costal cartilage that attaches it to the sternum
   b. Costal cartilage of ribs 8 through 10 joins the cartilage of the rib above to be indirectly attached to the sternum
   c. Ribs 11 and 12 are floating ribs because they do not attach even indirectly to the sternum

APPENDICULAR SKELETON

A. Upper extremity (Table 9-7)
1. Consists of the bones of the shoulder girdle, upper and lower parts of the arm, wrist, and hand
2. Shoulder girdle (Figure 9-17)
   a. Made up of the scapula and clavicle
   b. Clavicle forms the only bony joint with the trunk, the sternoclavicular joint
   c. At its distal end, the clavicle articulates with the acromion process of the scapula
3. Humerus (Figures 9-18 and 9-19)
   a. The long bone of the upper part of the arm
   b. Articulates proximally with the glenoid fossa of the scapula and distally with the radius and ulna
4. Ulna
   a. The long bone found on the little finger side of the forearm
   b. Articulates proximally with the humerus and radius and distally with a fibrocartilaginous disk
5. Radius
   a. The long bone found on the thumb side of the forearm
   b. Articulates proximally with the capitulum of the humerus and the radial notch of the ulna; articulates distally with the scaphoid and lunate carpal bones and with the head of the ulna
6. Carpal bones (Figure 9-20)
   a. Eight small bones that form the wrist
   b. Carpal bones are bound closely and firmly by ligaments and form two rows of four carpals each
      (1) Proximal row is made up of the pisiform, triquetrum, lunate, and scaphoid
      (2) Distal row is made up of the hamate, capitate, trapezoid, and trapezium
   c. The joints between the radius and carpal bones allow wrist and hand movements
7. Metacarpal bones
   a. Form the framework of the hand
   b. The thumb metacarpal forms the most freely movable joint with the carpal bones
   c. Heads of the metacarpal bones (the knuckles) articulate with the phalanges

B. Lower extremity
1. Consists of the bones of the hip, thigh, leg, ankle, and foot (Table 9-8)

2. Pelvic girdle is made up of the sacrum and the two coxal bones bound tightly by strong ligaments (Figure 9-21)
   a. A stable circular base that supports the trunk and attaches the lower extremities to it
   b. Each coxal bone is made up of three bones that fuse together (Figure 9-22):
      (1) Ilium—largest and uppermost
      (2) Ischium—strongest and lowermost
      (3) Pubis—anterior most
3. Femur—longest and heaviest bone in the body (Figure 9-23)
4. Patella—largest sesamoid bone in the body
5. Tibia
   a. The larger, stronger, and more medially and superficially located of the two leg bones
   b. Articulates proximally with the femur to form the knee joint
   c. Articulates distally with the fibula and talus
6. Fibula
   a. The smaller, more laterally and deeply placed of the two leg bones
   b. Articulates with the tibia
7. Foot (Figures 9-24 and 9-25)
   a. Structure is similar to that of the hand with adaptations for supporting weight
   b. Foot bones are held together to form spring arches
      (1) Medial longitudinal arch is made up of the calcaneus, talus, navicular, cuneiforms, and medial three metatarsal bones
      (2) Lateral longitudinal arch is made up of the calcaneus, cuboid, and fourth and fifth metatarsal bones

SKELETAL DIFFERENCES BETWEEN MEN AND WOMEN

A. Male skeleton is larger and heavier than female skeleton
B. Pelvic differences (Figure 9-26; Table 9-9)
   1. Male pelvis—deep and funnel-shaped with a narrow pubic arch
   2. Female pelvis—shallow, broad, and flaring with a wider pubic arch

CYCLE OF LIFE: THE SKELETAL SYSTEM

A. Changes in the skeleton begin at fertilization and continue over a lifetime; changes can be positive or negative
B. Incompletely ossified skeleton in children provides the resiliency needed to withstand stress without breaking easily
C. Dense bone structure in young and middle adulthood permits bearing heavy loads
D. In later adulthood, reduced bone density makes fractures more likely and causes changes in posture and overall height
E. Details of aging effects are found in Mechanisms of Disease section

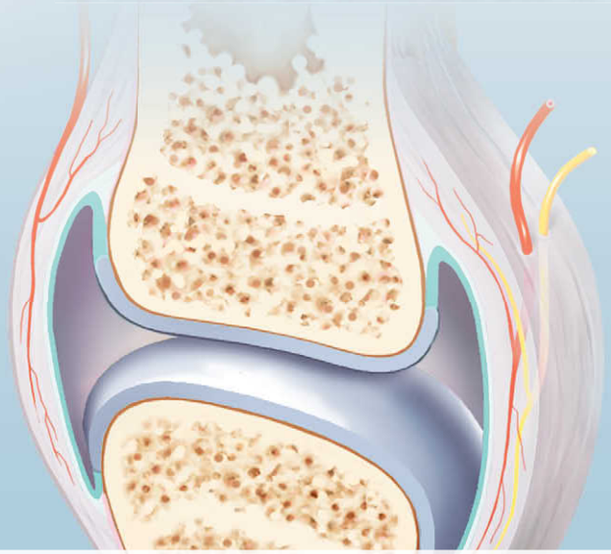
THE BIG PICTURE: SKELETAL SYSTEM

A. Skeletal system is a good example of increasing structural hierarchy in the body
   1. Skeletal tissues grouped into discrete organs—bones
   2. Skeletal system consists of bones, blood vessels, nerves, and other tissues grouped to form a complex operational unit
   3. Integration of skeletal system with other body organ systems permits homeostasis to occur
   4. Skeletal system more than a collection of individual bones—it represents a complex and interdependent functional unit of the body

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Describe the skeleton as a whole and identify its two major subdivisions.
2. Identify and differentiate the bones in the cranium and face.
3. Name and locate the fontanels and sutures of the skull.
4. Name the five pairs of bony sinuses in the skull.
5. Discuss the clinical (medical) importance of the cribriform plate of the ethmoid bone and the mastoid air cells in the temporal bone.
6. Identify and discuss the normal primary and secondary curves of the spine.
7. Describe and distinguish between the different kinds of bone fractures and discuss symptoms and treatments of broken bones.
8. Identify the bony components of the thorax.
9. Identify the bones of the shoulder and pelvic girdles.
10. Identify, compare, and organize the bones of the arm, forearm, wrist, and hand with those of the thigh, leg, ankle, and foot.
11. Discuss the arches of the foot and point out the functional importance of each.
12. Describe the role of the pubic symphysis during childbirth.
13. Describe vertebroplasty.



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. How would you compare and contrast the differences between the skeletal structure of males and females? What are the physiological reasons for these differences?
2. What are some functional advantages of the fontanels of a baby's skull during the birth process?
3. Explain how the shoulder and pelvic girdles stabilize the appendages.
4. What are some of the functions of foramina in the skeleton?
5. What is the functional advantage of having air spaces in skull bones? What is a disadvantage to having these spaces lined with mucous membrane?
6. Why do many bones of the skeleton have prominent bumps? What is their purpose?

10 Articulations

continued on p. 271

An articulation, or joint, is a point of contact between bones. Although most joints in the body allow considerable movement, some are completely immovable or permit only limited motion or motion in only one plane or direction. In the case of immovable joints, such as the sutures of the skull, adjacent bones are bound together into a strong and rigid protective plate. In other joints, movement is possible but highly restricted. For example, joints between the bodies of the spinal vertebrae perform two seemingly contradictory functions. They help firmly bind the components of the spine to each other and yet permit normal, but restricted movement to occur. Most joints in the body allow considerable movement to occur as a result of skeletal muscle contractions. It is the existence of such joints that permits us to execute complex, highly coordinated, and purposeful movements. Functional articulations between bones in the extremities, such as the shoulder, elbow, hip, and knee, contribute to controlled and graceful movement and provide a large measure of our enjoyment of life. This chapter begins by classifying joints and describing their identifying features. Coverage of joint classification and structure is followed by a discussion of body movements and a description of selected major joints. The chapter concludes by describing life cycle changes and some common joint diseases.

CLASSIFICATION OF JOINTS

Joints may be classified into three major categories by using a structural or a functional scheme. If a *structural classification* is used, joints are named according to the type of connective tissue that joins the bones together (fibrous or cartilaginous joints) or by the presence of a fluid-filled joint capsule (synovial joints). If a *functional classification* scheme is used, joints are divided into three classes according to the degree of movement they permit: **synarthroses** (immovable), **amphiarthroses** (slightly movable), and **diarthroses** (freely movable). Table 10-1 classifies joints according to structure, function, and range of movement. Refer often to this Table and to the illustrations that follow as you read about each of the major joint types in this chapter.

Fibrous Joints (Synarthroses)

The articulating surfaces of bones that form fibrous joints fit closely together. The different types and amount of connective tissue joining bones in this group may permit very limited movement in some fibrous joints, but most are fixed. There are three subtypes of fibrous joints: *syndesmoses*, *sutures*, and *gomphoses*.

SYNDESMOSES

Syndesmoses (SIN-dez-MO-seez) are joints in which fibrous bands (ligaments) connect two bones. The joint between the distal ends of the radius and ulna is joined by the *radioulnar interosseous ligament* (Figure 10-1). Although this joint is classified as a fibrous joint, some movement is possible because of ligament flexibility.

SUTURES

Sutures are found only in the skull. In most sutures, teethlike projections jut out from adjacent bones and interlock with each other with only a thin layer of fibrous tissue between them. Sutures become ossified in older adults and form extremely strong lines of fusion between opposing skull bones (see Figure 10-1).

GOMPHOSES

Gomphoses (gom-FOH-seez) are unique joints that occur between the root of a tooth and the alveolar process of the mandible or maxilla (see Figure 10-1). The fibrous tissue between the tooth's root and the alveolar process is a sheet made up of tiny ligaments and called the *periodontal membrane*.

Cartilaginous Joints (Amphiarthroses)

The bones that articulate to form cartilaginous joints are joined together by either hyaline cartilage or fibrocartilage. Joints characterized by the presence of hyaline cartilage between articulating bones are called *synchondroses*, and those joined by fibrocartilage are called *symphyses*. Cartilaginous joints permit only very limited movement between articulating bones in certain circumstances. During childbirth, for example, slight movement at the pubic symphysis facilitates the baby's passage through the pelvis.

SYNCHONDROSES

Note that joints identified as **synchondroses** (SIN-kon-DROH-seez) have hyaline cartilage between articulating bones. One example of a synchondrosis is the joint between the sphenoid bone and the

TABLE 10-1 Primary Joint Classifications

FUNCTIONAL NAME	STRUCTURAL NAME	DEGREE OF MOVEMENT PERMITTED	EXAMPLE
Synarthroses	Fibrous	Immovable	Sutures of the skull
Amphiarthroses	Cartilaginous	Slightly movable	Pubic symphysis
Diarthroses	Synovial	Freely movable	Shoulder joint

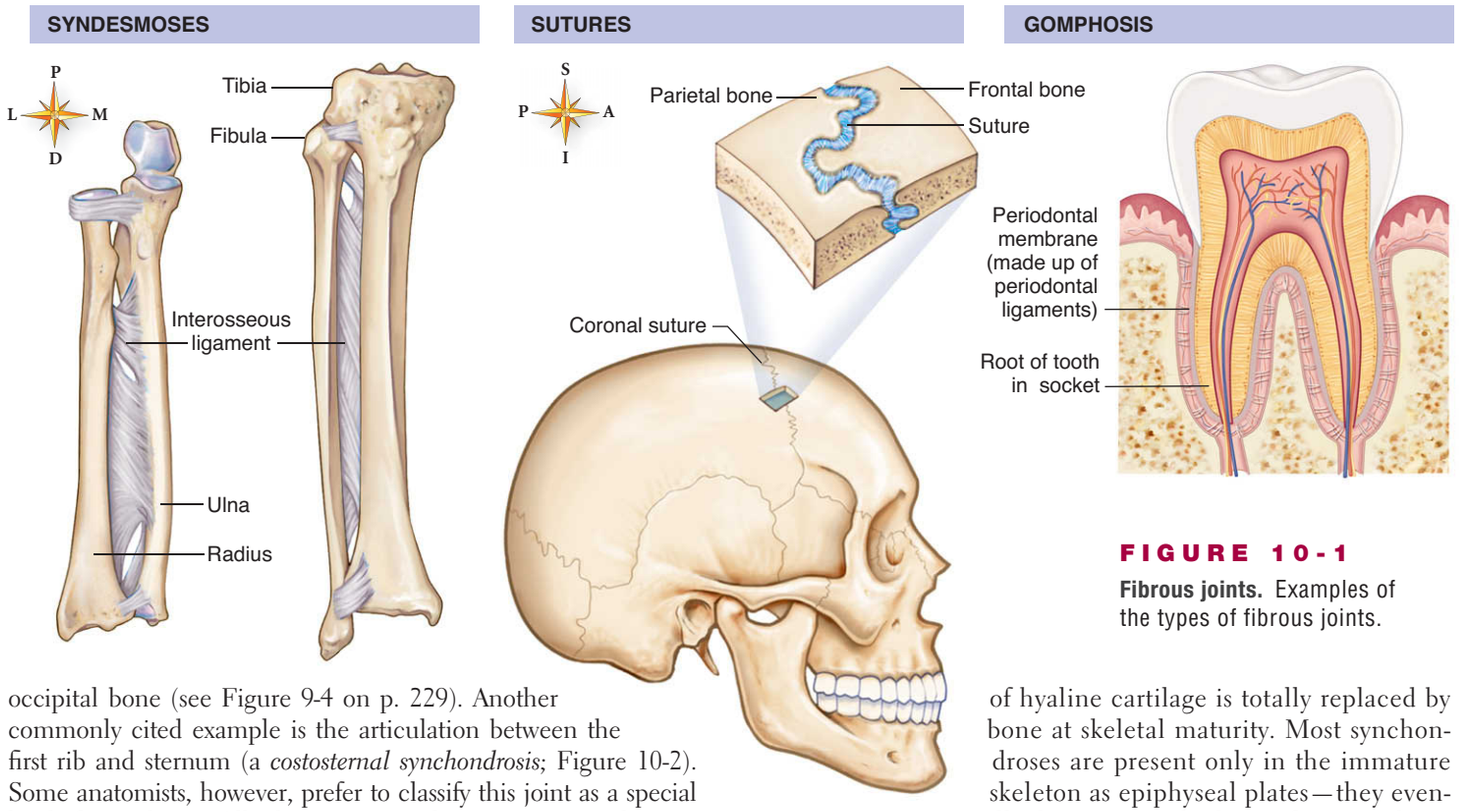

FIGURE 10-1
Fibrous joints. Examples of the types of fibrous joints.

occipital bone (see Figure 9-4 on p. 229). Another commonly cited example is the articulation between the first rib and sternum (a *costosternal synchondrosis*; Figure 10-2). Some anatomists, however, prefer to classify this joint as a special kind of synarthrosis. All other sternocostal joints are synovial joints, even though they often lack joint capsules.

The best example of a synchondrosis is the joint present during the growth years between the epiphyses of a long bone and its diaphysis (see Figure 10-2). The epiphyseal plate between the epiphysis and diaphyses of a long bone is a temporary synchondrosis that normally does not move. The plate of hyaline cartilage is totally replaced by bone at skeletal maturity. Most synchondroses are present only in the immature skeleton as epiphyseal plates—they eventually disappear as the bones fuse together.

SYMPHYSES

A **symphysis** (SIM-fi-sis) is a joint in which a pad or disk of fibrocartilage connects two bones. The tough fibrocartilage disks in these joints may permit slight movement when pressure is applied between the bones.

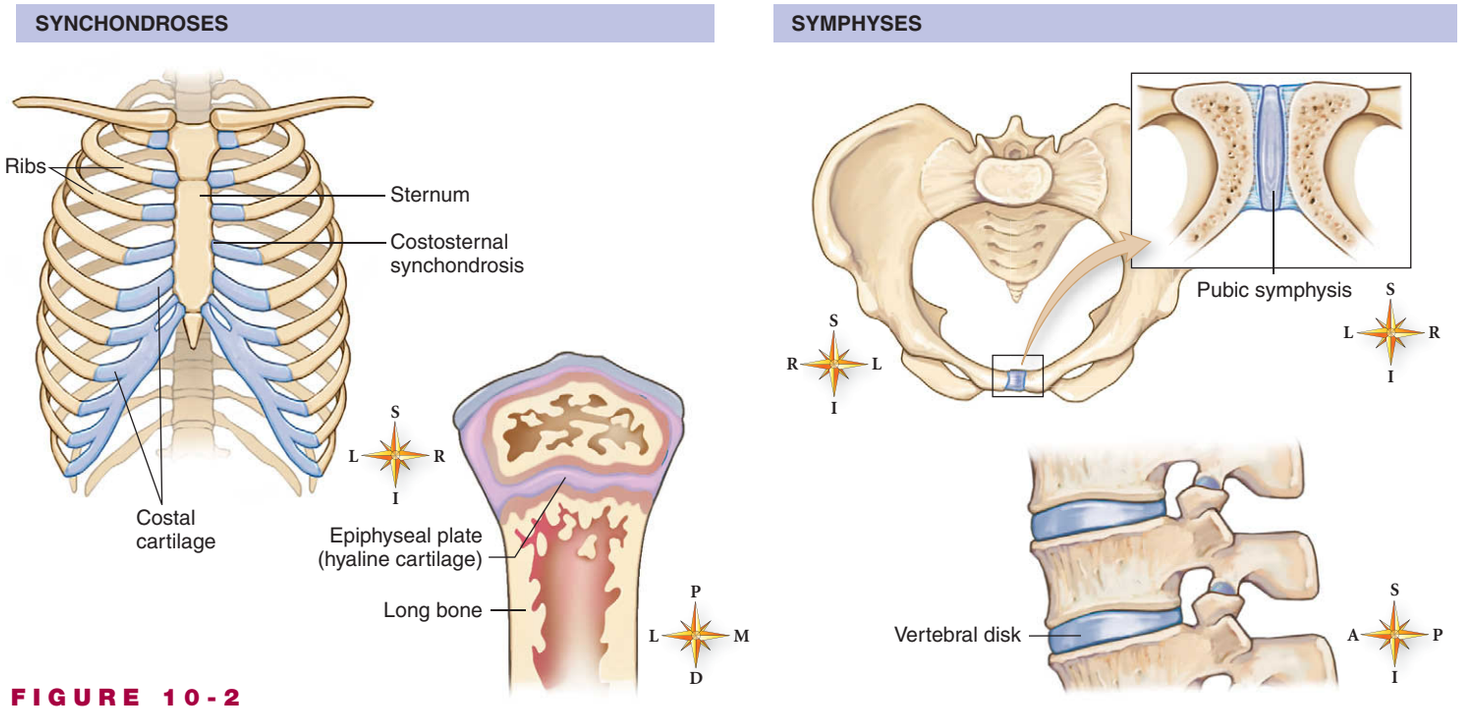

FIGURE 10-2
Cartilaginous joints. Examples of the types of cartilaginous joints.

Most symphyses are located in the midline of the body. Examples of symphyses include the pubic symphysis and the articulation between the *bodies* of adjacent vertebrae (see Figure 10-2). The intervertebral disk in these joints is composed of tough and resilient fibrocartilage that absorbs shock and permits limited movement. The bones of the vertebral column have numerous points of articulation between them. Collectively, these joints permit limited motion of the spine in a very restricted range. The articulation between the *bodies* of adjacent vertebrae is classified as a cartilaginous joint. The points of contact between the *articular facets* of adjacent vertebrae are, however, considered synovial joints and are described later in the chapter.

Table 10-2 summarizes the different kinds of fibrous and cartilaginous joints.

| QUICK CHECK |

1. Define the term *joint,* or *articulation.*
2. List the three major classes of joints according to both a structural and a functional scheme.
3. Name the three types of fibrous joints and give one example of each.
4. Identify the two types of cartilaginous joints and give one example of each.

Synovial Joints (Diarthroses)

Synovial joints are freely movable joints. They are not only the body's most mobile but also its most numerous and anatomically most complex joints. A majority of the joints between bones in the appendicular skeleton are synovial joints.

STRUCTURE OF SYNOVIAL JOINTS

The following seven structures characterize synovial, or freely movable, joints (Figure 10-3):

1. **Joint capsule.** Sleevelike extension of the periosteum of each of the articulating bones. The capsule forms a complete casing around the ends of the bones, thereby binding them to each other.
2. **Synovial membrane.** Moist, slippery membrane that lines the inner surface of the joint capsule. It attaches to the

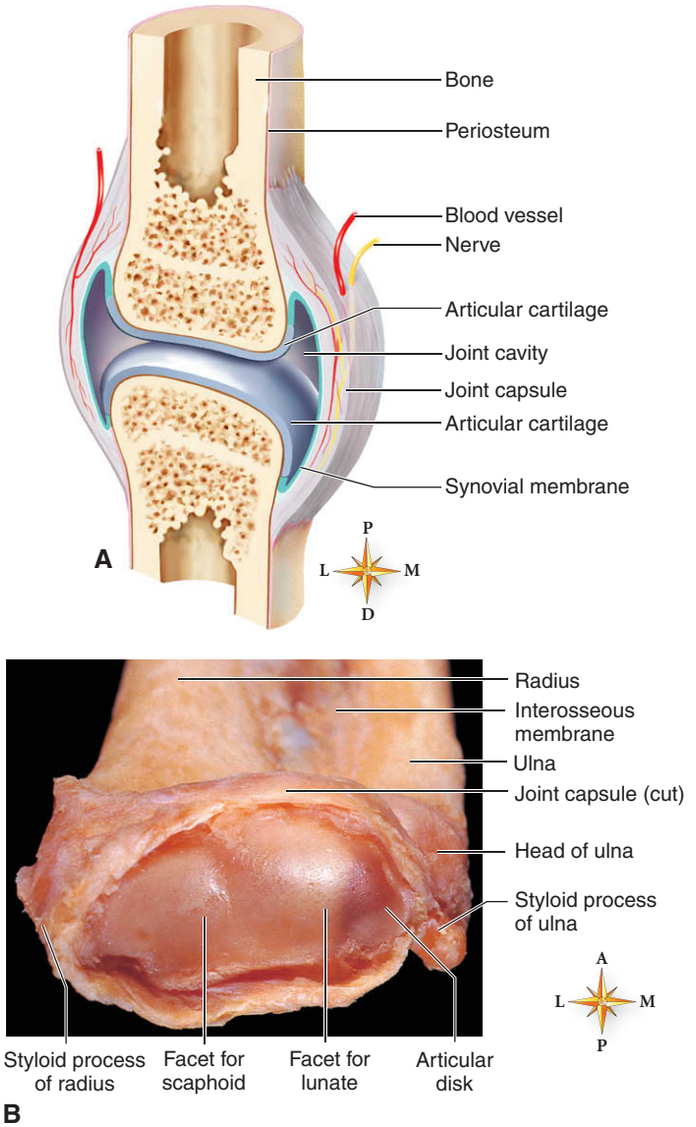

FIGURE 10-3

Structure of synovial joints. A, Artist's interpretation (composite drawing) of a typical synovial joint. **B,** Dissection photo showing the articular surface of a typical synovial joint—the distal radiocarpal joint (the joint capsule has been cut). See pp. 274–275 for a description of this joint.

TABLE 10-2 Classification of Fibrous and Cartilaginous Joints

TYPES	EXAMPLES	STRUCTURAL FEATURES	MOVEMENT
Fibrous Joints			
Syndesmoses	Joints between the distal ends of the radius and ulna	Fibrous bands (ligaments) connect articulating bones	Slight
Sutures	Joints between the skull bones	Teethlike projections of articulating bones interlock with a thin layer of fibrous tissue connecting them	None
Gomphoses	Joints between the roots of the teeth and the jaw bones	Fibrous tissue connects the roots of the teeth to the alveolar processes	None
Cartilaginous Joints			
Synchondroses	Costal cartilage attachments of the first rib to the sternum; epiphyseal plate between the diaphysis and epiphysis of a growing long bone	Hyaline cartilage connects articulating bones	Slight
Symphyses	Pubic symphysis; joints between *bodies* of vertebrae	Fibrocartilage between articulating bones	Slight

margins of the articular cartilage. It also secretes synovial fluid, which lubricates and nourishes the inner joint surfaces.

3. **Articular cartilage.** Thin layer of hyaline cartilage covering and cushioning the articular surfaces of bones.
4. **Joint cavity.** Small space between the articulating surfaces of the two bones of the joint. Absence of tissue between articulating bone surfaces permits extensive movement. Synovial joints are therefore diarthroses, or freely movable joints.
5. **Menisci (articular disks).** Pads of fibrocartilage located between the articulating ends of bones in some diarthroses. Usually these pads divide the joint cavity into two separate cavities. The knee joint contains two menisci (see Figure 10-10).
6. **Ligaments.** Strong cords of dense, white fibrous tissue at most synovial joints. They grow between the bones, and lash them even more firmly together than is possible with the joint capsule alone.
7. **Bursae.** Some synovial joints contain a closed pillowlike structure called a **bursa,** which consists of a synovial membrane filled with synovial fluid. Bursae tend to be associated with bony prominences (such as in the knee or the elbow), where they function to cushion the joint and facilitate movement of tendons.

TYPES OF SYNOVIAL JOINTS

Synovial joints are divided into three main groups: uniaxial, biaxial, and multiaxial. Each is subdivided further into two subtypes as follows:

1. **Uniaxial joints.** Synovial joints that permit movement around only one axis and in only one plane. Hinge and pivot joints are types of uniaxial joints (Figure 10-4, *A* and *B*).
   a. *Hinge joints.* Those in which the articulating ends of the bones form a hinge-shaped unit. Like a common door hinge, hinge joints permit only back-and-forth movements, namely, flexion and extension. If you have access to an articulated skeleton, examine the articulating end of the humerus (the trochlea) and the ulna (the semilunar notch). Observe their interaction as you flex and extend the forearm. Do you see why you can flex and extend your forearm but cannot move it in any other way at this joint? The shapes of the trochlea and the semilunar notch (see Figure 9-18, p. 252, and Figure 9-19, p. 253) permit only the uniaxial, horizontal-plane movements of flexion and extension at the elbow. Other hinge joints include the knee and interphalangeal joints.
   b. *Pivot joints.* Those in which a projection of one bone articulates with a ring or notch of another bone. Examples include a projection (dens) of the second cervical vertebra articulating with a ring-shaped portion of the first cervical vertebra and the head of the radius articulating with the radial notch of the ulna.
2. **Biaxial joints.** Diarthroses that permit movement around two perpendicular axes in two perpendicular planes. Saddle and condyloid joints are types of biaxial joints (Figure 10-4, *C* and *D*).
   a. *Saddle joints.* Those in which the articulating ends of the bones resemble reciprocally shaped miniature saddles. Only two saddle joints—one in each thumb—are present in the body. The thumb's metacarpal bone articulates in the wrist with a carpal bone (trapezium). The saddle-shaped articulating surfaces of these bones make it possible for the thumb to swing in an arc to touch the tips of the fingers—that is, to oppose the fingers. How important is this? To answer this for yourself, consider the following. Opposing the thumb to the fingers enables us

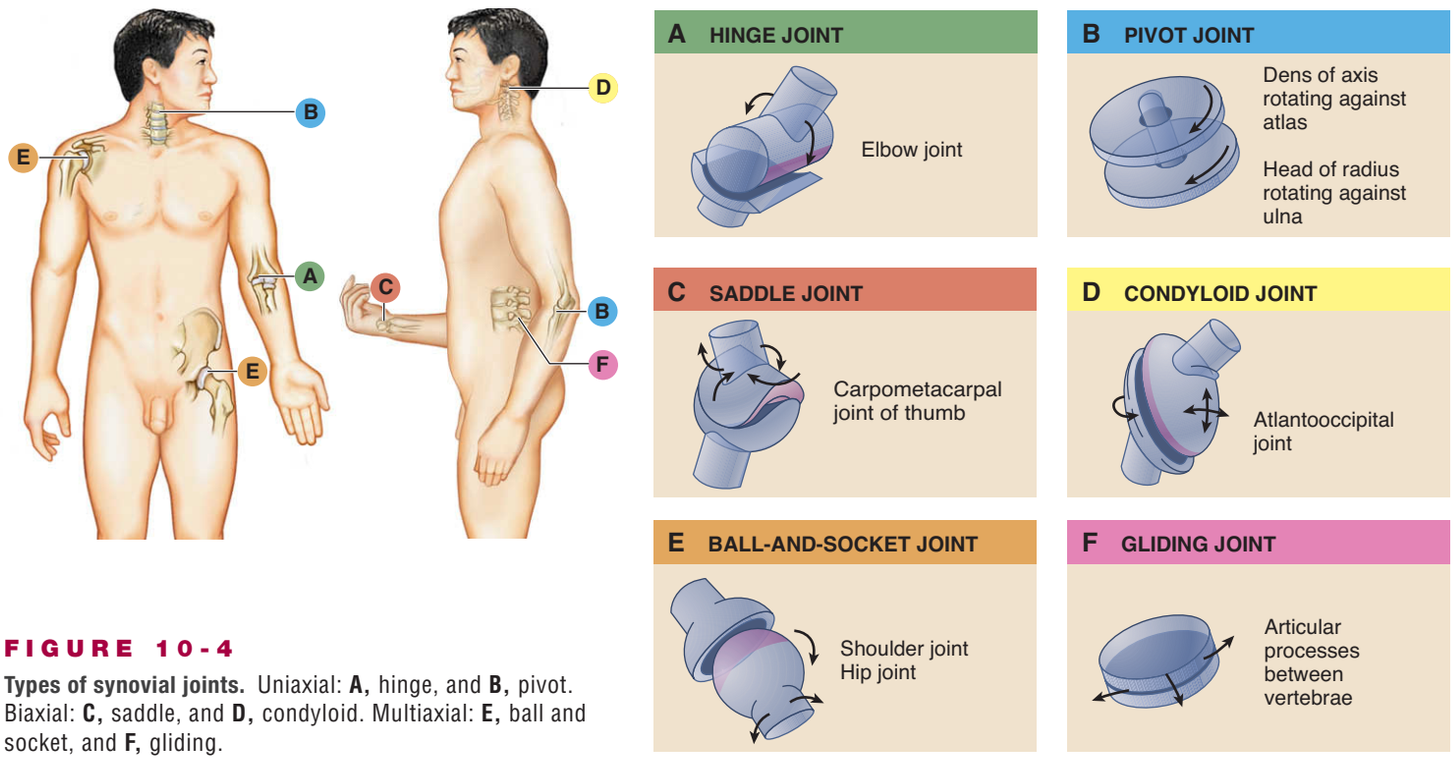

FIGURE 10-4

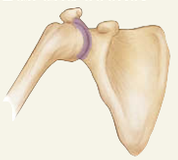
Types of synovial joints. Uniaxial: **A,** hinge, and **B,** pivot. Biaxial: **C,** saddle, and **D,** condyloid. Multiaxial: **E,** ball and socket, and **F,** gliding.

to grip small objects. Were it not for this movement, we would have much less manual dexterity. A surgeon could not grasp a scalpel or suture needle effectively, and none of us could easily hold a pen or pencil for writing.

b. *Condyloid (ellipsoidal) joints.* Those in which a condyle fits into an elliptical socket. Examples include condyles of the occipital bone fitting into elliptical depressions of the atlas and the distal end of the radius fitting into depressions of the carpal bones (scaphoid, lunate, and triquetrum).



3. **Multiaxial joints.** Joints that permit movement around three or more axes and in three or more planes (Figure 10-4, *E* and *F*).

a. *Ball-and-socket joints (spheroid joints).* Our most movable joints. A ball-shaped head of one bone fits into a concave depression on another, thereby allowing the first bone to move in many directions. Examples include the shoulder and hip joints.

b. *Gliding joints.* Characterized by relatively flat articulating surfaces that allow limited gliding movements along various axes. Examples include the joints between the articular surfaces of successive vertebrae. (Articulations between the bodies of successive vertebrae are symphysis-type cartilaginous joints.) As a group, gliding joints are the least movable of the synovial joints.

Table 10-3 summarizes the classes of synovial joints.

TABLE 10-3 Classification of Synovial Joints

TYPES	EXAMPLES	STRUCTURE	MOVEMENT
Uniaxial			*Around one axis; in one place*
Hinge 	Elbow joint	Spool-shaped process fits into a concave socket	Flexion and extension only
Pivot 	Joint between the first and second cervical vertebrae	Arch-shaped process fits around a peglike process	Rotation
Biaxial			*Around two axes, perpendicular to each other; in two planes*
Saddle 	Thumb joint between the first metacarpal and carpal bone	Saddle-shaped bone fits into a socket that is concave-convex-concave	Flexion, extension in one plane; abduction, adduction in the other plane; opposing the thumb to the fingers
Condyloid (ellipsoidal) 	Joint between the radius and carpal bones	Oval condyle fits into an elliptical socket	Flexion, extension in one plane; abduction, adduction in the other plane
Multiaxial			*Around many axes*
Ball and socket 	Shoulder joint and hip	Ball-shaped process fits into a concave socket	Widest range of movement: flexion, extension, abduction, adduction, rotation, circumduction
Gliding 	Joints between the articular facets of adjacent vertebrae; joints between the carpal and tarsal bones	Relatively flat articulating surfaces	Gliding movements without any angular or circular movements

| QUICK CHECK |

5. List the seven structures that characterize synovial joints.
6. Name the three main categories of synovial joints grouped according to axial movement and list the two subtypes of joints found in each category.
7. Name one specific joint as an example of each of the six types of synovial joints.

REPRESENTATIVE SYNOVIAL JOINTS

Humeroscapular Joint

The joint between the head of the humerus and the glenoid cavity of the scapula is the one we usually refer to as the *shoulder joint* (Figure 10-5). It is our most mobile joint. One anatomical detail, the shallowness of the glenoid cavity, largely accounts for this mobility. The shallowness offers little interference to movement of the head of the humerus. Were it not for the *glenoidal labrum* (Figure 10-5, C), a narrow rim of fibrocartilage around the glenoid cavity, it would have scarcely any depth at all.

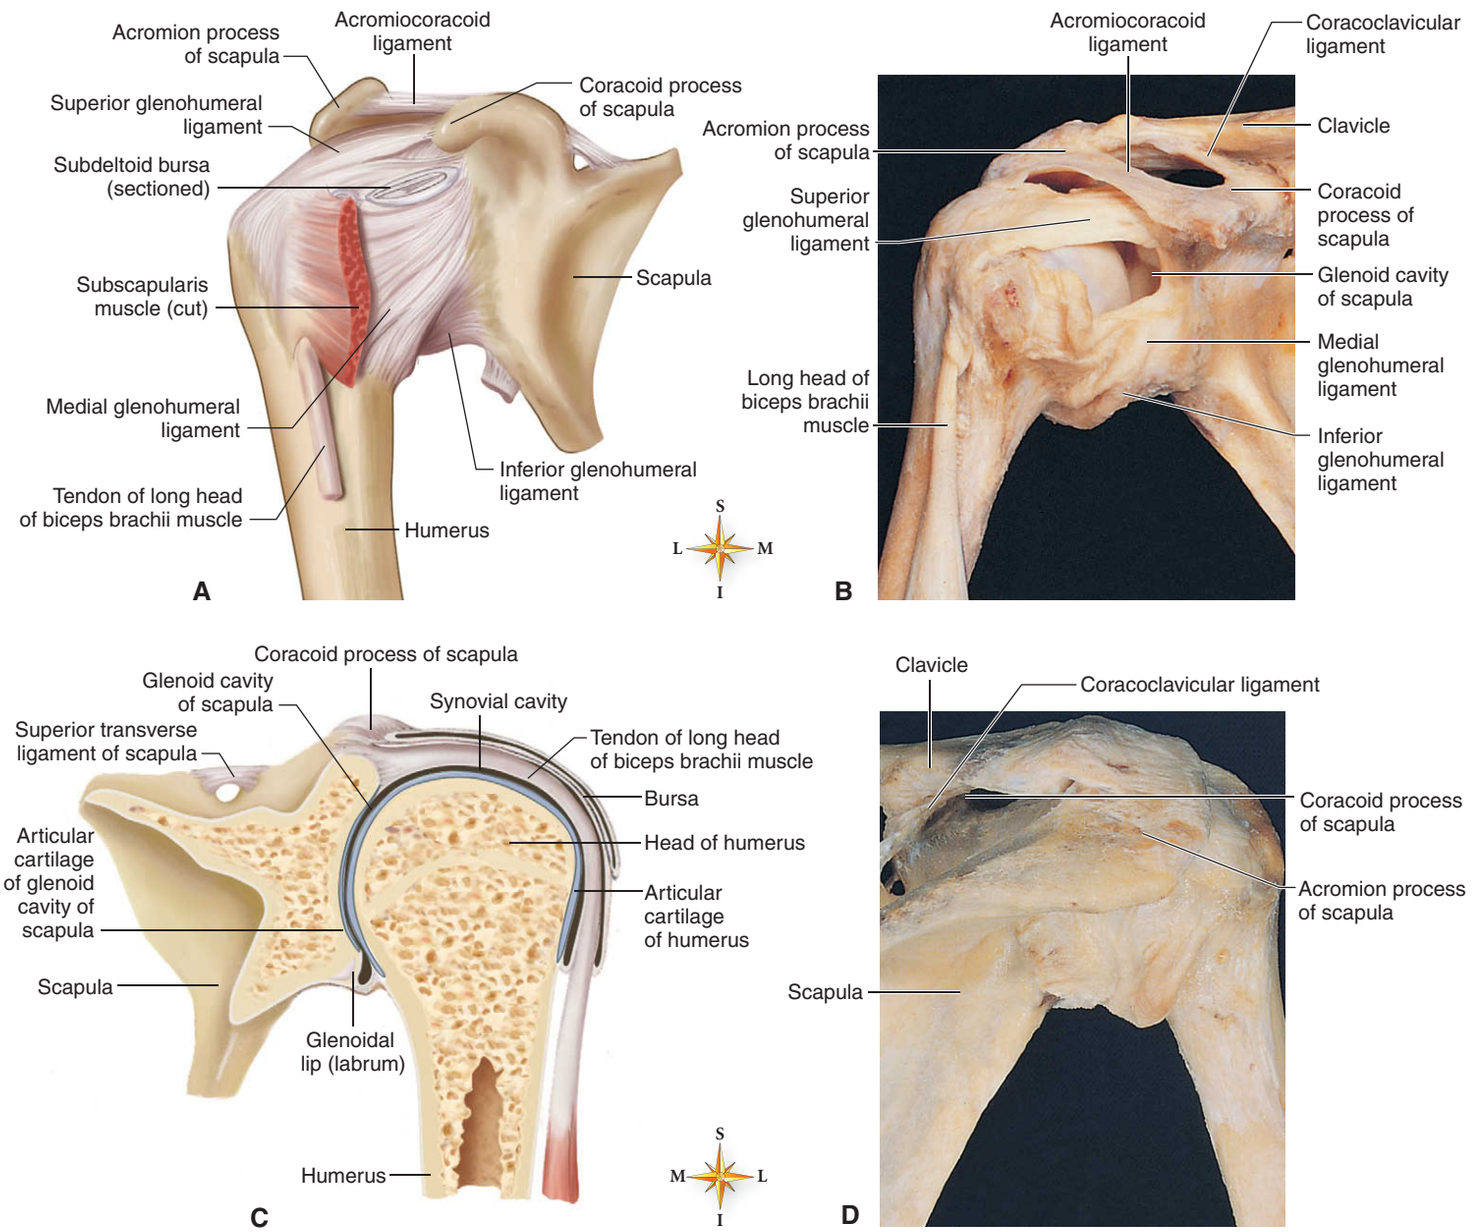


FIGURE 10-5

The shoulder joint. A, Artist's diagram, and **B,** dissection photo (anterior views). **C,** Artist's diagram, and **D,** dissection photo (viewed from behind through shoulder joint).

Some structures strengthen the shoulder joint and give it a degree of stability, notably several ligaments, muscles, tendons, and bursae. Note in Figure 10-5, *A*, for example, the superior, medial, and inferior glenohumeral ligaments. Each of these ligaments is a thickened portion of the joint capsule. Also in this figure, identify the subscapularis muscle, the tendon of the long head of the biceps brachii muscle, and a bursa.

Shoulder muscles and tendons form a cufflike arrangement around the joint. It is called the *rotator cuff*. Baseball pitchers frequently injure the rotator cuff in the shoulder of their pitching arms. The main bursa of the shoulder joint is the *subdeltoid bursa*. It lies wedged between the inferior surface of the deltoid muscle and the superior surface of the joint capsule. Other bursae of the shoulder joint are the subscapular, subacromial, and subcoracoid bursae. All in all, the shoulder joint is more mobile than stable. Dislocations of the head of the humerus from the glenoid cavity occur frequently.

| A&P CONNECT |

An x-ray photograph of the of the shoulder joint seen in ***Skeletal Radiography*** online at ***A&P Connect*** clearly shows the bony structures and their anatomical relationships in a living body. Other joints of the body are also illustrated there.

evolve

Elbow Joint

The elbow joint (Figure 10-6) is a classic hinge joint formed by two articulations occurring between the distal end of the humerus and the proximal ends of the radius and ulna. Laterally it is the capitulum of the humerus that articulates with the head of the radius in the *humeroradial joint*. Medially, the trochlea of the humerus articulates with the trochlear notch of the ulna in the *humeroulnar joint*. Both of these joint components are surrounded by a single joint capsule and by ligaments on either side, called *collateral ligaments*, that fuse with the capsule to stabilize the joint and help prevent disarticulation.

The articulation between the proximal ends of the radius and ulna just below the joint capsule is called the *proximal radioulnar joint*. The point of articulation is between the head of the radius and the radial notch of the ulna and is stabilized by the *annular ligament*. Although it is not a part of the elbow joint involved in hinge movements, it does permit rotation of the forearm as the radial head moves on the ulna. Dislocation of the radial head, called a "pulled elbow," is seen more often in young children than adults. The reason? The disk-shaped head of the radius does not attain its conical shape until late in childhood and therefore slips more easily from under the annular ligament. Figure 10-6, *B* shows the annular ligament attached to the proximal end of the ulna in an adult. It firmly holds the head of the radius against the articular surface of the radial notch on the ulna, thus allowing the radius to rotate freely.

A number of other anatomical or clinical "points of interest" are associated with the elbow joint. The medial and lateral epicondyles are palpable bony landmarks (see Box 9-2 on p. 227) on either side of the joint, and the **olecranon bursa,** which helps cushion the joint, is found just under the skin on its posterior surface overlying the olecranon of the ulna. **Olecranon bursitis** is inflammation of the bursa associated with prolonged pressure.

One of the most frequent sites for *venipuncture* (piercing a vein) to obtain blood is the median cubital vein located in the fossa just anterior to the joint.

Perhaps one of the most important structures near the joint is the ulnar nerve. It courses along the groove, sometimes called the "funny bone," between the olecranon and the medial epicondyle. Blows to this area produce unpleasant sensations in the hand and

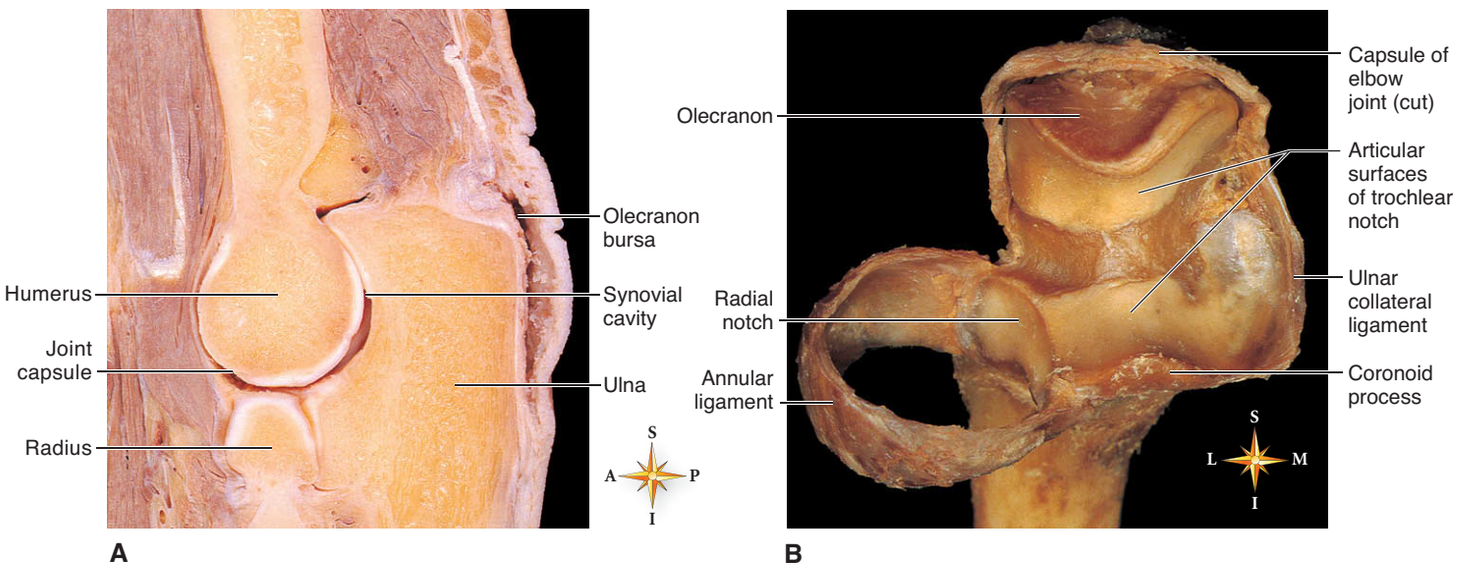

FIGURE 10-6

The elbow joint. A, Sagittal section through the elbow joint. **B,** Dissection photo showing the anterior view of the proximal end of the ulna with attached annular ligament.

fingers supplied by the nerve. More severe injuries may result in paralysis of hand muscles and produce "clawhand" or a reduction in wrist movements.

Forearm, Wrist, Hand, and Finger Joints

Proper function of the forearm, wrist, hand, and fingers, as well as the joints that permit movement in these areas, is often said to be the functional "reason" for the upper extremity. Our ability to grasp and manipulate small objects, to properly focus the movement and strength of our upper extremities, and the many movements required to coordinate or restore balance and equilibrium are only a few examples of activities that require normal functioning of our forearms, wrists, hands, and fingers.

In clinical medicine, treatment or repair of injuries to these important functional areas constitutes a highly specialized area of surgical practice. In addition to bones and joints, the relatively small area of the wrist and hand, especially, is packed with many other anatomical structures, such as muscles, ligaments, blood vessels, and nerves. Hand surgery, like many other forms of specialized surgery, requires both a mastery of complex techniques and an in-depth understanding of the anatomy involved.

There are seven categories of synovial joints between the bones of the forearm, wrist, hand, and fingers. They are named after the bones that touch or articulate with one another in the joints involved. Some of the movements produced are slight and subtle, whereas others are more apparent. All are important functionally and are illustrated later in the chapter.

RADIOULNAR JOINTS

The head of the radius and the radial notch of the ulna articulate just below the elbow joint to form the *proximal radioulnar joint* described earlier. Together with the *distal radioulnar joint*, which is the point of articulation between the ulnar notch of the radius and head of the ulna just above the wrist, the two **radioulnar joints** permit pronation and supination of the forearm.

RADIOCARPAL (WRIST) JOINTS

As the name in the heading implies, only the radius articulates directly with the wrist or carpal bones distally. The point of articulation between the head of the radius and the scaphoid and lunate carpal bones forms a typical synovial joint, in this case, a **radiocarpal joint,** and is shown in Figure 10-7. A full range of motions occur at the joint and are illustrated later in the chapter.

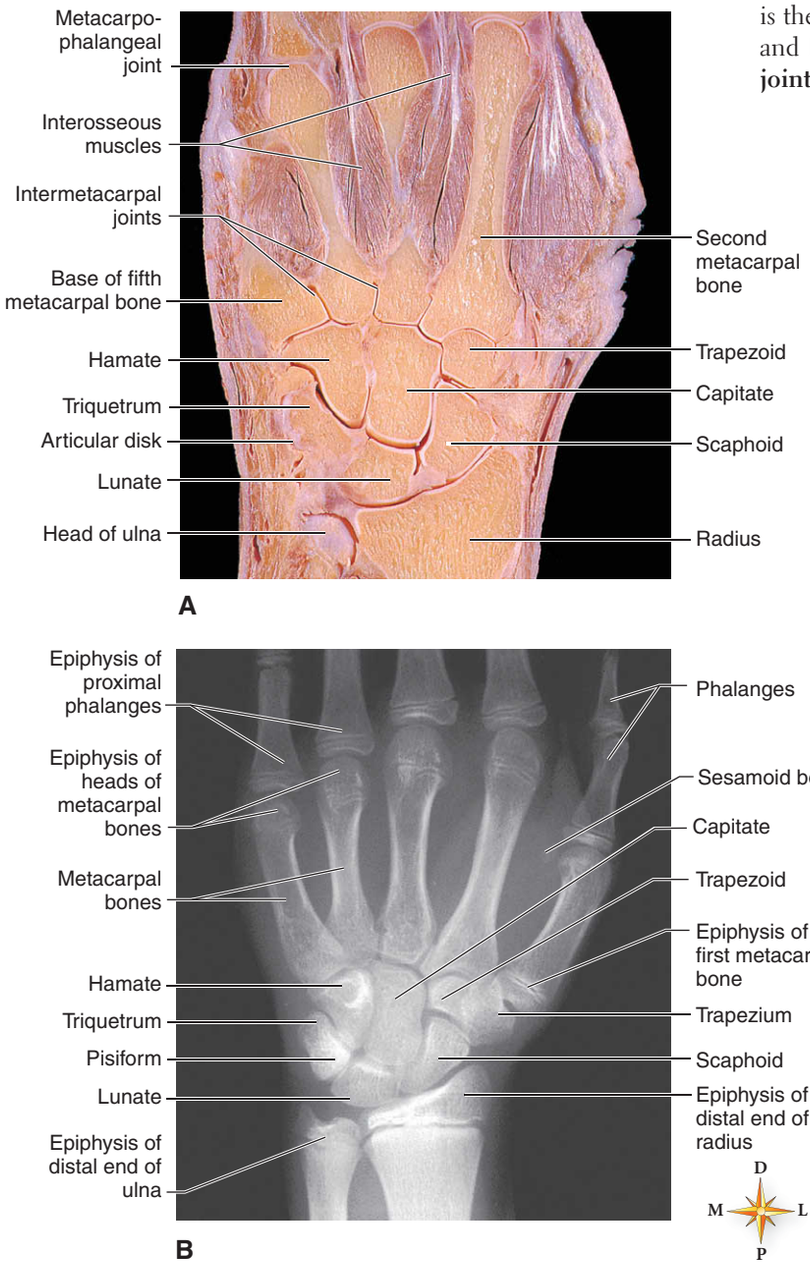

FIGURE 10-7

Joints of the wrist. A, Coronal section of the hand showing the joints of the wrist. Note that the thumb and little finger are not in the plane of section. **B,** Radiograph of an adolescent hand and wrist. Note that the epiphyseal plates are present. **C,** Major synovial spaces of the wrist: *1,* proximal; *2,* intermediate; *3,* distal.

Falls on an outstretched hand often result in fractures of the scaphoid bone. It is the scaphoid that transmits a majority of the applied force to the radial head. Unfortunately, loss of blood supply to a portion of the fractured scaphoid may result in necrosis of the broken fragment, which requires surgical removal or other specialized treatment. Note that a disk separates the distal part of the ulna from direct contact with the carpal bones.

INTERCARPAL JOINTS

The **intercarpal joints** occur at points of articulation between the eight carpal bones. Arranged in two rows (proximal and distal) of four bones each, the carpal bones and the joints between them are supported and stabilized by numerous ligaments. They are also stabilized by forearm muscle tendons acting on the wrist and digits that wrap around the wrist to form a sort of cuff.

The joint spaces usually communicate with each other, forming large joint spaces. You can see the three largest of these joint spaces in Figure 10-7, *C*. The relationships between the intercarpal joints are illustrated in Figure 10-7. Functionally, movements at the intercarpal joints are generally gliding with some abduction and flexion.

CARPOMETACARPAL JOINTS

There are a total of three **carpometacarpal joints,** one for the thumb and two for the fingers. The thumb carpometacarpal joint is unique in having both a loose-fitting joint capsule and a saddle-shaped articular surface between the first metacarpal bone and the trapezium. Movements possible at this joint include flexion, extension, adduction, abduction, and circumduction. In addition, because of the special anatomical features of this joint, a combination movement called *opposition* of the thumb (see p. 290) is possible. Opposition allows us to touch the tips of any of the fingers with the tip of the thumb. It is this unique movement that permits us to grasp and manipulate small objects—a functional movement of immense practical significance.

The remaining two carpometacarpal joints are much less mobile than the saddle-shaped one for the thumb and are limited to essentially gliding-type movements.

METACARPOPHALANGEAL JOINTS

In **metacarpophalangeal joints** the rounded heads of the metacarpal bones and the concave bases of the proximal phalanges articulate with each other (Figure 10-8). The capsule surrounding each joint is strengthened by collateral ligaments on both sides. The shape of the articular surfaces in these joints permits only limited adduction and abduction—and only when the fingers are extended. Much more extensive flexion and extension movements are possible.

INTERPHALANGEAL JOINTS

Interphalangeal joints are typical hinge-type synovial joints capable of flexion and extension. They exist between the heads of the phalanges and the bases of the more distal phalanges. In the fingers, two types of interphalangeal joints can be identified. The joints between the proximal and middle phalanges are called **proximal interphalangeal (PIP) joints,** whereas those between the middle and distal phalanges are called the **distal interphalangeal (DIP) joints.** Understanding the relationship of articulations between the phalanges will help in understanding the various finger movements discussed later in the chapter (see Figure 10-22).

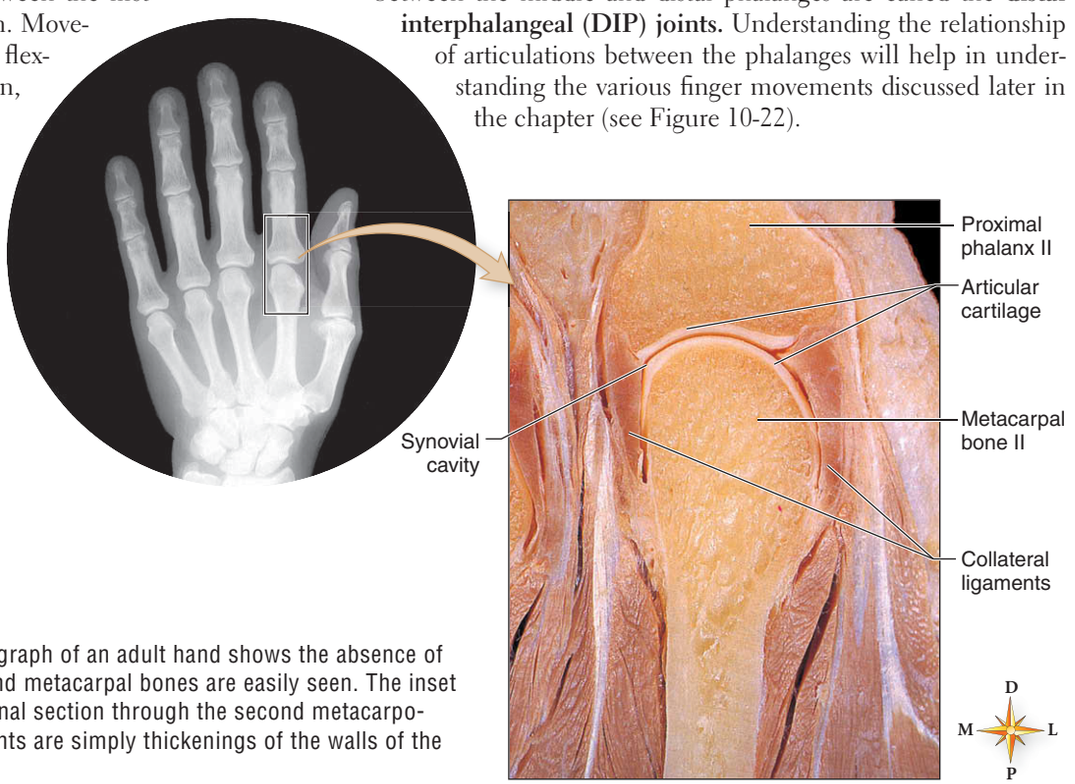

FIGURE 10-8

Joints of the hand and fingers. Radiograph of an adult hand shows the absence of epiphyseal plates. All the phalanges and metacarpal bones are easily seen. The inset shows a dissected specimen in a coronal section through the second metacarpophalangeal joint. The collateral ligaments are simply thickenings of the walls of the joint capsule.

Hip Joint

The first characteristic to remember about the hip joint is stability; the second is mobility (Figure 10-9). The stability of the hip joint derives largely from the shapes of the head of the femur and the acetabulum, the socket of the hip bone into which the femur head fits. Turn to Figure 9-22 and note the deep, cuplike shape of the acetabulum, and then observe the ball-like head of the femur in Figure 9-23, A. Compare these with the shallow, almost saucer-shaped glenoid cavity (see Figure 9-17, C) and the head of the humerus (see Figure 9-18). From these observations, do you see why the hip joint necessarily has a somewhat more limited range of movement than does the shoulder joint? Both joints, however, allow multiaxial movements. Both permit flexion, extension, abduction, adduction, rotation, and circumduction.

A joint capsule and several ligaments hold the femur and hip bones together and contribute to the hip joint's stability. The iliofemoral ligament connects the ilium with the femur, and the ischiofemoral and pubofemoral ligaments join the ischium and pubic bone to the femur. The iliofemoral ligament is one of the strongest ligaments in the body.

Knee Joint

The knee, or *tibiofemoral joint*, is the largest and one of the most complex and most frequently injured joints in the body

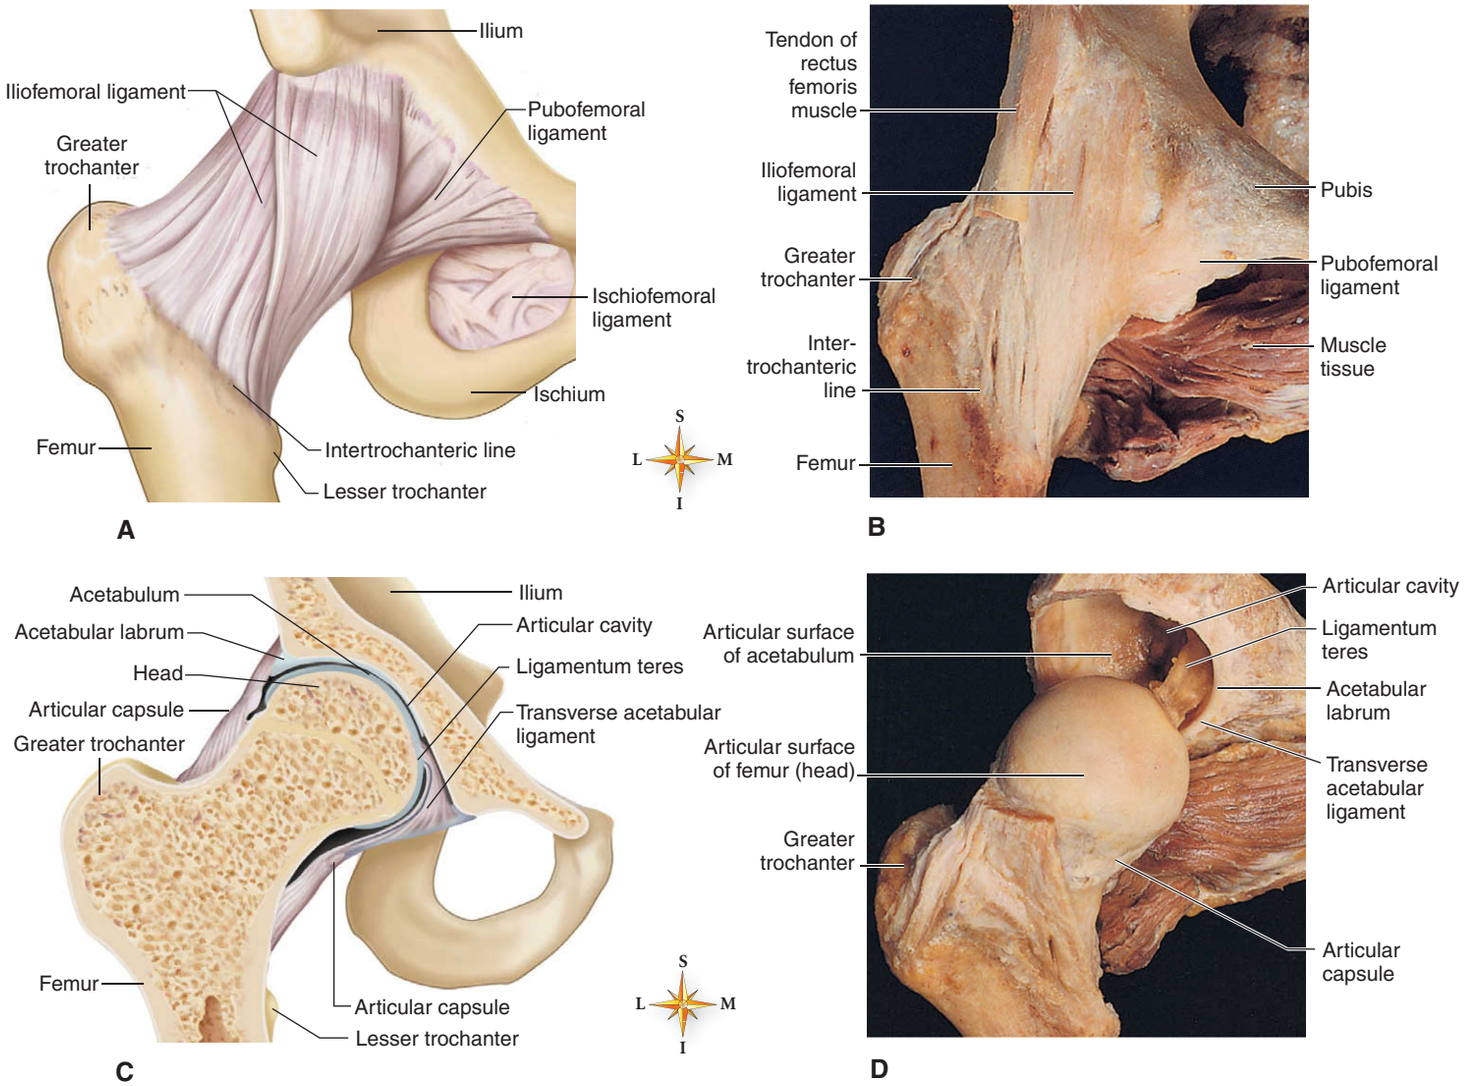

FIGURE 10-9

The hip joint. A, Artist's diagram, and **B,** dissection photo (anterior views). **C,** Artist's diagram, and **D,** dissection photo (frontal section).

(Figures 10-10 and 10-11, Box 10-1). The condyles of the femur articulate with the flat upper surface of the tibia. Although this arrangement is precariously unstable, counteracting forces are supplied by a joint capsule, cartilages, and numerous ligaments and muscle tendons. Note, for example, in Figure 10-10 the shape of the two cartilages labeled *medial meniscus* and *lateral meniscus.* They attach to the flat top of the tibia and, because of their concavity, form a kind of shallow socket for the condyles of the femur.

Of the many ligaments that hold the femur bound to the tibia, five can be seen in Figure 10-10. The *anterior cruciate ligament (ACL)* attaches to the anterior part of the tibia between its condyles, then crosses over and backward and attaches to the posterior part of the lateral condyle of the femur. The *posterior cruciate ligament (PCL)* attaches posteriorly to the tibia and lateral meniscus, then crosses over and attaches to the front part of the femur's medial condyle. The *posterior tibiofibular ligament* (ligament of Wrisberg) attaches posteriorly to the lateral meniscus and extends up and over to attach to the medial condyle behind the attachment of the posterior cruciate ligament (Figure 10-10, *C*). The *transverse ligament* connects the anterior margins of the two menisci. Strong ligaments, the *fibular* and *tibial collateral ligaments*, located at sides of the knee joint can be seen in Figure 10-10, *C*.

A baker's dozen of bursae serve as pads around the knee joint: four in front, four located laterally, and five medially. That is 13 in total. Of these, the largest is the *prepatellar bursa* (see Figure 10-11) inserted in front of the patellar ligament, between it and the skin. The painful ailment commonly called "housemaid's knee" or "surfer's knee" is **prepatellar bursitis.**

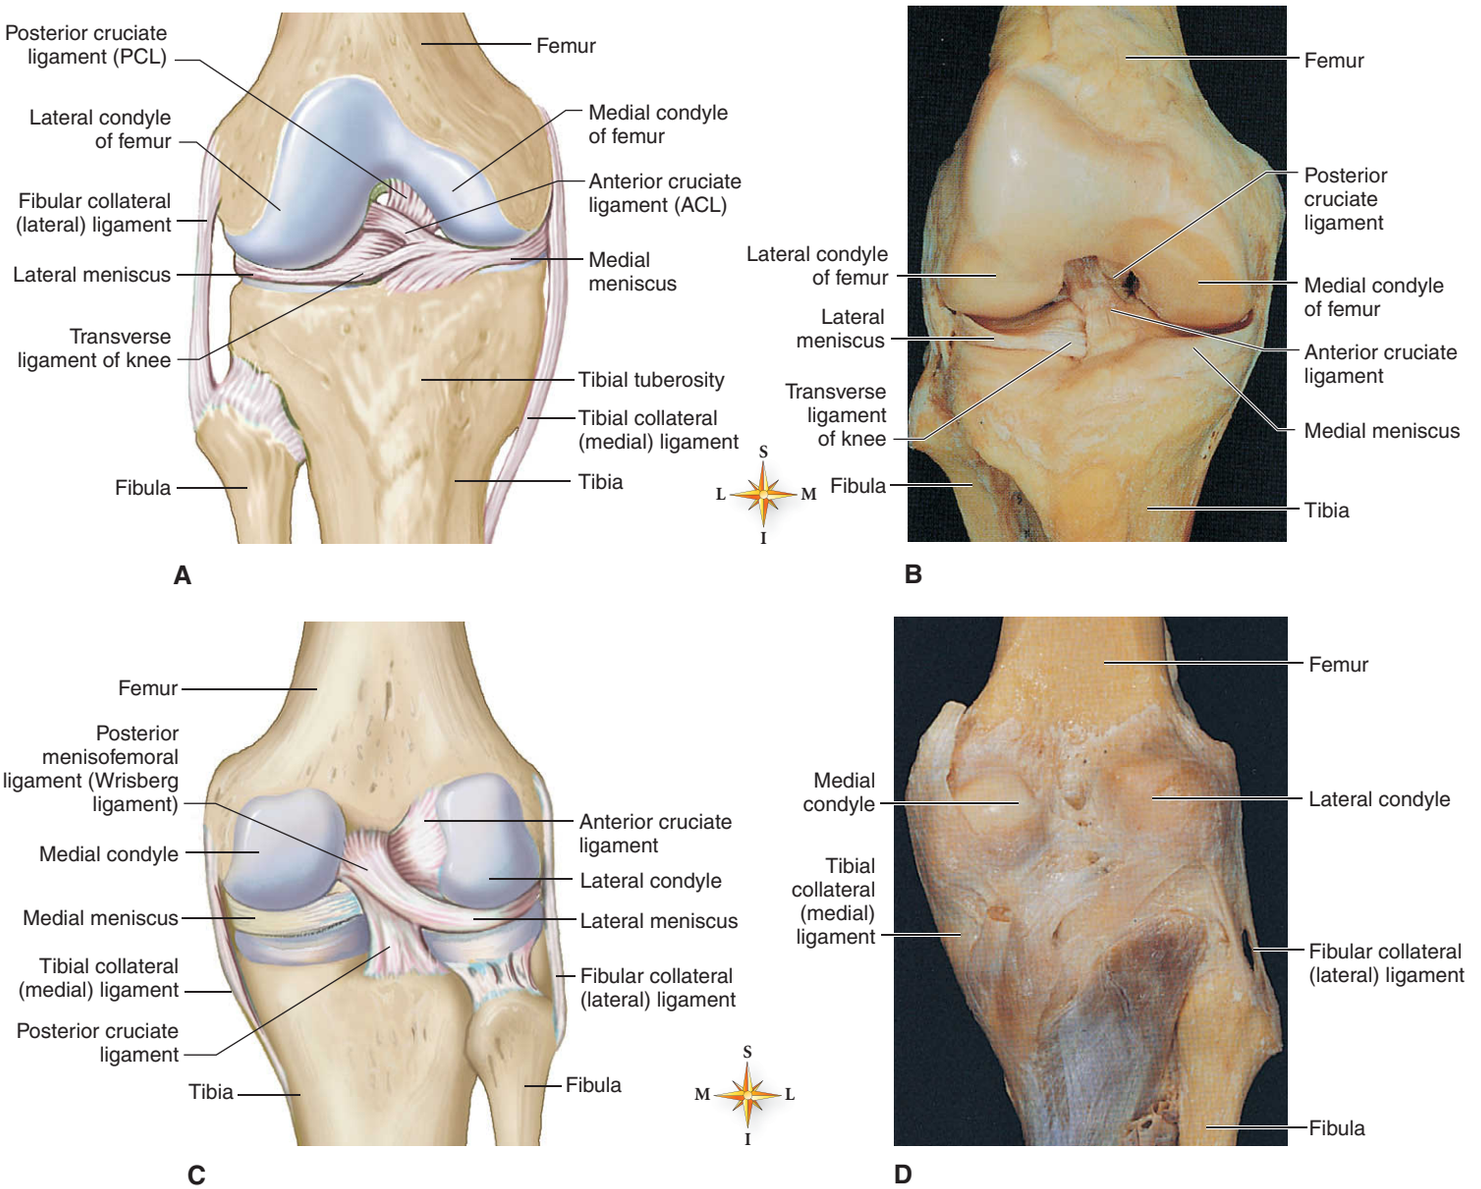

FIGURE 10-10

The right knee joint. A and **B,** Labeled dissection of the right knee viewed from in front. **C** and **D,** Viewed from behind.

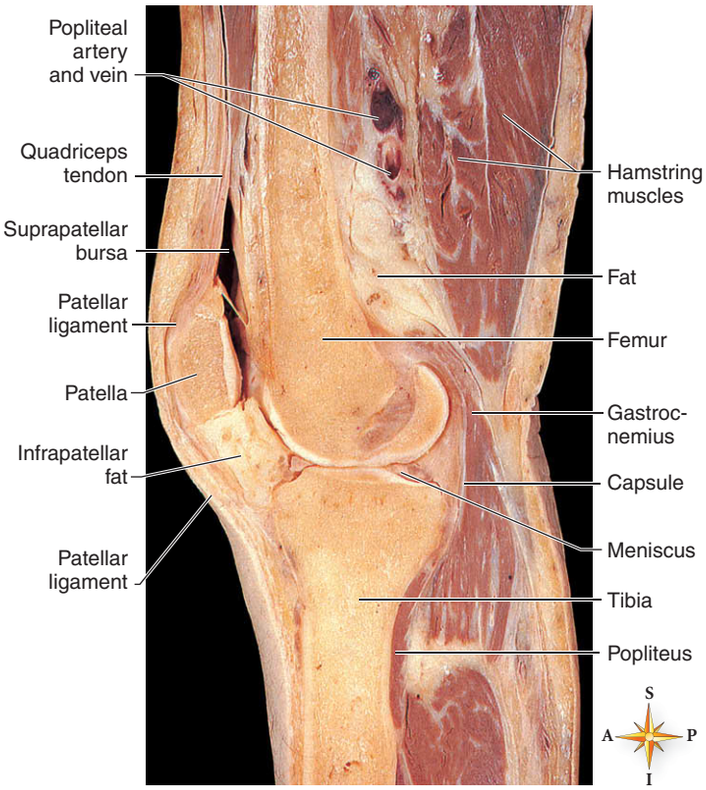

FIGURE 10-11

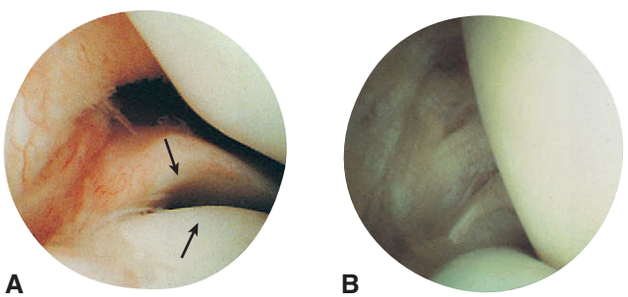
Knee joint (sagittal section). Cadaver dissection showing the articular surfaces and related structures.

When compared with the hip joint, the knee joint is relatively unprotected by surrounding muscles. Consequently, the knee, more often than the hip, is injured by blows or sudden stops and turns. Athletes, for example, are prone to tearing a knee cartilage, specifically, one of the menisci (see Figure 10-11).

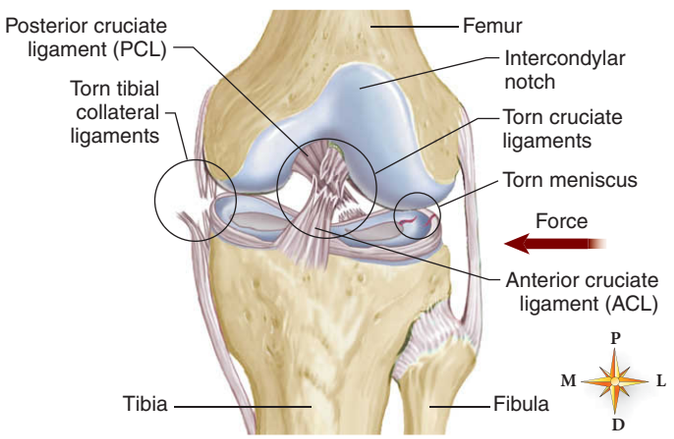
The structure of the knee joint permits the hingelike movements of flexion and extension. Also, with the knee flexed, some internal and external rotation can occur. In most of our day-to-day activities—even such ordinary ones as walking, going up and down stairs, and getting into and out of chairs—our knees bear the brunt of the load; they are the main weight bearers. Knee injury or disease can therefore be crippling.

Ankle Joint



Anatomical comparisons of the wrist, hand, and fingers are often made with the ankle, foot, and toes. Although many anatomical similarities do exist, functional differences abound. Hand anatomy is a marvel of functional design intended to permit flexibility and, especially with the presence of a saddle joint between the first metacarpal bone and the trapezium, discrete and precisely controlled movement. The bony structure of the ankle and foot, as well as the joints that exist between them, enhance stability and weight bearing rather than flexibility and a wide range of different movements.

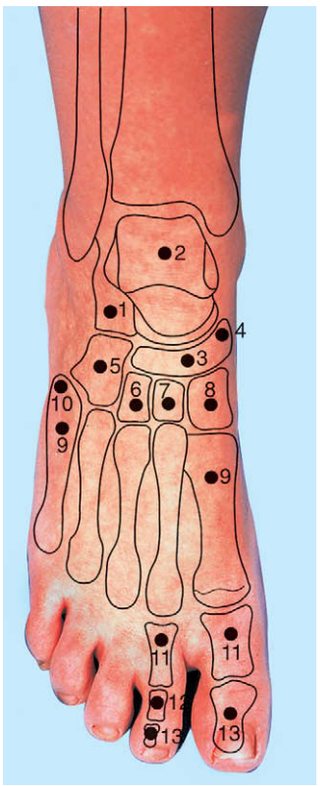
Box 10-1 | SPORTS and FITNESS



The Knee Joint

The knee is the largest and most vulnerable joint. Because the knee is often subjected to sudden, strong forces during athletic activity, knee injuries are among the most common type of athletic injury. Sometimes the articular cartilages on the tibia become torn when the knee twists while bearing weight. The ligaments holding the tibia and femur together and the medial and lateral menisci also can be injured in this way. Knee injuries also may occur when a weight-bearing knee collides with another person, especially from the side, as sometimes happens in sporting events.

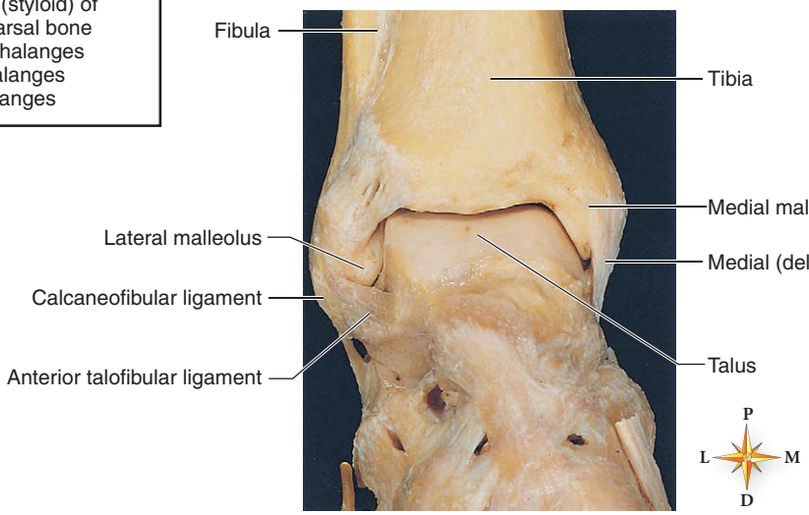
Knee arthrogram **A,** Normal medial meniscus. Spot film showing the normal triangular shape of the meniscus (arrows). **B,** Linear tear of the medial meniscus.



Compare the articulating bones, joint types, and movements in each area listed in Table 10-4. Note in Figure 10-12, *B*, that the lateral malleolus of the ankle joint is lower than the medial and contributes to a wedge or so-called *mortise-shaped* articulation with the talus below. The combination of a uniquely shaped articular surface and strong supporting ligaments results in an excellent platform for weight bearing during standing and walking. However, so-called rotational ankle injuries do occur—especially in certain types of dance or during athletic activity.

The most common type of **sprained ankle** is caused by an internal rotation injury to the anterior talofibular ligament, seen in Figure 10-12. Symptoms include pain and swelling over the lateral side of the ankle with severe "point tenderness" just anterior to the lateral malleolus. External ankle rotation injuries generally result in fractures rather than ligament tears. In first-degree ankle injuries the lateral malleolus is broken. Second-degree injuries result in fracture of both malleoli, and in third-degree injuries both malleoli and the articular surface of the tibia are fractured (OUCH!). The strong deltoid ligament, which helps maintain the medial longitudinal arch of the foot (see Chapter 9), is also frequently injured in severe twisting injuries affecting the ankle.

TABLE 10-4 Synovial (Diarthrotic) and Two Cartilaginous (Amphiarthrotic) Joints



NAME	ARTICULATING BONES	TYPE	MOVEMENTS
Atlantoepistropheal	Anterior arch of the atlas rotates about the dens of the axis (epistropheus)	Synovial (pivot)	Pivoting or partial rotation of the head
Vertebral	Between bodies of vertebrae	Cartilaginous (symphyses)	Slight movement between any two vertebrae but considerable motility for the column as a whole
	Between articular processes	Synovial (gliding)	Gliding
Sternoclavicular	Medial end of the clavicle with the manubrium of the sternum	Synovial (gliding)	Gliding
Acromioclavicular	Distal end of the clavicle with the acromion of the scapula	Synovial (gliding)	Gliding; elevation, depression, protraction, and retraction
Thoracic	Heads of ribs with bodies of vertebrae	Synovial (gliding)	Gliding
	Tubercles of ribs with transverse processes of vertebrae	Synovial (gliding)	Gliding
Shoulder	Head of the humerus in the glenoid cavity of the scapula	Synovial (ball and socket)	Flexion, extension, abduction, adduction, rotation, and circumduction of the upper part of the arm
Elbow	Trochlea of the humerus with the semilunar notch of the ulna; head of the radius with the capitulum of the humerus	Synovial (hinge)	Flexion and extension
	Head of the radius in the radial notch of the ulna	Synovial (pivot)	Supination and pronation of the forearm and hand; rotation of the forearm on the upper extremity
Wrist	Scaphoid, lunate, and triquetral bones articulate with the radius and articular disk	Synovial (condyloid)	Flexion, extension, abduction, and adduction of the hand
Carpal	Between various carpal bones	Synovial (gliding)	Gliding
Hand	Proximal end of the first metacarpal bone with the trapezium	Synovial (saddle)	Flexion, extension, abduction, adduction, and circumduction of the thumb and opposition to the fingers
	Distal end of the metacarpal bones with the proximal end of the phalanges	Synovial (hinge)	Flexion, extension, limited abduction, and adduction of the fingers
	Between phalanges	Synovial (hinge)	Flexion and extension of finger sections
Sacroiliac	Between the sacrum and two ilia	Synovial (gliding)	None or slight
Pubic symphysis	Between two pubic bones	Cartilaginous (symphysis)	Slight, particularly during pregnancy and delivery
Hip	Head of the femur in the acetabulum of the coxal bone	Synovial (ball and socket)	Flexion, extension, abduction, adduction, rotation, and circumduction
Knee	Between the distal end of the femur and proximal end of the tibia	Synovial (hinge)	Flexion and extension; slight rotation of the tibia
Tibiofibular (proximal)	Head of the fibula with the lateral condyle of the tibia	Synovial (gliding)	Gliding
Ankle	Distal end of the tibia and fibula with the talus	Synovial (hinge)	Flexion (dorsiflexion) and extension (plantar flexion)
Foot	Between tarsal bones	Synovial (gliding)	Gliding; inversion and eversion
	Between metatarsal bones and phalanges	Synovial (hinge)	Flexion, extension, slight abduction, and adduction
	Between phalanges	Synovial (hinge)	Flexion and extension

Vertebral Joints

One vertebra connects to another by several joints—between their *bodies*, as well as between their articular, transverse, and spinous *processes*. Recall that the cartilaginous (amphiarthrotic) joints between the *bodies* of adjacent vertebrae permit only very slight movement and are classified as symphyses. However, the synovial (diarthrotic) joints between the articulating surfaces of the vertebral *processes* are more movable and are classified as **gliding joints.** These joints hold the vertebrae firmly together so that they are not easily dislocated, but these joints also form a flexible column. Consider how many ways you can move the trunk of your body. You can flex it forward or laterally, you can extend it, and you can circumduct or rotate it (see Figure 10-18).

The bodies of adjacent vertebrae are connected by intervertebral disks and strong ligaments. Fibrous tissue and fibrocartilage form a disk's outer rim (called the *annulus fibrosus*). Its central core (the *nucleus pulposus*), in contrast, consists of a pulpy, elastic substance (Figure 10-13, A). With age, the nucleus loses some of its resiliency. It may then be suddenly compressed by exertion or trauma and pushed through the annulus, with the herniating part protruding into the spinal canal and pressing on spinal

nerves or the spinal cord itself. Severe pain results. In medical terminology, this is called a **herniated disk** or *herniated nucleus pulposus* (HNP); in popular language, it is called a "slipped disk" (Figure 10-13, *B*).

In Figure 10-14 the following ligaments that bind the vertebrae together can be identified: The *anterior longitudinal ligament*, a strong band of fibrous tissue, connects the anterior surfaces of the vertebral bodies from the atlas down to the sacrum. Connecting the posterior surfaces of the bodies is the *posterior longitudinal ligament*. The *ligamenta flava* bind the laminae of adjacent vertebrae firmly together. Spinous processes are connected by *interspinous ligaments*. In addition, the tips of the spinous processes of the cervical vertebrae are connected by the *ligamentum nuchae*; its extension, the *supraspinous ligament*, connects the tips of the rest of the vertebrae down to the sacrum. And finally, *intertransverse ligaments* connect the transverse processes of adjacent vertebrae.

Table 10-4 summarizes the entire chapter with descriptions of most of the individual joints of the body.

TYPES AND RANGE OF MOVEMENT AT SYNOVIAL JOINTS

The types of movement possible at synovial joints depend on the shapes of the articulating surfaces of the bones and on the positions of the joints' ligaments and nearby muscles and tendons. All synovial joints, however, permit one or more of the following types of movements:

1. Angular
2. Circular
3. Gliding
4. Special

Measuring Range of Motion

Measuring **range of motion (ROM)** is often one of the first assessment techniques used by a health care provider to determine the degree of damage in an injured joint. In the absence of disease or injury, major synovial joints should function within a normal ROM.

Joint ROM can be measured actively or passively. In active movements the individual moves the joint or body part through its ROM, and in passive movements the physician or other health care provider moves the part with the patient's muscles in a relaxed state. Normally, both active and passive ROM should be about equal.

If a joint has an obvious increase or limitation in its range of motion, an instrument called a **goniometer** is used to measure the angle (Figure 10-15). A goniometer consists of two rigid shafts that intersect at a hinge joint. A protractor is fixed to one shaft so that motion can be read directly from the scale in degrees. The starting position is defined as the point at which the movable segment is at 0 degrees (usually the anatomical position). Measuring joint ROM provides a physician, nurse, athletic trainer, or therapist with information required to assess normal joint function, accurately measure dysfunction, or gauge treatment and rehabilitative progress after injury or disease.

Illustrations in Figures 10-16 through 10-25 provide examples of types of movement at selected synovial joints. Refer to these illustrations frequently as you read about the various types of movement possible at synovial joints.

You will notice that the movements can often be classified as opposites: flexion is the opposite of extension, protraction is the opposite of retraction, and so on. Remembering this concept will be useful to you when the mechanism of antagonistic muscle groups is discussed in Chapter 11.

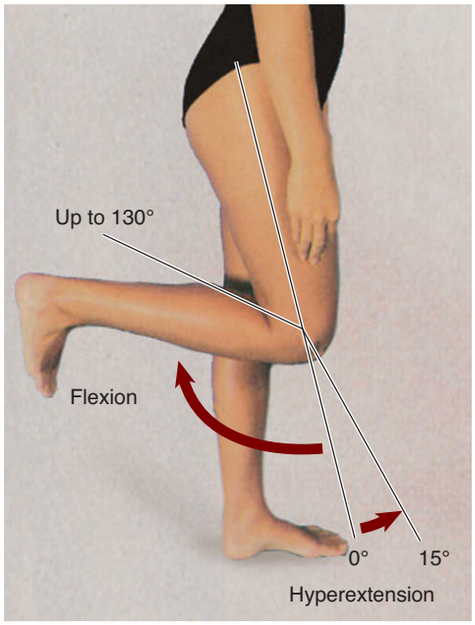

FIGURE 10-24

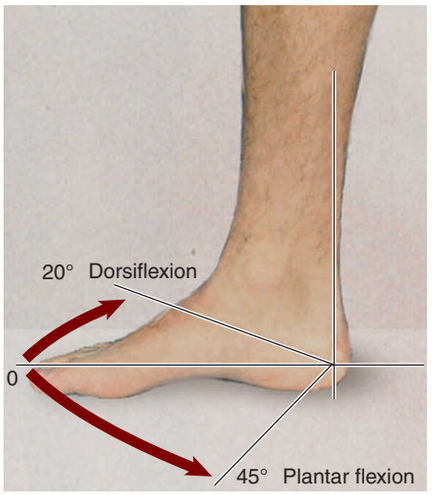
Movements and range of motion (ROM) of the knee. Flexion may reach 130 degrees. Extension occurs with movement from a 130-degree flexed position back to the 0-degree position. Hyperextension of 0 degrees to 15 degrees is possible in many individuals.

Angular Movements

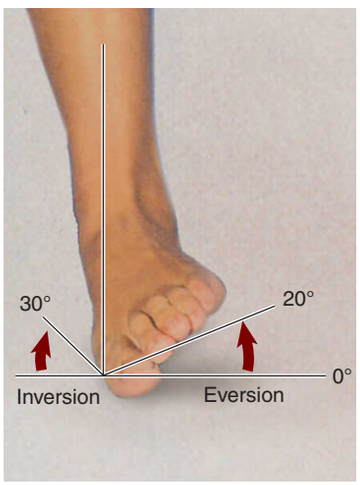
Angular movements change the size of the angle between articulating bones. Flexion, extension, abduction, and adduction are some of the different types of angular movements.

FLEXION



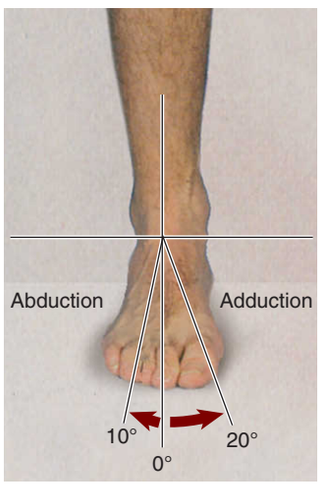
Flexion decreases the angle between bones. It bends or folds one part on another. For example, if you bend your head forward on your chest, you are flexing it. If you bend your arm at the elbow, you are flexing the lower part of your arm (see Figure 10-20, *A*). Flexion, in short, is bending, folding, or withdrawing a part. Flexion can also occur when an extended structure is returned to the anatomical position.

EXTENSION AND HYPEREXTENSION



Extension increases the angle between bones. It returns a part from its flexed position to its anatomical position. Extensions are straightening or stretching movements. Extending a part beyond its anatomical position is sometimes called **hyperextension.** Hyperextension of the shoulder is illustrated in Figure 10-19, *A*, and of the knee in Figure 10-24. Clinically, hyperextension often refers to abnormal extension beyond a part's normal range of motion.

PLANTAR FLEXION AND DORSIFLEXION



Plantar flexion occurs when the foot is stretched down and back (see Figure 10-25, *A*). This movement increases the angle between the top of the foot and the front of the leg. Recall that the definition of extension refers to an increase in the angle between articulating bones. Therefore, plantar flexion of the foot can also be described as extension. Look again at Figure 10-25, *A*, and note how the angle between the leg and the foot increases during plantar flexion.

A

B

C

FIGURE 10-25

Movements and range of motion (ROM) of the foot and ankle. **A,** Dorsiflexion and plantar flexion. **B,** Inversion and eversion. **C,** Abduction and adduction.

Dorsiflexion occurs when the foot is tilted upward, thus decreasing the angle between the top of the foot and the front of the leg (see Figure 10-25, *A*).

ABDUCTION AND ADDUCTION

Abduction moves a part away from the median plane of the body, as in moving the leg straight out to the side or fingers away from the midline of the hand. **Adduction** moves a part toward the median plane. Examples include bringing the arm back to the side or moving fingers toward the midline of the hand. Opposing movements in the shoulder can be seen in Figure 10-19, *B*.

Circular Movements

Circular movements result in the arclike rotation of a structure around an axis. The primary circular movements are rotation, circumduction, supination, and pronation (see Figure 10-16, *B*).

ROTATION AND CIRCUMDUCTION

Rotation consists of pivoting a bone on its own axis. For example, moving the head from side to side as in indicating "no" (see Figure 10-16, *D*). **Circumduction** moves a part so that its distal end moves in a circle. When a pitcher winds up to throw a ball, the pitcher circumducts the arm.

SUPINATION AND PRONATION

Supination and **pronation** of the hand are shown in Figure 10-20, *B*. Pronation twists the forearm, moving the palm so that the thumbs point medially. Supination twists the forearm in the opposite rotation, moving the palm so that the thumbs point laterally.

Gliding Movements

Gliding movements are the simplest of all movements. The articular surface of one bone moves over the articular surface of another without any angular or circular movement. Gliding movements occur between the carpal and tarsal bones and between the articular facets of adjoining spinal vertebrae.

Special Movements

Special movements are often unique or unusual movements that occur only in a very limited number of joints. These movements do not fit well into other movement categories and are generally described separately. Special movements include inversion, eversion, protraction, retraction, elevation, and depression.

INVERSION AND EVERSION

Inversion turns the sole of the foot inward, whereas **eversion** turns it outward (see Figure 10-25, *B*).

PROTRACTION AND RETRACTION

Protraction moves a part forward, whereas **retraction** moves it back. For instance, if you stick out your jaw, you protract it, and if you pull it back, you retract it (see Figure 10-17, *A*).

ELEVATION AND DEPRESSION

Elevation moves a part up, as in closing the mouth (see Figure 10-17, *B*). **Depression** lowers a part, moving it in the opposite direction from elevation.

| QUICK CHECK |

10. Name one example of each of the following types of movement at a synovial joint: angular, circular, gliding, and special.

Cycle of LIFE

Articulations

This chapter discusses the types of articulations that occur between bones and presents information on the common types of diseases that affect joints during the life cycle.

Changes in the way bones develop and in the sequence of ossification that occurs between birth and skeletal maturity also affect our joints. Fontanels, which exist between bones of the cranium, disappear with increasing age, and the epiphyseal plates, which serve as points of articulation between the epiphyses and diaphyses of growing long bones, ossify at skeletal maturity.

Range of motion at synovial joints is typically greater early in life. With advancing age, joints are often described as being "stiff," range of motion decreases, and changes in gait are common. The difficulty with locomotion that affects many elderly individuals may result from disease conditions that involve the functional unit comprising muscles, bones, and joints.

Some skeletal diseases have profound effects that are manifested as joint problems. Abnormal bone growth, or "lipping," which results in bone spurs, or sharp projections, on the articular surfaces of bones, dramatically influences joint function. Many of these disease conditions are associated with specific developmental periods, including early childhood, adolescence, and adulthood.

the BIG picture

Articulations

Anatomists sometimes refer to the hand as "the reason for the upper extremity" and the thumb as "the reason for the hand." Statements such as these, when they are used in a functional context, underscore the relationship that exists between structure and function. Furthermore, they serve as examples of how "big picture" thinking is helpful in examining the interaction between body structures and the rationale for how and why they function as they do. Proper functioning of the joints is crucial for meaningful, controlled, and purposeful movement to occur—movement that permits human beings to respond to and control their environment in ways that other animals are not capable of doing. The joints of the upper extremity are good examples.

The great mobility of the upper extremity is possible because of the following: (1) the arrangement of the bones in the shoulder girdle, arm, forearm, wrist, and hand; (2) the location and method of attachment of muscles to these bones; and (3) proper functioning of the joints involved. We give up a great deal of stability in the upper extremity (especially the shoulder joint) to achieve mobility. We need that mobility and extensive range of motion to position the entire upper extremity, and especially the hand, in ways that permit us to interact with objects in our physical environment effectively. It is the proper functioning of the thumb that allows us to grasp and manipulate objects with great dexterity and control. Although loss of mobility in the upper extremity as a whole presents a significant functional problem, loss of thumb function can present equally serious and disabling problems by dramatically decreasing the overall ability to manipulate and grasp objects. By enabling us to effectively interact with our external environment, the joints of the upper extremity contribute in a significant way to maintenance of homeostasis. It is in the "big picture" context that the hand and thumb are truly functional "reasons" for the upper extremity and the hand, respectively.

MECHANISMS of DISEASE

BURSITIS

Bursitis, or inflammation of a bursa, is a relatively common disorder. It is most often caused by prolonged pressure, excessive or repetitive exercise, or sudden trauma that involves one of these fluid-filled sacs. Although bursae are often associated with joints, where they may serve to cushion the joint or facilitate the movement of tendons over bony prominences, such as the olecranon of the elbow joint, the bursa itself is often completely separate from the joint space. Look again at Figure 10-6, *A*. It clearly shows the placement of the olecranon bursa just below the skin and independent of the joint space of the elbow. Therefore, inflammation of the olecranon bursa (Figure 10-26) may occur in the absence of any elbow joint inflammation or pathology. Bursitis near the knee joint is also common, especially in carpet layers, roofers, and others who work on their knees.

Joint Disorders

Joint disorders may be classified as **noninflammatory joint disease** or **inflammatory joint disease.** Serving as fulcrums, the joints permit smooth and precise movement to occur when a muscle contracts and pulls on bones. Because joints, bones, and muscles act together as a functional unit, joint disorders, regardless of type or classification, have profound effects on body mobility.

Noninflammatory Joint Disease

Noninflammatory types of joint disease can be distinguished from inflammatory joint conditions because they do not involve inflammation of the synovial membrane. Further, noninflammatory joint diseases do not produce systemic signs or symptoms, such as fever, or damage other body organs such as the heart and lungs.

Osteoarthritis, known also as *degenerative joint disease* (DJD), is the most common noninflammatory disorder of movable joints. It is characterized by "wear and tear" degeneration and fracturing of articular cartilage (Box 10-2) and by abnormal formation of new bone ("bone spurs") at joint surfaces. In DJD the articular cartilage no longer acts as a "shock absorber," the joint space narrows, the synovial membrane thickens, and the ligaments calcify.

Large weight-bearing joints, such as the hips and knees, are often involved first, followed by involvement of joints in the fingers. Swelling deformities of the *distal* interphalangeal joints called **Heberden nodes** and of the *proximal* interphalangeal joints called **Bouchard nodes** are common. Figure 10-27, *A*, shows the hands of a woman with osteoarthritis. The cause of osteoarthritis is unknown, but obesity, aging, and the "wear and tear" of mechanical stresses on joints over time are known to play a major role.

Unfortunately, no treatment is available to stop the degenerative joint disease process completely. Symptoms, which appear in many people in their fifties and sixties, include morning stiffness,

Box 10-2 | HEALTH matters

Joint Mice

The thin layer of cartilage that covers the articulating surfaces of bones in synovial joints may become cracked as a result of traumatic injury—especially to the knee. Such injuries are called **chondral fractures.** They result in fissuring of the articular cartilage, which can be likened to the cracking of an egg shell. If such an injury occurs, small fragments may become detached from the damaged layer of cartilage and enter the joint cavity. These fragments are called "loose bodies" or *joint mice* because they often cause clicking sounds or catching and locking sensations during joint movement. Symptoms often vary over time as cartilage fragments move about the joint cavity in the synovial fluid. Pain and loss of motion will occur if the fragments become lodged between opposing bone surfaces.

FIGURE 10-26

Olecranon bursitis. Pain, inflammation, and swelling of the bursa may limit motion, although the elbow joint itself may not be affected.

deep "achy" pain on movement that worsens with use, and limited joint motion. In many cases, symptoms can be treated effectively with standard **nonsteroidal antiinflammatory drugs (NSAIDs),** such as aspirin or ibuprofen, or by nutritional supplements such as glucosamine or chondroitin sulfate (see Chapter 8, p. 204). Injection into the joint space, especially of the knee, of a gelatinous type of lubricating fluid containing *hyaluronic acid* has proved useful in some cases. If the disease is more advanced, various types of prescription medications or partial or total joint replacements may be necessary (Box 10-3). Although the severity of symptoms may plateau or stabilize for varying periods, the disease is generally progressive once established and will continue over a lifetime. Osteoarthritis is the leading cause of long-term disability in aging, but otherwise healthy, individuals.

Traumatic injuries are a frequent cause of joint injury. **Dislocation** (subluxation) of a joint as a result of trauma can be an emergency because of associated damage to important blood vessels and nerves. In a dislocation, the articular surfaces of bones forming the joint are no longer in proper contact. This displacement of bone alters the normal contour of the joint and can tear surrounding ligaments. Refer once again to Figure 10-6, *B*. Recall that the annular ligament is intended to hold the head of the radius firmly against the radial notch of the ulna at the proximal radioulnar joint. Functionally, it is this anatomic relationship that allows the radius to rotate freely without dislocation during pronation and supination of the forearm. In children younger than 5 years especially, dislocation of the radial head, called a "pulled elbow," is a common traumatic joint injury. Pain and soft tissue swelling are associated with dislocation injuries. Effective treatment involves early reduction or realignment.

One of the most common traumatic joint injuries associated with athletic activity involves damage to the cartilaginous menisci of the knee. Because the menisci act as shock absorbers and stabilize the knee, severe tears may produce edema, pain, instability, and limited motion. Arthroscopic surgical procedures are frequently used in both the diagnosis and treatment of this type of knee injury (Figure 10-28).

Arthroscopy is an imaging technique that allows a physician to examine the internal structure of a joint without the use of extensive surgery (see Figure 10-28, A). A narrow tube with lenses and a fiberoptic light source is inserted into the joint space through a small puncture. Isotonic saline (salt) solution is injected through a needle to expand the volume of the synovial space. This spreads the joint structures and makes viewing easier (see Figure 10-28, *B*).

Although arthroscopy is often used as a diagnostic procedure, it also can be used to perform joint surgery. While the surgeon views the internal structure of the joint through the arthroscope or on an attached video monitor, instruments can be inserted through puncture holes and used to repair or remove damaged tissue. Arthroscopic surgery is much less traumatic than previous methods in which the joint cavity was completely opened.

Box 10-3 | SPORTS and FITNESS

Joint Replacement

Arthroplasty is the total or partial replacement of a diseased joint with an artificial device called a **prosthesis.** Prosthetic joints or joint components must allow for considerable mobility and be durable, strong, and compatible with surrounding tissues. Development of new prosthetic materials and surgical techniques to replace diseased joints gained momentum with the first successful total hip replacement (THR) procedure. It was performed by noted English orthopedic surgeon Sir John Charnley in 1963. Currently, hip and knee replacements are performed in nearly equal numbers and are the most common orthopedic operations performed on older persons, performed more than 300,000 times each year in the United States. In addition, large numbers of elbow, shoulder, finger, and other joint replacement procedures are performed annually. Osteoarthritis and other types of degenerative bone disease frequently destroy or severely damage joints and cause unremitting pain. Total joint replacement is often the only effective treatment option available.

The THR procedure involves replacement of the femoral head by a metallic alloy prosthesis and the acetabular socket with a high-density polyethylene cup. In the past, both pieces were generally cemented into place with methyl methacrylate adhesive. Many of the newer prostheses, however, are "porous coated" to permit natural ingrowth of bone for stability and retention. The advantage of bone ingrowth is prevention of loosening that occurs if the cement bond weakens. With advanced surgical techniques and newer metal prostheses fabricated from alloys of titanium, cobalt/chrome, and surgical steel, 10-to 15-year THR and total knee replacement success rates have risen to approximately 85% in older patients. However, even more durable metal and plastic components are necessary to extend the 10- to 15-year lifespan of most hip and knee prostheses currently in use. At the present time, younger patients who stress artificial joints more than older adults are encouraged to delay replacement and rely instead on evolving therapies, which are intended to heal or regenerate diseased joint tissues. The x-ray illustration shows placement of a noncemented, porous-coated femoral prosthesis made of titanium alloy and a cemented acetabular socket made of high-density plastic.

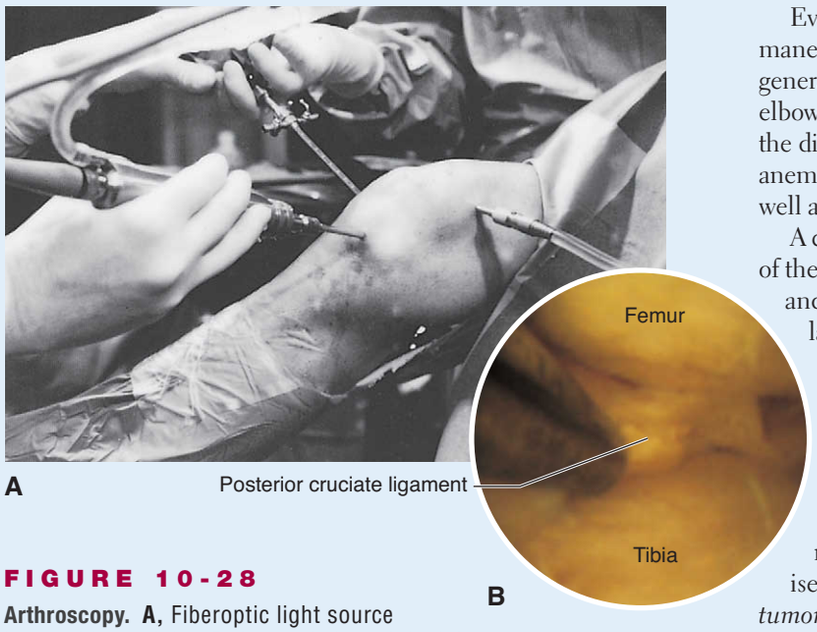

FIGURE 10-28

Arthroscopy. A, Fiberoptic light source inserted into a joint. **B,** Internal view of the joint.

A **sprain** is an acute musculoskeletal injury to the ligamentous structures surrounding a joint that disrupts the continuity of the synovial membrane. A common cause is a twisting or wrenching movement often associated with "whiplash"-type injuries. Blood vessels may be ruptured, and bruising and swelling may occur. Limitation of joint motion is common in all sprain injuries. External ankle rotation sprain injuries are discussed on p. 284.

Inflammatory Joint Disease

Arthritis is a general name for many different inflammatory joint diseases. Arthritis can be caused by a variety of factors, including infection, injury, genetic factors, and autoimmunity. Here is a brief list of the major types of arthritis:

Rheumatoid arthritis (RA) is a form of systemic autoimmune disease that involves chronic inflammation of many different tissues and organs of the body. Although organs such as the heart, lungs, skin, and muscles may become involved, the disease generally attacks joints first—and affects them most severely. A wide range of pathological joint changes are associated with RA. Initially, the synovial membrane becomes inflamed, thickened, and edematous. Soon, the diseased synovial membrane produces an aggregation of inflammatory cells, granulation tissue, and fibroblasts called **pannus** that adheres to the articular cartilage. It is the continued growth and spreading of pannus tissue that destroys articular cartilage and bridges the opposing bones.

Eventually, the bones fuse together, movement ceases, and permanent crippling occurs. Small joints in the hands and feet are generally affected first. As the disease progresses, the wrists, ankles, elbows, knees, and cervical spine may also be involved. Because the disease is systemic, most patients experience symptoms such as anemia, weight loss, fever, fatigue, and generalized muscle pain, as well as symptoms associated with specific types of joint pathology.

A characteristic deformity of the hands in RA is **ulnar deviation** of the fingers (Figure 10-27, *B*). A number of other common signs and symptoms are related to inflammation and loss of articular surface. They include reduction in joint mobility, pain, nodular swelling, and generalized aching and stiffness.

In the past, treatment for many patients was often limited to NSAIDs and other pain or antiinflammatory-type medication, corticosteroids, and so-called disease-modifying antirheumatic drugs such as methotrexate. Newer drugs influencing the altered immune system response in RA, called **TNF blockers,** are showing promise in many individuals suffering from this disease. *TNF,* or *tumor necrosis factor,* is a substance made in excess by the body's immune system in RA. It is involved in pannus formation, destruction of articular cartilage, and pain and swelling of joints. By blocking the effects of this substance, people with moderate RA often experience significant relief from symptoms and from continued damage to bone and joints.

Juvenile rheumatoid arthritis (JRA) is often more severe than the adult form but involves similar deterioration and deformity of joints. Onset is generally systemic and associated with rash, high fever, and swelling of the liver and spleen. Targeted joints, which include the wrists, elbows, knees, and ankles, are generally warm and swollen. The joint inflammatory process often destroys the growth of epiphyseal cartilage, and the growth of long bones is arrested. This form begins during childhood and is more common in girls. In addition to articular damage, JRA also affects the heart, lungs, muscles, and kidneys in many young patients.

Gouty arthritis is another type of inflammatory arthritis. It is a metabolic disorder in which excess blood levels of uric acid, a nitrogenous waste, are deposited as sodium urate crystals within the synovial fluid of joints and in other tissues. These deposits, called **tophi,** are often obvious in the soft tissues of patients with gouty arthritis (Figure 10-27, *C*). They trigger the chronic inflammation and tissue damage seen with the disease. Swelling, tenderness, or pain typically appears in the fingers, wrists, elbows, ankles, and knees. Allopurinol (Zyloprim) and febuxostat (Uloric) are drugs commonly used to treat the disease. They inhibit the synthesis of uric acid. Colchicine is an anti-inflammatory agent first used for treatment of articular pain in 1810. Today, it remains a preferred agent (Colcrys, others) in treatment of gouty arthritis.

CASE study

While sprinting after the soccer ball, Julia was so intensely concentrating on making a goal that she didn't see the opposing team player coming at her from the side. The two players collided, and Julia felt a "pop" in her right knee followed by intense pain. In the emergency department, the resident told her that she had torn her ACL.

1. What knee structure is the resident referring to when she says "ACL"?
   a. Anterior cruciate ligament
   b. Anatomical connecting ligament
   c. Anterior collateral ligament
   d. Arthroscopic colloidal ligament
2. What two articulating bones form the knee joint?
   a. Femur and fibula
   b. Humerus and ulna
   c. Tibia and femur
   d. Fibula and tibia

Julia's main concern is whether she will be able to play soccer again. Unfortunately, some further tests verify that not only is the ACL torn, but Julia also has damaged the medial meniscus.

3. Which choice best describes a meniscus?
   a. A ligament
   b. A piece of cartilage
   c. A portion of bone
   d. A tendon

HINT

To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook, ***A&P Connect,*** *and other resources.*

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

INTRODUCTION

A. Articulation—point of contact between bones
B. Joints are mostly very movable, but some are immovable or allow only limited motion
C. Movable joints allow complex, highly coordinated, and purposeful movements to be executed

CLASSIFICATION OF JOINTS

A. Joints may be classified by using a structural or functional scheme (Table 10-1)
   1. Structural classification—joints are named according to:
      a. Type of connective tissue that joins bones together (fibrous or cartilaginous joints)
      b. Presence of a fluid-filled joint capsule (synovial joint)
   2. Functional classification—joints are named according to the degree of movement allowed
      a. Synarthroses—immovable joint
      b. Amphiarthroses—slightly movable
      c. Diarthroses—freely movable
B. Fibrous joints (synarthroses)—bones of joints fit together closely, thereby allowing little or no movement (Figure 10-1)
   1. Syndesmoses—joints in which ligaments connect two bones
   2. Sutures—found only in the skull; teethlike projections from adjacent bones interlock with each other
   3. Gomphoses—between the root of a tooth and the alveolar process of the mandible or maxilla
C. Cartilaginous joints (amphiarthroses)—bones of joints are joined together by hyaline cartilage or fibrocartilage; allow very little motion (Figure 10-2)
   1. Synchondroses—hyaline cartilage present between articulating bones
   2. Symphyses—joints in which a pad or disk of fibrocartilage connects two bones
D. Synovial joints (diarthroses)—freely movable joints (Figure 10-3)
   1. Structures of synovial joints
      a. Joint capsule—sleevelike casing around the ends of the bones that binds them together
      b. Synovial membrane—membrane that lines the joint capsule and also secretes synovial fluid
      c. Articular cartilage—hyaline cartilage covering the articular surfaces of bones
      d. Joint cavity—small space between the articulating surfaces of the two bones of the joint
      e. Menisci (articular disks)—pads of fibrocartilage located between articulating bones
      f. Ligaments—strong cords of dense white fibrous tissue that hold the bones of a synovial joint more firmly together
      g. Bursae—synovial membranes filled with synovial fluid; cushion joints and facilitate movement of tendons
   2. Types of synovial joints (Figure 10-4)
      a. Uniaxial joints—synovial joints that permit movement around only one axis and in only one plane
         (1) Hinge joints—articulating ends of bones form a hinge-shaped unity that allows only flexion and extension
         (2) Pivot joints—a projection of one bone articulates with a ring or notch of another bone
      b. Biaxial joints—synovial joints that permit movements around two perpendicular axes in two perpendicular planes
         (1) Saddle joints—synovial joints in which the articulating ends of the bones resemble reciprocally shaped miniature saddles; only example in the body is in the thumbs
         (2) Condyloid (ellipsoidal) joints—synovial joints in which a condyle fits into an elliptical socket
      c. Multiaxial joints—synovial joints that permit movements around three or more axes in three or more planes
         (1) Ball-and-socket (spheroid) joints—most movable joints; the ball-shaped head of one bone fits into a concave depression
         (2) Gliding joints—relatively flat articulating surfaces that allow limited gliding movements along various axes

REPRESENTATIVE SYNOVIAL JOINTS

A. Humeroscapular joint (Figure 10-5)
   1. Shoulder joint
   2. Most mobile joint because of the shallowness of the glenoid cavity
   3. Glenoid labrum—narrow rim of fibrocartilage around the glenoid cavity that lends depth to the glenoid cavity
   4. Structures that strengthen the shoulder joint are ligaments, muscles, tendons, and bursae
B. Elbow joint (Figure 10-6)
   1. Humeroradial joint—lateral articulation of the capitulum of the humerus with the head of the radius
   2. Humeroulnar joint—medial articulation of the trochlea of the humerus with the trochlear notch of the ulna
   3. Both components of the elbow joint surrounded by a single joint capsule and stabilized by collateral ligaments
   4. Classic hinge joint
   5. Medial and lateral epicondyles are externally palpable bony landmarks
   6. Olecranon bursa independent of elbow joint space
      a. Inflammation called *olecranon bursitis*
      b. Trauma to nerve results in unpleasant sensations in the fingers and part of the hand supplied by the nerve
      c. Severe injury may cause paralysis of hand muscles or reduction in wrist movements

C. Proximal radioulnar joint—between the head of the radius and the medial notch of the ulna
   1. Stabilized by the annular ligament
   2. Permits rotation of the forearm
   3. Dislocation of the radial head called a "pulled elbow"

D. Distal radioulnar joint—point of articulation between the ulnar notch of the radius and the head of the ulna
   1. Acts with the proximal radioulnar joint
   2. Permits pronation and supination of the forearm

E. Radiocarpal (wrist) joints (Figure 10-7)
   1. Only the radius articulates directly with the carpal bones distally (scaphoid and lunate)
   2. Joints are synovial
   3. Scaphoid bone is fractured frequently
   4. Portion of the fractured scaphoid may become avascular

F. Intercarpal joints (Figure 10-7)
   1. Present between eight carpal bones
   2. Stabilized by numerous ligaments
   3. Joint spaces usually communicate
   4. Movements generally gliding with some abduction and flexion

G. Carpometacarpal joints—total of three joints
   1. One joint for the thumb—wide range of movements
   2. Two joints for the fingers—movements largely gliding type
   3. Thumb carpometacarpal joint is unique and important functionally
      a. Loose-fitting joint capsule
      b. Saddle-shaped articular surface
      c. Movements—extension, adduction, abduction, circumduction, and opposition
      d. Opposition—ability to touch the tip of the thumb to the tip of other fingers—movement of great functional significance

H. Metacarpophalangeal joints (Figure 10-8)
   1. Rounded heads of metacarpal bones articulate with concave bases of the proximal phalanges
   2. Capsule surrounding joints strengthened by collateral ligaments
   3. Primary movements are flexion and extension

I. Interphalangeal joints
   1. Typical diarthrotic, hinge-type, synovial joints
   2. Exist between heads of phalanges and bases of more distal phalanges
   3. Two categories:
      a. PIP joints—proximal interphalangeal joints (between proximal and middle phalanges)
      b. DIP joints—distal interphalangeal joints (between middle and distal phalanges)

J. Hip joint (Figure 10-9)
   1. Stable joint because of the shape of the head of the femur and the acetabulum
   2. A joint capsule and ligaments contribute to the joint's stability

K. Knee joint (Figures 10-10 and 10-11)
   1. Largest and one of the most complex and most frequently injured joints
   2. Tibiofemoral joint is supported by a joint capsule, cartilage, and numerous ligaments and muscle tendons
   3. Permits flexion, extension, and with the knee flexed, some internal and external rotation

L. Ankle joint (Figure 10-12)
   1. Synovial-type hinge joint
   2. Articulation between the lower ends of the tibia and fibula and the upper part of the talus
   3. Joint is "mortise" or wedge shaped
      a. Lateral malleolus lower than medial malleolus
   4. Internal rotation injury results in common "sprained ankle"
      a. Involves anterior talofibular ligament
   5. Other ankle ligaments also may be involved in sprain injuries—example is deltoid ligament
   6. External ankle rotation injuries generally involve bone fractures rather than ligament tears
      a. First-degree ankle injury—lateral malleolus fractured
      b. Second-degree ankle injury—both malleoli fractured
      c. Third-degree ankle injury—fracture of both malleoli and articular surface of tibia

M. Vertebral joints (Figures 10-13 and 10-14)
   1. Vertebrae are connected to one another by several joints to form a strong flexible column
   2. Bodies of adjacent vertebrae are connected by intervertebral disks and ligaments
   3. Intervertebral disks are made up of two parts
      a. Annulus fibrosus—disk's outer rim, made of fibrous tissue and fibrocartilage
      b. Nucleus pulposus—disk's central core, made of a pulpy, elastic substance

TYPES AND RANGE OF MOVEMENT AT SYNOVIAL JOINTS

A. Measuring range of motion (Figure 10-15)
   1. Range of motion (ROM) assessment used to determine extent of joint injury
   2. ROM can be measured actively or passively; both are generally about equal
   3. ROM measured by instrument called a *goniometer*

B. Angular movements—change the size of the angle between articulating bones
   1. Flexion—decreases the angle between bones; bends or folds one part on another (Figures 10-16, *A*; 10-18; and 10-19)
   2. Extension and hyperextension (Figure 10-18)
      a. Extension—increases the angle between bones, returns a part from its flexed position to its anatomical position
      b. Hyperextension—stretching or extending part beyond its anatomical position (Figures 10-19, 10-21, and 10-23)
   3. Plantar flexion and dorsiflexion (Figure 10-25)
      a. Plantar flexion—increases the angle between the top of the foot and the front of the leg
      b. Dorsiflexion—decreases the angle between the top of the foot and the front of the leg

4. Abduction and adduction (Figures 10-19 and 10-23)
   a. Abduction—moves a part away from the median plane of the body
   b. Adduction—moves a part toward the median plane of the body

C. Circular movements
1. Rotation and circumduction
   a. Rotation—pivoting a bone on its own axis (Figure 10-16, *D*)
   b. Circumduction—moves a part so that its distal end moves in a circle
2. Supination and pronation (Figure 10-20, *B*)
   a. Supination—turns the hand palm side up
   b. Pronation—turns the hand palm side down

D. Gliding movements—simplest of all movements; articular surface of one bone moves over the articular surface of another without any angular or circular movement

E. Special movements
1. Inversion and eversion (Figure 10-25, *B*)
   a. Inversion—turning the sole of the foot inward
   b. Eversion—turning the sole of the foot outward
2. Protraction and retraction (Figure 10-17, *A*)
   a. Protraction—moves a part forward
   b. Retraction—moves a part backward
3. Elevation and depression (Figure 10-17, *B*)
   a. Elevation—moves a part up
   b. Depression—lowers a part

CYCLE OF LIFE: ARTICULATIONS

A. Bone development and the sequence of ossification between birth and skeletal maturity affect joints
1. Fontanels between cranial bones disappear
2. Epiphysial plates ossify at maturity

B. Older adults
1. ROM decreases
2. Changes in gait

C. Skeletal diseases manifested as joint problems
1. Abnormal bone growth (lipping)—influences joint motion
2. Disease conditions can be associated with specific developmental periods

THE BIG PICTURE: ARTICULATIONS

A. Hand—"reason for the upper extremity"; thumb—"reason for the hand"
1. Examples of "big picture" type of thinking when used in functional context

B. Mobility of the upper extremity is extensive because of the following:
1. Arrangement of bones in the shoulder girdle, arms, forearm, wrist, and hand
2. Location and method of attachment of muscles to bones
3. Proper functioning of joints

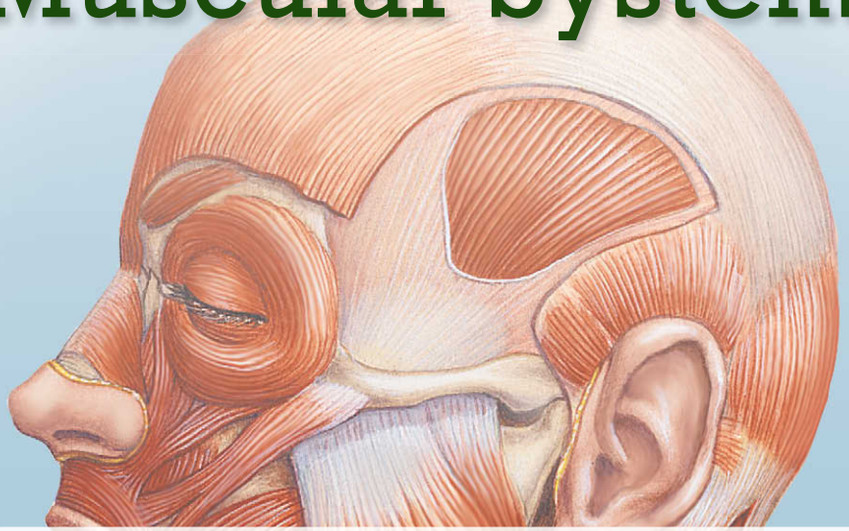
C. Mobility and extensive ROM needed to position upper extremity and hand to permit grasping and manipulation of objects, thus enabling effective interaction with objects in the external environment

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Classify joints and specify each group according to function and structure.
2. Define the terms *fibrous joints*, *cartilaginous joints*, and *synovial joints*.
3. Name and define three types of fibrous joints. Give an example of each.
4. Name and define two types of cartilaginous joints. Give an example of each.
5. List and describe the different types of synovial joints. Give an example of each.
6. Name and define four kinds of angular movements permitted by some synovial joints.
7. Define and give an example of the following: rotation, circumduction, pronation, supination.
8. Describe the function of a goniometer.
9. What joint makes possible much of the dexterity of the human hand? Describe it and the movements it permits.
10. Describe vertebral joints.
11. Describe and differentiate between the following joints: humeroscapular, hip, knee.
12. How do loose bodies, or cartilaginous "joint mice," differ from menisci?
13. Discuss the surgical procedure of total hip replacement (THR).
14. Name the two classifications of joint disorders and give examples of each.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. The elbow, the joint between the bodies of vertebrae, and the root of a tooth in the jaw are all joints given different functional names. What are these names and what characteristic distinguishes them from one another?
2. A synovial joint is the most freely moving type of joint in the body, but joints require stability and protection also. Evaluate the seven structural characteristics of a synovial joint as primarily necessary for stability, movement, and protection.
3. Compare the range of movement at different joints.
4. Describe the anatomical structure of the knee and explain why the knee joint is the most frequently injured joint in the body.

Anatomy of the Muscular System

continued on p. 343

Survival depends on the ability to maintain a relatively constant internal environment. Such stability often requires movement of the body. Whereas many different systems of the body have some role in accomplishing movement, it is the skeletal and muscular systems acting together that actually produce most body movements. We have investigated the architectural plan of the skeleton and have seen how its firm supports and joint structures make movement possible. However, bones and joints cannot move themselves. They must be moved by something. Our subject for now, then, is the large mass of skeletal muscle that moves the framework of the body: the **muscular system.**

Movement is one of the most distinctive and easily observed "characteristics of life." When we walk, talk, run, breathe, or engage in a multitude of other physical activities that are under the "willed" control of the individual, we do so by contraction of skeletal muscle.

There are more than 600 skeletal muscles in the body. Collectively, they constitute 40% to 50% of our body weight. And, together with the scaffolding provided by the skeleton, muscles also determine the form and contours of our body.

Contraction of individual muscle cells is ultimately responsible for purposeful movement. In Chapter 12 the physiology of muscular contraction is discussed. In this preliminary chapter, however, we will learn how contractile units are grouped into unique functioning organs—or muscles.

The manner in which muscles are grouped, the relationship of muscles to joints, and how muscles attach to the skeleton determine purposeful body movement. A discussion of muscle shape and how muscles attach to and move bones is followed by information on specific muscles and muscle groups. The chapter ends with a review of the concept of posture.

SKELETAL MUSCLE STRUCTURE

Connective Tissue Components

The skeletal muscle cells, or *muscle fibers*, are covered by a delicate connective tissue membrane called the **endomysium** (Figure 11-1). Groups of skeletal muscle fibers, called *fascicles*, are then bound together into bundles by a tougher connective tissue envelope called the **perimysium.** The muscle as a whole is covered by a coarse sheath called the **epimysium.** Because all three of these structures are continuous with the fibrous structures that attach muscles to bones or other structures, muscles are firmly harnessed to the structures they pull on during contraction. The epimysium, perimysium, and endomysium of a muscle, for example, may be continuous with fibrous tissue that extends from the muscle as a **tendon,** a strong tough cord continuous at its other end with the fibrous periosteum covering a bone. Alternatively, the fibrous wrapping of a muscle may extend as a broad, flat sheet of connective tissue called an **aponeurosis,** which usually merges with the fibrous wrappings of another muscle. So tough and strong are tendons and aponeuroses that they are not often torn, even by injuries forceful enough to break bones or tear muscles. They are, however, occasionally pulled away from bones.

Fibrous connective tissue surrounding the muscle organ and located outside the epimysium and tendon is called **fascia.** *Fascia* is a general term for the fibrous connective tissue found under the skin and surrounding many deeper organs, including skeletal muscles and bones. Fascia just under the skin (the hypodermis) is sometimes called *superficial fascia*, and the fascia around muscles and bones is sometimes called *deep fascia*.

Sheets of fibrous connective tissue form double-walled tubes called **tendon sheaths** that enclose certain tendons, notably those of the wrist and ankle. Like bursae, the walls of tendon sheaths have a lining of synovial membrane. The moist, smooth surfaces that face each other within the double wall of a tendon sheath enables the tendon to move easily, almost without friction. Table 11-1 clarifies the arrangement of the fibrous coverings of a muscle organ.

TABLE 11-1 Fibrous Coverings of Muscle Organs

FIBROUS STRUCTURE*	PART COVERED
Fascia	External to muscles, bones, other organs
Superficial fascia	Under the skin
Deep fascia	Surrounds deeper organs, including epimysium of muscle
Tendon sheath	Tubelike tunnel around tendon of muscle; lined with synovial membrane
Epimysium†	Surrounds entire muscle organ
Perimysium†	Surrounds a fascicle (bundle) of muscle fibers
Endomysium†	Surrounds an individual muscle fiber

*Listed here from superficial to deep; all of these fibrous structures are continuous with one another (that is, their fibers blend together).
†Continue and fuse together to form a tendon or aponeurosis.

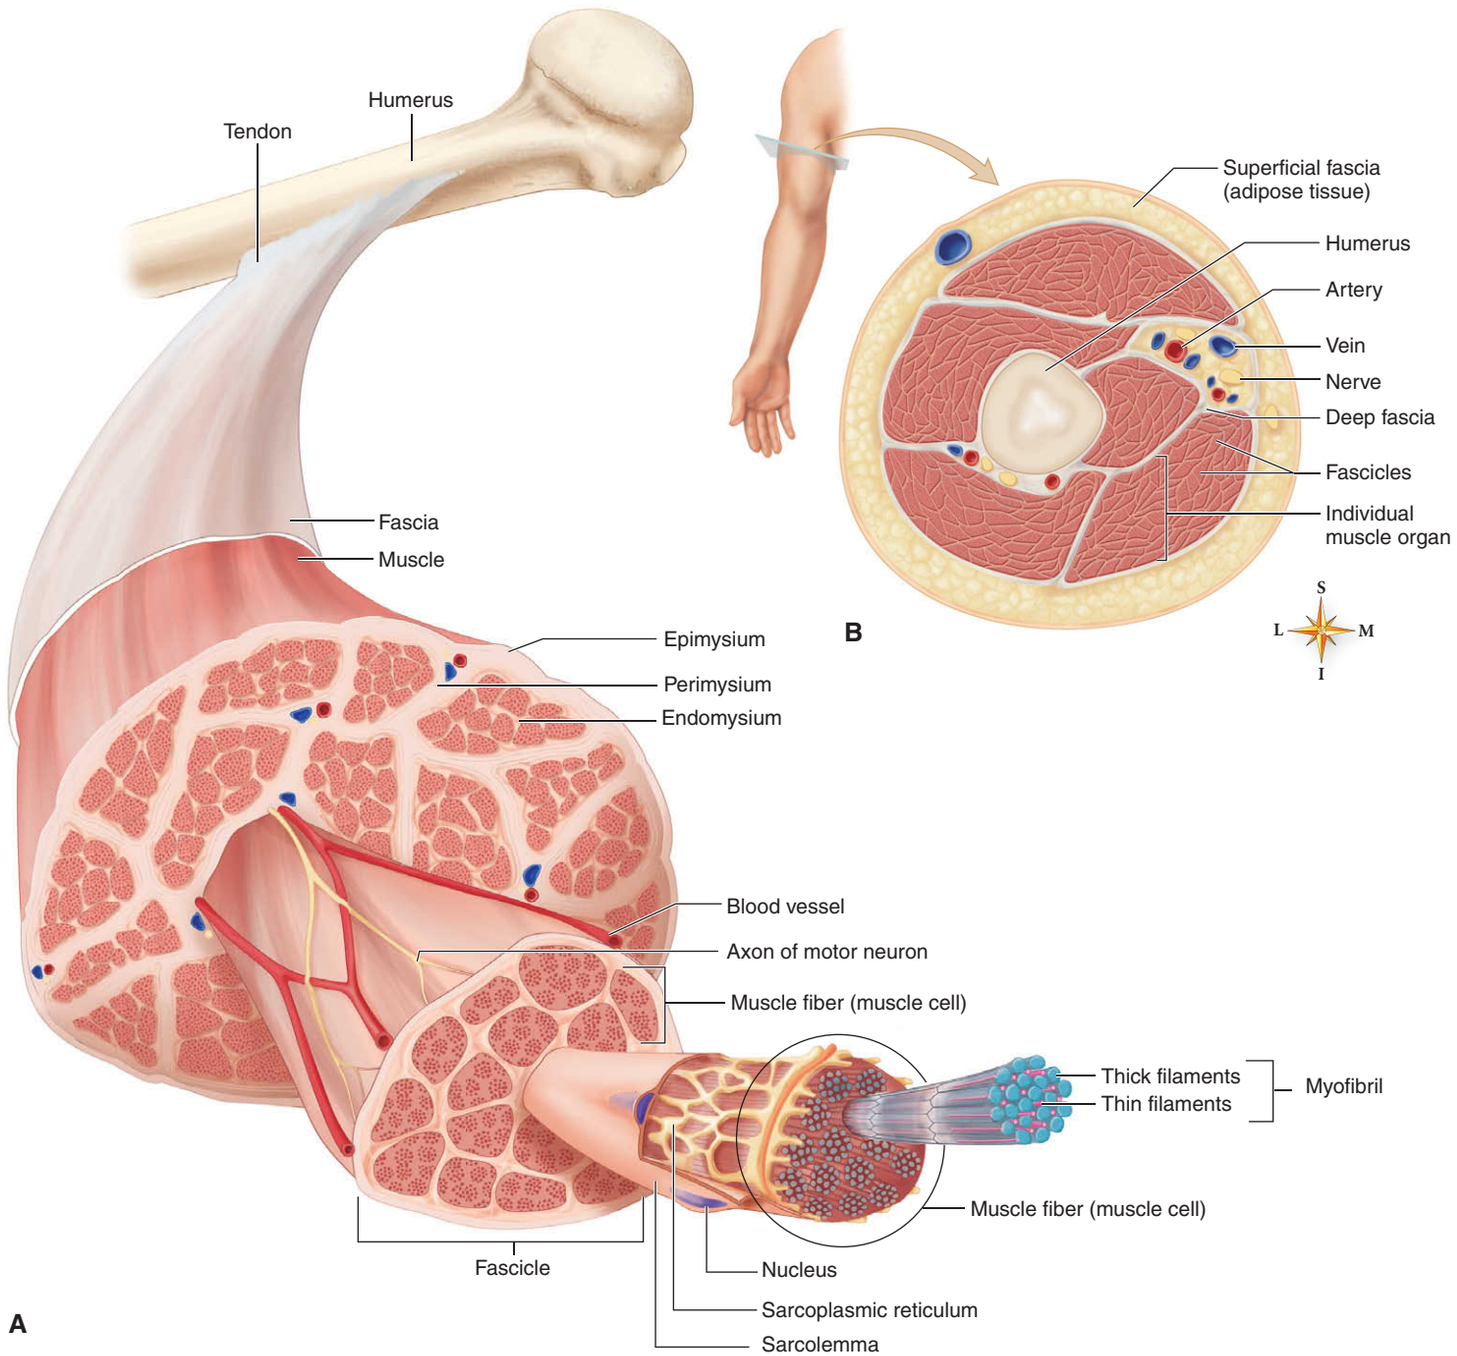

FIGURE 11-1

Structure of a muscle organ. A, Note that the connective tissue coverings, the epimysium, perimysium, and endomysium, are continuous with each other and with the tendon. Note also that muscle fibers are held together by the perimysium in groups called *fascicles.* **B,** Diagram showing the arm in cross section. Note the relationships of superficial and deep fascia to individual muscles and other structures in the plane of section.

Size, Shape, and Fiber Arrangement

The structures called *skeletal muscles* are organs. They consist mainly of skeletal muscle tissue plus important connective and nervous tissue components. Skeletal muscles vary considerably in size, shape, and arrangement of fibers. They range from extremely small strands, such as the stapedius muscle of the middle ear, to large masses, such as the muscles of the thigh. Some skeletal muscles are broad in shape and some are narrow. Some are long and tapering and some are short and blunt. Some are triangular, some quadrilateral, and some irregular. Some form flat sheets and others form bulky masses.

The strength and type of movement produced by the shortening of a muscle is related to the orientation of its fibers and overall shape, as well as its attachments to bone and involvement in joints. This is yet another example of the relationship between structure and function. Six muscle shapes are often used to describe and categorize skeletal muscles (Figure 11-2).

1. **Parallel muscles** can vary in length, but long straplike muscles with parallel fascicles are perhaps most typical. The sartorius muscle of the leg is a good example. The rectus abdominis muscles, which run the length of the anterior abdominal wall, have parallel muscle fascicles that are "interrupted" by transverse intersections.
2. **Convergent muscles** have fascicles that radiate out from a small to a wider point of attachment, much like the blades in a fan. The pectoralis major muscle is a good example.
3. **Pennate muscles** are said to be "featherlike" in appearance. Three categories of these muscles have uniquely different types of fascicle attachments that in some ways resemble the feathers in an old-fashioned plume pen. *Unipennate muscles*, such as the soleus, have fascicles that anchor to only one side of the connective tissue shaft. *Bipennate muscles*, such as the rectus femoris in the thigh, have a type of double-feathered attachment of fascicles. In *multipennate muscles*, such as the deltoid, the numerous interconnecting quill-like fascicles converge on a common point of attachment.
4. **Fusiform muscles** have fascicles that may be close to parallel in the center, or "belly," of the muscle but converge to a tendon at one or both ends. The brachioradialis is a good example.
5. **Spiral muscles,** such as the latissimus dorsi, have fibers that twist between their points of attachment.
6. **Circular muscles,** sometimes called *orbicular muscles* and *sphincters*, often circle body tubes or openings. The orbicularis oris around the mouth is an example. The external anal sphincter around the anus is another example.

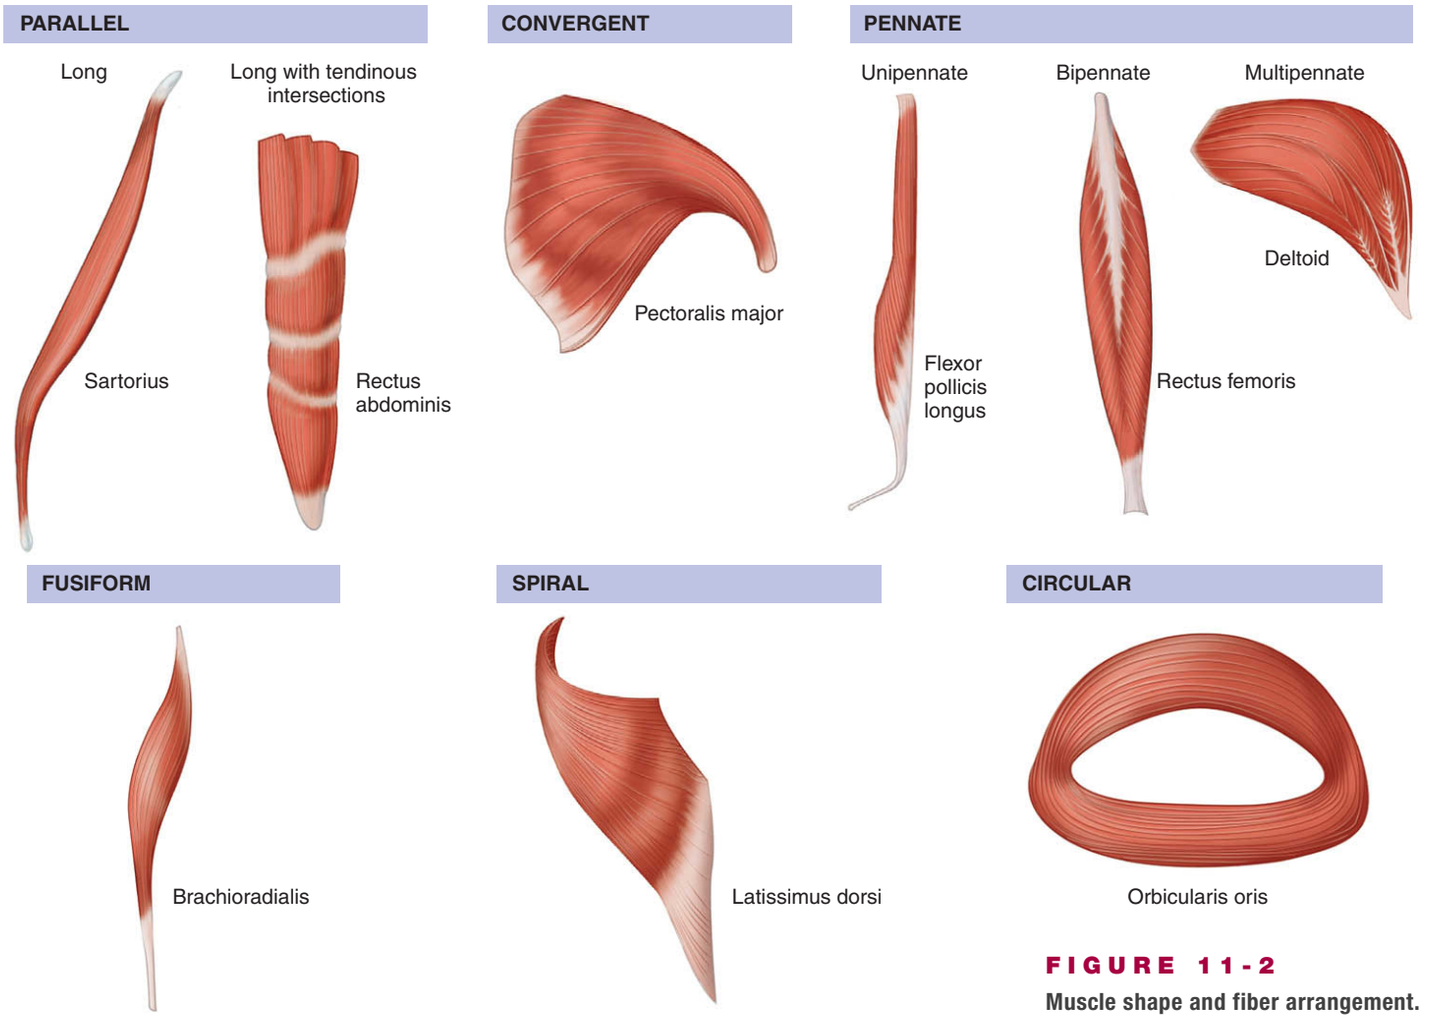

FIGURE 11-2
Muscle shape and fiber arrangement.

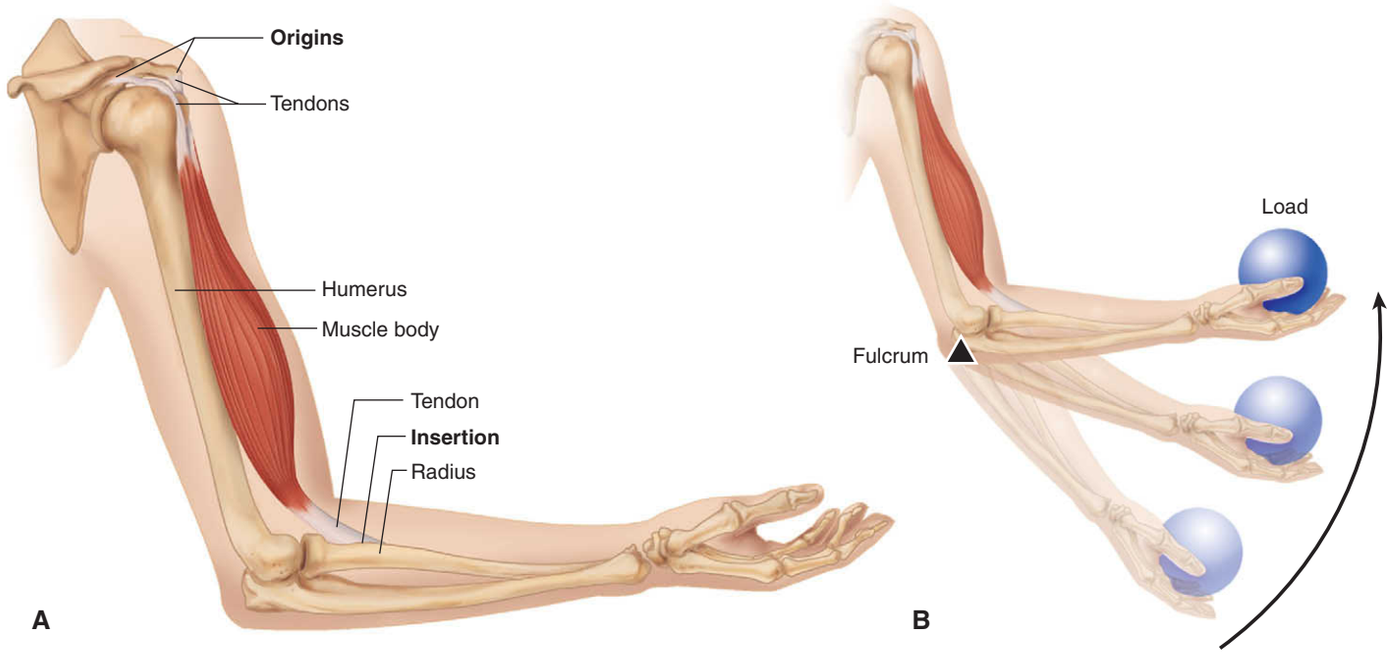

FIGURE 11-3

Attachments of a skeletal muscle. A, Origin and insertion of a skeletal muscle. A muscle originates at a relatively stable part of the skeleton (origin) and inserts at the skeletal part that is moved when the muscle contracts (insertion). **B,** Movement of the forearm during weightlifting. Muscle contraction moves bones, which serve as levers, and by acting on joints, which serve as fulcrums for those levers. See the text for discussion and review Figure 11-4, which illustrates types of levers.

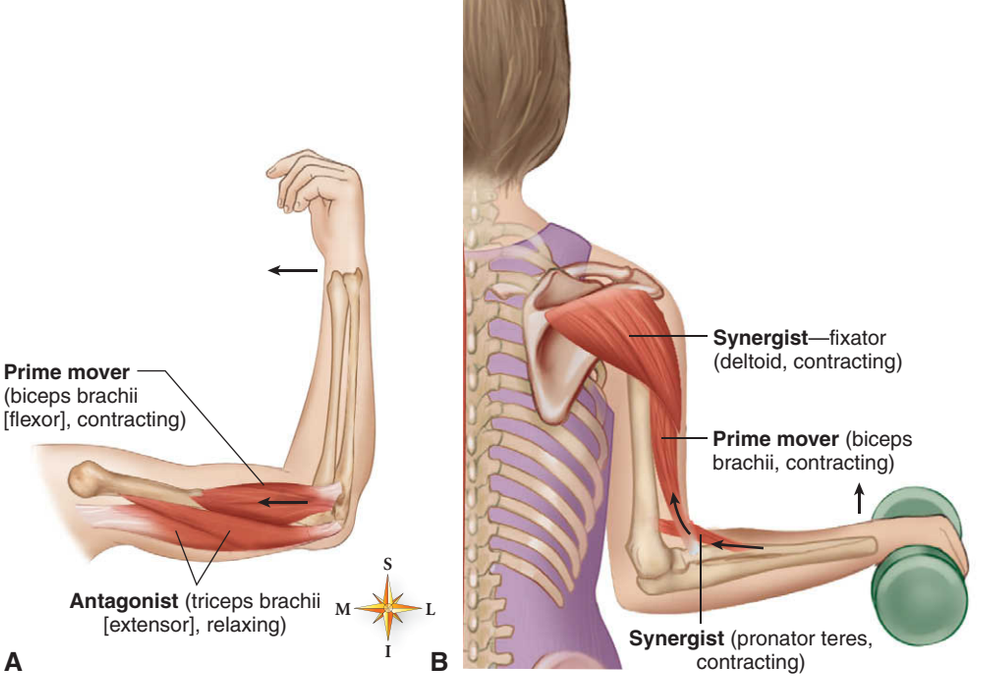
| QUICK CHECK |

1. Identify (a) the connective tissue membrane that covers individual muscle fibers, (b) the membrane that surrounds groups of skeletal muscle fibers (fascicles), and (c) the membrane that covers the muscle as a whole.
2. Name the tough connective tissue cord that serves to attach a muscle to a bone.
3. Name three types of fiber arrangements seen in skeletal muscle.

Attachment of Muscles

Most of our muscles span at least one joint and attach to both articulating bones. When contraction occurs, one bone usually remains fixed and the other moves. The points of attachment are called the *origin* and *insertion*. The **origin** is the point of attachment that does not move when the muscle contracts. Therefore, the origin bone is the more stationary of the two bones at a joint when contraction occurs. The **insertion** is the point of attachment that moves when the muscle contracts (Figure 11-3). The insertion bone therefore moves toward the origin bone when the muscle shortens. In case you are wondering why both bones do not move because both are pulled on by the contracting muscle, the answer is one of them is normally stabilized by isometric contractions of other muscles or by certain features of its own that make it less mobile.

The terms *origin* and *insertion* provide us with useful points of reference. Many muscles have multiple points of origin or insertion. Understanding the functional relationship of these attachment points during muscle contraction helps in deducing muscle actions. The attachment points of the biceps brachii shown in Figure 11-3 help provide functional information. Distal insertion on the radius in the forearm causes flexion to occur at the elbow when contraction occurs. It should be realized, however, that origin and insertion are points that may change under certain circumstances. For example, not only can you grasp an object above your head and pull it down, but you can also pull yourself up to the object. Although origin and insertion are convenient terms, they do not always provide the necessary information needed to understand the full functional potential of muscle action.



Muscle Actions

Skeletal muscles almost always act in groups rather than singly. As a result, most movements are produced by the coordinated action of several muscles. Some of the muscles in the group contract while others relax. The result is a movement pattern that allows for the functional classification of muscles or muscle groups. Several terms are used to describe muscle action during any particular movement pattern. The terms *prime mover (agonist)*, *antagonist*, *synergist*, and *fixator* are especially important and are discussed in the following paragraphs. Each term suggests an important concept that is essential to understanding such functional muscle patterns as flexion, extension, abduction, adduction, and other movements discussed in Chapter 10.

Any muscle that performs an action is a "mover." The term **prime mover** is used to describe a muscle that directly performs a specific movement. The movement produced by a muscle acting as a prime mover is described as the "action" or "function" of that

FIGURE 11-4

Muscle actions. A, The flexor muscle (biceps brachii) is the prime mover in flexing the elbow. The extensor muscle (triceps brachii) is the antagonist, which in this case must relax to permit easy flexion of the elbow. The pronator teres muscle acts as a synergist by also flexing the elbow. **B,** Here the biceps brachii is again the prime mover of flexion of the elbow. The pronator teres muscle acts as a synergist by also flexing the elbow. To prevent the biceps from also moving the shoulder while straining against a heavy weight, the posterior portion of the deltoid muscle tenses to stabilize the shoulder joint—thus acting as a fixator muscle in this action.

muscle. For example, the biceps brachii shown in Figures 11-3 and 11-4 is acting as a prime mover during flexion of the forearm. The term **agonist** can be applied to the prime mover, or any other "mover" muscle that directly contributes to the same action as the prime mover.

Antagonists are muscles that when contracting, directly oppose prime movers (or agonists). They are relaxed while the prime mover is contracting to produce movement (see Figure 11-4). Simultaneous contraction of a prime mover and its antagonist muscle results in rigidity and lack of motion. The term *antagonist* is perhaps unfortunate because muscles cooperate, rather than oppose, in normal movement patterns. Antagonists are important in providing precision and control during contraction of prime movers.

Synergists are muscles that contract at the same time as the prime mover. They facilitate or complement prime mover actions so that the prime mover produces a more effective movement.

Fixator muscles generally function as joint stabilizers (see Figure 11-4, *B*). They frequently serve to maintain posture or balance during contraction of prime movers acting on joints in the arms and legs. Because fixator muscles assist the prime mover in performing an action, they are a type of synergist.

Movement patterns are complex, and most muscles function not only as prime movers but also at times as antagonists, synergists, or fixators. A prime mover in a particular movement pattern, such as flexion, may be an antagonist during extension or a synergist or fixator in other types of movement.

| QUICK CHECK |

4. Identify the point of attachment of a muscle to a bone that (a) does not move when the muscle contracts and (b) one that does move when the muscle contracts.
5. What name is used to describe a muscle that directly performs a specific movement?
6. What type of muscles helps maintain posture or balance during contraction of muscles acting on joints in the arms and legs?
7. Name the type of muscles that generally function as joint stabilizers.

Lever Systems

When a muscle shortens, the central body portion, called the **belly,** contracts. The type and extent of movement are determined by the load or resistance that is moved, the attachment of the tendinous extremities of the muscle to bone (origin and insertion), and the particular type of joint involved. In almost every instance, muscles that move a part do not lie over that part. Instead, the muscle belly lies proximal to the part moved. Thus muscles that move the forearm lie proximal to it, that is, in the upper part of the arm.

Knowledge of lever systems is important in understanding muscle action. By definition, a **lever** is any rigid bar free to turn about a fixed point called its *fulcrum*. Bones serve as levers, and joints serve as fulcrums of these levers. A contracting muscle applies a pulling force on a bone lever at the point of the muscle's attachment to the bone (Box 11-1). This force causes the insertion bone to move about its joint fulcrum.

A **lever system** is a simple mechanical device that makes the work of moving a weight or other load easier in some way. Lever systems are composed of four component parts:

1. A rigid rod or bar (bone) called a *lever*
2. A fixed pivot, or fulcrum (F), around which the lever moves (joint)
3. A load (L), or resistance, that is moved
4. A force, or pull (P), which produces movement (muscle contraction).

Figure 11-5 shows the three different types of lever arrangements. All three types are found in the human body.

FIRST-CLASS LEVERS

As you can see in Figure 11-5, A, the fulcrum in a first-class lever lies between the effort, or pull (P), and the resistance, or load (W), as in a set of scales, a pair of scissors, or a child's seesaw. In the body the head being raised or tipped backward on the atlas is an example of a first-class lever in action. The facial portion of the skull is the load, the joint between the skull and atlas is the fulcrum, and the muscles of the back produce the pull. In the human body first-class levers are not abundant. They generally serve as levers of stability.

Box 11-1 | SPORTS and FITNESS

Assessing Muscle Strength

Physical therapists, certified athletic trainers, and other health care providers are often required to assess muscle strength. A basic principle of muscle action in a lever system is called the *optimum angle of pull.* An understanding of this principle is required for correct assessment of muscle strength.

Generally, the optimum angle of pull for any muscle is a right angle to the long axis of the bone to which it is attached. When the angle of pull departs from a right angle and becomes more parallel to the long axis, the strength of contraction decreases dramatically. Contraction of the brachialis muscle demonstrates this principle very well. The brachialis crosses the elbow from the humerus to the ulna. In the anatomical position the elbow is extended and the angle of pull of the brachialis is parallel to the long axis of the ulna (see Figure 11-21, *D*). Contraction of the brachialis at this angle is very inefficient. As the elbow is flexed and the angle of pull approaches a right angle, the contraction strength of the muscle is greatly increased. Therefore, to test brachialis muscle strength correctly, the forearm should be flexed at the elbow. Understanding the optimum angle of pull for any given muscle makes a rational approach to correct assessment of functional strength in that muscle possible.

SECOND-CLASS LEVERS

In second-class levers the load lies between the fulcrum and the joint at which the pull is exerted. The wheelbarrow is often used as an example. The presence of second-class levers in the human body is a controversial issue. Some authorities interpret the raising of the body on the toes as an example of this type of lever (see Figure 11-5, *B*). In this example the point of contact between the toes and the ground is the fulcrum, the load is located at the ankle, and pull is exerted by the gastrocnemius muscle through the Achilles tendon. Opening the mouth against resistance (depression of the mandible) is also considered to be an example of a second-class lever.

THIRD-CLASS LEVERS

In a third-class lever the pull is exerted between the fulcrum and the resistance or load to be moved. Flexing of the forearm at the elbow joint is a frequently used example of this type of lever (see Figure 11-5, C). Third-class levers permit rapid and extensive movement and are the most common type found in the body. They allow insertion of a muscle very close to the joint that it moves.

| A&P CONNECT |

Leverage is the change in effort needed when using a lever to do work. Want to know more about how muscles power the levers of the body? Check it out in ***Leverage*** online at ***A&P Connect.***

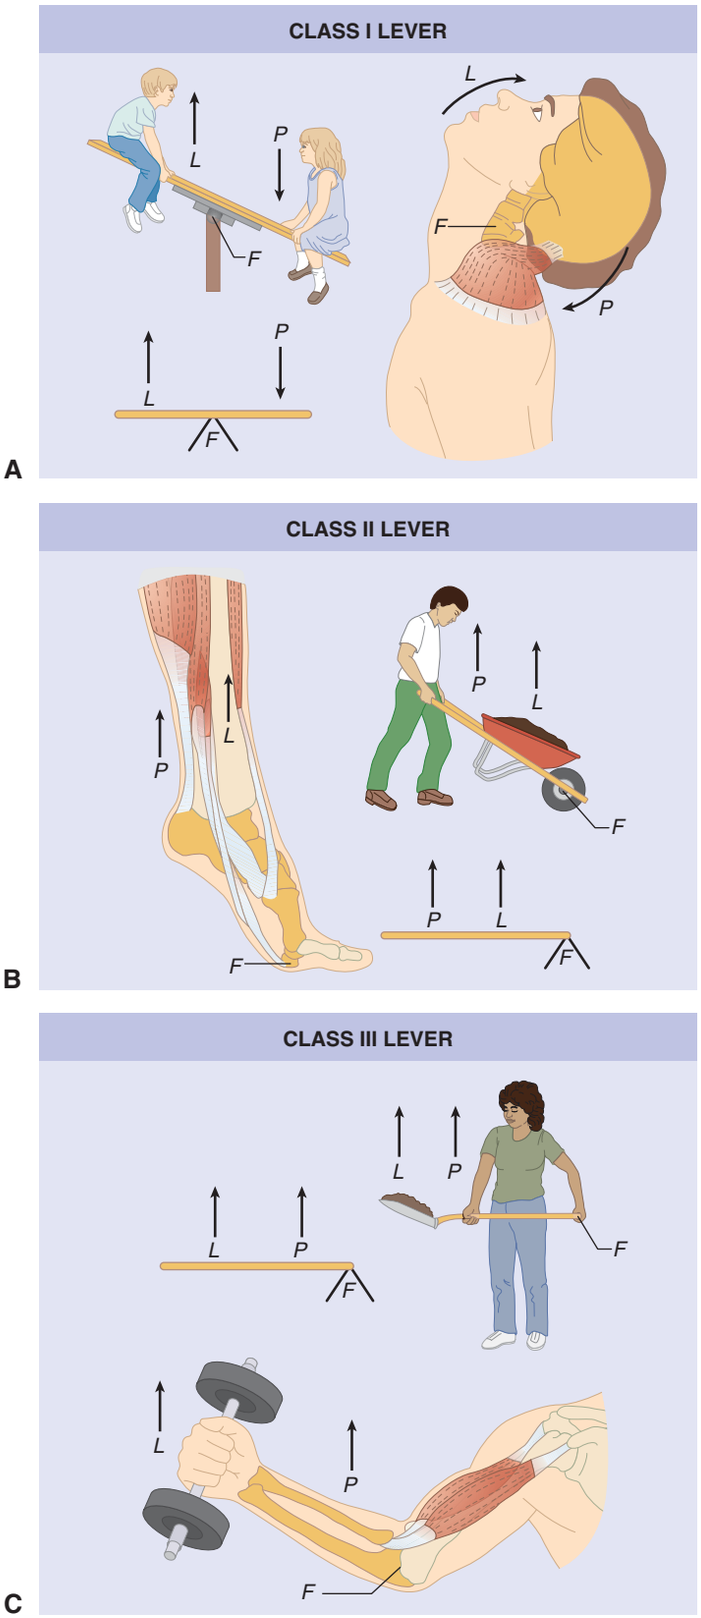


FIGURE 11-5

Lever classes. A, Class I: fulcrum (*F*) between the load (*L*) and force or pull (*P*). **B,** Class II: load (*L*) between the fulcrum (*F*) and force or pull (*P*). **C,** Class III: force or pull (*P*) between the fulcrum (*F*) and the load (*L*). The lever rod is *yellow* in each.

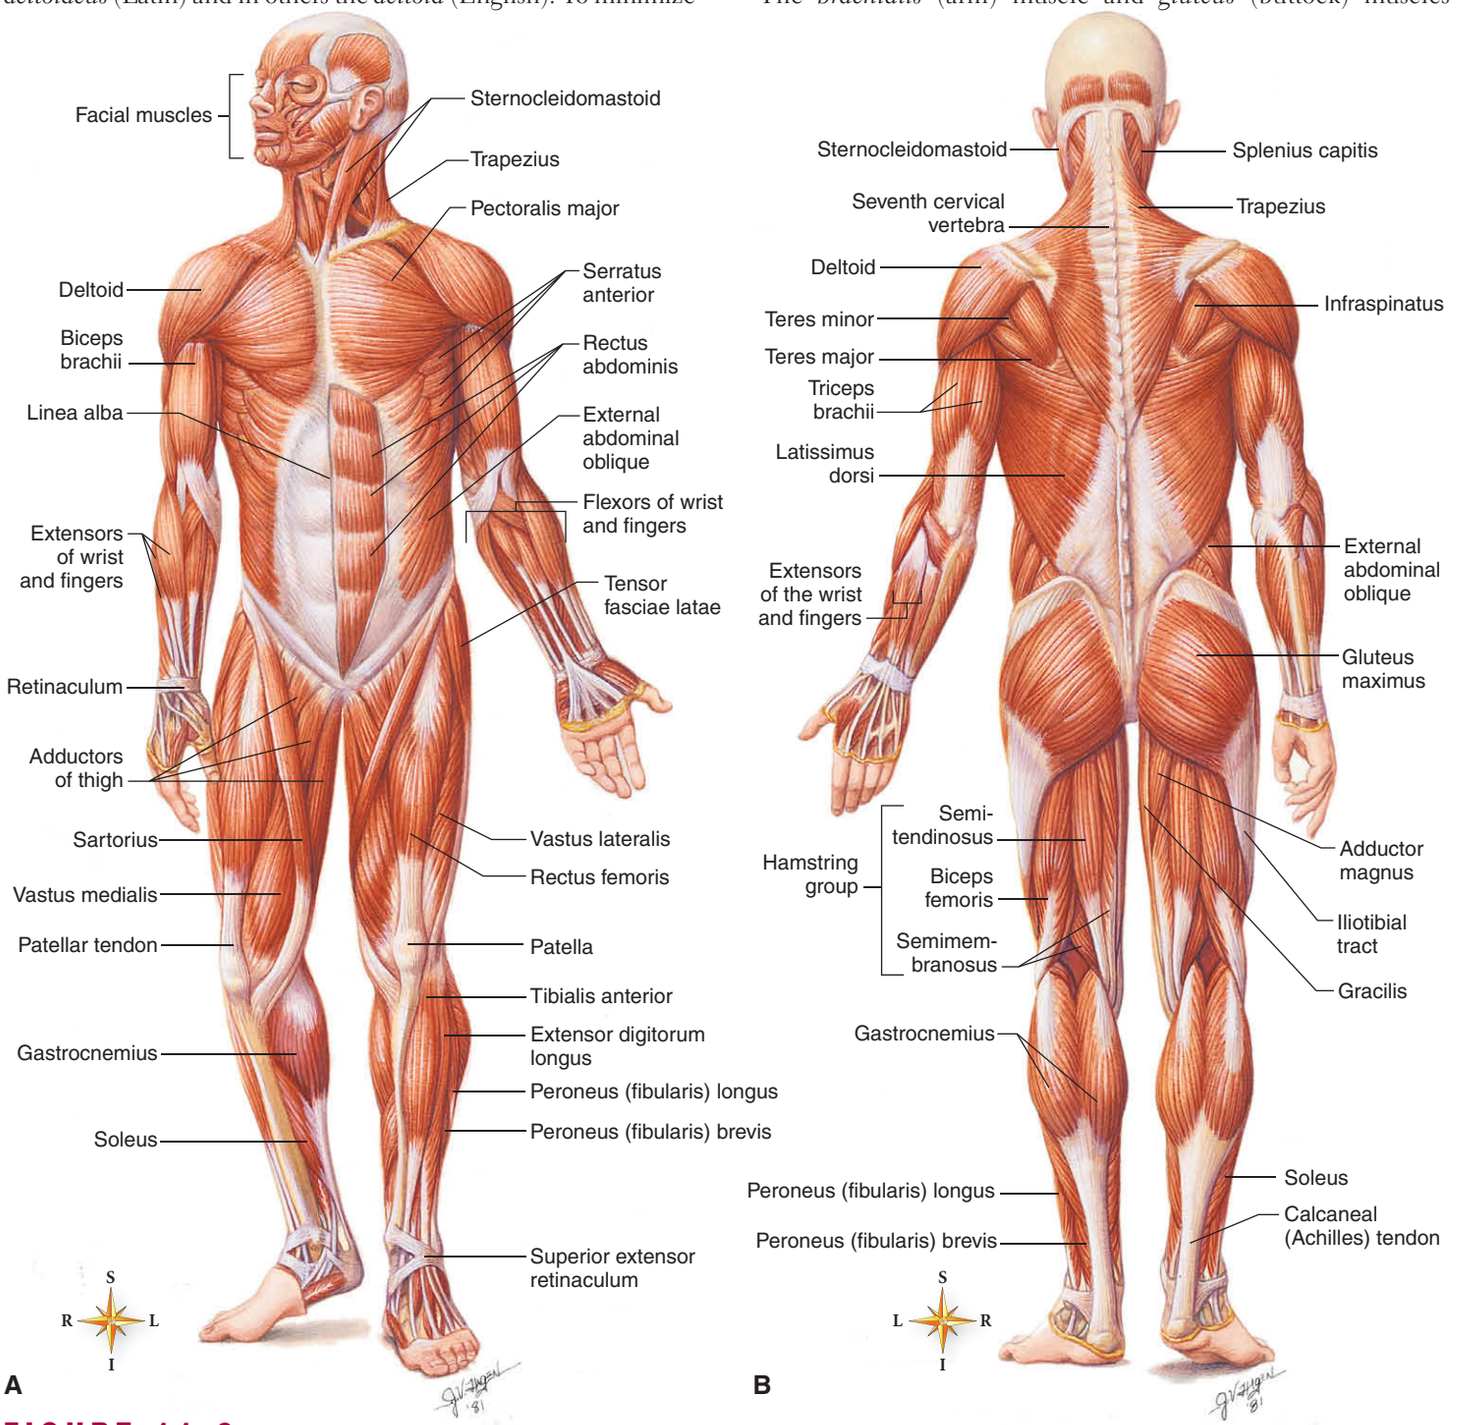
HOW MUSCLES ARE NAMED

The first thing you may notice as you start studying the muscles of the body is that many of the names seem difficult and foreign. The terms are less difficult if you keep in mind that most anatomical terms come from Latin.

Although we have strived to use only English names in this edition, some Latin terms still remain in common usage—especially in anatomy. This is certainly true in the health-related disciplines. For example, in some texts the deltoid muscle is called the *deltoideus* (Latin) and in others the *deltoid* (English). To minimize confusion, the terms used here will be the English versions from the *Terminologia Anatomica* (see Chapter 1). Even so, you will soon discover that the English versions are often the same or similar to the Latin versions!

Regardless of the muscle name used, when one understands the reasons for the term used, it will seem more logical and be easier to learn and understand. Many of the muscles of the body shown in Figure 11-6 or listed in Tables 11-2 through 11-6 are named according to one or more of the following features:

Location. Many muscles are named as a result of location. The *brachialis* (arm) muscle and *gluteus* (buttock) muscles



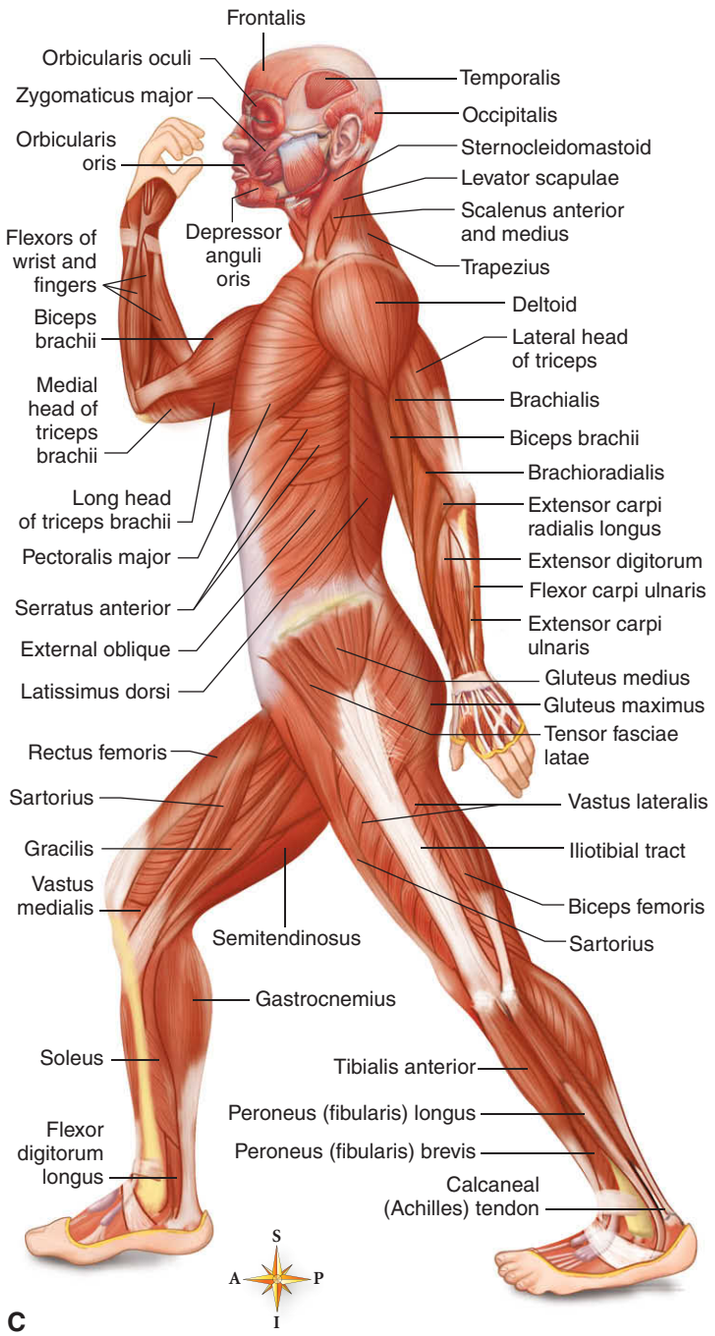


FIGURE 11-6

General overview of the body's musculature. A, Anterior view. **B,** Posterior view. **C,** Lateral view.

are examples. Table 11-2 gives a listing of some major muscles grouped by location.

Function. The function of a muscle often is a part of its name. The *adductor* muscles of the thigh adduct, or move, the leg toward the midline of the body. Table 11-3 lists selected muscles grouped according to function.

Shape. Shape is a descriptive feature used for naming many muscles. The *deltoid* (triangular) muscle covering the shoulder is deltoid, or triangular, in shape (see Table 11-4).

C

Direction of fibers. Muscles may be named according to the orientation of their fibers. The term *rectus* means straight. The fibers of the *rectus abdominis* muscle run straight up and down and are parallel to each other (see Table 11-5).

Number of heads or divisions. The number of divisions or heads (points of origin) may be used to name a muscle. The word part *-cep-* means *head. Biceps* (two), *triceps* (three), and *quadriceps* (four) refer to multiple heads, or points of origin. The *biceps brachii* is a muscle having two heads located in the arm (see Table 11-5).

Points of attachment. Origin and insertion points may be used to name a muscle. For example, the *sternocleidomastoid* has its origin on the sternum and clavicle and inserts on the mastoid process of the temporal bone.

TABLE 11-2 Selected Muscles Grouped According to Location

LOCATION	MUSCLES
Neck	Sternocleidomastoid
Back	Trapezius Latissimus dorsi
Chest	Pectoralis major Serratus anterior
Abdominal wall	External oblique
Shoulder	Deltoid
Arm	Biceps brachii Triceps brachii Brachialis
Forearm	Brachioradialis Pronator teres
Buttocks	Gluteus maximus Gluteus minimus Gluteus medius Tensor fascia latae
Thigh	
Anterior surface	Quadriceps femoris group Rectus femoris Vastus lateralis Vastus medialis Vastus intermedius
Medial surface	Gracilis Adductor group (brevis, longus, magnus)
Posterior surface	Hamstring group Biceps femoris Semitendinosus Semimembranosus
Leg	
Anterior surface	Tibialis anterior
Posterior surface	Gastrocnemius Soleus
Pelvic floor	Levator ani Coccygeus

TABLE 11-3 Selected Muscles Grouped According to Function

PART MOVED	EXAMPLE OF FLEXOR	EXAMPLE OF EXTENSOR	EXAMPLE OF ABDUCTOR	EXAMPLE OF ADDUCTOR
Head	Sternocleidomastoid	Semispinalis capitis		
Arm	Pectoralis major	Trapezius Latissimus dorsi	Deltoid	Pectoralis major with latissimus dorsi
Forearm	With forearm supinated: biceps brachii With forearm pronated: brachialis With semisupination or semipronation: brachioradialis	Triceps brachii		
Hand	Flexor carpi radialis and ulnaris Palmaris longus	Extensor carpi radialis, longus, and brevis Extensor carpi ulnaris	Flexor carpi radialis	Flexor carpi ulnaris
Thigh	Iliopsoas Rectus femoris (of quadriceps femoris group)	Gluteus maximus	Gluteus medius and minimus	Adductor group
Leg	Hamstrings	Quadriceps femoris group		
Foot	Tibialis anterior	Gastrocnemius Soleus	Evertors Fibularis longus Fibularis brevis	Invertor Tibialis anterior
Trunk	Iliopsoas Rectus abdominis	Erector spinae		

TABLE 11-4 Selected Muscles Grouped According to Shape

NAME	MEANING	EXAMPLE
Deltoid	Triangular	Deltoid
Gracilis	Slender	Gracilis
Trapezius	Trapezoid	Trapezius
Serratus	Notched	Serratus anterior
Teres	Round	Pronator teres
Rhomboid	Rhomboidal	Rhomboid major
Orbicularis	Round or circular	Orbicularis oris
Pectinate	Comblike	Pectineus
Piriformis	Wedge-shaped	Piriformis
Platys	Flat	Platysma
Quadratus	Square	Quadratus femoris
Lumbrical	Wormlike	Lumbricals

TABLE 11-5 Selected Muscles Grouped According to Number of Heads and Direction of Fiber

NAME	MEANING	EXAMPLE
Number of Heads		
Biceps	Two heads	Biceps brachii
Triceps	Three heads	Triceps brachii
Quadriceps	Four heads	Quadriceps
Digastric	Two bellies	Digastric
Direction of Fibers		
Oblique	Diagonal	External oblique rectus
Rectus	Straight	Rectus abdominis
Transverse	Transverse	Transversus abdominis
Circular	Around	Orbicularis oris
Spiral	Oblique	Supinator

TABLE 11-6 Selected Muscles Grouped According to Size

NAME	MEANING	EXAMPLE
Major	Large	Pectoralis major
Maximus	Largest	Gluteus maximus
Minor	Small	Pectoralis minor
Minimus	Smallest	Gluteus minimus
Longus	Long	Adductor longus
Brevis	Short	Extensor pollicis brevis
Latissimus	Very wide	Latissimus dorsi
Longissimus	Very long	Longissimus
Magnus	Very large	Adductor magnus
Vastus	Vast or huge	Vastus medialis

Size of muscle. The relative size of a muscle can be used to name a muscle, especially if it is compared to the size of nearby muscles (see Table 11-6). For example, the *gluteus maximus* is the largest muscle of the gluteal (Greek *glautos*, meaning "buttock") region. Nearby, there is a small gluteal muscle, the *gluteus minimus*, and a midsize gluteal muscle, the *gluteus medius*.

| QUICK CHECK |

8. Name the four major components of any lever system.
9. Identify the three types of lever systems found in the human body and give one example of each.
10. What type of lever system permits rapid and extensive movement and is the most common type found in the body?
11. List six criteria that may determine a muscle's name, and give an example of a specific muscle named according to each criterion.

Hints on How to Deduce Muscle Actions

To understand muscle actions, you first need to know certain anatomical facts, such as which bones muscles attach to and which joints they pull across. Then, if you relate these structural features to functional principles, you may find your study of muscles more interesting and less difficult than you may anticipate. Some specific suggestions for deducing muscle actions follow:

1. Start by making yourself familiar with the names, shapes, and general locations of the larger muscles by using Table 11-2 as a guide.
2. Try to deduce which bones the two ends of a muscle attach to from your knowledge of the shape and general location of the muscle. For example, look carefully at the deltoid muscle as illustrated in Figures 11-6 and 11-17. To which bones does it seem to attach? Check your answer with Table 11-14, p. 324.
3. Next, determine which bone moves when the muscle shortens. (The bone moved by a muscle's contraction is its insertion bone; the bone that remains relatively stationary is its origin bone.) In many cases you can tell which is the insertion bone by trying to move one bone and then another. In some cases either bone may function as the insertion bone. Although not all muscle attachments can be deduced as readily as those of the deltoid, they can all be learned more easily by using this deduction method than by relying on rote memory alone.
4. Deduce a muscle's actions by applying the principle that its insertion moves toward its origin. Check your conclusions with the text. Here, as in steps 2 and 3, the method of deduction is intended merely as a guide and is not adequate by itself for determining muscle actions.
5. To deduce which muscle produces a given action (instead of which action a given muscle produces, as in step 4), start by inferring the insertion bone (bone that moves during the action). The body and origin of the muscle will lie on one or more of the bones toward which the insertion moves—often a bone, or bones, proximal to the insertion bone. Couple these conclusions about origin and insertion with your knowledge of muscle names and locations to deduce the muscle that produces the action.

For example, if you wish to determine the prime mover for the action of raising the upper parts of the arms straight out to the sides, you infer that the muscle inserts on the humerus because this is the bone that moves. It moves toward the shoulder—that is, the clavicle and scapula—so the muscle probably has its origin on these bones. Because you know that the deltoid muscle fulfills these conditions, you conclude, and rightly so, that it is the muscle that raises the upper parts of the arms sideways.

IMPORTANT SKELETAL MUSCLES

The major skeletal muscles of the body are listed, grouped, and illustrated in the tables and figures that follow. Begin your study with an overview of important superficial muscles, shown in Figure 11-6. The remaining figures in this chapter illustrate individual muscles or important muscle groups.

Basic information about many muscles is given in Tables 11-7 to 11-19. Each table has a description of a group of muscles that move one part of the body. The actions listed for each muscle are those for which it is a prime mover. Remember, however, that a single muscle acting alone rarely accomplishes a given action. Instead, muscles act in groups as prime movers, synergists, antagonists, and fixators to bring about movements.

TABLE 11-7 Muscles of Facial Expression and Mastication

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Muscles of Facial Expression				
Occipitofrontalis (part of epicranius)				
Frontal belly	Epicranial aponeurosis	Tissues of eyebrows and bridge of nose	Raises eyebrows, wrinkles forehead horizontally	Cranial nerve VII
Occipital belly	Occipital bone (highest nuchal line)	Epicranial aponeurosis	Draws scalp backward	Cranial nerve VII
Corrugator supercilii	Frontal bone (superciliary ridge	Skin of eyebrow	Wrinkles forehead vertically	Cranial nerve VII
Orbicularis oculi	Encircles eyelid		Closes eye	Cranial nerve VII
Zygomaticus major	Zygomatic bone	Angle of mouth	Laughing (elevates angle of mouth)	Cranial nerve VII
Orbicularis oris	Encircles mouth		Draws lips together	Cranial nerve VII
Buccinator	Maxillae	Skin of sides of mouth	Facilitates smiling; blowing, as in playing trumpet	Cranial nerve VII
Depressor anguli oris	Mandible	Angle of mouth	Draws ends of mouth downward, as when frowning	Cranial IV
Muscles of Mastication				
Masseter	Zygomatic arch	Mandible (external surface)	Elevates mandible, closing jaw	Cranial nerve V
Temporalis	Temporal bone	Mandible	Elevates mandible; closing jaw	Cranial nerve V
Pterygoids (lateral and medial)	Undersurface of skull	Mandible (medial surface)	Grates teeth	Cranial nerve V

Muscles of Facial Expression

The muscles of facial expression (Table 11-7 and Figures 11-7 and 11-8) are unique in that at least one of their points of attachment is to the deep layers of the skin over the face or neck. Contraction of these muscles produces a variety of facial expressions.

The **occipitofrontalis** (ok-sip-i-toh-fron-TAL-is) is in reality two muscles. One portion lies over the forehead (frontal bone); the other covers the occipital bone in back of the head. The two muscular parts, or bellies, are joined by a connective tissue aponeurosis (the *epicranial aponeurosis*) that covers the top of the skull. The two occipitofrontalis bellies, along with the epicranial aponeurosis, are together called the *epicranius muscle*. The frontal belly of the occipitofrontalis raises the

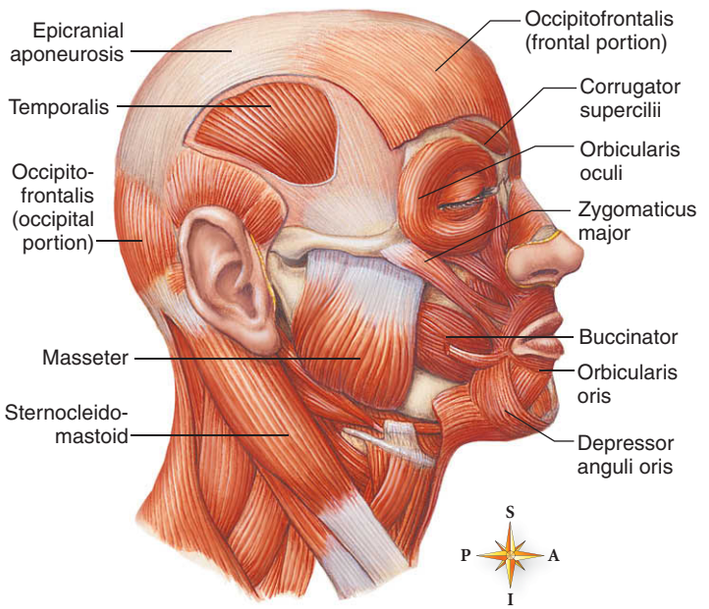

FIGURE 11-7

Muscles of facial expression and mastication. Lateral view.

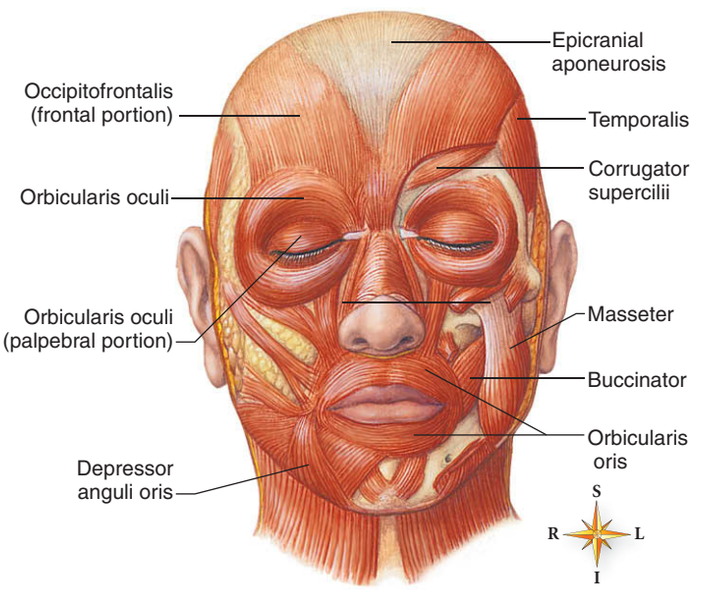

FIGURE 11-8

Muscles of facial expression and mastication. Anterior view.

eyebrows (surprise) and wrinkles the skin of the forehead horizontally. The posterior belly draws the scalp back toward the posterior neck.

The **corrugator supercilii** (COR-uh-gay-tor soo-per-SIL-ee-eye) draws the eyebrows together and produces vertical wrinkles above the nose (frowning). The **orbicularis oculi** (or-bik-yoo-LAIR-is OK-yoo-lye) encircles and closes the eye (blinking), whereas the **orbicularis oris** (OR-iss) and **buccinator** (BUK-si-NAY-tor) pucker the mouth (kissing) and press the lips and cheeks against the teeth. The **zygomaticus** (zye-goh-MAT-ik-us) **major** draws the corner of the mouth upward (laughing).

Muscles of Mastication

The muscles of **mastication** (mass-ti-KAY-shun) shown in Figure 11-9 are responsible for chewing movements. These powerful muscles (see Table 11-7) either elevate and retract the mandible (**masseter** [mah-SEE-ter] and **temporalis** [tem-poh-RAL-is]) or open and protrude it while causing sideways movement (**pterygoids** [TER-i-goidz]). The pull of gravity helps open the mandible during mastication, and the buccinator muscles play an important function by holding food between the teeth as the mandible moves up and down and from side to side.

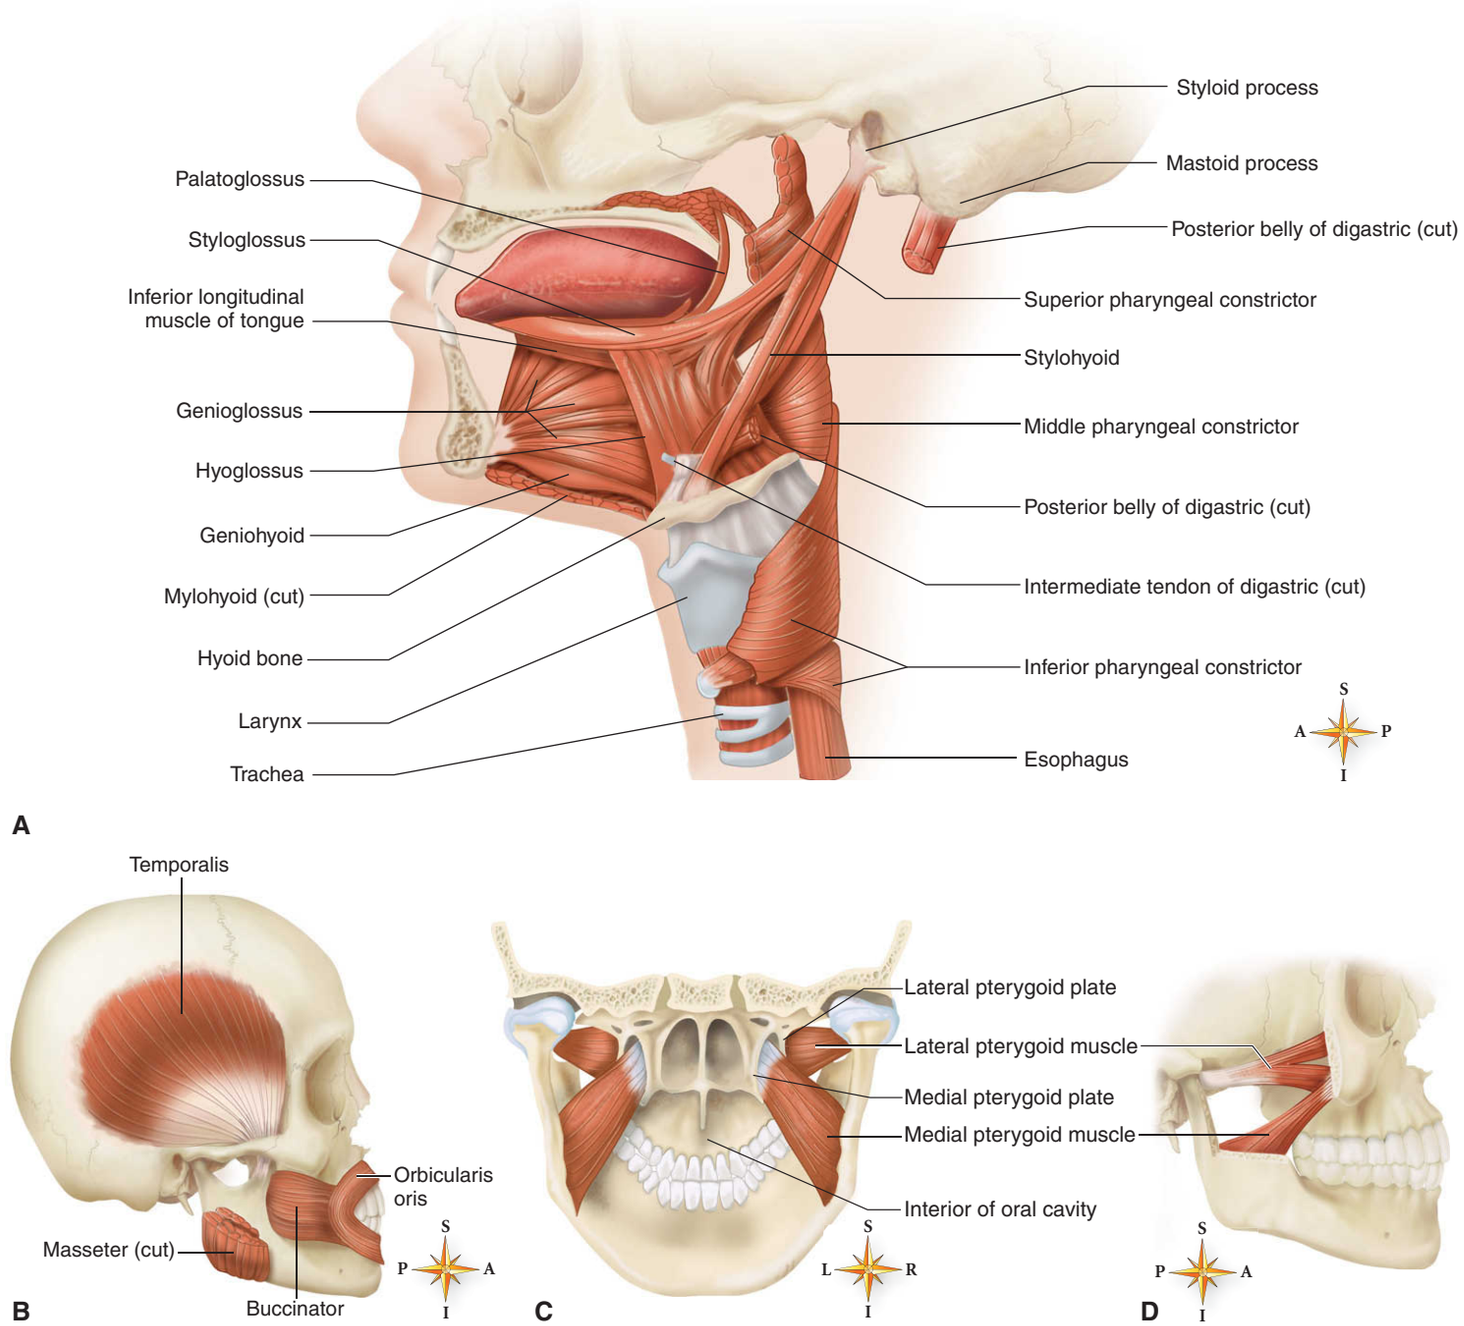

FIGURE 11-9

Muscles of mastication. A, Muscles of the tongue and pharynx. **B,** Right lateral dissection view showing the insertion of the temporalis muscle on the mandible—the masseter muscle is cut and part of the zygomatic arch has been removed. **C,** View of the pterygoids in a posterior dissection view. **D,** Lateral and medial pterygoid muscles viewed from the right side after removal of the zygomatic arch.

Muscles That Move the Head

Paired muscles on either side of the neck are responsible for head movements (Figure 11-10). Note the points of attachment and functions of important muscles in this group listed in Table 11-8. When both **sternocleidomastoid** (STERN-oh-KLYE-doh-MAS-toyd) muscles (see Figure 11-7) contract at the same time, the head is flexed on the thorax—hence the name "prayer muscle." If only one muscle contracts, the head and face are turned to the opposite side.

The broad *semispinalis capitis* (sem-ee-spi-NAL-is KAP-i-tis) is an extensor of the head and helps bend it laterally. Acting together, the **splenius capitis** (SPLE-nee-us KAP-i-tis) muscles serve as strong extensors that return the head to the upright position after flexion. When either muscle acts alone, contraction results in rotation and tilting toward that side. The bandlike **longissimus capitis** (lon-JIS-i-mus KAP-i-tis) muscles are covered and not visible in Figure 11-10. They run from the neck vertebrae to the mastoid process of the temporal bone on either side and cause extension of the head when acting together. One contracting muscle will bend and rotate the head toward the contracting side.

| QUICK CHECK |

12. What is meant by the terms *origin* and *insertion?*
13. Which muscle of facial expression has two parts, one lying over the forehead and the other covering the back of the skull?
14. What group of muscles facilitates chewing movements?
15. What is the action of the sternocleidomastoid muscle?

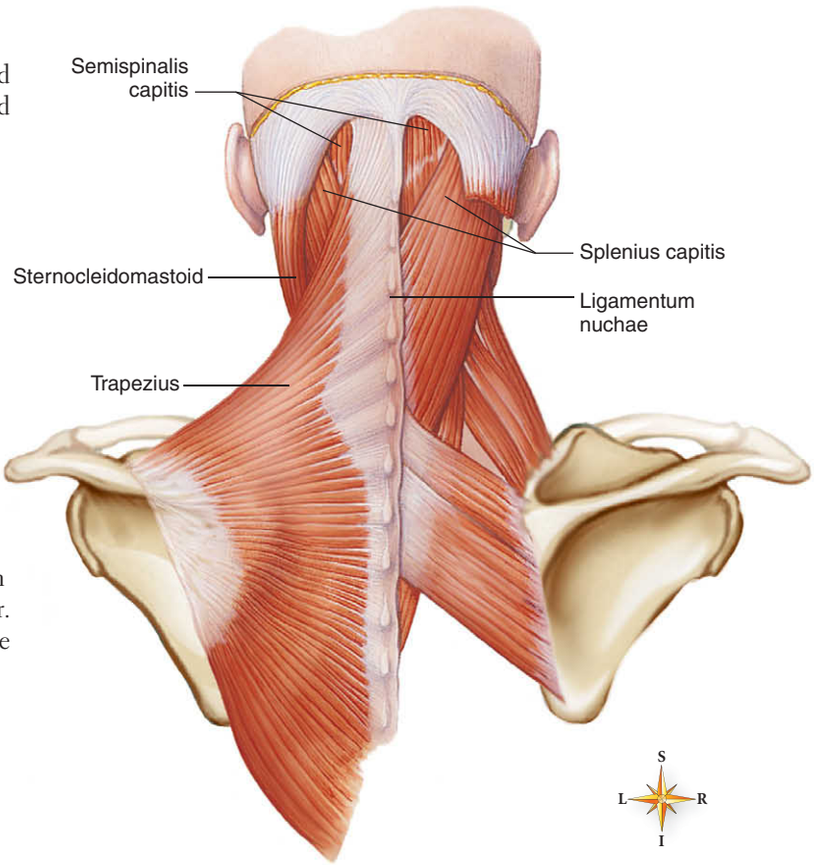

FIGURE 11-10

Muscles that move the head. Posterior view of muscles of the neck and the back.

TABLE 11-8 Muscles That Move the Head

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Sternocleidomastoid	Sternum	Temporal bone (mastoid process)	Flexes head and neck (prayer muscle)	Accessory nerve
	Clavicle		One muscle alone, rotates head toward opposite side; spasm of this muscle alone or associated with trapezius called *torticollis,* or wryneck	
Semispinalis capitis	Vertebrae (transverse processes of upper six thoracic, articular processes of lower four cervical)	Occipital bone (between superior and inferior nuchal lines)	Extends head and neck; bends it laterally	First five cervical nerves
Splenius capitis	Ligamentum nuchae	Temporal bone (mastoid process)	Extends head/neck	Second, third, and fourth cervical nerves
	Vertebrae (spinous processes of upper three or four thoracic)	Occipital bone	Bends and rotates head toward same side as contracting muscle	
Longissimus capitis	Vertebrae (transverse processes of upper six thoracic, articular processes of lower four cervical)	Temporal bone (mastoid process)	Extends head and neck Bends and rotates head toward contracting side	Multiple innervation

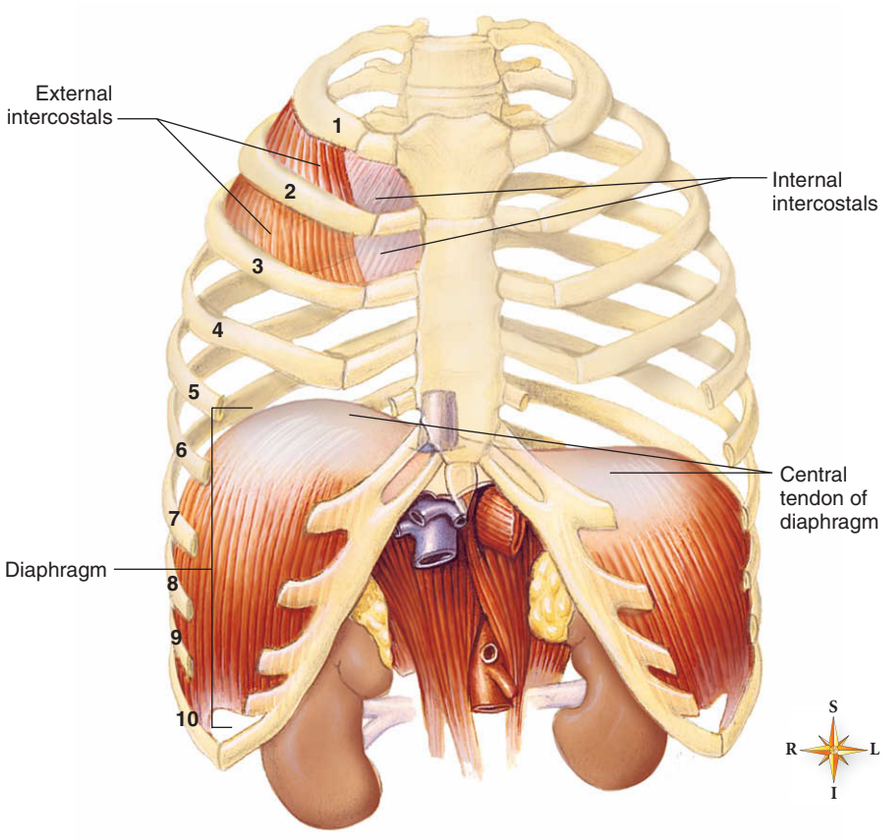

FIGURE 11-11

Muscles of the thorax. Anterior view. Note the relationship of the internal and external intercostal muscles and placement of the diaphragm.

TRUNK MUSCLES

Muscles of the Thorax

The muscles of the thorax are of critical importance in respiration (discussed in Chapter 27). Note in Figure 11-11 and Table 11-9 that the **internal** and **external intercostal** (IN-ter-KOS-tal) **muscles** attach to the ribs at different places and their fibers are oriented in different directions. As a result, contraction of the external intercostals elevates and contraction of the internal intercostals depresses the ribs—important in the breathing process. During inspiration the dome-shaped **diaphragm** (DYE-ah-fram) flattens, thus increasing the size and volume of the thoracic cavity. As a result, air enters the lungs.

TABLE 11-9 **Muscles of the Thorax**

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
External intercostals	Rib (lower border; forward fibers)	Rib (upper border of rib below origin)	Elevate ribs	Intercostal nerves
Internal intercostals	Rib (inner surface, lower border; backward fibers)	Rib (upper border of rib below origin)	Depress ribs	Intercostal nerves
Diaphragm	Lower circumference of thorax (of rib cage)	Central tendon of diaphragm	Enlarges thorax, thereby causing inspiration	Phrenic nerves

Muscles of the Abdominal Wall

The muscles of the anterior and lateral abdominal wall (Figures 11-12 and 11-13; Table 11-10) are arranged in three layers, with the fibers in each layer running in different directions much like the layers of wood in a sheet of plywood. The result is a very strong "girdle" of muscle that covers and supports the abdominal cavity and its internal organs.

The fibers in the three layers of muscle in the anterolateral wall are arranged to provide maximum strength. In the **external oblique** the muscle fascicles or fibers extend inferiorly and medially, whereas the fibers of the middle muscle layer, the **internal oblique,** run almost at right angles to those of the external oblique above it. The fibers of the **transversus abdominis,** the innermost muscle layer, are, as the name implies, directed transversely. In addition to these sheetlike muscles, the band- or strap-shaped

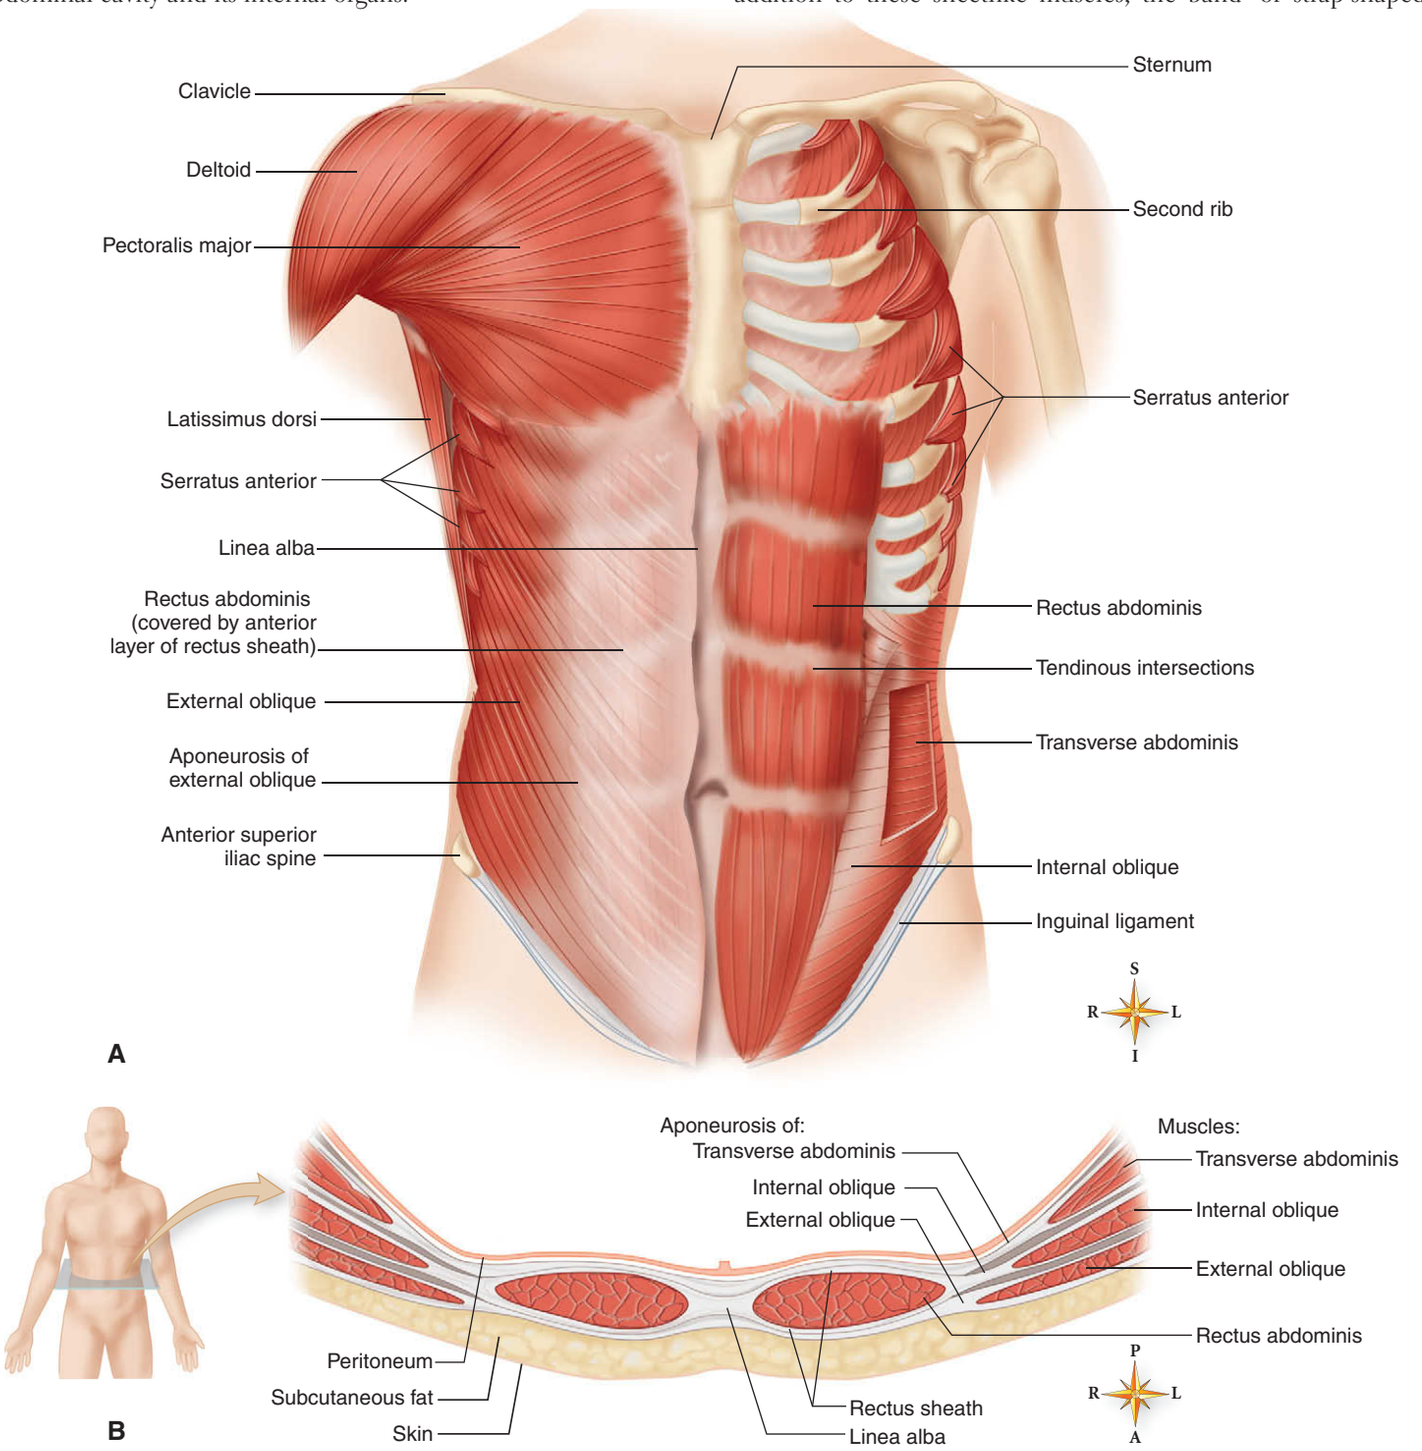

FIGURE 11-12

Muscles of the trunk and abdominal wall. A, Superficial muscles are visible on the right side of the body and deeper muscles on the left side of the body. **B,** Transverse section of the anterior wall above the umbilicus (see inset for location).

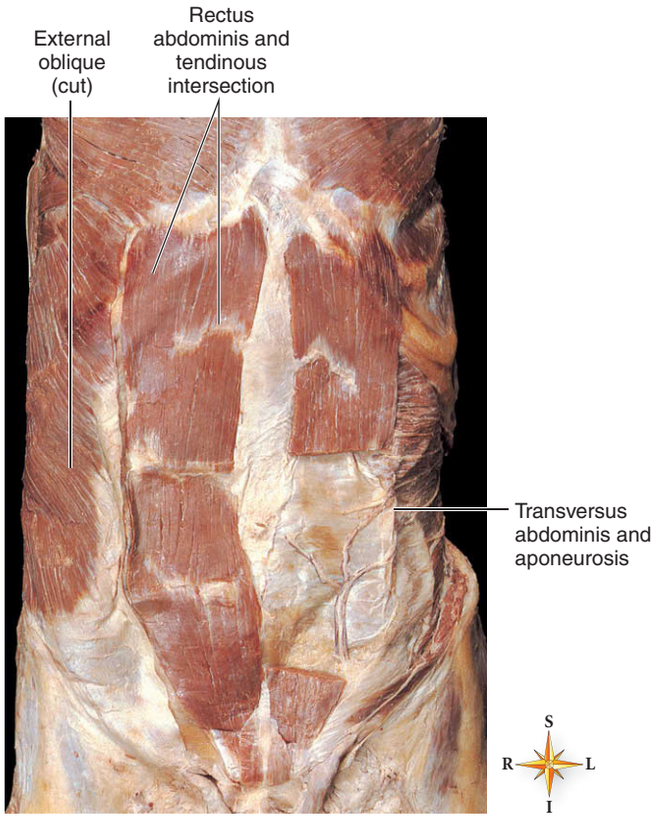

FIGURE 11-13

Dissection photo of the abdominal wall. The covering rectus sheaths, the left oblique muscles, and part of the left rectus have been removed.

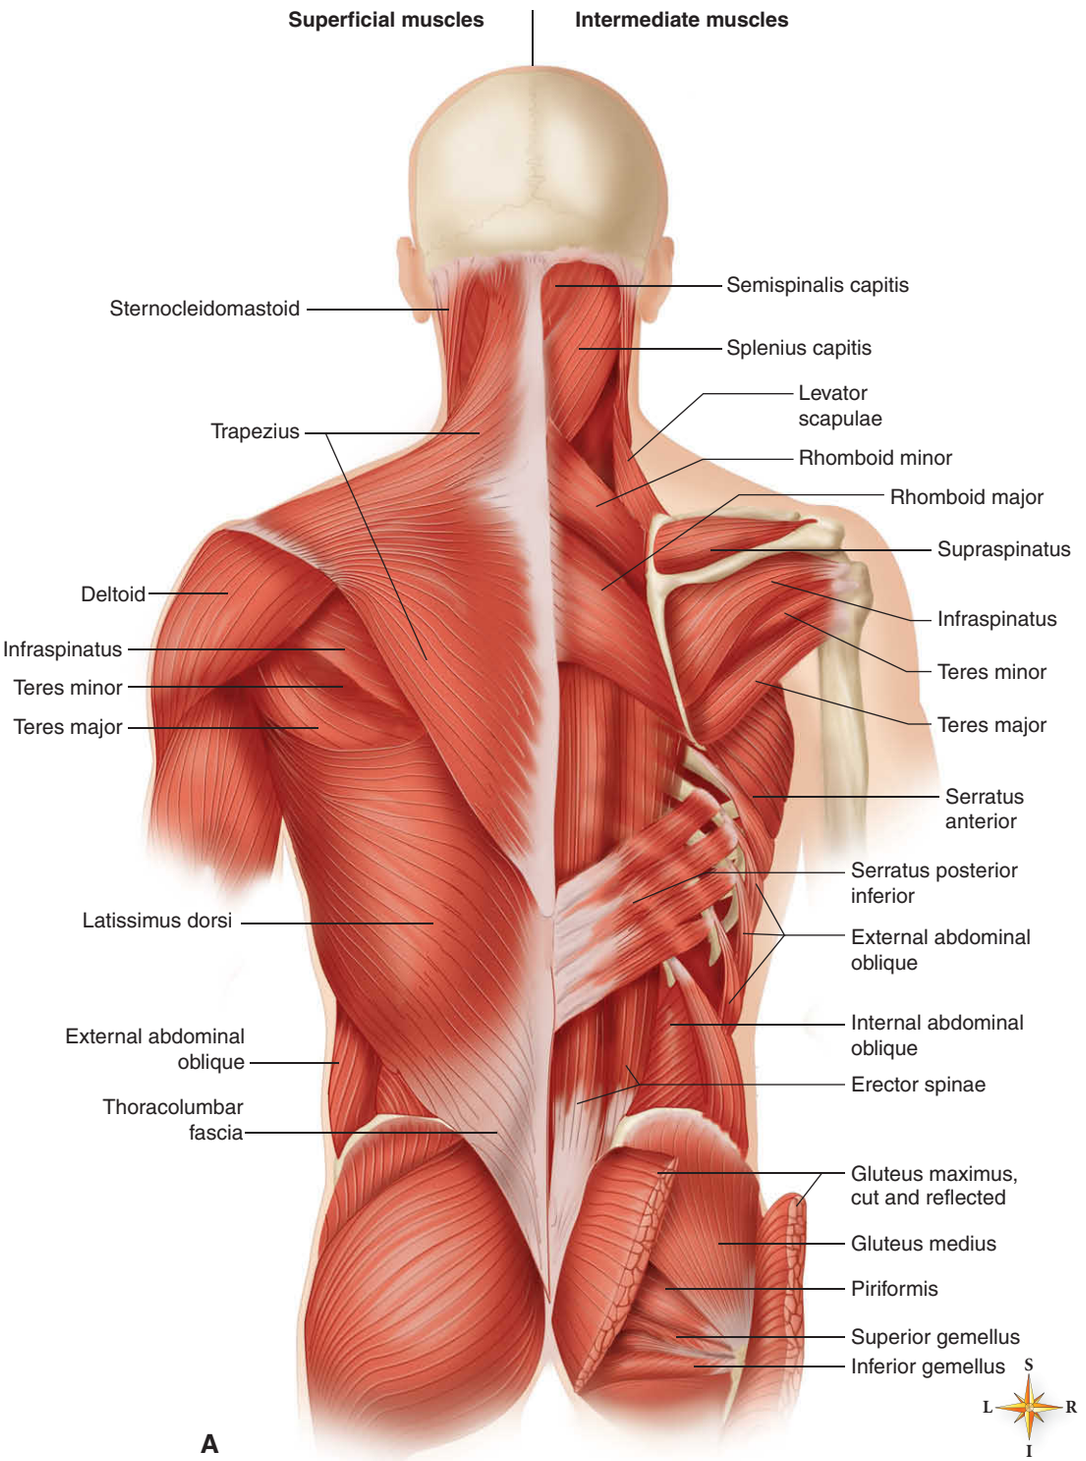
rectus abdominis muscle runs down the midline of the abdomen from the thorax to the pubis. Note in Figure 11-12 that its parallel running fibers are "interrupted" by three tendinous intersections. When a surgeon "opens" or "closes" an incision through the anterolateral wall, attempts are made to maintain the inherent strength of the wall after surgery by sparing important nerves and blood vessels and by using suturing techniques during closure that will restore the direction of fibers in the cut layers of muscle.

In Figure 11-13, a number of superficial structures have been cut or partially removed. For example, part of the internal oblique has been removed to expose the underlying transversus abdominis, and the anterior (superficial) layer of the **rectus sheath** has been removed to better visualize the **rectus abdominis muscle** and its tendinous intersections. Note also in Figure 11-12, *B*, that the aponeuroses of the external oblique, internal oblique, and transversus abdominis muscles form the rectus sheaths that cover the rectus abdominis muscles and then fuse in the midline to form a tough band of connective tissue called the **linea alba** (white line), that extends from the xiphoid process to the pubis. Occasionally, a surgical procedure will permit an incision through the linea alba rather than through abdominal musculature. Since the linea alba is essentially avascular in some areas, blood loss in such procedures is generally less than what may occur in other approaches.

Working as a group, the abdominal muscles not only protect and hold the abdominal viscera in place, they are responsible for a number of vertebral column movements, including flexion, lateral bending, and some rotation. These important muscles are

TABLE 11-10 Muscles of the Abdominal Wall

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
External oblique	Ribs (lower eight)	Pelvis (iliac crest and pubis by way of the inguinal ligament)	Compresses abdomen	Lower seven intercostal nerves and iliohypogastric nerves
		Linea alba by way of an aponeurosis	Rotates trunk laterally	
Internal oblique	Pelvis (iliac crest and iliopsoas fascia)	Ribs (lower three)	Important postural function of all abdominal muscles is to pull the front of the pelvis upward, thereby flattening the lumbar curve of the spine; when these muscles lose their tone, common figure faults of protruding abdomen and lordosis develop	Last three intercostal nerves; iliohypogastric and ilioinguinal nerves
	Lumbodorsal fascia	Linea alba		
Transversus abdominis	Ribs (lower six) Pelvis (iliac crest, iliopsoas fascia)	Pubic bone Linea alba	Same as external oblique	Last three intercostal nerves; iliohypogastric and ilioinguinal nerves
	Lumbodorsal fascia	Ribs (costal cartilage of fifth, sixth, and seventh ribs)	Same as external oblique	Last five intercostal nerves; iliohypogastric and ilioinguinal nerves
Rectus abdominis	Pelvis (pubic bone and pubic symphysis)	Sternum (xiphoid process)	Same as external oblique; because abdominal muscles compress the abdominal cavity, they aid in straining, defecation, forced expiration, childbirth; abdominal muscles are antagonists of the diaphragm, relaxing as it contracts and vice versa Flexes trunk	Last six intercostal nerves
Quadratus lumborum	Iliolumbar ligament; iliac crest	Last rib; transverse process of vertebrae (L1-L4)	Flexes vertebral column laterally; depresses last rib	Lumbar



also involved in respiration and in helping "push" a baby through the birth canal during delivery. They also play a role in assisting in urination, defecation, and vomiting.

Muscles of the Back

Considering the large number of us who suffer from back pain, strain, and injury either occasionally or chronically, you can imagine the importance of the back muscles to health and fitness. Statistics show that 80% of the population in most areas of the world experience backache at some time in their lives. Although symptoms may vary from mild to disabling, "back problems" continue to plague large numbers of individuals and pose significant financial, social, and health care problems. The superficial back muscles play a major role in moving the head and limbs and are illustrated in Figure 11-14, *A*. The deep back muscles (Figure 11-14, *B*) not only allow us to move our vertebral column,

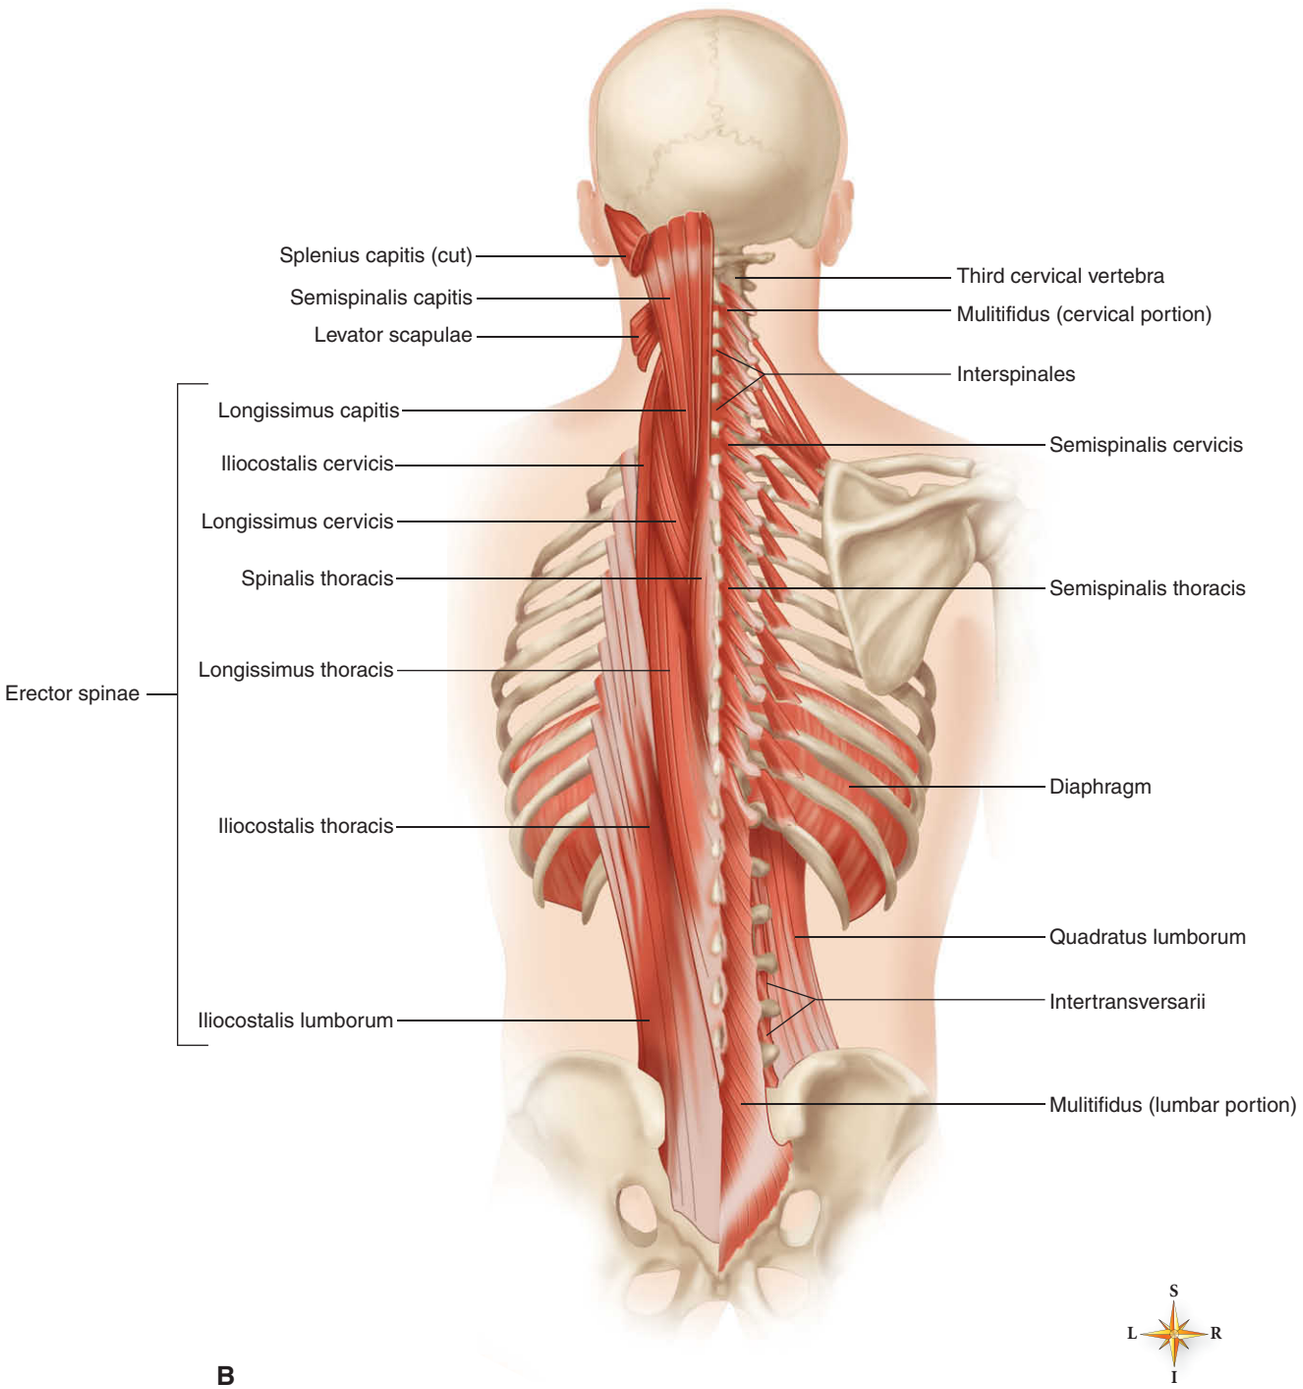


FIGURE 11-14

Muscles of the back. A, Superficial *(left)* and intermediate *(right)* muscle dissection of the back—posterior view. The illustration shows a two-stage dissection. Superficial muscles of the neck and back are shown on the left side and an intermediate-depth dissection is shown on the right. **B,** Deep muscle dissection of the back—posterior view. The superficial and intermediate muscles have been removed. The muscles in the gluteal region have been removed to expose the pelvic insertion of the multifidus.

thus helping us bend this way and that, but also stabilize our trunk so that we can maintain a stable posture. These muscles really get a work-out when we lift something heavy because they have to hold the body straight while the load is trying to bend the back.

The **erector spinae muscle** group consists of a number of long, thin muscles that travel all the way down our backs (see Figure 11-14). These muscles extend (straighten or pull back) the vertebral column and also flex the back laterally and rotate it a little. Even deeper than the erector spinae muscles are several additional back muscles. The **interspinales** and **multifidus groups,** for example, each connect one vertebra to the next; they also help extend the back and neck or flex them to the side. Table 11-11 and Figure 11-14 summarize some of the important deep back muscles.

B

TABLE 11-11 Muscles of the Back

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Erector spinae group				
Iliocostalis group	Various regions of the pelvis and ribs	Ribs and vertebra (superior to the origin)	Extends, laterally flexes the vertebral column	Spinal, thoracic, or lumbar nerves
Longissimus group	Cervical and thoracic vertebrae, ribs	Mastoid process, upper cervical vertebrae, or upper lumbar vertebrae	Extends head, neck, or vertebral column	Cervical or thoracic and lumbar nerves
Spinalis group	Lower cervical or lower thoracic/upper lumbar vertebrae	Upper cervical or middle/upper thoracic vertebrae (superior to the origin)	Extends the neck or vertebral column	Cervical or thoracic nerves
Transversospinalis group				
Semispinalis group	Transverse processes of vertebrae (T2–T11)	Spinous processes of vertebrae (C2–T4)	Extends neck or vertebral column	Cervical or thoracic nerves
Multifidus group	Transverse processes of vertebrae; sacrum and ilium	Spinous processes of (next superior) vertebrae	Extends, rotates vertebral column	Spinal nerves
Rotatores group	Transverse processes of vertebrae	Spinous processes of (next superior) vertebrae	Extends, rotates vertebral column	Spinal nerves
Splenius	Spinous processes of vertebrae (C7–T1 or T3–T6)	Lateral occipital/mastoid or transverse processes of vertebrae (C1–C4)	Rotates, extends neck and flexes neck laterally	Cervical nerves
Interspinales group	Spinous processes of vertebrae	Spinous processes (of next superior vertebra)	Extends back and neck	Spinal nerves

Muscles of the Pelvic Floor

Structures in the pelvic cavity are supported by a reinforced muscular floor that guards the outlet below. The muscular pelvic floor filling the diamond-shaped outlet is called the **perineum** (pair-i-NEE-um). Passing through the floor are the anal canal and urethra in both sexes and the vagina in the female.

The two **levator ani** and **coccygeus muscles** form most of the pelvic floor. They stretch across the pelvic cavity like a hammock. This diamond-shaped outlet can be divided into two triangles by a line drawn from side to side between the ischial tuberosities. The **urogenital triangle** is anterior to this line (above) and extends to the pubic symphysis, and the **anal triangle** is posterior (behind it) and ends at the coccyx. Note in Figure 11-15 that structures in the urogenital triangle include the **ischiocavernosus** and **bulbospongiosus muscles** associated with the penis in the male and the vagina in the female. Constriction of muscles called the **urethral sphincter,** which encircle the urethra in both sexes, helps control urine flow. The anal triangle allows passage of the anal canal. The terminal portion of the canal is surrounded by the **external anal sphincter,** which regulates defecation. The origin, insertion, function, and innervation of important muscles of the pelvic floor are listed in Table 11-12. The coccygeus muscles lie behind the levator ani and are not visible in Figure 11-15.

16. Name the skeletal muscles that produce respiratory movements.
17. Name two functions of the rectus abdominis muscle.
18. What is the perineum?

TABLE 11-12 Muscles of the Pelvic Floor

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Levator ani	Pubis and spine of the ischium	Coccyx	Together with the coccygeus muscles form the floor of the pelvic cavity and support the pelvic organs	Pudendal nerve
Ischiocavernosus	Ischium	Penis or clitoris	Compress the base of the penis or clitoris	Perineal nerve
Bulbospongiosus				
Male	Bulb of the penis	Perineum and bulb of the penis	Constricts the urethra and erects the penis	Pudendal nerve
Female	Perineum	Base of the clitoris	Erects the clitoris	Pudendal nerve
Deep transverse perineal	Ischium	Central tendon (median raphe)	Supports the pelvic floor	Pudendal nerve
Urethral sphincter	Pubic ramus	Central tendon (median raphe)	Constricts the urethra	Pudendal nerve
External anal sphincter	Coccyx	Central tendon (median raphe)	Closes the anal canal	Pudendal and S4

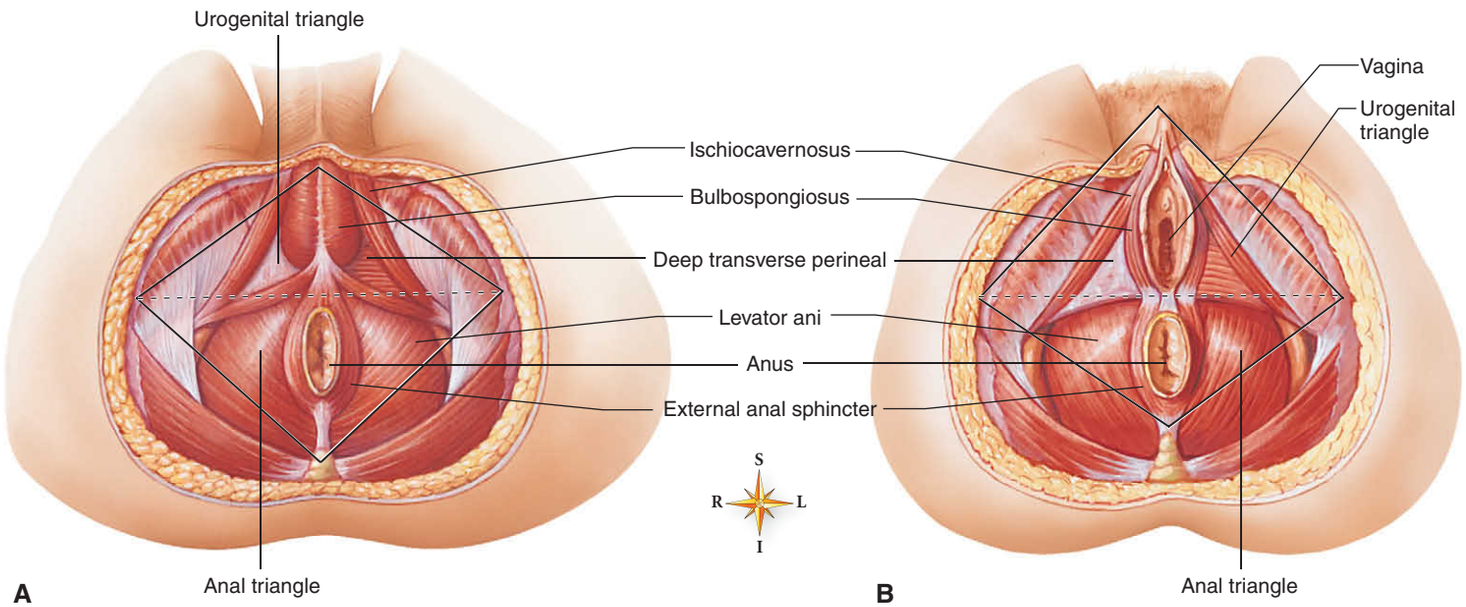

FIGURE 11-15

UPPER LIMB MUSCLES

The muscles of the upper limb include those acting on the shoulder or pectoral girdle and muscles located in the arm, forearm, and hand.

Muscles Acting on the Shoulder Girdle

Attachment of the upper extremity to the torso is by muscles that have an anterior location (chest) or posterior placement (back and neck). Six muscles (Table 11-13; Figure 11-16) that pass from the axial skeleton to the shoulder or pectoral girdle (scapula and clavicle) serve to not only "attach" the upper extremity to the body but also do so in such a way that extensive movement is possible. The clavicle can be elevated and depressed and moved forward and back. The scapula is capable of an even greater variety of movements.

The **pectoralis** (pek-toh-RAL-is) **minor** lies under the larger pectoralis major muscle on the anterior chest wall. It helps "fix" the scapula against the thorax and also raises the ribs during forced inspiration. Another anterior chest wall muscle—the **serratus** (ser-RAY-tus) **anterior**—helps hold the scapula against the thorax to prevent "winging" and is a strong abductor that is useful in pushing or punching movements.

The posterior muscles acting on the shoulder girdle include the **levator scapulae** (leh-VAY-tor SCAP-yoo-lee), which elevates the scapula; the **trapezius** (trah-PEE-zee-us), which is used to "shrug" the shoulders; and the **rhomboid** (ROM-boyd) **major** and **minor muscles,** which serve to adduct and elevate the scapula.

TABLE 11-13 Muscles Acting on the Shoulder Girdle

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Trapezius	Occipital bone (protuberance)	Clavicle	Raises or lowers the shoulders and shrugs them	Spinal accessory; second, third, and fourth cervical nerves
	Vertebrae (cervical and thoracic)	Scapula (spine and acromion)	Extends the head and neck when the occiput acts as the insertion	
Pectoralis minor	Ribs (second to fifth)	Scapula (coracoid)	Pulls the shoulder girdle down and forward	Medial and lateral anterior thoracic nerve
Serratus anterior	Ribs (upper eight or nine)	Scapula (anterior surface, vertebral border)	Pulls the shoulder down and forward; abducts and rotates it upward	Long thoracic nerve
Levator scapulae	C1–C4 (transverse processes)	Scapula (superior angle)	Elevates and retracts the scapula and abducts the neck	Dorsal scapular nerve
Rhomboid				
Major	T1–T4	Scapula (medial border)	Retracts, rotates, and fixes the scapula	Dorsal scapular nerve
Minor	C6–C7	Scapula (medial border)	Retracts, rotates, elevates, and fixes the scapula	Dorsal scapular nerve

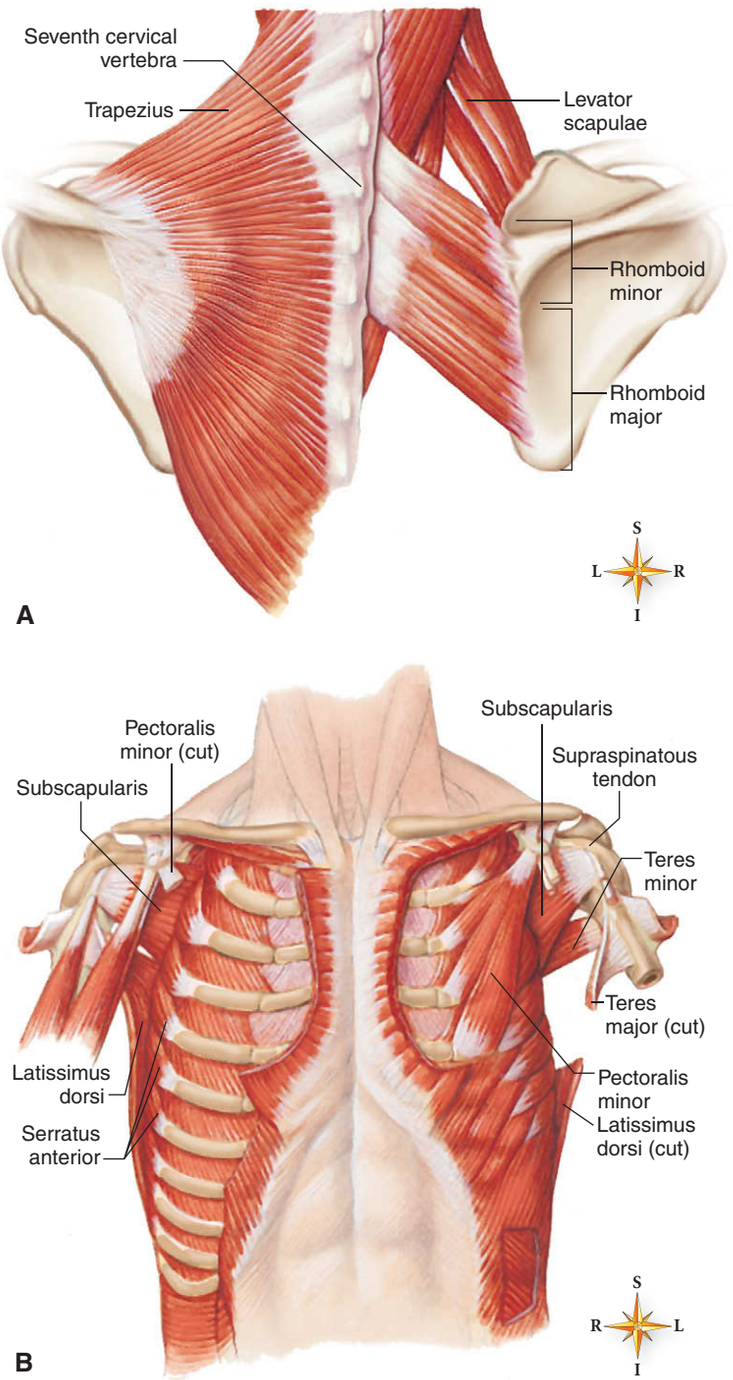

FIGURE 11-16

Muscles acting on the shoulder girdle. A, Posterior view. The trapezius has been removed on the right to reveal the deeper muscles. **B,** Anterior view. The pectoralis major has been removed on both sides. The pectoralis minor has also been removed on the right side.

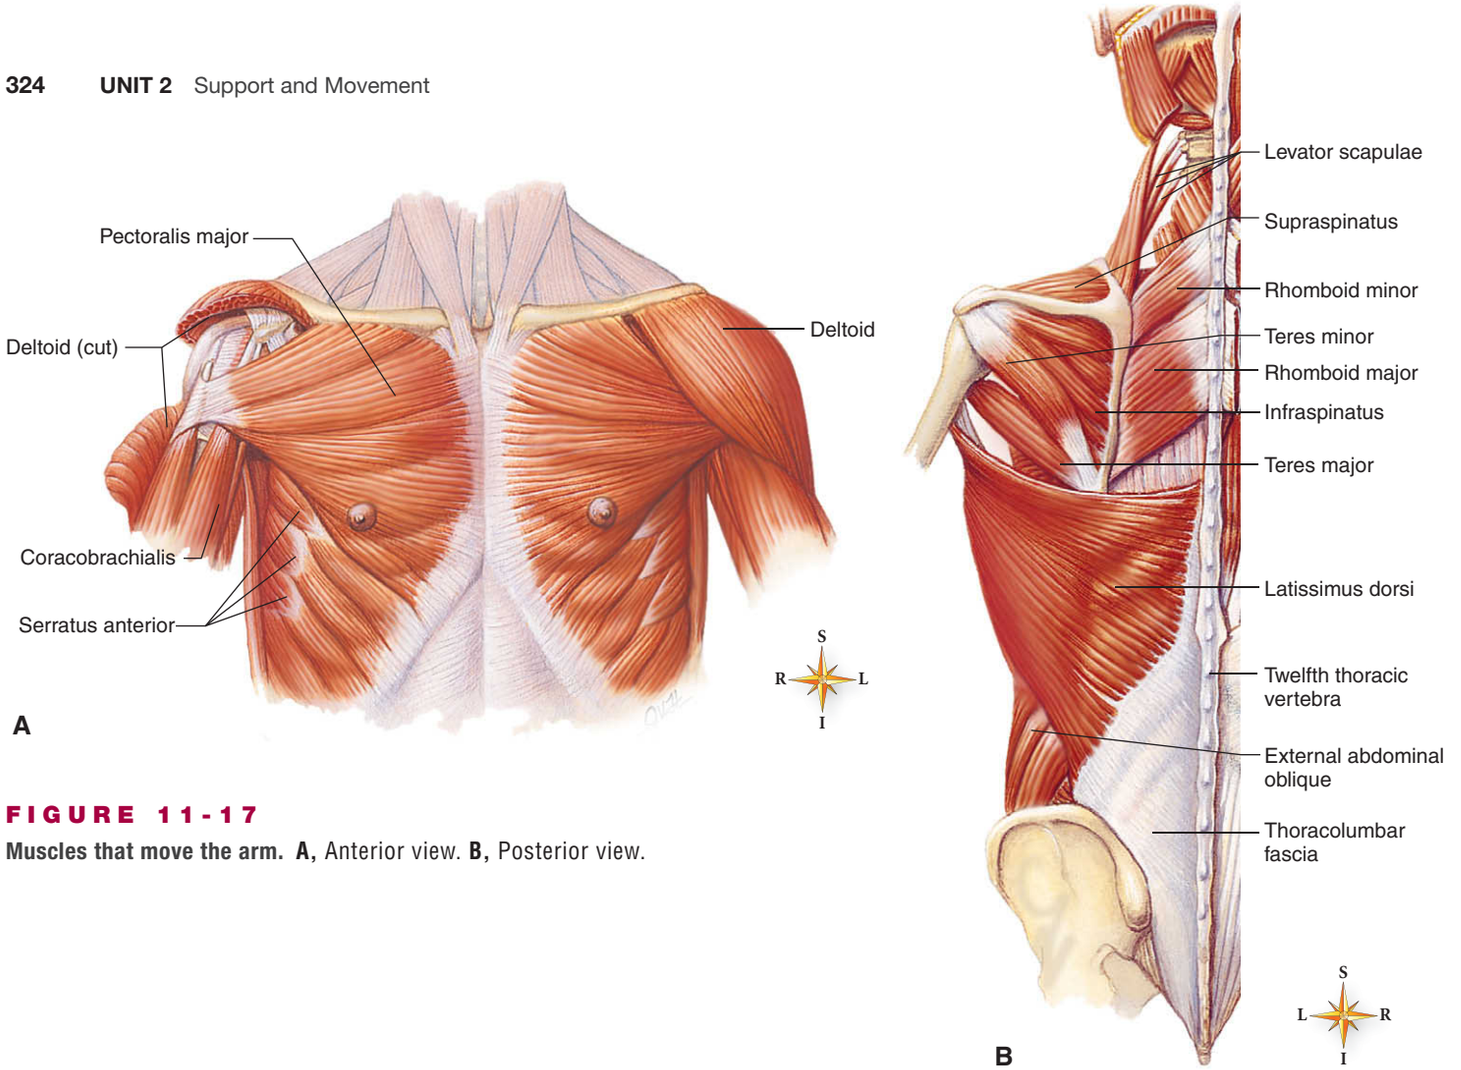

FIGURE 11-17

Muscles that move the arm. **A,** Anterior view. **B,** Posterior view.

TABLE 11-14 Muscles That Move the Arm

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Axial*				
Pectoralis major	Clavicle (medial half) Sternum Costal cartilages of the true ribs	Humerus (greater tubercle)	Flexes the arm Adducts the arm anteriorly; draws it across the chest	Medial and lateral anterior thoracic nerves
Latissimus dorsi	Vertebrae (spines of the lower thoracic, lumbar, and sacral) Ilium (crest) Lumbodorsal fascia	Humerus (intertubercular groove)	Extends the arm Adducts the arm posteriorly	Thoracodorsal nerve
Scapular*				
Deltoid	Clavicle Scapula (spine and acromion)	Humerus (lateral side about halfway down—deltoid tubercle)	Abducts the arm Assists in flexion and extension of the arm	Axillary nerve
Coracobrachialis	Scapula (coracoid process)	Humerus (middle third, medial surface)	Adduction; assists in flexion and medial rotation of the arm	Musculocutaneous nerve
Supraspinatus†	Scapula (supraspinous fossa)	Humerus (greater tubercle)	Assists in abducting the arm	Suprascapular nerve
Teres minor†	Scapula (axillary border)	Humerus (greater tubercle)	Rotates the arm outward	Axillary nerve
Teres major	Scapula (lower part, axillary border)	Humerus (upper part, anterior surface)	Assists in extension, adduction, and medial rotation of the arm	Lower subscapular nerve
Infraspinatus†	Scapula (infraspinatus border)	Humerus (greater tubercle)	Rotates the arm outward	Suprascapular nerve
Subscapularis†	Scapula (subscapular fossa)	Humerus (lesser tubercle)	Medial rotation	Suprascapular nerve

**Axial* muscles originate on the axial skeleton. *Scapular* muscles originate on the scapula.
†Muscles of the rotator cuff (SITS muscles).

Muscles That Move the Arm

The shoulder is a synovial joint of the ball-and-socket type. As a result, extensive movement is possible in every plane of motion (Box 11-2). Muscles that move the upper part of the arm can be grouped according to function as flexors, extensors, abductors, adductors, and medial and lateral rotators (Table 11-14; Figure 11-17). The actions listed in Table 11-14 include primary actions and important secondary functions.

The **deltoid** (DEL-toyd) is a good example of a multifunction muscle. It has three groups of fibers and may act as three separate muscles. Contraction of the anterior fibers will flex the arm, whereas the lateral fibers abduct and the posterior fibers serve as extensors. Four other muscles serve as both a structural and functional cuff around the shoulder joint and are referred to as the **rotator cuff muscles** (Figure 11-18). They include the **supraspinatus, infraspinatus, teres minor,** and **subscapularis**—the so-called *SITS muscles*.

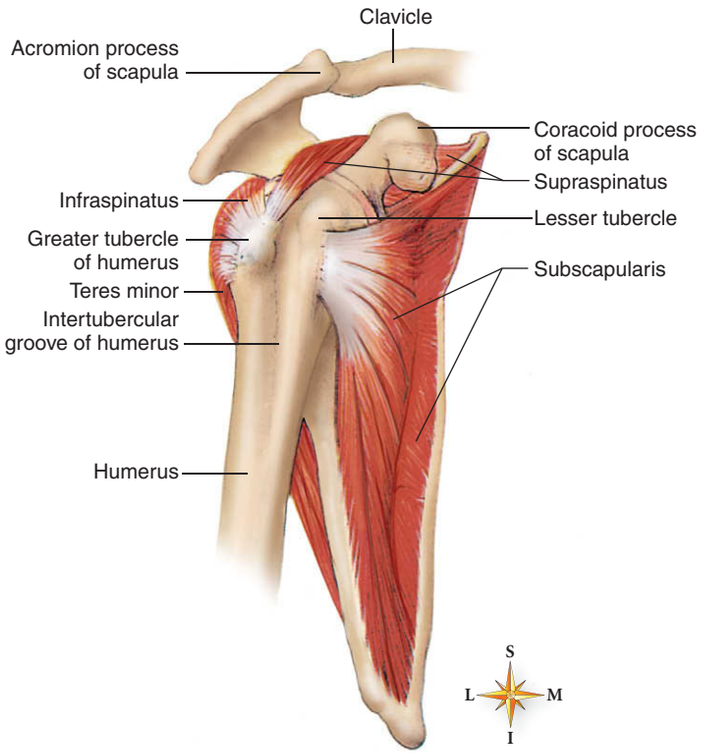

FIGURE 11-18

Rotator cuff muscles. Anterior view of the right shoulder showing the tendons of the teres minor, infraspinatus, supraspinatus, and subscapularis muscles surrounding the head of the humerus.

Box 11-2 | SPORTS and FITNESS

Shoulder Joint Stability

The disparity in size between the large and nearly hemispheric head of the humerus and the much smaller and shallow glenoid cavity of the scapula is of great clinical significance. Because the head of the humerus is more than two times larger than the shallow glenoid concavity that receives it, only about a quarter of the articular surface of the humeral head is in contact with the fossa in any given position of the joint. This anatomical fact helps explain the inherent instability of the shoulder—our most mobile joint. The soft tissues surrounding the shoulder, such as the joint capsule, ligaments, and adjacent muscles, provide the primary restraint against excessive motion and potential dislocation.

Unfortunately, only a thin articular capsule surrounds the shoulder joint. It is extremely loose and does not function to keep the articulating bones of the joint in contact. This fact is obviously correlated with both the great range of motion (ROM) possible at this articulation and its tendency to dislocate as a result of athletic injury or other trauma. The tendons of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles (called the *SITS muscles*) all blend with and strengthen the articular capsule. The musculotendinous cuff resulting from this fusion is called the **rotator cuff** (see Figure 11-18). The rotator cuff provides the necessary strength to help prevent anterior, superior, and posterior displacement of the humeral head during most types of activity.

The rotator cuff stabilizes the shoulder during athletic activities.

Muscles That Move the Forearm

Selected superficial and deep muscles of the upper extremity are shown in Figures 11-19 and 11-20. Recall that most muscles acting on a joint lie proximal to that joint. Muscles acting directly on the forearm, therefore, are found proximal to the elbow and attach the bones of the forearm (ulna and radius) to the humerus or scapula above. Table 11-15 lists the muscles acting on the forearm and gives the origin, insertion, function, and innervation of each. Figure 11-21 shows the detail of attachment of several important muscles in this group.

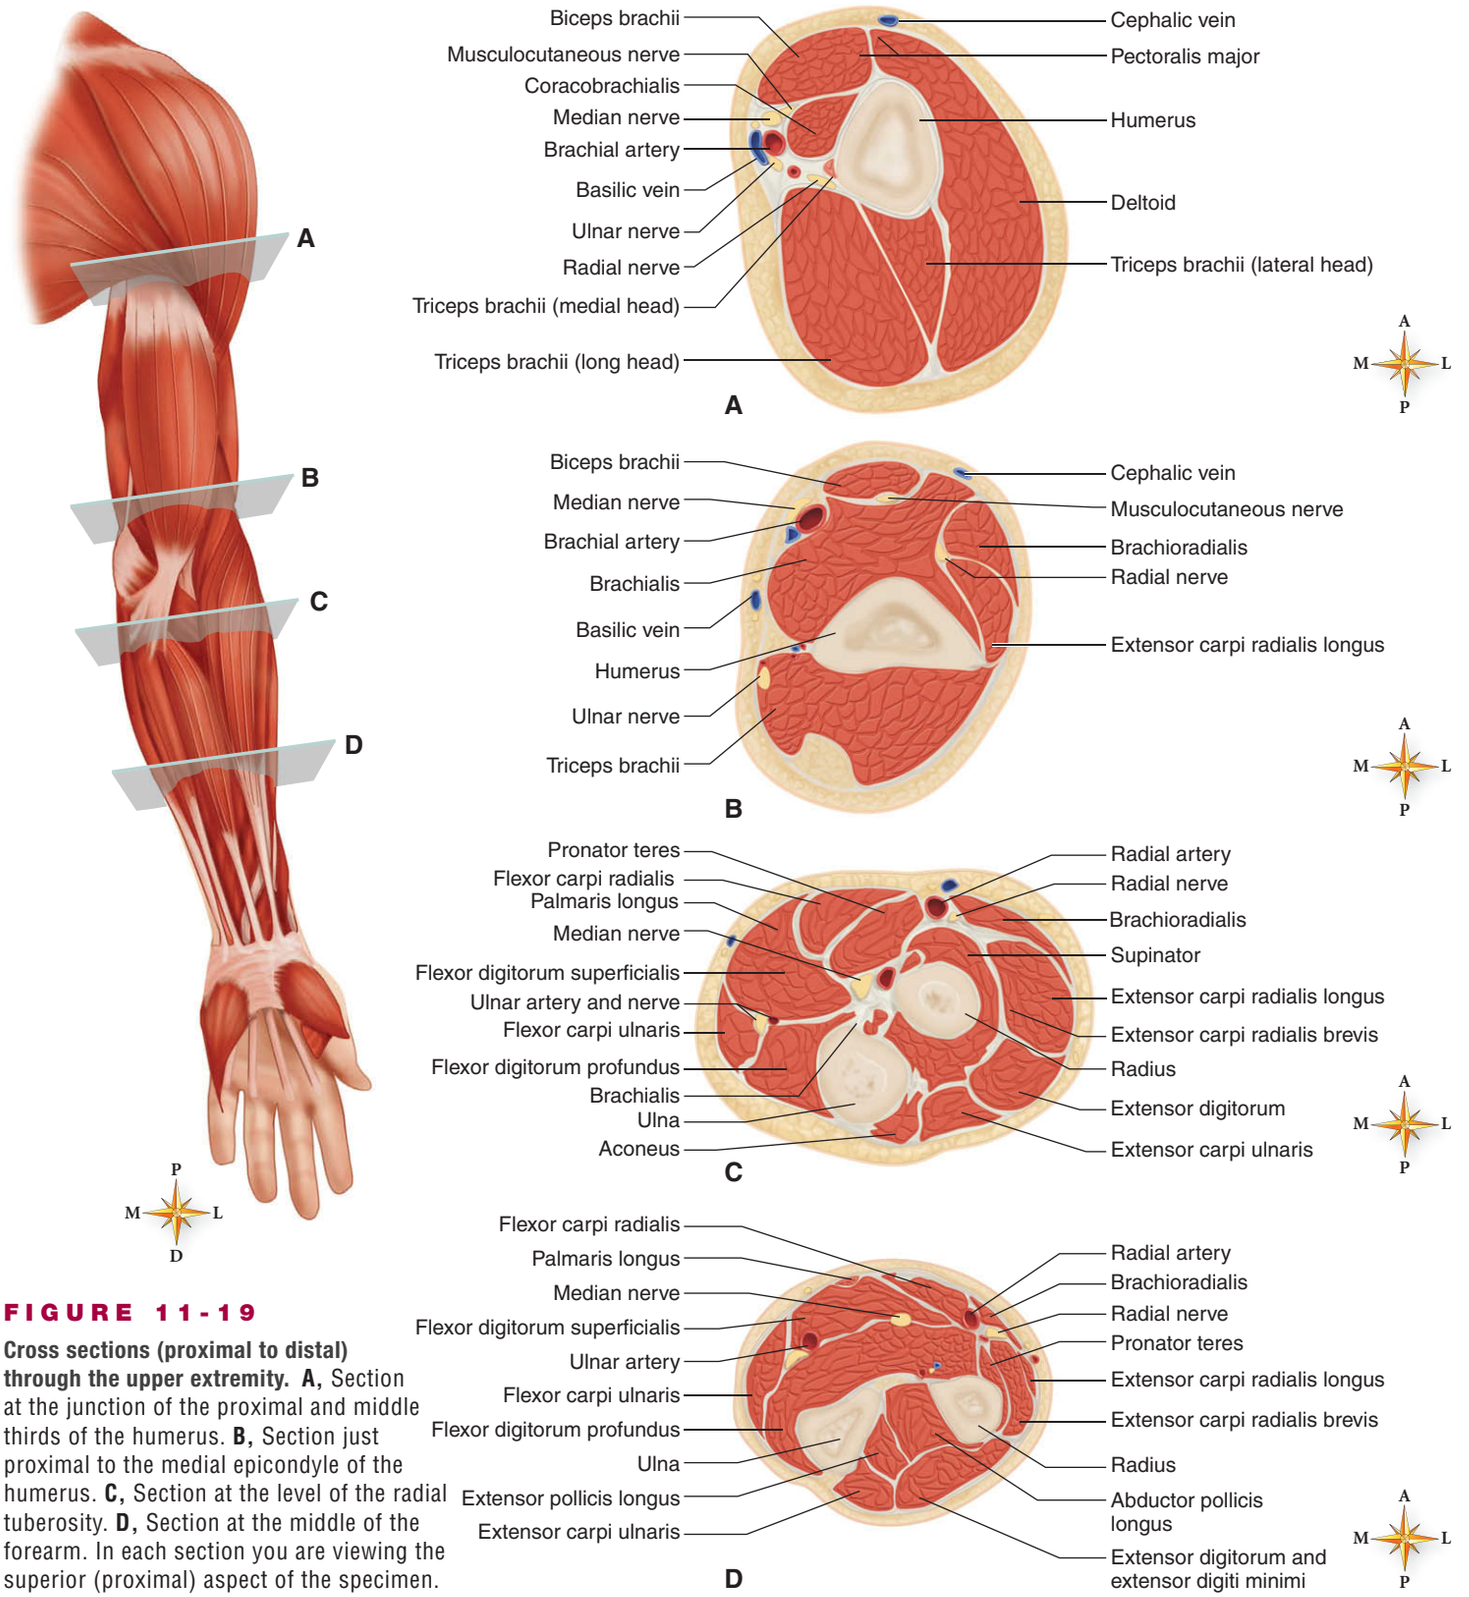

FIGURE 11-19

Cross sections (proximal to distal) through the upper extremity. A, Section at the junction of the proximal and middle thirds of the humerus. **B,** Section just proximal to the medial epicondyle of the humerus. **C,** Section at the level of the radial tuberosity. **D,** Section at the middle of the forearm. In each section you are viewing the superior (proximal) aspect of the specimen.

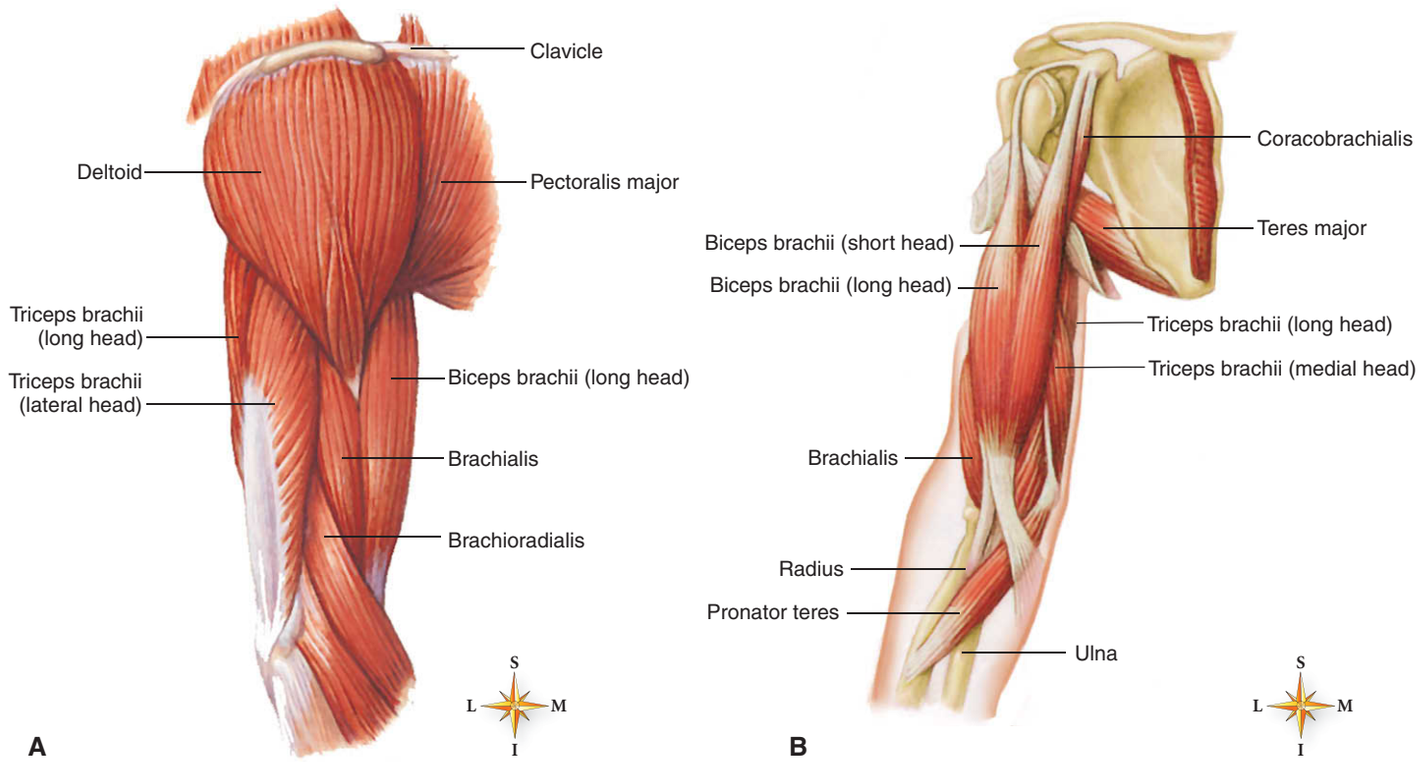

FIGURE 11-20

Muscles acting on the forearm. A, Lateral view of the right shoulder and arm. **B,** Anterior view of the right shoulder and arm (deep). The deltoid and pectoralis major muscles have been removed to reveal deeper structures.

TABLE 11-15 Muscles That Move the Forearm

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Flexors				
Biceps brachii	Scapula (supraglenoid tuberosity) Scapula (coracoid)	Radius (tuberosity at the proximal end)	Flexes the supinated forearm Supinates the forearm and hand	Musculocutaneous nerve
Brachialis	Humerus (distal half, anterior surface)	Ulna (front of the coronoid process)	Flexes the pronated forearm	Musculocutaneous nerve
Brachioradialis	Humerus (above the lateral epicondyle)	Radius (styloid process)	Flexes the semipronated or semisupinated forearm; supinates the forearm and hand	Radial nerve
Extensor				
Triceps brachii	Scapula (infraglenoid tuberosity) Humerus (posterior surface—lateral head above the radial groove; medial head, below)	Ulna (olecranon)	Extends the lower arm	Radial nerve
Pronators				
Pronator teres	Humerus (medial epicondyle) Ulna (coronoid process)	Radius (middle third of the lateral surface)	Pronates and flexes the forearm	Median nerve
Pronator quadratus	Ulna (distal fourth, anterior surface)	Radius (distal fourth, anterior surface)	Pronates the forearm	Median nerve
Supinator				
Supinator	Humerus (lateral epicondyle) Ulna (proximal fifth)	Radius (proximal third)	Supinates the forearm	Radial nerve

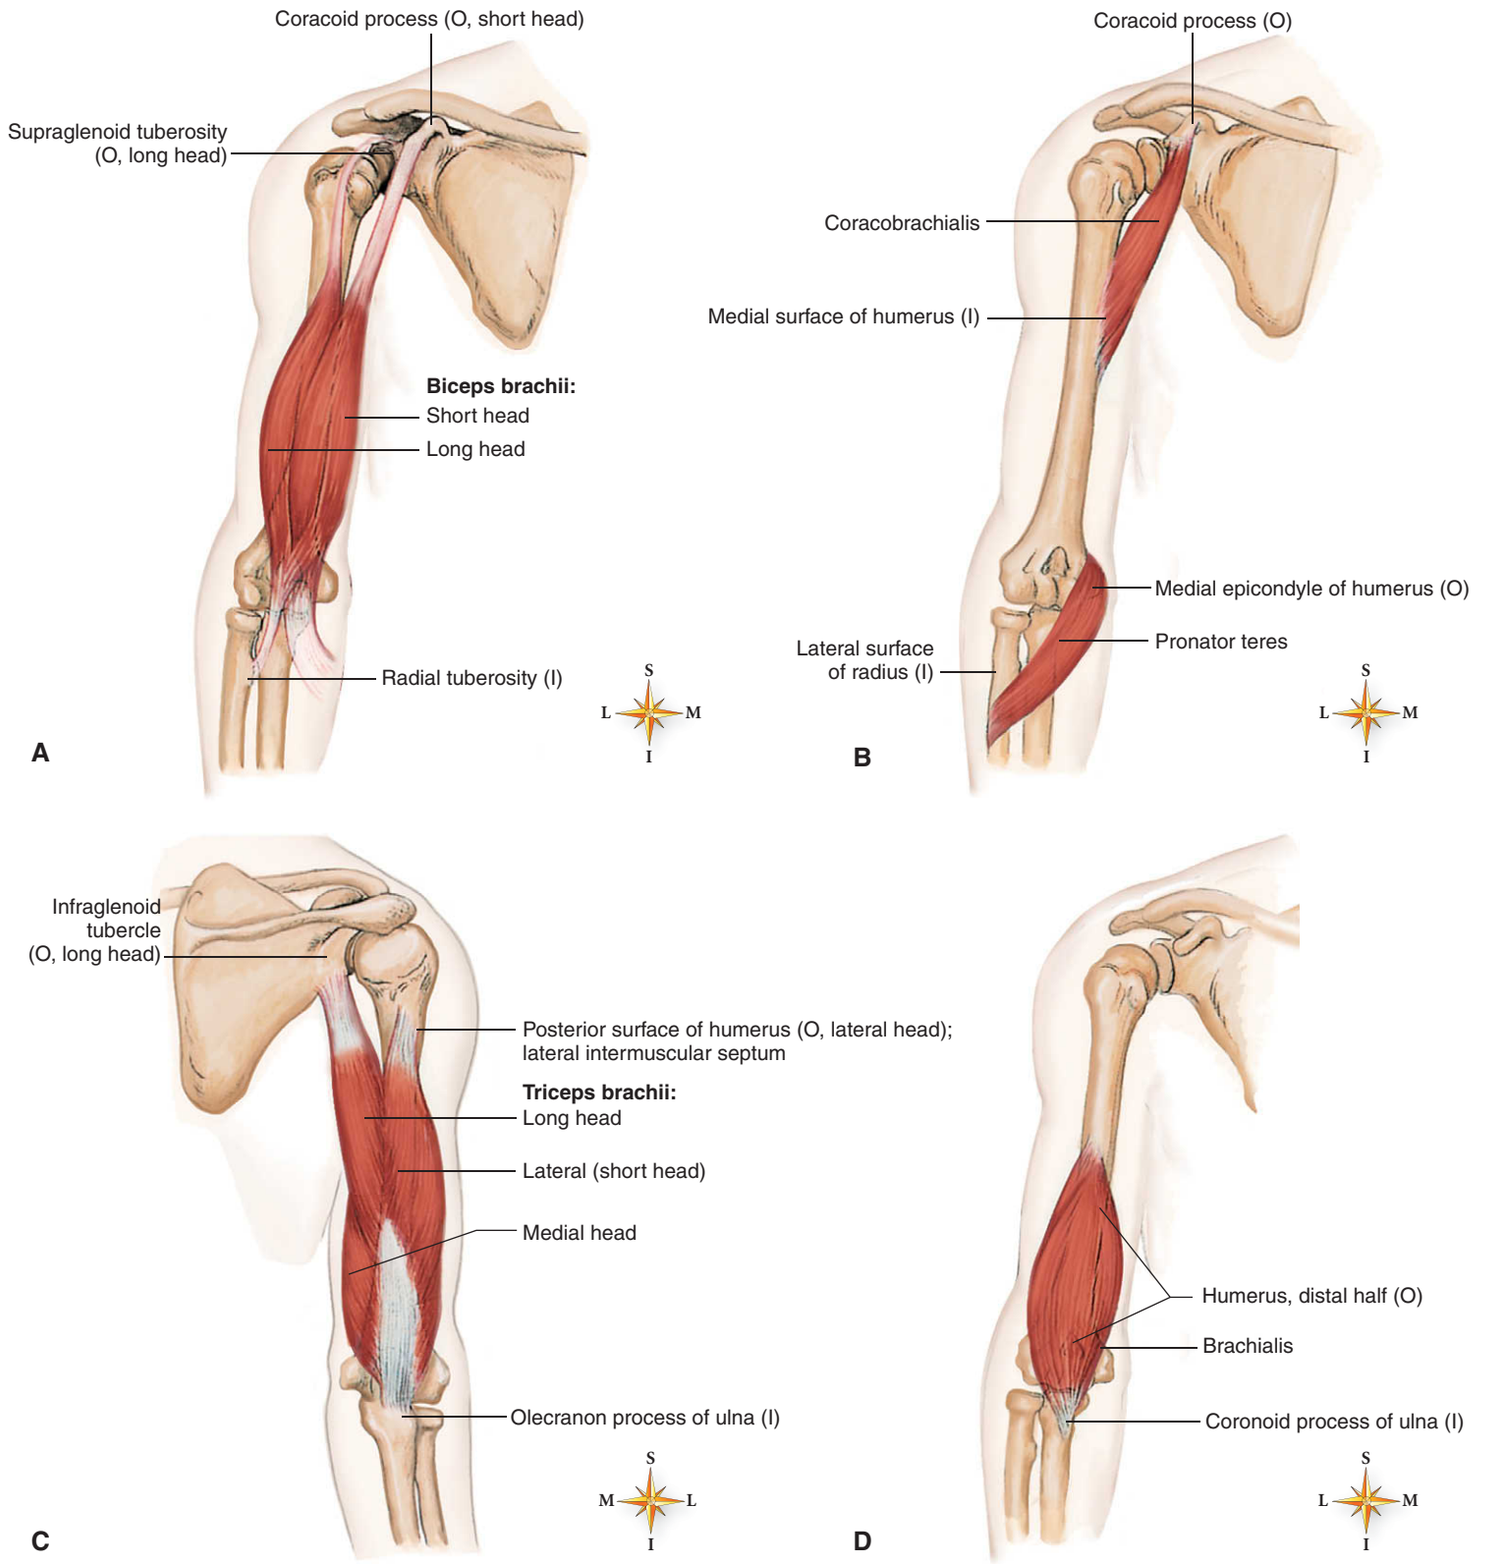

FIGURE 11-21

Muscles That Move the Wrist, Hand, and Fingers

Muscles that move the wrist, hand, and fingers can be **extrinsic muscles** or **intrinsic muscles.** The term *extrinsic* means *from the outside* and refers to muscles originating outside of the part of the skeleton moved. Extrinsic muscles originating in the forearm can pull on their insertions in the wrist, hand, and fingers to move them. The term *intrinsic*, meaning *from within*, refers to muscles that are actually within the part moved. Muscles that begin and end at different points within the hand can produce fine finger movements, for example.

Extrinsic muscles acting on the wrist, hand, and fingers are located on the anterior or the posterior surfaces of the forearm (Figure 11-22). In most instances, the muscles located on the anterior surface of the forearm are flexors and those on the posterior surface are extensors of the wrist, hand, and fingers (Table 11-16).

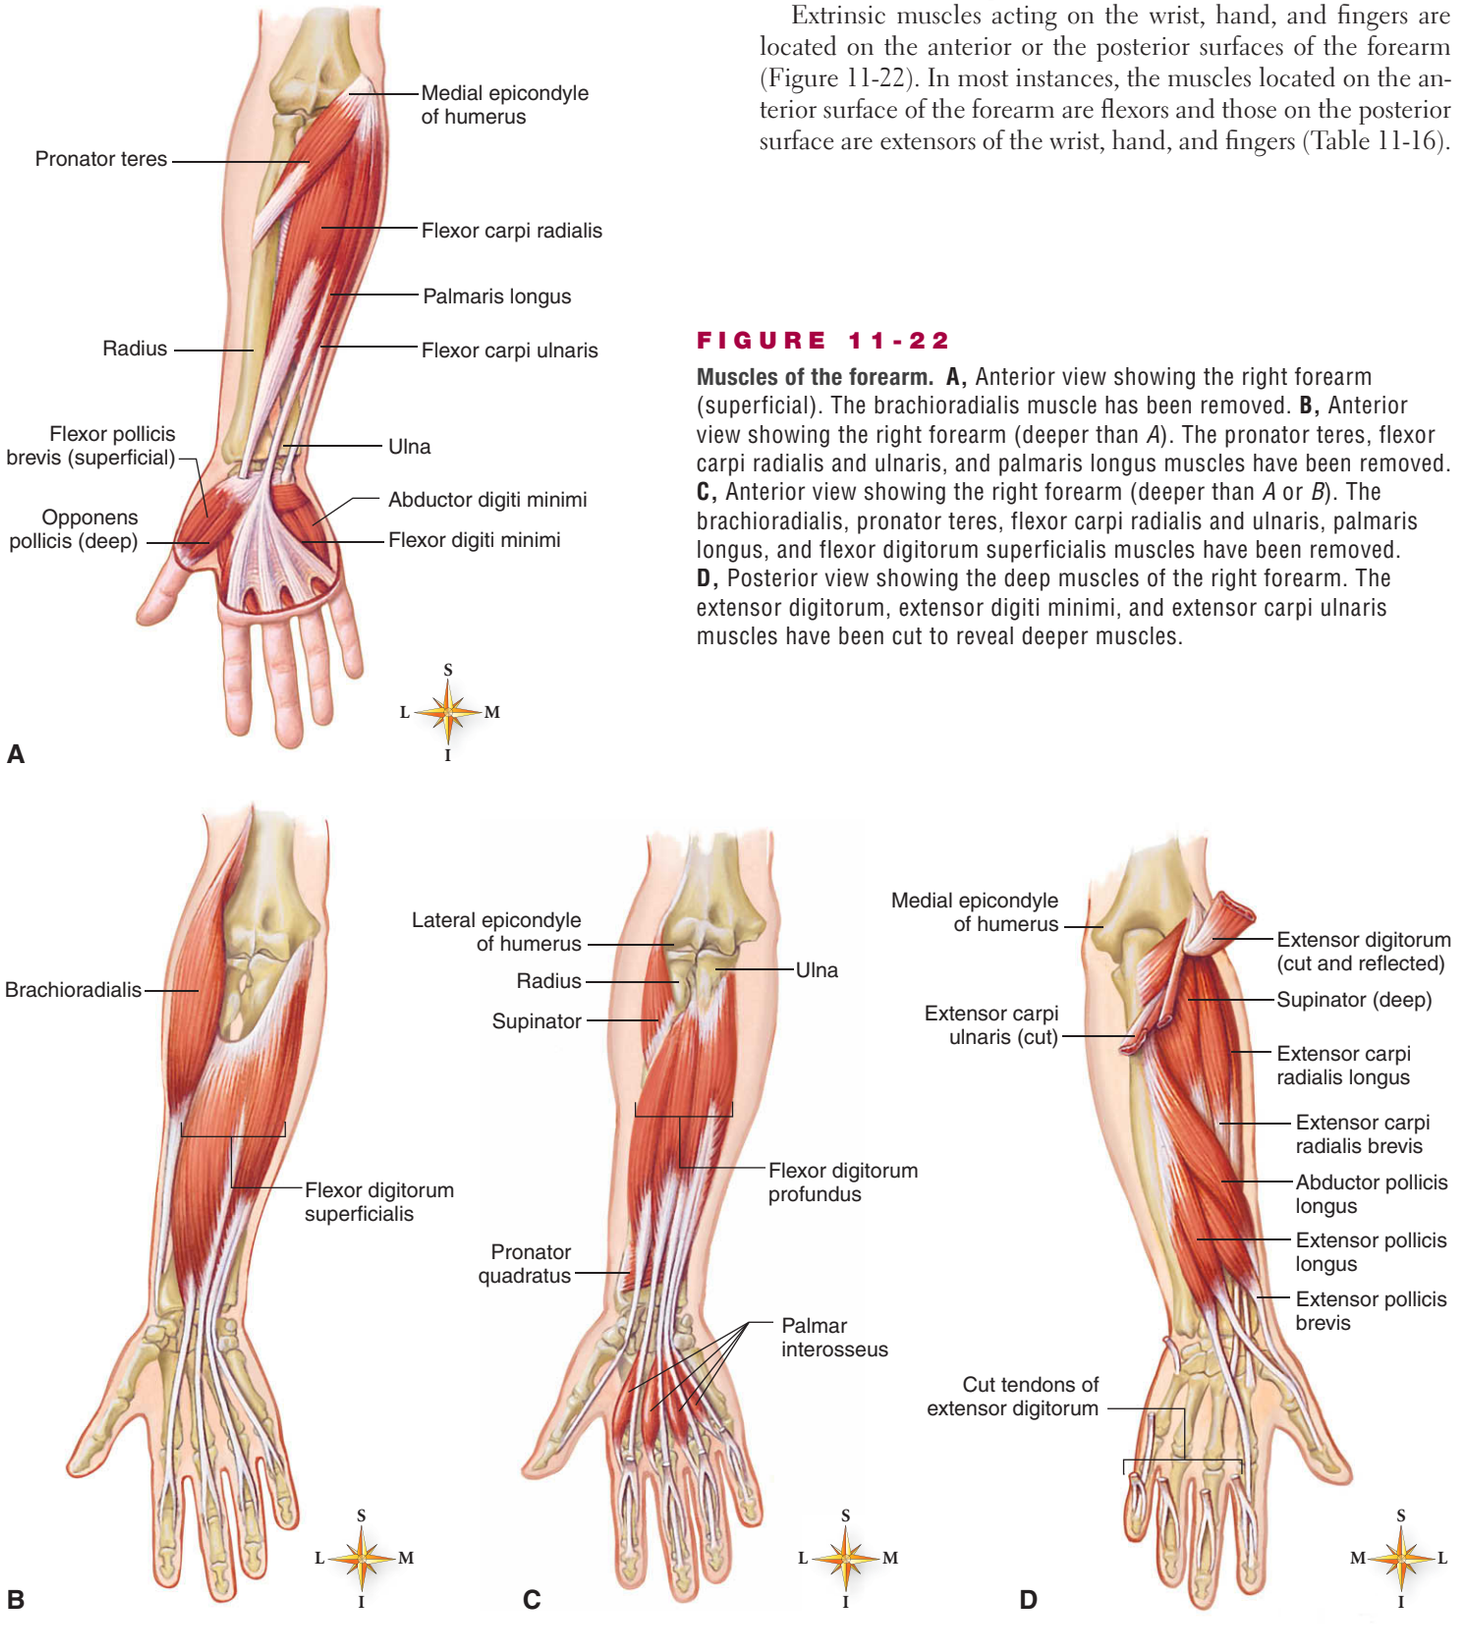

FIGURE 11-22

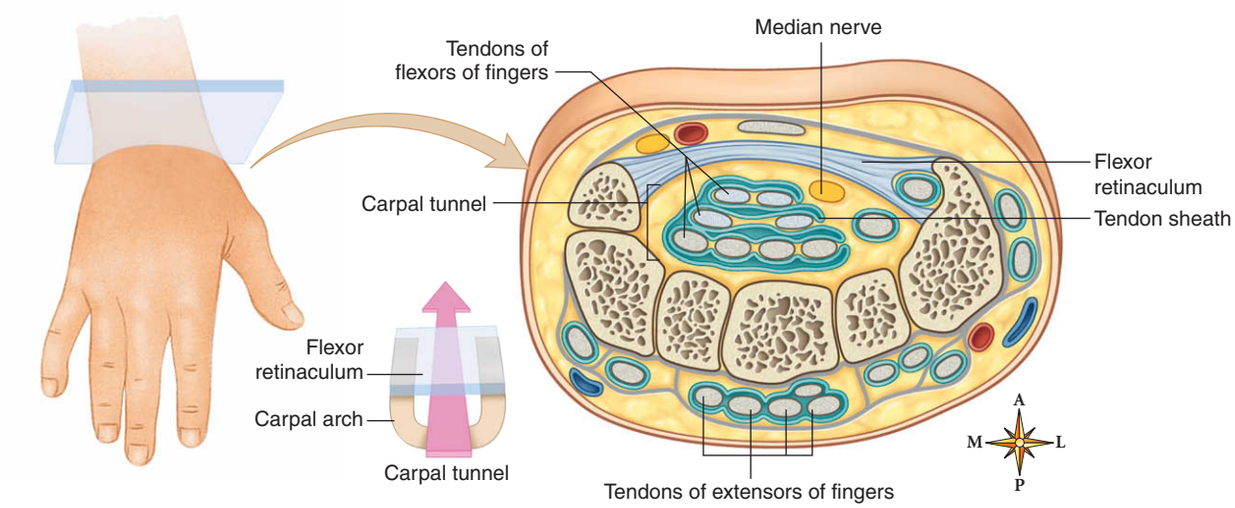
Muscles of the forearm. A, Anterior view showing the right forearm (superficial). The brachioradialis muscle has been removed. **B,** Anterior view showing the right forearm (deeper than *A*). The pronator teres, flexor carpi radialis and ulnaris, and palmaris longus muscles have been removed. **C,** Anterior view showing the right forearm (deeper than *A* or *B*). The brachioradialis, pronator teres, flexor carpi radialis and ulnaris, palmaris longus, and flexor digitorum superficialis muscles have been removed. **D,** Posterior view showing the deep muscles of the right forearm. The extensor digitorum, extensor digiti minimi, and extensor carpi ulnaris muscles have been cut to reveal deeper muscles.

TABLE 11-16 Muscles That Move the Wrist, Hand, and Fingers

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Extrinsic				
Flexor carpi radialis	Humerus (medial epicondyle)	Second metacarpal (base of)	Flexes the hand Flexes the forearm	Median nerve
Palmaris longus	Humerus (medial epicondyle)	Fascia of the palm	Flexes the hand	Median nerve
Flexor carpi ulnaris	Humerus (medial epicondyle)	Pisiform bone	Flexes the hand	Ulnar nerve
	Ulna (proximal two thirds)	Third, fourth, and fifth metacarpals	Adducts the hand	
Extensor carpi radialis longus	Humerus (ridge above the lateral epicondyle)	Second metacarpal (base of)	Extends the hand Abducts the hand (moves toward the thumb side when the hand is supinated)	Radial nerve
Extensor carpi radialis brevis	Humerus (lateral epicondyle)	Second, third metacarpals (bases of)	Extends the hand	Radial nerve
Extensor carpi ulnaris	Humerus (lateral epicondyle) Ulna (proximal three fourths)	Fifth metacarpal (base of)	Extends the hand Adducts the hand (moves toward the little finger side when the hand is supinated)	Radial nerve
Flexor digitorum profundus	Ulna (anterior surface)	Distal phalanges (fingers 2 to 5)	Flexes the distal interphalangeal joints	Median and ulnar nerves
Flexor digitorum superficialis	Humerus (medial epicondyle) Radius Ulna (coronoid process)	Tendons of the fingers	Flexes the fingers	Median nerve
Extensor digitorum	Humerus (lateral epicondyle)	Phalanges (fingers 2 to 5)	Extends the fingers	Radial nerve
Intrinsic				
Opponens pollicis	Trapezium	Thumb metacarpal	Opposes the thumb to the fingers	Median nerve
Abductor pollicis brevis	Trapezium	Proximal phalanx of the thumb	Abducts the thumb	Median nerve
Adductor pollicis	Second and third metacarpals Trapezoid Capitate	Proximal phalanx of the thumb	Adducts the thumb	Ulnar nerve
Flexor pollicis brevis	Flexor retinaculum	Proximal phalanx of the thumb	Flexes the thumb	Median and ulnar nerves
Abductor digiti minimi	Pisiform	Proximal phalanx of the fifth finger (base of)	Abducts the fifth finger Flexes the fifth finger	Ulnar nerve
Flexor digiti minimi brevis	Hamate	Proximal and middle phalanx of the fifth finger	Flexes the fifth finger	Ulnar nerve
Opponens digiti minimi	Hamate Flexor retinaculum	Fifth metacarpal	Opposes the fifth finger slightly	Ulnar nerve
Interosseous (palmar and dorsal)	Metacarpals	Proximal phalanges	Adducts the second, fourth, and fifth fingers (palmar) Abducts the second, third, and fourth fingers (dorsal)	Ulnar nerve
Lumbricals	Tendons of the flexor digitorum profundus	Phalanges (2 to 5)	Flexes the proximal phalanges (2 to 5) Extends the middle and distal phalanges (2 to 5)	Median nerve (phalanges 2 and 3) Ulnar nerve (phalanges 4 and 5)

Box 11-3 | HEALTH matters



Carpal Tunnel Syndrome

Some epidemiologists specialize in the field of occupational health, the study of health matters related to work or the workplace. Many problems seen by occupational health experts are caused by repetitive motions of the wrists or other joints. Meat cutters and workers who use word processors, for example, are at risk for conditions caused by repetitive motion injuries.

One common problem often caused by such repetitive motion is **tenosynovitis** (ten-oh-sin-oh-VYE-tis)—inflammation of a tendon sheath. Tenosynovitis can be painful, and the swelling characteristic of this condition can limit movement in affected parts of the body. For example, swelling of the tendon sheath around tendons in an area of the wrist known as the *carpal tunnel* can limit movement of the wrist, hand, and fingers.

The figure shows the relative positions of the tendon sheath and median nerve within the carpal tunnel. The carpal tunnel is formed as a fibrous band called the *flexor retinaculum* wraps over the tendons of the flexor muscles that lie within an arch formed by the carpal bones. If swelling, or any other lesion within the carpal tunnel, presses on the *median nerve,* a condition called **carpal tunnel syndrome** may result. Because the median nerve connects to the palm and radial side (thumb side) of the hand, carpal tunnel syndrome is characterized by weakness, pain, and tingling in this part of the hand. The pain and tingling may also radiate to the forearm and shoulder. Prolonged or severe cases of carpal tunnel syndrome may be relieved by injection of antiinflammatory agents. A permanent cure is sometimes accomplished by surgically cutting the flexor retinaculum to relieve the pressure on the median nerve.

The procedure called *carpal tunnel release* is the most common hand operation in the United States. Such operations are performed more than 200,000 times every year. When the procedure was first introduced in 1933, it was performed as an "open" procedure. A less invasive endoscopic approach was introduced in 1989; that and many other innovative surgical techniques and advances are now being used.

The carpal tunnel. The median nerve and muscles that flex the fingers pass through a concavity in the wrist called the *carpal tunnel.*

Many of the flexors of the wrist and hand pass through a curve formed by the carpal bones called the *carpal tunnel*. The long tendons of these muscles slide through the carpal tunnel more easily because tendon sheaths lined with synovial membrane are present. Box 11-3 discusses the importance of the carpal tunnel in occupational health.

A number of intrinsic muscles are responsible for precise movements of the hand and fingers. Examples include the **lumbrical** (LUM-bri-kal) and **interosseous** (in-ter-OSS-ee-us) **muscles,** which originate from and fill the spaces between the metacarpal bones and then insert on the phalanges of the fingers. As a group, the intrinsic muscles abduct and adduct the fingers and aid in flexing them. Eight additional muscles serve the thumb and enable it to be placed in opposition to the fingers in tasks requiring grasping and manipulation. The **opponens pollicis** (oh-POH-nenz POL-i-cis) is a particularly important thumb muscle.

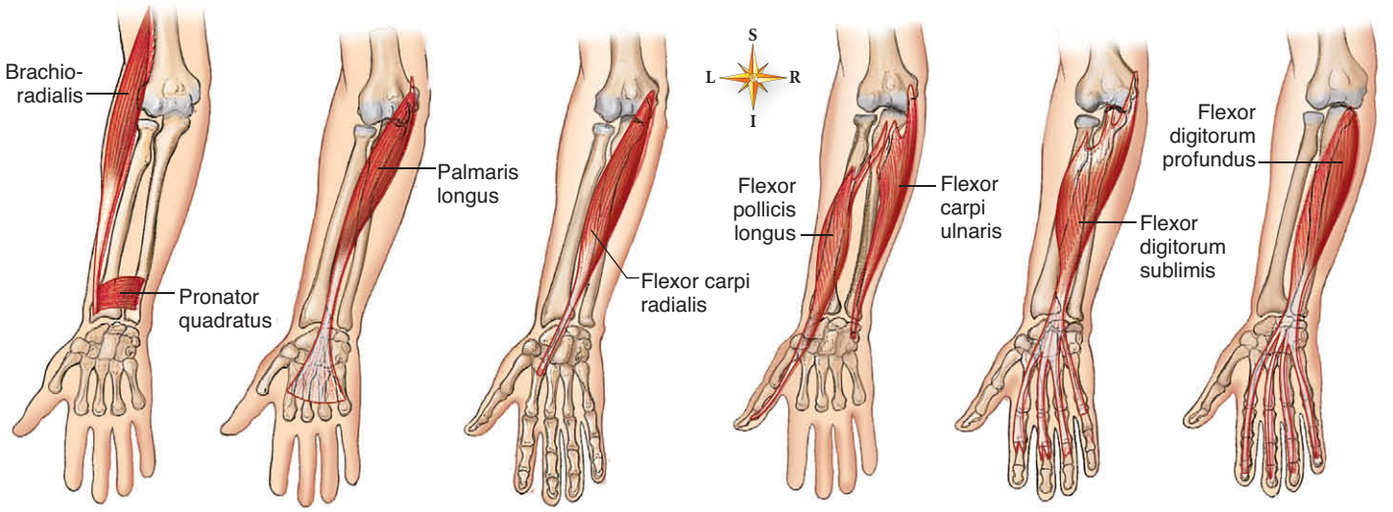


FIGURE 11-23

Some muscles of the anterior aspect of the right forearm.

It allows the thumb to be drawn across the palm to touch the tip of any finger—a critical movement for many manipulative-type activities. Figure 11-23 shows the placement and points of attachment for various individual extrinsic muscles acting on the wrist, hand, and fingers. Figure 11-24 provides a detailed illustration of many of the intrinsic muscles of the hand.

| QUICK CHECK |

19. What are the functions of the deltoid muscle?
20. What is the function of the biceps brachii muscle?
21. Distinguish the extrinsic from the intrinsic muscles of the hand and wrist.

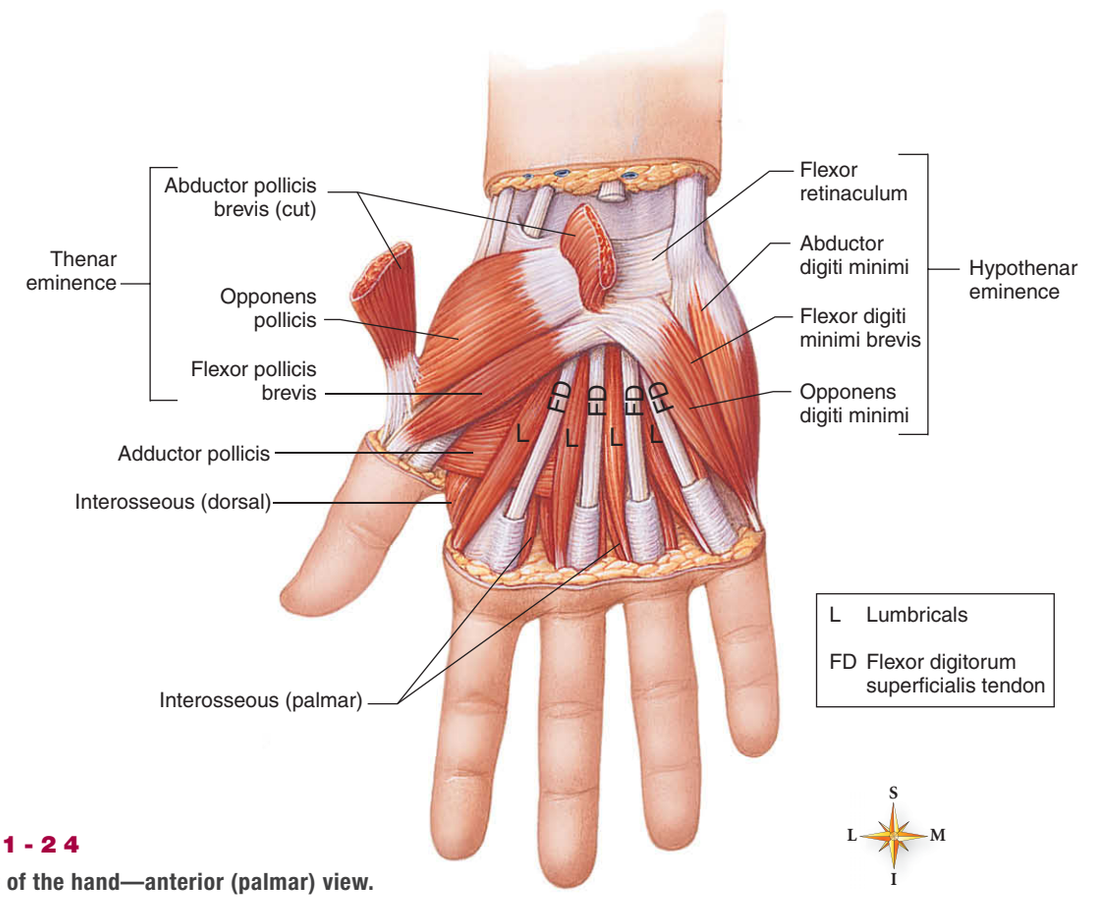

FIGURE 11-24

Intrinsic muscles of the hand—anterior (palmar) view.

TABLE 11-17 Muscles That Move the Thigh

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Iliopsoas (iliacus, psoas major, and psoas minor)	Ilium (iliac fossa)	Femur (lesser trochanter)	Flexes the thigh	Femoral and second to fourth lumbar nerves
	Vertebrae (bodies of twelfth thoracic to fifth lumbar)		Flexes the trunk (when the femur acts as the origin)	
Rectus femoris	Ilium (anterior, inferior spine)	Tibia (by way of the patellar tendon)	Flexes the thigh Extends the leg	Femoral nerve
Gluteal group				
Maximus	Ilium (crest and posterior surface) Sacrum and coccyx (posterior surface) Sacrotuberous ligament	Femur (gluteal tuberosity) Iliotibial tract	Extends the thigh—rotates outward	Inferior gluteal nerve
Medius	Ilium (lateral surface)	Femur (greater trochanter)	Abducts the thigh—rotates outward; stabilizes the pelvis on the femur	Superior gluteal nerve
Minimus	Ilium (lateral surface)	Femur (greater trochanter)	Abducts the thigh; stabilizes the pelvis on the femur Rotates the thigh medially	Superior gluteal nerve
Tensor fasciae latae	Ilium (anterior part of the crest)	Tibia (by way of the iliotibial tract)	Abducts the thigh Tightens the iliotibial tract	Superior gluteal nerve
Adductor group				
Brevis	Pubic bone	Femur (linea aspera)	Adducts the thigh	Obturator nerve
Longus	Pubic bone	Femur (linea aspera)	Adducts the thigh	Obturator nerve
Magnus	Pubic bone	Femur (linea aspera)	Adducts the thigh	Obturator nerve
Gracilis	Pubic bone (just below the symphysis)	Tibia (medial surface behind the sartorius)	Adducts the thigh and flexes and adducts the leg	Obturator nerve

LOWER LIMB MUSCLES

The musculature, bony structure, and joints of the pelvic girdle and lower extremity function in locomotion and maintenance of stability. Powerful muscles at the back of the hip, at the front of the thigh, and at the back of the leg also serve to raise the full body weight from a sitting to a standing position. The muscles of the lower limb include those acting on the hip or pelvic girdle, as well as muscles located in the thigh, leg, and foot. Unlike the highly mobile shoulder girdle, the pelvic girdle is essentially fixed. Therefore, our study of muscles in the lower extremity begins with those arising from the pelvic girdle and passing to the femur; they produce their effects at the hip joint by moving the thigh.

Muscles That Move the Thigh and Leg

Table 11-17 identifies muscles that move the thigh and lists the origin, insertion, function, and nerve supply of each (Figure 11-25). Refer to Figure 11-6 and Figures 11-25 through 11-29, which show individual muscles, as you study the information provided in the table. Muscles acting on the thigh can be divided into three groups: (1) muscles crossing the front of the hip, (2) the three **gluteal** (GLOO-tee-al) **muscles,** and the **tensor fasciae latae** (TEN-sor FASH-ee LAT-tee), and (3) the thigh adductors. One of the gluteal muscles, the gluteus medius muscle, is often the site of intramuscular injections (Box 11-4).

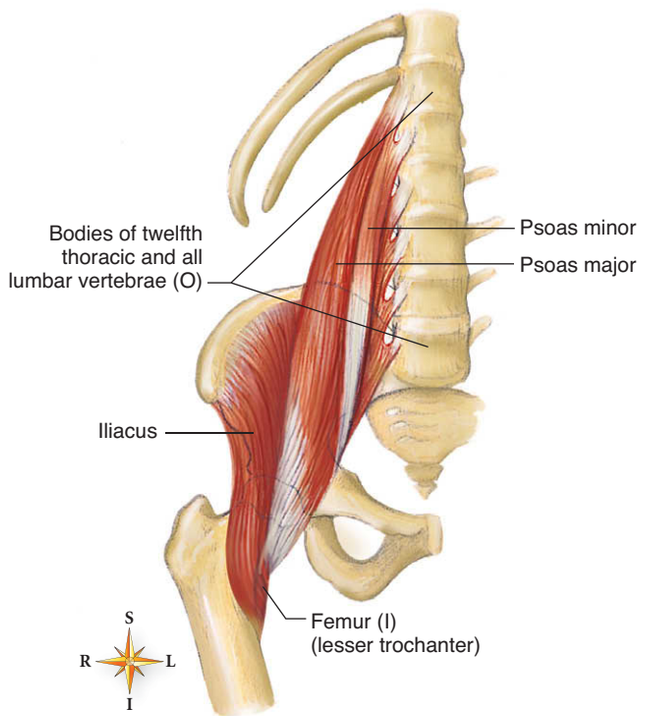

FIGURE 11-25

Box 11-4 | HEALTH matters

Intramuscular Injections

Many drugs are administered by **intramuscular injection.** If the amount to be injected is 2 ml or less, the deltoid muscle is often selected as the site of injection. Note that in part *A* of this figure, the needle is inserted into the muscle about two fingers' breadth below the acromion process of the scapula and lateral to the tip of the acromion.

If the amount of medication to be injected is 2 to 3 ml, the gluteal area shown in part *B* of the figure is often used. Injections are made into the gluteus medius muscle near the center of the upper outer quadrant.

Another technique of locating the proper injection site is to draw an imaginary diagonal line from a point of reference on the back of the bony pelvis (posterior superior iliac spine) to the greater trochanter of the femur. The injection is given about three fingers' breadth above and one third of the way down the line. It is important to avoid the sciatic nerve and the superior gluteal blood vessels during administration of the injection. Proper technique requires knowledge of the underlying anatomy.

Intramuscular injection sites. A, Deltoid injection site for small doses. **B,** Gluteal injection site for larger doses.

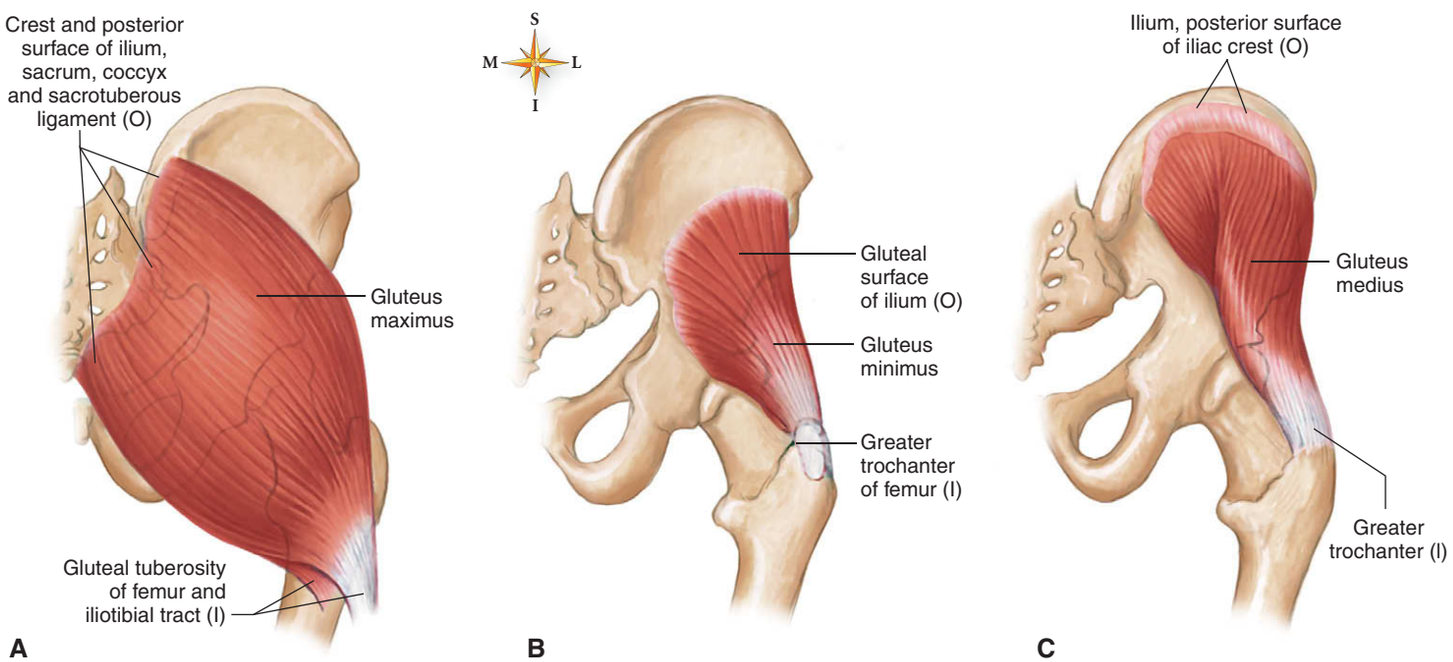

FIGURE 11-29

Table 11-18 identifies muscles that move the leg. Note that the quadriceps femoris group is made up of four large muscles that flex the thigh and extend the leg. The hamstring group is made up of three muscles that extend the thigh and flex the leg. Again, see Figure 11-6 and refer to Figures 11-30 and 11-31 as you study the table.

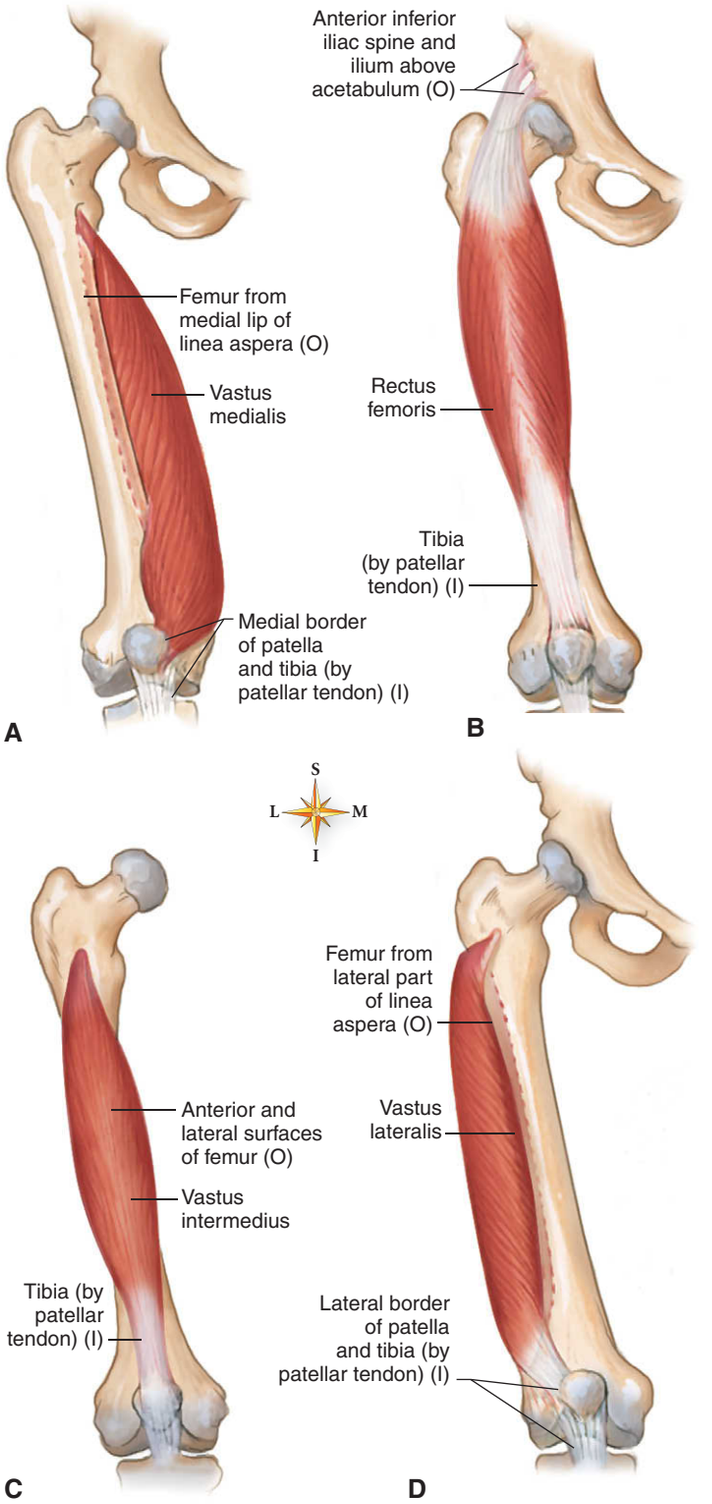

FIGURE 11-30

Quadriceps femoris group of thigh muscles. **A,** Vastus medialis. **B,** Rectus femoris. **C,** Vastus intermedius. **D,** Vastus lateralis. *O,* Origin; *I,* insertion.

TABLE 11-18 Muscles That Move the Lower Leg

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Quadriceps femoris group				
Rectus femoris	Ilium (anterior inferior spine)	Tibia (by way of patellar tendon) Extends the leg	Flexes the thigh	Femoral nerve
Vastus lateralis	Femur (linea aspera)	Tibia (by way of the patellar tendon)	Extends the leg	Femoral nerve
Vastus medialis	Femur	Tibia (by way of the patellar tendon)	Extends the leg	Femoral nerve
Vastus intermedius	Femur (anterior surface)	Tibia (by way of the patellar tendon)	Extends the leg	Femoral nerve
Sartorius	Coxal (anterior superior iliac spines)	Tibia (medial surface of the upper end of the shaft)	Adducts and flexes the leg Permits crossing of the legs tailor fashion	Femoral nerve
Hamstring group				
Biceps femoris	Ischium (tuberosity)	Fibula (head of)	Extends the thigh; flexes the leg	Hamstring nerve (branch of the sciatic nerve)
	Femur (linea aspera)	Tibia (lateral condyle)	Flexes the leg	Hamstring nerve
Semitendinosus	Ischium (tuberosity)	Tibia (proximal end, medial surface)	Extends the thigh; flexes the leg	Hamstring nerve
Semimembranosus	Ischium (tuberosity)	Tibia (medial condyle)	Extends the thigh; flexes the leg	Hamstring nerve

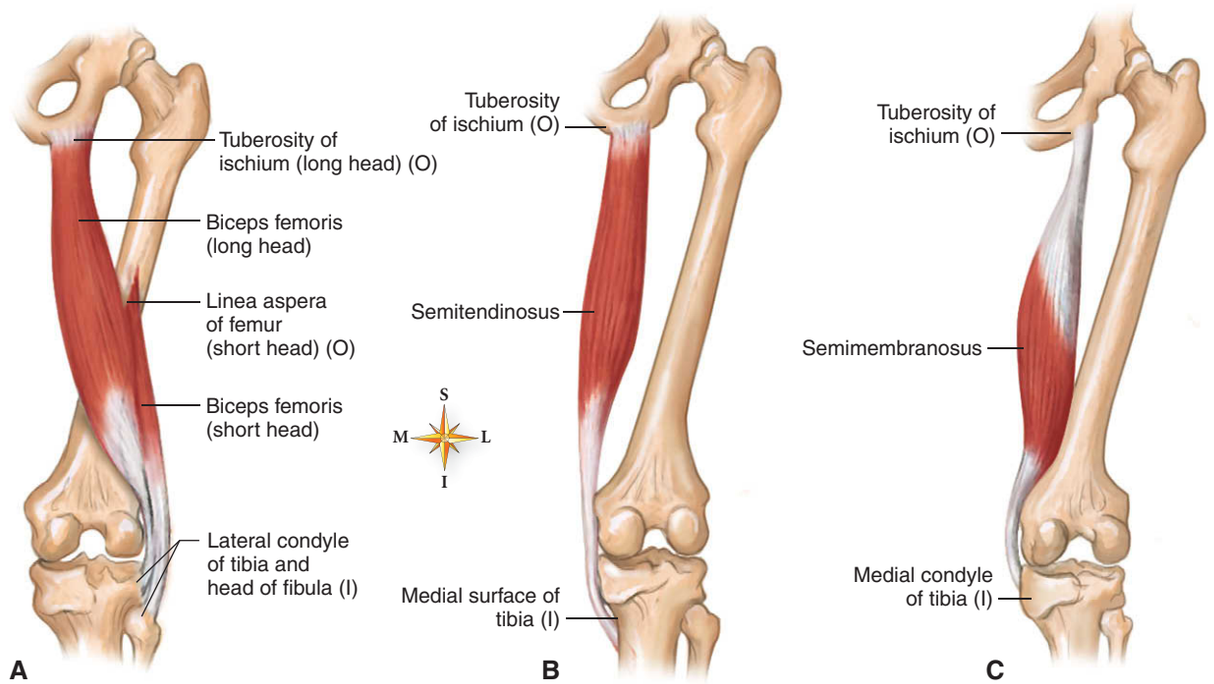

FIGURE 11-31

Hamstring group of thigh muscles. A, Biceps femoris. **B,** Semitendinosus. **C,** Semimembranosus. *O,* Origin; *I,* insertion.

Muscles That Move the Ankle and Foot

The muscles listed in Table 11-19 and shown in Figure 11-32 are responsible for movements of the ankle and foot. These muscles, called **extrinsic foot muscles,** are located in the leg but exert their actions by pulling on tendons that insert on bones in the ankle and foot. Extrinsic foot muscles are responsible for such movements as dorsiflexion, plantar flexion, inversion, and eversion of the foot. Muscles located within the foot itself are called **intrinsic foot muscles** (Figure 11-33). They are responsible for flexion, extension, abduction, and adduction of the toes.

The extrinsic muscles listed in Table 11-19 may be divided into four functional groups: (1) dorsal flexors, (2) plantar flexors, (3) invertors, and (4) evertors of the foot.

The superficial muscles located on the posterior surface of the leg form the bulging "calf." The common tendon of the **gastrocnemius** (GAS-trok-NEE-mee-us) and **soleus** is called the **calcaneal,** or *Achilles,* **tendon.** It inserts into the calcaneus, or heel bone. By acting together, these muscles serve as powerful flexors (plantar flexion) of the foot.

Dorsal flexors of the foot, located on the anterior surface of the leg, include the **tibialis** (tib-ee-AL-is) **anterior, fibularis tertius** (fib-yoo-LAIR-is TER-shee-us), and **extensor digitorum longus.** In addition to functioning as a dorsiflexor of the foot, the extensor digitorum longus also everts the foot and extends the toes. Note in Table 11-19 that the *fibularis* (fib-you-LAIR-is) muscles are also called *peroneus* (per-oh-NEE-us) muscles.

| QUICK CHECK |

22. Name the three gluteal muscles.
23. What is the function of the gastrocnemius muscle?

TABLE 11-19 Muscles That Move the Foot

MUSCLE	ORIGIN	INSERTION	FUNCTION	NERVE SUPPLY
Extrinsic				
Tibialis anterior	Tibia (lateral condyle of the upper body)	Tarsal (first cuneiform) Metatarsal (base of first)	Flexes the foot Inverts the foot	Common and deep peroneal nerves
Gastrocnemius	Femur (condyles)	Tarsal (calcaneus by way of the Achilles tendon)	Extends the foot Flexes leg	Tibial nerve (branch of the sciatic nerve)
Soleus	Tibia (underneath the gastrocnemius) Fibula	Tarsal (calcaneus by way of the Achilles tendon)	Extends the foot (plantar flexion)	Tibial nerve
Fibularis longus (peroneus longus)	Tibia (lateral condyle)	First cuneiform	Extends the foot (plantar flexion)	Common peroneal nerve
	Fibula (head and shaft)	Base of the first metatarsal	Everts the foot	
Fibularis brevis (peroneus brevis)	Fibula (lower two thirds of the lateral surface of the shaft)	Fifth metatarsal (tubercle, dorsal surface)	Everts the foot Flexes the foot	Superficial peroneal nerve
Fibularis tertius (peroneus tertius)	Fibula (distal third)	Fourth and fifth metatarsals (bases of)	Flexes the foot Everts the foot	Deep peroneal nerve
Extensor digitorum longus	Tibia (lateral condyle) Fibula (anterior surface)	Second and third phalanges (four lateral toes)	Dorsiflexion of the foot; extension of the toes	Deep peroneal nerve
Intrinsic				
Lumbricals	Tendons of the flexor digitorum longus	Phalanges (2 to 5)	Flex the proximal phalanges Extend the middle and distal phalanges	Lateral and medial plantar nerve
Flexor digiti minimi brevis	Fifth metatarsal	Proximal phalanx of the fifth toe	Flexes the fifth (small) toe	Lateral plantar nerve
Flexor hallucis brevis	Cuboid Medial and lateral cuneiform	Proximal phalanx of the first (great) toe	Flexes the first (great) toe	Medial and lateral plantar nerve
Flexor digitorum brevis	Calcaneus Plantar fascia	Middle phalanges of the toes (2 to 5)	Flexes toes 2 through 5	Medial plantar nerve
Abductor digiti minimi	Calcaneus	Proximal phalanx of the fifth (small) toe	Abducts the fifth (small) toe Flexes the fifth toe	Lateral plantar nerve
Abductor hallucis	Calcaneus	First (great) toe	Abducts the first (great) toe	Medial plantar nerve

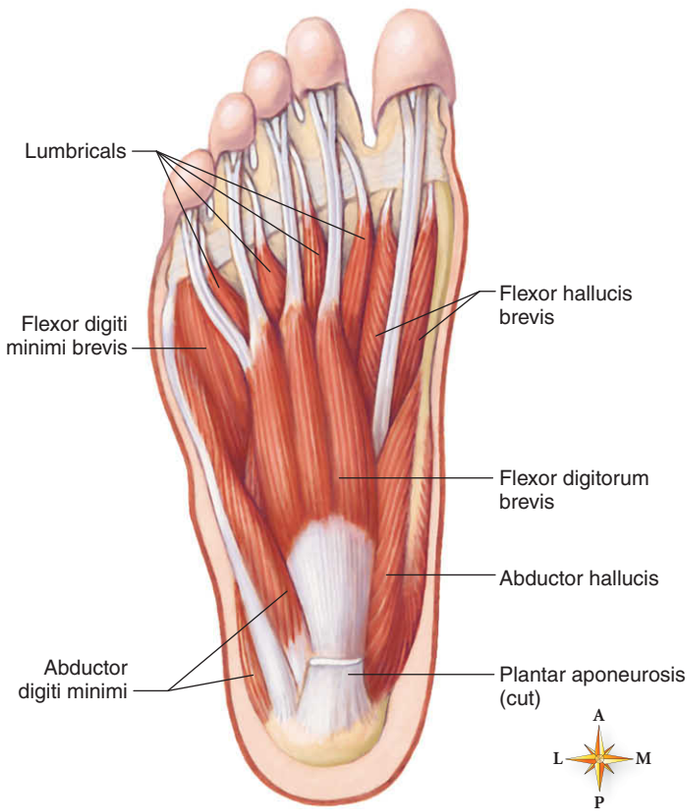

FIGURE 11-33

Intrinsic muscles of the foot. Inferior (plantar) view.

POSTURE

We have already discussed the major role of muscles in movement and heat production. We now turn our attention to a third way in which muscles serve the body as a whole—that of maintaining the posture of the body. Let us consider a few aspects of this important function.

The term **posture** means simply maintaining optimal body position. "Good posture" means many things. It means body alignment that most favors function; it means the position that requires the least muscular work to maintain, specifically, the position that places the least strain on muscles, ligaments, and bones; and often it means keeping the body's center of gravity over its base. Good posture in the standing position, for example, means the head and chest held high; the chin, abdomen, and buttocks pulled in; the knees bent slightly; and the feet placed firmly on the ground about 6 inches (15 cm) apart. Good posture in a sitting position varies with the position that one is trying to maintain. Good posture during exercise, such as riding a horse or dribbling a basketball, means moving or tensing different parts of the body frequently to avoid falling.

How Posture Is Maintained

Gravity pulls on the various parts of the body at all times. Because bones are too irregularly shaped to balance themselves on each other, the only way the body can be held in any particular position is for muscles to exert a continual pull on bones. The muscles must pull in the opposite direction from gravity or other forces that pull on body parts.

When the body is in a standing position, gravity tends to pull the head and trunk forward and downward. Extensor muscles must therefore pull backward and upward on the head and trunk. Likewise, as gravity pulls the lower jaw downward; muscles must pull upward on it—to keep the mouth closed.

Muscles exert their pull against gravity by virtue of a property called **tonicity.** Tonicity, or **muscle tone,** literally means *tension* and refers to the continuous, low level of sustained contraction maintained by all skeletal muscles. Because tonicity is absent during deep sleep, muscle pull does not then counteract the pull of gravity. Hence, we cannot sleep standing up. Interestingly, astronauts in the low-gravity conditions of space station missions *can* sleep in a standing position, as long as they are secured inside special sleeping bags on the wall of the space station.

Many structures other than muscles and bones play a part in the maintenance of posture. The nervous system triggers skeletal muscle contractions and is thus responsible for the existence of muscle tone. The nervous system regulates and coordinates the amount of pull exerted by the individual muscles. Breathing in the respiratory system, abdominal activity by the digestive system, and other systemic activities all can affect posture. This is one of many examples of the important principle that body functions are interdependent.

The importance of posture can perhaps be best evaluated by considering some of the effects of poor posture. Poor posture throws more work on muscles to counteract the pull of gravity and therefore leads to fatigue more quickly than does good posture. Poor posture puts more strain on ligaments. It puts abnormal strain on bones and may eventually produce deformities. It also interferes with various functions such as respiration, heart action, and digestion.

| A&P CONNECT |

As we discussed earlier in this chapter, it is important to remember that muscles, tendons, and fascia work in teams to maintain posture and produce movement. Explore one of the ways that they work together in ***Whole-Body Muscle Mechanics*** online at ***A&P Connect.***

evolve

Cycle of LIFE

Muscular System

Acting together, the muscular, skeletal, and nervous systems make it possible for us to move in a coordinated and controlled way. However, it is the contraction, or shortening, of muscles that ultimately provides the actual movement necessary for physical activity. Dramatic changes occur in the muscular system throughout the cycle of life. Muscle cells may increase or decrease in size and in their ability to shorten most effectively at different periods in life. In addition to age-related changes, many pathological conditions occurring at different ages may also affect the muscular system.

Because of the functional interdependence of the musculoskeletal and nervous systems, life cycle changes affecting the muscles are often manifested in other components of the functional unit. During infancy and childhood, the ability to coordinate and control the strength of muscle contraction permits a sequential series of developmental steps to occur. A developing youngster learns to hold the head up, roll over, sit up, stand alone, and then walk and run as developmental changes permit better control and coordination of muscular contraction.

Degenerative changes associated with advancing age often result in replacement of muscle cell volume with nonfunctional connective tissue. As a result, the strength of muscular contraction diminishes. Recent findings show that much, if not all, of this age-related decrease in muscle strength actually results from disuse atrophy (see Box 12-6 in Chapter 12) and may thus be avoidable. Pathological conditions associated with specific age ranges can also affect one or more components of the functional unit that permits us to move smoothly and effortlessly.

the BIG picture

Skeletal Muscles and the Whole Body

As you read through this chapter, what struck you most was probably the large number of individual muscles and their many actions. Although learning the names, locations, origins, insertions, and other details of the major muscles is a worthwhile endeavor, such an activity can cause you to lose sight of the "big picture." Step back from the details a moment to appreciate that the muscles work as coordinated teams of biological engines that move the various components of the flexible skeleton.

As a matter of fact, in this chapter you learned that the fibrous wrappings of each muscle are continuous with its tendons, which in turn are continuous with the fibrous structure of the bone to which they are attached. Thus we can see that the muscular and skeletal systems are in essence a single structure. This fact is very important in seeing a "big picture" comprising many individual muscles and bones. The entire skeletomuscular system, as it is often called, is actually a single, continuous structure that provides a coordinated, dynamic framework for the body.

Taking another step back, an even bigger picture comes into focus. Other systems of the body must play a role in the actions of the skeletomuscular system. For example, the nervous system senses changes in body position and degrees of movement—thereby permitting integration of feedback loops that ultimately regulate the muscular contractions that maintain posture and produce movements. The cardiovascular system maintains blood flow in the muscles, and the urinary and respiratory systems rid the body of wastes produced in the muscles. The respiratory and digestive systems bring in the oxygen and nutrients necessary for muscle function.

The picture is still not complete, however. We will see even more when Chapter 12 continues the story of muscle function by delving into the details of how each muscle works as an engine to drive the movement of the body.

CASE study

At the sound of the starting pistol, Jeremy burst forward out of the blocks, sprinting down the track. About 20 meters into the race, he suddenly felt a sharp pain along the backside of his right thigh. Wincing, he slowed down and hobbled to a stop.

1. What muscle or muscle group has Jeremy likely injured?
   a. Quadriceps femoris group
   b. Hamstring group
   c. Gastrocnemius
   d. Triceps brachii
2. What muscle did Jeremy use when he closed his eyes in pain?
   a. Orbicularis oris
   b. Masseter
   c. Buccinator
   d. Orbicularis oculi

Jeremy made his way over to the grassy area beside the track and collapsed onto his side. In an effort to control the pain, he concentrated on taking deep, slow breaths in and out.

3. Which of the following muscles did Jeremy NOT use in breathing?
   a. Diaphragm
   b. External intercostals
   c. Latissimus dorsi
   d. Internal intercostals

After several minutes, Jeremy rolled onto his back and tried to sit up.

4. Which of the following muscles would contract to pull him to a sitting position?
   a. Rectus abdominis
   b. Pectoralis major
   c. Trapezius
   d. Pronator teres

INTRODUCTION (FIGURES 11-5 AND 11-6)

A. There are more than 600 skeletal muscles in the body
B. From 40% to 50% of our body weight is skeletal muscle
C. Muscles fill in the form and contour of the body

SKELETAL MUSCLE STRUCTURE (FIGURE 11-1)

A. Connective tissue components (Table 11-1)
   1. Endomysium—delicate connective tissue membrane that covers skeletal muscle fibers
   2. Perimysium—tough connective tissue binding together fascicles
   3. Epimysium—coarse sheath covering the muscle as a whole
   4. These three fibrous components continue and fuse to become a tendon or aponeurosis; a tendon sheath (lined with synovial membrane) covers some longer tendons
B. Size, shape, and fiber arrangement (Figure 11-2)
   1. Vary considerably in size, shape, and fiber arrangement
   2. Size—range from extremely small to large masses
   3. Shape—variety of shapes, such as broad, narrow, long, tapering, short, blunt, triangular, quadrilateral, irregular, flat sheets, or bulky masses
   4. Arrangement—variety of arrangements, such as parallel to a long axis, converging to a narrow attachment, oblique, pennate, bipennate, or curved; the direction of fibers is significant because of its relationship to function
C. Attachment of muscles (Figure 11-3)
   1. Origin—point of attachment that does not move when the muscle contracts
   2. Insertion—point of attachment that moves when the muscle contracts
D. Muscle actions (Figure 11-4)
   1. Most movements are produced by the coordinated action of several muscles; some muscles in the group contract while others relax
      a. Prime mover—a muscle that directly performs a specific movement
      b. Agonists—any "mover" muscle that directly performs a movement, including the prime mover
      c. Antagonist—muscles that when contracting, directly oppose prime movers; relax while the prime mover (agonist) is contracting to produce movement; provide precision and control during contraction of prime movers
      d. Synergists—muscles that contract at the same time as the prime movers; they facilitate prime mover actions to produce a more efficient movement
      e. Fixator muscles—joint stabilizers (type of synergist)
E. Lever systems
   1. In the human body, bones serve as levers and joints serve as fulcrums; contracting muscle applies a pulling force on a bone lever at the point of the muscle's attachment to the bone, which causes the insertion bone to move about its joint fulcrum
   2. Lever system—composed of four component parts (Figure 11-5)
      a. Rigid bar (bone)
      b. Fulcrum (F) around which the rod moves (joint)
      c. Load (L) that is moved
      d. Pull (P) that produces movement (muscle contraction)
   3. First-class levers
      a. Fulcrum lies between the pull and the load
      b. Not abundant in the human body; serve as levers of stability
   4. Second-class levers
      a. Load lies between the fulcrum and the joint at which the pull is exerted
      b. Presence of these levers in the human body is a controversial issue
   5. Third-class levers
      a. Pull is exerted between the fulcrum and load
      b. Permit rapid and extensive movement
      c. Most common type of lever found in the body

HOW MUSCLES ARE NAMED

A. Muscle names can be in Latin or English (this book uses English)
B. Muscles are named according to one or more of the following features:
   1. Location, function, shape (Tables 11-2; 11-3; 11-4)
   2. Direction of fibers—named according to fiber orientation (Table 11-5)
   3. Number of heads or divisions (Table 11-5)
   4. Points of attachment—origin and insertion points
   5. Relative size—small, medium, or large (Table 11-6)

IMPORTANT SKELETAL MUSCLES (FIGURE 11-6)

A. Muscles of facial expression—unique in that at least one point of attachment is to the deep layers of the skin over the face or neck (Figures 11-7 and 11-8; Table 11-7)
B. Muscles of mastication—responsible for chewing movements (Figure 11-9)
C. Muscles that move the head—paired muscles on either side of the neck are responsible for head movements (Figure 11-10; Table 11-8)

TRUNK MUSCLES

A. Muscles of the thorax—of critical importance in respiration (Figure 11-11; Table 11-9)
B. Muscles of the abdominal wall—arranged in three layers, with fibers in each layer running in different directions to increase strength (Figure 11-12; Table 11-10)
C. Muscles of the back—bend or stabilize the back (Figure 11-14; Table 11-11)

D. Muscles of the pelvic floor—support the structures in the pelvic cavity (Figure 11-15; Table 11-12)

UPPER LIMB MUSCLES

A. Muscles acting on the shoulder girdle—muscles that attach the upper extremity to the torso are located anteriorly (chest) or posteriorly (back and neck); these muscles also allow extensive movement (Figure 11-16; Table 11-13)
B. Muscles that move the arm—the shoulder is a synovial joint allowing extensive movement in every plane of motion (Figure 11-17; Table 11-14)
C. Muscles that move the forearm—found proximal to the elbow and attach to the ulna and radius (Figures 11-19, 11-20, and 11-21; Table 11-15)
D. Muscles that move the wrist, hand, and fingers—these muscles are located on the anterior or posterior surfaces of the forearm (Figures 11-22 through 11-24; Table 11-16)

LOWER LIMB MUSCLES

A. The pelvic girdle and lower extremity function in locomotion and maintenance of stability
B. Muscles that move the thigh and leg (Figures 11-6 and 11-25 through 11-29; Tables 11-17 and 11-18)
C. Muscles that move the ankle and foot (Figures 11-32 and 11-33; Table 11-19)
    1. Extrinsic foot muscles in the leg pull on tendons that insert on bones in the ankle and foot; responsible for dorsiflexion, plantar flexion, inversion, and eversion
    2. Intrinsic foot muscles are located within the foot; responsible for flexion, extension, abduction, and adduction of the toes

POSTURE

A. Maintaining body posture is a major role of muscles
B. "Good posture"—body alignment that most favors function; achieved by keeping the body's center of gravity over its base and requires the least muscular work to maintain
C. How posture is maintained
    1. Muscles exert a continual pull on bones in the opposite direction from gravity
    2. Structures other than muscle and bones have a role in maintaining posture
        a. Nervous system—responsible for the existence of muscle tone and also for regulation and coordination of the amount of pull exerted by individual muscles
        b. Respiratory, digestive, excretory, and endocrine systems all contribute to maintain posture

CYCLE OF LIFE: MUSCULAR SYSTEM

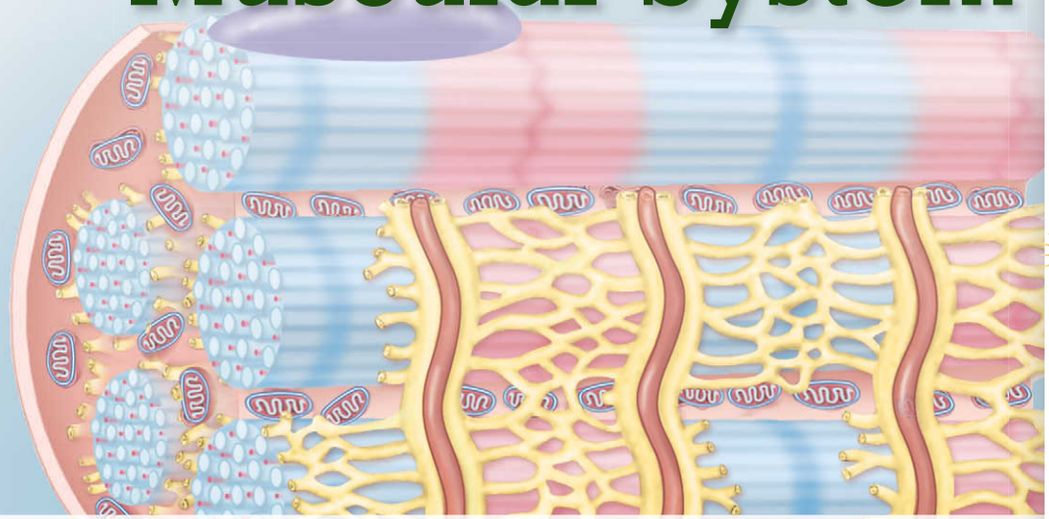
A. Muscle cells—increase or decrease in number, size, and ability to shorten at different periods
B. Pathological conditions at different periods of the life cycle may affect the muscular system
C. Life cycle changes—manifested in other components of functional unit:
    1. Infancy and childhood—coordination and control of muscle contraction permit sequential development steps
    D. Degenerative changes of advancing age result in replacement of muscle cells with nonfunctional connective tissue

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the terms *endomysium*, *perimysium*, and *epimysium*.
2. Identify/describe the most common type of lever in the body.
3. Give an example of a muscle named by location, function, shape, fiber direction, number of heads, and points of attachment.
4. Name the main muscles of the back, chest, abdomen, neck, shoulder, upper part of the arm, forearm, thigh, buttocks, leg, and pelvic floor.
5. Name the main muscles that flex, extend, abduct, and adduct the arm; that raise and lower the shoulder.
6. Name the main muscles that flex and extend the forearm; that flex and extend the wrist and hand.
7. Name the main muscles that flex, extend, abduct, and adduct the thigh; that flex and extend the leg and thigh; that flex and extend the foot.
8. Name the main muscles that flex, extend, abduct, and adduct the head.
9. Name the main muscles that move the abdominal wall; that move the chest wall.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Identify the muscles of facial expression. What muscles facilitate smiling and frowning?
2. How do the origin and insertion of a muscle relate to each other in regard to actual movement?
3. When the biceps brachii contracts, the elbow flexes. When the triceps brachii contracts, the elbow extends. Explain the role of both muscles in terms of agonist and antagonist in both of these movements.
4. Describe how the body maintains posture.
5. Describe the clinical significance regarding the difference in size between the large head of the humerus and the small and shallow glenoid cavity of the scapula.
6. If a person working as a word processor complained of weakness, pain, and tingling in the palm and thumb side of the hand, what type of problem might that person be experiencing? Explain specifically what would be happening to cause this discomfort.
7. Baseball players, particularly pitchers, often incur rotator cuff injuries. List the muscles that make up the rotator cuff and explain the importance of these muscles and their role in joint stability.

Physiology of the Muscular System

In Chapter 11, we explored the anatomy of skeletal muscle organs and how they work together to accomplish specific body movements. In this chapter, we continue our study of the muscular system by examining the basic characteristics of skeletal muscle tissue. We uncover the mechanisms that permit skeletal muscle tissue to move the body's framework, as well as perform other functions vital to maintaining a constant internal environment. We also briefly examine smooth and cardiac muscle tissues and contrast them with skeletal muscle tissue.

GENERAL FUNCTIONS

If you have any doubts about the importance of muscle function to normal life, think about what it would be like without it. It is hard to imagine what life would be like if this matchless power were lost. However, as cardinal as it is, movement is not the only contribution muscles make to healthy survival. They also perform two other essential functions: production of a large proportion of body heat and maintenance of posture.

1. **Movement.** Skeletal muscle contractions produce movement of the body as a whole (locomotion) or movement of its parts.
2. **Heat production.** Muscle cells, like all cells, produce heat by the process known as catabolism (discussed in Chapters 4 and 30). The heat produced by just one cell is inconsequential, but because skeletal muscle cells are both highly active and numerous, together they produce a major share of total body heat. Skeletal muscle contractions therefore constitute one of the most important parts of the mechanism for maintaining homeostasis of temperature.
3. **Posture.** The continued partial contraction of many skeletal muscles makes possible standing, sitting, and maintaining a relatively stable position of the body while walking, running, or performing other movements.

FUNCTION OF SKELETAL MUSCLE TISSUE

Skeletal muscle cells have several characteristics that permit them to function as they do. One such characteristic is the ability to be stimulated, often called **excitability** or *irritability*. Because skeletal muscle cells are excitable, they can respond to regulatory mechanisms such as nerve signals.

Contractility of muscle cells, the ability to contract or shorten, allows muscle tissue to pull on bones and thus produce body movement. Sometimes muscle fibers do work by steadily resisting a load without actually becoming shorter. In such a case, the muscle cell is still said to be contracting. The term *contraction*, when applied to muscles, is meant in a broad sense of pulling the ends together—regardless of whether the cell actually gets shorter.

Extensibility, the ability to extend or stretch, allows muscles to return to their resting length after having contracted. Muscles may also extend while still exerting force, as when lowering a heavy object in your hand.

All of these characteristics of muscle cells are related to the microscopic structure of skeletal muscle cells. In the following passages, we first discuss the basic structure of a muscle cell. We then explain how a muscle cell's structural components allow it to perform its unique functions.

Overview of the Muscle Cell

Look at Figure 12-1. As you can see, a skeletal muscle is composed of bundles of skeletal muscle fibers that generally extend the entire length of the muscle. Muscle cells or *myocytes* are most frequently called "muscle fibers." One reason they are often called *fibers* instead of *cells* is their long, thin, threadlike shape. They are 1 to 40 mm long but have a diameter of only 10 to 100 μm. The gastrocnemius muscle of the calf, for example, has approximately a million threadlike muscle fibers.

During muscle tissue development, individual precursor cells fuse together to form a new, combined structure with many nuclei—the mature muscle fiber. That is why muscle fibers don't follow the general rule of one nucleus per cell: each fiber is made up of several cells that are combined into one. Some adult muscle fibers have one of these tiny precursor cells hugging their outer boundary. These *satellite cells* are stem cells that fuse with myocytes during strength training to make bigger muscle fibers. The satellite cells can also become active after a muscle injury to produce more muscle fibers. Scientists are now trying to understand this mechanism better in the hope of developing new therapies for replacing lost muscle tissues.

Skeletal muscle fibers have many of the same structural parts as other cells. Several of these parts, however, are referred to by different names in regard to muscle fibers. For example, **sarcolemma** is a name often used for the plasma membrane of a muscle fiber. **Sarcoplasm** is its cytoplasm.

Muscle fibers contain many more mitochondria than usually found in other types of cells (Figure 12-2), and as we have already learned, each fiber has several nuclei. Muscle cells contain networks of tubules and sacs known as the **sarcoplasmic reticulum (SR)**—the muscle fiber's version of smooth endoplasmic reticulum. The function of the SR is to temporarily store calcium ions (Ca^{++}). The membrane of the SR continually pumps Ca^{++} from the sarcoplasm and stores the ions within its sacs.

A structure unique to muscle cells is a system of transverse tubules, or **T tubules.** This name derives from the fact that these tubules extend transversely across the sarcoplasm, at a right angle to the long axis of the cell. As Figures 12-1, *B*, and 12-2 show, T tubules are formed by inward extensions of the sarcolemma. The chief function of T tubules is to allow electrical signals, or *impulses*, traveling along the sarcolemma to move deeper into the cell.

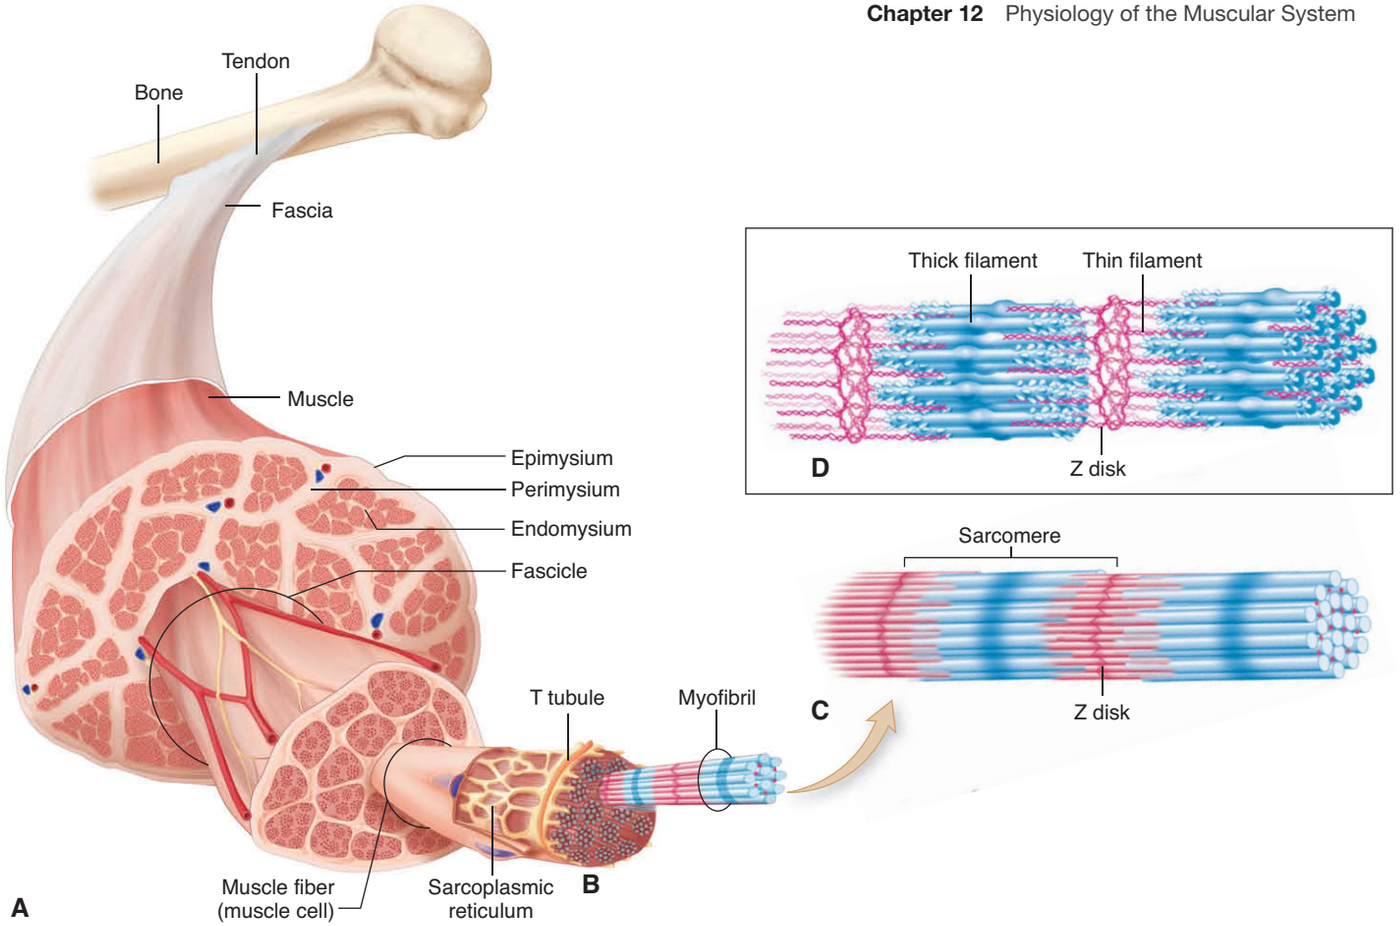

FIGURE 12-1

Structure of skeletal muscle. A, Skeletal muscle organ composed of bundles of contractile muscle fibers held together by connective tissue. **B,** Greater magnification of a single fiber showing smaller fibers—myofibrils—in the sarcoplasm. Note the sarcoplasmic reticulum and T tubules forming a three-part structure called a *triad.* **C,** Myofibril magnified further to show a sarcomere between successive Z disks (Z lines). Cross striae are visible. **D,** Molecular structure of a myofibril showing thick myofilaments and thin myofilaments.

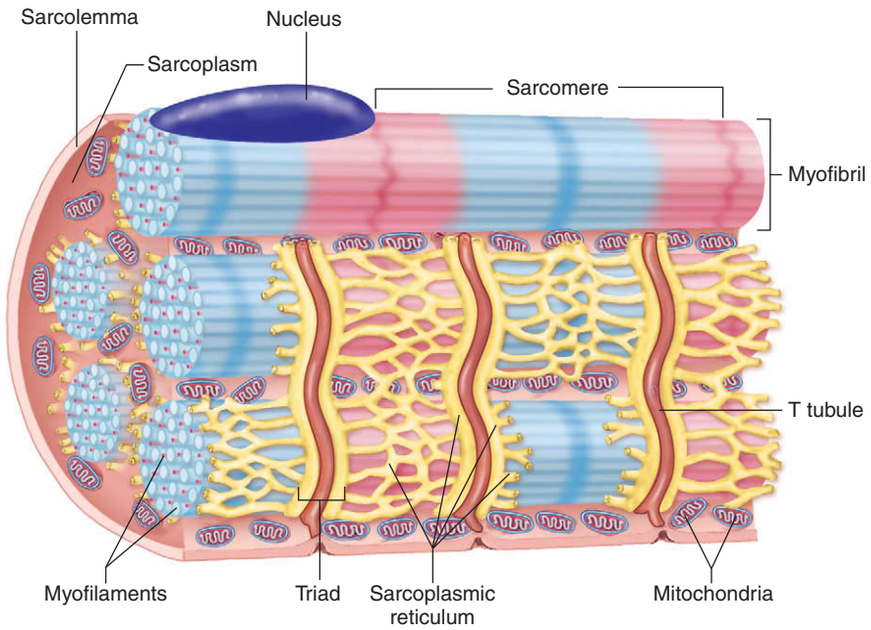

FIGURE 12-2

Unique features of the skeletal muscle cell. Notice especially the T tubules, which are extensions of the plasma membrane, or sarcolemma, and the sarcoplasmic reticulum (SR), a type of smooth endoplasmic reticulum that forms networks of tubular canals and sacs containing stored calcium ions. A triad is a triplet of adjacent tubules: a terminal (end) sac of the SR, a T tubule, and another terminal sac of the SR.

Notice in Figures 12-1, *B*, and 12-2 that a tubular sac of the SR butts up against each side of every T tubule in a muscle fiber. This triplet of tubules (a T tubule sandwiched between sacs of the SR) is called a **triad.** The triad is an important feature of the muscle cell because it allows an electrical impulse traveling along a T tubule to stimulate the membranes of adjacent sacs of the SR. Figure 12-3 shows how this works. At rest, calcium ion pumps in the SR membrane pump Ca^{++} into the terminal sacs of the SR. However, when an electrical impulse travels along the sarcolemma and down the T tubule, gated Ca^{++} channels in the SR open in response to the voltage fluctuation. This floods the sarcoplasm with calcium ions—an important step in initiating muscle contraction, as we shall see.

Additional structures not found in other cells are present in skeletal muscle fibers. For instance, the cytoskeleton of the muscle fiber is quite unique. **Myofibrils** are bundles of very fine cytoskeletal filaments that extend lengthwise along skeletal muscle fiber and almost fill the sarcoplasm. A typical muscle fiber may have somewhere in the neighborhood of a thousand or more myofibrils tightly packed inside it.

Myofibrils, in turn, are made up of still finer fibers called **myofilaments.** Notice in Figure 12-1, *D*, that there are two types of myofilaments in the myofibril: *thick filaments* and *thin filaments.* You can see at a glance that some of the filaments are much thicker than others. Although they appear in contrasting colors in the diagram, they are actually colorless.

A **sarcomere** is a segment of the myofibril between two successive **Z disks** (Z lines) (Box 12-1). Find the label *sarcomere* in Figure 12-1, *C*. You will note that each myofibril consists of a lineup of many sarcomeres. Each sarcomere functions as a contractile unit. The A bands of sarcomeres appear as relatively wide, dark stripes (cross striae) under the microscope, and they alternate with narrower, lighter-colored stripes formed by the I bands (see the figure in Box 12-1). Because of its cross striations (or *striae*), skeletal muscle is sometimes called *striated muscle.* Electron microscopy of skeletal muscle (Figure 12-4) reveals details that help us understand concepts of its structure and function.

| QUICK CHECK |

1. What are the three major functions of the skeletal muscles?
2. Name some features of the muscle cell that are not found in other types of cells.
3. What causes the striations observed in skeletal muscle fibers?
4. Why is the triad relationship between T tubules and the SR important?

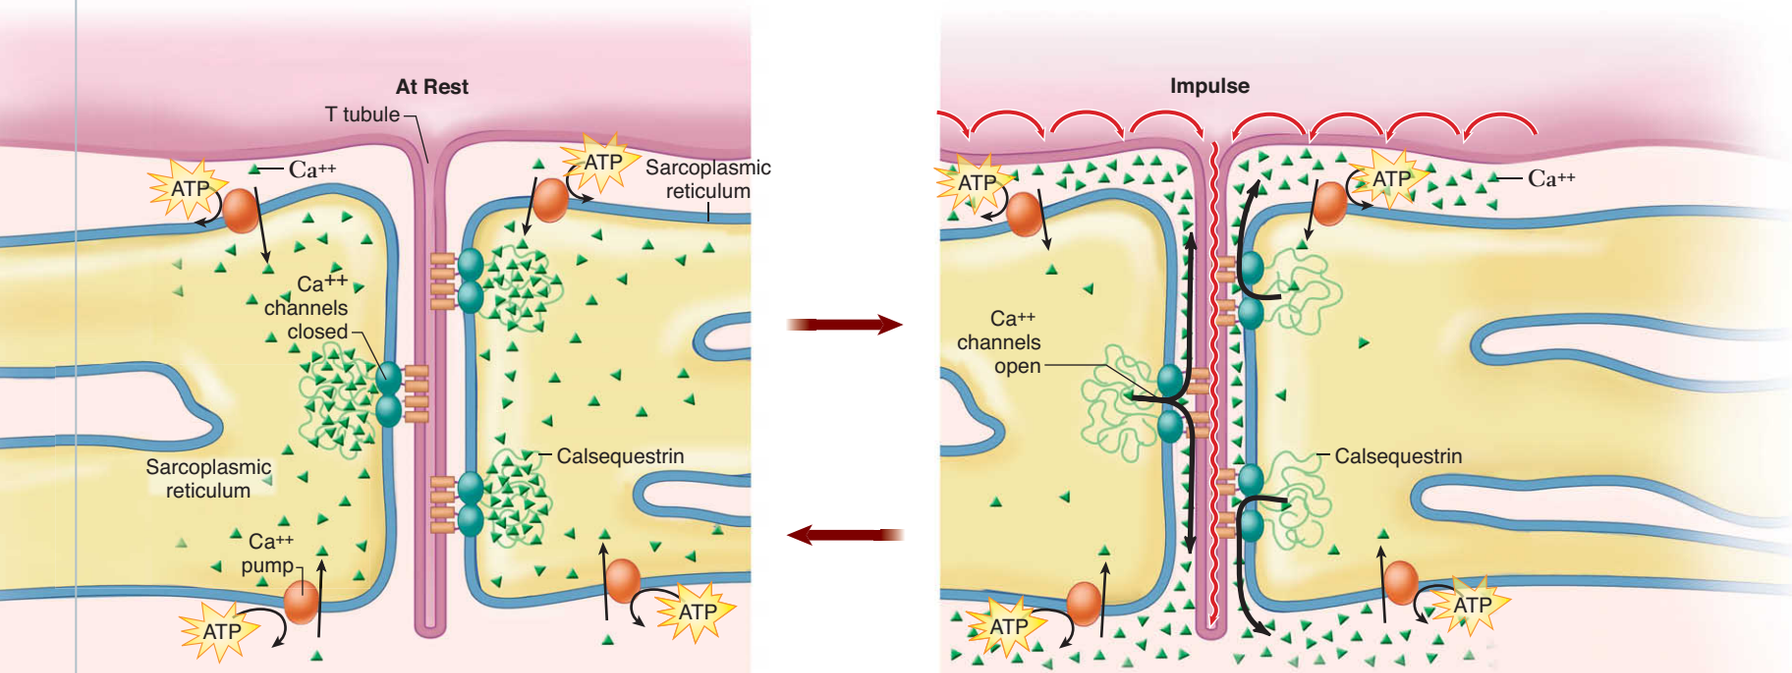

FIGURE 12-3

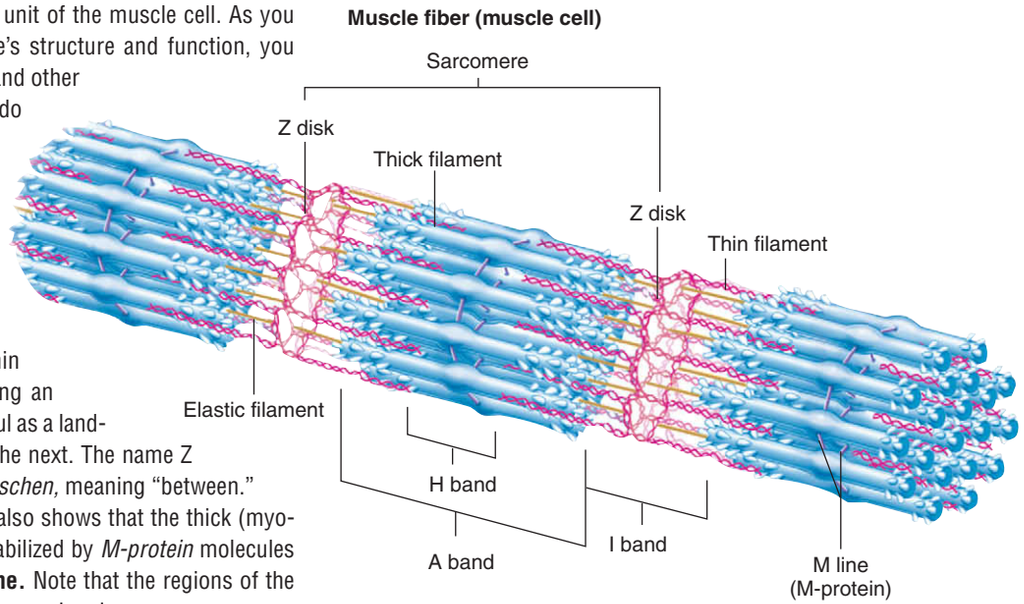
Storage and release of calcium ions at the triad. At rest *(left),* calcium ion pumps in the sarcoplasmic reticulum (SR) membrane actively pull Ca^{++} into the SR—thus creating a concentration gradient with very little Ca^{++} left in the sarcoplasm. Note that the Ca^{++} is sequestered by protein filaments *(calsequestrin)* in "bunches" just inside the closed Ca^{++} channels. When the fiber is stimulated *(right),* an electrical impulse travels from the sarcolemma and down the T tubule, where the voltage fluctuation triggers the opening of voltage-gated calcium channels. This allows passive diffusion of the Ca^{++} inside the SR out to the sarcoplasm, where it will trigger the contraction process. Almost immediately after stimulation, the calcium channels close and the Ca^{++} is once again pumped into the sacs of the SR *(left). ATP,* Adenosine triphosphate.

Box 12-1 | A More Detailed Look at the Sarcomere

The sarcomere is the basic contractile unit of the muscle cell. As you read the explanation of the sarcomere's structure and function, you might wonder what the Z disk, M line, and other components really are—and what they do for the muscle cell.

First of all, it is important that you appreciate the three-dimensional nature of the sarcomere. You can then realize that the Z disk (Z line), which often looks like a zigzag line in a flat diagram, is really a dense plate or disk to which the thin filaments directly anchor. Besides being an anchor for myofibrils, the Z disk is useful as a landmark separating one sarcomere from the next. The name Z disk comes from the German word *zwischen,* meaning "between."

Detailed analysis of the sarcomere also shows that the thick (myosin) filaments are held together and stabilized by *M-protein* molecules that form a middle line called the **M line.** Note that the regions of the sarcomere are identified by specific zones or bands:



A band—the segment that runs the entire length of the thick filaments (also called *anisotropic band*)

I band—the segment that includes the Z disk and the ends of the thin filaments where they do not overlap the thick filaments (also called *isotropic band*)

H band—the middle region of the thick filaments where they do not overlap the thin filaments (H is German for *heller* "bright")

Note in Figure 12-2 that the T tubules in human muscle fibers align themselves along the borders between the A band and I band.

Later, as you review the process of contraction, note how the regions listed above change during each step of the process.

In addition to thin and thick filaments, each sarcomere has numerous **elastic filaments.** Elastic filaments, composed of a protein called *titin (connectin),* anchor the thick filaments to the Z disk, as the figure shows. The elastic filaments are believed to give myofibrils, and thus muscle fibers, their characteristic elasticity. *Dystrophin,* not shown here, is a protein that holds the actin filaments to the sarcolemma. Dystrophin and a complex of connected molecules anchors the muscle fiber to surrounding matrix so that the muscle does not break during a contraction. Dystrophin and its role in muscular dystrophy are discussed further on p. 373.

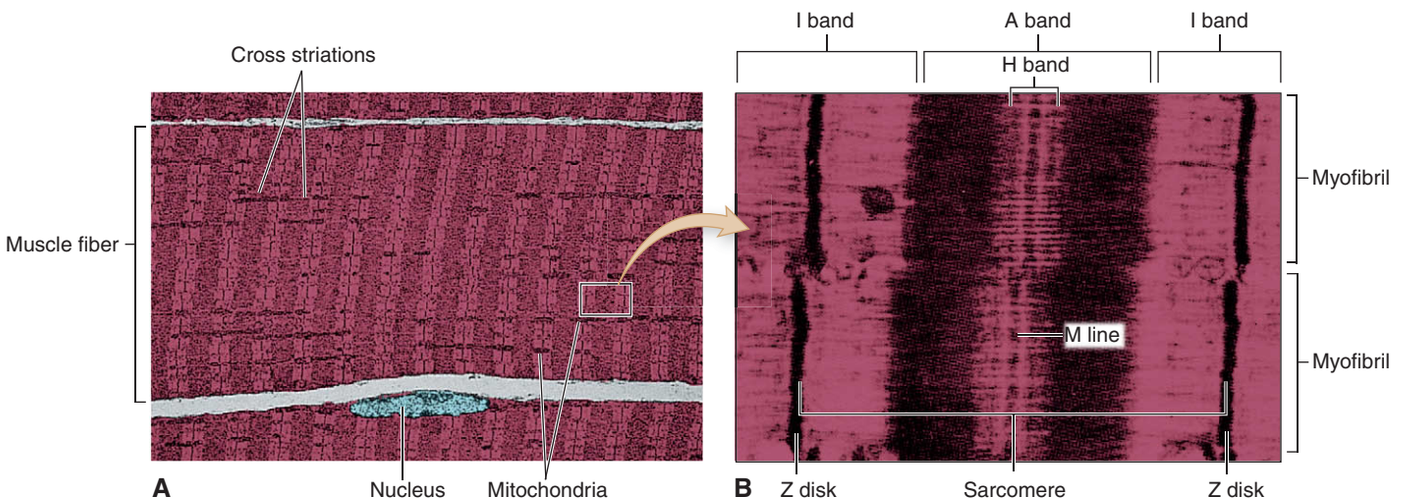


FIGURE 12-4

Skeletal muscle striations. Color-enhanced scanning electron micrographs (SEMs) showing longitudinal views of skeletal muscle fibers. **B** shows detail of **A** at greater magnification. Note that the myofilaments of each myofibril form a pattern that when viewed together, produces the striated (striped) pattern typical of skeletal muscle.

Myofilaments

Each muscle fiber contains a thousand or more parallel myofibrils that are only about 1 µm thick. Lying side by side in each myofibril are approximately 15,000 sarcomeres, each made up of hundreds of thick and thin filaments. The molecular structure of these myofilaments reveals the mechanism of how muscle fibers contract and do so powerfully. It is wise, therefore, to take a moment to first study the structure of myofilaments before discussing the detailed mechanism of muscle contraction.

First of all, four different kinds of protein molecules make up myofilaments: **myosin, actin, tropomyosin,** and **troponin.** The thin filaments are made of a combination of three proteins: actin, tropomyosin, and troponin. Figure 12-5, *A*, shows that globular actin molecules (*g-actin*) are strung together like beads to form two fibrous strands (*f-actin*) that twist around each other to form the bulk of each thin filament. Actin and myosin molecules have a chemical attraction for one another, but at rest, the active sites on the actin molecules are covered by long tropomyosin molecules. The tropomyosin molecules seem to be held in this blocking position by troponin molecules spaced at intervals along the thin filament (see Figure 12-5, *A*).

As Figure 12-5, *B*, shows, the thick filaments are made almost entirely of myosin molecules. Notice that the myosin molecules are shaped like two golf clubs twisted together. Their long shafts bundle together to form a thick filament and their doubled "heads" stick out from the bundle. The myosin heads are chemically attracted to the actin molecules of the nearby thin filaments, so they angle toward the thin filaments. When they bridge the gap between adjacent myofilaments, the myosin heads are usually called **cross bridges.** Recall from Figure 3-17 (p. 82) that myosin acts as a molecular motor. The myosin in thick filaments can actively pull on actin when adenosine triphosphate (ATP) is available.

Within a myofibril, the thick and thin filaments alternate, as shown in Figure 12-1, *D*. They are also very close to one another, as you can see in the cross section in Figure 12-5, *C*, and Figure 12-6. This arrangement is crucial for contraction. Another fact important for contraction is that the thin filaments attach to both Z disks (Z lines) of a sarcomere and that they extend in from the Z disks partway toward the center of the sarcomere. When the muscle fiber is relaxed, the thin filaments terminate at the outer edges of the H bands. In contrast, the thick myosin filaments do not attach directly to the Z disks, and they extend only to the length of the A bands of the sarcomeres.

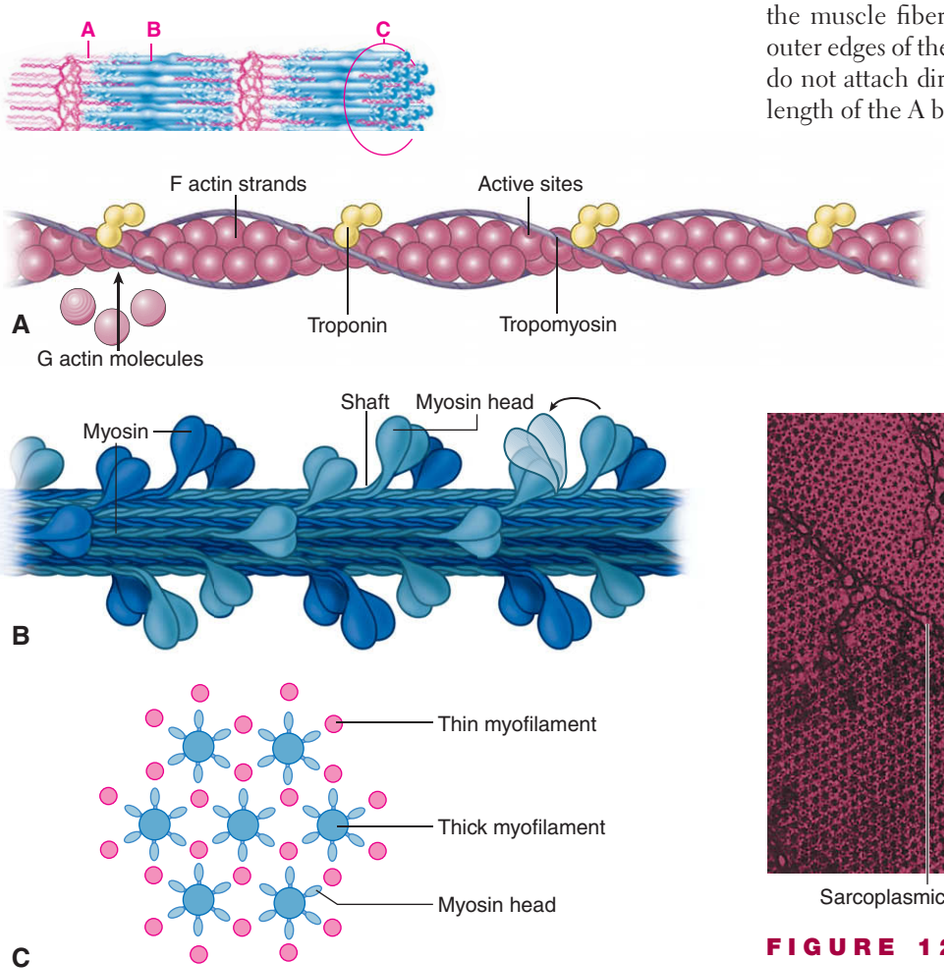

FIGURE 12-5

Structure of myofilaments. A, Thin myofilament. **B,** Thick myofilament. **C,** Cross section of several thick and thin myofilaments showing the relative positions of myofilaments and the myosin heads that will form cross bridges between them.

Mechanism of Contraction

To accomplish the powerful shortening, or contraction, of a muscle fiber, several processes must be coordinated in a stepwise fashion. These steps are summarized in the following sections and in Box 12-2.

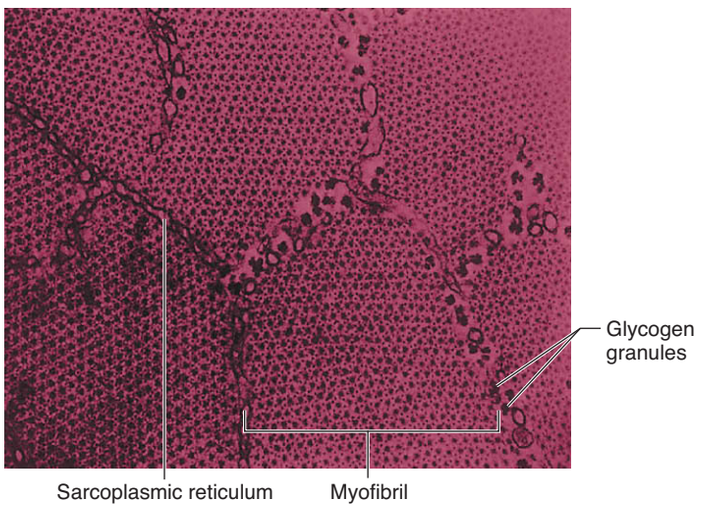

FIGURE 12-6

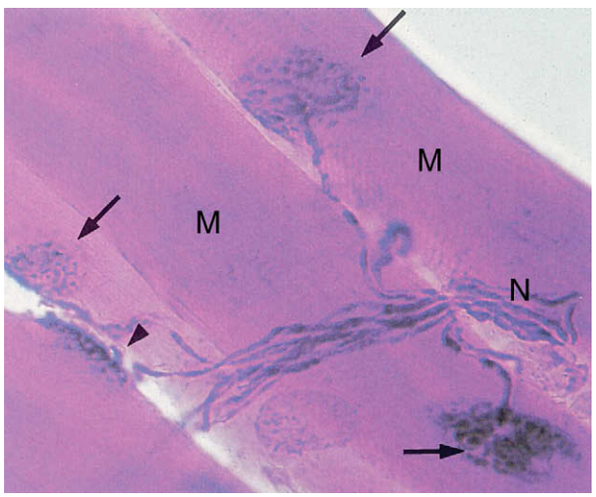
Cross section of myofibrils. Color-enhanced scanning electron micrographs (SEMs) showing a cross section from a skeletal muscle fiber. Note the dense arrangement of thick and thin filaments, seen here in cross section as mere dots. Note also the dark glycogen granules and sarcoplasmic reticulum tubules sandwiched between the myofibrils.

Box 12-2 | Major Events of Muscle Contraction and Relaxation

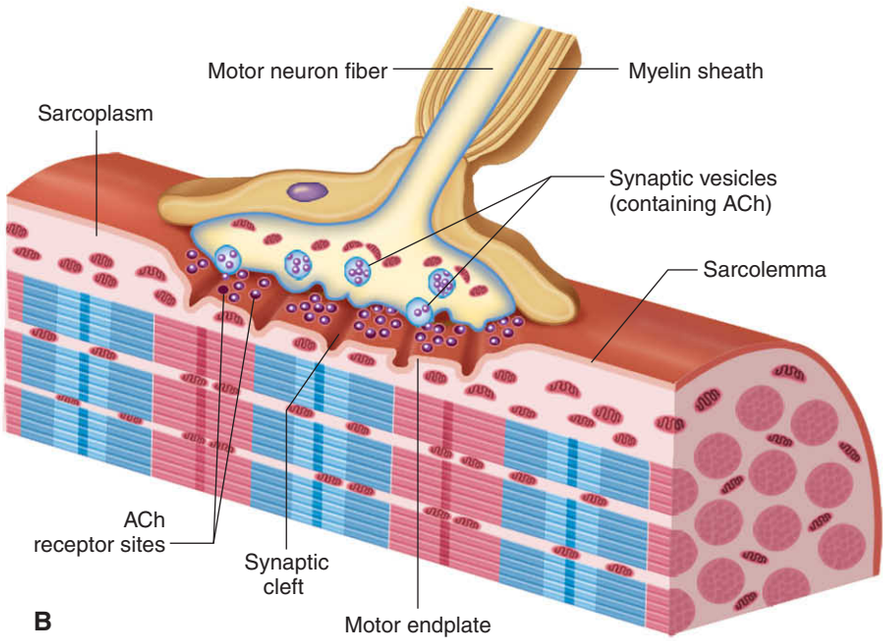
Excitation and Contraction

1. A nerve impulse reaches the end of a motor neuron and triggers release of the neurotransmitter acetylcholine (ACh).
2. ACh diffuses rapidly across the gap of the neuromuscular junction and binds to ACh receptors on the motor endplate of the muscle fiber.
3. Stimulation of ACh receptors initiates an impulse that travels along the sarcolemma, through the T tubules, to the sacs of the sarcoplasmic reticulum (SR).
4. Ca^{++} is released from the SR into the sarcoplasm, where it binds to troponin molecules in the thin myofilaments.
5. Tropomyosin molecules in the thin myofilaments shift and thereby expose actin's active sites.
6. Energized myosin cross bridges of the thick myofilaments bind to actin and use their energy to pull the thin myofilaments toward the center of each sarcomere. This cycle repeats itself many times per second, as long as adenosine triphosphate is available.
7. As the filaments slide past the thick myofilaments, the entire muscle fiber shortens.



Relaxation

1. After the impulse is over, the SR begins actively pumping Ca^{++} back into its sacs.
2. As Ca^{++} is stripped from troponin molecules in the thin myofilaments, tropomyosin returns to its position and blocks actin's active sites.
3. Myosin cross bridges are prevented from binding to actin and thus can no longer sustain the contraction.
4. Because the thick and thin myofilaments are no longer connected, the muscle fiber may return to its longer, resting length.



EXCITATION OF THE SARCOLEMMA

Under normal circumstances, a skeletal muscle fiber remains "at rest" until it is stimulated by a signal from a special type of nerve cell called a **motor neuron.** As Figure 12-7 shows, motor neurons connect to the sarcolemma of a muscle fiber at a folded **motor endplate** to form a junction called a *neuromuscular junction.*

A **neuromuscular junction (NMJ)** is a type of connection called a *synapse* and is characterized by a narrow gap, or synaptic cleft, across which *neurotransmitter* molecules transmit signals. When nerve impulses reach the end of a motor neuron fiber, small vesicles release a neurotransmitter, **acetylcholine (ACh),** into the synaptic cleft. Diffusing swiftly across this microscopic gap, acetylcholine molecules contact the sarcolemma of the adjacent muscle fiber. There they stimulate acetylcholine receptors and thereby initiate an electrical impulse in the sarcolemma. The process of synaptic transmission and induction of an impulse—a process often called *excitation*—is discussed in detail in Chapter 13.

A

B

FIGURE 12-7

Neuromuscular junction (NMJ). A, Micrograph showing four neuromuscular junctions (NMJs). Three are surface views *(arrows)* and one is a side view *(arrowhead). N,* Nerve fibers; *M,* muscle fibers. **B,** This sketch shows a side view of the NMJ. Note how the distal end of a motor neuron fiber forms a synapse, or "chemical junction," with an adjacent muscle fiber. Neurotransmitter molecules (specifically, acetylcholine, or ACh) are released from the neuron's synaptic vesicles and diffuse across the synaptic cleft. There they stimulate receptors in the motor endplate region of the sarcolemma.

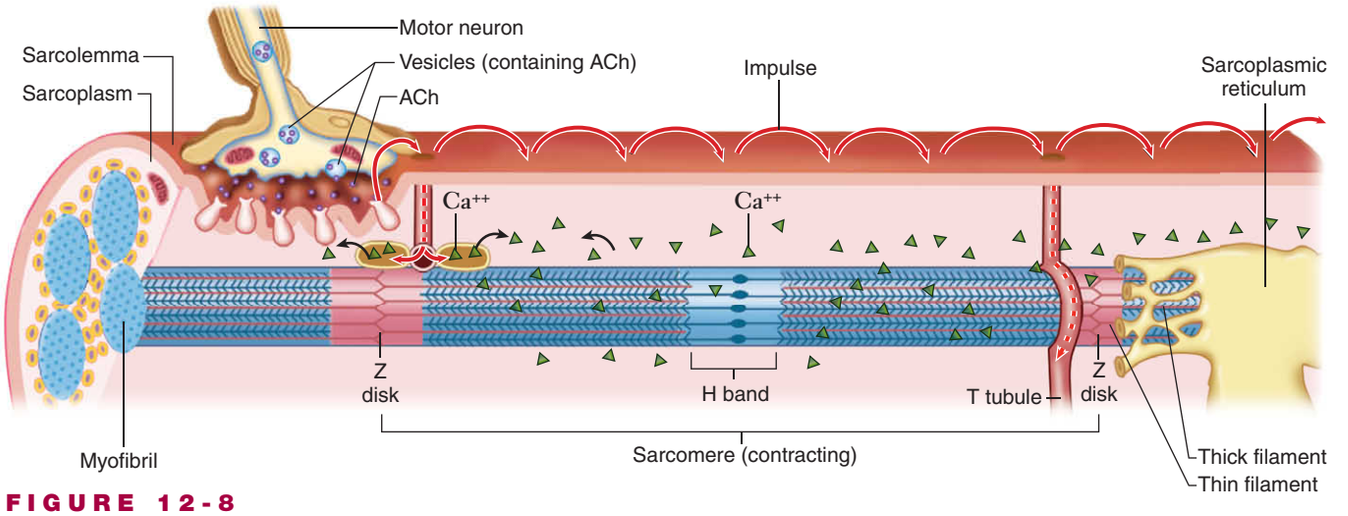


FIGURE 12-8

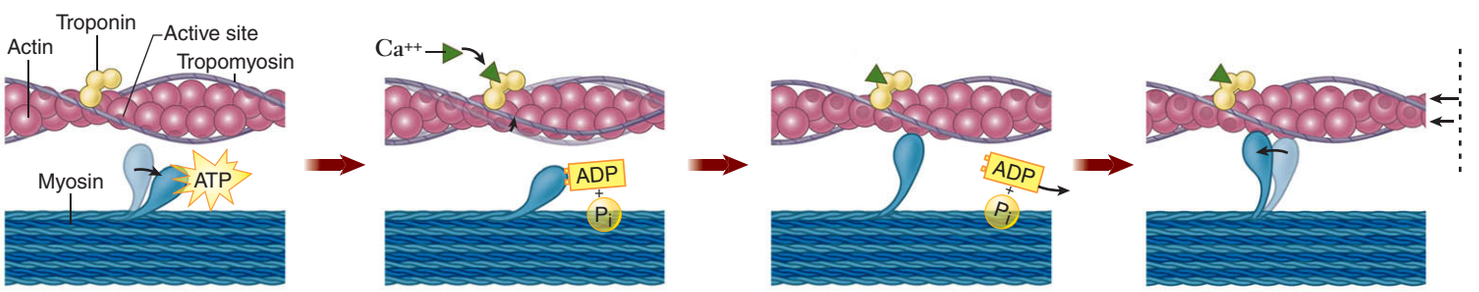

Effects of excitation on a muscle fiber. Excitation of the sarcolemma by a nerve impulse initiates an impulse in the sarcolemma. The impulse travels across the sarcolemma and through the T tubules, where it triggers adjacent sacs of the sarcoplasmic reticulum to release a flood of calcium ions (Ca^{++}) into the sarcoplasm. Ca^{++} is then free to bind to troponin molecules in the thin filaments. This binding, in turn, initiates the chemical reactions that produce a contraction.

CONTRACTION

The impulse, a temporary electrical voltage imbalance, is conducted over the muscle fiber's sarcolemma and inward along the T tubules (Figure 12-8). The impulse in the T tubules triggers the release of a flood of calcium ions from the adjacent sacs of the SR (see Figures 12-3 and 12-8).

In the sarcoplasm, the calcium ions combine with troponin molecules in the thin filaments of the myofibrils (Figure 12-9). Recall that troponin normally holds tropomyosin strands in a position that blocks the chemically active sites of actin. When calcium binds to troponin, however, the tropomyosin shifts to expose active binding sites on the actin molecules (Figure 12-10). Once the active sites are exposed, energized myosin heads of the thick filaments bind to actin molecules in the nearby thin filaments. The myosin head temporarily forms a *cross bridge* between the thick and thin filaments (Figure 12-11). After forming cross bridges, the myosin heads bend with great force, literally pulling the thin filaments past them. Each head then releases itself, binds to the next active site, and pulls again. Figure 12-12 shows how sliding of the thin filaments toward the center of each sarcomere quickly shortens the entire myofibril—and thus the entire muscle fiber.

This model of muscle contraction has been called the **sliding-filament model.** Perhaps a better name might be

1. Each myosin head in the thick filament moves into a resting position after an ATP molecule binds and transfers its energy.
2. Calcium ions released from the sarcoplasmic reticulum bind to troponin in the thin filament, thereby allowing tropomyosin to shift from its position blocking the active sites of actin molecules.
3. Each myosin head then binds to an active site on a thin filament and displaces the remnants of ATP hydrolysis—adenosine diphosphate (ADP) and inorganic phosphate (P_i).
4. The release of stored energy from step 1 provides the force needed for each head to move back to its original position and pull actin along with it. Each head will remain bound to actin until another ATP molecule binds to it and pulls it back into its resting position (step 1).

FIGURE 12-9

The molecular basis of muscle contraction.

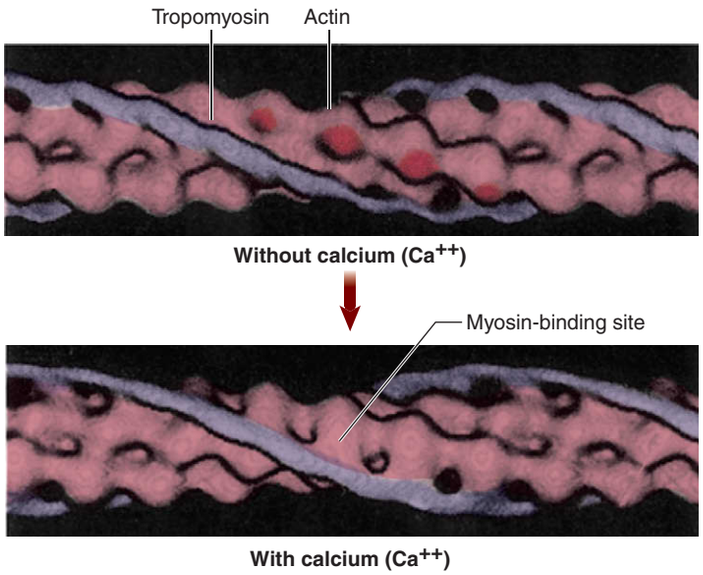

FIGURE 12-10

Role of calcium in muscle contraction. Color-enhanced scanning electron micrograph (SEM) of a thin filament. When calcium is absent, the active myosin binding sites on actin are covered by tropomyosin. However, after calcium becomes available and binds to troponin, the tropomyosin is pulled out of its blocking position and reveals the active binding sites on actin.

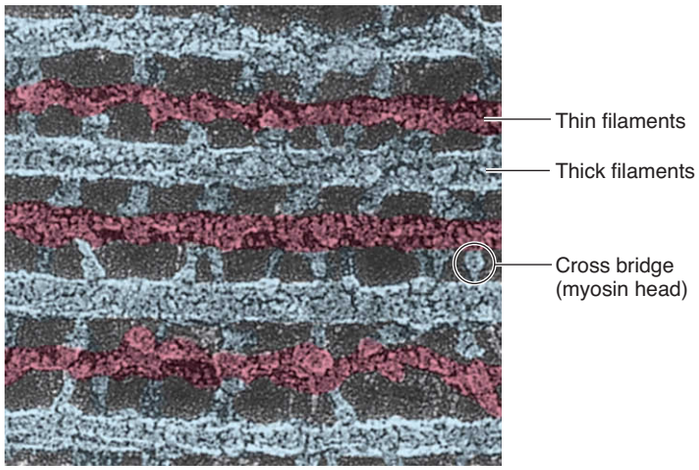

FIGURE 12-11

Cross bridges. Color-enhanced scanning electron micrograph (SEM) showing the myosin heads functioning as cross bridges that connect the thick filaments to the thin filaments, pulling on the thin filaments and causing them to slide.

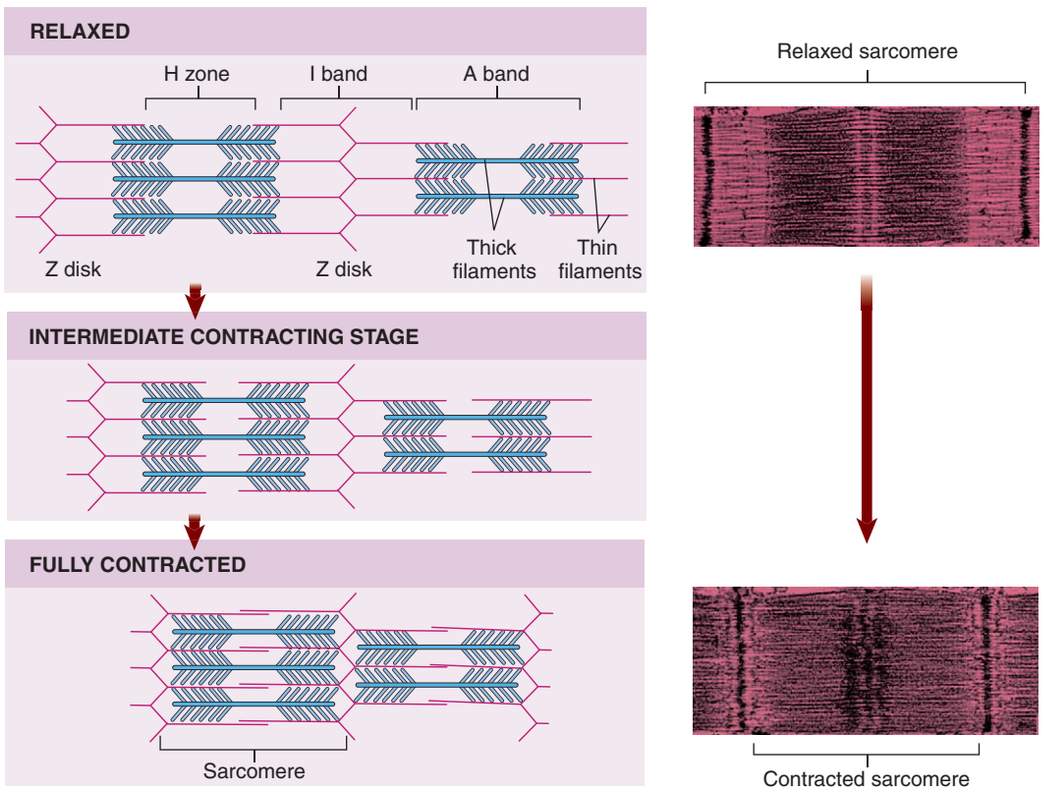

FIGURE 12-12

Sliding-filament model. A, During contraction, myosin cross bridges pull the thin filaments toward the center of each sarcomere, thus shortening the myofibril and the entire muscle fiber. **B,** Color-enhanced transmission electron micrographs (TEMs) showing the shortening of a sarcomere caused by the sliding of filaments during muscle contraction.

ratcheting-filament model because the myosin heads actively ratchet the thin filaments toward the center of the sarcomere with great force.

Muscle fibers usually contract to about 80% of their starting length—rarely to 60% or 70%. Some muscle fibers contract hardly at all because they are pulling on an unmoving load. Even so, such muscle fibers are still said to be "contracting" in a broad sense. Their sarcomeres are still working hard to pull the ends toward one another, as though they are at a steady "draw" in a game of tug-of-war (Figure 12-13). Because the actin-myosin bond is not permanent, the sarcomere cannot "lock up" once it has shortened to hold its position passively. Thus it takes energy to actively maintain a shortened position—by continually repeating the actin-myosin reaction as long as necessary.

RELAXATION

Almost immediately after the SR releases its flood of calcium ions into the sarcoplasm, it begins actively pumping them back into its sacs once again. Within a few milliseconds, much of the calcium is recovered. Because the active transport carriers of the SR have greater affinity for calcium than the troponin molecules do, the calcium ions are stripped off the troponin molecules and returned to the sacs of the SR. As you might suspect, this shuts down the entire process of contraction. Troponin without its bound calcium allows the tropomyosin to once again block actin's active sites. Myosin heads reaching for the next active site on actin are blocked, and thus the thin filaments are no longer being held—or pulled—by the thick filaments.

If no new nerve impulse immediately follows, the muscle fiber relaxes. The relaxed muscle fiber may remain at its contracted length, but forces outside the muscle fiber are likely to pull it back to its longer resting length.

As we have seen, the contraction process in a skeletal muscle fiber automatically shuts itself off within a small fraction of a second after the initial stimulation. However, a muscle fiber may sustain a contraction for some time if there are many stimuli in rapid succession, thus permitting calcium ions to remain available in the sarcoplasm for a longer period.

6. What is a neuromuscular junction (NMJ)? How does it work?
7. What is the role of calcium ions (Ca^{++}) in muscle contraction?

Energy Sources for Muscle Contraction

ATP

The energy required for muscular contraction is obtained by hydrolysis of a nucleotide called *adenosine triphosphate*, or *ATP*. Recall from Chapter 2 (Figure 2-33, p. 59) that this molecule has an adenine and ribose group (together called *adenosine*) attached to three phosphate groups. Two of the three phosphate groups in ATP are attached to the molecule by *high-energy bonds*. Breaking of these high-energy bonds provides the energy necessary to pull the thin myofilaments during muscle contraction.

As Figure 12-9, *Step 1*, shows, before contraction occurs, each myosin cross-bridge head moves into a resting position when an ATP molecule binds to it. The ATP molecule breaks its outermost high-energy bond, thereby releasing inorganic phosphate (P_i) and transferring the energy to the myosin head. In a way, this is like pulling back the elastic band of a slingshot—the apparatus is "at rest" but ready to spring. When myosin binds to actin, the stored energy is released, and the myosin head does indeed spring back to its original position. Thus the energy transferred from ATP is used to do the work of pulling the thin filaments during contraction. Another ATP molecule then binds to the myosin head, which then releases actin and moves into its resting position again—all set for the next "pull." This cycle repeats as long as ATP is available and actin's active sites are unblocked.

Muscle fibers must continually resynthesize ATP because they can store only small amounts of it. There is only enough ATP in a muscle fiber for about 2 to 4 seconds of maximum contraction. However, energy for the resynthesis of ATP can be quickly supplied by the breakdown of another high-energy compound, **creatine phosphate (CP)**, as you can see in Figure 12-14. CP is a sort of backup energy molecule that provides enough energy for about 20 additional seconds of maximal contraction. Both ATP and CP

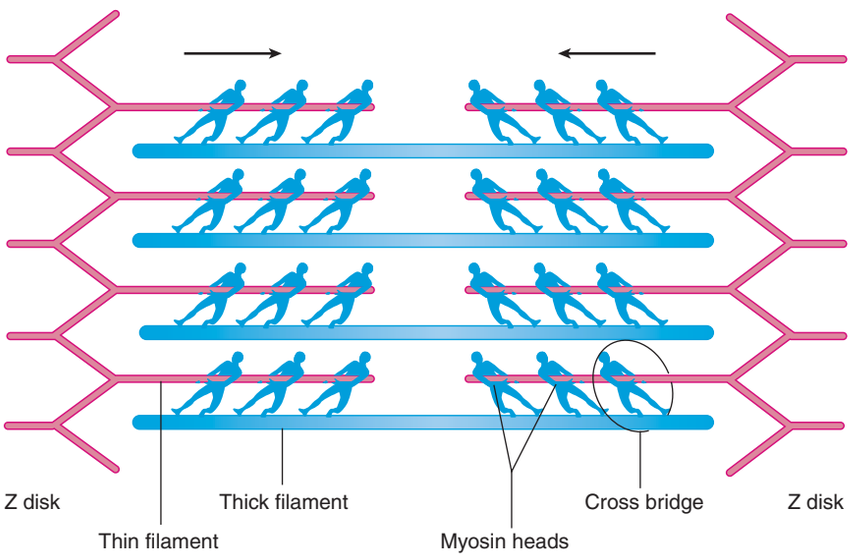

FIGURE 12-13

Simplified contracting sarcomere. This diagram illustrates the concept of muscle contraction as a sort of tug-of-war game in which the myosin heads (shown here as little people) hold onto thin filament "ropes"—thus forming cross bridges. As the myosin heads pull on the thin filaments, the Z disks (Z lines) get closer together—thus shortening the sarcomere. Likewise, the short length of a sarcomere may be held in position by the continued effort of the myosin heads.

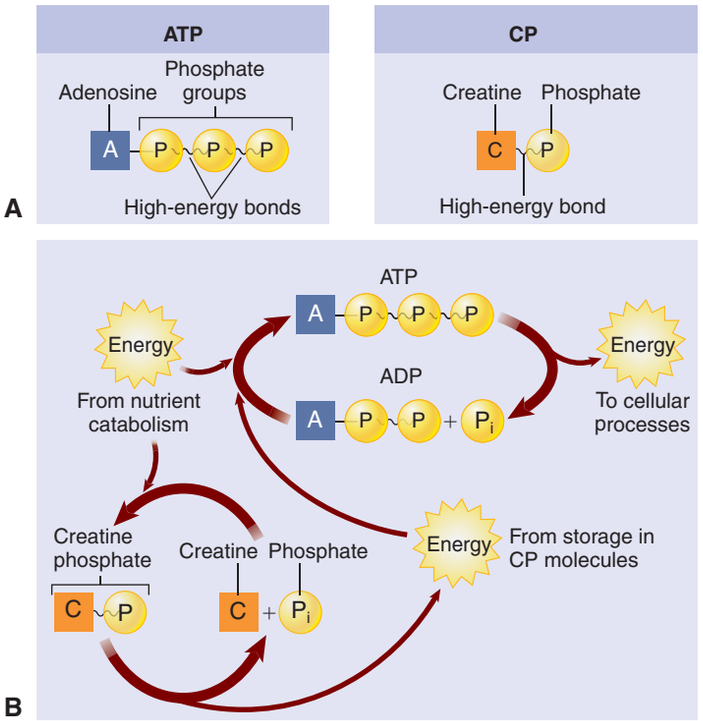

FIGURE 12-14

Energy sources for muscle contraction. A, The basic structure of two high-energy molecules in the sarcoplasm: adenosine triphosphate (ATP) and creatine phosphate (CP). **B,** This diagram shows how energy released during the catabolism of nutrients can be transferred to the high-energy bonds of ATP directly or, instead, stored temporarily in the high-energy bond of CP. During contraction, ATP is hydrolyzed and the energy of the broken bond is transferred to a myosin head.

are continually resynthesized—or "recharged"—by cellular respiration. Ultimately, energy for both ATP and CP synthesis comes from the catabolism of food.

If a cell runs out of ATP completely and cannot resynthesize more, contraction stops—possibly resulting in stiffness caused by the inability of myosin heads to disengage from actin (see Figure 12-9). When this happens after death, it is called *rigor mortis* (Box 12-3).

GLUCOSE AND OXYGEN

Continued, efficient nutrient catabolism by muscle fibers requires two essential ingredients: glucose and oxygen.

Glucose is a nutrient molecule that contains many chemical bonds. The potential energy stored in these chemical bonds is released during catabolic reactions in the sarcoplasm and mitochondria and transferred to ATP or CP molecules. Ultimately, all the glucose needed by muscle fibers comes from the blood. Skeletal muscle fibers are surrounded by a network of blood capillaries, the tiny "exchange" vessels that allow molecules to enter or leave the blood (Figure 12-15). Some muscle fibers ensure an uninterrupted supply of glucose by storing it in the form of *glycogen*. Recall from Chapter 2 that glycogen is a polysaccharide made up of thousands of glucose subunits.

Box 12-3 | FYI

Rigor Mortis

The term **rigor mortis** is a Latin phrase that means "stiffness of death." In a medical context the term *rigor mortis* refers to the stiffness of skeletal muscles sometimes observed shortly after death. What causes rigor mortis? At the time of death, stimulation of muscle cells ceases. However, the muscle fibers of postural muscles may have been in midcontraction at the time of death—when the myosin-actin cross bridges are still intact. In addition, the sarcoplasmic reticulum (SR) releases much of the Ca^{++} it had been storing, thereby causing even more cross bridges to form. Adenosine triphosphate (ATP) is required to release the cross bridges and "energize" the myosin heads for their next attachment. Because the last of a cell's ATP supply is used up at the time it dies, many cross bridges may be left "stuck" in the contracted position. Thus muscles in a dead body may be stiff because individual muscle fibers ran out of the ATP required to "turn off" a muscle contraction.

Oxygen, which is needed for a catabolic process known as *aerobic respiration*, also ultimately comes from the blood. Most of the oxygen carried in the blood is temporarily bound to *hemoglobin* molecules—a reddish pigment inside red blood cells.

Oxygen can also be stored by cells to ensure an uninterrupted supply. During rest, excess oxygen molecules in the sarcoplasm are attracted to a large protein molecule called **myoglobin.** Like hemoglobin, myoglobin is a reddish pigment with iron (Fe) groups that attract oxygen molecules and hold them temporarily. When the oxygen concentration inside a muscle fiber decreases rapidly—as it does during exercise—it can be quickly resupplied from myoglobin. Muscle fibers that contain large amounts of

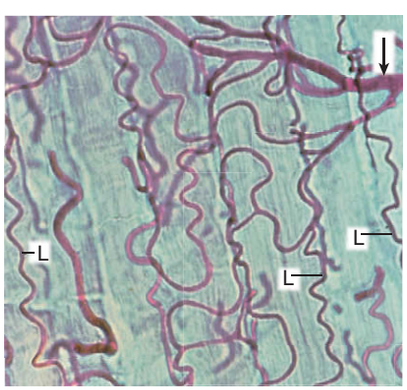

FIGURE 12-15

Blood supply of muscle fibers. Tiny "exchange" vessels called *capillaries* branch out longitudinally *(L)* from small arteries *(arrow)* to form a network that supplies muscle fibers with glucose and oxygen and removes carbon dioxide and lactic acid. In this micrograph, the muscle fibers appear translucent and the blood vessels appear reddish.

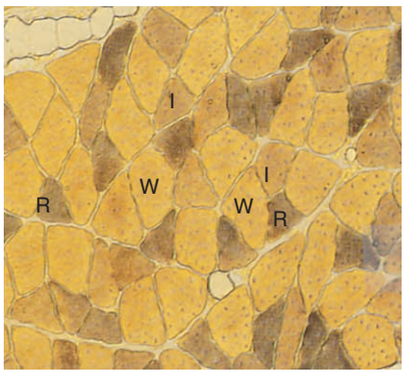
myoglobin take on a deep red appearance and are often called *red fibers.* Muscle fibers with little myoglobin in them are light pink and are often called *white fibers.* Most muscle tissues contain a mixture of red and white fibers (Box 12-4).

CATABOLIC PATHWAYS

The *aerobic* (oxygen-requiring) *pathway* is a catabolic process that produces the maximum amount of energy available from each glucose molecule. When the oxygen concentration is low, however,

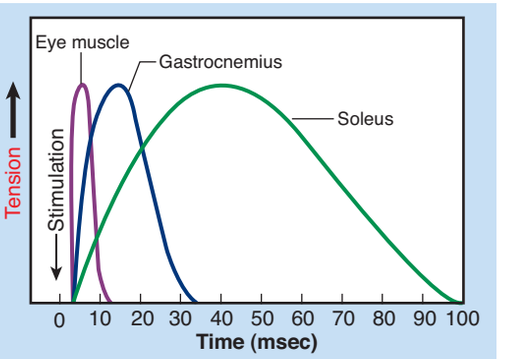
Box 12-4 | SPORTS and FITNESS

Types of Muscle Fibers



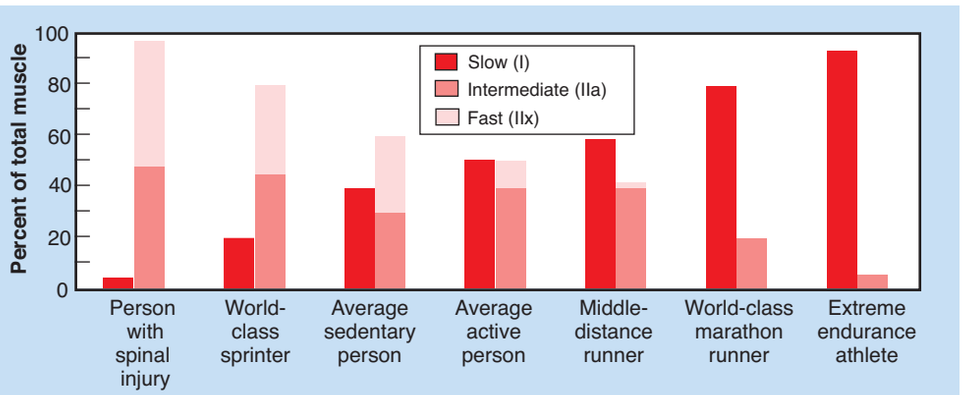
Skeletal muscle fibers can be classified into three types according to their structural and functional characteristics: (1) *slow* (red) *fibers,* (2) *fast* (white) *fibers,* and (3) *intermediate fibers.* Each type is best suited to a particular type or style of muscular contraction—a fact that is useful in considering how different muscles are used during different athletic activities. Although each muscle organ contains a mix of all three fiber types (part *A* of the figure), different organs have these fibers in different proportions, depending on the types of contraction that they most often perform (part *B* of the figure).

Slow fibers are also called *red fibers* because they contain a high concentration of myoglobin, the reddish pigment used by muscle cells to store oxygen. They are called *slow fibers* because their thick myofilaments are made of a type of myosin (type I) that reacts at a slow rate. Because they contract so slowly, slow fibers are usually able to produce ATP quickly enough to keep pace with the energy needs of the myosin and thus avoid fatigue. This effect is enhanced by the larger number of mitochondria, more than found in other fiber types, and the rich oxygen store provided by the myoglobin. The slow, nonfatiguing characteristics of slow fibers make them especially well suited to the sustained contractions exhibited by postural muscles. Postural muscles containing a high proportion of slow fibers can hold the skeleton upright for long periods without fatigue.



Fast fibers are also called *white fibers* because they contain very little myoglobin. Fast fibers can contract much more rapidly than slow fibers because they have a faster type of myosin (type IIx) and because their system of T tubules and sarcoplasmic reticulum (SR) is more efficient at quickly delivering Ca^{++} to the sarcoplasm. The price of a rapid contraction mechanism is rapid depletion of ATP. Despite the fact that fast fibers typically contain a high concentration of glycogen, they have few mitochondria and thus must rely primarily on anaerobic processes to regenerate ATP. Because the anaerobic pathway produces relatively small amounts of ATP, fast fibers cannot produce enough ATP to sustain a contraction for very long. Because they can generate great force very quickly but not for a long duration, fast fibers are best suited for muscles that move the fingers and eyes in darting motions.

Intermediate fibers have characteristics somewhere in between fast and slow fibers because they have moderately fast myosin (type IIa). They are more fatigue resistant than fast fibers and can generate more force more quickly than slow fibers. This type of muscle fiber predominates in muscles that both provide postural support and are occasionally required to generate rapid, powerful contractions. One example is the *gastrocnemius* of the calf, which helps support the leg but is also used in walking, running, and jumping (part *B* of the figure).



The bar graph in part *C* of the figure shows that the relative proportions of muscle fiber types, body wide, varies with the type of work a person does with his or her muscles. This graph underscores the fact that athletic training, for example, can produce changes in the mix of different fiber types in muscle tissue.

FIGURE 12-16

Aerobic and anaerobic pathways during muscular activity. A, The aerobic pathway (dark bars) can supply energy for muscle contraction for a longer time than can the anaerobic pathway (light bars). **B,** The lines show that 100% of the energy used at the beginning of maximal exercise comes from anaerobic processes. However, the muscles soon switch to aerobic sources of energy so after 1 hour of maximal exercise, nearly 100% of the energy comes from aerobic respiration in the muscle fibers. More information on aerobic and anaerobic energy metabolism is found in Chapter 30.

muscle fibers can shift toward increased use of another catabolic process: the *anaerobic pathway*. As its name implies, the anaerobic pathway does not require the immediate use of oxygen. Besides its ability to produce ATP without oxygen, the anaerobic pathway has the added advantage of being very rapid. Muscle fibers having difficulty getting oxygen—or fibers that generate a great deal of force very quickly—may rely on the anaerobic pathway to resynthesize their ATP molecules.

Anaerobic processes may allow the body to avoid the use of oxygen in the short term, but not in the long term (Figure 12-16). Anaerobic processes called *fermentation* result in the formation of an incompletely catabolized molecule called **lactic acid.** Lactic acid may accumulate in muscle tissue during exercise and cause a burning sensation. As oxygen becomes available, it may be converted back to glucose and used for energy. Any lactic acid not converted in the muscle fiber may eventually diffuse into the blood and be delivered to the liver, where an oxygen-consuming process later converts it back into glucose. This is one of the reasons that after heavy exercise, when the lack of oxygen in some tissues has caused the production of lactic acid, a person may still continue to breathe heavily. The body is repaying the so-called *oxygen debt* by using the extra oxygen gained by heavy breathing to process the lactic acid that was produced during exercise. This "oxygen debt" is often called the *excess postexercise oxygen consumption (EPOC)*.

evolve

HEAT PRODUCTION

Because the catabolic processes of cells are never 100% efficient, some of the energy released is lost as heat. Because skeletal muscle tissues produce such a massive amount of heat—even when they are doing hardly any work—they have a great effect on body temperature. Recall from Chapter 7 that various heat loss mechanisms of the skin can be used to cool the body when it becomes overheated (see Figure 7-15, p. 183). Skeletal muscle tissues can likewise be used when the body's temperature falls below the set point value determined by the "thermostat" in the hypothalamus of the brain. As Figure 12-17 shows, a low external temperature can reduce body temperature below the set point. Temperature

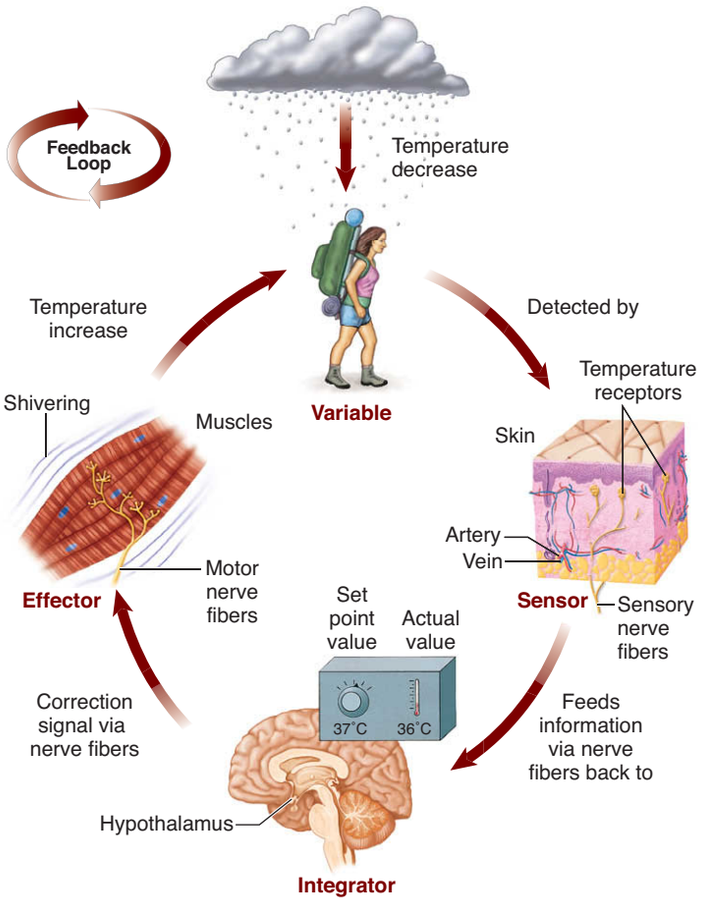

FIGURE 12-17

The role of skeletal muscle tissues in maintaining a constant body temperature. This diagram shows that a drop in body temperature caused by cold weather can be corrected by a negative feedback mechanism that triggers shivering (muscle contraction), which in turn produces enough heat to warm the body.

sensors in the skin and other parts of the body feed this information back to the hypothalamus, which compares the actual value with the set point value (usually about 37° C). The hypothalamus responds to a decrease in body temperature by signaling skeletal muscles to contract. The shivering contractions that result produce enough waste heat to warm the body back to the set point temperature—and homeostatic balance is maintained.

The subject of energy metabolism is discussed more thoroughly in Chapter 30.

10. What is the role of myoglobin in muscle fibers?

FUNCTION OF SKELETAL MUSCLE ORGANS

Although each skeletal muscle fiber is distinct from all other fibers, it operates as part of the large group of fibers that form a skeletal muscle organ. Skeletal muscle organs, often simply called *muscles*, are composed of bundle upon bundle of muscle fibers held together by fibrous connective tissues (see Figure 12-1, A). The details of muscle organ anatomy are discussed in Chapter 11. For now, we turn attention to the matter of how skeletal muscle organs function as a single unit.

Motor Unit

Recall that each muscle fiber receives its stimulus from a motor neuron. This neuron, often called a *somatic motor neuron*, is one of several nerve cells that enter a muscle organ together in a bundle called a *motor nerve*. One of these motor neurons, plus the muscle fibers to which it attaches, constitutes a functional unit called a **motor unit** (Figure 12-18).

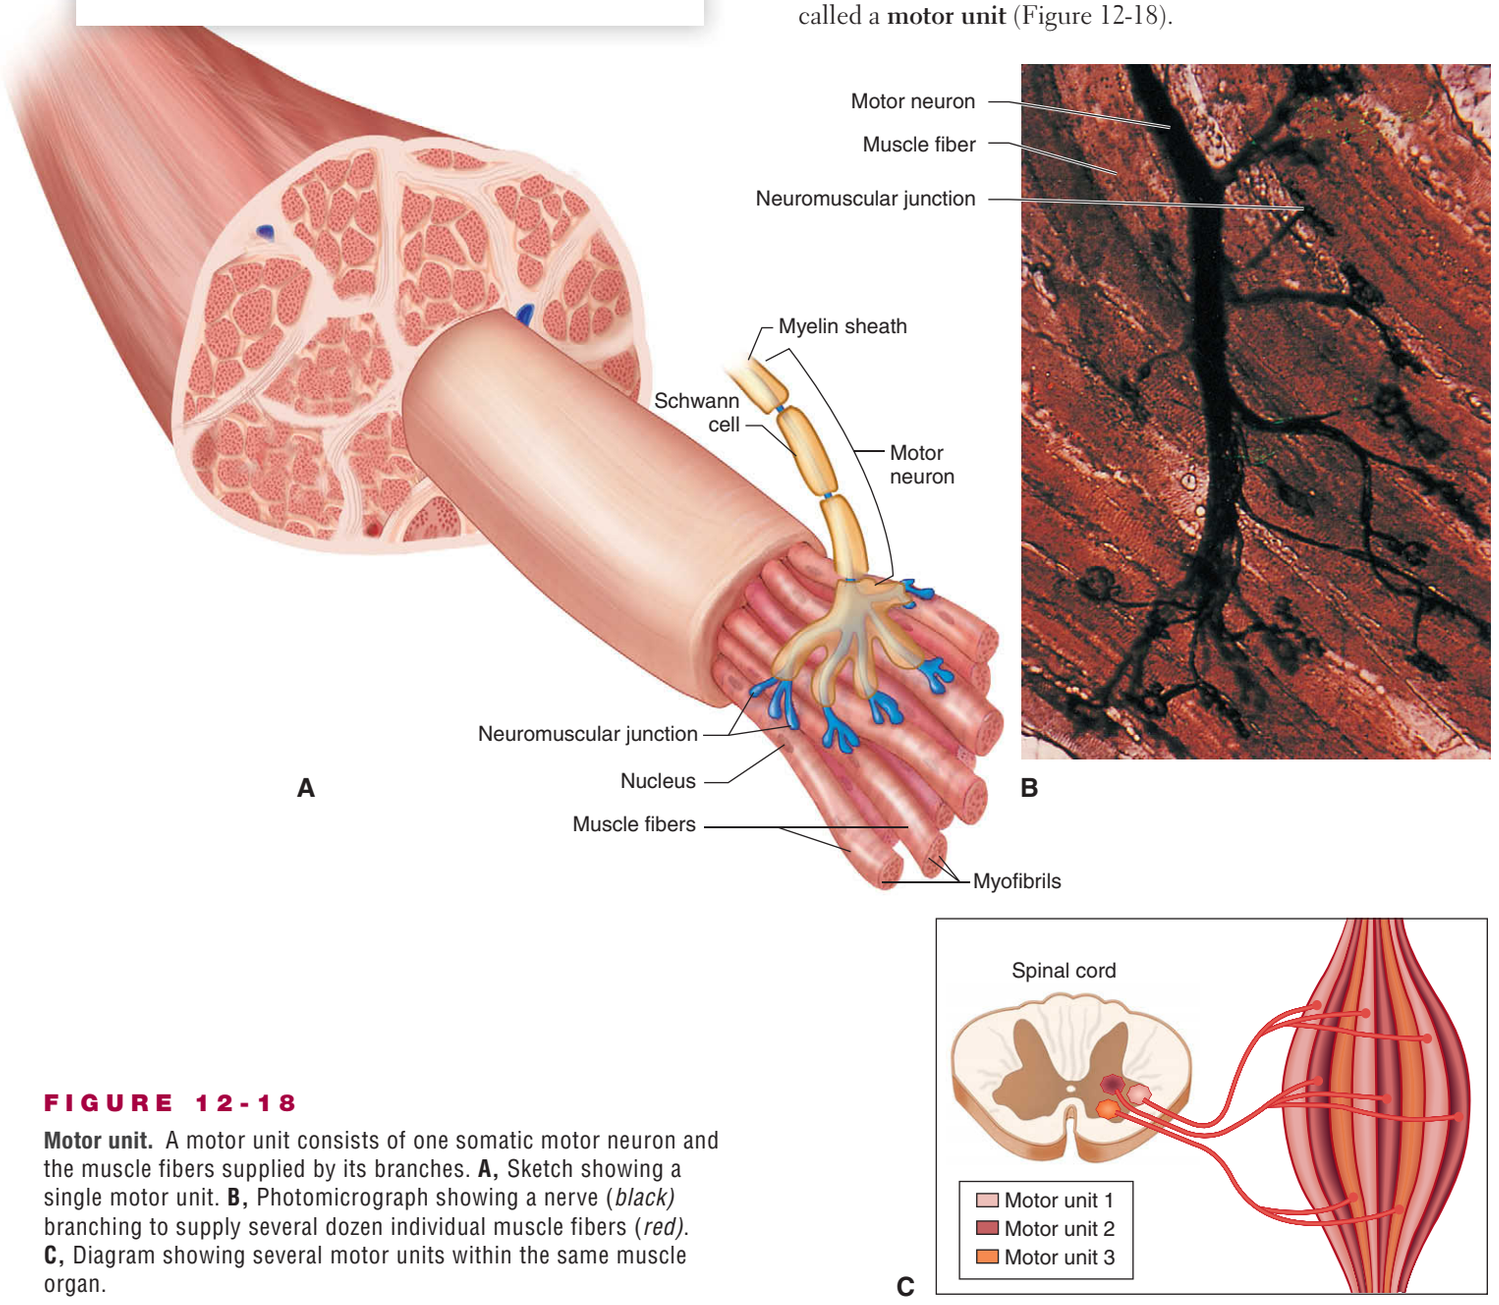

FIGURE 12-18

Motor unit. A motor unit consists of one somatic motor neuron and the muscle fibers supplied by its branches. **A,** Sketch showing a single motor unit. **B,** Photomicrograph showing a nerve (*black*) branching to supply several dozen individual muscle fibers (*red*). **C,** Diagram showing several motor units within the same muscle organ.

The single fiber of a somatic motor neuron divides into a variable number of branches upon entering the skeletal muscle. The neuron branches of some motor units terminate in only a few dozen muscle fibers, whereas others terminate in a few thousand fibers. Consequently, impulse conduction by one motor unit may stimulate only a small part of a muscle organ, whereas conduction by another motor unit may activate a much larger portion of a muscle organ. This fact bears a relationship to the function of the muscle as a whole. As a rule, the fewer the number of fibers supplied by a skeletal muscle's individual motor units, the more precise the movements that muscle can produce. For example, in certain small muscles of the hand, each motor unit includes only a few muscle fibers, and these muscles produce precise finger movements. In contrast, motor units in large abdominal muscles that do not produce precise movements may have thousands of muscle fibers.

Myography

Many experimental methods have been used to study the contractions of skeletal muscle organs. They vary from relatively simple procedures, such as observing or palpating muscles in action, to the more complicated method of *electromyography* (recording electrical impulses from muscles as they contract). One method of studying muscle contraction particularly useful for the purposes of our discussion is called simply *myography*, a term that means "muscle graphing." This is a procedure in which the force or tension from the contraction of an isolated muscle is recorded as a line that rises and falls as the muscle contracts and relaxes (Figure 12-19). To get the muscle to contract, an electrical stimulus of sufficient intensity (the **threshold stimulus**) is applied to the muscle. A single, brief threshold stimulus produces a quick jerk of the muscle, called a **twitch contraction.**

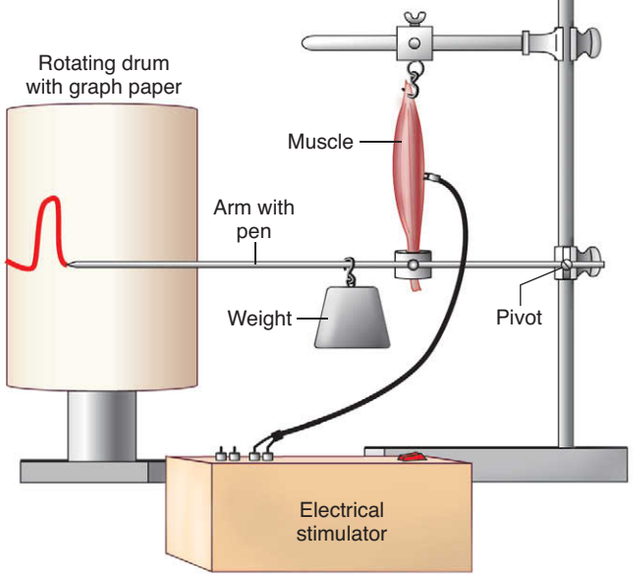

FIGURE 12-19

Myography. This classic type of myograph, called a *kymograph,* records muscle contractions as graphs showing changes in length. An isolated muscle moves the pen upward during contraction, and the weight pulls the muscle and pen downward as the muscle relaxes. A change in tension produces this change in length. Electrical voltage simulates a nerve impulse to stimulate the fibers in the muscle. Modern myography often uses computer-based systems that record similar muscle tension graphs.

The Twitch Contraction

The quick, jerky twitch contraction seen in a myogram serves as the fundamental model for how muscles operate. The myogram of a twitch contraction shown in Figure 12-20 shows that the muscle does not begin to contract at the instant of stimulation but rather a fraction of a second later. The muscle then increases its tension (or shortens) until a peak is reached, after which it gradually returns to its resting state. These three phases of the twitch contraction are called, respectively, the *latent period*, the *contraction phase*, and the *relaxation phase*. The entire twitch usually lasts less than one tenth of a second.

During the latent period, the impulse initiated by the stimulation travels through the sarcolemma and T tubules to the SR, where it triggers the release of calcium ions into the sarcoplasm. It is not until the calcium binds to troponin and sliding of the myofilaments begins that contraction is observed. After a few milliseconds, the forceful sliding of the myofilaments ceases and relaxation begins. By the end of the relaxation phase, all of the myosin-actin reactions in all the fibers have ceased.

Twitch contractions of muscle organs rarely happen in the body. Even if we tried to make our muscles twitch voluntarily, they won't. Instead, our nervous system subconsciously "smoothes out" the movements to prevent injury and to make our movements more useful to us. Sustaining a smooth contraction is something that we will discuss a little later. But, to begin our discussion, a look at the twitch contraction gives us important insight about the mechanisms of more typical types of muscle organ contractions.

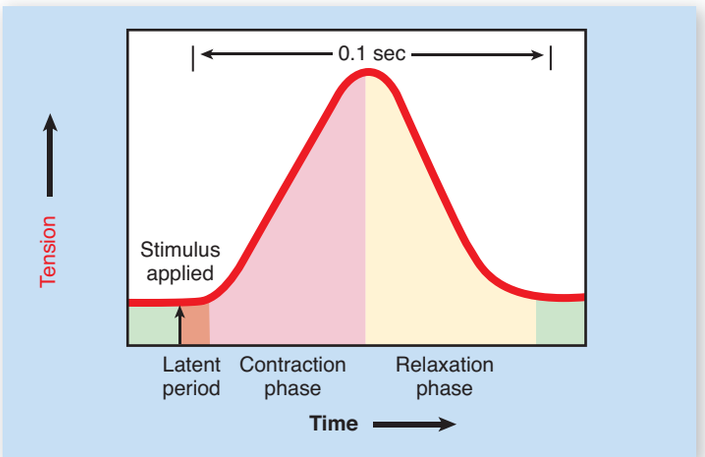

FIGURE 12-20

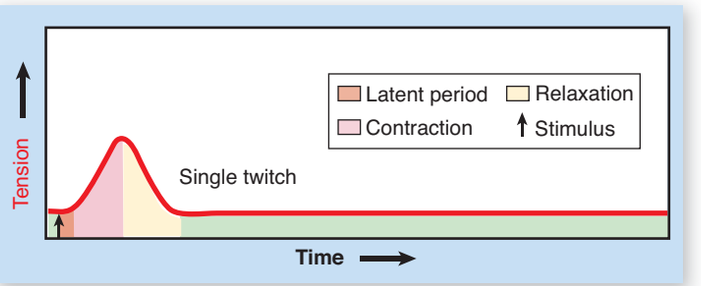
The twitch contraction. Three distinct phases are apparent: **(1)** the latent period, **(2)** the contraction phase, and **(3)** the relaxation phase.

Treppe: The Staircase Phenomenon

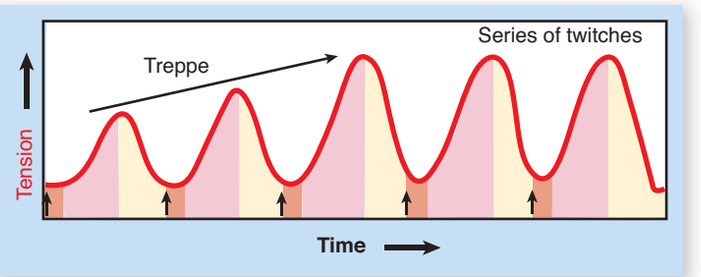
One interesting effect that can be seen in myographic studies of the twitch contraction is called **treppe,** or the *staircase phenomenon.* Treppe is a gradual, steplike increase in the strength of contraction that can be observed in a series of twitch contractions that occur about 1 second apart (Figure 12-21, *B*).

In other words, a muscle contracts more forcefully after it has contracted a few times than when it first contracts—a principle used by athletes when they warm up. Several factors contribute to this phenomenon. For example, in warm muscle fibers, calcium ions diffuse through the sarcoplasm more efficiently and more actin-myosin reactions occur. In addition, calcium ions accumulate in the sarcoplasm of muscles that have not had time to relax and pump much of the calcium back into their SR. Thus, up to a point, a warm fiber contracts more strongly than does a cool fiber. Thus, after the first few stimuli, muscle responds to successive stimuli with maximal contractions. Eventually though, it will respond with less and less strong contractions. The relaxation phase becomes shorter and finally disappears entirely. In other words, the muscle stays partially contracted—an abnormal state of prolonged contraction called *contracture.*



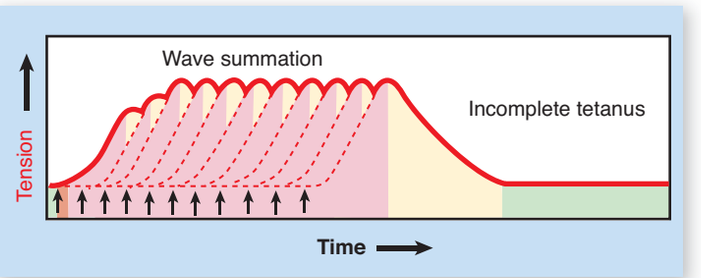
Repeated stimulation of muscle in time lessens its excitability and contractility and may result in **muscle fatigue,** a condition in which the muscle does not respond to the strongest stimuli. Complete muscle fatigue can be readily induced in an isolated muscle but very seldom occurs in the body (Box 12-5).

Tetanus



The concept of the simple twitch can help us understand the smooth, sustained types of contraction that are commonly observed in the body. Such smooth, sustained contractions are called *tetanic contractions* or, simply, **tetanus.** Figure 12-21, *C,* shows that if a series of stimuli come in a rapid enough succession, the muscle does not have time to relax completely before the next contraction phase begins. Muscle physiologists describe this effect as *multiple wave summation*—so named because it seems as though multiple twitch waves have been added together to sustain muscle tension for a longer time. The type of tetanus produced when very short periods of relaxation occur between peaks of tension is called *incomplete tetanus.* It is "incomplete" because the tension is not sustained at a completely constant level. Figure 12-21, *D,* shows that when the frequency of stimuli increases, the distance between peaks of tension decrease to a point at which they seem to fuse into a single, sustained peak. This produces a very smooth type of tetanic contraction called *complete tetanus.*

Figure 12-22 shows the role of calcium in maintaining tetanus. Recall that it is a surge in intracellular calcium (from the SR) that triggers contraction (see Box 12-2, p. 349). When there is a single stimulus, there is a single surge in intracellular calcium and thus a single, rapid contraction. When there is a series of stimuli, close together in time, the intracellular calcium surges overlap and maintain a high level of calcium availability for a longer time. The force of contraction can be maintained as long as the calcium remains at a high enough level in the muscle fibers.



In a normal body, tetanus results from two factors working at the same time. One factor is the rapid-fire stimulation of nerve fibers

B

C

D

FIGURE 12-21

Myograms of various types of muscle contractions. A, A single twitch contraction. **B,** The treppe phenomenon, or "staircase effect," is a steplike increase in the force of contraction over the first few in a series of twitches. **C,** Incomplete tetanus occurs when a rapid succession of stimuli produces "twitches" that seem to add together (wave summation) to produce a rather sustained contraction. **D,** Complete tetanus is a smoother sustained contraction produced by the summation of "twitches" that occur so close together that the muscle cannot relax at all.

Box 12-5 | SPORTS and FITNESS

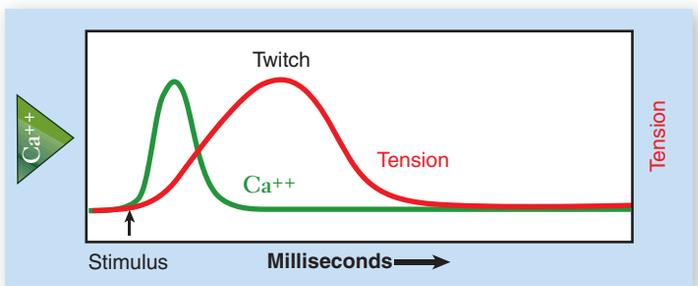
Muscle Fatigue

Broadly defined, **muscle fatigue** is simply a state of exhaustion (a loss of strength or endurance) produced by strenuous muscular activity.

Physiological muscle fatigue is caused by any combination of local failure in the steps of muscle contraction (see Box 12-2 on p. 349).

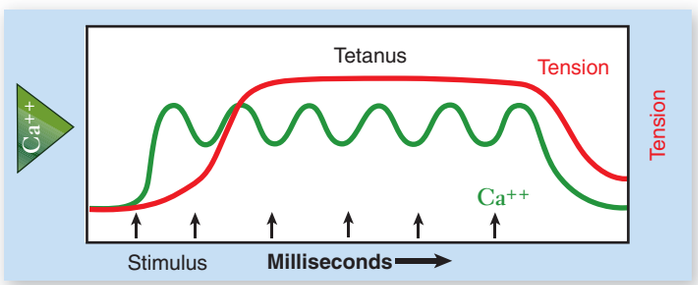
For example, failure of the sodium-potassium pumps to maintain the ion concentration gradients needed to produce action potentials may cause fatigue. Individual muscle fibers become less contractile until the proper Na^+ and K^+ gradients can be restored.

Depending on the muscle fiber type and the kind of activity, the cause may be a relative lack of ATP, which renders the myosin heads incapable of producing the force required for further muscle contractions. The low levels of adenosine triphosphate (ATP) that produce fatigue may result from depletion of oxygen or glucose in muscle fibers or from an inability to regenerate ATP quickly enough. Thus depletion of glycogen in the muscle often produces fatigue.



Accumulation of phosphate molecules (from the breakdown of ATP) may further interfere with contraction by binding to calcium ions that would otherwise be participating in the contraction process. Decreased pH from the buildup of lactic acid may also contribute to physiological fatigue by interfering with normal chemical reactions in the muscle fiber.

Muscle tissue can limit physiological fatigue by increasing blood flow, thus bringing in additional oxygen and glucose—and taking away more CO_2 and lactic acid. Muscle tissue also produces hormones that trigger the release of more glucose and other nutrients into the bloodstream. But eventually a muscle may not be able to sustain its work.



Under ordinary circumstances, however, complete physiological fatigue seldom occurs. It is usually *psychological fatigue* that produces the exhausted feeling that stops us from continuing a muscular activity. Such fatigue is regulated by feedback loops that increase our feelings of fatigue as muscles work hard and thus protect the muscles from reaching a point where they could become seriously impaired.

In physiological muscle fatigue we *cannot* contract our muscles, but in psychological muscle fatigue, we simply *will not* contract our muscles because we feel tired.

that permits wave summation to occur in each fiber. Another factor is the coordinated contractions of different motor units within the muscle organ. These motor units fire in an asynchronous, overlapping time sequence to produce a "relay team" effect that results in a sustained contraction. Tetanus is the kind of contraction exhibited by normal skeletal muscle organs most of the time.

Muscle Tone

A **tonic contraction** (*tonus*, "tone") is a continual, partial contraction in a muscle organ. At any one moment a small number of the total fibers in a muscle contract and produce tautness of the muscle rather than a recognizable contraction and movement. Different groups of fibers scattered throughout the muscle contract in relays. Tonic contraction, or **muscle tone,** is the low level of continuous contraction characteristic of the muscles of normal individuals when they are awake. It is particularly important for maintaining posture. A striking illustration of this fact is the following: when a person loses consciousness, muscles lose their tone, and the person collapses in a heap, unable to maintain a sitting or standing posture. Muscles with less tone than normal are described as *flaccid*, and those with more than normal tone are called *spastic*.

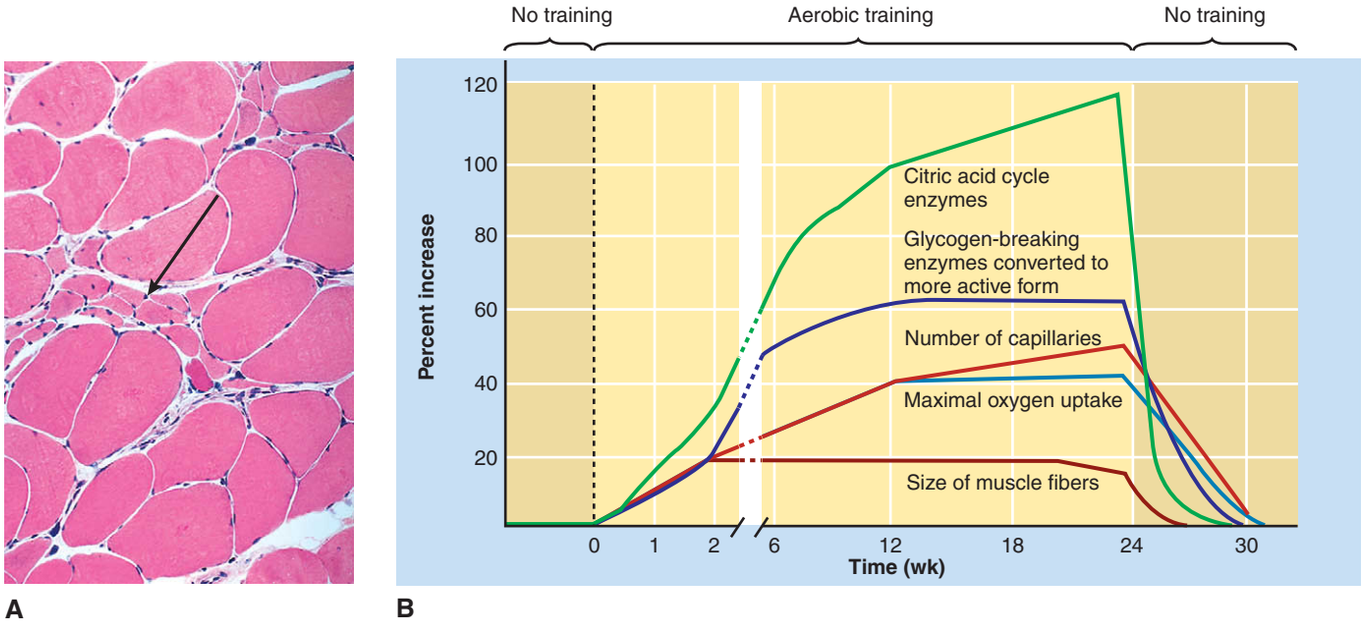
Muscle tone is maintained by negative feedback mechanisms centered in the nervous system, specifically in the spinal cord. Stretch sensors in the muscles and tendons detect the degree of stretch in a muscle organ and feed this information back to an integrator mechanism in the spinal cord. When the actual stretch (detected by the stretch receptors) deviates from the set point stretch, signals sent via the somatic motor neurons adjust the strength of tonic contraction. This type of subconscious mechanism is often called a *spinal reflex* (discussed further in Chapters 13 to 15).

GRADED STRENGTH PRINCIPLE

Skeletal muscles contract with varying degrees of strength at different times—a fact called the **graded strength principle.** Because muscle organs can generate different grades of strength, we can match the force of a movement to the demands of a specific task (Box 12-6).

Various factors contribute to the phenomenon of graded strength. We have already discussed some of these factors. For example, we stated that the metabolic condition of individual fibers influences their capacity to generate force. Thus, if many fibers of a muscle organ are unable to maintain a high level of ATP and become fatigued, the entire muscle organ suffers some loss in its ability to generate maximum force of contraction. On the other hand, the improved metabolic conditions that produce the treppe effect allow a muscle organ to increase its contraction strength.

Another factor that influences the grade of strength exhibited by a muscle organ is the number of fibers contracting simultaneously. Obviously, the more muscle fibers contracting at the same time, the stronger the contraction of the entire muscle organ. How large this number is depends on how many motor units are activated or **recruited.** Recruitment of motor units, in turn, depends on the



Box 12-6 | Effects of Exercise on Skeletal Muscles

Most of us believe that exercise is good for us, even if we have no idea what or how many specific benefits can come from it. Some of the good consequences of regular, properly practiced exercise are greatly improved muscle tone, better posture, more efficient heart and lung function, less fatigue, and looking and feeling better.

Skeletal muscles undergo changes that correspond to the amount of work that they normally do. During prolonged inactivity, muscles usually shrink in mass, a condition called **disuse atrophy** (part *A* of the figure). Disuse atrophy may result from general lack of use, but it is most often seen when a body part is immobilized by a cast or when the motor nerves are damaged. Exercise, on the other hand, may cause an increase in muscle size called **hypertrophy.**

Muscle hypertrophy can be enhanced by **strength training,** which involves contracting muscles against heavy resistance. Isometric exercises and weightlifting are common strength-training activities. This type of training results in increased numbers of satellite cells merging with muscle fibers to form additional myofilaments in each muscle fiber. Although the number of muscle fibers stays the same, the increased number of myofilaments greatly increases the mass of the muscle. When strength training stops, the extra myofilaments are dismantled and the muscle atrophies. However, the extra nuclei may remain for years and thus enable a quick restoration of muscle mass and strength if strength training resumes.

Endurance training, often called **aerobic training** (part *B* of the figure), does not usually result in as much muscle hypertrophy as strength training does. Instead, this type of exercise program increases a muscle's ability to sustain moderate exercise over a long period. Aerobic activities such as running, bicycling, or other primarily isotonic movements increase the number of blood vessels in a muscle (see Figure 12-15). The increased blood flow allows more efficient delivery of oxygen and glucose to muscle fibers during exercise. Aerobic training also causes an increase in the number of mitochondria in muscle fibers. This allows production of more ATP as a rapid energy source.

A, Disuse atrophy. The arrow points to a group of muscle fibers that have atrophied from disuse (in this case from nerve damage). Notice how much smaller they are than the surrounding, normal fibers. **B, Effects of aerobic training.** The graph shows that aerobic training increases the metabolic condition of muscles mainly by increasing levels of enzymes and the availability of oxygen. Only moderate increases in muscle fiber size occur.

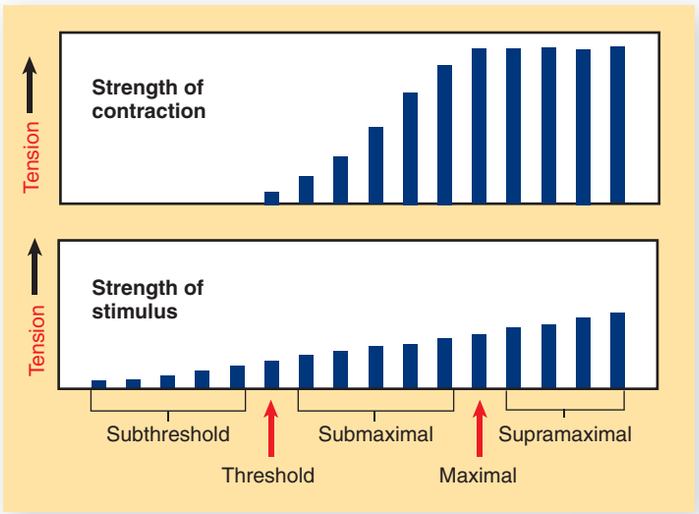


FIGURE 12-23

The strength of muscle contraction compared with the strength of the stimulus. After the threshold stimulus is reached, a continued increase in stimulus strength produces a proportional increase in muscle strength until the maximal level of contraction strength is reached.

intensity and frequency of stimulation. In general, the more intense and the more frequent a stimulus, the more motor units that are recruited and the stronger the contraction. Figure 12-23 shows that increasing the strength of the stimulus beyond the threshold level of the most sensitive motor units causes an increase in the strength of contraction. As the threshold level of each additional motor unit is reached, the strength of contraction increases. This process continues as the strength of stimulation increases until the maximal level of contraction is reached. At this point, the limits of the muscle organ to recruit new motor units have been reached. Even if stimulation increases above the maximal level, the muscle cannot contract any more strongly. As long as the supply of ATP holds out, the muscle organ can sustain a tetanic contraction at the maximal level, with motor units contracting and relaxing in overlapping "relays" (see Figure 12-21, *D*).

The maximal strength that a muscle can develop is directly related to the initial length of its fibers—this is the *length-tension relationship* (Figure 12-24). A muscle that begins a contraction from a short initial length cannot develop much tension because its sarcomeres are already compressed. Conversely, a muscle that begins a contraction from an overstretched initial length cannot develop much tension because the thick myofilaments are too far away from the thin myofilaments to effectively pull them and thus compress the sarcomeres. The strongest maximal contraction is possible only when the muscle organ has been stretched to an optimal initial length. To illustrate this point, extend your elbow fully and try to contract the *biceps brachii* muscle on the ventral side of the upper part of your arm. Now flex the elbow just a little and contract the biceps again. Try it a third time with the elbow completely flexed. The greatest tension—seen as the largest "bulge" of the biceps—occurs when the elbow is partly flexed and the biceps only moderately stretched.

Another factor that influences the strength of a skeletal muscle contraction is the amount of load imposed on the muscle. Within certain limits, the heavier the load, the stronger the contraction. Lift your hand with palm up in front of you and then put this book in your palm. You can feel your arm muscles contract more strongly as the book is placed in your hand. This occurs because of a *stretch reflex*, a response in which the body tries to maintain

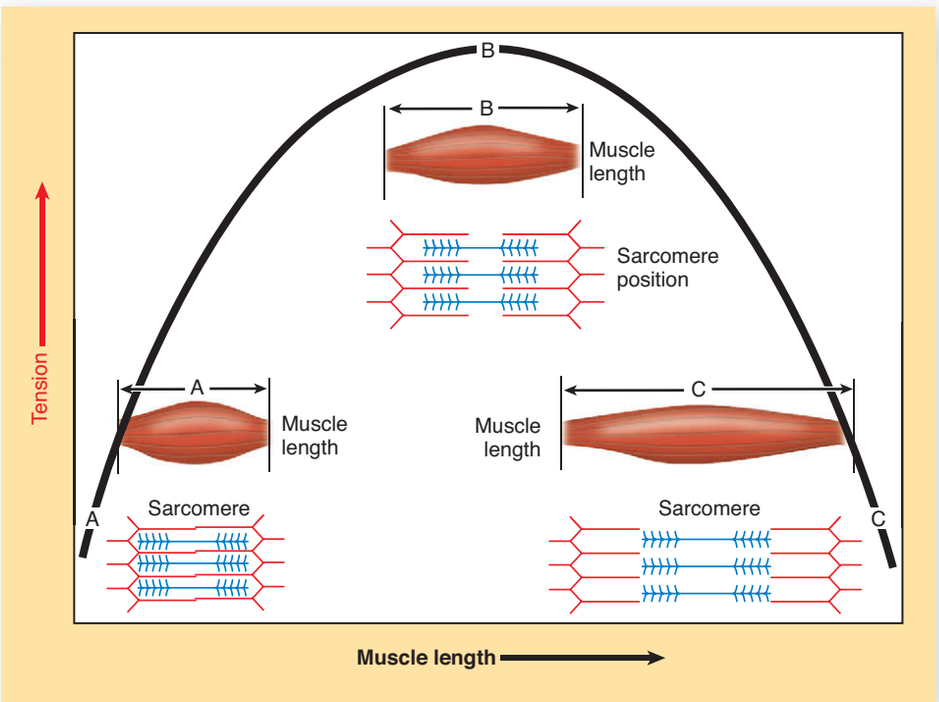

FIGURE 12-24

The length-tension relationship. As this graph of muscle tension shows, the maximum strength that a muscle can develop is directly related to the initial length of its fibers. At a short initial length, the sarcomeres are already compressed, and thus the muscle cannot develop much tension (position *A*). Conversely, the thick and thin myofilaments are too far apart in an overstretched muscle to generate much tension (position *C*). Maximum tension can be generated only when the muscle has been stretched to a moderate, optimal length (position *B*).

constancy of muscle length (Figure 12-25). An increased load threatens to stretch the muscle beyond the set point length that you are trying to maintain. Your body exhibits a negative feedback response when it detects the increased stretch caused by an increased load, feeds the information back to an integrator in the nervous system, and increases its stimulation of the muscle to counteract the stretch. This reflex maintains a relatively constant muscle length as load is increased up to a maximum sustainable level. When the load becomes too heavy and thus threatens to cause injury to the muscle or skeleton, the body abandons this reflex and forces you to relax and drop the load.

The major factors involved in the graded strength principle are summarized in Figure 12-26.

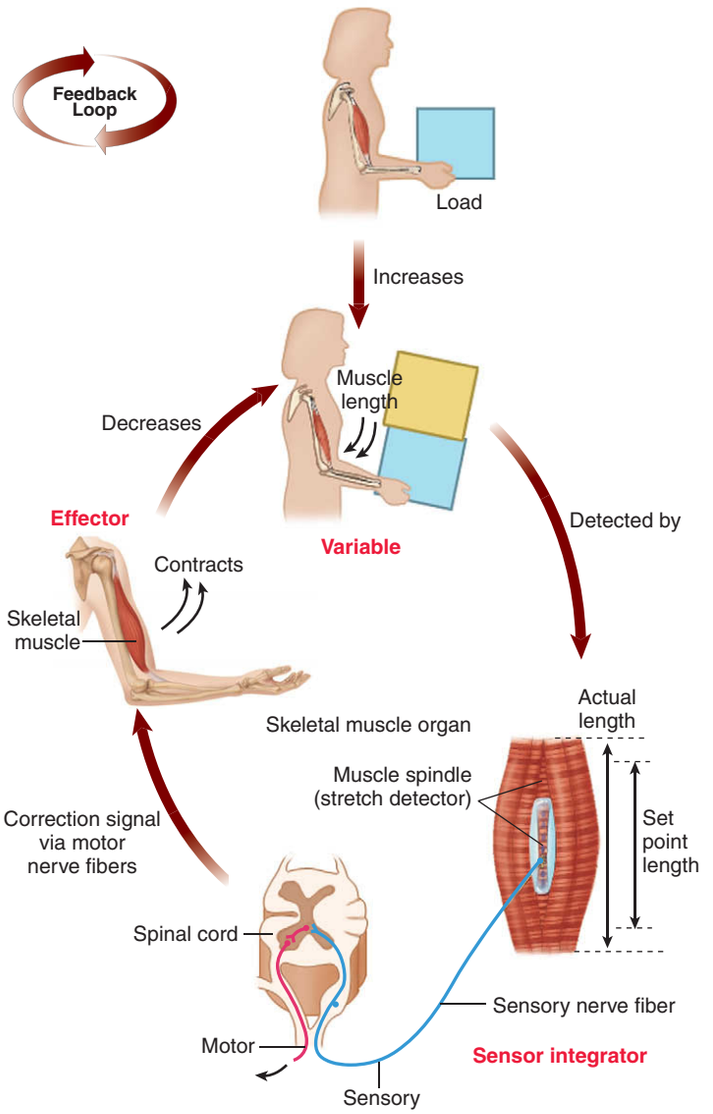

FIGURE 12-25

The stretch reflex. The strength of a muscle organ can be matched to the load imposed on it by a negative feedback response centered in the spinal cord. Increased stretch (caused by increased load) is detected by a sensory nerve fiber attached to a muscle cell (called a *muscle spindle*). The information is integrated in the spinal cord and a correction signal is relayed through motor neurons back to the same muscle, which increases tension to return to the set point muscle length.

Isotonic and Isometric Contractions

The term *isotonic* literally means "same tension" (*iso-*, "equal," *-tonic*, "relating to tension"). An **isotonic contraction** is a contraction in which the tone or tension within a muscle remains the same as the length of the muscle changes (Figure 12-27, A). Because the muscle is moving against its resistance (load) in an isotonic contraction, the energy of contraction is used to pull on the thin myofilaments and thus change the length of a fiber's sarcomeres. Put another way, in isotonic contractions the myosin cross bridges "win" the tug-of-war against a light load and are thus able to pull the thin myofilaments. Because the muscle is moving in an isotonic contraction, it is also called *dynamic tension*.

There are two basic varieties of isotonic contractions (see Figure 12-27, A). **Concentric contractions** are those in which the movement results in shortening of the muscle, as when you pick up this book. **Eccentric contractions** are those in which the movement results in lengthening of the muscle being contracted. For example, when you slowly lower the book you have just picked up, you are contracting the same muscle you just used to lift it—but this time you are lengthening the muscle, not shortening it.

An **isometric contraction,** in contrast to an isotonic contraction, is a contraction in which muscle length remains the same while muscle tension increases (Figure 12-27, *B*). The term *isometric* literally means "same length." You can observe isometric contraction by lifting up on a stationary handrail and feeling the tension increase in your arm muscles. Isometric contractions can

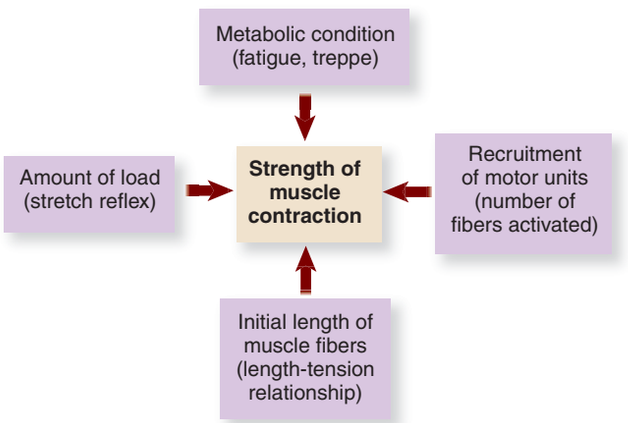

FIGURE 12-26

Factors that influence the strength of muscle contraction.

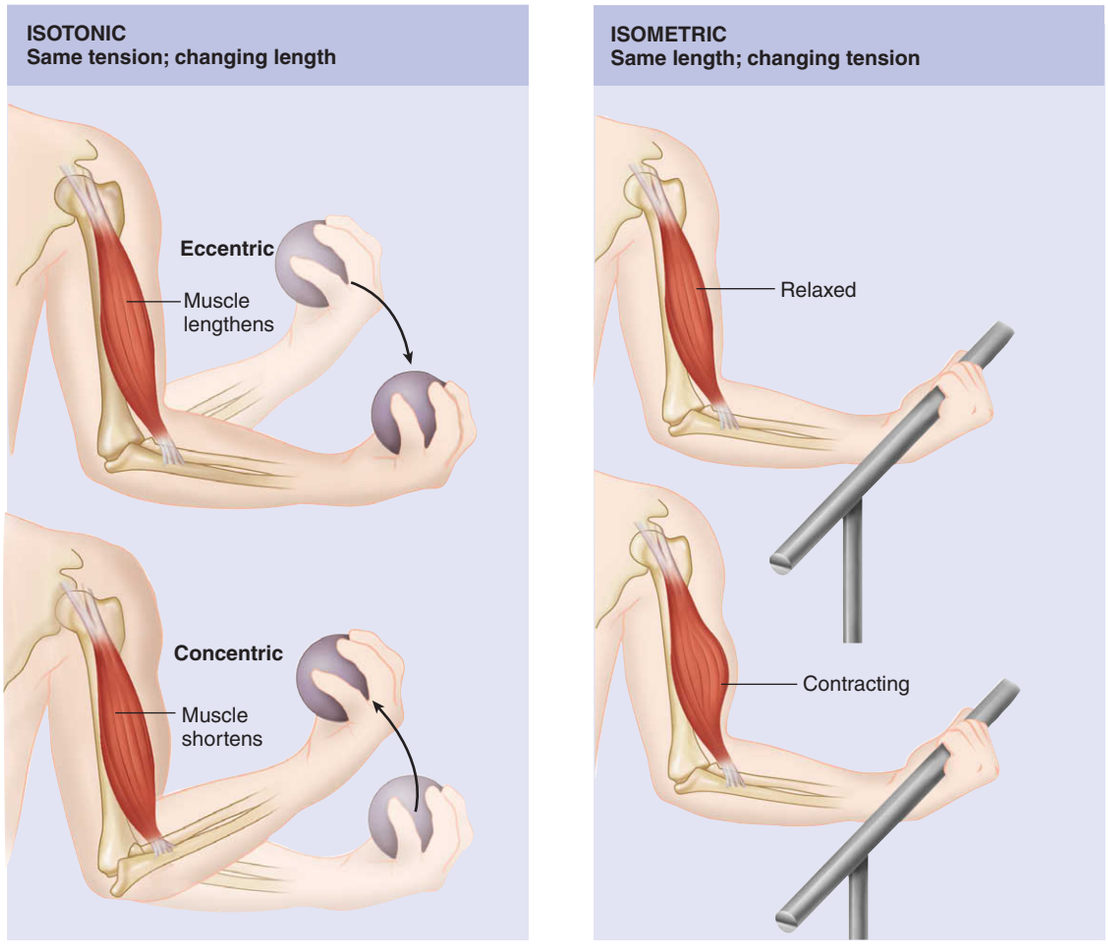

FIGURE 12-27

Isotonic and isometric contraction. A, In isotonic contraction the muscle shortens and produces movement. Concentric contractions occur when the muscle shortens during the movement. Eccentric contractions occur when the contracting muscle lengthens. **B,** In isometric contraction the muscle pulls forcefully against a load but does not shorten because it cannot overcome the resistance.

do work by "tightening" to resist a force, but they do not produce movements. In isometric contractions, the tension produced by the "power stroke" of the myosin cross bridges cannot overcome the load placed on the muscle. Using the tug-of-war analogy, we can say that in isometric contractions the myosin cross bridges reach a "draw"—they hold their own against the load placed on the muscle but do not make any progress in sliding the thin myofilaments. Because muscles remain stable during isometric contraction, it is also called *static tension*.

18. What is the difference between isotonic and isometric contractions? Concentric and eccentric?

FUNCTION OF CARDIAC AND SMOOTH MUSCLE TISSUE

Cardiac and smooth muscle tissues operate by mechanisms similar to those in skeletal muscle tissues. Detailed study of cardiac and smooth muscle function will be set aside until we discuss specific smooth and cardiac muscle organs in later chapters. However, it may be helpful to preview some of the basic principles of cardiac and smooth muscle physiology so that we can compare them with those that operate in skeletal muscle tissue. Table 12-1 summarizes the characteristics of the three major types of muscle.

Cardiac Muscle

Cardiac muscle, also known as *striated involuntary muscle*, is found in only one organ of the body: the heart. Forming the bulk of the wall of each heart chamber, cardiac muscle contracts rhythmically and continuously to provide the pumping action necessary to maintain a relative constancy of blood flow through the internal environment. As you shall see, its physiological mechanisms are well adapted to this function.

The functional anatomy of cardiac muscle tissue resembles that of skeletal muscle to a degree, but it exhibits certain unique features related to its role of continuously pumping blood. As Figure 12-28 shows, each cardiac muscle fiber contains parallel myofibrils. Each myofibril includes sarcomeres that give the whole fiber a striated appearance. However, cardiac muscle fiber does not taper like skeletal muscle fiber but, instead, forms strong, electrically coupled junctions (intercalated disks) with other fibers. This feature, along with the branching exhibited by individual cells, allows cardiac fibers to form a continuous, electrically coupled mass called a **syncytium** (meaning "unit of combined cells"). Cardiac muscles thus form a continuous, contractile band around the heart chambers that conducts a single impulse across a virtually continuous sarcolemma—features necessary for an efficient, coordinated pumping action.

Unlike skeletal muscle, in which a nervous impulse excites the sarcolemma to produce its own impulse, cardiac muscle is self-exciting. Cardiac muscle cells thus exhibit a continuing rhythm of excitation and contraction on their own, although the rate of self-induced impulses can be altered by nervous or hormonal input. Figure 12-29 shows that impulses triggering

TABLE 12-1 Characteristics of Muscle Tissues

	SKELETAL	CARDIAC	SMOOTH
Principal location	Skeletal muscle organs	Wall of heart	Walls of many hollow organs
Principal functions	Movement of bones, heat production, posture	Pumping of blood	Movement in walls of hollow organs (peristalsis, mixing of fluids)
Type of control	Voluntary	Involuntary	Involuntary
Structural features			
Striations	Present	Present	Absent
Nucleus	Many near the sarcolemma	Single (sometimes double); near the center of the cell	Single; near the center of the cell
T tubules	Narrow; form triads with the SR	Large diameter; form diads with the SR, regulate Ca^{++} entry into the sarcoplasm	Absent
Sarcoplasmic reticulum	Extensive; stores and releases Ca^{++}	Less extensive than in skeletal muscle	Very poorly developed
Cell junctions	No gap junctions	Intercalated disks	*Single-unit*:* many gap junctions *Multiunit:* few gap junctions
Contraction style	Rapid twitch contractions of motor units usually summate to produce sustained tetanic contractions; must be stimulated by a neuron	Syncytium of fibers compress the heart chambers in slow, separate contractions (does not exhibit tetanus or fatigue); exhibits autorhythmicity	*Single-unit:* electrically coupled sheets of fibers contract autorhythmically and produce peristalsis or mixing movements *Multiunit:* individual fibers contract when stimulated by a neuron

*Also referred to as *visceral smooth muscle tissue.*
SR, Sarcoplasmic reticulum.

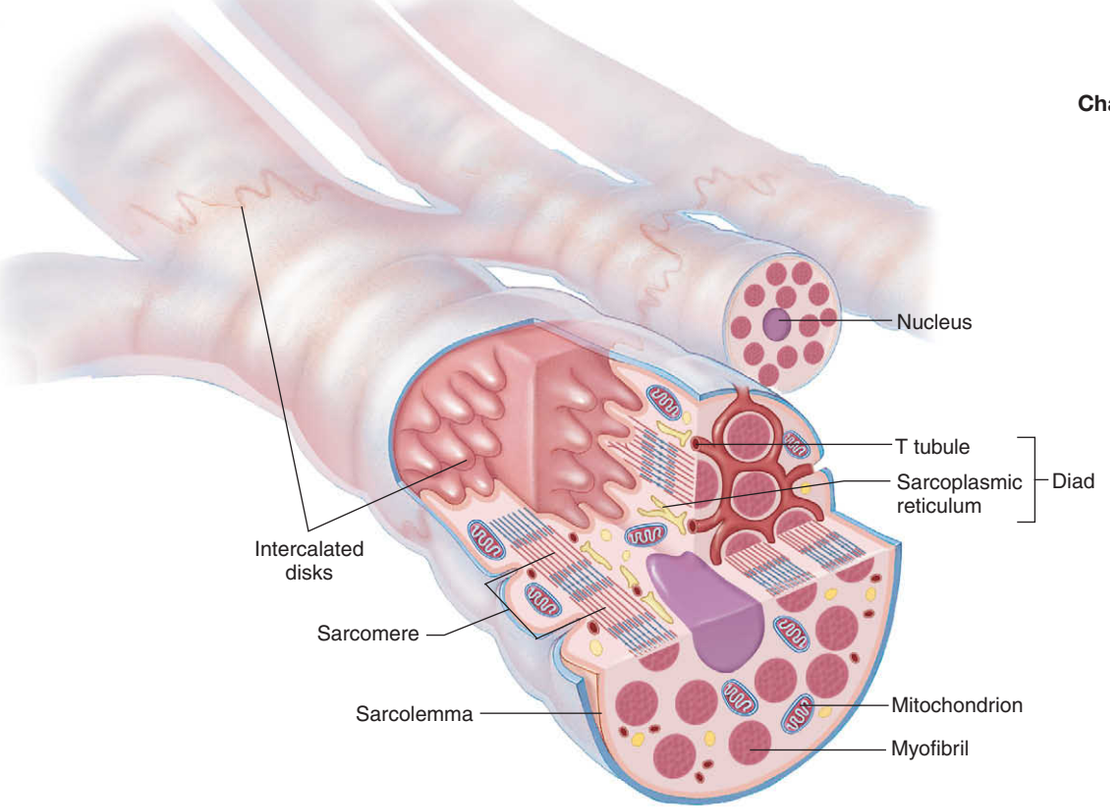

FIGURE 12-28

Cardiac muscle fiber. Unlike other types of muscle fibers, cardiac muscle fiber is typically branched and forms junctions, called *intercalated disks,* with adjacent cardiac muscle fibers. Like skeletal muscle fibers, cardiac muscle fibers contain sarcoplasmic reticula and T tubules—although these structures are not as highly organized as in skeletal muscle fibers.

cardiac muscle contractions are much more prolonged than those triggering skeletal muscle contractions. Because the sarcolemma of cardiac muscle sustains each impulse longer than in skeletal muscle, Ca^{++} remains in the sarcoplasm longer. This means that even though many adjacent cardiac muscle cells contract simultaneously, they exhibit a prolonged contraction rather than a rapid twitch. It also means that impulses cannot come rapidly enough to produce tetanus. Because it cannot sustain long tetanic contractions, cardiac muscle does not normally run low on ATP and thus does not experience fatigue. Obviously, this characteristic of cardiac muscle is vital to keeping the heart continuously pumping.

Although cardiac muscle fiber has T tubules and SR, they are arranged a little differently than in skeletal muscle fibers. The T tubules are larger, and they form diads (double structures) rather than triads (triple structures), with a rather sparse SR. Much of the calcium that enters the sarcoplasm during contraction enters from outside the cells through the T tubules rather than from storage in the SR.

The structure and function of the heart are discussed further in Chapters 21 and 22.

Smooth Muscle

As we mentioned in Chapter 6, smooth muscle is composed of small, tapered cells with single nuclei. Smooth muscle cells do not have T tubules and have only loosely organized sarcoplasmic reticula. The calcium required for contraction comes from

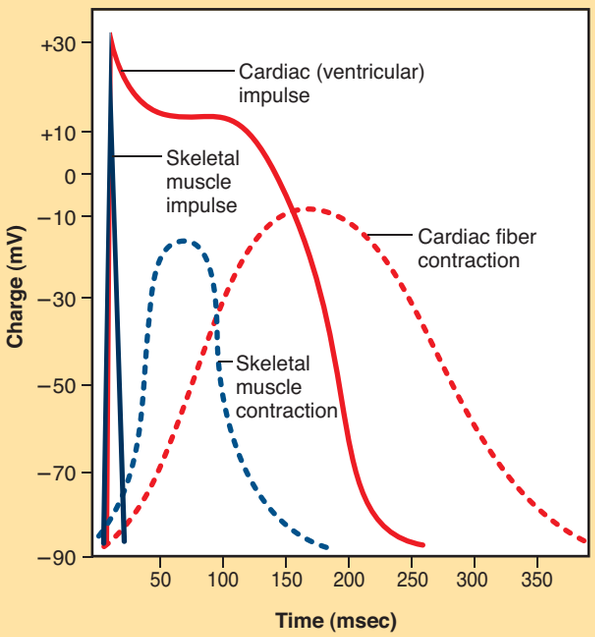

FIGURE 12-29

Cardiac and skeletal muscle contractions compared. A brief nerve impulse triggers a brief twitch contraction in skeletal muscle *(blue)*, but a prolonged impulse in the heart tissue produces a rather slow, drawn out contraction in cardiac muscle *(red)*.

outside the cell and binds to a protein called *calmodulin*, rather than to troponin, to trigger a contraction event.

The lack of striations in smooth muscle fibers results from the fact that the thick and thin myofilaments are arranged quite differently than in skeletal or cardiac muscle fibers. As Figure 12-30 shows, thin arrangements of myofilaments crisscross the cell and attach at their ends to the cell's plasma membrane. When cross bridges pull the thin filaments together, the muscle "balls up" and thus contracts the cell. Because the myofilaments are not organized into sarcomeres, they have more freedom of movement and as a result can contract a smooth muscle fiber to shorter lengths than in skeletal and cardiac muscle.

There are two types of smooth muscle tissue: *single-unit* and *multiunit* (Figure 12-31) smooth muscle.

In *visceral*, or **single-unit, smooth muscle,** gap junctions join individual smooth muscle fibers into large, continuous sheets—much like the syncytium of fibers observed in cardiac muscle. This type of smooth muscle is the most common, and it forms a muscular layer in the walls of many hollow structures such as the digestive, urinary, and reproductive tracts. Like cardiac muscle, this type of smooth muscle commonly exhibits a rhythmic self-excitation, or *autorhythmicity* (meaning "self-rhythm"), that spreads across the entire tissue. When these rhythmic, spreading waves of contraction become strong enough, they can push the contents of a hollow organ progressively along its lumen. This phenomenon, called *peristalsis*, moves food along the digestive tract, assists the flow of urine to the bladder, and pushes a baby out of the womb during labor. Such contractions can also be coordinated to produce mixing movements in the stomach and other organs.

Multiunit smooth muscle tissue does not act as a single unit (as in visceral muscle) but instead is composed of many independent single-cell units. Each independent fiber does not usually generate its own impulse but rather responds only to nervous input. Although this type of smooth muscle can form thin sheets, as in the walls of large blood vessels, it is more often found in bundles (for example, the *arrector pili* muscles of the skin or muscles that control the lens of the eye) or as single fibers (such as those surrounding small blood vessels).

The structure and function of smooth muscle organs are discussed in later chapters.

| QUICK CHECK |

19. How do slow, separate, autorhythmic contractions of cardiac muscle make it well suited to its role in pumping blood?
20. What produces the striations in cardiac muscle?
21. How are myofilaments arranged in a smooth muscle fiber?
22. What is the difference between single-unit and multiunit smooth muscle?

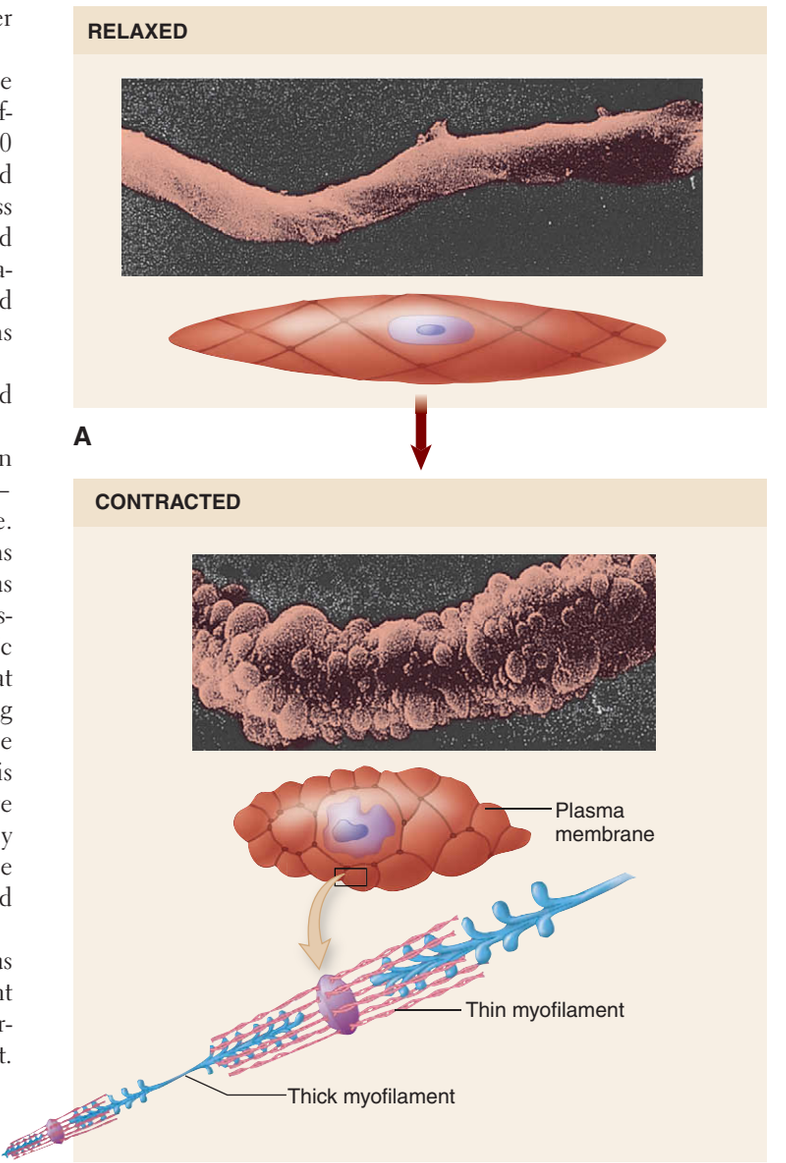

FIGURE 12-30

Smooth muscle fiber. A, Thin bundles of myofilaments span the diameter of a relaxed fiber. The scanning electron micrograph *(above)* shows that the surface of the cell is rather flat when the fiber is relaxed. **B,** During contraction, sliding of the myofilaments causes the fiber to shorten by "balling up." The micrograph *(above)* shows that the fiber becomes shorter and thicker and exhibits "dimples" where the myofilament bundles are pulling on the plasma membrane.

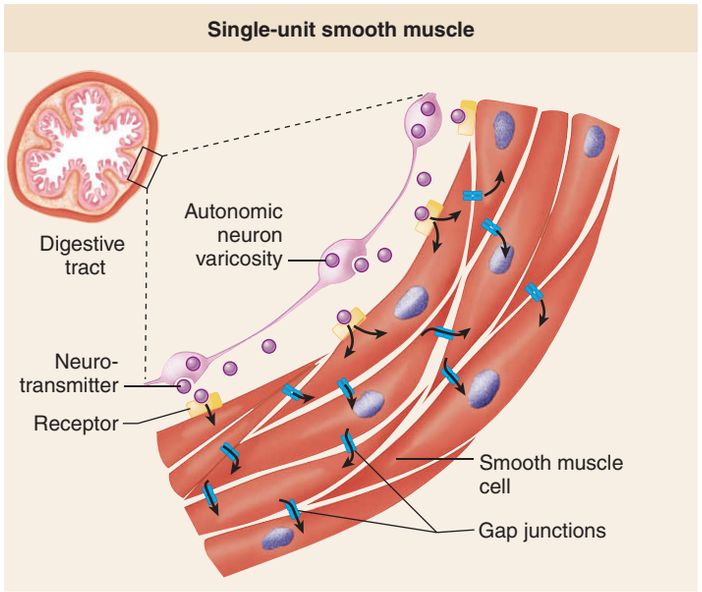

FIGURE 12-31

Types of smooth muscle. A, Single-unit (visceral) smooth muscle. Neurotransmitters released from varicosities (bulges) in the nerve fiber trigger impulses in the smooth muscle membranes—an event that is transmitted to adjacent muscle fibers through gap junctions. Thus a large mass of muscle fibers acts as a single unit. **B,** Multiunit smooth muscle. Each muscle fiber is triggered independently by nerve stimulation.

the BIG picture

Muscle Tissue and the Whole Body

The function of all three major types of muscle (skeletal, smooth, and cardiac) is integral to the function of the entire body. What does the function of muscle tissue contribute to homeostasis of the whole body? First, all three types of muscle tissue provide the movement necessary for survival. Skeletal muscle moves the skeleton so that we can seek shelter, gather food, and defend ourselves. All three muscle types produce movements that power vital homeostatic mechanisms such as breathing, blood flow, digestion, and urine flow.

The relative constancy of the body's internal temperature could not be maintained in a cool external environment if not for the "waste" heat generated by muscle tissue—especially the large mass of skeletal muscle found throughout the body. Maintenance of a relatively stable body position—posture—is also a primary function of the skeletal muscular system. Posture, specific body movements, and other contributions of the skeletal muscular system to homeostasis of the whole body were discussed in Chapter 11. The homeostatic roles of smooth muscle organs and the cardiac muscle organ (the heart) are examined in later chapters.

Like all tissues of the body, muscle tissue gives and takes. A number of systems support the function of muscle tissues. Without these systems, muscle would cease to operate. For example, the nervous system directly controls the contraction of skeletal muscle and multiunit smooth muscle. It also influences the rate of rhythmic contractions in cardiac muscle and visceral smooth muscle. The endocrine system produces hormones that assist the nervous system in regulation of muscle contraction throughout the body. The blood delivers nutrients and carries away waste products. Nutrients for the muscle are ultimately procured by the respiratory system (oxygen) and digestive system (glucose and other foods). The respiratory system also helps get rid of the waste of muscle metabolism, as does the urinary system. The liver processes lactic acid produced by muscles and converts it back to glucose. The immune system helps defend muscle tissue against infection and cancer—as it does for all body tissues. The fibers that make up muscle tissues, then, are truly members of the large, interactive "society of cells" that forms the human body.

MECHANISMS of DISEASE

MAJOR MUSCULAR DISORDERS

As you might expect, muscle disorders, or **myopathies,** generally disrupt the normal movement of the body. In mild cases, these disorders vary from inconvenient to slightly troublesome. Severe muscle disorders, however, can impair the muscles used in breathing—a life-threatening situation.

Muscle Injury

Injuries to skeletal muscles caused by overexertion or trauma usually result in a muscle **strain.** Figure 12-32 shows an unusually severe muscle strain that resulted in a massive tear in the entire muscle organ. Muscle strains are characterized by muscle pain, or **myalgia** (my-AL-jee-ah), and involve overstretching or tearing of muscle fibers. If an injury occurs in the area of a joint and a ligament is damaged, the injury may be called a **sprain.** Any muscle inflammation, including that caused by a muscle strain, is termed **myositis** (my-oh-SYE-tis). If tendon inflammation occurs with myositis, as with a "charley horse," the condition is termed **fibromyositis** (fye-broh-my-oh-SYE-tis). Although inflammation may subside in a few hours or days, it usually takes weeks for damaged muscle fibers to repair. Some damaged muscle cells may be replaced by fibrous tissue, thereby forming scars. Occasionally, hard calcium is deposited in the scar tissue.

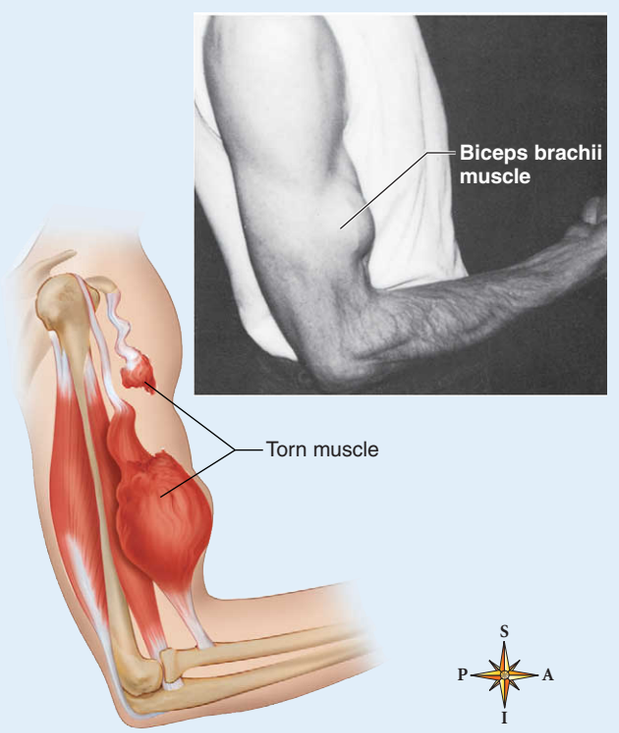

FIGURE 12-32

Muscle strain. Severe strain of the biceps brachii muscle. In a severe muscle strain, a muscle may break in two pieces and result in a visible gap in muscle tissue under the skin. Notice how the broken ends of the muscle reflexively contract (spasm) to form a knot of tissue.

Box 12-7 | HEALTH matters

Abnormal Muscle Contractions

Cramps are painful muscle spasms (involuntary twitches). Cramps often occur when a muscle organ is fatigued or mildly inflamed, but they can be a symptom of any irritation or ion and water imbalance.

Convulsions are abnormal, uncoordinated tetanic contractions of varying groups of muscles. Convulsions may result from a disturbance in the brain, or seizure, in which the output along motor nerves increases and becomes disorganized.

Fibrillation is an abnormal type of contraction in which individual fibers contract asynchronously rather than at the same time. This produces a flutter of the muscle but no effective movement. Fibrillation can also occur in cardiac muscle, where it reduces the heart's ability to pump blood.

Cramps often result from mild myositis or fibromyositis, but they can be a symptom of any irritation or an ion and water imbalance. Box 12-7 outlines a few types of abnormal muscle contractions.

Minor trauma to the body, especially a limb, may cause a muscle bruise, or **contusion.** Muscle contusions involve local internal bleeding and inflammation. Severe trauma to a skeletal muscle may cause a *crush injury.* Crush injuries greatly damage the affected muscle tissue, and the release of muscle fiber contents into the bloodstream can be life threatening. For example, the reddish muscle pigment myoglobin can accumulate in the blood and cause kidney failure.

Stress-induced muscle tension can result in myalgia and stiffness in the neck and back and is thought to be one cause of "stress headaches." Headache and back pain clinics use various strategies to treat stress-induced muscle tension. These treatments include massage, biofeedback, and relaxation training.

Muscle Infections

Several bacteria, viruses, and parasites may infect muscle tissue—often producing local or widespread myositis. For example, in trichinosis, widespread myositis is common. The muscle pain plus stiffness that sometimes accompanies influenza is another example.

One bacterial infection you have probably heard of is called *tetanus*—a confusing name because that word also refers to normal, sustained muscle contractions (see Figure 12-21). However, tetanus *the infection* is an abnormal condition caused by infection of the central nervous system with the bacterium *Clostridium tetani.* This bacterium releases a toxin called *tetanospasmin* that triggers overactivity of the nervous system, often involving painful spasms of the muscles throughout the body. Because the spasms frequently begin in the head and cause the jaw muscles to tense involuntarily, the infection is often called "lockjaw."

Once a tragically common disease, **poliomyelitis** is a viral infection of the nerves that control skeletal muscle movement. Although the disease can be asymptomatic, it often causes paralysis

that may progress to death. Although virtually eliminated in the United States as a result of a comprehensive vaccination program, it still affects millions in other parts of the world.

Muscular Dystrophy

Muscular dystrophy (DISS-troh-fee) is not a single disorder but a group of genetic diseases characterized by atrophy (wasting) of skeletal muscle tissues. Some, but not all, forms of muscular dystrophy can be fatal.

The common form of muscular dystrophy is **Duchenne** (doo-SHEN) **muscular dystrophy (DMD).** This form of the disease is also called *pseudohypertrophy* (meaning "false muscle growth") because the atrophy of muscle is masked by excessive replacement of muscle by fat and fibrous tissue. DMD is characterized by mild leg muscle weakness that progresses rapidly to include the shoulder muscles. The first signs of DMD are apparent at about 3 years of age, and the stricken child is usually severely affected within 5 to 10 years. Death from respiratory or cardiac muscle weakness often occurs by the time the individual is 21 years old.

DMD is caused by a mutation in the X chromosome, although other factors may be involved. DMD occurs primarily in boys. Because girls have two X chromosomes and boys only one, genetic diseases involving X chromosome abnormalities are more likely to occur in boys. This is true because girls with one damaged X chromosome may not exhibit an "X-linked" disease if their other X chromosome is normal (see Chapter 37). The gene involved in DMD normally codes for the protein **dystrophin** (DIS-trof-in), which forms strands in each skeletal muscle fiber and helps hold the cytoskeleton to the sarcolemma (see Figure 3-21 on p. 85). Dystrophin thus helps keep the muscle fiber from breaking during contractions. Normal dystrophin is missing in those with DMD because a deletion or mutation of part of the dystrophin gene causes the resulting protein to be nonfunctional (it has the wrong shape to do the job). Therefore, in DMD muscle fibers break apart more easily—causing the symptoms of progressive muscle weakness.

Myasthenia Gravis

Myasthenia gravis (my-es-THEE-nee-ah GRAH-vis) is a chronic disease characterized by muscle weakness, especially in the face and throat. Most forms of this disease begin with mild weakness and chronic muscle fatigue in the face, then progress to wider muscle involvement. An acute episode of widespread and severe muscle weakness is called a *myasthenic crisis*. A person in myasthenic crisis is in danger of dying of respiratory failure because of weakness in the respiratory muscles.

Myasthenia gravis is an autoimmune disease in which the immune system attacks the acetylcholine receptors in the sarcolemma of muscle cells and results in a defect in the conduction of nerve impulses at the neuromuscular junction. Nerve impulses from motor neurons are then unable to fully stimulate the affected muscle (see figures 12-7 and 12-8).

Hernias

Weakness of abdominal muscles can lead to a *hernia*, or protrusion, of an abdominal organ (commonly the small intestine or stomach) through an opening in the abdominal wall. There are several types of hernias.

| A&P CONNECT |

If you have not experienced a hernia before now, there is a good chance that one day you may. Hernias are quite common. See some examples of the common hernia types in ***Hernias*** online at ***A&P Connect.***

CASE study

"It can't be snowing again!" Isabel was so tired of shoveling snow, and it was only the beginning of February—at least 6 more weeks of winter to go. As she pushed the snow shovel across the driveway and tossed the snow onto an ever-growing mountain, she could feel her muscles begin to ache.

1. By what process would Isabel's muscles first get their energy for contraction?
a. Anaerobic pathway
b. Aerobic pathway
c. Recruitment
d. Breakdown of creatine phosphate

2. What substance in her muscles may be causing the aching or burning sensation?
a. Lactase
b. Glucose
c. Lactic acid
d. Glycogen

3. What protein molecules are interacting to allow Isabel's muscles to contract?
a. Myosin and troponin
b. Actin and myosin
c. Actin and tropomyosin
d. Troponin and tropomyosin

After several minutes of shoveling, Isabel stopped to take off her coat. She was surprised to find she was sweating even though it was below freezing.

4. What was causing Isabel's increased body temperature?
a. Contraction of cardiac muscle cells
b. Her increased respirations
c. Contraction of skeletal muscle cells
d. Conversion of ATP to glucose

5. To pick up a heavier shovelful of snow, Isabel will recruit more _____.
a. Motor units
b. Myoglobin
c. Individual muscle fibers
d. Myosin

CAREER choices

Massage Therapist

Massage therapy improves circulation and helps correct imbalances in the soft tissue areas of the body, as in muscles and fascia. As a massage therapist, I am self-employed. My clientele consists of hospital-referred patients for lymph drainage therapy (see Chapter 23) and people who seek traditional massage for various reasons. The majority of my work consists of home visits; however, I also do some work at health facilities and with organized groups.

Some of the current trends in the massage profession are La Stone Therapy, treatment of cancer patients (with a doctor's approval), and stress and pain relief.

My job is extremely rewarding. I rarely encounter a client in a bad mood before a massage, and never after completion! It is very rewarding to see that a client or patient's problem has improved after massage therapy, or simply to see a look of contentment on that person's face. There is a personal, respectful bond between the therapist and the client. In addition, this profession can be financially rewarding.

Monteo Myers, CMT

Knowledge of anatomy and physiology is definitely needed to effectively treat muscular/skeletal problems because isolation of the involved muscle is necessary. I still review anatomy and physiology of the muscular, skeletal, and lymphatic areas all the time. My advice is to study anatomy and physiology in a quiet room, do not study an entire chapter in one sitting, spread the chapter out, and take notes!

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

INTRODUCTION

A. Muscular system is responsible for moving the framework of the body
B. In addition to movement, muscle tissue performs various other functions

GENERAL FUNCTIONS

A. Movement of the body as a whole or movement of its parts
B. Heat production
C. Posture

FUNCTION OF SKELETAL MUSCLE TISSUE

A. Characteristics of skeletal muscle cells
   1. Excitability (irritability)—ability to be stimulated
   2. Contractility—ability to contract, or shorten, and produce body movement
   3. Extensibility—ability to extend, or stretch, thereby allowing muscles to return to their resting length

B. Overview of the muscle cell (Figures 12-1 and 12-2)
   1. Muscle cells are called *fibers* because of their threadlike shape
   2. Sarcolemma—plasma membrane of muscle fibers
   3. Sarcoplasmic reticulum (SR)
      a. T tubules—network of tubules and sacs found within muscle fibers
      b. Membrane of the SR continually pumps calcium ions from the sarcoplasm and stores the ions within its sacs for later release (Figure 12-3)
   4. Muscle fibers contain many mitochondria and several nuclei
   5. Myofibrils—numerous fine fibers packed close together in sarcoplasm
   6. Sarcomere
      a. Segment of myofibril between two successive Z disks
      b. Each myofibril consists of many sarcomeres
      c. Contractile unit of muscle fibers
   7. T tubules
      a. Transverse tubules extend across the sarcoplasm at right angles to the long axis of the muscle fiber
      b. Formed by inward extensions of the sarcolemma
      c. Membrane has ion pumps that continually transport Ca^{++} ions inward from the sarcoplasm
      d. Allow electrical impulses traveling along the sarcolemma to move deeper into the cell

8. Striated muscle (Figure 12-4)
   a. Dark stripes called *A bands;* light H band runs across the midsection of each dark A band
   b. Light stripes called *I bands;* dark Z disk extends across the center of each light I band
9. Triad
   a. Triplet of tubules; a T tubule sandwiched between two sacs of sarcoplasmic reticulum
   b. Allows an electrical impulse traveling along a T tubule to stimulate the membranes of adjacent sacs of the sarcoplasmic reticulum

C. Myofilaments (Figures 12-5 and 12-6)
1. Each myofibril contains thousands of thick and thin myofilaments
2. Four different kinds of protein molecules make up myofilaments
   a. Myosin
      (1) Makes up almost all the thick filament
      (2) Myosin "heads" are chemically attracted to actin molecules
      (3) Myosin "heads" are known as *cross bridges* when attached to actin
   b. Actin—globular protein that forms two fibrous strands twisted around each other to form the bulk of the thin filament
   c. Tropomyosin—protein that blocks the active sites on actin molecules
   d. Troponin—protein that holds tropomyosin molecules in place
3. Thin filaments attach to both Z disks (Z lines) of a sarcomere and extend part way toward the center
4. Thick myosin filaments do not attach to the Z disks

D. Mechanism of contraction
1. Excitation and contraction (Figures 12-7 through 12-13; Table 12-1)
   a. A skeletal muscle fiber remains at rest until stimulated by a motor neuron
   b. Neuromuscular junction—motor neurons connect to the sarcolemma at the motor endplate (Figure 12-7)
   c. Neuromuscular junction is a synapse where neurotransmitter molecules transmit signals
   d. Acetylcholine—the neurotransmitter released into the synaptic cleft that diffuses across the gap, stimulates the receptors, and initiates an impulse in the sarcolemma
   e. Nerve impulse travels over the sarcolemma and inward along the T tubules, which triggers the release of calcium ions
   f. Calcium binds to troponin, which causes tropomyosin to shift and expose active sites on actin
   g. Sliding filament model (Figures 12-12 and 12-13)
      (1) When active sites on actin are exposed, myosin heads bind to them
      (2) Myosin heads bend and pull the thin filaments past them
      (3) Each head releases, binds to the next active site, and pulls again
      (4) The entire myofibril shortens
2. Relaxation
   a. Immediately after the Ca^{++} ions are released, the sarcoplasmic reticulum begins actively pumping them back into the sacs (Figure 12-3)
   b. Ca^{++} ions are removed from the troponin molecules, thereby shutting down the contraction
3. Energy sources for muscle contraction (Figure 12-14)
   a. Hydrolysis of ATP yields the energy required for muscular contraction
   b. ATP binds to the myosin head and then transfers its energy to the myosin head to perform the work of pulling the thin filament during contraction
   c. Muscle fibers continually resynthesize ATP from the breakdown of creatine phosphate (CP)
   d. Catabolism by muscle fibers requires glucose and oxygen
   e. Glucose and oxygen supplied to muscle fibers by blood capillaries (Figure 12-15)
   f. At rest, excess O_2 in the sarcoplasm is bound to myoglobin (Box 12-4)
      (1) Red fibers—muscle fibers with high levels of myoglobin
      (2) White fibers—muscle fibers with little myoglobin
   g. Catabolic pathways
      (1) Aerobic pathway
         (a) Occurs when adequate O_2 is available from blood (Figure 12-15)
         (b) Slower than anaerobic pathway, thus supplies energy for the long term rather than the short term
      (2) Anaerobic pathway (Figure 12-16)
         (a) Very rapid, providing energy during first minutes of maximal exercise (Figure 12-16)
         (b) May occur when low levels of O_2 are available
         (c) Results in the formation of lactic acid, which requires oxygen to convert back to glucose, the producing of an "oxygen debt" or excess postexercise oxygen consumption (EPOC)
   h. Skeletal muscle contraction produces waste heat that can be used to help maintain the set point body temperature (Figure 12-17)

FUNCTION OF SKELETAL MUSCLE ORGANS

A. Muscles are composed of bundles of muscle fibers held together by fibrous connective tissue

B. Motor unit (Figure 12-18)
1. Motor unit—motor neuron plus the muscle fibers to which it attaches
2. Some motor units consist of only a few muscle fibers, whereas others consist of numerous fibers
3. Generally, the smaller the number of fibers in a motor unit, the more precise the movements available; the larger the number of fibers in a motor unit, the more powerful the contraction available

C. Myography—method of graphing the changing tension of a muscle as it contracts (Figure 12-19)

D. Twitch contraction (Figure 12-20)
   1. A quick jerk of a muscle that is produced as a result of a single, brief threshold stimulus (generally occurs only in experimental situations)
   2. The twitch contraction has three phases
      a. Latent phase—nerve impulse travels to the sarcoplasmic reticulum to trigger release of Ca^{++}
      b. Contraction phase—Ca^{++} binds to troponin and sliding of filaments occurs
      c. Relaxation phase—sliding of filaments ceases

E. Treppe—the staircase phenomenon (Figure 12-21, *B*)
   1. Gradual, steplike increase in the strength of contraction that is seen in a series of twitch contractions that occur 1 second apart
   2. Eventually, the muscle responds with less forceful contractions, and the relaxation phase becomes shorter
   3. If the relaxation phase disappears completely, a contracture occurs

F. Tetanus—smooth, sustained contractions
   1. Multiple wave summation—multiple twitch waves are added together to sustain muscle tension for a longer time
   2. Incomplete tetanus—very short periods of relaxation occur between peaks of tension (Figure 12-21, *C*)
   3. Complete tetanus—the stimulation is such that twitch waves fuse into a single, sustained peak (Figure 12-21, *D*)
   4. The availability of calcium determines whether a muscle will contract; if the calcium is continuously available, then contraction will be sustained (Figure 12-22)

G. Muscle tone
   1. Tonic contraction—continual, partial contraction of a muscle
   2. At any one time, a small number of muscle fibers within a muscle contract and produce a tightness or muscle tone
   3. Muscles with less tone than normal are flaccid
   4. Muscles with more tone than normal are spastic
   5. Muscle tone is maintained by negative feedback mechanisms

GRADED STRENGTH PRINCIPLE

A. Graded strength principle—skeletal muscles contract with varying degrees of strength at different times

B. Factors that contribute to the phenomenon of graded strength (Figure 12-26)
   1. Metabolic condition of individual fibers
   2. Number of muscle fibers contracting simultaneously; the greater the number of fibers contracting, the stronger the contraction
   3. Number of motor units recruited
   4. Intensity and frequency of stimulation (Figure 12-23)
   5. Length-tension relationship (Figure 12-24)
      a. Maximal strength that a muscle can develop bears a direct relationship to the initial length of its fibers
      b. A shortened muscle's sarcomeres are compressed; therefore, the muscle cannot develop much tension
      c. An overstretched muscle cannot develop much tension because the thick myofilaments are too far from the thin myofilaments
      d. Strongest maximal contraction is possible only when the skeletal muscle has been stretched to its optimal length
   6. Stretch reflex (Figure 12-25)
      a. The load imposed on a muscle influences the strength of a skeletal contraction
      b. Stretch reflex—the body tries to maintain constancy of muscle length in response to increased load
      c. Maintains a relatively constant length as load is increased up to a maximum sustainable level

C. Isotonic and isometric contractions (Figure 12-27)
   1. Isotonic contraction
      a. Contraction in which the tone or tension within a muscle remains the same as the length of the muscle changes
         (1) Concentric—muscle shortens as it contracts
         (2) Eccentric—muscle lengthens while contracting
      b. Isotonic—literally means "same tension"
      c. All of the energy of contraction is used to pull on thin myofilaments and thereby change the length of a fiber's sarcomeres
   2. Isometric contraction
      a. Contraction in which muscle length remains the same while muscle tension increases
      b. Isometric—literally means "same length"
   3. Most body movements occur as a result of both types of contractions

FUNCTION OF CARDIAC AND SMOOTH MUSCLE TISSUE (TABLE 12-1)

A. Cardiac muscle (Figure 12-28)
   1. Found only in the heart; forms the bulk of the wall of each chamber
   2. Also known as *striated involuntary muscle*
   3. Contracts rhythmically and continuously to provide the pumping action needed to maintain constant blood flow
   4. Cardiac muscle resembles skeletal muscle but has unique features related to its role in continuously pumping blood
      a. Each cardiac muscle contains parallel myofibrils (Figure 12-28)
      b. Cardiac muscle fibers form strong, electrically coupled junctions (intercalated disks) with other fibers; individual cells also exhibit branching
      c. Syncytium—continuous, electrically coupled mass
      d. Cardiac muscle fibers form a continuous, contractile band around the heart chambers that conducts a single impulse across a virtually continuous sarcolemma
      e. T tubules are larger and form diads with a rather sparse sarcoplasmic reticulum
      f. Cardiac muscle sustains each impulse longer than in skeletal muscle; therefore, impulses cannot come rapidly enough to produce tetanus (Figure 12-29)
      g. Cardiac muscle does not run low on ATP and does not experience fatigue
      h. Cardiac muscle is self-stimulating

B. Smooth muscle
   1. Smooth muscle is composed of small, tapered cells with single nuclei (Figure 12-30)
   2. No T tubules are present, and only a loosely organized sarcoplasmic reticulum is present
   3. Ca^{++} comes from outside the cell and binds to calmodulin instead of troponin to trigger a contraction
   4. No striations because thick and thin myofilaments are arranged differently than in skeletal or cardiac muscle fibers; myofilaments are not organized into sarcomeres
   5. Two types of smooth muscle tissue (Figure 12-31)
      a. Single-unit (visceral) smooth muscle
         (1) Gap junctions join smooth muscle fibers into large, continuous sheets
         (2) Most common type; forms a muscular layer in the walls of hollow structures such as the digestive, urinary, and reproductive tracts
         (3) Exhibits autorhythmicity and produces peristalsis
      b. Multiunit smooth muscle
         (1) Does not act as a single unit but is composed of many independent cell units
         (2) Each fiber responds only to nervous input

THE BIG PICTURE: MUSCLE TISSUE AND THE WHOLE BODY

A. Function of all three major types of muscle is integral to function of the entire body
B. All three types of muscle tissue provide the movement necessary for survival
C. Relative constancy of the body's internal temperature is maintained by "waste" heat generated by muscle tissue
D. Maintains the body in a relatively stable position

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the terms *sarcolemma*, *sarcoplasm*, and *sarcoplasmic reticulum*.
2. Describe the function of the sarcoplasmic reticulum.
3. How are acetylcholine, Ca^{++}, and adenosine triphosphate (ATP) involved in the excitation and contraction of skeletal muscle?
4. Describe the general structure of ATP and tell how it relates to its function.
5. How does ATP provide energy for muscle contraction?
6. Describe the anatomical arrangement of a motor unit.
7. List and describe the different types of skeletal muscle contractions.
8. Define the term *recruited* as it applies to muscles.
9. Describe rigor mortis.
10. What are the effects of exercise on skeletal muscles?

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Explain how skeletal muscles provide movement, heat, and posture. Are all of these functions unique to muscles? Explain your answer.
2. The characteristic of excitability is shared by what other system? Relate contractility and extensibility to the concept of agonist and antagonist discussed in Chapter 11.
3. What structures are unique to skeletal muscle fibers? Which of the structures are involved primarily in contractility and which are involved in excitability?
4. Explain how the structure of myofilaments is related to their function.
5. Explain how the sliding filament theory allows for the shortening of a muscle fiber.
6. Compare and contrast the role of Ca^{++} in excitation, contraction, and relaxation of skeletal muscle.
7. People who exercise seriously are sometimes told to work a muscle until they "feel the burn." In terms of how the muscle is able to release energy, explain what is going on in the muscle early in the exercise and when the muscle is "burning."
8. Using fiber types, design a muscle for a marathon runner and a different muscle for a 100-yard–dash sprinter. Explain your choice.
9. Explain the meaning of a "unit of combined cells" as it relates to cardiac muscle. How does this structural arrangement affect its function?
10. Which of the two smooth muscle types would be most affected by damage to the nerves that stimulate them?

Unit Three

Communication, Control, and Integration

The anatomical structures and functional mechanisms that permit communication, control, and integration of bodily functions are discussed in the chapters of Unit Three. To maintain homeostasis, the body must have the ability to monitor and then respond appropriately to changes that may occur in either the internal or external environment. The nervous and endocrine systems provide this capability. Information originating in sensory nerve endings found in complex special sense organs such as the eye and in simple receptors located in skin or other body tissues provides the body with the necessary input. Nervous signals traveling rapidly from the brain and spinal cord over nerves to muscles and glands initiate immediate coordinating and regulating responses. Slower-acting chemical messengers, hormones produced by endocrine glands, serve to effect more long-term changes in physiological activities to maintain homeostasis.

Case Study, 414

The nervous system and the endocrine system together perform a vital function for the body—communication. Communication provides the means to control and integrate the many different functions performed by organs, tissues, and cells. Integrating means unifying. Unifying body functions allows them to work together like a machine to maintain homeostasis and thus survival.

The nervous system—*made up of the brain, spinal cord, and nerves—is probably the most intriguing body system (Figure 13-1). Facts, theories, and questions about this system are as fascinating as they are abundant. We shall begin our study of the nervous system in this chapter by considering the cells of the nervous system and how they work together to accomplish their function. Then in Chapter 14 we discuss the brain and spinal cord. Chapter 15 presents the major peripheral nerves of the body and Chapter 16 discusses the role of the autonomic nervous system in the subconscious control of body functions. Chapter 17 continues the discussion by describing the structure and function of the sense organs.*

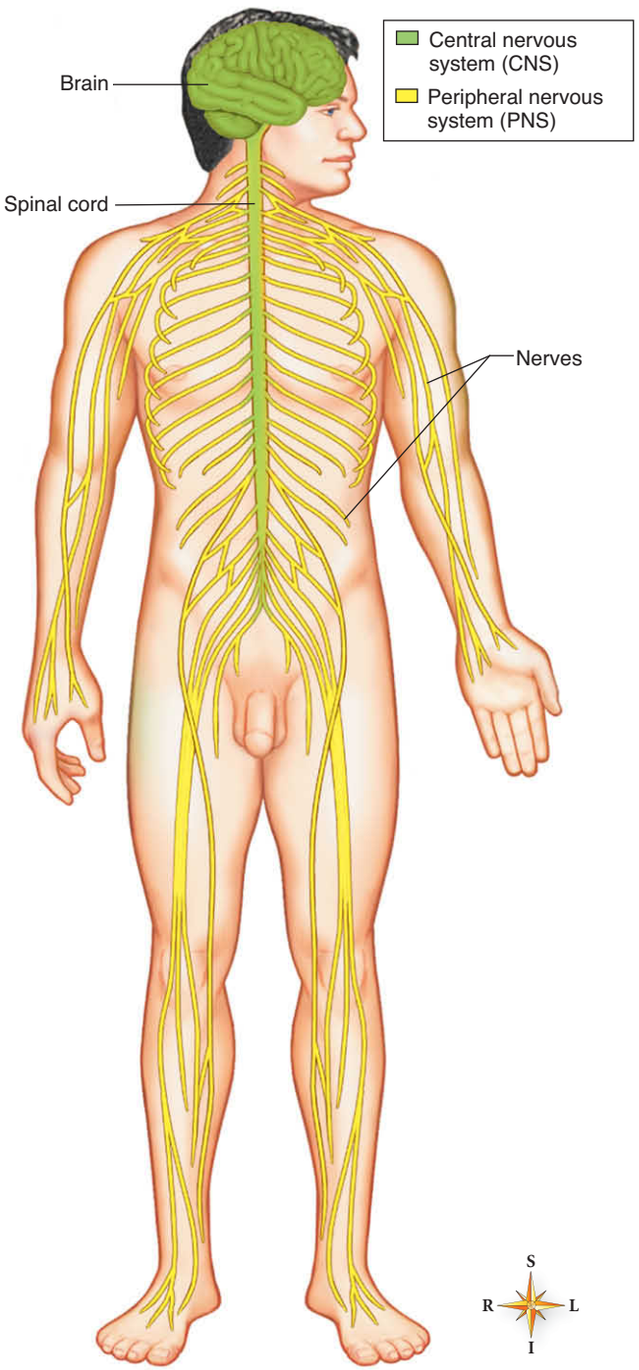

FIGURE 13-1

The nervous system. Major anatomical features of the human nervous system include the brain, the spinal cord, and each of the individual nerves. The brain and spinal cord make up the central nervous system (CNS), and all the nerves and their branches make up the peripheral nervous system (PNS). Nerves originating from the brain are classified as *cranial nerves,* and nerves originating from the spinal cord are called *spinal nerves.*

ORGANIZATION OF THE NERVOUS SYSTEM

The nervous system is organized to detect changes (stimuli) in the internal and external environment, evaluate that information, and possibly respond by initiating changes in muscles or glands. To make this complex network of information lines and processing circuits easier to understand, biologists have subdivided the nervous system into the smaller "systems" and "divisions" described in the following paragraphs and illustrated in Figure 13-2. Note as you read through the next several sections that the nervous system can be divided in various ways: according to structure, direction of information flow, or control of effectors.

Central and Peripheral Nervous Systems

The classical manner of subdividing the nervous system is based on the gross dissections of early anatomists. It simply categorizes all nervous system tissues according to their relative positions in the body: central or peripheral.

The **central nervous system** (CNS) is, as its name implies, the structural and functional center of the entire nervous system. Consisting of the brain and spinal cord, the CNS integrates incoming pieces of sensory information, evaluates the information, and initiates an outgoing response. Today, neurobiologists include only those cells that begin and end within the anatomical boundaries of the brain and spinal cord as part of the CNS. Cells that begin in the brain or cord but extend out through a nerve are thus not included in the central nervous system.

The **peripheral nervous system** (PNS) consists of the nerve tissues that lie in the periphery, or "outer regions," of the nervous system. Nerves that originate from the brain or exit through the skull are called *cranial nerves*, and nerves that originate from the spinal cord and do not exit the skull are called *spinal nerves*.

The terms *central* and *peripheral* are often used as directional terms in the nervous system. For example, nerve cell extensions called *nerve fibers* may be called *central fibers* if they extend from the cell body toward the CNS. Likewise, they may be called

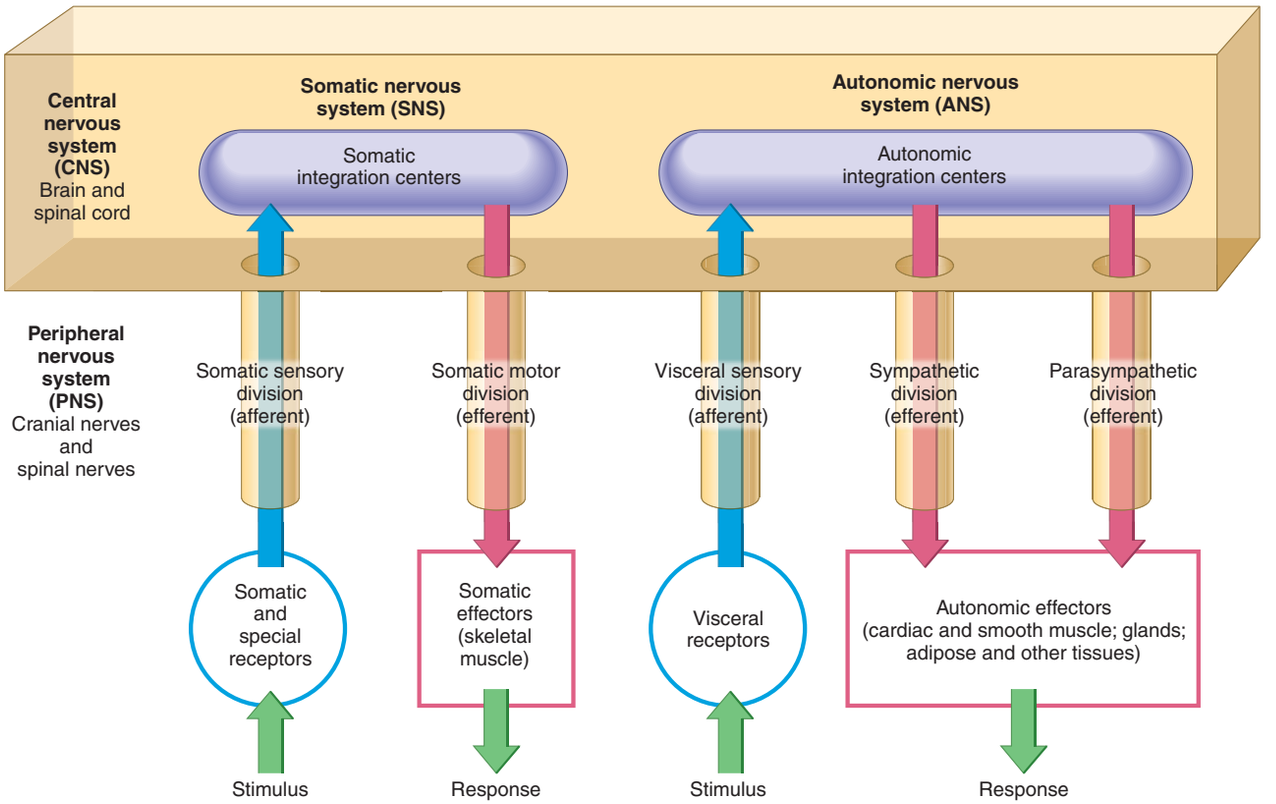

FIGURE 13-2

Organizational plan of the nervous system. Diagram summarizes the scheme used by most neurobiologists in studying the nervous system. Both the somatic nervous system (SNS) and the autonomic nervous system (ANS) include components in the central nervous system (CNS) and peripheral nervous system (PNS). Somatic sensory pathways conduct information toward integrators in the CNS, and somatic motor pathways conduct information toward somatic effectors. In the ANS, visceral sensory pathways conduct information toward CNS integrators, whereas the sympathetic and parasympathetic pathways conduct information toward autonomic effectors.

peripheral fibers if they extend from the cell body away from the CNS.

Figure 13-1 represents the anatomical components of the CNS and PNS and their relative positions in the body. Figure 13-2 represents the relationship of the CNS and PNS in diagram form.

Afferent and Efferent Divisions

The tissues of both the central and the peripheral nervous systems include nerve cells that form incoming information pathways and outgoing pathways. For this reason, it is often convenient to categorize the nervous pathways into divisions according to the direction in which they carry information. The **afferent division** of the nervous system consists of all of the incoming *sensory* or *afferent* pathways. The **efferent division** of the nervous system consists of all the outgoing *motor* or *efferent* pathways. The literal meanings of the terms *afferent* (carry toward) and *efferent* (carry away) may help you distinguish between these two divisions of the nervous system more easily.

Look at Figure 13-2 and try to distinguish the afferent and efferent pathways represented there. Here, and throughout the rest of this book, afferent pathways are typically represented in blue and efferent pathways in red.

Somatic and Autonomic Nervous Systems

Yet another way to organize the components of the nervous system for ease of study is to categorize them according to the type of effectors they regulate. Some pathways of the **somatic nervous system (SNS)** carry information to the *somatic effectors*, which are the skeletal muscles. These motor pathways make up the somatic motor division. As Figure 13-2 shows, the somatic nervous system also includes the afferent pathways, making up the **somatic sensory division,** that provide feedback from the somatic effectors. The SNS also includes the integrating centers that receive the sensory information and generate the efferent response signal.

Efferent pathways of the **autonomic nervous system (ANS)** carry information to the *autonomic*, or *visceral*, effectors, which are mainly the smooth muscles, cardiac muscle, glands, adipose tissue, and other "involuntary" tissue. As its name implies, the autonomic nervous system seems autonomous of voluntary control—it usually appears to govern itself without our conscious knowledge. We now know that the autonomic nervous system is influenced by the conscious mind, but the historical name for this part of the nervous system has remained.

The efferent pathways of the ANS can be divided into the *sympathetic division* and the *parasympathetic division*. The sympathetic division, made up of pathways that exit the middle portions of the spinal cord, is involved in preparing the body to deal with immediate threats to the internal environment. It produces the "fight-or-flight" response. The parasympathetic pathways exit at the brain or lower portions of the spinal cord and coordinate the body's normal resting activities. The parasympathetic division is thus sometimes called the "rest-and-repair" division.

The afferent pathways of the ANS belong to the **visceral sensory division,** which carries feedback information to the autonomic integrating centers in the central nervous system.

Figure 13-2 summarizes the various ways in which the nervous system is subdivided and combines these approaches into a single "big picture."

| QUICK CHECK |

1. List the major subdivisions of the human nervous system.
2. What two organs make up the central nervous system?
3. Contrast the somatic nervous system with the autonomic nervous system.

CELLS OF THE NERVOUS SYSTEM

Two main types of cells compose the nervous system, namely, *neurons* and *glia*. **Neurons** are excitable cells that conduct the impulses that make possible all nervous system functions. In other words, they form the "wiring" of the nervous system's information circuits. **Glia,** or *glial cells,* on the other hand, do not usually conduct information themselves but support the function of neurons in various ways. Some of the major types of glia and neurons are described in the following sections.

Glia

Our understanding of glia, or **neuroglia** as they are sometimes called, has been slow in coming. In the late nineteenth century the Italian cell biologist Camillo Golgi (after whom the Golgi apparatus is named) accidentally dropped a piece of brain tissue in a bath of silver nitrate. When he finally found it, Golgi could see a vast network of various kinds of darkly stained cells surrounding the neurons—proof that glia existed. However, they were almost immediately set aside as mere packing material. In fact, *glia* literally means "glue." For more than a century almost all research efforts focused on neurons. Fortunately, the tide has turned, and studies of glia and their functions are one of the hottest areas in *neurobiology*, the study of the nervous system. We are now finding that they have a major role in how the nervous system works.

The number of glia in the human nervous system is beyond imagination. One estimate places the figure at a staggering 900 billion, or nine times the estimated number of stars in our galaxy! Unlike some neurons, glial cells retain their capacity for cell division throughout adulthood. Although this characteristic gives them the ability to replace themselves, it also makes them susceptible to abnormalities of cell division—such as cancer. Most benign and malignant tumors found in the nervous system originate in glial cells.

As stated earlier, glia serve various roles in supporting the function of neurons. To get a sense of this variety of functions, we shall briefly examine five major types of glia (Figure 13-3):

1. Astrocytes
2. Microglia
3. Ependymal cells
4. Oligodendrocytes
5. Schwann cells

The first four glial types in this list are located in the CNS. Only the Schwann cells are located in the PNS.

The star-shaped glia, **astrocytes** (Figure 13-3, A), derive their name from the Greek *astron*, "star." Found only in the central nervous system, they are the largest and most numerous type of glia. Their long, delicate "points" extend through brain tissue, attaching to both neurons and the tiny blood capillaries of the brain. Astrocytes have recently been called "stars of the nervous system" because of the many important functions they perform. Astrocytes actually "feed" the neurons by picking up glucose from the blood, converting it to lactic acid, and passing it along to the neurons to which they are connected. (See Chapter 30 for a fuller discussion of the role of lactic acid in cellular respiration.)

Because webs of astrocytes form tight sheaths around the brain's blood capillaries, they help form the *blood-brain barrier* (BBB). The

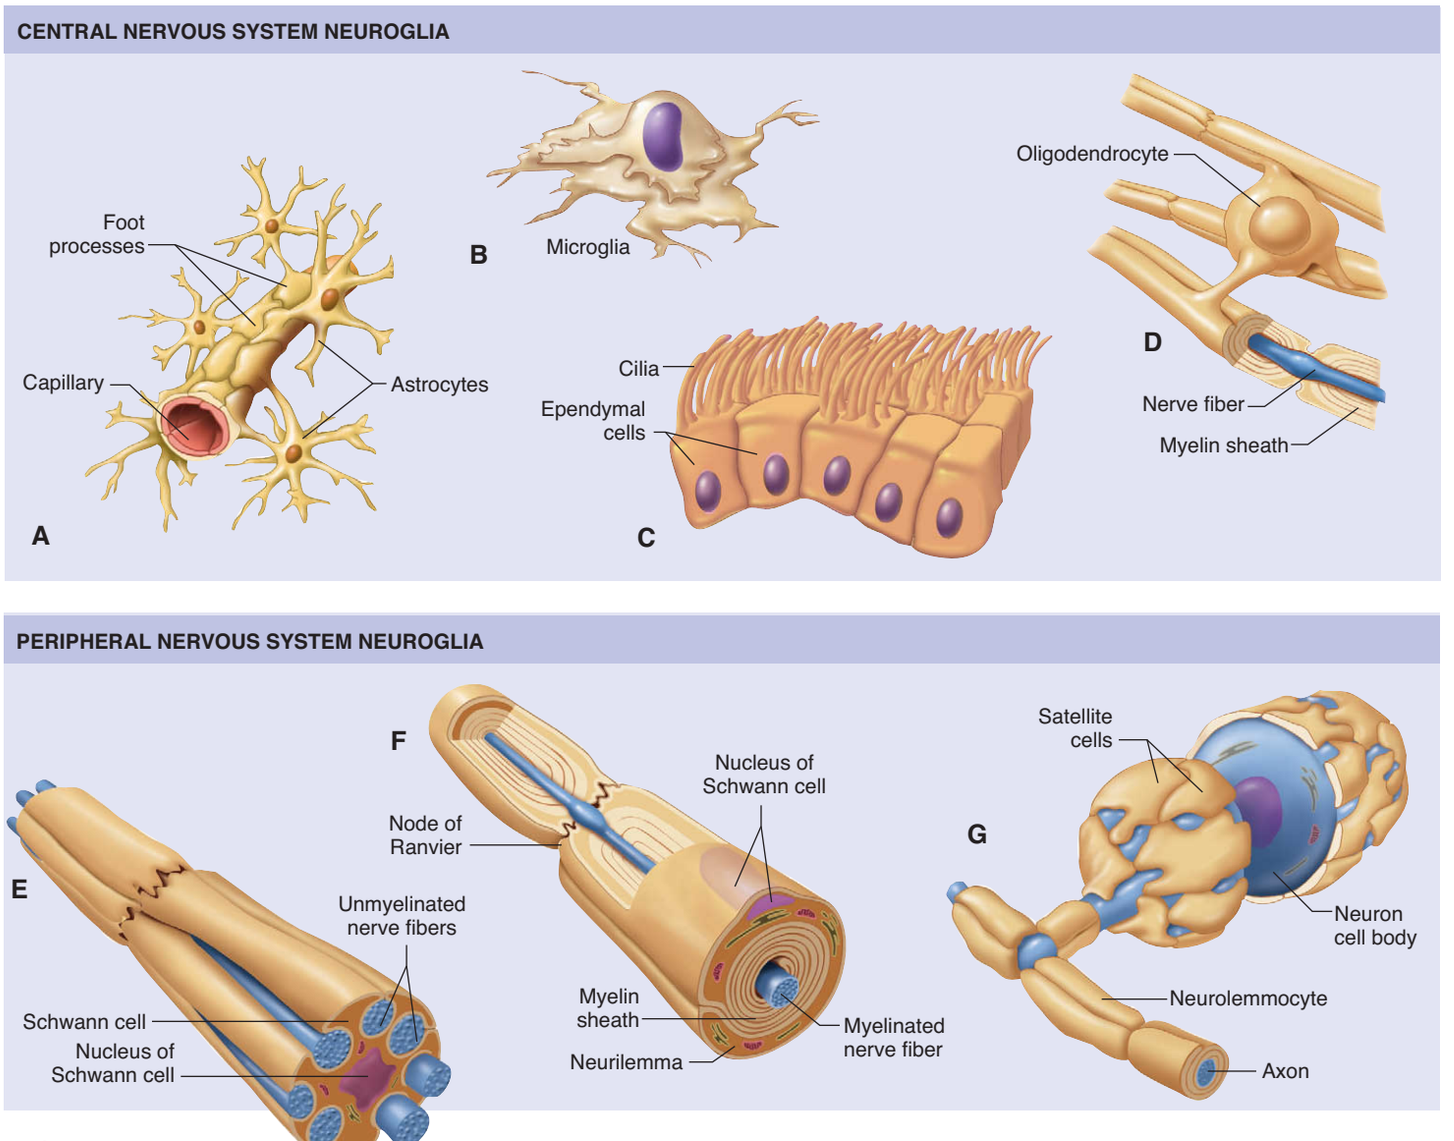

FIGURE 13-3

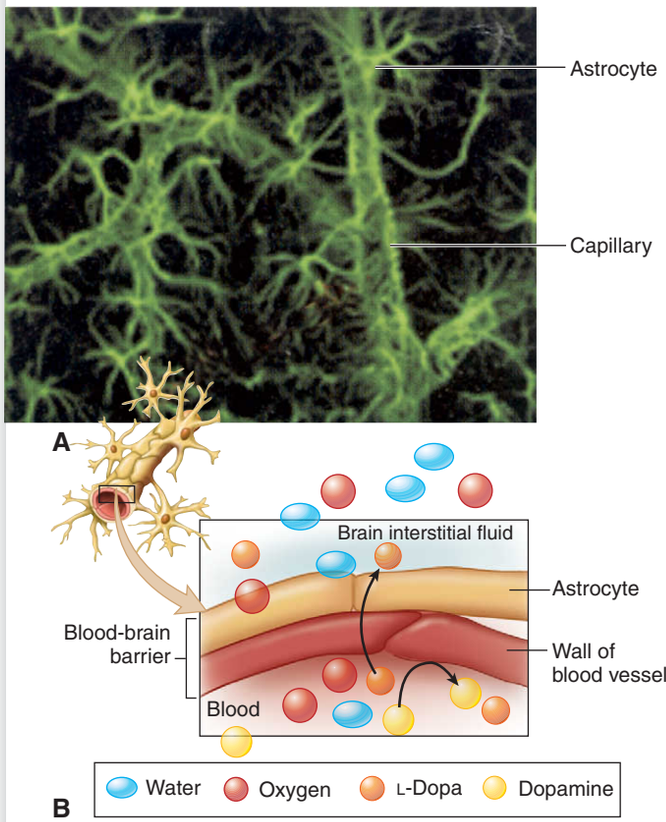
Types of neuroglia. Neuroglia of the central nervous system (CNS): **A,** Astrocytes attached to the outside of a capillary blood vessel in the brain. **B,** A phagocytic microglial cell. **C,** Ciliated ependymal cells forming a sheet that usually lines fluid cavities in the brain. **D,** An oligodendrocyte with processes that wrap around nerve fibers in the CNS to form myelin sheaths. Neuroglia of the peripheral nervous system (PNS): **E,** A Schwann cell supporting a bundle of nerve fibers in the PNS. **F,** Another type of Schwann cell wrapping around a peripheral nerve fiber to form a thick myelin sheath. **G,** Satellite cells, another type of Schwann cell, surround and support cell bodies of neurons in the PNS.

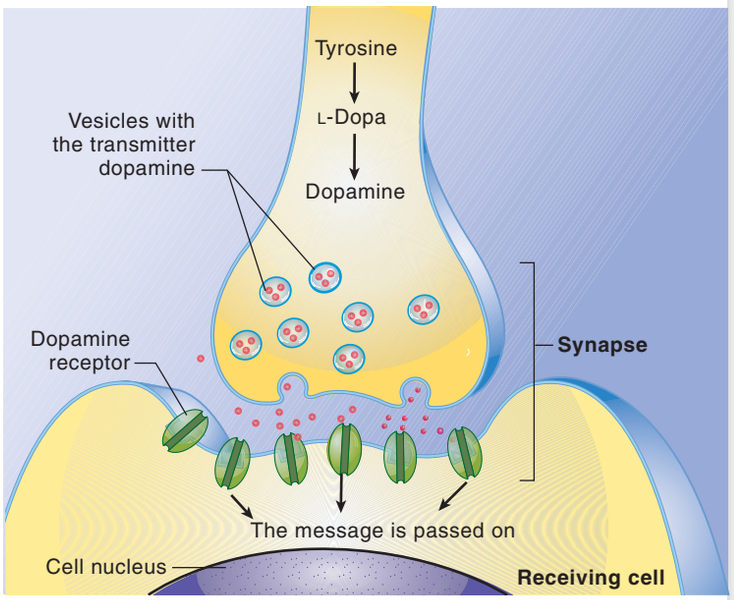
BBB is a double barrier made up of astrocyte "feet" and the endothelial cells that make up the walls of the capillaries. Small molecules (e.g., oxygen, carbon dioxide, water, alcohol) diffuse rapidly through the barrier to reach brain neurons and other glia. Larger molecules penetrate it slowly or not at all (Box 13-1). More recent findings suggest that astrocytes may not only influence the growth of neurons and how the neurons connect to form circuits but also transmit information along "astrocyte pathways" themselves.

Microglia (Figure 13-3, *B*) are small, usually stationary cells found in the central nervous system. In inflamed or degenerating brain tissue, however, microglia enlarge, move about, and carry on phagocytosis. In other words, they engulf and destroy microorganisms and cellular debris. Although classified as glia, microglia are functionally and developmentally unrelated to other nervous system cells.

Ependymal cells (Figure 13-3, *C*) are glia that resemble epithelial cells, forming thin sheets that line fluid-filled cavities in the brain and spinal cord. Some ependymal cells take part in producing the fluid that fills these spaces. Other ependymal cells have cilia that help keep the fluid circulating within the cavities.



Oligodendrocytes (Figure 13-3, *D*) are smaller than astrocytes and have fewer processes. The name *oligodendrocytes* literally means "cell with few branches" (*oligo-* few, *-dendro-* branch, *-cyte* cell). Some oligodendrocytes lie clustered around nerve cell



Box 13-1 | HEALTH matters

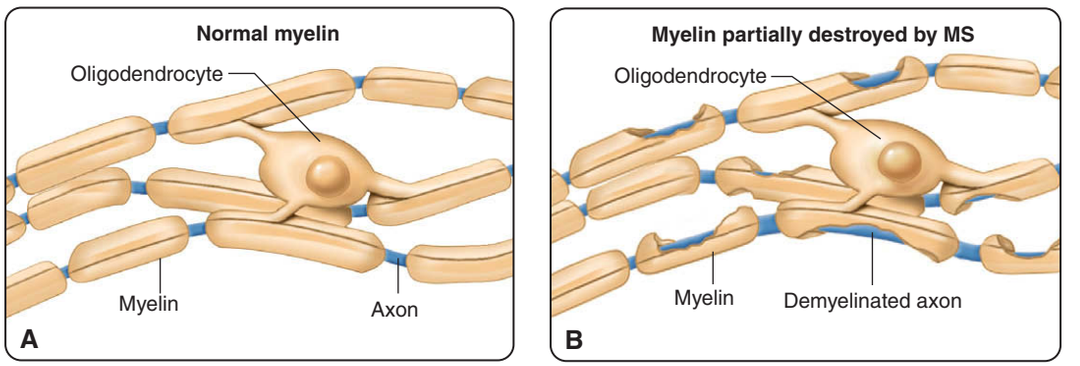
The Blood-Brain Barrier

The **blood-brain barrier (BBB)** helps maintain the very stable environment required for normal functioning of the brain. The BBB is formed as astrocytes wrap their "feet" around capillaries in the brain (part *A* of figure). The tight junctions between epithelial cells in the capillary wall, along with the covering formed by footlike extensions of the astrocytes, form a barrier that regulates the passage of most ions between the blood and the brain tissue (part *B* of figure). If they crossed to and from the brain freely, ions such as sodium (Na^+) and potassium (K^+) could disrupt the transmission of nerve impulses. Water, oxygen, carbon dioxide, and glucose can cross the barrier easily. Small, lipid-soluble molecules such as alcohol can also diffuse easily across the barrier.

The blood-brain barrier must be considered by researchers trying to develop new drug treatments for brain disorders. Many drugs and other chemicals simply will not pass through the barrier, although they might have therapeutic effects if they could get to the cells of the brain. For example, the abnormal control of muscle movements characteristic of **Parkinson disease (PD)** can often be alleviated by the substance dopamine, which is deficient in the brains of PD patients. Because dopamine cannot cross the blood-brain barrier, dopamine injections or tablets are ineffective. Researchers found that the chemical used by brain cells to make dopamine, **levodopa (L-dopa),** can cross the barrier. Part *C* of the figure shows how L-dopa is used in brain cells to form dopamine. Levodopa administered to patients with Parkinson disease crosses the barrier and converts to dopamine, and the effects of the condition are thereby reduced.

Blood-brain barrier. A, Micrograph of fluorescent-stained astrocytes shows how they attach to capillaries, forming a coating around these tiny blood vessels. **B,** Diagram showing a cross section of the blood-brain barrier, made up of the foot processes of astrocytes and the wall of the blood capillary. **C,** Diagram showing how dopamine is formed from L-dopa before being released as a neurotransmitter. See Figure 13-31 for a more detailed look at the formation of dopamine.

UNIT 3



Box 13-2 | HEALTH matters

Multiple Sclerosis (MS)

Several diseases are associated with disorders of the oligodendrocytes. Because these glial cells are involved in myelin formation, the diseases are called **myelin disorders.** The most common primary disease of the central nervous system is a myelin disorder called **multiple sclerosis (MS).** It is characterized by myelin loss and destruction accompanied by varying degrees of oligodendrocyte injury and death. The result is demyelination throughout the white matter of the central nervous system. Hard plaquelike lesions replace the destroyed myelin, and affected areas are invaded by inflammatory cells. As the myelin surrounding nerve fibers is lost, nerve conduction is impaired and weakness, loss of coordination, visual impairment, and speech disturbances occur. Although the disease occurs in both sexes and among all age-groups, it is most common in women between 20 and 40 years of age.

The cause of MS is thought to be related to autoimmunity and to viral infections in some individuals. Susceptibility to MS is inherited in some individuals. MS is characteristically relapsing and chronic in nature, but some cases of acute and unremitting disease have been reported. In most instances, the disease is prolonged, with remissions and relapses occurring over a period of many years. There is no known cure.

Effects of multiple sclerosis (MS). **A,** A normal myelin sheath allows rapid conduction. **B,** In MS, the myelin sheath is damaged, disrupting nerve conduction.

bodies; and some are arranged in rows between nerve fibers in the brain and cord. They help hold nerve fibers together and also serve another and probably more important function—they produce the fatty **myelin sheath** around nerve fibers in the central nervous system (Box 13-2).

Notice in Figure 13-3, *D*, how their processes wrap around surrounding nerve fibers to form this sheath.

Schwann cells (Figure 13-3, *E* to G) are found only in the peripheral nervous system. Here they serve as the functional equivalent of the oligodendrocytes, supporting nerve fibers and sometimes forming a myelin sheath around them. As Figure 13-3, *F*, shows, many Schwann cells can wrap themselves around a single nerve fiber. The myelin sheath is formed by layers of Schwann cell membrane containing the white, fatty substance **myelin.** Microscopic gaps in the sheath, between adjacent Schwann cells, are called **nodes of Ranvier** or simply *myelin sheath gaps.* The myelin sheath and its tiny gaps are important in the proper conduction of impulses along nerve fibers in the peripheral nervous system. As you can see in Figure 13-4, the developing Schwann cell wraps around the nerve fiber in a way that forms an inner core of many layers of plasma membrane, made up mostly of the myelin (a type of phospholipid). Notice that the Schwann cell's

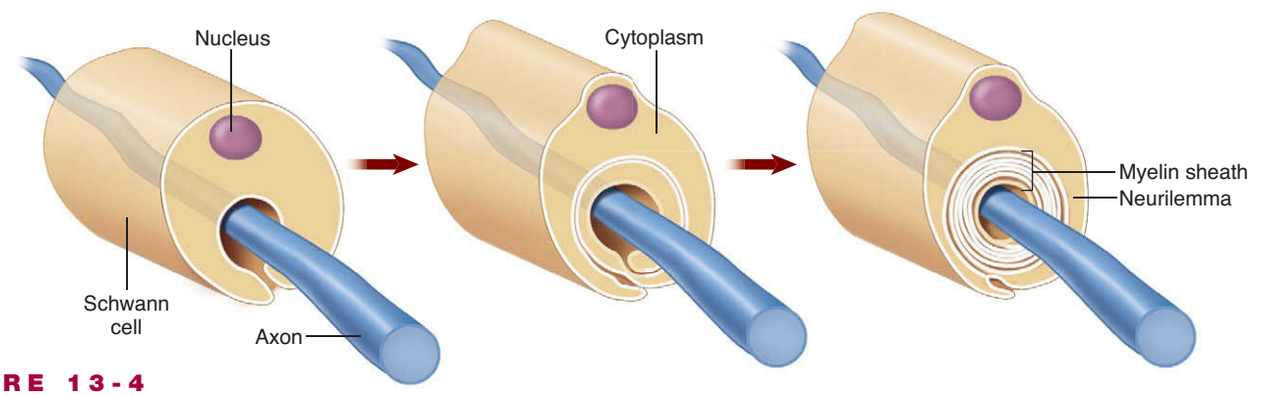


FIGURE 13-4

Development of the myelin sheath. A Schwann cell (neurolemmocyte) migrates to a neuron and wraps around an axon. The Schwann cell's cytoplasm is pushed to the outer layer, leaving a dense multilayered covering of plasma membrane around the axon. Because the plasma membrane of the Schwann cell is mostly the phospholipid myelin, the dense wrapping around the axon is called a *myelin sheath.* The outer layer of cytoplasm is called the *neurilemma.* The extensions of oligodendrocytes also wrap around axons to form a myelin sheath.

nucleus and cytoplasm are squeezed to the perimeter to form the **neurilemma.** The neurilemma is essential to normal nerve growth and the regeneration of injured nerve fibers. Schwann cells are also called *neurolemmocytes.* The myelin sheath along with the neurilemma is sometimes called the *neuronal sheath.*

Figure 13-3, *E,* shows that some Schwann cells do not wrap around nerve fibers to form a thick myelin sheath but simply hold fibers together in a bundle. Nerve fibers with many Schwann cells forming a thick myelin sheath are called **myelinated fibers,** or *white fibers.* When several nerve fibers are held by a single Schwann cell that does not wrap around them to form a thick myelin sheath, the fibers are called *unmyelinated fibers,* or *gray fibers.*

Figure 13-3, *G,* shows a type of Schwann cell often called a **satellite cell.** Like satellites positioned around a planet, these special Schwann cells surround the cell body of a neuron. Satellite cells support neuronal cell bodies in regions called *ganglia* in the peripheral nervous system.

6. What is a neurilemma?
7. Describe the three different forms of Schwann cells.

Neurons

The human brain is estimated to contain almost 100 billion neurons, or about half of the total number of nervous system cells in the brain. All neurons consist of a **cell body** (also called the **perikaryon,** or *soma*) and at least two processes: one **axon** and one or more **dendrites** (Figure 13-5). Because dendrites and axons are thread-like extensions from a neuron's cell body, they are often called **nerve fibers.**

In many respects the cell body, the largest part of a nerve cell, resembles other cells. It contains a nucleus, cytoplasm, and various organelles found in other cells, for example, mitochondria and a Golgi apparatus. The location of the nucleus in the cell body not only makes it easy to find in a microscopic specimen but also provides the name *perikaryon* (literally, "surrounding the nucleus"). A neuron's cytoplasm extends through its cell body and its processes. A plasma membrane encloses the entire neuron.

In the cell body, rough endoplasmic reticulum (ER) and its attached ribosomes provide protein molecules for the neuron. Some of these proteins are then processed and packaged into vesicles by the Golgi apparatus. Some protein molecules in these vesicles are needed for the transmission of nerve signals from one neuron to another. Such proteins are called **neurotransmitters.** Other proteins are used in the maintenance and repair of the neuron.

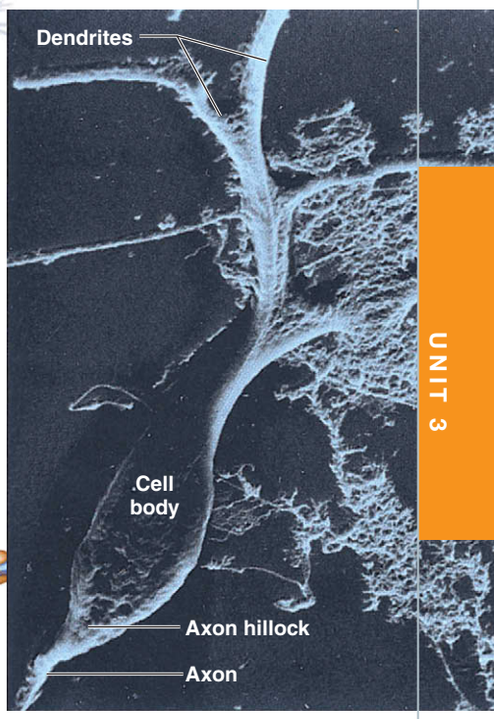

FIGURE 13-5

Structure of a typical neuron. The inset is a scanning electron micrograph of a neuron.

The cell body also contains many mitochondria, which replicate themselves in the cell body. Some of the resulting mitochondria are transported to the end of the axon to provide energy (adenosine triphosphate [ATP]) for nerve signaling there.

Dendrites usually branch extensively from the cell body—like tiny trees. In fact, their name derives from the Greek word for *tree.* The distal ends of dendrites of sensory neurons may be called *receptors* because they receive the stimuli that initiate nerve signals. Some dendrites in the brain have small knoblike *dendritic spines,* which serve as connection points for other neurons. Dendrites receive stimuli and conduct electrical signals toward the cell body and/or axon of the neuron.

The axon of a neuron is a single process that usually extends from a tapered portion of the cell body called the **axon hillock.** Axons conduct impulses away from the cell body. Although a neuron has only one axon, that axon often has one or more side branches, called *axon collaterals.* Moreover, the distal tips of axons form branches called **telodendria** that each terminate in a **synaptic knob** (see Figure 13-5). Each synaptic knob contains mitochondria and numerous vesicles.

Some axons have *varicosities*, or swellings, which act as points of contact with other cells such as smooth muscle fibers (see Figure 12-31 on p. 371). Axons vary in both length and diameter. Some are a meter long. Some, however, measure only a few millimeters. Axon diameters also vary considerably, from about 20 µm down to about 1 µm—a point of interest because axon diameter relates to velocity of impulse conduction. In general, the larger the diameter, the more rapid the conduction.

Whether an axon is myelinated or not also affects the speed of impulse conduction. Figure 13-6 shows a cross section of a typical myelinated axon. Notice in the figure how a series of Schwann cells have grown over the axon in a spiral fashion to form the myelin sheath and neurilemma (see also Figure 13-4). Only axons may have a myelin sheath—dendrites do not. The role of the myelin sheath and nodes of Ranvier in impulse conduction is discussed later.

Extending through the cytoplasm of each neuron are fine strands sometimes called **neurofibrils** (see Figure 13-6). Neurofibrils are bundles of intermediate filaments called *neurofilaments.* Microtubules and microfilaments are additional components of the neuron's cytoskeleton. Along with providing structural support, a neuron's cytoskeleton forms a sort of "railway" for the rapid transport of small organelles to and from the far ends of a neuron. Figure 13-7 shows how small "motor molecules" attach to mitochondria and vesicles containing neurotransmitters and carry them to the end of the axon. The "used" vesicles and transmitters are then returned to the cell body by the same process, but in reverse, for recycling. This type of movement is called **axonal transport.**

Figure 13-8 summarizes the different functional regions of the neurons, based on their role in receiving and conducting nerve signals. The dendrites and cell body act primarily as an *input zone*, receiving nerve stimulation and initiating nerve

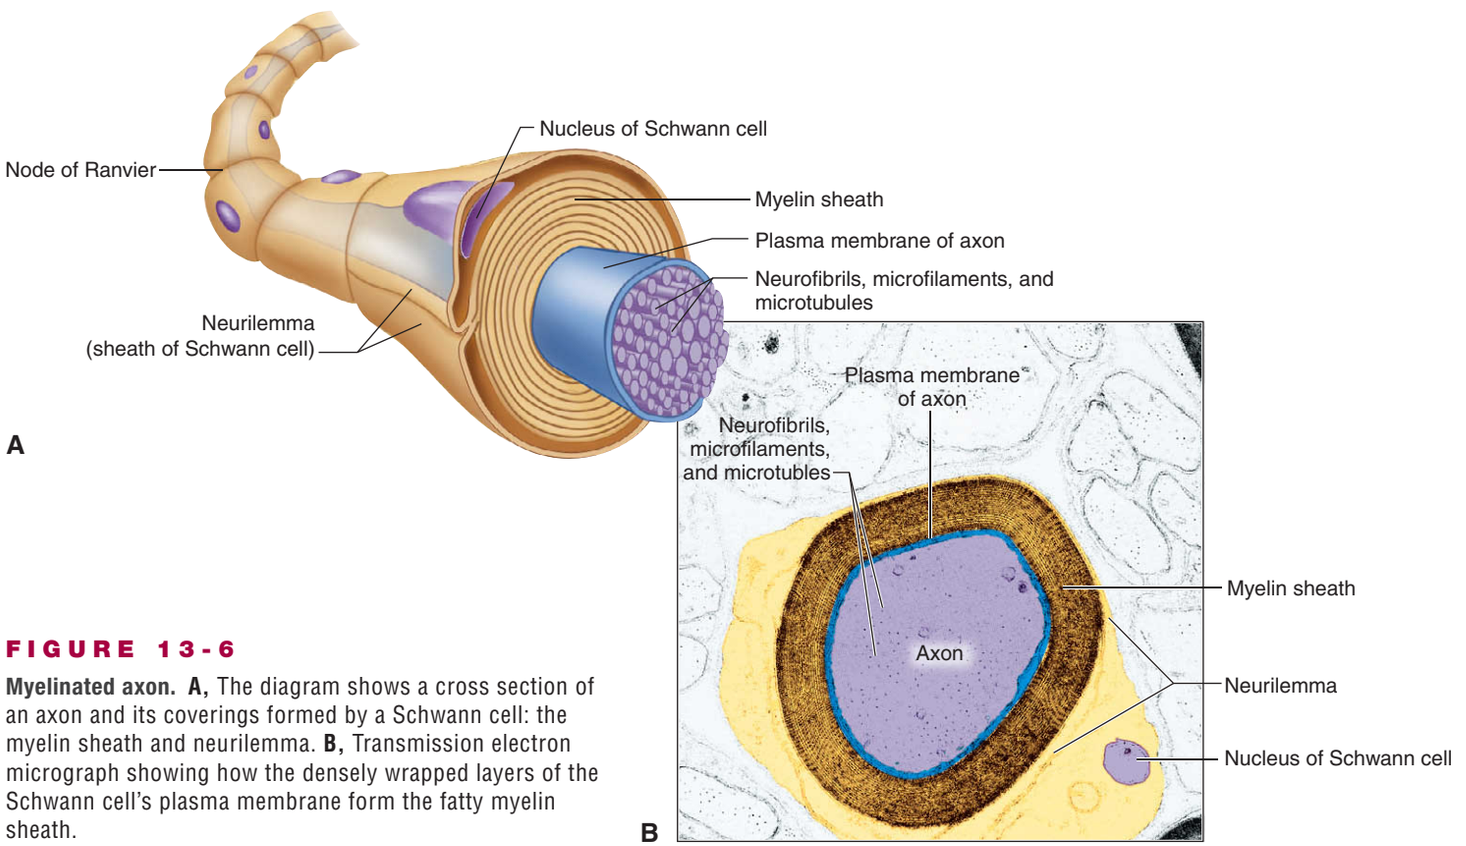

FIGURE 13-6

Myelinated axon. A, The diagram shows a cross section of an axon and its coverings formed by a Schwann cell: the myelin sheath and neurilemma. **B,** Transmission electron micrograph showing how the densely wrapped layers of the Schwann cell's plasma membrane form the fatty myelin sheath.

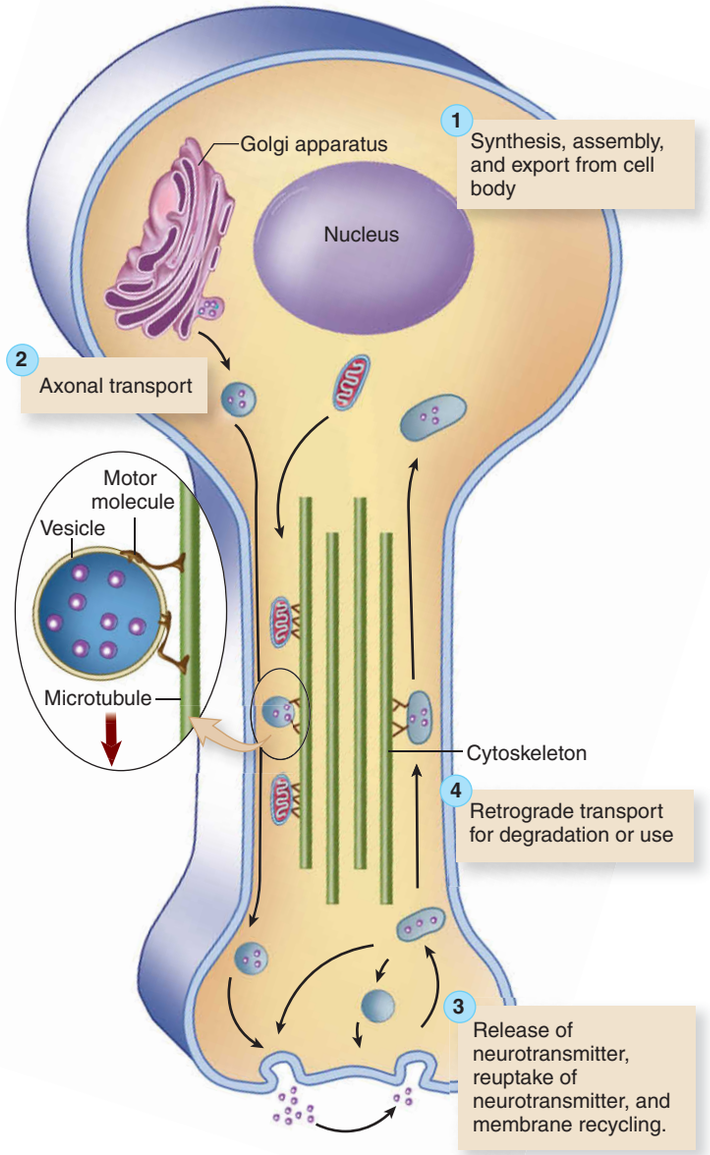

FIGURE 13-7

Axonal transport. Various cellular materials such as mitochondria and vesicles containing neurotransmitter can be shuttled quickly and efficiently from their point of origin in the soma (perikaryon) all the way to the end of the axon by using the neuron's cytoskeleton as a kind of railway system. The inset shows how motor molecules "walk" the material along a microtubule in the axon. The system also permits reverse transport, such as bringing the membranes of spent neurotransmitter vesicles back up to the soma.

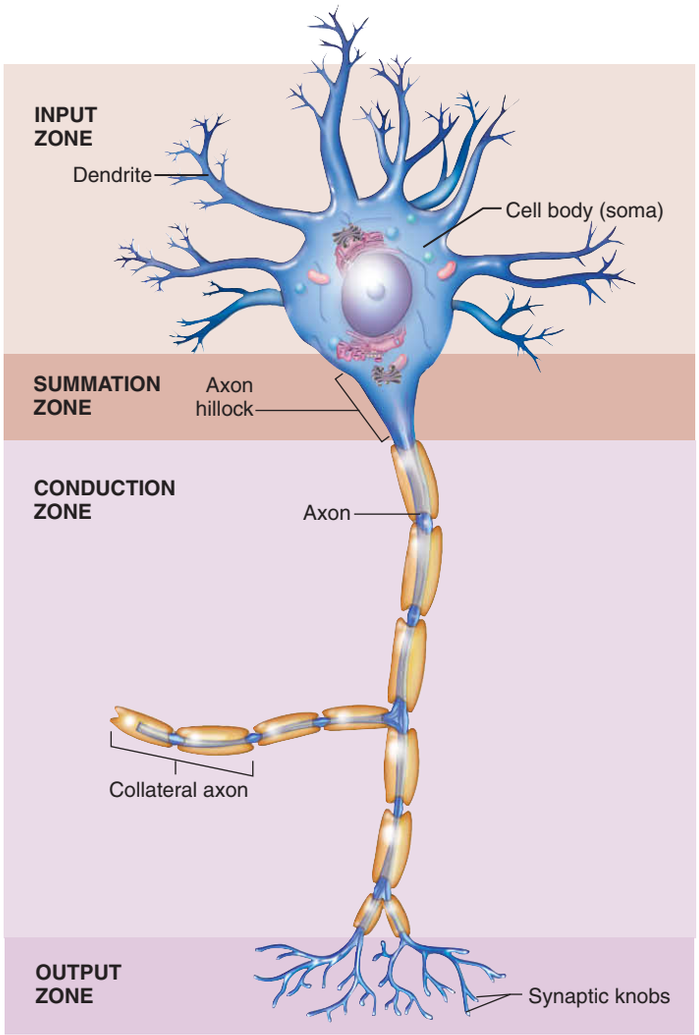

FIGURE 13-8

Functional regions of the neuron's plasma membrane. The *input zone* (dendrites and soma) receives input from other neurons or from sensory stimuli (stimulus-gated ion channels present). The *summation zone* (axon hillock) serves as the site where the nerve impulses combine and possibly trigger an impulse that will be conducted along the axon—or *conduction zone.* Both the summation (trigger) zone and conduction zone have many voltage-gated Na^+ channels and K^+ channels imbedded in the plasma membrane. The *output zone* (distal end of axon) is where the nerve impulse triggers the release of neurotransmitters. The output zone includes many voltage-gated Ca^{++} channels in the membrane.

impulses in response. The axon hillock acts as a *summation zone* by adding together all the nerve impulses arriving from the cell body and dendrites—and deciding whether to send the impulse any farther along the neuron. The axon is the *conduction zone* because its primary job is to conduct the nerve impulse from the axon hillock all the way to the end of the neuron. The telodendria of the axon, along with their synaptic knobs, together act as an *output zone* where vesicles of neurotransmitter are released for possible reception by a nearby neuron or effector cell (muscle or gland cell).

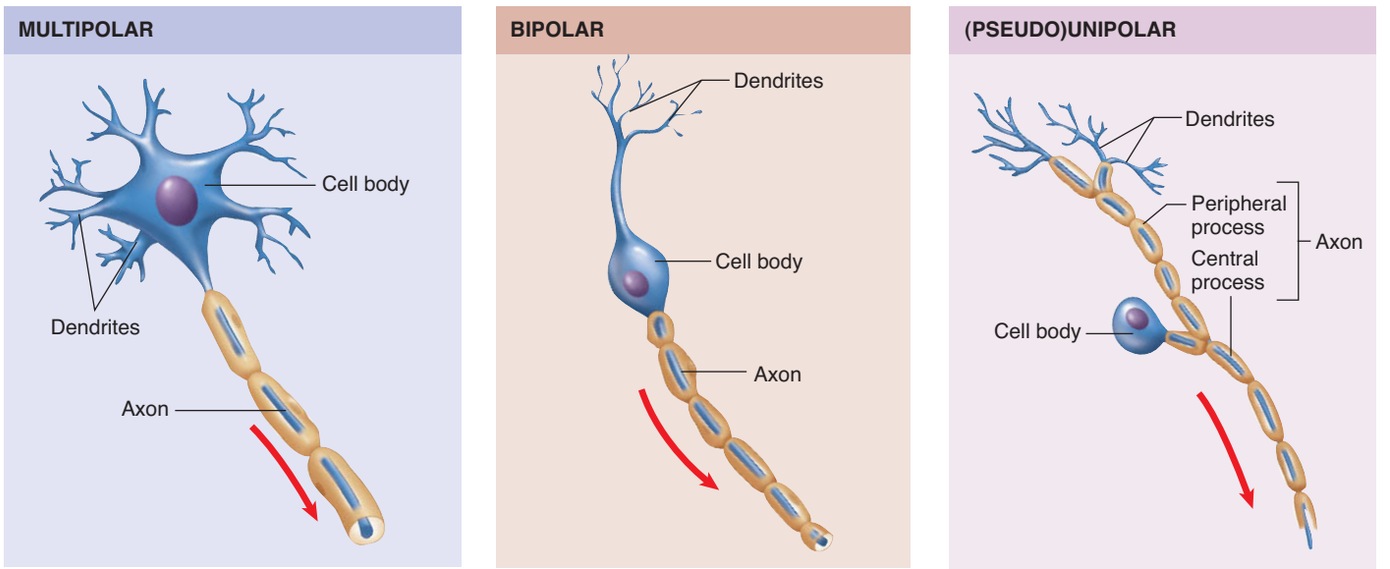

FIGURE 13-9

Structural classification of neurons. A, Multipolar neuron: neuron with multiple extensions from the cell body. **B,** Bipolar neuron: neuron with exactly two extensions from the cell body. **C,** (Pseudo) unipolar neuron: neuron with only one extension from the cell body. The central process is an axon; the peripheral process is a modified axon with branched dendrites at its extremity. (The *red arrows* show the direction of impulse travel.)

Classification of Neurons

STRUCTURAL CLASSIFICATION

The three types of neurons classified according to the number of their extensions from the cell body (Figure 13-9) are as follows:

1. Multipolar
2. Bipolar
3. Unipolar

Multipolar neurons have only one axon but several dendrites. Most of the neurons in the brain and spinal cord are multipolar. **Bipolar neurons** have only one axon and also only one highly branched dendrite. Bipolar neurons are the least numerous kind of neuron. They are found in the retina of the eye, in the inner ear, and in the olfactory pathway. **Unipolar (pseudounipolar) neurons** have a single process extending from the cell body. This single process branches to form a central process (toward the CNS) and a peripheral process (away from the CNS). These two processes together form an axon, conducting impulses away from the dendrites found at the distal end of the peripheral process. Unipolar neurons are always sensory neurons, conducting information toward the central nervous system.

FUNCTIONAL CLASSIFICATION

The three types of neurons classified according to the direction in which they conduct impulses are as follows:

1. Afferent neurons
2. Efferent neurons
3. Interneurons

Figure 13-10 shows one neuron of each of these types. **Afferent (sensory) neurons** transmit nerve impulses to the spinal cord or brain. **Efferent (motor) neurons** transmit nerve impulses away from the brain or spinal cord to or toward muscles or glands. **Interneurons** conduct impulses from afferent neurons to or toward motor neurons. Interneurons lie entirely within the central nervous system (brain and spinal cord).

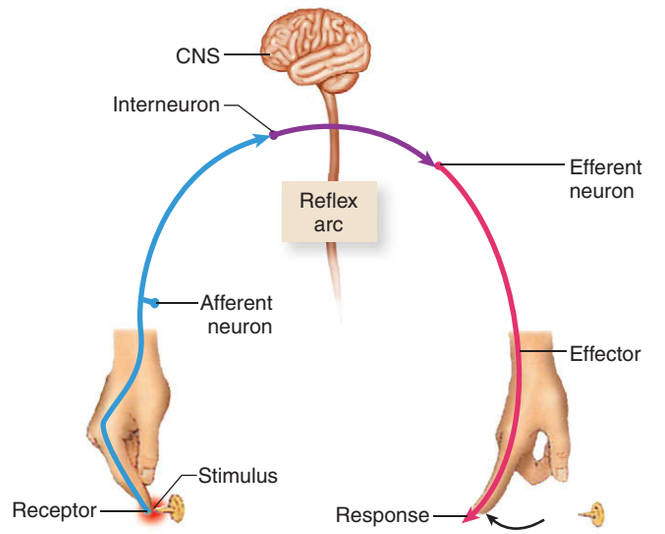

FIGURE 13-10

Functional classification of neurons in a reflex arc. Neurons can be classified according to the direction in which they conduct impulses. Notice that the most basic route of signal conduction follows a pattern called the *reflex arc.*

Reflex Arc

Notice in Figure 13-10 that neurons are often arranged in a pattern called a **reflex arc.** Basically, a reflex arc is a signal conduction route to and from the central nervous system (the brain and spinal cord). The most common form of reflex arc is the three-neuron arc (Figure 13-11, *A*). It consists of an afferent neuron, an interneuron, and an efferent neuron. Afferent, or sensory, neurons conduct signals to the central nervous system from *sensory receptors* in the peripheral nervous system. Efferent neurons, or *motor neurons*, conduct signals from the central nervous system to effectors. An effector is muscle tissue or glandular tissue. Interneurons conduct signals from afferent neurons toward or to motor neurons. In its simplest form, a reflex arc consists of an afferent neuron and an efferent neuron; this is called a *two-neuron arc.* In essence, a reflex arc is a signal conduction route from receptors to the central nervous system and out to effectors. By now you should recognize that the reflex arc is an example of the information pathway described in Chapter 1 as a regulatory *feedback loop.* To confirm this point, compare the reflex arc (see Figure 13-10) with the feedback loop illustrated in Figure 1-13, *B*, p. 22.

Now look again at Figure 13-11, *A.* Note the two labels for synapse. A **synapse** is the place where nerve information is transmitted from one neuron to another. Synapses are located between the synaptic knobs on one neuron and the dendrites or cell body of another neuron. For example, in Figure 13-11, *A*, the first synapse lies between the sensory neuron's synaptic knobs and the interneuron's dendrites. The second synapse lies between the interneuron's synaptic knobs and the motor neuron's dendrites. This reflex arc is called an *ipsilateral reflex arc* because the receptors and effectors are located on the same side of the body. Figure 13-11, *B*, shows a *contralateral reflex arc*, one whose receptors and effectors are located on opposite sides of the body.

Besides simple two-neuron and three-neuron arcs, *intersegmental arcs* (Figure 13-11, *C*)—even more complex multineuron, multisynaptic arcs—also exist. An important principle is this: all electrical signals that start in receptors do not invariably travel over a complete reflex arc and terminate in effectors. Many signals fail to be conducted across synapses. Moreover, all signals that terminate in effectors do not invariably start in receptors. Many of them, for example, are thought to originate in the brain.

| QUICK CHECK |

8. What is the difference between an axon and a dendrite?
9. What are the three structural categories of neurons?
10. What are the three main functional categories of neurons?
11. What are the essential components of a reflex arc?

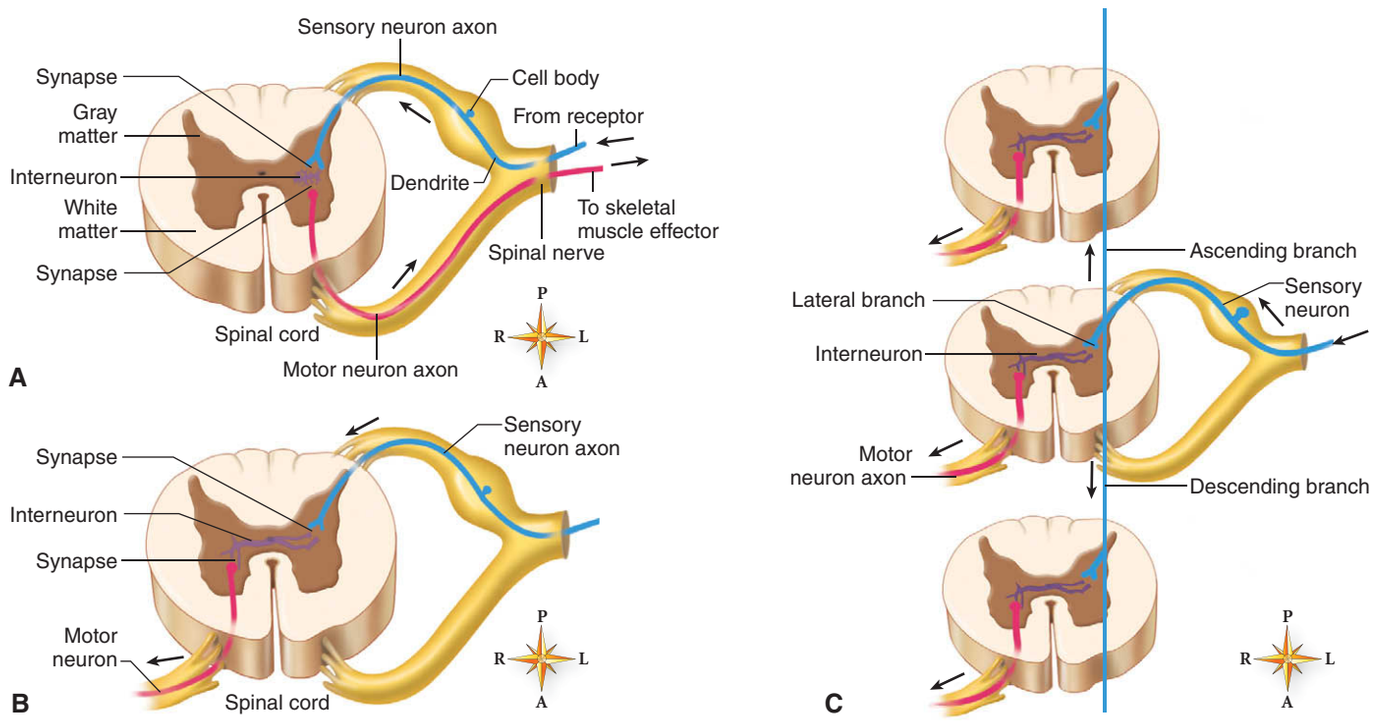

FIGURE 13-11

Examples of reflex arcs. A, Three-neuron ipsilateral reflex arc. Sensory information enters the central nervous system (CNS) and motor information leaves the CNS on the same side. **B,** Three-neuron contralateral reflex arc. Sensory information enters on the side of the CNS that is opposite from the side where motor information exits the CNS. **C,** Intersegmental contralateral reflex arc. Divergent branches of a sensory neuron bring information to several segments of the CNS at the same time. Motor information leaves each segment on the opposite side of the CNS.

NERVES AND TRACTS

Nerves are bundles of peripheral nerve fibers held together by several layers of connective tissues (Figure 13-12). Surrounding each nerve fiber is a delicate layer of fibrous connective tissue called the **endoneurium.** Bundles of fibers (each with its own endoneurium), called *fascicles*, are held together by a connective tissue layer called the **perineurium.** Numerous fascicles, along with the blood vessels that supply them, are held together to form a complete nerve by a fibrous coat called the **epineurium.** As you can see in Figure 13-2, the epineurium has a superficial part that surrounds the whole nerve and a deep part that extends between the fascicles. The deep epineurium is made up of wavy collagen bundles along with adipose tissue and blood vessels.

Within the central nervous system, however, bundles of nerve fibers are called **tracts** rather than nerves. Unlike nerves, tracts do not have connective tissue coverings. Individual nerve fibers that originate in the peripheral nervous system and pass through a nerve may continue into the spinal cord or brain as part of a tract. Likewise, an individual nerve fiber that originates in the brain or spinal cord and passes through a tract may continue into the peripheral nervous system within a nerve.

The creamy white color of myelin distinguishes bundles of myelinated fibers from surrounding unmyelinated tissues, which appear darker in comparison. Bundles of myelinated fibers make up the so-called **white matter,** or *white substance*, of the nervous system. In the peripheral nervous system, white matter consists of myelinated nerves; in the central nervous system, white matter consists of myelinated tracts.

Cell bodies and unmyelinated fibers make up the darker **gray matter,** or *gray substance*, of the nervous system. Small, distinct regions of gray matter within the central nervous system are usually called *nuclei*. In peripheral nerves, similar regions of gray matter are more often called *ganglia*.

Most nerves in the human nervous system are *mixed nerves*. That is, they contain both sensory (afferent) and motor (efferent) fibers. Nerves that contain predominantly afferent fibers are often called *sensory nerves*. Likewise, nerves that contain mostly efferent fibers are called *motor nerves*.

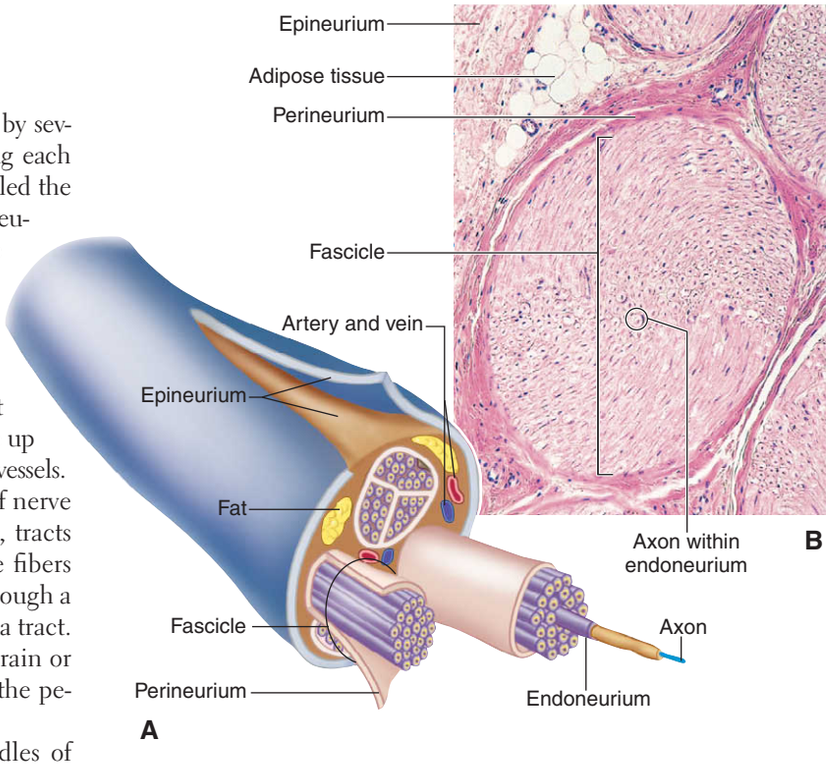

FIGURE 13-12

The nerve. A, Each nerve contains axons bundled into fascicles. A fibrous endoneurium surrounds each axon and its Schwann cells within a fascicle. A perineurium surrounds each fascicle. A connective tissue epineurium wraps the entire nerve. The superficial epineurium is shown in blue and the deep epineurium (collagen fibers, adipose tissue, and blood vessels) is shown in brown. **B,** A light micrograph of a cross section of a nerve.

REPAIR OF NERVE FIBERS

For a long time, neuroscientists believed that mature neurons could not be replaced—and therefore nervous tissue had severe limitations to self-healing of damage. Evidence now clearly shows that neurons are in fact replaced. In fact, fresh new neurons are often added to the existing network. As we learn more about this process, neuroscientists hope to understand the details of these mechanisms and develop therapies to prevent and treat nerve damage or degeneration.

Another option in the body for healing injured or diseased nervous tissue is repairing the neurons that are already present. Unfortunately, neurons have a somewhat limited capacity to repair themselves. Nerve fibers can sometimes be repaired if the damage is not extensive, when the cell body and neurilemma remain intact, and when scarring has not occurred. Figure 13-13 shows the stages of the healing process in the axon of a peripheral motor neuron.

Immediately after the injury occurs, the distal portion of the axon degenerates, as does its myelin sheath. Macrophages then move into the area and remove the debris. The remaining neurilemma and endoneurium form a pathway or tunnel from the point of injury to the effector. New Schwann cells grow within this tunnel, maintaining a path for regrowth of the axon.

Meanwhile, the cell body of the damaged neuron has reorganized its ribosomes (sometimes called Nissl bodies, or *Nissl substance*) to provide the proteins necessary to extend the remaining healthy portion of the axon. Several growing axon "sprouts" appear. When one of these growing fibers reaches the tunnel, it increases its growth rate—growing as much as 3 to 5 mm per day. If all goes well, the neuron's connection with the effector is quickly reestablished.

Notice in Figure 13-13 that the skeletal muscle cell supplied by the damaged neuron atrophies during the absence of nervous input. Only after the nervous connection is reestablished and stimulation resumed does the muscle cell grow back to its original size. If the damaged axon fails to repair itself, a nearby, undamaged axon from an adjacent neuron may form a sprout that reaches the effector cell and thus reestablishes a connection with the nervous system.

If the damaged nerve is connected to another nerve, the receiving nerve may also wither and die. In fact, because the preceding neuron may now have no functioning neuron to send a signal to, it may wither as well. In short, damage to a single axon can shut down an entire nerve pathway if not repaired—and repaired quickly.

In the central nervous system, similar repair of damaged nerve fibers is very unlikely. First of all, neurons in the central nervous system lack the neurilemma needed to form the guiding tunnel from the point of injury to the distal connection. Second, astrocytes quickly fill

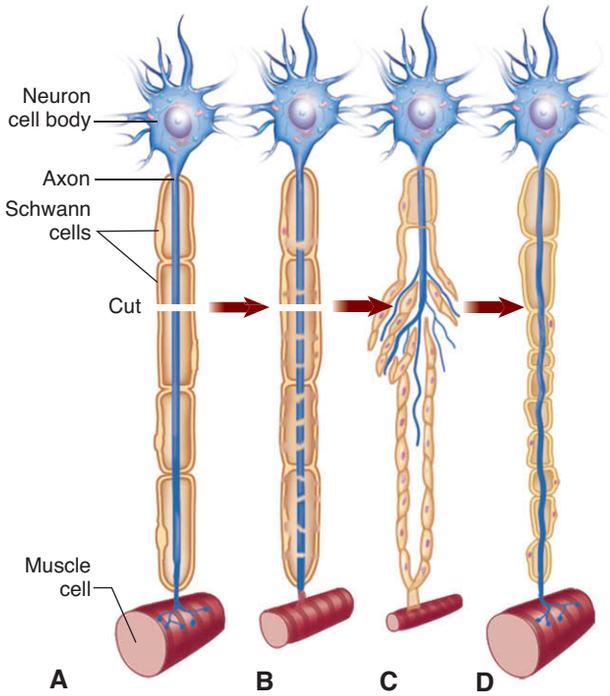

FIGURE 13-13

Repair of a peripheral nerve fiber. A, An injury results in a cut nerve. **B,** Immediately after the injury occurs, the distal portion of the axon degenerates, as does its myelin sheath. **C,** The remaining neurilemma tunnels from the point of injury to the effector. New Schwann cells grow within this tunnel, maintaining a path for regrowth of the axon. Meanwhile, several growing axon "sprouts" appear. When one of these growing fibers reaches the tunnel, it increases its growth rate—growing as much as 3 to 5 mm per day. (The other sprouts eventually disappear.) **D,** The neuron's connection with the effector is reestablished.

damaged areas and thus block regrowth of the axon with scar tissue. Despite great strides made by researchers looking for ways to stimulate the repair of neurons in the central nervous system, most injuries to the brain and spinal cord cause permanent damage (Box 13-3).

| QUICK CHECK |

12. What are the three layers of connective tissues that hold the fibers of a nerve together?
13. What is the difference between a nerve and a tract?
14. How does white matter differ from gray matter?
15. Under what circumstances can a nerve fiber be repaired?

Box 13-3 | Neuroglobin

Neuroglobin (Ngb) is a protein molecule very similar to the oxygen-binding proteins *hemoglobin (Hb)* in red blood cells (see Chapters 20 and 27) and *myoglobin* in muscle fibers (see Chapter 12). As the myoglobin in muscle fibers, neuroglobin temporarily stores a "backup" supply of oxygen for times when oxygen availability is low. In brain tissues, such a circumstance may occur during a stroke, or *cerebrovascular accident (CVA),* when the blood supply to the brain is disrupted. It could also occur during respiratory accidents, such as suffocation. Until normal blood flow is restored, neuroglobin can supply oxygen to the cell for a short time.

NERVE IMPULSES

Neurons are remarkable among cells because they initiate and conduct signals called *nerve impulses.* Expressed differently, neurons exhibit both *excitability* and *conductivity.* What exactly is a nerve impulse? How is a neuron able to conduct this signal along its entire length—sometimes a full meter? These questions, and more, are answered in the paragraphs that follow.

Membrane Potentials

One way to describe a nerve impulse is as a wave of electrical fluctuation that travels along the plasma membrane. To understand this phenomenon more fully, however, requires some familiarity with the electrical nature of the plasma membrane.

All living cells, including neurons, maintain a difference in the concentration of ions across their membranes. There is a slight excess of positive ions on the outside of the membrane and a slight excess of negative ions on the inside of the membrane. This, of course, results in a difference in electrical charge across their plasma membranes called the **membrane potential.** This difference in electrical charge is called a *potential* because it is a type of stored energy called *potential energy.* Whenever opposite electrical charges (in this case, opposite ions) are thus separated by a membrane, they have the potential to move toward one another if they are allowed to cross the membrane. When a membrane potential is maintained by a cell, opposite ions are held on opposite sides of the membrane like water behind a dam—ready to rush through with force when the proper membrane channels open.

A membrane that exhibits a membrane potential is said to be *polarized.* That is, its membrane has a negative pole (the side on which there is an excess of negative ions) and a positive pole (the side on which there is an excess of positive ions). The magnitude of potential difference between the two sides of a polarized membrane is measured in volts (V) or millivolts (mV). The voltage across a membrane can be measured by a device called a *voltmeter,* which is shown in Figure 13-14. The sign of a membrane's voltage indicates the charge on the inside surface of a polarized membrane. For example, the value –70 mV indicates that the potential difference has a magnitude of 70 mV and that the inside of the membrane is negative with respect to the outside surface (see Figure 13-14). A value of +30 mV indicates a

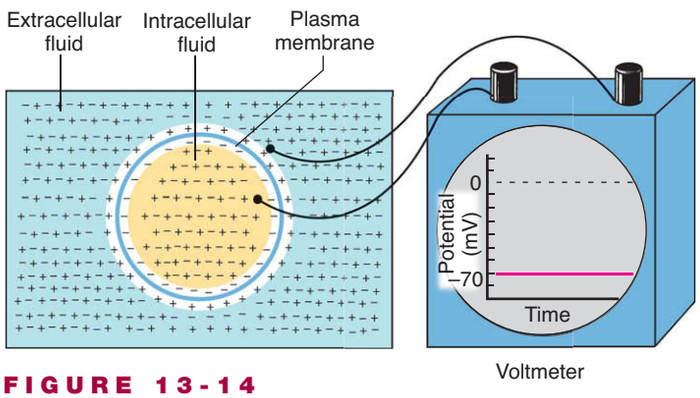

FIGURE 13-14

Membrane potential. The diagram on the left represents a cell maintaining a very slight difference in the concentration of oppositely charged ions across its plasma membrane. The voltmeter records the magnitude of electrical difference over time, which, in this case, does not fluctuate from –70 mV (voltage recorded over time as a red line).

potential difference of 30 mV and that the inside of the membrane is positive (and thus the outside of the membrane is negative).

To understand the electrical activity of the neuron—which is an essential concept of neurobiology—we will need to understand the different membrane potentials that occur in different circumstances in the plasma membrane of a neuron.

Resting Membrane Potentials

When a neuron is not conducting electrical signals, it is said to be "resting." At rest, a neuron's membrane potential is typically maintained at about –70 mV (see Figure 13-14). The membrane potential maintained by a nonconducting neuron's plasma membrane is called the **resting membrane potential (RMP).** Although the RMP can vary somewhat, we will use –70 mV as our typical value for the sake of discussion.

The mechanisms that produce and maintain the RMP do so by promoting a slight ionic imbalance across the neuron's plasma membrane. Specifically, these mechanisms produce a slight excess of positive ions on its outer surface. This imbalance of ion concentrations is produced primarily by ion transport mechanisms in the neuron's plasma membrane.

Recall from Chapters 3 and 4 that the permeability characteristics of each cell's plasma membrane are determined in part by the presence of specific membrane transport channels. Many of these channels are *gated channels*, allowing specific molecules to diffuse across the membrane only when the "gate" of each channel is open (see Figure 4-6 on p. 95).

In the neuron's plasma membrane, channels for the transport of the major anions (negative particles) are either nonexistent or closed. For example, there are no channels to allow the exit of the large anionic protein molecules that dominate the intracellular fluid. Chloride ions (Cl^-), the dominant extracellular anions, are likewise "trapped" on one side of the membrane because chloride ions are repelled by the protein anions inside the cell. This means that the only ions that can move efficiently across a neuron's membrane are the positive ions sodium and potassium.

In a resting neuron, some of the potassium channels are open, but most of the sodium channels are closed (Figure 13-15). This means that potassium ions pumped into the neuron can diffuse back out of the cell in an attempt to equalize its concentration gradient, but very little of the sodium pumped out of the cell can diffuse back into the neuron (Figure 13-16). Thus the membrane's selective permeability characteristics create and maintain a slight excess of positive ions on the outer surface of the membrane.

Another mechanism also operates to maintain the RMP. The sodium-potassium pump is an active transport mechanism in the plasma membrane that transports sodium ions (Na^+) and potassium ions (K^+) in opposite directions and at different rates (see Figure 13-16). It moves three sodium ions out of a neuron for every two potassium ions it moves into it. If, for instance, the pump transports 100 potassium ions into a neuron from the extracellular fluid, it concurrently transports 150 sodium ions out of the cell. The sodium-potassium pump thus maintains an imbalance in the distribution of positive ions, maintaining a difference in electrical charge across the membrane. As this pump operates, the inside surface of the membrane becomes slightly less positive—that is, slightly negative—with respect to its outer surface.

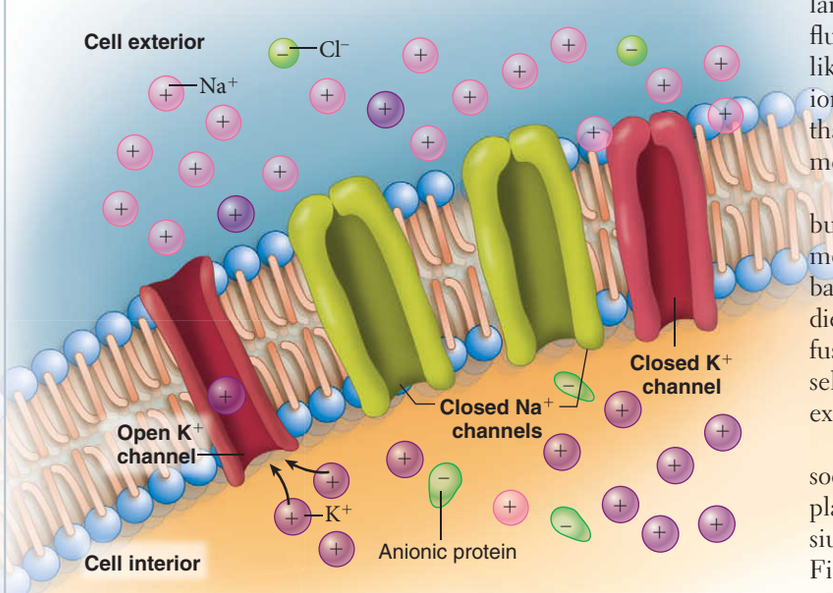

FIGURE 13-15

Role of ion channels in maintaining the resting membrane potential (RMP). Some K^+ channels are open in a "resting" membrane, allowing K^+ to diffuse down its concentration gradient (out of the cell) and thus add to the excess of positive ions on the outer surface of the plasma membrane. Diffusion of Na^+ in the opposite direction would counteract this effect but is prevented from doing so by closed Na^+ channels. Compare this figure with Figure 13-16.

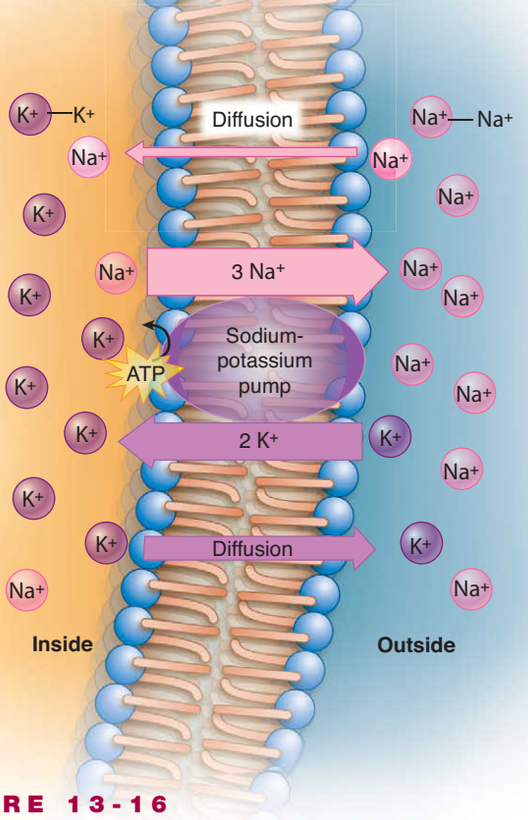

FIGURE 13-16

Sodium-potassium pump. This mechanism in the plasma membrane actively pumps sodium ions (Na^+) out of the neuron and potassium ions (K^+) into the neuron—at an unequal (3:2) rate. Because very little sodium reenters the cell via diffusion, this maintains an imbalance in the distribution of ions and thus maintains the resting potential. (See Figure 13-15 for the role of ion channels in the diffusion of ions.)

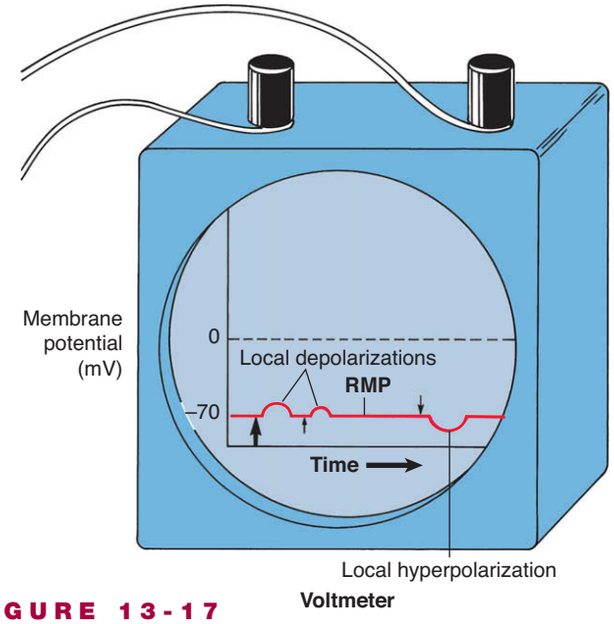

FIGURE 13-17

Local potentials. Recording voltmeter shows that excitatory stimuli (↑) cause depolarizations (movements toward 0 mV) in proportion to the strength of the stimuli. Inhibitory stimuli (↓) cause hyperpolarizations, local deviations away from 0 mV that cause the membrane potential to dip below the level of the resting membrane potential (RMP). Voltage is recorded as a red line on the screen of the voltmeter. Upward deviations of the red line are depolarizations; downward deviations of the red line are hyperpolarizations.

The RMP can be maintained by a cell as long as its sodium-potassium pumps continue to operate and its permeability characteristics remain stable. If either of these mechanisms is altered, the RMP is altered as well.

Local Potentials

In neurons, membrane potentials can fluctuate above or below the resting membrane potential in response to certain stimuli (Figure 13-17). A slight shift away from the RMP in a specific region of the plasma membrane is often called a **local potential.**

Excitation of a neuron occurs when a stimulus triggers the opening of stimulus-gated Na^+ channels. **Stimulus-gated channels** are ion channels that open in response to a sensory stimulus or a chemical stimulus from another neuron. Many stimulus-gated channels are located in the membrane of the neuron's input zone—the dendrites and soma (see Figure 13-8). The opening of stimulus-gated Na^+ channels in response to a stimulus permits more Na^+ to enter the cell. As the excess of positive ions outside the plasma membrane decreases, the magnitude of the membrane potential is reduced. Such movement of the membrane potential toward zero is called **depolarization.** In *inhibition*, a stimulus triggers the opening of stimulus-gated K^+ channels. As more K^+ diffuses out of the cell, the excess of positive ions outside the plasma membranes increases—increasing the magnitude of the membrane potential. Movement of the membrane potential away from zero (thus below the usual RMP) is called **hyperpolarization.**

Local potentials are called *graded potentials* because the magnitude of deviation from the RMP is proportional to the magnitude of the stimulus. In short, local potentials can be large or small—they are not all-or-none events. Local potentials exhibit *decremental* conduction, which means that their magnitude decreases as they travel along a membrane. Local potentials are called "local" nerve signals because they are more or less isolated to a particular region of the plasma membrane. That is, local potentials do not spread all the way to the end of a neuron's axon.

16. What mechanisms are involved in producing the resting membrane potential?
17. In a resting neuron, what positive ion is most abundant outside the plasma membrane? What positive ion is most abundant inside the plasma membrane?
18. How does depolarization of a membrane differ from hyperpolarization?

ACTION POTENTIAL

An **action potential** is, as the term suggests, the membrane potential of an active neuron, that is, one that is conducting an impulse. A synonym commonly used for action potential is *nerve impulse.* The action potential is an electrical fluctuation that travels along the surface of a neuron's plasma membrane.

As with local potentials, understanding how action potentials are generated requires familiarity with gated ion channels. Table 13-1 summarizes the types and functions of gated channels for sodium and potassium that are important for understanding changes in membrane potential.

TABLE 13-1 Sodium and Potassium Channel Types and Functions

CHANNEL	EFFECT ON ION TRANSPORT*	EFFECT ON MEMBRANE POTENTIAL	TYPES	TRIGGER	RESPONSE
Sodium (Na^+) channels	Na^+ ions diffuse into cell	Increase (more positive)	Stimulus-gated	Sensory stimulus	Rapid response
				Chemical stimulus (neurotransmitter)	Rapid response
			Voltage-gated	Increase in membrane potential (to threshold potential [–59 mV] or beyond)	Rapid response
Potassium (K^+) channels	K^+ ions diffuse out of cell	Decrease (more negative)	Stimulus-gated	Sensory stimulus	Rapid response
				Chemical stimulus (neurotransmitter)	Rapid response
			Voltage-gated	Increase in membrane potential (to threshold potential [–59 mV] or beyond)	Slow response

*Net diffusion of ions down their respective concentration gradients.

TABLE 13-2 Steps of the Mechanism That Produces an Action Potential

STEP	DESCRIPTION
1	A stimulus triggers stimulus-gated Na^+ channels to open and allow inward Na^+ diffusion. This causes the membrane to depolarize.
2	As the threshold potential is reached, voltage-gated Na^+ channels open.
3	As more Na^+ enters the cell through voltage-gated Na^+ channels, the membrane depolarizes even further.
4	The magnitude of the action potential peaks (at +30 mV) when voltage-gated Na^+ channels close.
5	Repolarization begins when voltage-gated K^+ channels open, allowing outward diffusion of K^+.
6	After a brief period of hyperpolarization, the resting potential is restored by the sodium-potassium pump and the return of ion channels to their resting state.

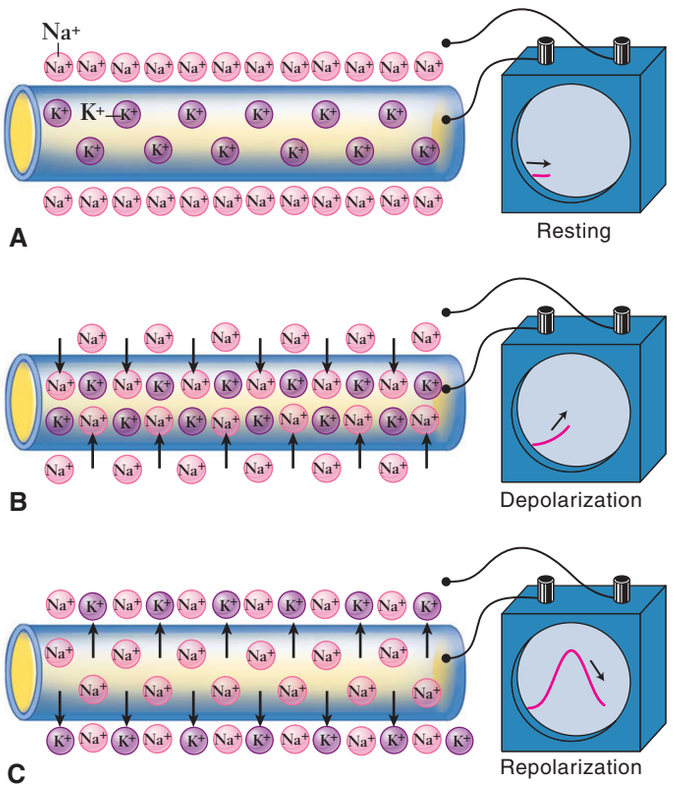

FIGURE 13-18

Depolarization and repolarization. A, Resting membrane potential (RMP) results from an excess of positive ions on the outer surface of the plasma membrane. More Na^+ ions are on the outside of the membrane than K^+ ions are on the inside of the membrane. **B,** Depolarization of a membrane occurs when Na^+ channels open, allowing Na^+ to move to an area of lower concentration (and more negative charge) *inside* the cell—reversing the polarity to an inside-positive state. **C,** Repolarization of a membrane occurs when K^+ channels then open, allowing K^+ to move to an area of lower concentration (and more negative charge) *outside* the cell—reversing the polarity back to an inside-negative state. Each voltmeter records the changing membrane potential as a red line.

A step-by-step description of the mechanism that produces the action potential is given in the following paragraphs and in Table 13-2. Refer to Figures 13-18 and 13-19 as you read each step.

1. When an adequate stimulus is applied to a neuron, the stimulus-gated Na^+ channels at the point of stimulation open. Na^+ diffuses rapidly into the cell because of the concentration gradient and electrical gradient, producing a local depolarization (see Figure 13-18, *B*).
2. If the magnitude of the local depolarization surpasses a limit called the **threshold potential** (for example, −59 mV), voltage-gated Na^+ channels are stimulated to open. **Voltage-gated channels** are ion channels that open in response to voltage fluctuations, usually at least −50 mV to −60 mV. There are many voltage-gated Na^+ channels and K^+ channels in the membrane of the neuron's summation zone (axon hillock) and conduction zone (axon) (see Figure 13-8). The threshold potential is the minimum magnitude a voltage fluctuation in the summation or conduction zone must have to trigger the opening of a voltage-gated ion channel.
3. As more Na^+ rushes into the cell, the membrane moves rapidly toward 0 mV and then continues in a positive direction to a peak of +30 mV (see Figure 13-19). The positive value at the peak of the action potential indicates that there is an excess of positive ions *inside* the membrane. If the local depolarization fails to cross the threshold of −59 mV, the voltage-gated Na^+ channels do not open, and the membrane simply recovers back to the resting potential of −70 mV without producing an action potential.
4. Voltage-gated Na^+ channels stay open for only about 1 millisecond (ms) before they automatically close. This means that once they are stimulated, the Na^+ channels always allow sodium to rush in for the same amount of time, which in turn

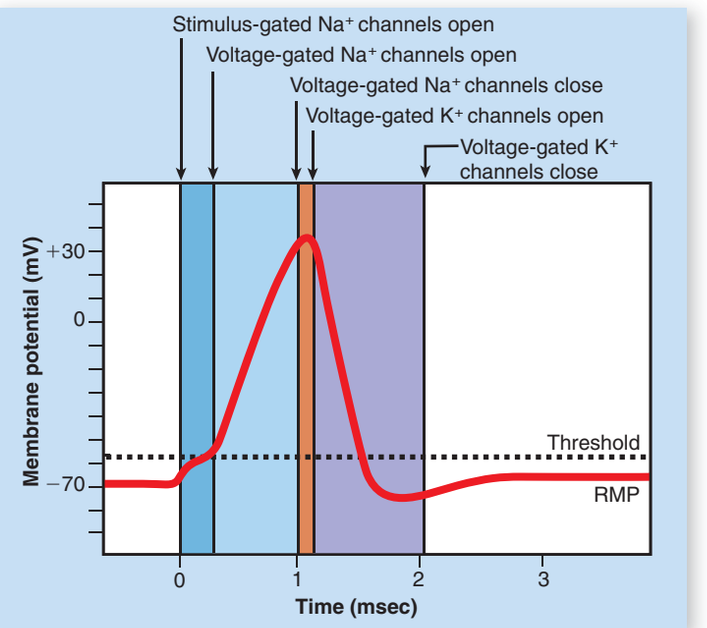

FIGURE 13-19

The action potential. Changes in membrane potential in a local area of a neuron's membrane result from changes in membrane permeability.

TABLE 13-3 Types of Membrane Potentials

MEMBRANE POTENTIAL	POLARIZATION	TYPICAL VOLTAGE*	SUMMATION	CONDUCTION	DESCRIPTION
Resting membrane potential (RMP)	Polarized	–70 mV	Not applicable	Not applicable	Membrane voltage when the neuron is not excited and not conducting an impulse
Local potential	Depolarized (excitatory; EPSP)	Graded; varies higher than –70 mV	Yes	Decremental	Temporary fluctuation in a local region of the membrane in response to a sensory or nerve stimulus; may be an upward or downward fluctuation in voltage; loses amplitude as it spreads along membrane
	Hyperpolarized (inhibitory; IPSP)	Graded; varies lower than –70 mV	Yes	Decremental	
Threshold potential	Depolarized	–59 mV	Yes	Triggers action potential	Minimum local depolarization needed to trigger voltage-gated channels that produce the action potential
Action potential	Depolarized	+30 mV	No	Nondecremental	Temporary maximum depolarization of membrane voltage that travels to end of axon without losing amplitude

*Example used in this chapter; actual values in body vary depending on many diverse factors.
EPSP, Excitatory postsynaptic potential; *IPSP,* inhibitory postsynaptic potential.

produces the same magnitude of action potential. In other words, the action potential is an *all-or-none* response. If the threshold potential is surpassed, the full peak of the action potential is always reached; if the threshold potential is not surpassed, no action potential will occur at all.

5. Once the peak of the action potential is reached, the membrane potential begins to move back toward the resting potential (–70 mV) in a process called **repolarization.** Surpassing the threshold potential triggers the opening of not only voltage-gated Na^+ channels but also voltage-gated K^+ channels. The voltage-gated K^+ channels are slow to respond, however, and thus do not begin opening until the inward diffusion of Na^+ ions has caused the membrane potential to reach +30 mV. Once the K^+ channels open, K^+ rapidly diffuses out of the cell because of the concentration gradient and because it is repulsed by the now-positive interior of the cell. The outward rush of K^+ restores the original excess of positive ions on the outside surface of the membrane—thus repolarizing the membrane (see Figure 13-18).
6. Because the K^+ channels often remain open as the membrane reaches its resting potential, too much K^+ may rush out of the cell. This causes a brief period of hyperpolarization before the resting potential is restored by the action of the sodium-potassium pump and the return of ion channels to their resting state.

Table 13-3 summarizes essential characteristics of the action potential along with other important types of membrane potentials discussed so far in this chapter.

Refractory Period

The refractory period is a brief period during which a local area of an axon's membrane resists restimulation (Figure 13-20, *A*). For

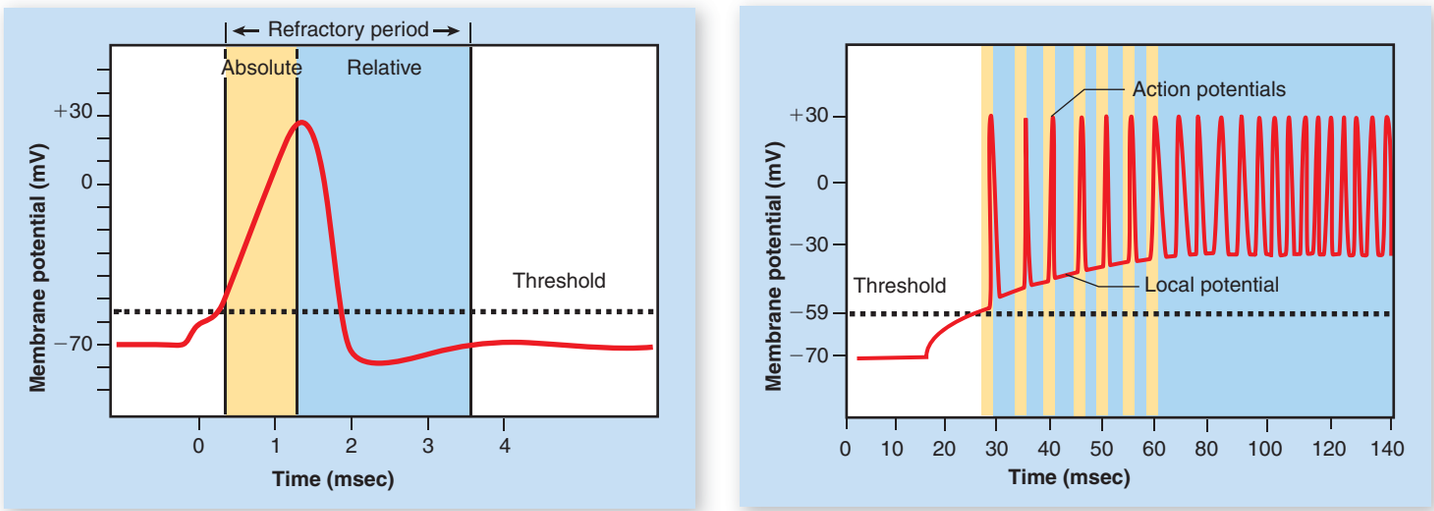

FIGURE 13-20

Refractory period. A, During the absolute refractory period, the membrane will not respond to any stimulus. During the relative refractory period, however, a very strong stimulus may elicit a response in the membrane. **B,** As the local potential increases, a new action potential may begin during the relative refractory period. The higher the local potential, the sooner a new action potential can be generated. As the graph shows, high local potentials produce a higher frequency of action potentials than lower local potentials.

about 0.5 ms after the membrane surpasses the threshold potential, it will not respond to any stimulus, no matter how strong. This is called the **absolute refractory period.** The **relative refractory period** is the few milliseconds after the absolute refractory period—the time during which the membrane is repolarizing and restoring the resting membrane potential. During the relative refractory period the membrane will respond only to very strong stimuli.

Because only very strong stimuli can produce an action potential during the relative refractory period, a series of closely spaced action potentials can occur only when the magnitude of the stimulus is great. The greater the magnitude of the stimulus, the earlier a new action potential can be produced, and thus the greater the frequency of action potentials (Figure 13-20, *B*). This means that although the magnitude of the stimulus does not affect the magnitude of the action potential, which is an all-or-none response, it does cause a proportional increase in the frequency of impulses. Thus the nervous system uses the frequency of nerve impulses to code for the strength of a stimulus—not changes in the magnitude of the action potential.

Conduction of the Action Potential

At the peak of the action potential, the inside of the axon's plasma membrane is positive relative to the outside. That is, its polarity is now the reverse of that of the resting membrane potential. Such reversal in polarity causes electrical current to flow between the site of the action potential and the adjacent regions of membrane. This local current flow triggers voltage-gated Na^+ channels in the next segment of membrane to open. As Na^+ rushes inward, this next segment exhibits an action potential. The action potential thus has moved from one point to the next continuously along the axon's membrane (Figure 13-21). This cycle repeats itself because each action potential always causes enough local current flow to surpass the threshold potential for the next region of membrane. Because each action potential is an all-or-none phenomenon, the fluctuation in membrane potential moves along the membrane without any decrement, or decrease, in magnitude.

The action potential never moves backward, restimulating the region from which it just came. It is prevented from doing so because the previous segment of membrane remains in a refractory period too long to allow such restimulation. This is the mechanism responsible for the one-way movement of action potentials along axons.

In myelinated fibers, the insulating properties of the thick myelin sheath resist ion movement and the resulting local flow of current. Electrical changes in the membrane can only occur at gaps in the myelin sheath, that is, at the nodes of Ranvier. Figure 13-22 shows that when an action potential occurs at one node, most of the current flows *under* the insulating myelin sheath to the next node. This stimulates regeneration of an action potential at that node by opening voltage-gated channels, which in turn stimulates the next node. Thus the action potential seems to "leap" from

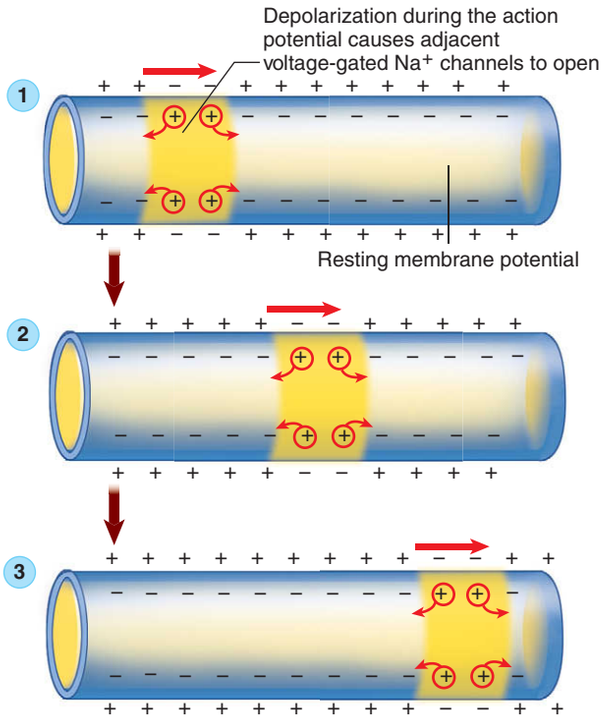

FIGURE 13-21

Continuous conduction of the action potential. The reverse polarity characteristic of the peak of the action potential causes local current flow to adjacent regions of the membrane *(small arrows).* This stimulates voltage-gated Na^+ channels to open and thus create a new action potential. This cycle continues, producing wavelike conduction of the action potential from point to point along a nerve fiber. Adjacent regions of membrane behind the action potential do not depolarize again because they are still in their refractory period.

node to node along the myelinated fiber. This type of impulse regeneration is called **saltatory conduction** (from the Latin verb *saltare*, "to leap").

How fast does a nerve fiber conduct impulses? It depends on its diameter and on the presence or absence of a myelin sheath. The speed of conduction of a nerve fiber is proportional to its diameter: the larger the diameter, the faster it conducts impulses. Myelinated fibers conduct impulses more rapidly than unmyelinated fibers. This is because saltatory conduction is more rapid than point-to-point, continuous conduction. The fastest fibers, such as those that innervate the skeletal muscles, can conduct impulses up to about 130 meters per second (close to 300 miles per hour). The slowest fibers, such as those from sensory receptors in the skin, may conduct impulses at only about 0.5 meter per second (little more than 1 mile per hour).

Box 13-4 outlines how disrupting conduction of nerve impulses can be used to block pain signals.

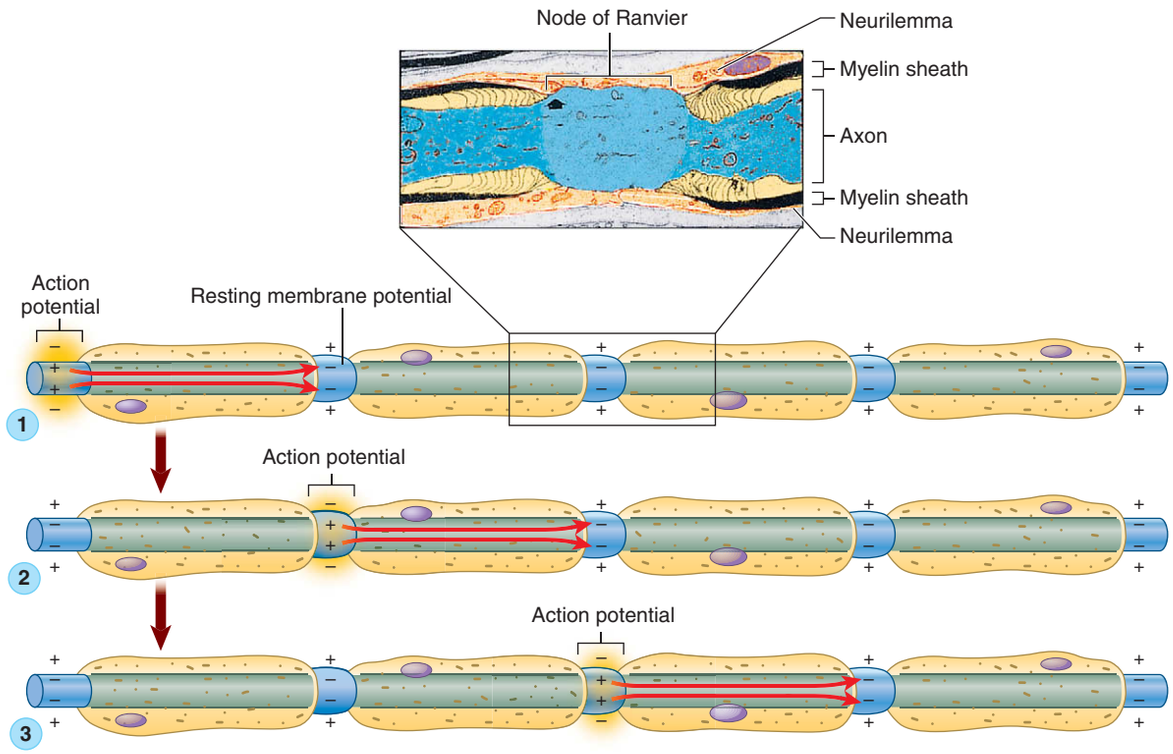

FIGURE 13–22

Saltatory conduction. This series of diagrams shows that the insulating nature of the myelin sheath prevents ion movement everywhere but at the nodes of Ranvier. The action potential at one node triggers current flow *(arrows)* across the myelin sheath to the next node—producing an action potential there. The action potential thus seems to "leap" rapidly from node to node. The inset is a transmission electron micrograph showing a node of Ranvier in a myelinated fiber.

Box 13-4 | HEALTH matters

Reducing Damage to Nerve Fibers

Crushing and bruising cause most injuries to the spinal cord—often damaging nerve fibers irreparably. This usually results in **paralysis** or loss of function in the muscles normally supplied by the damaged fibers. Unfortunately, the inflammation of the injury site usually damages even more fibers and thus increases the extent of the paralysis. However, early treatment of the injury with the antiinflammatory drug *methylprednisolone* can reduce the inflammatory response in the damaged tissue and thus limit the severity of a spinal cord injury. Although early studies failed to confirm the effectiveness of standard doses of this steroid drug, later studies showed that very large doses administered within 8 hours of the injury reduced the extent of nerve cell damage dramatically. Since about 95% of the 10,000 Americans suffering spinal cord injuries each year are admitted for treatment well before the 8-hour limit, this drug may prove to be the first effective therapy for spinal cord injuries.

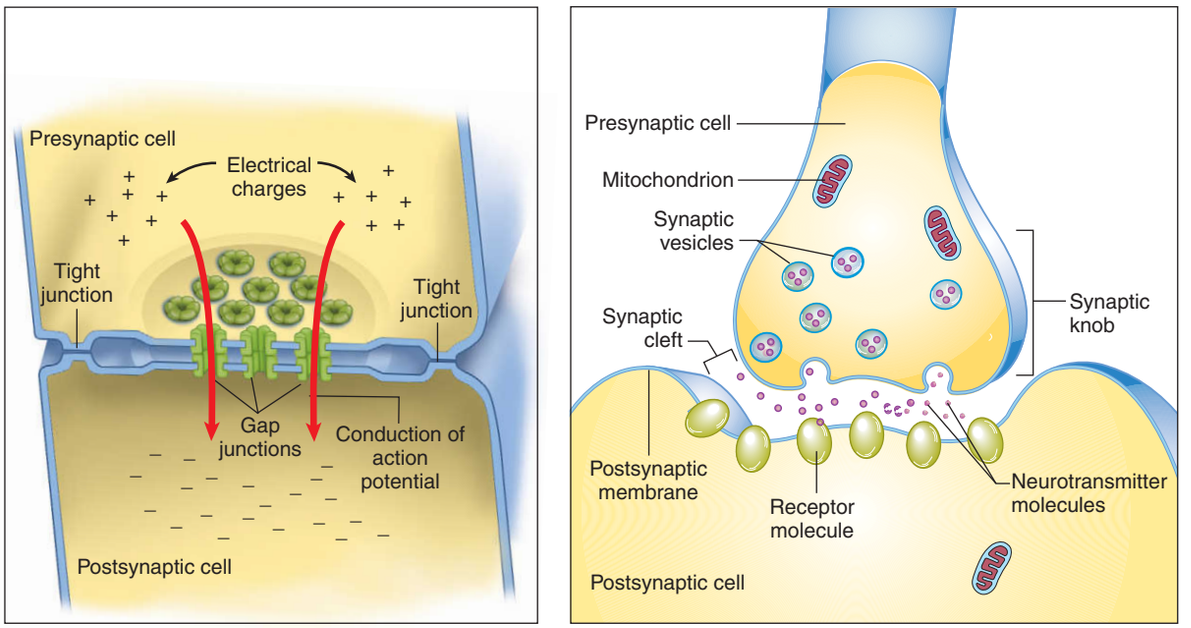
21. How does impulse conduction in an unmyelinated fiber differ from impulse conduction in a myelinated fiber?

SYNAPTIC TRANSMISSION

Structure of the Synapse



A synapse is the place where signals are transmitted from one neuron, called the *presynaptic neuron*, to another neuron, called the *postsynaptic neuron*. The postsynaptic cell could also be an effector, such as a muscle. There are many such connections in our nervous system—over 100 trillion synapses in our brain alone!

Types of Synapses

There are two types of synapses: electrical synapses and chemical synapses.

FIGURE 13-23

Electrical and chemical synapses. A, Electrical synapses involve gap junctions that allow action potentials to move from cell to cell directly by allowing electrical current to flow between cells. **B,** Chemical synapses involve transmitter chemicals (neurotransmitters) that signal postsynaptic cells, possibly inducing an action potential.

Electrical synapses occur where two cells are joined end-to-end by gap junctions (Figure 13-23, A). Because the plasma membranes and cytoplasm are functionally continuous in this type of junction, an action potential can simply continue along the postsynaptic plasma membrane as if it belonged to the same cell. Electrical synapses occur between cardiac muscle cells and between some types of smooth muscle cells. Electrical synapses are found throughout the nervous system early in development. These early electrical synapses are thought to be eventually replaced by the more complex chemical synapses. However, evidence suggests that electrical synapses may be more abundant, and more critical to certain functions, in adults than previously thought.

Chemical synapses are called that because they use a chemical transmitter called a *neurotransmitter* to send a signal from the **presynaptic** cell to the **postsynaptic** cell (Figure 13-23, *B*). Because of its importance and complexity, it is the chemical synapse that we will consider carefully in the following paragraphs.

CHEMICAL SYNAPSE

Three structures make up a chemical synapse:

1. A synaptic knob
2. A synaptic cleft
3. The plasma membrane of a postsynaptic neuron

A *synaptic knob* is a tiny bulge at the end of a terminal branch of a presynaptic neuron's axon (see Figure 13-23). Each synaptic knob, or synaptic terminal, contains numerous small sacs or vesicles. Each vesicle contains about 10,000 neurotransmitter molecules. Some of these are released from the presynaptic neuron into a **synaptic cleft**—the space between a synaptic knob and the plasma membrane of a postsynaptic neuron.

The synaptic cleft is an incredibly narrow space—only 20 to 30 nanometers (nm), or about one millionth of an inch in width.

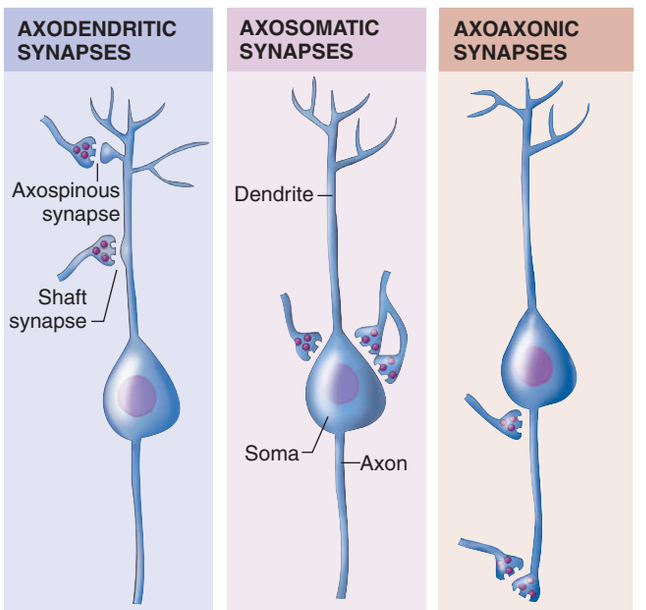


FIGURE 13-24

Arrangements of synapses. The axon of a presynaptic neuron may form a synapse at the dendrite, soma, or axon of another neuron.

Identify the synaptic cleft in Figure 13-23. The synaptic cleft is not an empty space—it contains fluid, enzymes, adhesion molecules, and other substances.

Figure 13-24 shows that an axon may form a synapse at any of several points along a postsynaptic neuron:

- At the dendrite (axodendritic synapses)
- At the soma (axosomatic synapses)
- At the axon (axoaxonic synapses)

Synapses at the dendrite or soma are the most common arrangements in many areas of the nervous system. Synapses of an axon with the axon of another neuron are less common but offer a way for one neuron to inhibit or facilitate synaptic transmission by another neuron.

The plasma membrane of a postsynaptic neuron has protein molecules embedded in it, each facing toward the synaptic knob (see Figure 13-23). These membrane molecules serve as receptors to which neurotransmitter molecules bind and trigger responses in the postsynaptic cell.

Mechanisms of Synaptic Transmission

An action potential that has traveled the length of a neuron stops at its axon terminals. Action potentials cannot cross synaptic clefts, minuscule barriers though they are. Instead, neurotransmitters are released from the synaptic knob, cross the synaptic cleft, and bring about a response by the postsynaptic neuron. *Excitatory* neurotransmitters cause depolarization of the postsynaptic membrane, whereas *inhibitory* neurotransmitters cause hyperpolarization of the postsynaptic membrane (see Figure 13-17).

The mechanism of synaptic transmission, summarized in Figures 13-23 and 13-25, consists of the following sequence of events:

1. When an action potential reaches a synaptic knob, voltage-gated calcium channels in its membrane open and allow calcium ions (Ca^{++}) to diffuse into the knob rapidly. Many voltage-gated Ca^{++} channels are present in the membrane of the neuron's output zone (see Figure 13-8).
2. The increase in intracellular Ca^{++} concentration triggers the movement of neurotransmitter vesicles to the plasma

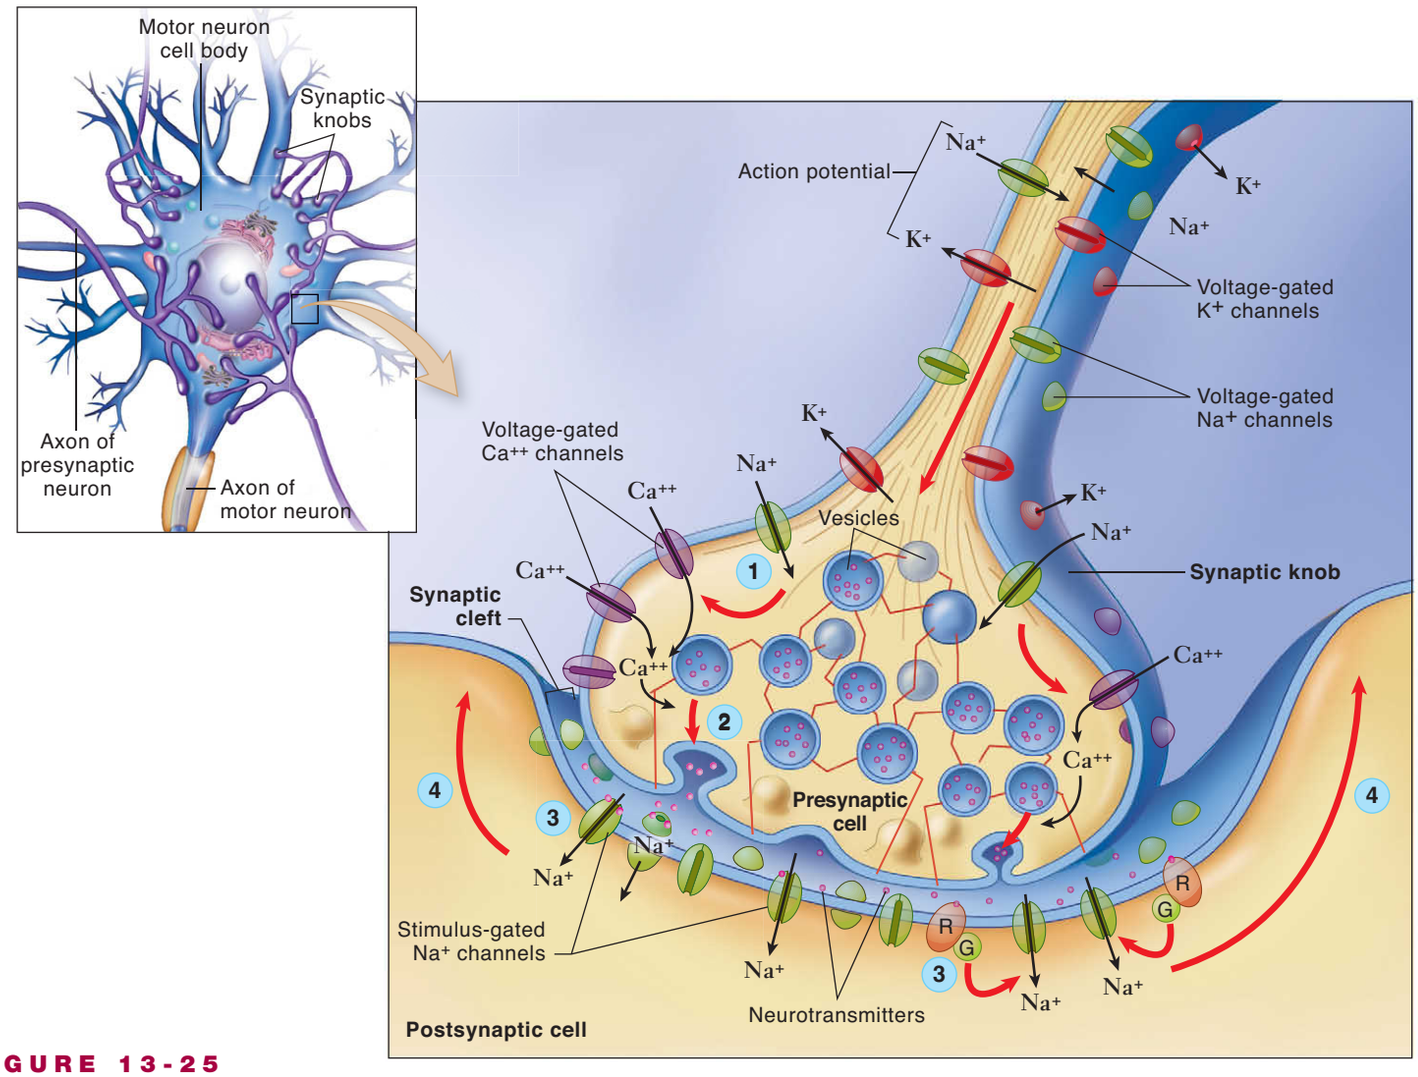

FIGURE 13-25

The chemical synapse. Diagram shows detail of synaptic knob, or axon terminal, of presynaptic neuron, the plasma membrane of a postsynaptic neuron, and a synaptic cleft. On the arrival of an action potential at a synaptic knob, voltage-gated Ca^{++} channels open and allow extracellular Ca^{++} to diffuse into the presynaptic cell *(step 1)*. In step 2, the Ca^{++} triggers the rapid exocytosis of neurotransmitter molecules from vesicles in the knob. In step 3, neurotransmitter diffuses into the synaptic cleft and binds to receptor molecules in the plasma membrane of the postsynaptic neuron. The postsynaptic receptors directly or indirectly trigger the opening of stimulus-gated ion channels, initiating a local potential in the postsynaptic neuron. In step 4, the local potential may move toward the axon, where an action potential may begin.

membrane of the synaptic knob. Once there, they fuse with the membrane and release their neurotransmitter via exocytosis. Thousands of neurotransmitter molecules spurt out of the open vesicles into the synaptic cleft.

3. The released neurotransmitter molecules almost instantaneously diffuse across the narrow synaptic cleft and contact the postsynaptic neuron's plasma membrane. Here, neurotransmitters briefly bind to receptor molecules that are also gated channels or that are coupled to gated channels. Binding of neurotransmitters triggers the channels to open.
4. The opening of ion channels in the postsynaptic membrane may produce a local potential called a **postsynaptic potential.** Excitatory neurotransmitters cause both Na^+ channels and K^+ channels to open. Because Na^+ rushes inward faster than K^+ rushes outward, there is a temporary depolarization called an **excitatory postsynaptic potential (EPSP).** Inhibitory neurotransmitters cause K^+ channels and/or Cl^- channels to open. If K^+ channels open, K^+ rushes outward; if Cl^- channels open, Cl^- rushes inward. Either event makes the inside of the membrane even more negative than at the resting potential. This temporary hyperpolarization is called an **inhibitory postsynaptic potential (IPSP).**
5. Once a neurotransmitter binds to its postsynaptic receptors, its action is quickly terminated (Figure 13-26). Several mechanisms bring this about. Some neurotransmitter molecules are transported back into the synaptic knobs, where they can be repacked into vesicles and used again. Some neurotransmitter molecules are metabolized into inactive compounds by synaptic enzymes. Other neurotransmitter molecules simply diffuse out of the synaptic cleft and are transported into nearby glial cells. The glial cells may release them again for reuptake by the presynaptic neuron, sometimes after breaking them down into another form.

Some mechanisms of synaptic transmission are illustrated in Figures 13-25 and 13-26. The diagram in Figure 13-27 summarizes all the main events of synaptic transmission.

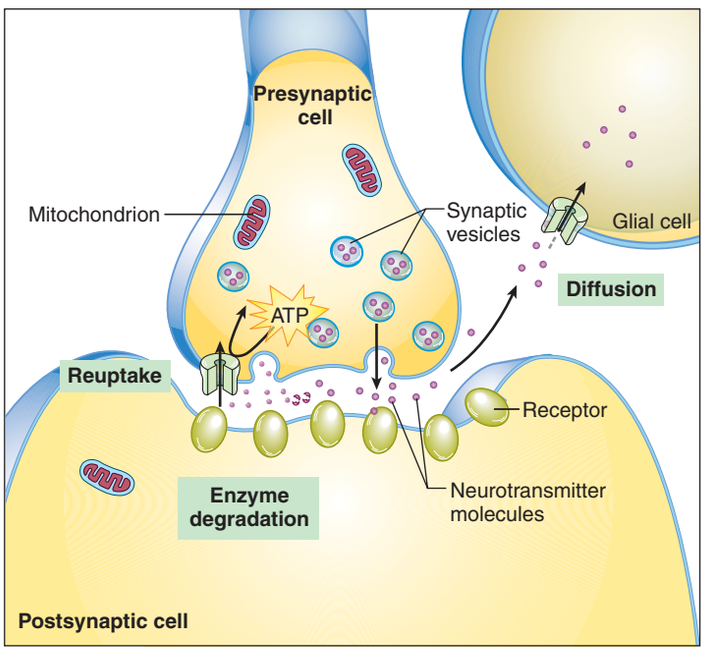

FIGURE 13-26

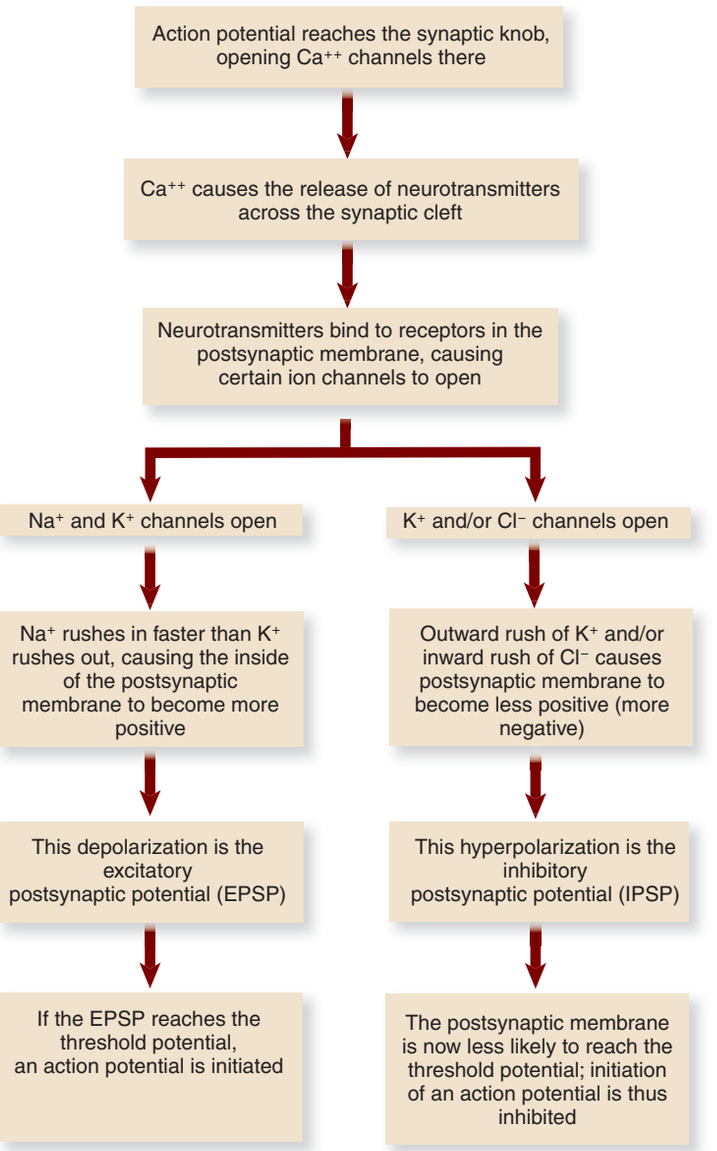
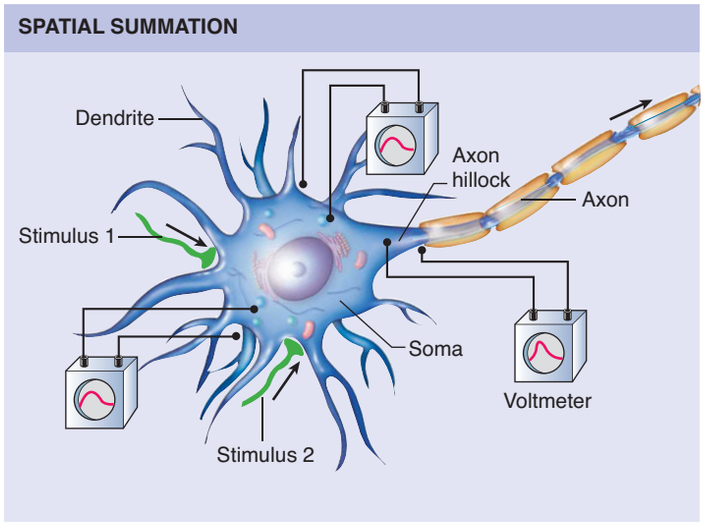
Fate of neurotransmitters. After synaptic transmission, the signal must be stopped by removing neurotransmitters from the synaptic cleft. Many neurotransmitters are immediately transported back into the presynaptic neuron in a process called *reuptake.* Some neurotransmitters are broken down by enzymes in the synaptic cleft, and the resulting molecules are transported back into the presynaptic neuron for recycling. Some neurotransmitter molecules may diffuse out of the synapse and be transported into a nearby glial cell (which may return an altered form of the molecule to the presynaptic neuron).





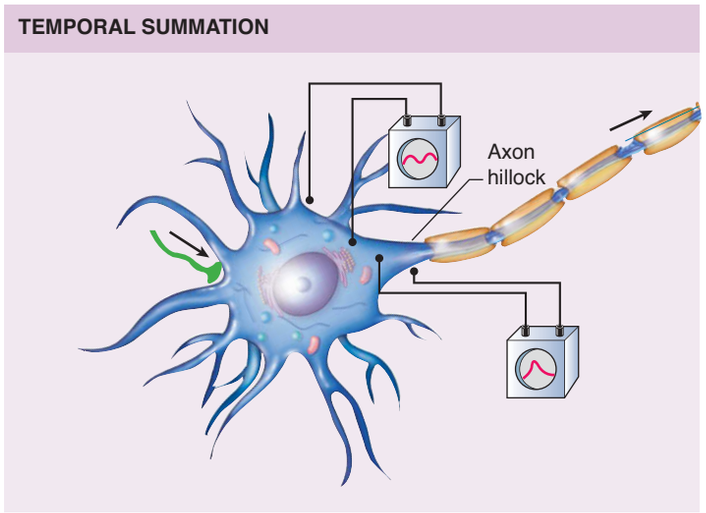


FIGURE 13-27

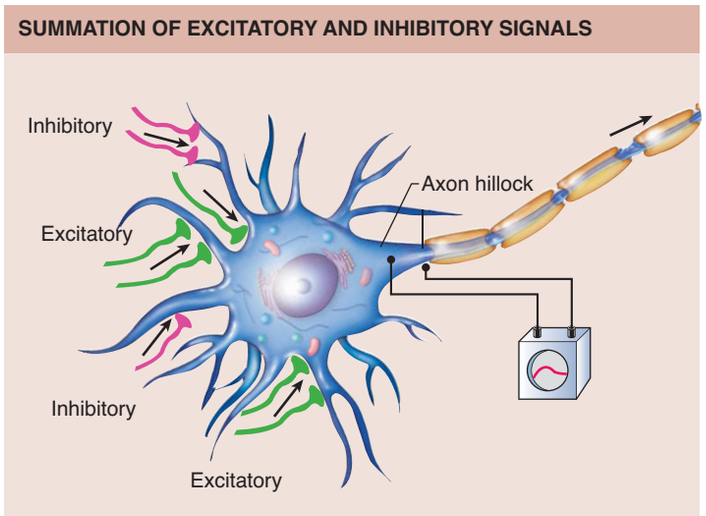

Summary of synaptic transmission.

A

B

C

Summation

At least several, usually thousands, and in some cases more than 100,000, knobs synapse with a single postsynaptic neuron. The amount of excitatory neurotransmitter released by one knob is not enough to trigger an action potential. It may, however, *facilitate* initiation of an action potential by producing a local depolarization of the synaptic membrane—an EPSP. When several knobs are activated simultaneously, neurotransmitters stimulate different locations on the postsynaptic membrane. These local potentials may spread far enough to reach the axon hillock, where they may add together, or *summate*. If the sum of the local potentials reaches the threshold potential, voltage-gated channels in the axon membrane open, producing an action potential (Figure 13-28, *A*). This phenomenon is called **spatial summation.**

Likewise, when synaptic knobs stimulate a postsynaptic neuron in rapid succession, their effects can add up over a brief period of time to produce an action potential (Figure 13-28, *B*). This type of summation is called **temporal summation.**

Usually both excitatory and inhibitory transmitters are released at the same postsynaptic neuron. The excitatory neurotransmitters produce local EPSPs, and the inhibitory neurotransmitters produce local IPSPs. Summation of these opposing local potentials occurs at the axon hillock, where many voltage-gated ion channels are located. If the EPSPs predominate over the IPSPs enough to depolarize the membrane to the threshold potential, the voltage-gated channels will respond and produce an action potential (Figure 13-28, *C*). The action potential is then conducted without decrement along the axon's membrane.

On the other hand, if the IPSPs predominate over the EPSPs, the membrane will not reach the threshold potential. The voltage-gated channels at the axon hillock will not respond, and no action potential will be conducted along the axon.

One reason summation is important for our understanding of the nervous system is that it helps explain how information can be processed as it moves through a network of neurons. For example, not all of the sensory information your sensory neurons are receiving right now is actually getting to the conscious part of your brain.

FIGURE 13-28

Summation. A, Spatial summation is the effect produced by simultaneous stimulation by a number of synaptic knobs on the same postsynaptic neuron. Voltmeters placed near the site of stimulation show small depolarizations, and a voltmeter at the axon hillock shows the large depolarization resulting from the combined effect of both smaller depolarizations. **B,** Temporal summation is the effect produced by a rapid succession of stimuli on a single postsynaptic neuron. The figure shows two stimuli in a short burst that produce two small depolarizations that combine at the axon hillock to produce a large depolarization. **C,** Summation of many excitatory and inhibitory effects produces the potential at the axon hillock. Here, depolarizations triggered by five excitatory presynaptic neurons *(green),* are partially offset by hyperpolarizations triggered by three inhibitory presynaptic neurons *(red)* to produce only a small depolarization at the axon hillock. This will occur only if there is sufficient depolarization to surpass the threshold potential.

Of course, it would be overwhelming if all that information did get into your consciousness. Much of it would have been stopped at synapses where threshold was not reached, as described in the preceding paragraphs. Thus summation is a mechanism for *making decisions* about what information should continue onward in the neural network.

Synapses and Memory

Current theories of memory state that synapses play a key role in how memories are stored in the nervous system. The most widely held idea is that information is stored in the form of an increased flow of information at synapses in particular pathways (depending on the memory stored). In other words, memories form when the flow of information is facilitated at synapses.

Short-term memories, lasting only a few seconds or minutes, may result from presynaptic facilitation or inhibition at particular synapses. Go back to Figure 13-24 on p. 401 to see how an axoaxonic synapse would permit one neuron to influence the presynaptic events of another neuron.

Intermediate long-term memory lasts from minutes to weeks. To get these memories to remain that long, facilitation of presynaptic activity has to last longer. One way that the nervous system does this involves the neurotransmitter *serotonin*. Serotonin is released at an axoaxonal synapse and triggers the axon terminal of a presynaptic neuron to block its potassium channels for up to several weeks. Thus whenever there is an action potential arriving at that presynaptic neuron, it lasts longer (because potassium fails to rapidly repolarize the membrane as shown in Figure 13-19 on p. 396). A prolonged action potential means that the presynaptic calcium channels stay open longer and trigger the release of more neurotransmitter than usual—thus facilitating synaptic transmission.

Long-term memories, the kind of memories needed for learning anatomy and physiology, last for months or years. Such long-term facilitation of synaptic transmission requires longer-lasting structural changes in the synapses. These changes may involve just one element or be a combination of the following: an increase in the number of vesicles stored, an increase in membrane locations from which the vesicles can release their neurotransmitters, an increase in the number of presynaptic axon terminals, and/or changes in the dendrites that permit postsynaptic facilitation.

Because nearby astrocytes can enhance or alter synaptic transmission by releasing transmitters of their own, they may also play a role in storing memories. Prion proteins (PrP), which can change shape and then cause other proteins in a neuron to change shape, have also been suggested as a memory mechanism.

NEUROTRANSMITTERS

Neurotransmitters are the means by which neurons talk to one another. At billions, or more likely, trillions, of synapses throughout the body, presynaptic neurons release neurotransmitters that act to facilitate, stimulate, or inhibit postsynaptic neurons and effector cells. More than 50 compounds are known to be neurotransmitters. At least 50 other compounds are suspected of being neurotransmitters. For the most part, they are not distributed diffusely or at random throughout the nervous system. Instead, specific neurotransmitters are localized in discrete groups of neurons and thus released in specific nerve pathways (Box 13-5).

Classification of Neurotransmitters

Neurotransmitters are commonly classified by their function or by their chemical structure, depending on the context in which they are discussed. You are already familiar with two major functional classifications: *excitatory neurotransmitters* and *inhibitory neurotransmitters*. Some neurotransmitters can have inhibitory effects at some synapses and excitatory effects at other synapses. For example, the neurotransmitter *acetylcholine*, discussed in Chapter 12, excites skeletal muscle cells but inhibits cardiac muscle cells. This illustrates an important point about the action of neurotransmitters: their function is determined by the postsynaptic receptors, not by the neurotransmitters themselves.

Another way to classify neurotransmitters by function is to identify the mechanism by which they cause a change in the postsynaptic neuron or effector cell. Some neurotransmitters trigger the opening or closing of ion channels directly, by binding to one or both receptor sites on the channel itself (see figure in Box 13-6). This "direct mechanism" is illustrated in Figure 13-29.

Box 13-5 | HEALTH matters

Anesthetics

Anesthetics are substances that are administered to reduce or eliminate the sensation of pain—thus producing a state called **anesthesia.** Many anesthetics produce their effects by inhibiting the opening of sodium channels and thus blocking the initiation and conduction of nerve impulses. Anesthetics such as bupivacaine (Marcaine) are often used in dentistry to minimize pain involved in tooth extractions and other dental procedures. Procaine has likewise been used to block the transmission of electrical signals in sensory pathways of the spinal cord. Benzocaine and phenol, local anesthetics found in several over-the-counter products that relieve pain associated with teething in infants, sore throat pain, and other ailments, also produce their effect by blocking initiation and conduction of nerve impulses.

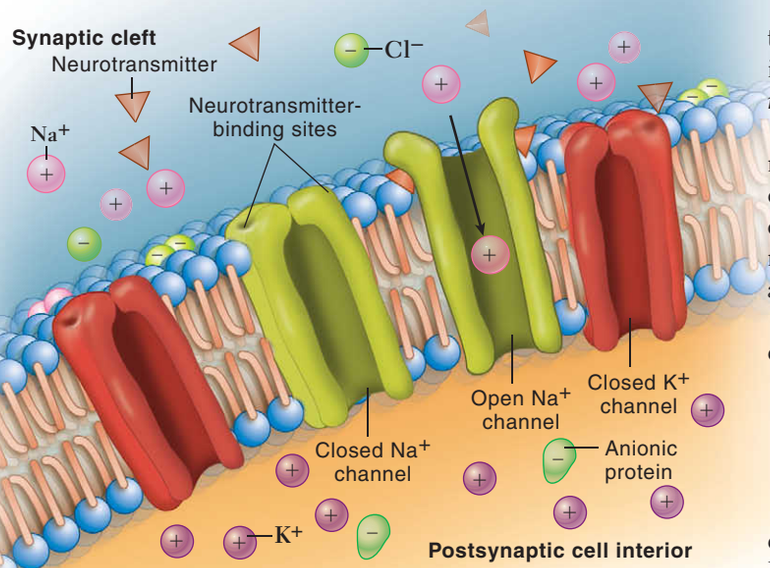

FIGURE 13-29

Direct stimulation of postsynaptic receptor. Some neurotransmitters, such as acetylcholine, initiate nerve signals by binding directly to one or both neurotransmitter-binding sites on the stimulus-gated ion channel. Such binding causes the channel to change its shape to an open position. When the neurotransmitter is removed, the channel again closes.

their chemical structure. Neurotransmitters can thus be grouped into two main groupings: *small-molecule transmitters* and *large-molecule transmitters.*

Small-molecule neurotransmitters are, as their name implies, molecules of a smaller size than those in the large-molecule category. Small-molecule neurotransmitters are amino acids or are derived from individual amino acids. Large-molecule neurotransmitters, on the other hand, are made up of more than one amino acid—usually chains of 2 to 40 amino acids.

Small-molecule transmitters are subdivided into four main chemical classes:

Class I Acetylcholine
Class II Amines
Class III Amino acids
Class IV Other small molecules

Large-molecule neurotransmitters are all neuropeptides—chains of several amino acids strung together by peptide bonds. Examples of neurotransmitters in each of these groupings are

Other neurotransmitters produce their effects by binding to receptors linked to G proteins that, in turn, activate chemical messengers within the postsynaptic cell. An example of this *second messenger* mechanism occurs when the neurotransmitter *norepinephrine* binds to **G-protein–coupled receptors (GPCRs).** Triggering the GPCR causes G proteins to activate the membrane-bound enzyme adenyl cyclase. The adenyl cyclase removes phosphate groups from adenosine triphosphate (ATP) to form cyclic adenosine monophosphate (cAMP). Cyclic AMP is the "second messenger," triggering the activation of the protein kinase A enzyme that eventually causes Na^+ channels in the postsynaptic membrane to open (Figure 13-30).

The second messenger mechanism is usually slower and longer lasting than the direct mechanism. And because the second messenger mechanism involves intracellular messengers, it can regulate other cellular processes, such as cytoskeleton movement, gene expression, and shuttling of proteins along the axonal transport system.

Learning about these mechanisms of neurotransmitter signaling has revolutionized our understanding of neurobiology—and thus our ability to prevent and treat illnesses. Many drugs and herbal supplements used in prevention and therapy today either enhance or inhibit particular steps of the mechanisms just described.

Because the functions of specific neurotransmitters vary by location, it is often most useful to classify them according to

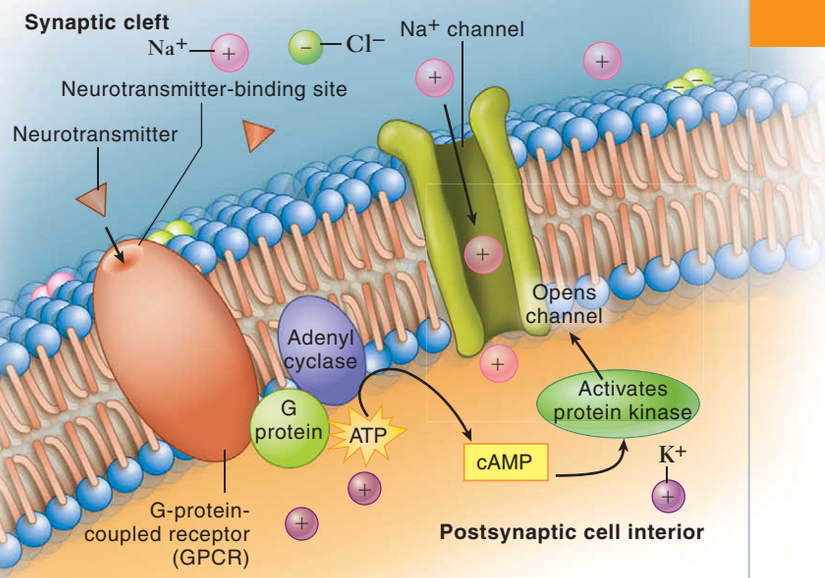

FIGURE 13-30

Second messenger stimulation of postsynaptic receptor. Norepinephrine and many other neurotransmitters initiate nerve signals indirectly by binding to a G-protein–coupled receptor (GPCR) that changes shape to activate the enzyme *adenylate cyclase,* which in turn catalyzes the conversion of ATP to cyclic AMP (cAMP). cAMP is a "second messenger" that induces a change in the shape of a stimulus-gated channel. (Compare with Figure 13-29.)

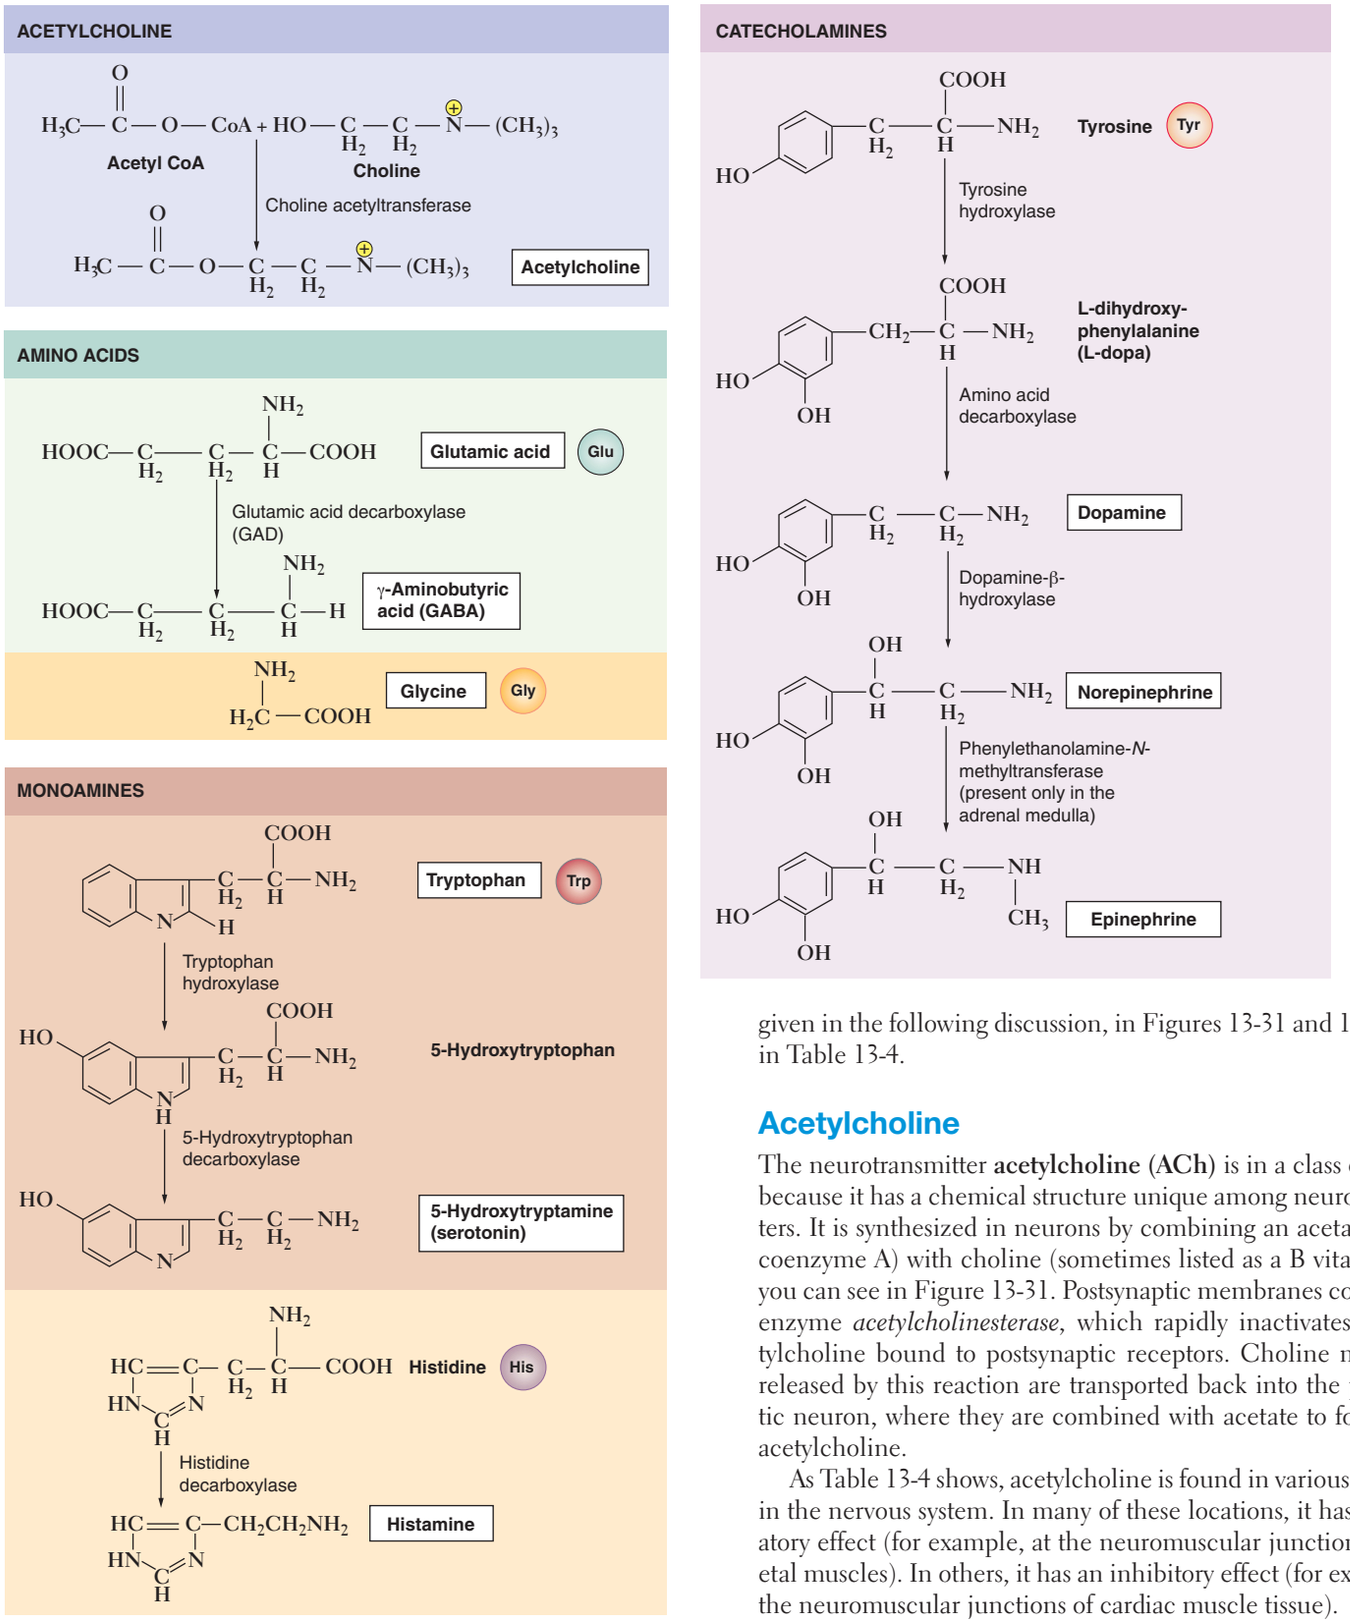

FIGURE 13-31

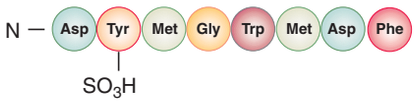
Examples of small-molecule neurotransmitters. Many of the small-molecule transmitters are amino acid molecules or are derived from the amino acids tryptophan, histidine, or tyrosine.

given in the following discussion, in Figures 13-31 and 13-32, and in Table 13-4.

Acetylcholine

The neurotransmitter **acetylcholine (ACh)** is in a class of its own because it has a chemical structure unique among neurotransmitters. It is synthesized in neurons by combining an acetate (acetyl coenzyme A) with choline (sometimes listed as a B vitamin)—as you can see in Figure 13-31. Postsynaptic membranes contain the enzyme *acetylcholinesterase*, which rapidly inactivates the acetylcholine bound to postsynaptic receptors. Choline molecules released by this reaction are transported back into the presynaptic neuron, where they are combined with acetate to form more acetylcholine.

As Table 13-4 shows, acetylcholine is found in various locations in the nervous system. In many of these locations, it has an excitatory effect (for example, at the neuromuscular junctions of skeletal muscles). In others, it has an inhibitory effect (for example, at the neuromuscular junctions of cardiac muscle tissue).



Amines

Amine neurotransmitters are synthesized from amino acid molecules, such as tyrosine, tryptophan, or histidine. Amines include

Vasoactive intestinal peptide (VIP)

Cholecystokinin-like peptide (CCK8)

Met-enkephalin

Substance P

Leu-enkephalin

β-Endorphin

FIGURE 13-32

Examples of neuropeptides. Large-molecule transmitters are made up of more than one amino acid.

TABLE 13-4 Examples of Neurotransmitters

NEUROTRANSMITTER	LOCATION*	FUNCTION*
Small-Molecule Transmitters		
Class I		
Acetylcholine (ACh)	Junctions with motor effectors (muscles, glands); many parts of brain	Excitatory or inhibitory; involved in memory
Class II: Amines		
Monoamines		
Serotonin (5-HT†)	Several regions of the CNS	Mostly inhibitory; involved in moods and emotions, sleep
Histamine	Brain	Mostly excitatory; involved in emotions and regulation of body temperature and water balance
Catecholamines		
Dopamine (DA)	Brain; autonomic system	Mostly inhibitory; involved in emotions/moods and in regulating motor control
Epinephrine	Several areas of the CNS and in the sympathetic division of the ANS	Excitatory or inhibitory; acts as a hormone when secreted by sympathetic neurosecretory cells of the adrenal gland
Norepinephrine (NE)	Several areas of the CNS and in the sympathetic division of the ANS	Excitatory or inhibitory; regulates sympathetic effectors; in brain, involved in emotional responses
Class III: Amino Acids		
Glutamate (glutamic acid, Glu)	CNS	Excitatory; most common excitatory neurotransmitter in CNS
Gamma-aminobutyric acid (GABA)	Brain	Inhibitory; most common inhibitory neurotransmitter in brain
Glycine (Gly)	Spinal cord	Inhibitory; most common inhibitory neurotransmitter in brain
Class IV: Other Small Molecules		
Nitric oxide (NO)	Several regions of the nervous system	May be a signal from postsynaptic to presynaptic neuron

*These are examples only; most of these neurotransmitters are also found in other locations, and many have additional functions.
†5-hydroxytryptamine (synonym for serotonin).
CNS, Central nervous system; *ANS,* autonomic nervous system.

(continued)

TABLE 13-4 Examples of Neurotransmitters *(continued)*

NEUROTRANSMITTER	LOCATION*	FUNCTION*
Large-Molecule Transmitters		
Neuropeptides		
Vasoactive intestinal peptide (VIP)	Brain; some ANS and sensory fibers; retina; gastrointestinal tract	Function in nervous system uncertain
Cholecystokinin (CCK)	Brain; retina	Function in nervous system uncertain
Substance P	Brain, spinal cord, sensory pain pathways; gastrointestinal tract	Mostly excitatory; transmits pain information
Enkephalins	Several regions of CNS; retina; intestinal tract	Mostly inhibitory; act like opiates to block pain
Endorphins	Several regions of CNS; retina; intestinal tract	Mostly inhibitory; act like opiates to block pain
Neuropeptide Y (NPY)	Brain, some ANS fibers	Variety of functions including enhancing blood vessel constriction by ANS, regulation of energy balance, learning, and memory

*These are examples only; most of these neurotransmitters are also found in other locations, and many have additional functions.
†5-hydroxytryptamine (synonym for serotonin).
CNS, Central nervous system; *ANS,* autonomic nervous system.

the neurotransmitters of the **monoamine** subclass: *serotonin* and *histamine*. Also included are neurotransmitters of the **catecholamine** subclass: *dopamine*, *epinephrine*, and *norepinephrine*.

Figure 13-31 shows how these subclasses of neurotransmitters are derived from different amino acids. It is not important to focus on the detailed chemical structures shown in the diagram. However, seeing that these neurotransmitters are chemically related to amino acids—and to each other—will help you better understand concepts in nutrition, pharmacology, and other health science applications.

The amine neurotransmitters are found in various regions of the brain, where they affect learning, emotions, motor control, and other activities (Box 13-6). In a previous section, we discussed the role of serotonin in forming memories. Dopamine, another amine, has an inhibitory effect on certain somatic motor pathways. When dopamine is deficient, the tremors and general overstimulation of muscles characteristic of *parkinsonism* occur. This effect will be discussed further in Chapter 14. Epinephrine and norepinephrine are also involved in motor control, specifically in the sympathetic pathways of the autonomic nervous system. Some autonomic neurons in the adrenal gland do not terminate at a postsynaptic effector cell but instead release their neurotransmitters directly into the bloodstream. When this occurs, epinephrine and norepinephrine are called *hormones* instead of neurotransmitters.

Amino Acids

Many biologists now believe that amino acids are among the most common neurotransmitters in the central nervous system. For example, it is thought that the amino acid *glutamate (glutamic acid)* is responsible for up to 75% of the excitatory signals in the brain. *Gamma-aminobutyric acid (GABA)*, which is derived from glutamate, is the most common inhibitory neurotransmitter in the brain. In the spinal cord, the most widely distributed inhibitory neurotransmitter is the simple amino acid *glycine*. These three neurotransmitters are shown in Figure 13-31.

Amino acids are found in all cells of the body, where they are used to synthesize various structural and functional proteins. In the nervous system, however, they are also stored in synaptic vesicles and used as neurotransmitters. Certain membrane receptors in the postsynaptic membrane are sensitive to high quantities of certain amino acids and thus trigger specific responses in the postsynaptic cell. It is believed that an imbalance of certain amino acids in the body could produce similar effects, and thus alter the function of the nervous system.

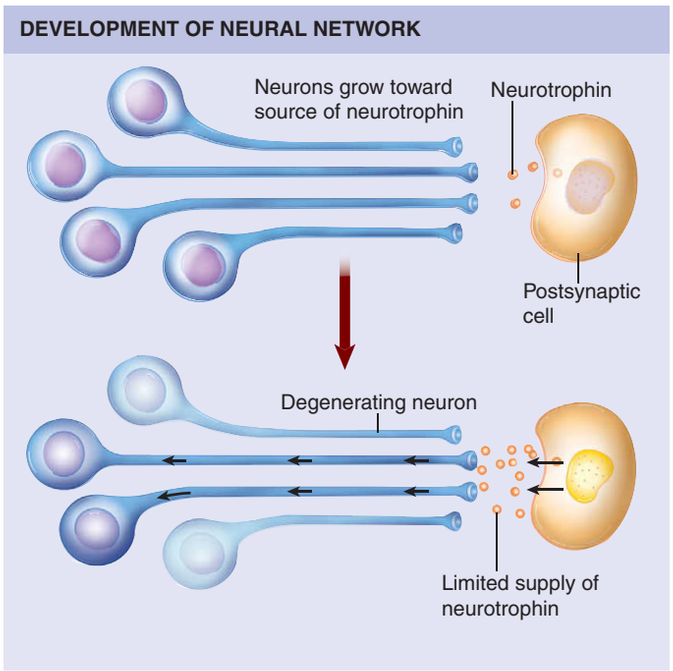
Other Small-Molecule Transmitters

The term "other" is not a very descriptive term for a category of compounds, but the discovery of a new group of small neurotransmitter molecules is so recent that a standard name for Class IV neurotransmitters has not been adopted. The prime example of this group is **nitric oxide (NO).** Nitric oxide is a small gas molecule that the cell makes from the amino acid arginine. NO was the first gas to be identified as a transmitter, but carbon monoxide (CO) may be another. Nitric acid is released from postsynaptic neurons and *diffuses backward* toward the presynaptic neuron, where it has its biochemical effects. This gives postsynaptic neurons a mechanism by which they can "talk back" to the presynaptic neuron, establishing the opportunity for feedback.

Neuropeptides

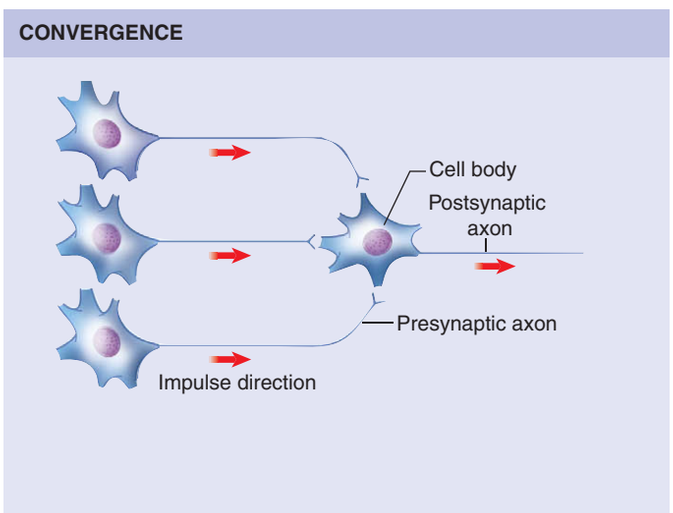
The **neuropeptide** neurotransmitters are short strands of amino acids called *polypeptides* or, more simply, *peptides*. Neuropeptide neurotransmitters are often called *neuroactive peptides*. Because they are made up of chains of amino acids, peptides are very large molecules compared to the neurotransmitters previously discussed, most of which are derived from a single amino acid (see Figure 13-32).

Box 13-6 | Neural Networks



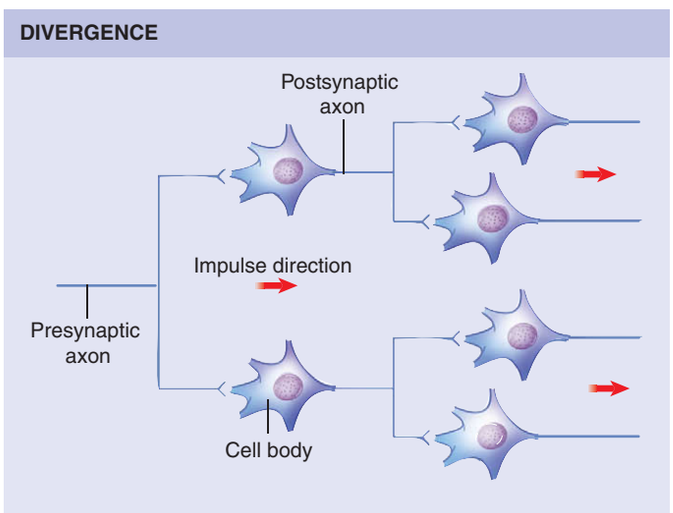
Nervous pathways, or **neural networks,** conduct information along complex series of neurons joined together by synapses.

Research shows that such networks develop during a person's early life and are influenced by the various sensory learning experiences that we have as our nerve tissue develops. One process that facilitates the formation of connections involves *neurotrophic factors* or *neurotrophins*—nerve growth factors that are released by various cells of the body. As part *A* of the figure shows, the axons of several developing neurons grow toward the cell that releases neurotrophins. However, only those axons that can be supported by the amount of available neurotrophin will remain—the rest of the neurons will degenerate. Many other factors, such as repeated stimulation of a pathway, influence this process. Once neural networks become mature in adulthood, they are less likely to accept the addition of new neurons—even though neural stem cells do exist in the adult nervous system.



Something that makes the pathways of neural networks complex is that they often *converge* and *diverge.*

Convergence occurs when more than one presynaptic axon synapses with a single postsynaptic neuron (part *B* of the figure). Convergence allows information from several different pathways to be funneled into a single pathway. For example, the pathways that innervate the skeletal muscles may originate in several different areas of the central nervous system. Because pathways from each of these motor control areas converge on a single motor neuron, each area has an opportunity to control the same muscle.



Divergence occurs when a single presynaptic axon synapses with many different postsynaptic neurons (part *C* of the figure). Divergence allows information from one pathway to be "split" or "copied" and sent to different destinations in the nervous system. For example, a single bit of visual information may be sent to many different areas of the brain for processing.

A

B

C

Peptides were first discovered to have regulatory effects in the digestive tract, where they act as hormones and regulate digestive function. In the 1970s some of these "gut" polypeptides, such as *vasoactive intestinal peptide (VIP)*, *cholecystokinin (CCK)*, and *substance P*, were also found to be acting as neurotransmitters in the brain. In addition, researchers found that receptors of many of the gut-brain peptides also bind morphine and other opium derivatives. For example, two subclasses of peptides—*enkephalins* and *endorphins*—that bind to the opiate receptors serve as the body's own supply of opiates. Enkephalins and endorphins have important pain-relieving effects in the body.

Although neuropeptides may be secreted by a synaptic knob by themselves, some may be secreted along with a second, or even third, neurotransmitter. In such cases, the neuropeptide is thought to act as a **neuromodulator.** A neuromodulator is a "cotransmitter" that regulates or modulates the effects of the neurotransmitter(s) released along with it.

An important class of neuropeptides in the nervous system is the **neurotrophins,** or *neurotrophic factors*. When first discovered, researchers found that they stimulate neuron development, hence the name neurotrophin (literally, "nerve growth factor"). Box 13-6, part *A* of the figure, shows how neurotrophins help regulate neuron growth. More recently, we have discovered that neurotrophins also participate in synaptic transmission and neuromodulation. In fact, one type of neurotrophin released by neurons is required to form any memory lasting more than a day.

ROLE OF NERVOUS SYSTEM CELLS

From the very birth of neuroscience, biologists have argued about which metaphor is best to describe the role of cells in the nervous system. One camp has argued on behalf of the *neuron doctrine*, which states that the neuron is the basic structural and functional unit of the nervous system and that neurons are independent units connected by chemical synapses. The competing *reticular theory* stated that the nervous system is best understood as a large integrated network—one endless piece. Once the presence of chemical synapses separating independent neurons was confirmed, it seemed as if the neuron doctrine was proved true and the reticular theory proved wrong.

However, today neuroscience has advanced to a point at which the neuron doctrine has been expanded to include concepts of the reticular theory. For example, we now know that along with chemical synapses, there are many electrical synapses that functionally unite neurons into large information-processing networks. We also know that signals can be sent both forwards and backwards in the chemical synapses of the neural network. We know that the concentration of neurotransmitters at synapses in certain neural pathways can affect health (Box 13-7). And today, we are learning more about how neuroglia communicate with each other and regulate the information-carrying functions of neurons. In fact, a very active area of neuroscience research relates to studying the integrated behavior of large neural networks. Our understanding of the role of nervous system cells is growing rapidly.

| A&P CONNECT |

The concept that signals can be sent "backwards" at a synapse is called *retrograde signaling.* See how this works at ***Retrograde Signaling*** online at ***A&P Connect.***

27. How do excitatory neurotransmitters differ from inhibitory neurotransmitters?
28. What are the four chemical classes of neurotransmitters?
29. What are neuromodulators?

Box 13-7 | HEALTH matters

Antidepressants

Severe psychic depression occurs when a deficit of norepinephrine, dopamine, serotonin, and other amines exists in certain brain synapses. This fact led to the development of **antidepressant** drugs.

Certain of these antidepressants inhibit *catechol-O-methyl transferase* (COMT), the enzyme that inactivates norepinephrine. When COMT is inhibited by an antidepressant drug, the amount of active norepinephrine in brain synapses increases—relieving the symptoms of depression. Antidepressants such as phenelzine (Nardil) block the action of *monoamine oxidase* (MAO), the enzyme that inactivates dopamine and serotonin. Such drugs are in a class called *MAOIs (monoamine oxidase inhibitors).*

Widely used antidepressants such as imipramine (Tofranil) and amitriptyline (Elavil) increase amine levels at brain synapses by blocking their uptake into the axon terminals. The popular drugs fluoxetine (Prozac), citalopram (Celexa), and related drugs called *SSRIs (serotonin-specific reuptake inhibitors)* produce antidepressant effects by inhibiting the uptake of serotonin. *Norepinephrine reuptake inhibitors (NRIs)* such as atomoxetine (Strattera) selectively reduce the reuptake of noradrenaline. *SNRIs (serotonin and norepinephrine reuptake inhibitors)* such as venlafaxine (Effexor) and duloxetine (Cymbalta) are also used to treat depression.

Cocaine, which is often used in medical practice as a local anesthetic, produces a temporary feeling of well being in cocaine abusers by similarly blocking the uptake of dopamine. Unfortunately, cocaine and similar drugs can also adversely affect blood flow and heart function when taken in large amounts—leading to death in some individuals.

Cycle of LIFE

Nervous System Cells

The development of nerve tissue begins from the *ectoderm* during the first weeks after conception and exhibits many complicated stages before becoming mature by early adulthood. The most rapid and obvious development of nervous tissue occurs in the womb and for several years shortly after birth.

One of the most remarkable aspects of neural development involves the way in which nervous cells become organized to form a coordinated network spread throughout the body. Although we know very little about these processes, we do know that neurons require the coordinated actions of several agents to promote proper "wiring" of the nervous system. For example, we know that *nerve growth factors* released by effector cells stimulate the growth of neuron processes and help direct them to the proper destination.

During the first years of neural development, synapses are made, broken, and reformed until the basic organization of the nervous system is intact. Neurobiologists believe that the sensory stimulation that serves as the essence of early learning in infants and children has a critical role in directing the formation of synapses in the nervous system. The formation of new synapses, selective strengthening of existing synapses, and selective removal of synapses are thought to be primary physiological mechanisms of learning and memory.

In older adulthood, our brain processing may slow a bit. But that often allows us to make better use of stored memories and learned problem-solving skills to exhibit enhanced wisdom. In advanced old age, degeneration of neurons, glia, and the blood vessels that supply them may destroy certain portions of nervous tissue. This, coupled with age-related syndromes such as *Alzheimer disease (AD)*, may produce a loss of memory, coordination, and other neural functions sometimes referred to as *senility*.

the BIG picture

Nervous System Cells and the Whole Body

Neurons, the conducting cells of the nervous system, act as the "wiring" that connects the structures needed to maintain the internal constancy that is so vital to our survival. They also form processing "circuits" that make decisions regarding appropriate responses to stimuli that threaten our internal constancy. Sensory neurons act as sensors or receptors that detect changes in our external and internal environment that may be potentially threatening. Sensory neurons then relay this information to integrator mechanisms in the central nervous system. There, the information is processed—often by one or more interneurons—and an outgoing response signal is relayed to effectors by way of motor neurons. At the effector, a chemical messenger or neurotransmitter triggers a response that tends to restore homeostatic balance. Neurotransmitters released into the bloodstream, where they are called *hormones,* can enhance and prolong such homeostatic responses.

Of course, neurons do much more than simply respond to stimuli in a preprogrammed manner. Circuits of interneurons are capable of remembering, learning new responses, generating rational and creative thought, and implementing other complex processes. The exact mechanisms of many of these complex integrative functions are yet to be discovered, but you will learn some of what we already know in Chapter 14, in our discussion of the central nervous system.

UNIT 3

MECHANISMS of DISEASE

DISORDERS OF NERVOUS SYSTEM CELLS

Most disorders of nervous system cells involve glia rather than neurons. **Multiple sclerosis (MS),** one of the **myelin disorders** discussed in Box 13-2 (p. 386), is a good example of this principle. A few other important disorders involving glia are described in the following paragraphs.

The general name for tumors arising in nervous system structures is **neuroma** (noo-ROH-mah). Tumors do not usually develop directly from neurons but from glia, membrane tissues, and blood vessels. A common type of brain tumor—**glioma** (glee-OH-mah)—occurs in glia. Gliomas are usually benign but may still be life threatening. Because they often develop in deep areas of the brain, they are difficult to treat. Untreated gliomas may grow to a size that disrupts normal brain function—perhaps leading to death. Most malignant tumors of glia and other tissues in the nervous system do not originate there but are secondary tumors resulting from metastasis of cancer cells from the breast, lung, or other organs.

Tumors in the Central Nervous System

Astrocytoma is a type of glioma that originates from astrocytes. It is a slow-growing, infiltrating tumor of the brain that usually appears during the fourth decade of life. Seizures, headaches, or neurological deficits indicative of the area of the brain involved are usual presenting symptoms. **Glioblastoma multiforme,** a highly malignant form of astrocytic tumor, spreads throughout the white matter of the brain. Because of its invasive nature, surgical removal is difficult and the average survival is less than 1 year. **Ependymoma** is a glial tumor arising from ependymal cells, which line the fluid-filled cavities *(ventricles)* of the brain and spinal cord. This is the most common glioma in

children but can occur in adults. Because of its location, fluid pathways are obstructed, causing increased pressure in the brain, which in turn causes neurological damage. Surgical correction is possible, and the average postoperative survival is roughly 5 years. Glioma of oligodendrocytes is called **oligodendroglioma.** This tumor commonly occurs in the anterior portion of the brain and has a peak incidence at 40 years of age. The prognosis is better, with an average survival of 10 years after the onset of symptoms.

Tumors in the Peripheral Nervous System

Glial tumors can also develop in or on the cranial nerves. **Acoustic neuroma** is a lesion of the sheath of Schwann cells surrounding the eighth cranial nerve, responsible for hearing and balance. This tumor may be only the size of a pea or walnut, but the afflicted person typically experiences difficulty deciphering speech through the affected ear, dizziness, tinnitus (ringing in the ear), and a slow, progressive hearing loss. With the use of microsurgical techniques, the tumor can be removed, but some nerve damage caused by the surgical procedure is common.

Glial tumors can also appear in other regions of the peripheral nervous system. **Neurofibromatosis** (nooroh-fye-broh-mah-TOH-sis) is a group of genetic diseases often characterized by numerous fibrous neuromas and skin spots throughout the body (Figure 13-33). Although usually inherited, many cases occur from spontaneous mutations of the genetic code in an individual—who can then pass along the disease to offspring. The tumors are benign, appearing first as small nodules in the Schwann cells of nerve fibers in the skin. In some cases, involvement spreads in the form of large, disfiguring fibrous tumors that develop in many areas of the body, including muscles, bones, and internal organs.

FIGURE 13-33

Neurofibromatosis. Multiple tumors of supportive cells in nerves of the skin that are characteristic of this group of genetic conditions.

UNIT 3

CASE study

Kelly had been having difficulty focusing her eyes for a couple of weeks. She assumed her recent lack of sleep was the cause. But when she started dropping her keys and feeling unsteady when walking down the stairs, she became worried enough to go to the doctor. After the results of several tests were known, the doctor told her she had myasthenia gravis. This is a disease in which the body's own white blood cells start attacking acetylcholine receptors.

1. What's the connection between acetylcholine and Kelly's symptoms?
   a. Acetylcholine is a hormone released during stress
   b. Acetylcholine is found primarily in sensory neuron connections
   c. Acetylcholine is found primarily in motor neuron connections
   d. Acetylcholine affects communication primarily with smooth muscles

2. If the binding of acetylcholine opened sodium channels on the postsynaptic membrane, this would cause a temporary _____, called an _____.
   a. depolarization; excitatory postsynaptic potential
   b. hyperpolarization; excitatory postsynaptic potential
   c. depolarization; inhibitory postsynaptic potential
   d. hyperpolarization; inhibitory postsynaptic potential

Some muscle relaxants used during surgery bind to acetylcholine receptors, effectively blocking the action of acetylcholine—just as in myasthenia gravis. The drugs (anticholinesterases) used after surgery to reverse the relaxants are the same as those used to treat myasthenia gravis.

3. What do you think the action of these drugs would be?
   a. Blocking the release of acetylcholine
   b. Blocking the action of acetylcholinesterase
   c. Increasing the production of choline
   d. Increasing the action of acetylcholinesterase

INTRODUCTION

A. Function of nervous system, along with the endocrine system, is to communicate
B. Nervous system made up of the brain, spinal cord, and nerves (Figure 13-1)

ORGANIZATION OF THE NERVOUS SYSTEM

A. Organized to detect changes in internal and external environments, evaluate the information, and initiate an appropriate response
B. Subdivided into smaller "systems" by location (Figure 13-2)
   1. Central nervous system (CNS)
      a. Structural and functional center of the entire nervous system
      b. Consists of the brain and spinal cord
      c. Integrates sensory information, evaluates it, and initiates an outgoing response
   2. Peripheral nervous system (PNS)
      a. Nerves that lie in the "outer regions" of the nervous system
      b. Cranial nerves—originate from the brain
      c. Spinal nerves—originate from the spinal cord
C. Afferent and efferent divisions
   1. Afferent division—consists of all incoming sensory pathways
   2. Efferent division—consists of all outgoing motor pathways
D. "Systems" categorized according to types of organs they innervate (Figure 13-2)
   1. Somatic nervous system (SNS)
      a. Somatic motor division carries information to the somatic effectors (skeletal muscles)
      b. Somatic sensory division carries feedback information to somatic integration centers in the CNS
   2. Autonomic nervous system (ANS)
      a. Efferent division of ANS carries information to the autonomic or visceral effectors (smooth and cardiac muscles, glands, and adipose and other tissues)
         (1) Sympathetic division—prepares the body to deal with immediate threats to the internal environment; produces "fight-or-flight" response
         (2) Parasympathetic division—coordinates the body's normal resting activities; sometimes called the "rest-and-repair" division

b. Visceral sensory division carries feedback information to autonomic integrating centers in the CNS

CELLS OF THE NERVOUS SYSTEM

A. Glia (neuroglia)
1. Glial cells support the neurons
2. Five major types of glia (Figure 13-3)
   a. Astrocytes (in CNS)
      (1) Star-shaped, largest, and most numerous type of glia
      (2) Cell extensions connect to both neurons and capillaries
      (3) Astrocytes transfer nutrients from the blood to the neurons
      (4) Form tight sheaths around brain capillaries, which, with tight junctions between capillary endothelial cells, constitute the blood-brain barrier (BBB)
   b. Microglia (in CNS)
      (1) Small, usually stationary cells
      (2) In inflamed brain tissue, they enlarge, move about, and carry on phagocytosis
   c. Ependymal cells (in CNS)
      (1) Resemble epithelial cells and form thin sheets that line fluid-filled cavities in the CNS
      (2) Some produce fluid; others aid in circulation of fluid
   d. Oligodendrocytes (in CNS)
      (1) Smaller than astrocytes with fewer processes
      (2) Hold nerve fibers together and produce the myelin sheath
   e. Schwann cells (in PNS)
      (1) Found only in peripheral neurons
      (2) Support nerve fibers and form myelin sheaths (Figure 13-4)
      (3) Myelin sheath gaps are often called *nodes of Ranvier*
      (4) Neurilemma is formed by cytoplasm of Schwann cell (neurolemmocyte) wrapped around the myelin sheath; essential for nerve regrowth
      (5) Neuronal sheath is the myelin sheath plus the neurilemma (that is, the whole Schwann wrapping around the axon)
      (6) Satellite cells are Schwann cells that cover and support cell bodies in the PNS

B. Neurons
1. Excitable cells that initiate and conduct impulses that make possible all nervous system functions
2. Components of neurons (Figure 13-5)
   a. Cell body (perikaryon)
      (1) Ribosomes, rough endoplasmic reticulum (ER), Golgi apparatus
         (a) Provide protein molecules (neurotransmitters) needed for transmission of nerve signals from one neuron to another
         (b) Neurotransmitters are packaged into vesicles
         (c) Provide proteins for maintaining and regenerating nerve fibers
      (2) Mitochondria provide energy (ATP) for neuron; some are transported to end of axon
   b. Dendrites
      (1) Each neuron has one or more dendrites, which branch from the cell body
      (2) Conduct nerve signals to the cell body of the neuron
      (3) Distal ends of dendrites of sensory neurons are receptors
      (4) Dendritic spines—small knoblike protrusions on dendrites of some brain neurons; serve as connection points for axons of other neurons
   c. Axon
      (1) A single process extending from the axon hillock, sometimes covered by a fatty layer called a *myelin sheath* (Figure 13-6)
      (2) Conducts nerve impulses away from the cell body of the neuron
      (3) Distal tips of axons are telodendria, each of which terminates in a synaptic knob
      (4) Axon varicosities—swellings that make contact (synapse) with other cells
   d. Cytoskeleton
      (1) Microtubules and microfilaments, as well as neurofibrils (bundles of neurofilaments)
      (2) Allow the rapid transport of small organelles (Figure 13-7)
         (a) Vesicles (some containing neurotransmitters), mitochondria
         (b) Motor molecules shuttle organelles to and from the far ends of a neuron
   e. Functional regions of the neuron (Figure 13-8)
      (1) Input zone—dendrites and cell body
      (2) Summation zone—axon hillock
      (3) Conduction zone—axon
      (4) Output zone—telodendria and synaptic knobs of axon

C. Classification of neurons
1. Structural classification—classified according to number of processes extending from cell body (Figure 13-9)
   a. Multipolar—one axon and several dendrites
   b. Bipolar—only one axon and one dendrite; least numerous kind of neuron
   c. Unipolar (pseudounipolar)—one process comes off neuron cell body but divides almost immediately into two fibers: central fiber and peripheral fiber
2. Functional classification (Figure 13-10)
   a. Afferent (sensory) neurons—conduct impulses to spinal cord or brain
   b. Efferent (motor) neurons—conduct impulses away from spinal cord or brain toward muscles or glandular tissue
   c. Interneurons

D. Reflex arc
1. A signal conduction route to and from the CNS, with the electrical signal beginning in receptors and ending in effectors

2. Three-neuron arc—most common; consists of afferent neurons, interneurons, and efferent neurons (Figure 13-11)
   a. Afferent neurons—conduct impulses to the CNS from the receptors
   b. Efferent neurons—conduct impulses from the CNS to effectors (muscle or glandular tissue)
3. Two-neuron arc—simplest form; consists of afferent and efferent neurons
4. Synapse
   a. Where nerve signals are transmitted from one neuron to another
   b. Two types: electrical and chemical; chemical synapses are typical in the adult
   c. Chemical synapses are located at the junction of the synaptic knob of one neuron and the dendrites or cell body of another neuron

NERVES AND TRACTS

A. Nerves—bundles of peripheral nerve fibers held together by several layers of connective tissue (Figure 13-12)
   1. Endoneurium—delicate layer of fibrous connective tissue surrounding each nerve fiber
   2. Perineurium—connective tissue holding together fascicles (bundles of fibers)
   3. Epineurium—fibrous coat surrounding numerous fascicles and blood vessels to form a complete nerve
B. Tracts—bundles of nerve fibers within the CNS
   1. Unlike nerves, tracts do not have connective tissue coverings
   2. Individual fibers may extend through both a nerve and a tract as it passes into or out of the CNS
C. White matter
   1. PNS—myelinated nerves
   2. CNS—myelinated tracts
D. Gray matter
   1. Made up of cell bodies and unmyelinated fibers
   2. CNS—referred to as *nuclei*
   3. PNS—referred to as *ganglia*
E. Mixed nerves
   1. Contain sensory and motor neurons
   2. Sensory nerves—nerves with predominantly sensory neurons
   3. Motor nerves—nerves with predominantly motor neurons

REPAIR OF NERVE FIBERS

A. Mature neurons are incapable of cell division; therefore damage to nervous tissue can be permanent
B. Neurons have limited capacity to repair themselves
C. If the damage is not extensive, the cell body and neurilemma are intact, and scarring has not occurred, nerve fibers can be repaired
D. Stages of repair of an axon in a peripheral motor neuron (Figure 13-13)
   1. Following injury, distal portion of axon and myelin sheath degenerates
   2. Macrophages remove the debris
   3. Remaining neurilemma and endoneurium form a tunnel from the point of injury to the effector
   4. New Schwann cells grow in the tunnel to maintain a path for regrowth of the axon
   5. Cell body reorganizes its Nissl bodies to provide the needed proteins to extend the remaining healthy portion of the axon
   6. Axon "sprouts" appear
   7. When "sprout" reaches tunnel, its growth rate increases
   8. The skeletal muscle cell atrophies until the nervous connection is reestablished
E. In CNS, similar repair of damaged nerve fibers is unlikely

NERVE IMPULSES

A. Membrane potentials
   1. All living cells maintain a difference in the concentration of ions across their membranes
   2. Membrane potential—slight excess of positively charged ions on the outside of the membrane and slight deficiency of positively charged ions on the inside of the membrane (Figure 13-14)
   3. Difference in electrical charge is called *potential* because it is a type of stored energy
   4. Polarized membrane—a membrane that exhibits a membrane potential
   5. Magnitude of potential difference between the two sides of a polarized membrane is measured in volts (V) or millivolts (mV); the sign of a membrane's voltage indicates the charge on the inside surface of a polarized membrane
B. Resting membrane potential (RMP)
   1. Membrane potential maintained by a nonconducting neuron's plasma membrane; typically –70 mV
   2. The slight excess of positive ions on a membrane's outer surface is produced by ion transport mechanisms and the membrane's permeability characteristics
   3. The membrane's selective permeability characteristics help maintain a slight excess of positive ions on the outer surface of the membrane (Figure 13-15)
   4. Sodium-potassium pump (Figure 13-16)
      a. Active transport mechanism in plasma membrane that transports Na^+ and K^+ in opposite directions and at different rates
      b. Maintains an imbalance in the distribution of positive ions, resulting in the inside surface becoming slightly negative with respect to its outer surface
C. Local potentials
   1. Local potentials—slight shift away from the resting membrane in a specific region of the plasma membrane (Figure 13-17)
   2. Excitation—when a stimulus triggers the opening of additional Na^+ channels, allowing the membrane potential to move toward zero (depolarization)
   3. Inhibition—when a stimulus triggers the opening of additional K^+ channels, increasing the membrane potential (hyperpolarization)

4. Local potentials are called *graded potentials* because the magnitude of deviation from the resting membrane potential is proportional to the magnitude of the stimulus

ACTION POTENTIAL

A. Action potential—the membrane potential of a neuron that is conducting an impulse; also known as a *nerve impulse*
B. Mechanism that produces the action potential (Figures 13-18 and 13-19)
   1. When an adequate stimulus triggers stimulus-gated Na^+ channels to open, allowing Na^+ to diffuse rapidly into the cell, a local depolarization is produced
   2. As threshold potential is reached, voltage-gated Na^+ channels open and more Na^+ enters the cell, causing further depolarization
   3. As more Na^+ rushes into cell, the membrane moves rapidly toward and continues in a positive direction to the peak of the action potential
   4. Voltage-gated Na^+ channels stay open for only about 1 ms before they automatically close; action potential is an all-or-none response
   5. After action potential peaks, membrane begins to move back toward the resting membrane potential when K^+ channels open, allowing outward diffusion of K^+; process is known as *repolarization*
   6. Brief period of hyperpolarization occurs, and then the resting membrane potential is restored by the sodium-potassium pumps
C. Refractory period (Figure 13-20)
   1. Absolute refractory period—brief period (lasting approximately 0.5 ms) during which a local area of a neuron's membrane resists restimulation and will not respond to a stimulus, no matter how strong
   2. Relative refractory period—time during which the membrane is repolarized and restoring the resting membrane potential; the few milliseconds after the absolute refractory period; will respond only to a very strong stimulus
D. Conduction of the action potential
   1. At the peak of the action potential, the plasma membrane's polarity is now the reverse of the RMP
   2. The reversal in polarity causes electrical current to flow between the site of the action potential and the adjacent regions of membrane and triggers voltage-gated Na^+ channels in the next segment to open; this next segment exhibits an action potential (Figure 13-21)
   3. This cycle continues to repeat, producing continuous conduction
   4. The action potential never moves backward because of the refractory period
   5. In myelinated fibers, action potentials in the membrane only occur at the nodes of Ranvier; this type of impulse conduction is called *saltatory conduction* (Figure 13-22)
   6. Speed of nerve conduction depends on diameter and on the presence or absence of a myelin sheath

SYNAPTIC TRANSMISSION

A. Two types of synapses (junctions) (Figure 13-23)
   1. Electrical synapses occur where cells joined by gap junctions allow an action potential to simply continue along postsynaptic membrane
   2. Chemical synapses occur where presynaptic cells release chemical transmitters (neurotransmitters) across a tiny gap to the postsynaptic cell, possibly inducing an action potential there
B. Structure of the chemical synapse (Figure 13-25)
   1. Synaptic knob—tiny bulge at the end of a terminal branch of a presynaptic neuron's axon that contains vesicles housing neurotransmitters
   2. Synaptic cleft—space between a synaptic knob and the plasma membrane of a postsynaptic neuron
   3. Arrangements of synapses
      a. Axodendritic—axon signals postsynaptic dendrite; common
      b. Axosomatic—axon signals postsynaptic soma; common
      c. Axoaxonic—axon signals postsynaptic axon; may regulate action potential of postsynaptic axon
   4. Plasma membrane of a postsynaptic neuron—has protein molecules that serve as receptors for the neurotransmitters
C. Mechanism of synaptic transmission (Figure 13-25)—sequence of events is as follows:
   1. Action potential reaches a synaptic knob, causing calcium ions to diffuse into the knob rapidly
   2. Increased calcium concentration triggers the release of neurotransmitter by way of exocytosis
   3. Neurotransmitter molecules diffuse across the synaptic cleft and bind to receptor molecules, causing ion channels to open
   4. Opening of ion channels produces a postsynaptic potential, either an excitatory postsynaptic potential (EPSP) or an inhibitory postsynaptic potential (IPSP)
   5. The neurotransmitter's action is quickly terminated by neurotransmitter molecules being transported back into the synaptic knob (reuptake) and/or metabolized into inactive compounds by enzymes and/or diffused and taken up by nearby glia (Figure 13-26)
D. Summation (Figure 13-28)
   1. Spatial summation—adding together the effects of several knobs being activated simultaneously and stimulating different locations on the postsynaptic membrane, producing an action potential
   2. Temporal summation—when synaptic knobs stimulate a postsynaptic neuron in rapid succession, their effects can summate over a brief period of time to produce an action potential
E. Synapses and memory
   1. Memories are stored by facilitating (or inhibiting) synaptic transmission
   2. Short-term memories (seconds or minutes) may result from axoaxonic facilitation or inhibition of the presynaptic axon terminal

3. Intermediate long-term memory (minutes to weeks) happens when serotonin blocks potassium channels in the presynaptic terminal—thus prolonging the action potential and increasing the amount of neurotransmitter released
4. Long-term memories (months or years) require structural changes at the synapse—for example, more vesicles, more vesicle release sites, more presynaptic terminals, more sensitive postsynaptic membranes

NEUROTRANSMITTERS

A. Neurotransmitters—means by which neurons communicate with one another; there are more than 50 compounds known to be neurotransmitters, and dozens of others are suspected
B. Classification of neurotransmitters—commonly classified by the following:
   1. Function—the function of a neurotransmitter is determined by the postsynaptic receptor; two major functional classifications are excitatory neurotransmitters and inhibitory neurotransmitters; can also be classified according to whether the receptor directly opens a channel or instead uses a second messenger mechanism involving G-protein–coupled receptors (GPCRs) and intracellular signals (Figures 13-29 and 13-30)
   2. Chemical structure—the mechanism by which neurotransmitters cause a change; there are four main classes; since the functions of specific neurotransmitters vary by location, they are usually classified according to chemical structure
C. Small-molecule neurotransmitters (Figure 13-31)
   1. Acetylcholine
      a. Unique chemical structure; acetate (acetyl coenzyme A) with choline
      b. Acetylcholine is deactivated by acetylcholinesterase, with the choline molecules being released and transported back to presynaptic neuron to combine with acetate
      c. Present at various locations, sometimes in an excitatory role; other times, inhibitory
   2. Amines
      a. Synthesized from amino acid molecules
      b. Two categories: monoamines and catecholamines
      c. Found in various regions of the brain, affecting learning, emotions, motor control, and so on
   3. Amino acids
      a. Believed to be among the most common neurotransmitters of the CNS
      b. In the PNS, amino acids are stored in synaptic vesicles and used as neurotransmitters
   4. Other small-molecule transmitters
      a. Nitric oxide (NO) derived from an amino acid
      b. NO from a postsynaptic cell signals the presynaptic neuron, providing feedback in a neural pathway
D. Neuropeptides—large-molecule neurotransmitters
   1. Neuropeptides are short strands of amino acids called polypeptides or peptides (Figure 13-32)
   2. Peptides first discovered to have regulatory effects in the digestive tract; also act as neurotransmitters in the brain
   3. May be secreted by themselves or in conjunction with a second or third neurotransmitter; in this case, neuropeptides act as a neuromodulator, a "co-transmitter" that regulates the effects of the neurotransmitter released along with it
   4. Neurotrophins (neurotrophic [nerve growth] factors) stimulate neuron development but also can act as neurotransmitters or neuromodulators

ROLE OF NERVOUS SYSTEM CELLS

A. Neuron doctrine—proposes neuron is basic structural and functional unit of the nervous system and neurons are independent units connected by chemical synapses
B. Reticular theory—proposes nervous system is best understood as a large integrated network
C. Today, the dominant neuron doctrine has expanded to include concepts of the reticular theory—neurons are distinct units but also participate in a network; some neurons are functionally connected by electrical synapses, and chemical signals can move in two directions at the same synapse
D. Because neuroglia also participate in the neural network, the whole concept of nervous system cell function is rapidly expanding

CYCLE OF LIFE: NERVOUS SYSTEM CELLS

A. Nerve tissue development
   1. Begins in ectoderm
   2. Occurs most rapidly in womb and in first 2 years
B. Nervous cells organize into body network
C. Synapses
   1. Form and re-form until nervous system is intact
   2. Formation of new synapses and strengthening or elimination of old synapses stimulate learning and memory
D. Aging causes degeneration of the nervous system, which may lead to senility

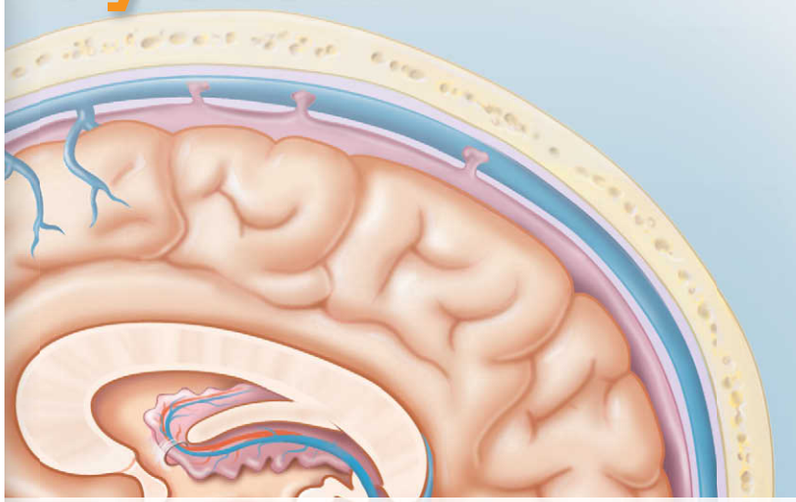
THE BIG PICTURE: NERVOUS SYSTEM CELLS AND THE WHOLE BODY

A. Neurons act as the "wiring" that connects structures needed to maintain homeostasis
B. Sensory neurons—act as receptors to detect changes in the internal and external environment; relay information to integrator mechanisms in the CNS
C. Information is processed, and a response is relayed to the appropriate effectors through the motor neurons
D. At the effector, neurotransmitter triggers a response to restore homeostasis
E. Neurotransmitters released into the bloodstream are called *hormones*
F. Neurons are responsible for more than just responding to stimuli; circuits are capable of remembering or learning new responses, generation of thought, and so on

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Briefly explain the general function the nervous system performs for the body.
2. Identify the other body system that performs the same general function.
3. Describe the function of sodium and potassium in the generation of an action potential.
4. Why is an action potential an all-or-none response?
5. How does the myelin sheath affect the speed of an action potential? What about the diameter of the nerve fiber?
6. Describe the structure of a synapse.
7. Describe the series of events that mediate conduction across synapses.
8. List and describe the four main chemical classes of transmitters.
9. Describe the actions of acetylcholine.
10. List and describe disorders of the nervous system cells.



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Compare and contrast the characteristics of the central nervous system and the peripheral nervous system. Also, explain how the somatic and autonomic nervous systems could be included in the afferent and efferent divisions.
2. There are relatively few neurons in the brain. How would you describe the other cells in the brain? What do they do?
3. All neurons have axons and dendrites. Explain where these parts of the neuron are located in multipolar, bipolar, and unipolar neurons.
4. Compare and contrast white and gray matter. What would result if there were a loss of myelination?
5. Explain how high doses of methylprednisolone act to reduce the severity of spinal cord injuries.
6. Nerve fibers in the peripheral nervous system are much more successful than nerve fibers in the central nervous system in repairing themselves. How would you explain this difference?
7. Define *potential*. The following is a list of times and charges taken during a nerve impulse. Identify them as being either an action potential or not and as occurring either during the absolute or relative refractory period. (Assume the stimulus starts at 0 msec.)
   0 mV at 1 msec
   −50 mV at 0.5 msec
   +25 mV at 1.5 msec
   +25 mV at 3 msec
8. Describe the mechanisms that allow subthreshold stimuli to generate an action potential.
9. Many antibiotics that should kill the causative agents of meningitis are ineffective if given orally. Can you explain the anatomical mechanism that could cause this ineffectiveness?
10. Explain one of the ways an anesthetic may relieve the sensation of pain.
11. Referred pain is a condition in which the pain is not felt where the injury is actually occurring but rather is felt over a wider area or in some other part of the body. What structural aspect of the nervous system might explain referred pain?

14 Central Nervous System

LANGUAGE OF SCIENCE

HINT

Before reading the chapter, say each of these terms out loud. This will help you avoid stumbling over them as you read.

amygdaloid nucleus
(ah-MIG-dah-loyd NOO-klee-us)
[*amygdal-* **almond,** *-oid* **like**] *pl.,* nuclei

anterior corticospinal tract
(an-TEER-ee-or KOR-ti-koh-spy-nal)

Cycle of Life: Central Nervous System, 451
The Big Picture: The Central Nervous System and the Whole Body, 452
Mechanisms of Disease, 452
Case Study, 456

Recall from Chapter 13 that the nervous system is said to be composed of two major divisions: the central nervous system (CNS) and the peripheral nervous system (PNS). The reason for designating two distinct divisions is to make the study of the nervous system easier. In this chapter, we discuss the part of the nervous system that lies at the center of the regulatory process: the central nervous system. Comprising both the brain and the spinal cord, the central nervous system is the principal integrator of sensory input and motor output. Thus the central nervous system is capable of evaluating incoming information and formulating responses to changes that threaten our homeostatic balance.

This chapter begins with a description of the protective coverings of the brain and spinal cord. After that, we briefly discuss the watery cerebrospinal fluid (CSF) *and the spaces in which it is found. We then outline the overall structure and function of the major organs of the central nervous system, beginning at the bottom with the spinal cord; this is the simplest and least complex part of the CNS. Then our focus moves upward to the more complex brain, beginning first with the narrow brainstem (Figure 14-1) and the roughly spherical cerebellum attached to its dorsal surface. Again shifting our attention upward, we describe the structure and function of the diencephalon and then move on to a discussion of the cerebrum. As we move up the central nervous system, the complexity of both structure and function increases. The spinal cord mediates simple reflexes, whereas the brainstem and diencephalon are involved in the regulation of the more complex maintenance functions, such as regulation of heart rate and breathing. The cerebral hemispheres, which together form the largest part of the brain, perform complex integrative functions such as conscious thought, learning, memory, language, and problem solving. We end the chapter with a discussion of the somatic sensory pathways and the somatic motor pathways. This prepares us for Chapter 15, which covers the peripheral nervous system, Chapter 16, which covers autonomic regulation of vital functions, and Chapter 17, which covers the sense organs.*

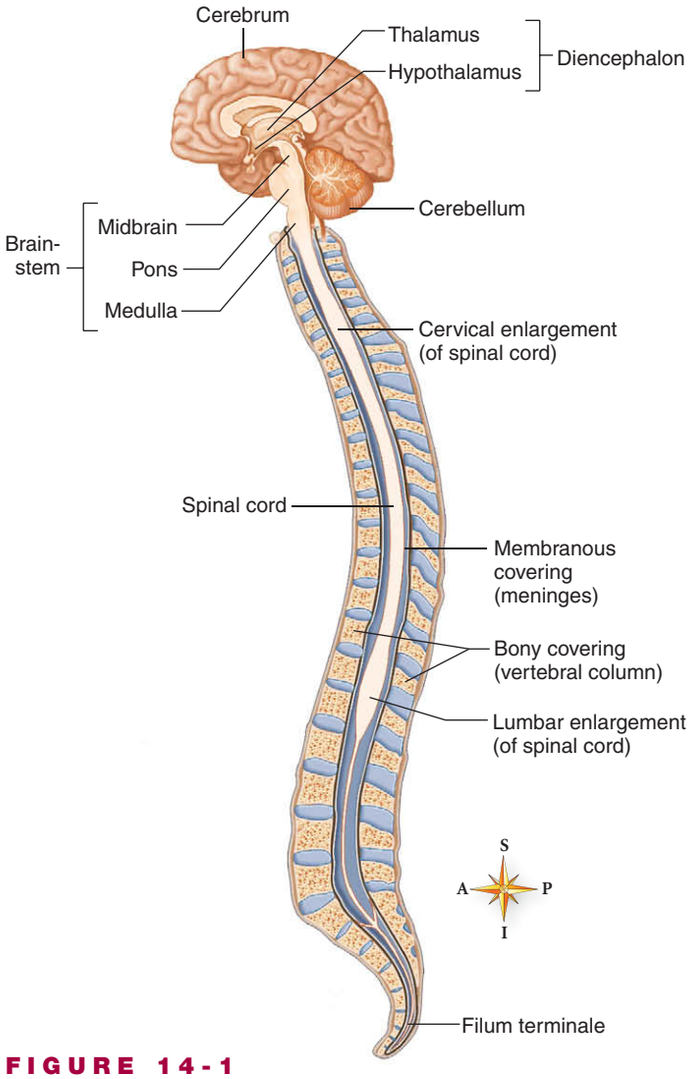

FIGURE 14-1

The central nervous system. Details of both the brain and the spinal cord are easily seen in this figure.

COVERINGS OF THE BRAIN AND SPINAL CORD

Because the brain and spinal cord are both delicate and vital, nature has provided them with two protective coverings. The outer covering consists of bone: cranial bones encase the brain; vertebrae encase the spinal cord. The inner covering consists of membranes known as **meninges.** Three distinct layers compose the meninges:

1. Dura mater
2. Arachnoid mater
3. Pia mater

Observe their respective locations in Figures 14-2 and 14-3. The dura mater, made of strong white fibrous tissue, serves as the outer layer of the meninges and also as the inner periosteum of the cranial bones. The arachnoid mater, a delicate, spiderweb-like layer, lies between the dura mater and the pia mater, or innermost layer of the meninges. The transparent pia mater adheres to the outer surface of the brain and spinal cord and contains blood vessels.

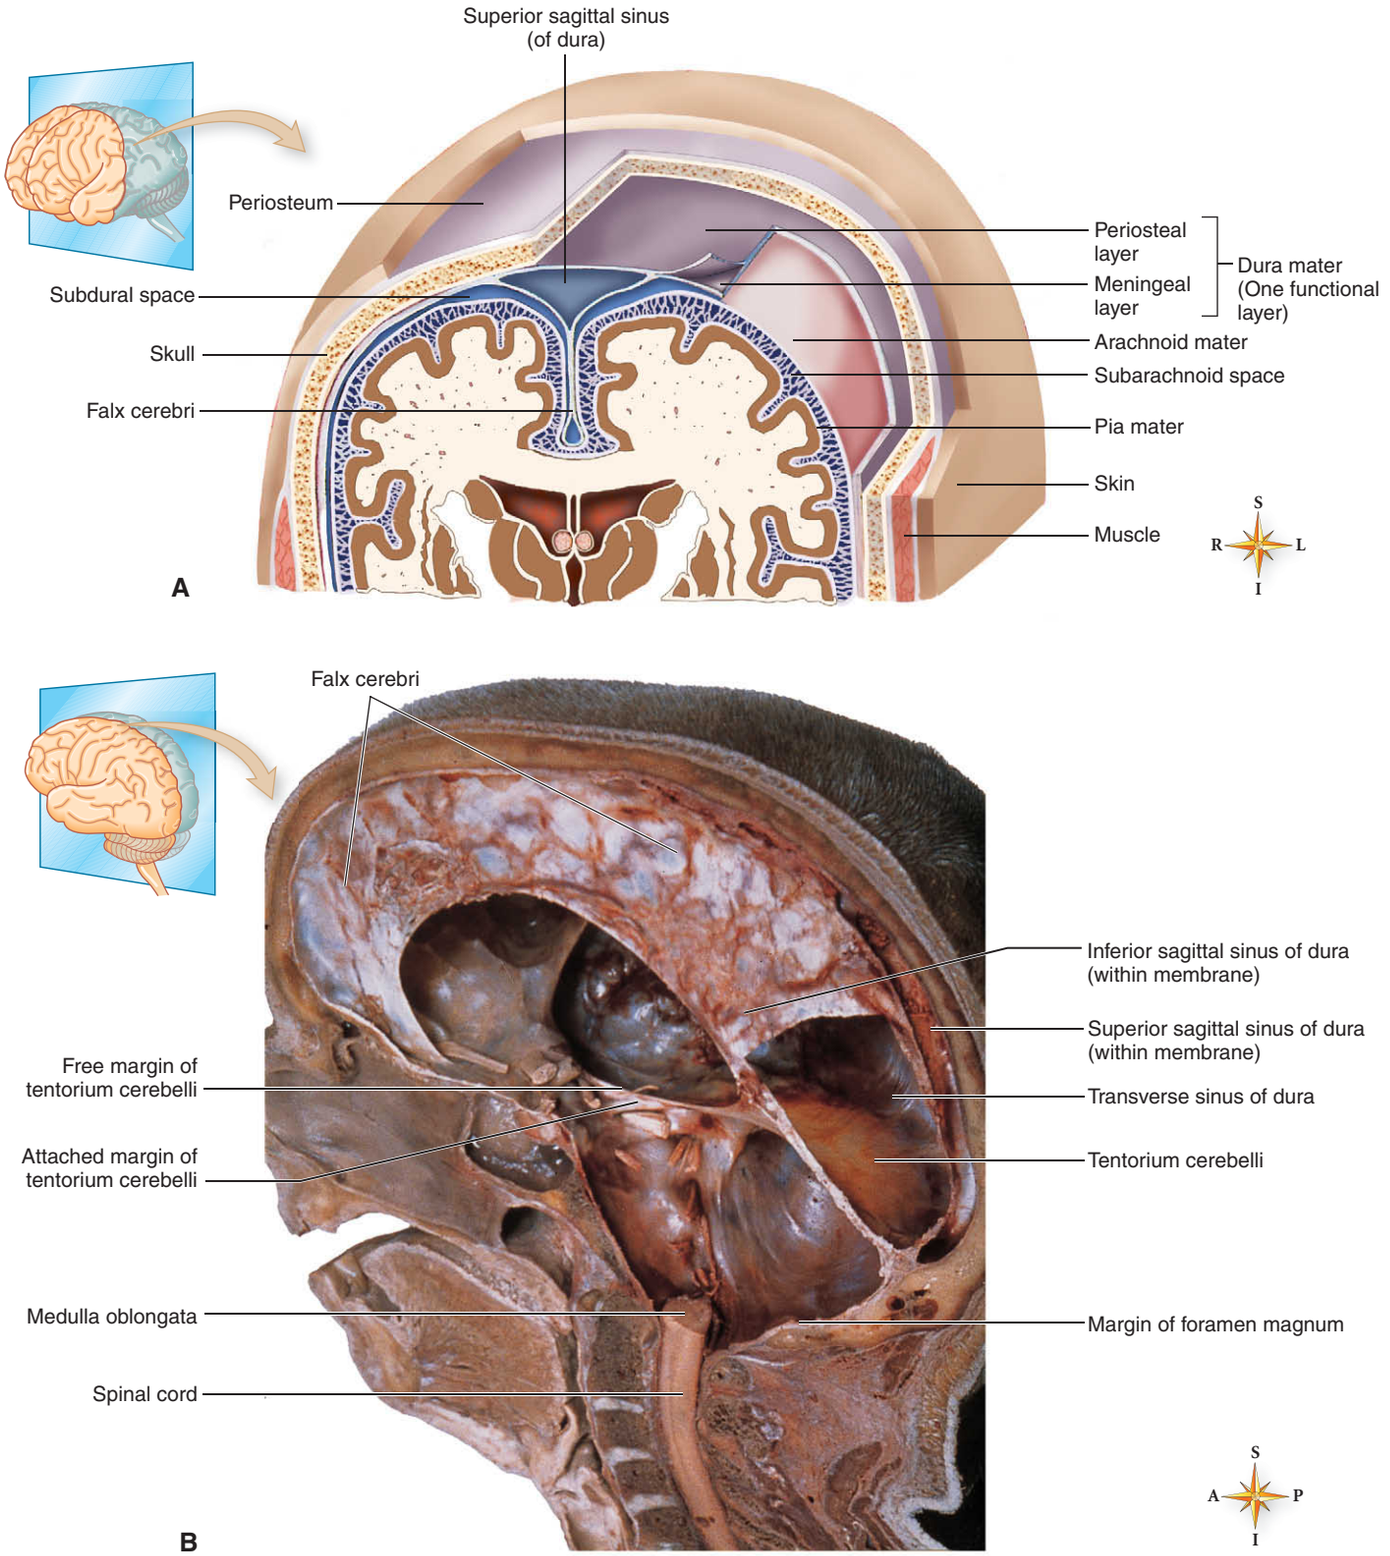

FIGURE 14-2

Coverings of the brain. A, Frontal section of the superior portion of the head, as viewed from the front. Both the bony and the membranous coverings of the brain can be seen. **B,** Sagittal section of the skull, viewed from the left. The dura mater has been retained in this specimen to show how it lines the inner roof of the cranium and the falx cerebri extending inward.

The dura mater has three important inward extensions:

1. **Falx cerebri.** The falx cerebri projects downward into the longitudinal fissure to form a kind of partition between the two cerebral hemispheres. The Latin word *falx* means "sickle" and refers to the curving sickle shape of this partition as it extends from the roof of the cranial cavity (see Figure 14-2, *B*).
2. **Falx cerebelli.** The falx cerebelli is a sickle-shaped extension that separates the two halves, or hemispheres, of the cerebellum.

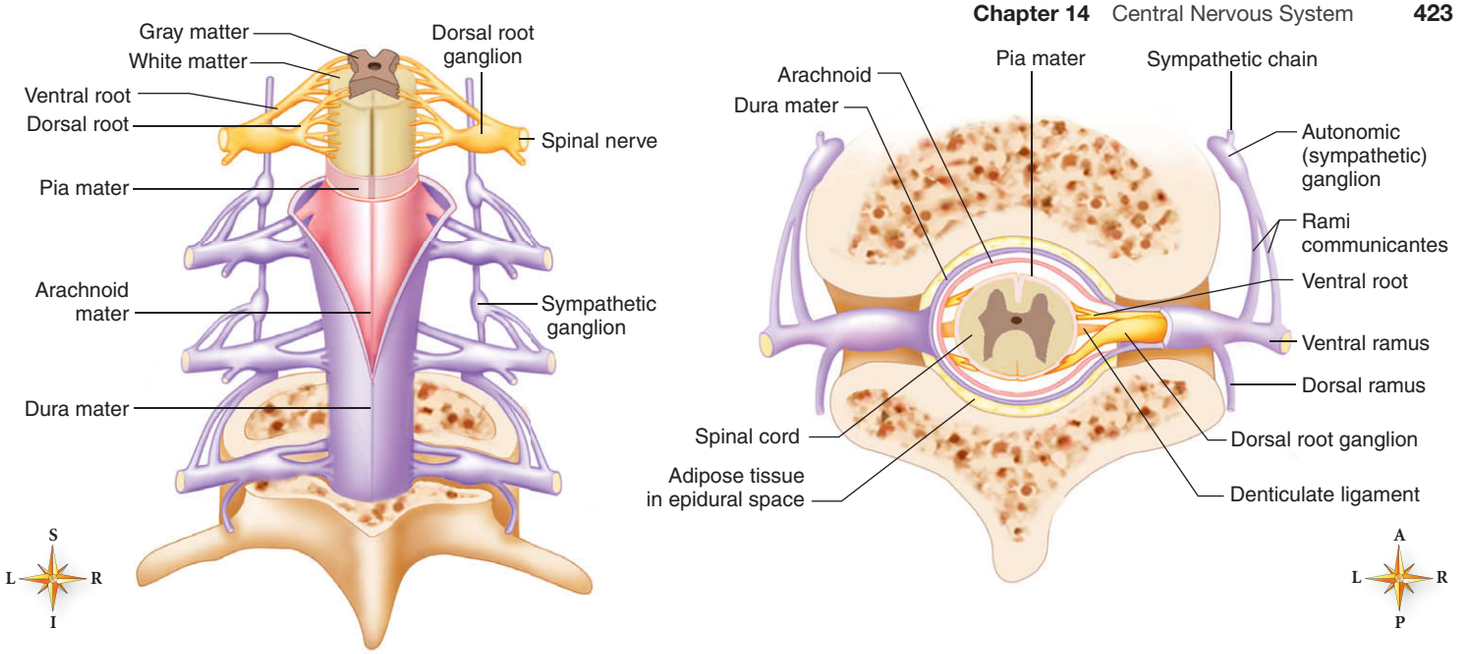

FIGURE 14-3

Coverings of the spinal cord. The dura mater is shown in purple. Note how it extends to cover the spinal nerve roots and nerves. The arachnoid is highlighted in pink and the pia mater in orange.

3. **Tentorium cerebelli.** The tentorium cerebelli separates the cerebellum from the cerebrum. It is called a *tentorium* (meaning "tent") because it forms a tentlike covering over the cerebellum.

Figure 14-2 shows a large space within the dura, where the falx cerebri begins to descend between the left and right cerebral hemispheres. This space, called the *superior sagittal sinus*, is one of several dural sinuses. Dural sinuses function as venous reservoirs, collecting blood from brain tissues for the return trip to the heart.

A number of spaces lie between and around the meninges (see Figure 14-2). Three of these spaces are the following:

1. **Epidural space.** The epidural ("on the dura") space is immediately outside the dura mater but inside the bony coverings of the spinal cord. It contains a supporting cushion of fat and other connective tissues. Around the brain, because the dura mater is continuous with the periosteum on the inside face of the cranial bones, no epidural space is normally present.
2. **Subdural space.** The subdural ("under the dura") space is between the dura mater and arachnoid mater. The subdural space contains a small amount of lubricating serous fluid.
3. **Subarachnoid space.** As its name suggests, the *subarachnoid space* is under the arachnoid and outside the pia mater. This space contains a significant amount of cerebrospinal fluid.

The meninges of the cord (see Figure 14-3) continue on down inside the spinal cavity for some distance below the end of the spinal cord. The pia mater forms a slender filament known as the **filum terminale** (see Figure 14-1). At the level of the third segment of the sacrum, the filum terminale blends with the dura mater to form a fibrous cord that disappears in the periosteum of the coccyx.

Infections of the meninges are discussed in Box 14-1.

Box 14-1 | HEALTH matters

Meningitis

Infection or inflammation of the meninges is termed *meningitis.* It most often involves the arachnoid and pia mater, or the *leptomeninges* ("thin meninges"). Meningitis is most commonly caused by bacteria such as *Neisseria meningitidis* (meningococcus), *Streptococcus pneumoniae,* or *Haemophilus influenzae.* However, viral infections, mycoses (fungal infections), and tumors also may cause inflammation of the meninges. Individuals with meningitis usually complain of fever and severe headaches, as well as neck stiffness and pain. Signs also include avoidance of bright lights and loud sounds, lethargy, and confusion. Persons experiencing these symptoms, some of which mimic the flu, should seek medical help immediately. In infants and very young children, so-called projective vomiting is common. College campuses are often the sites for localized outbreaks of meningitis, and several bacterial forms are highly contagious.

Depending on the primary cause, meningitis may be mild and self-limiting or may progress to a severe, even fatal, condition. If only the spinal meninges are involved, the condition is called *spinal meningitis.* A lumbar puncture ("spinal tap") can be diagnostic, especially for bacterial meningitis such as the type caused by *H. influenzae.* Spinal meningitis must be treated immediately to avoid an increase in intracranial pressure and damage to the nervous system. If not treated quickly, meningitis can lead to deafness, deficits in cognitive ability, and permanent brain disorders such as epilepsy. Meningitis caused by *H. influenzae* type B, pneumococci bacteria, or the mumps virus can be prevented by immunization.

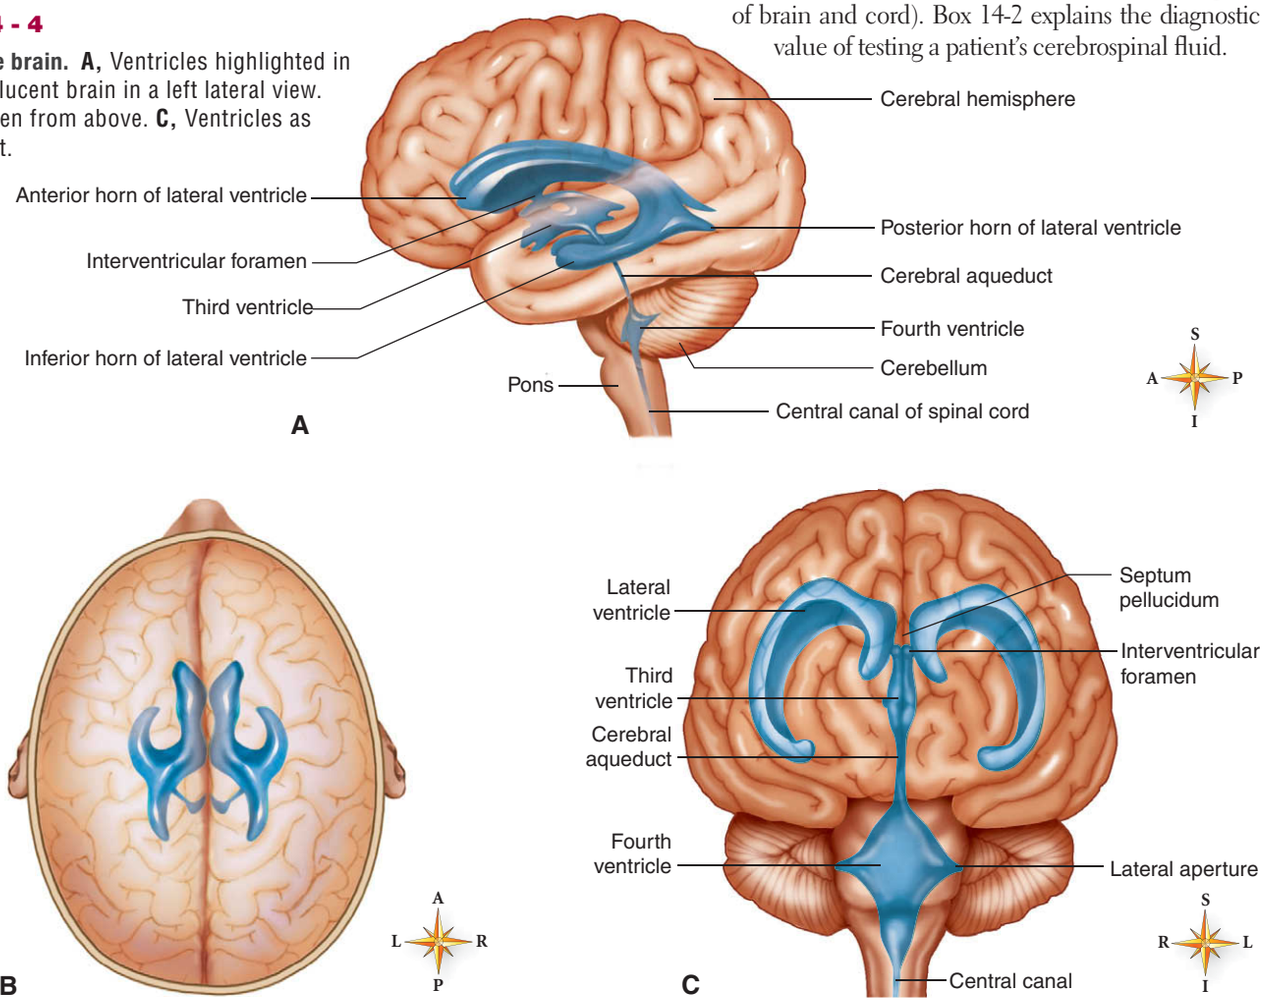
CEREBROSPINAL FLUID

In addition to its bony and membranous coverings, nature has further protected the brain and spinal cord against injury by providing a cushion of fluid both around the organs and within them. This fluid is the **cerebrospinal fluid (CSF).** The CSF does more than simply provide a supportive, protective cushion, however. It is also a reservoir of circulating fluid that, along with blood, the brain monitors for changes in the internal environment. For example, changes in the carbon dioxide (CO_2) content of CSF trigger homeostatic responses in the respiratory control centers of the brainstem that help regulate the overall CO_2 content and pH of the body.

Fluid Spaces

Cerebrospinal fluid is found in the subarachnoid space around the brain and spinal cord and within the cavities and canals of the brain and spinal cord.

The four large, fluid-filled spaces within the brain are called **ventricles.** Two of them, the lateral (or first and second) ventricles, are located one in each hemisphere of the cerebrum. As you can see in Figure 14-4, the third ventricle is little more than a thin, vertical pocket of fluid below and medial to the lateral ventricles. The fourth ventricle is a tiny, diamond-shaped space where the cerebellum attaches to the back of the brainstem. Actually, the fourth ventricle is simply a slight expansion of the central canal extending up from the spinal cord.



Formation and Circulation of Cerebrospinal Fluid

Formation of CSF occurs mainly by separation of fluid from blood in the **choroid plexuses.** Choroid plexuses are networks of capillaries that project from the pia mater into the lateral ventricles and into the roofs of the third and fourth ventricles. Each choroid plexus is covered with a sheet of a special type of ependymal (glial) cell that releases the CSF into the fluid spaces. From each lateral ventricle the fluid seeps through an opening, the *interventricular foramen (of Monro)*, into the third ventricle, then through a narrow channel, the *cerebral aqueduct (of Sylvius)*, into the fourth ventricle (Figure 14-5). Some of the fluid moves from the fourth ventricle directly into the central canal of the cord. Some of it moves out of the fourth ventricle through openings in its roof, two *lateral foramina (of Luschka)* and one *median foramen (of Magendie)*. These openings allow CSF to move into the *cisterna magna*, a space behind the medulla that is continuous with the subarachnoid space around the brain and cord. The fluid circulates in the subarachnoid space and then is absorbed into venous blood through the *arachnoid villi* (fingerlike projections of the arachnoid mater into the brain's venous sinuses). Briefly, here is the circulation route of cerebrospinal fluid: it is formed as fluid is separated from blood in the choroid plexuses, then it flows into the ventricles of the brain, circulates through the ventricles and into the central canal and subarachnoid spaces, and is then absorbed back into blood.

The amount of CSF in the average adult is about 140 ml (about 23 ml in the ventricles and 117 ml in the subarachnoid space of brain and cord). Box 14-2 explains the diagnostic value of testing a patient's cerebrospinal fluid.

FIGURE 14-4

Fluid spaces of the brain. A, Ventricles highlighted in blue within a translucent brain in a left lateral view. **B,** Ventricles as seen from above. **C,** Ventricles as seen from the front.

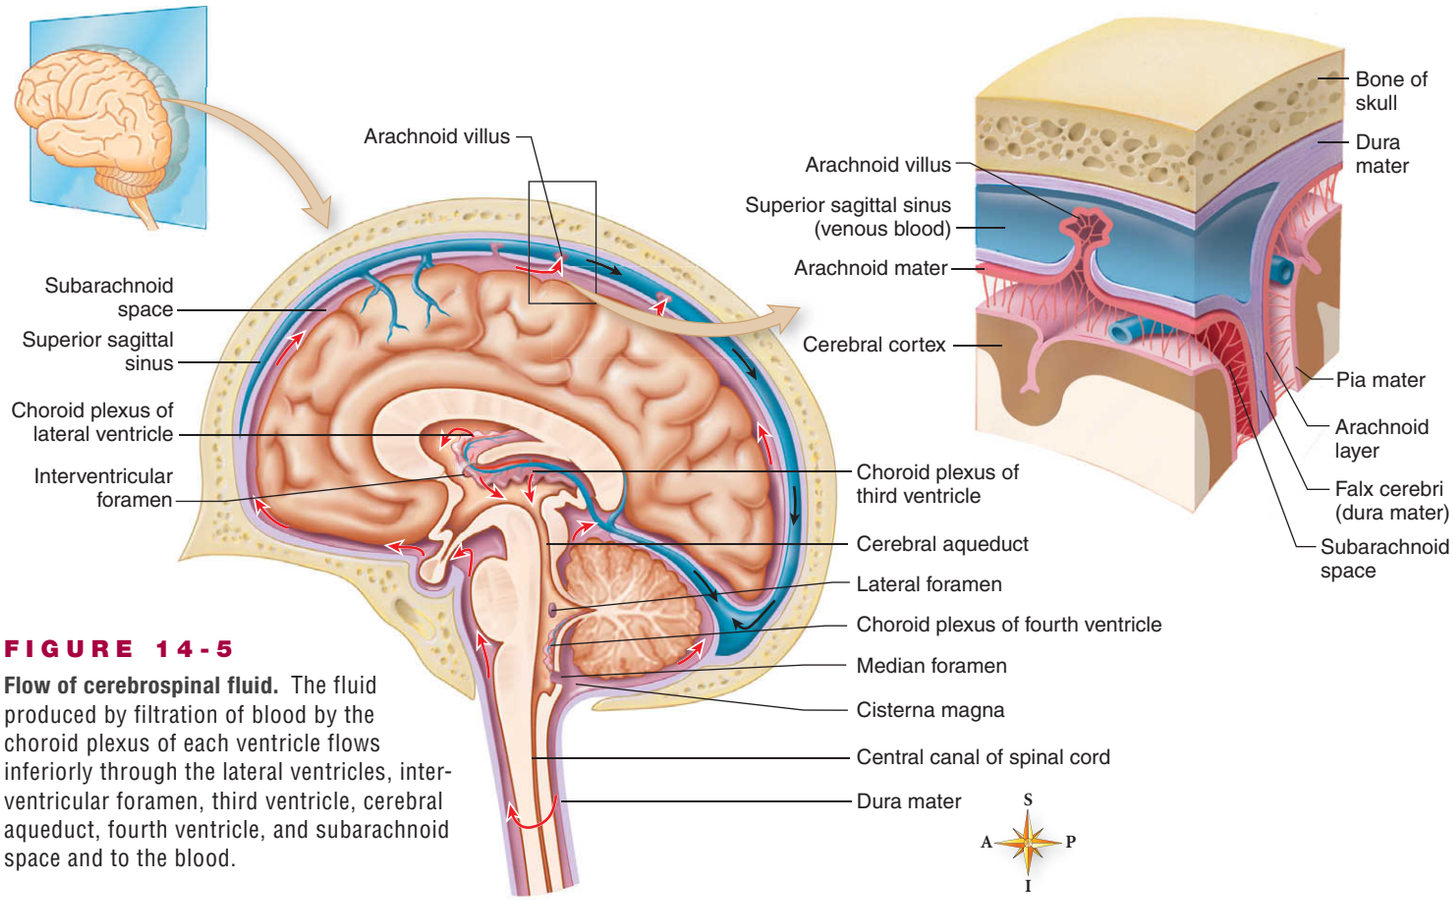


FIGURE 14-5

Flow of cerebrospinal fluid. The fluid produced by filtration of blood by the choroid plexus of each ventricle flows inferiorly through the lateral ventricles, interventricular foramen, third ventricle, cerebral aqueduct, fourth ventricle, and subarachnoid space and to the blood.

Box 14-2 | DIAGNOSTIC study

Lumbar Puncture

The meninges extends beyond the cord, which provides a convenient location for performing lumbar punctures without danger of injuring the spinal cord. A **lumbar puncture** is a withdrawal of some of the cerebrospinal fluid (CSF) from the subarachnoid space in the lumbar region of the vertebral column. The physician inserts a needle just above or below the fourth lumbar vertebra, knowing that the spinal cord ends 2 or more centimeters (about an inch) above that level (Figure 1). The fourth lumbar vertebra can be easily located because it lies on a line with the iliac crest. Placing a patient on his or her side with the knees and chest drawn together to arch the back separates the vertebrae sufficiently to create a space in which the needle can be inserted. As the needle enters the CSF, the thin nerve roots roll off the tip of the needle—thus allowing collection of CSF without damaging nerve tissue.

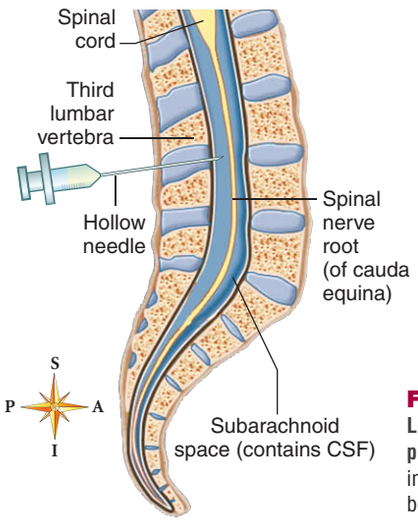

FIGURE 1

Location of lumbar puncture. The needle is inserted a few centimeters below the spinal cord.

Cerebrospinal fluid removed through a lumbar puncture can be tested for the presence of blood cells, bacteria, or other abnormal characteristics that may indicate an injury or infection, such as meningitis (Figure 2). A sensor called a *manometer* is sometimes attached to the needle to determine the pressure of the CSF within the subarachnoid space. The lumbar puncture can also be used to introduce diagnostic agents, such as radiopaque dyes for **x-ray photography,** into the subarachnoid space.

FIGURE 2

Cerebrospinal fluid (CSF) examination. These samples were taken by a lumbar puncture or "spinal tap." The top sample shows the normal, clear appearance of CSF. The bottom sample was taken from a patient with hemorrhage in the subarachnoid space. Blood is seen settling to the bottom of the sample. The yellowish tinge of the fluid is from the breakdown of blood cells before the fluid was removed from the body.

| A&P CONNECT |

When the circulation of cerebrospinal fluid (CSF) is blocked, there can be dramatic effects on the structure of the brain. An example is **hydrocephalus,** a condition in which the CSF produces abnormal fluid pressure in the brain. A brief description of hydrocephalus and how it can be treated, along with some dramatic clinical images, can be found in ***Hydrocephalus*** online at ***A&P Connect.***

evolve

| QUICK CHECK |

1. Name the three membranous coverings of the central nervous system in order, beginning with the outermost layer.
2. Trace the path of cerebrospinal fluid from its formation by a choroid plexus to its reabsorption into the blood.

SPINAL CORD

Structure of the Spinal Cord

The spinal cord lies within the spinal cavity, extending from the foramen magnum to the lower border of the first lumbar vertebra (Figure 14-6), a distance of about 45 cm (18 inches) in the average body. The spinal cord does not completely fill the spinal cavity—which also contains the meninges, CSF, a cushion of adipose tissue, and blood vessels.

The spinal cord is an oval-shaped cylinder that tapers slightly as it descends and has two bulges, one in the cervical region and the other in the lumbar region (see Figure 14-6). Two deep grooves, the *anterior median fissure* and the *posterior median sulcus*, just miss dividing the cord into separate symmetrical halves. The anterior fissure is the deeper and the wider of the two grooves—a useful factor to remember when you examine spinal cord diagrams. It enables you to tell at a glance which part of the cord is anterior and which is posterior.

Two bundles of nerve fibers called *nerve roots* project from each side of the spinal cord (see Figure 14-6). Fibers comprising the **dorsal (posterior) nerve root** carry sensory information into the spinal cord. Cell bodies of these unipolar, sensory neurons make up a small region of gray matter in the dorsal nerve root called the *dorsal (posterior) root ganglion*. Fibers of the **ventral (anterior) nerve root** carry motor information out of the spinal cord. Cell bodies of these multipolar, motor neurons are in the gray matter that composes the inner core of the spinal cord. Numerous interneurons are also located in the gray matter core of the spinal cord. On each side of the spinal cord, the dorsal and ventral nerve roots join together to form a single mixed nerve called, simply, a **spinal nerve.** Spinal nerves, components of the peripheral nervous system, are considered in more detail in the next chapter.

The spinal cord ends at vertebra L1 in a tapered cone called the **conus medullaris.** As you can see in Figure 14-7, many nerve roots extending from the conus medullaris form a sort of "horse tail" of spinal nerve roots called the **cauda equina.** Within the cauda equina the long cordlike *filum terminale* is formed from the spinal meninges.

Although the gray matter core of the spinal cord looks like a flat letter H in transverse sections of the cord, it actually has three dimensions, because the gray matter extends the length of the cord. The H-shaped rod of gray matter is made up of anterior, lateral, and posterior **gray columns.** When viewed in a cross section, as in Figure 14-6, the columns forming the H appear to spread out like animal horns—and thus are also called *anterior, posterior,* and *lateral gray horns.* The left and right gray columns are joined in the middle by a band called the **gray commissure.** It is through the gray commissure that the central canal carries CSF through the spinal cord. The gray columns consist predominantly of cell bodies of interneurons and motor neurons.

White matter surrounding the gray matter is subdivided in each half of the cord into three white columns or **funiculi:** the anterior,

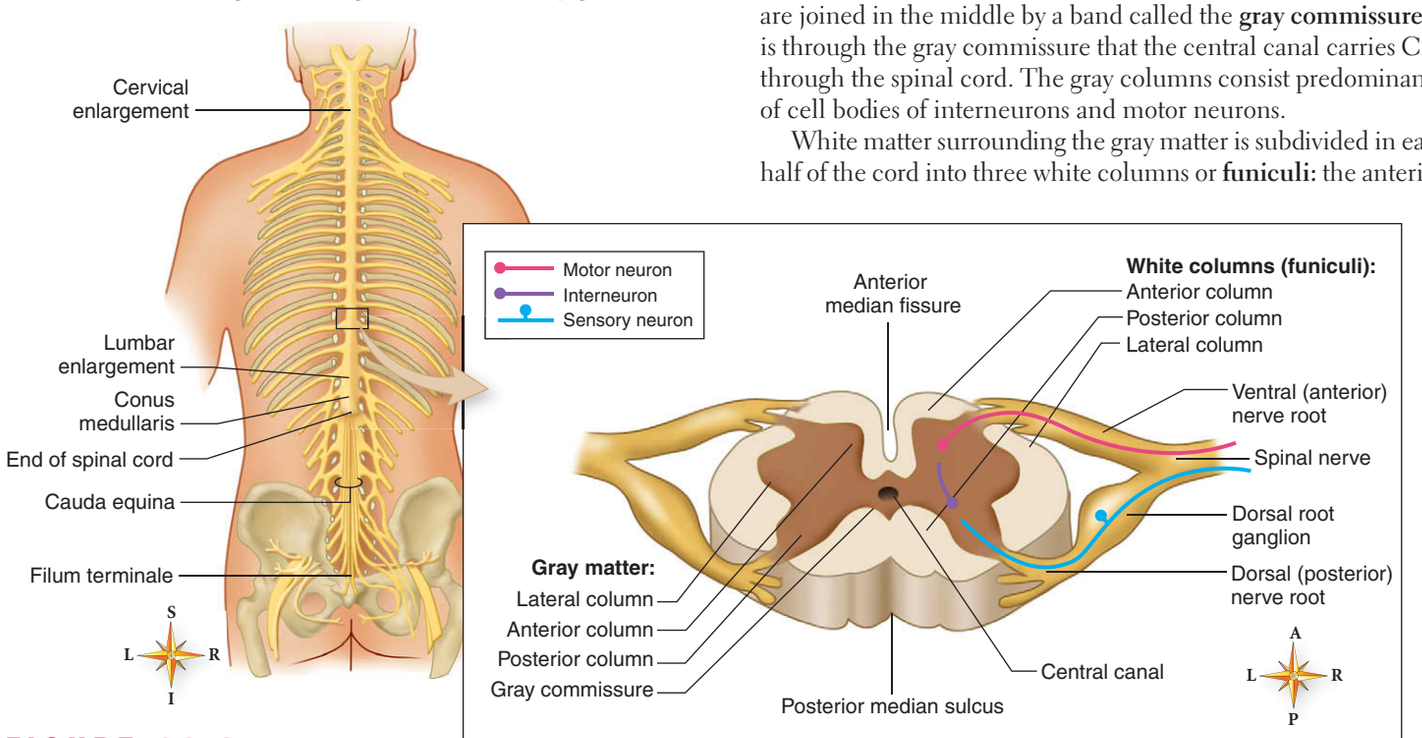

FIGURE 14-6

Spinal cord. The inset illustrates a transverse section of the spinal cord shown in the broader view.

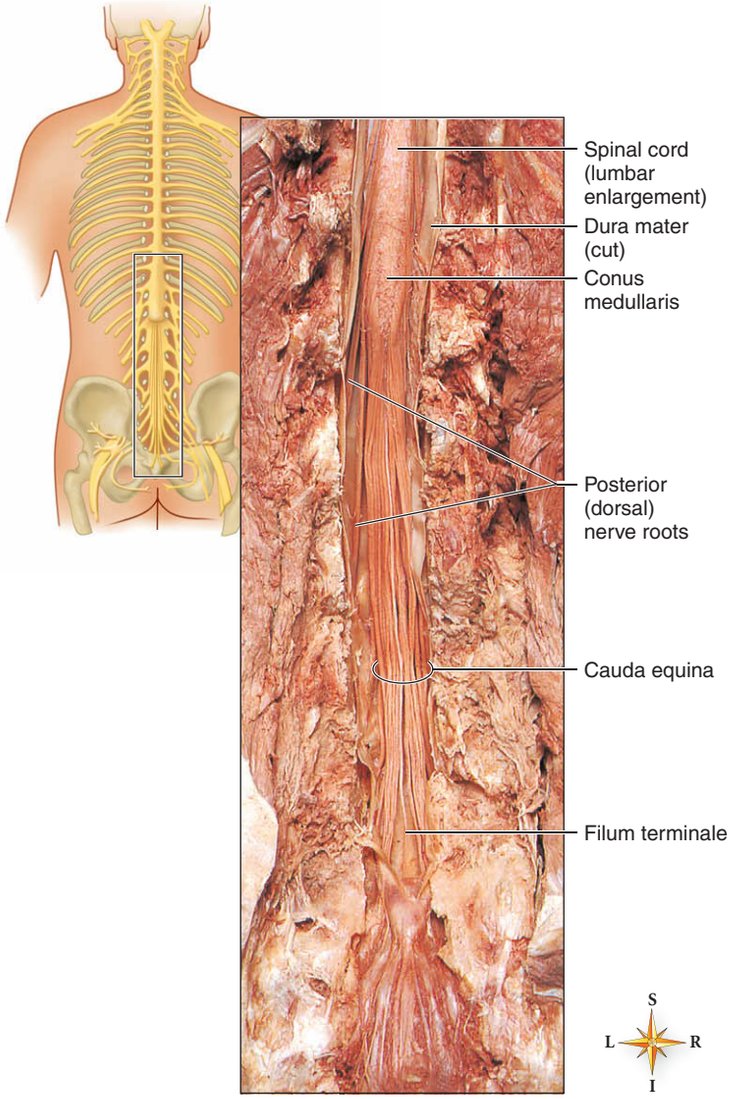

FIGURE 14-7

Cauda equina. Photograph shows the inferior portion of the dura mater dissected posteriorly, revealing the cauda equine and nearby structures.

posterior, and lateral white columns. Each white column, or funiculus, consists of a large bundle of nerve fibers (axons) divided into smaller bundles called **spinal tracts,** shown in Figure 14-8. The names of most spinal cord tracts indicate the white column in which the tract is located, the structure in which the axons that make up the tract originate, and the structure in which they terminate. For example, the lateral corticospinal tract is located in the lateral white column of the cord. The axons that compose it originate from neuron cell bodies in the spinal cortex (of the cerebrum) and terminate in the spinal cord. The anterior spinothalamic tract lies in the anterior white column. The axons that compose it originate from neuron cell bodies in the spinal cord and terminate in a portion of the brain called the *thalamus.*

You may wish to refer to the atlas that accompanies this book, where you will find detailed photographs of a human spinal cord. How many structures can you identify in the atlas by sight?

Functions of the Spinal Cord

The spinal cord performs two general functions. Briefly, it provides conduction routes to and from the brain and serves as the integrator, or reflex center, for all spinal reflexes.

Spinal cord tracts provide conduction paths to and from the brain. **Ascending tracts** conduct sensory impulses up the cord to the brain. **Descending tracts** conduct motor impulses down the cord from the brain. Bundles of axons compose all tracts.

Tracts are both structural and functional organizations of the nerve fibers of the spinal cord. They are *structural* organizations in that all the axons of any one tract originate from neuron cell bodies located in the same area of the central nervous system, and all the axons terminate in a single structure elsewhere in the central nervous system. For example, all the fibers of the spinothalamic tract are axons originating from neuron cell bodies located in the spinal cord and terminating in the thalamus. Tracts are *functional* organizations in that all the axons that compose one tract serve one general function. For instance, fibers of the spinothalamic tracts serve a sensory function. They transmit impulses that produce the sensations of crude touch, pain, and temperature.

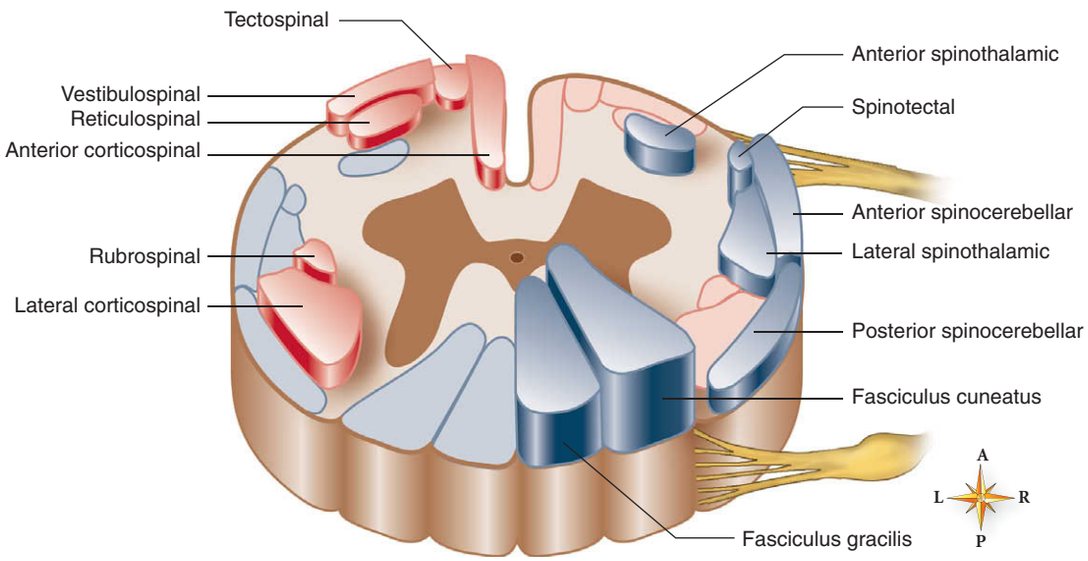

FIGURE 14-8

Major tracts of the spinal cord. The major ascending (sensory) tracts are highlighted in blue. The major descending (motor) tracts are highlighted in red.

TABLE 14-1 Major Ascending Tracts of Spinal Cord

NAME	FUNCTION	LOCATION	ORIGIN*	TERMINATION†
Lateral spinothalamic	Pain, temperature, and crude touch on opposite side	Lateral white columns	Posterior gray column on opposite side	Thalamus
Anterior spinothalamic	Crude touch and pressure	Anterior white columns	Posterior gray column on opposite side	Thalamus
Fasciculi gracilis and cuneatus	Discriminating touch and pressure sensations, including vibration, stereognosis, and two-point discrimination; also conscious kinesthesia	Posterior white columns	Spinal ganglia on same side	Medulla
Anterior and posterior spinocerebellar	Unconscious kinesthesia	Lateral white columns	Anterior or posterior gray column	Cerebellum
Spinotectal	Touch related to visual reflexes	Lateral white columns	Posterior gray columns	Superior colliculus (midbrain)

*Location of cell bodies of neurons from which axons of tract arise.
†Structure in which axons of tract terminate.

Because so many different tracts make up the white columns of the cord, we mention only a few of the more important ones. Locate each tract in Figure 14-8. Consult Tables 14-1 and 14-2 for a brief summary of these tracts.

Five important ascending, or sensory, tracts and their functions, stated very briefly, are as follows:

1. **Lateral spinothalamic tracts:** crude touch, pain, and temperature
2. **Anterior spinothalamic tracts:** crude touch and pressure
3. **Fasciculi gracilis** and **cuneatus tracts:** discriminating touch and conscious sensation of position and movement of body parts (kinesthesia)
4. **Spinocerebellar tracts:** subconscious kinesthesia
5. **Spinotectal tracts:** touch that triggers visual reflexes

Further discussion of the sensory neural pathways may be found on pp. 506–507.

Six important descending, or motor, tracts and their functions described in brief are as follows:

1. **Lateral corticospinal tracts:** voluntary movement; contraction of individual or small groups of muscles, particularly those moving hands, fingers, feet, and toes on opposite side of body
2. **Anterior corticospinal tracts:** same as preceding except mainly muscles of same side of body
3. **Reticulospinal tracts:** help maintain posture during skeletal muscle movements
4. **Rubrospinal tracts:** transmit impulses that coordinate body movements and maintenance of posture
5. **Tectospinal tracts:** head and neck movement related to visual reflexes
6. **Vestibulospinal tracts:** coordination of posture and balance

Further discussion of motor neural pathways may be found on pp. 490–491.

TABLE 14-2 Major Descending Tracts of Spinal Cord

NAME	FUNCTION	LOCATION	ORIGIN*	TERMINATION†
Lateral corticospinal (or crossed pyramidal)	Voluntary movement, contraction of individual or small groups of muscles, particularly those moving hands, fingers, feet, and toes of opposite side	Lateral white columns	Motor areas or cerebral cortex of opposite side from tract location in cord	Lateral or anterior gray columns
Anterior corticospinal (direct pyramidal)	Same as lateral corticospinal except mainly muscles of same side	Anterior white columns	Motor cortex but on same side as location in cord	Lateral or anterior gray columns
Reticulospinal	Maintain posture during movement	Anterior white columns	Reticular formation (midbrain, pons, medulla)	Anterior gray columns
Rubrospinal	Coordination of body movement and posture	Lateral white columns	Red nucleus (of midbrain)	Anterior gray columns
Tectospinal	Head and neck movement during visual reflexes	Anterior white columns	Superior colliculus (midbrain)	Medulla and anterior gray columns
Vestibulospinal	Coordination of posture/balance	Anterior white columns	Vestibular nucleus (pons, medulla)	Anterior gray columns

*Location of cell bodies of neurons from which axons of tract arise.
†Structure in which axons of tract terminate.

The spinal cord also serves as the reflex center for all spinal reflexes. The term *reflex center* means the center of a reflex arc or the place in the arc where incoming sensory impulses become outgoing motor impulses. They are structures that switch impulses from afferent to efferent neurons. In two-neuron arcs, reflex centers are merely synapses between neurons. In all other arcs, reflex centers consist of interneurons interposed between afferent and efferent neurons. Spinal reflex centers are located in the gray matter of the cord.

| A&P CONNECT |

Reflex centers can act as **pain control areas.** Pain control areas can inhibit the pain information heading toward the conscious processing centers of the brain. Identifying pain control areas and how they work has lead to the development of **transcutaneous electrical nerve stimulation (TENS)** units and other therapies to reduce pain. To learn more about this check out ***Pain Control Areas*** online at ***A&P Connect.***

evolve

| QUICK CHECK |

3. What are spinal nerve roots? How does the dorsal root differ from the ventral root?
4. Name the regions of the white and gray matter seen in a horizontal section of the spinal cord.
5. Contrast ascending tracts and descending tracts of the spinal cord. Can you give an example of each?

BRAIN

The brain is one of the largest organs in adults (Box 14-3). It consists, in round numbers, of almost 100 billion neurons and roughly the same number of glia. In most adults, it weighs about 1.4 kg (3 pounds).

Most of the production of new neurons in the brain occurs during prenatal development and during the first few months of postnatal life. Malnutrition during the crucial prenatal months of neuron multiplication can result in fewer brain cells. After birth, the neurons grow mainly in size rather than in number. The brain attains full size by about the eighteenth year but grows rapidly only during the first 9 years or so. However, some regions of the brain retain *neural stem cells (NSCs)* that can continue to add small numbers of new neurons to the brain throughout adulthood. Throughout life many new synapses form while others are broken, making the brain a very dynamic and adaptive structure.

Six major divisions of the brain, named from below, upward, are as follows: *medulla oblongata*, *pons*, *midbrain*, *cerebellum*, *diencephalon*, and *cerebrum*. Very often the medulla oblongata, pons, and midbrain are referred to collectively as the *brainstem*. Look at these three structures in Figure 14-9. Do you agree that they seem to form a stem for the rest of the brain?

Structure of the Brainstem

Three divisions of the brain make up the **brainstem.** The **medulla oblongata** forms the lowest part of the brainstem, the **midbrain** forms the uppermost part, and the **pons** lies between them, that is, above the medulla and below the midbrain. Ten of the twelve pairs of cranial nerves arise from the brainstem.

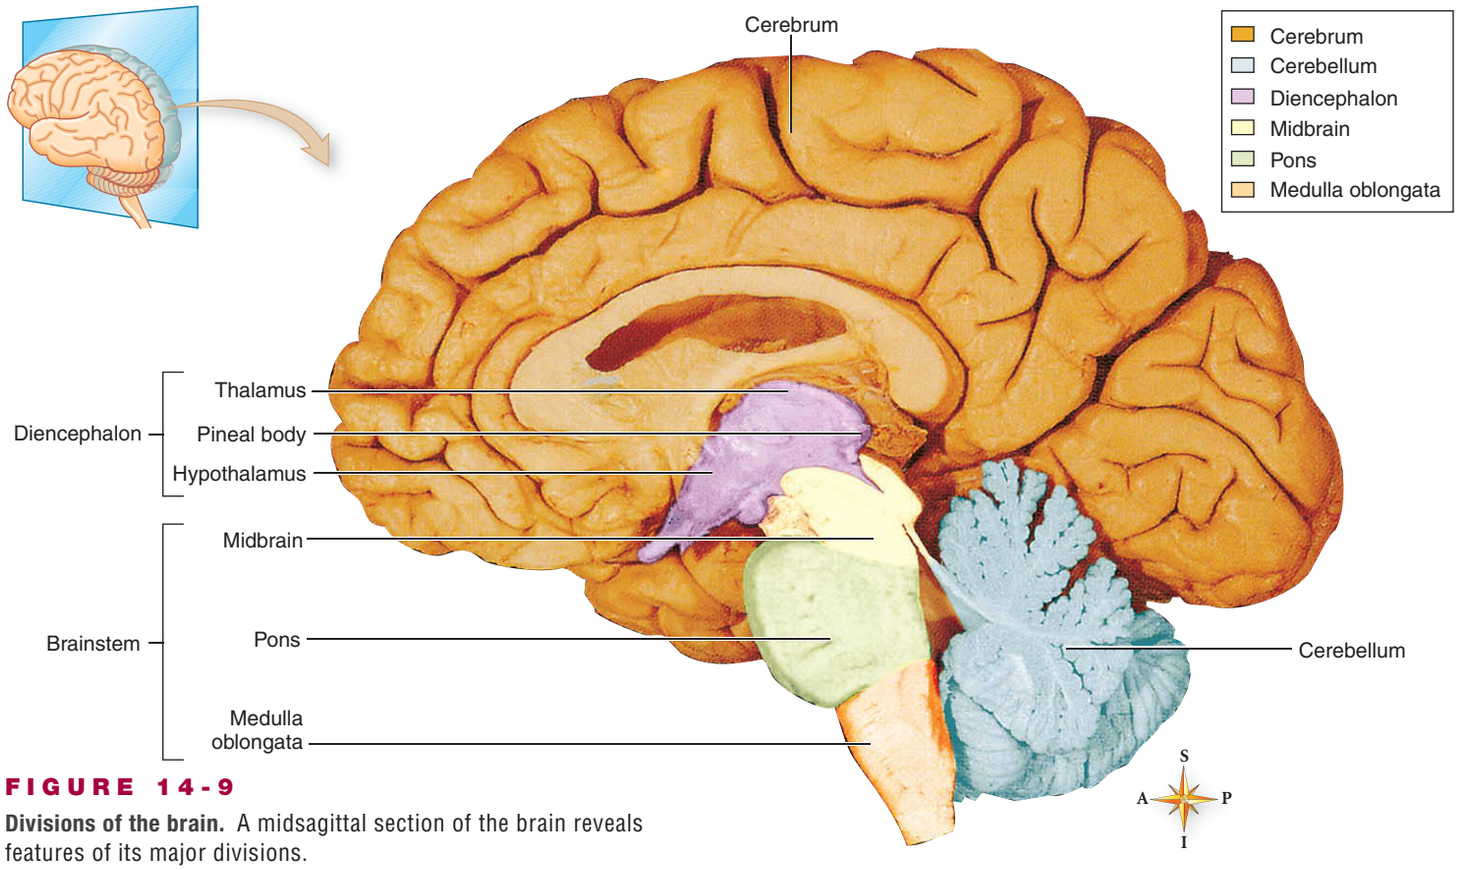

FIGURE 14-9

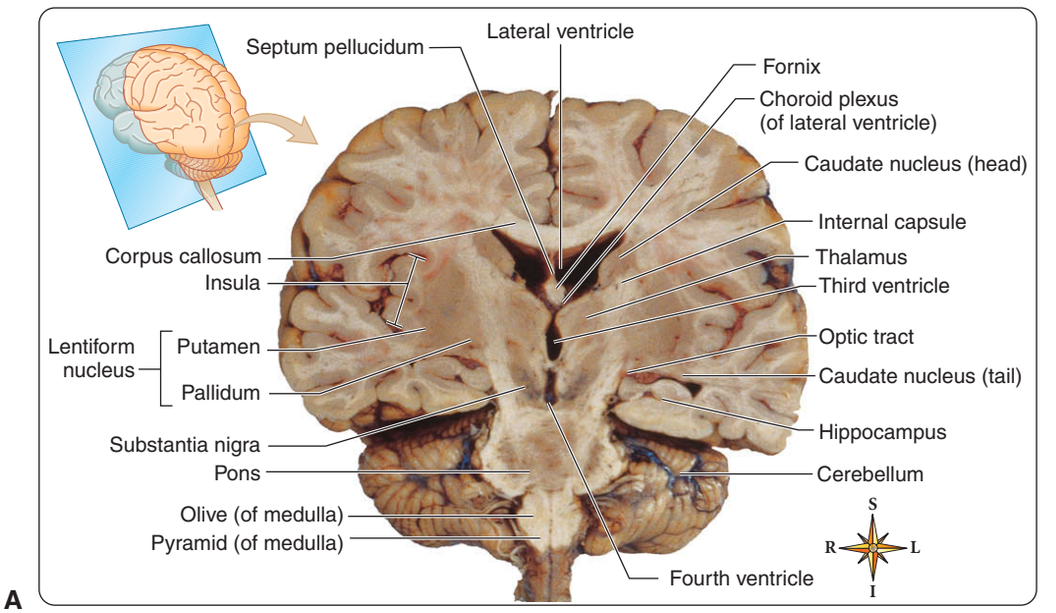
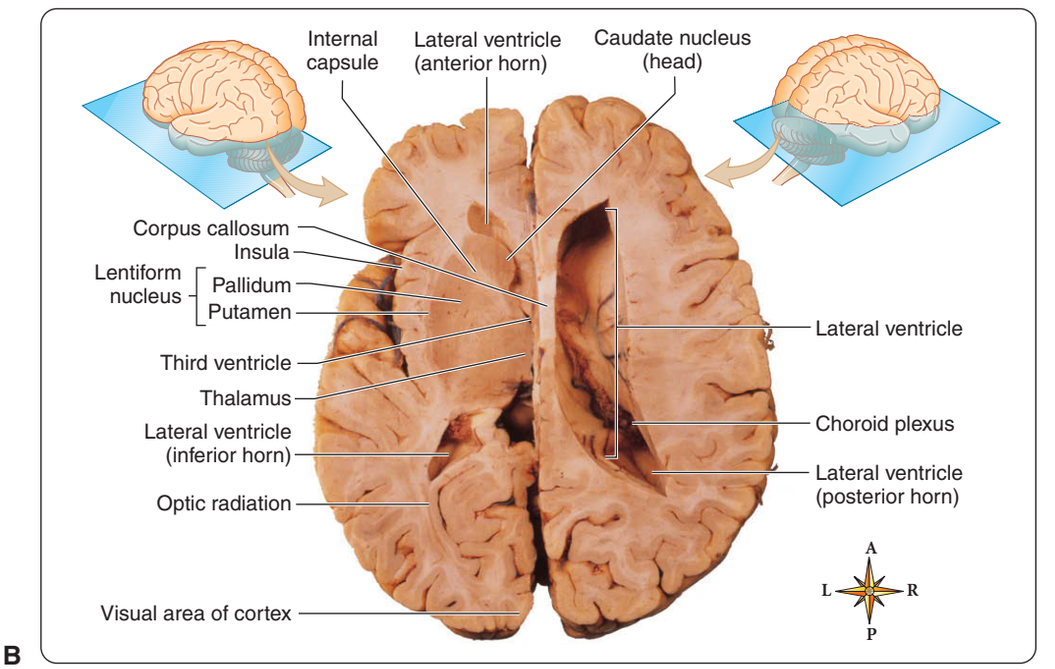
Divisions of the brain. A midsagittal section of the brain reveals features of its major divisions.

Box 14-3 | FYI



Studying Human Brains

As with any part of the body, the best way to learn the anatomy of the brain is to look at actual specimens. Recall from Chapter 1 (see Figure 1-1, p. 4) that this is the traditional method of learning human anatomy. When cadavers are not available for this purpose, one useful alternative is photographs of well-dissected cadavers.



Part *A* of the figure below is an oblique frontal (coronal) section of the human brain, as seen from the front of the subject. This photograph shows details of the internal features of all the major brain divisions. Compare this view of the brain with part *B,* which shows the brain cut on horizontal (transverse) planes at two slightly different levels, as seen from above. Then compare these photographs with those shown in the small atlas that accompanies this book. How does viewing sections in different planes of the brain benefit your understanding of the three-dimensional aspects of brain anatomy? What benefits are there to studying the brains of human cadavers, rather than relying solely on artists' renderings of the brain? Are there any advantages to using artists' renderings of brain anatomy?

Refer to these photographs—and those in the atlas that accompanies this book—often as you study the details of brain anatomy.

Human brain specimens. A, Oblique frontal section. **B,** Horizontal sections (left section is slightly inferior to right section).

A

B

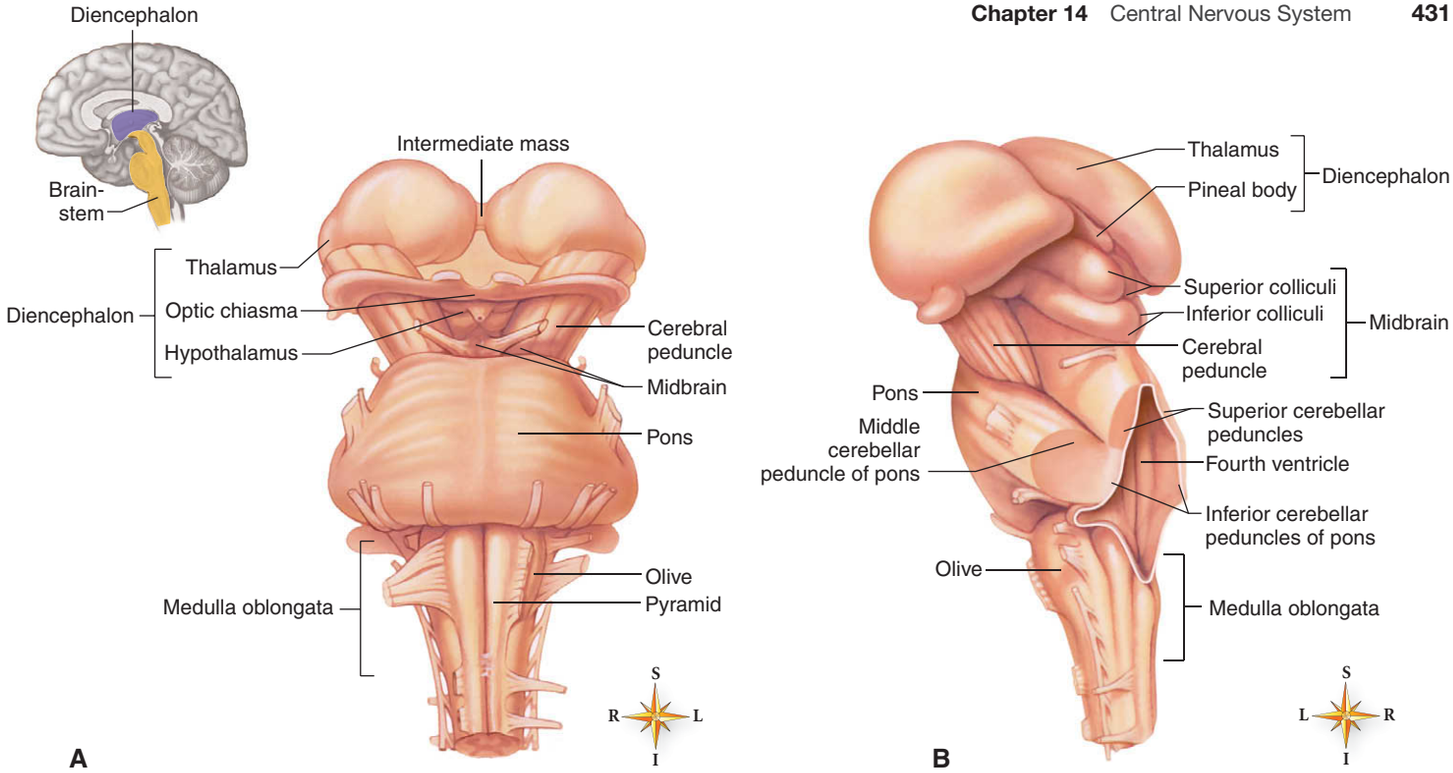


FIGURE 14-10

The brainstem and diencephalon. A, Anterior aspect. **B,** Posterior aspect (shifted slightly to lateral).

MEDULLA OBLONGATA

The medulla oblongata is the part of the brain that attaches to the spinal cord. It is, in fact, an enlarged extension of the spinal cord located just above the foramen magnum. It measures only a few centimeters (about 1 inch) in length and is separated from the pons above by a horizontal groove. It is composed of white matter (projection tracts) and a network of gray and white matter called the **reticular formation** (look ahead to Figure 14-21).

The **pyramids** (Figure 14-10) are two bulges of white matter located on the ventral surface of the medulla. Fibers of the so-called pyramidal tracts form the pyramids.

The **olive** (see Figure 14-10) of the medulla is an oval projection appearing one on each side of the ventral surface of the medulla, lateral to the pyramids.

Located in the medulla's reticular formation are various *nuclei*, or clusters of neuron cell bodies. Some nuclei are called *control centers*—for example, the cardiac, respiratory, and vasomotor control centers (Box 14-4).

PONS

Just above the medulla lies the pons, composed, like the medulla, of white matter and reticular formation. Fibers that run transversely across the pons and through the middle cerebellar peduncles into the cerebellum make up the external white matter of the pons and give it its arching, bridgelike appearance.

MIDBRAIN

The midbrain *(mesencephalon)* is appropriately named. It forms the midsection of the brain, because it lies above the pons and below the cerebrum. Both white matter (tracts) and reticular formation compose the midbrain. Extending divergently through it are two ropelike masses of white matter named **cerebral peduncles** (see Figure 14-10). Tracts in the peduncles conduct impulses between the midbrain and cerebrum. In addition to the cerebral peduncles, another landmark of the midbrain is the **corpora quadrigemina** (literally, "body of fourfold twins"). The corpora quadrigemina are two **inferior colliculi** and two **superior colliculi.** Note the location of the two sets of twin colliculi, or the corpora quadrigemina, in Figure 14-10, *B*. They form the posterior, upper part of the midbrain, the part that lies just above the cerebellum. Certain auditory centers are located in the inferior colliculus. The superior colliculus contains visual centers. Two other midbrain structures are the *red nucleus* and the *substantia nigra*. Each of these consists of clusters of cell bodies of neurons involved in muscular control. The substantia nigra (literally, "black matter") gets its name from the dark pigment in some of its cells.

Box 14-4 | HEALTH matters

Vital Centers

Because the cardiac, vasomotor, and respiratory control centers are essential for survival, they are called the *vital centers.* They serve as the centers for various reflexes controlling heart action, blood vessel diameter, and respiration. Because the medulla contains these centers, it is the most vital part of the entire brain—so vital that injury or disease of the medulla often proves fatal. Blows at the base of the skull and bulbar poliomyelitis, for example, cause death if they interrupt impulse conduction in the vital respiratory centers.

Functions of the Brainstem

The brainstem, like the spinal cord, performs sensory, motor, and reflex functions. The spinothalamic tracts are important sensory tracts that pass through the brainstem on their way to the thalamus in the diencephalon. The fasciculi cuneatus and gracilis and the spinoreticular tracts are sensory tracts whose axons terminate in the gray matter of the brainstem. Corticospinal and reticulospinal tracts are two of the major tracts present in the white matter of the brainstem.

Nuclei in the medulla contain a number of reflex centers. Of first importance are the cardiac, vasomotor (vessel muscle), and respiratory centers. Other centers present in the medulla are for various nonvital reflexes such as vomiting, coughing, sneezing, hiccupping, and swallowing.

The pons contains centers for reflexes mediated by the fifth, sixth, seventh, and eighth cranial nerves. The locations and functions of these peripheral nerves are discussed in Chapter 15. In addition, the pons contains the pneumotaxic centers that help regulate respiration.

The midbrain, like the pons, contains reflex centers for certain cranial nerve reflexes, for example, pupillary reflexes and eye movements, mediated by the third and fourth cranial nerves, respectively.

Structure of the Cerebellum

The **cerebellum** (literally "little brain") is located just below the posterior portion of the cerebrum and is partially covered by it (Figure 14-11). A transverse fissure separates the cerebellum from the cerebrum. The cerebellum is the second largest part of the brain (after the cerebrum) but has more neurons than all the other parts of the nervous system combined! Thus the cerebellum has a lot of "computing power" compared with other parts of the brain.

The cerebrum and cerebellum have several structural characteristics in common. For instance, gray matter makes up the outer portion, or *cortex*, of each. White matter predominates in the interior of each. Look at Figure 14-11, *C*, and find the internal white matter of the cerebellum called the **arbor vitae** (literally "tree of life"). Note the arbor vitae's distinctive pattern, similar to the branches of a tree. Note, too, that the surfaces of both the cerebellum and the cerebrum have numerous grooves *(sulci)* and raised areas *(gyri)*. The gyri of the cerebellum, however, are much more slender and less prominent than those of the cerebrum. These delicate, roughly parallel gyri are also called **folia** (literally "leaves"). Like the cerebrum, the cerebellum consists of two large lateral masses, the left and right *cerebellar hemispheres*, and a central section called the **vermis.**

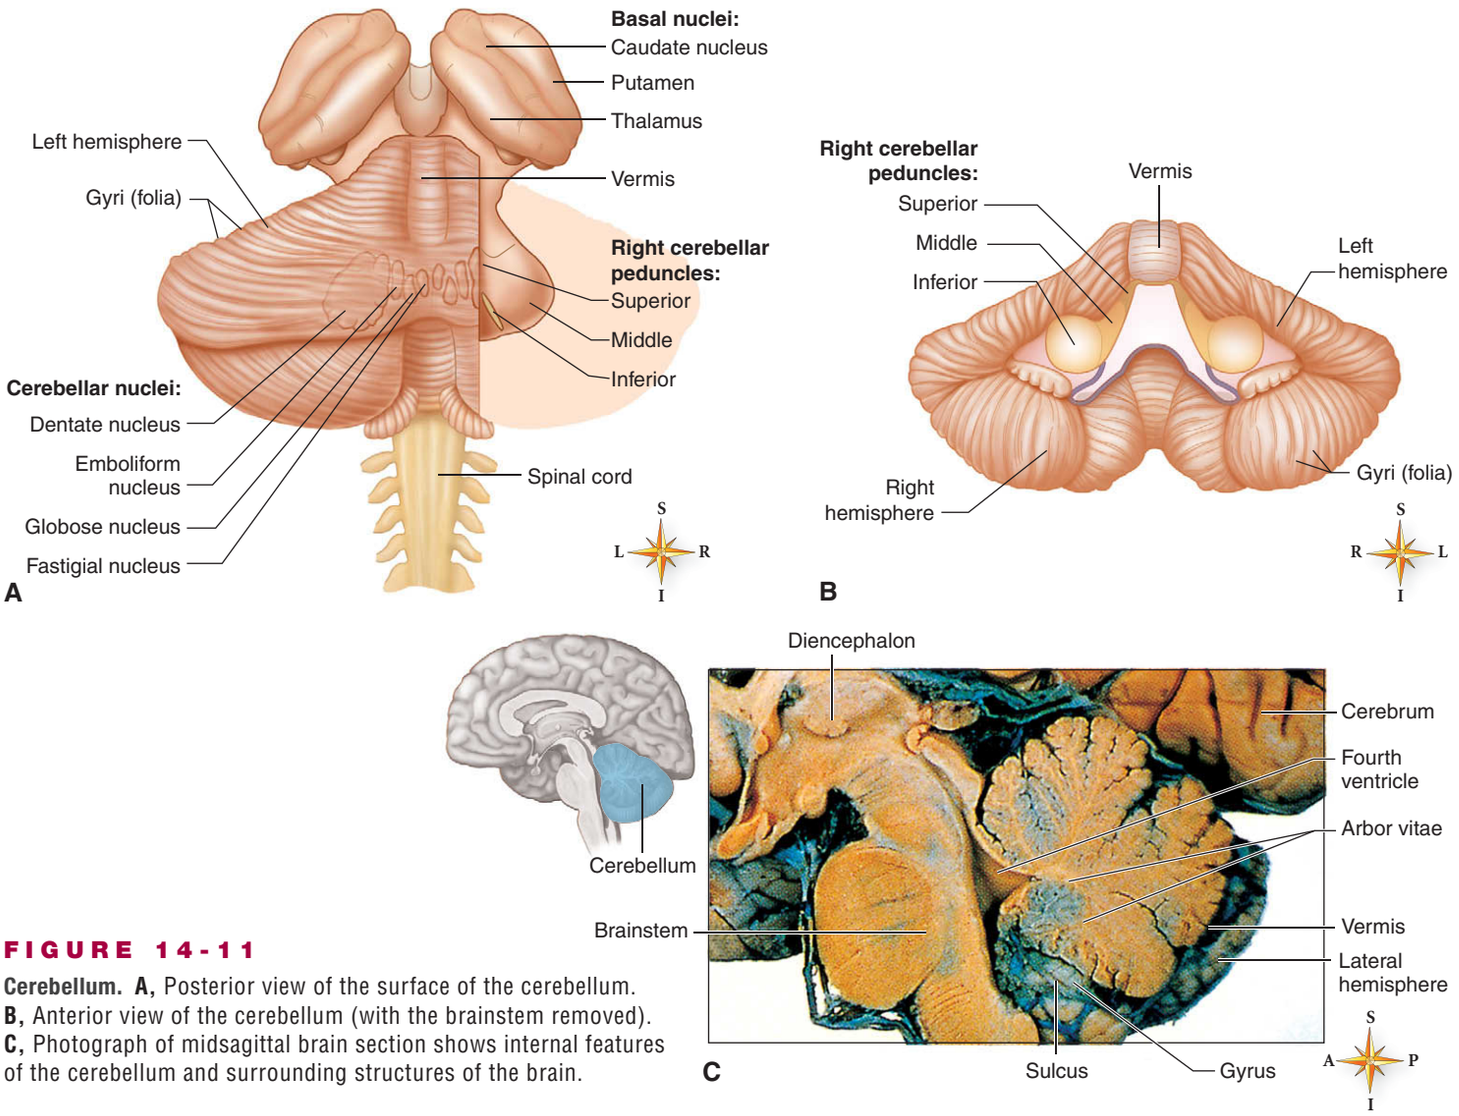

FIGURE 14-11

Cerebellum. A, Posterior view of the surface of the cerebellum. **B,** Anterior view of the cerebellum (with the brainstem removed). **C,** Photograph of midsagittal brain section shows internal features of the cerebellum and surrounding structures of the brain.

The internal white matter of the cerebellum is composed of some short and some long tracts. The shorter tracts conduct impulses from neuron cell bodies located in the cerebellar cortex to neurons whose dendrites and cell bodies compose nuclei located in the interior of the cerebellum. The longer tracts conduct impulses to and from the cerebellum. Fibers of the longer tracts enter or leave the cerebellum by way of its three pairs of peduncles (see Figure 14-11, *B*), as follows:

1. **Inferior cerebellar peduncles:** composed chiefly of tracts into the cerebellum from the medulla and cord (notably spinocerebellar, vestibulocerebellar, and reticulocerebellar tracts)
2. **Middle cerebellar peduncles:** composed almost entirely of tracts into the cerebellum from the pons, that is, pontocerebellar tracts
3. **Superior cerebellar peduncles:** composed principally of tracts from dentate nuclei in the cerebellum through the red nucleus of the midbrain to the thalamus

An important pair of cerebellar nuclei is the **dentate nuclei,** one of which lies in each hemisphere. Tracts connect these nuclei with the thalamus and with motor areas of the cerebral cortex. By means of these tracts, cerebellar impulses influence the motor cortex. Impulses in other tracts enable the motor cortex to influence the cerebellum.

Functions of the Cerebellum

The cerebellum shares similarities with the cerebrum, functionally as well as structurally. The current view of cerebellar function states that the cerebellum performs a variety of different functions that complement or assist the cerebrum, many of which involve the planning and coordination of skeletal muscle activity and maintaining balance in the body.

Coordinated control of muscle action is a function of the upper part of the cerebellum working with the motor control areas of the cerebrum. Normal muscle action involves groups of muscles, the various members of which function together as a unit. In any given action, for example, the prime mover contracts and the antagonist relaxes but then contracts weakly at the proper moment to act as a brake, checking the action of the prime mover. Also, the synergists contract to assist the prime mover, and the fixation muscles of the neighboring joint contract. Through such harmonious, coordinated patterns and group action, normal movements are smooth, steady, and precise as to force, rate, and extent. These patterns, such as the sequence of leg movements needed for walking, are learned and stored in the cerebellum.

Achievement of coordinated movements results from the combined efforts of the cerebrum and cerebellum. Impulses from the cerebrum may trigger the action, but those from the cerebellum plan and coordinate the contractions and relaxations of the various muscles once they have begun. Figure 14-12 shows how the cerebrum and cerebellum work together. Impulses from the motor control areas of the cerebrum travel down the corticospinal tract and, through peripheral nerves, to skeletal muscle tissue. At the same time, the impulses go to the cerebellum. The cerebellum compares the motor commands of the cerebrum with information coming in from sensory receptors in the muscles (proprioception). Using "sensory maps" of the body, the cerebellum compares the intended movement with the actual state of the body and its current position or movement. Impulses then travel from the cerebellum to both the cerebrum and the muscle tissue to adjust or coordinate the movements to produce the intended action.

Interestingly, the cerebellum becomes involved when a person is just thinking about doing some activity, thus "getting ready" for

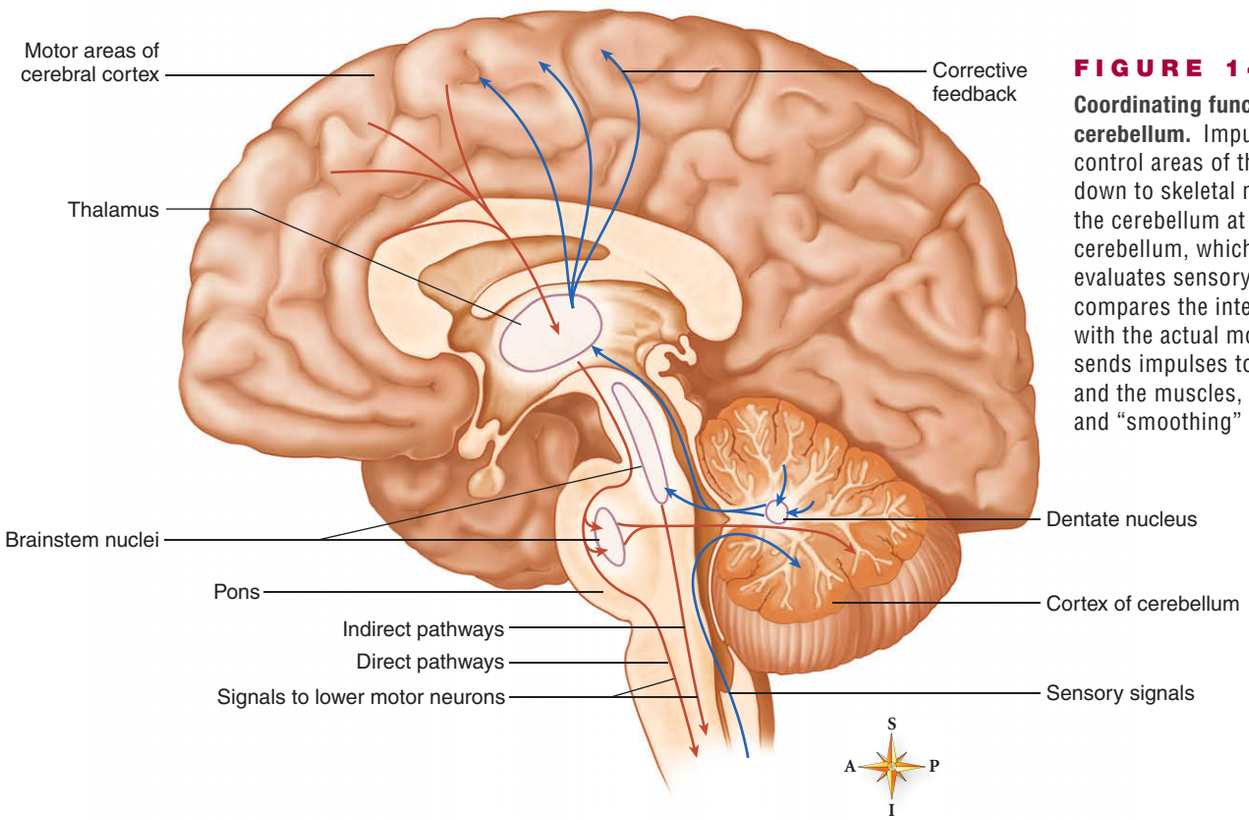

FIGURE 14-12

Coordinating function of the cerebellum. Impulses from the motor control areas of the cerebrum travel down to skeletal muscle tissue and to the cerebellum at the same time. The cerebellum, which also receives and evaluates sensory information, compares the intended movement with the actual movement. It then sends impulses to both the cerebrum and the muscles, thus coordinating and "smoothing" muscle activity.

possible later movement. Some physiologists consider the planning and coordination of movement to be the main functions of the cerebellum.

The cerebellum is also thought to be concerned with both exciting and inhibiting the postural reflexes that help us maintain a stable body position. Sensory impulses from equilibrium (balance) receptors in the ear reach the cerebellum. Using this information, the cerebellum then stimulates or inhibits various muscles to maintain stability of the body.

Not only does the cerebellum work with the cerebrum as a sort of "executive assistant" to coordinate and plan movement and maintain balance—current evidence suggests that the cerebellum is an all-around assistant or planner of a variety of functions normally associated with the cerebrum. In fact, it is becoming clear that the cerebellum coordinates incoming sensory information as much or more than it coordinates outgoing motor information. Cerebellar disease (e.g., abscess, hemorrhage, tumors, trauma) produces certain characteristic symptoms. Predominant among them are ataxia (muscle incoordination), hypotonia, tremors, and disturbances of gait and balance. One example of ataxia is overshooting a mark or stopping before reaching it when trying to touch a given point on the body (finger-to-nose test). Drawling, scanning, and singsong speech are also examples of ataxia. Tremors are particularly pronounced toward the end of the movements and with the exertion of effort. Disturbances of gait and balance vary, depending on the muscle groups involved. The walk, for instance, is often characterized by staggering or lurching and by a clumsy manner of raising the foot too high and bringing it down with a clap. Paralysis does not result from loss of cerebellar function.

To briefly summarize its general functions, the cerebellum:

- Acts with the cerebral cortex to produce skilled movements by planning and coordinating the activities of groups of muscles
- Helps control posture: functions below the level of consciousness to make movements smooth instead of jerky, steady instead of trembling, and efficient and coordinated instead of ineffective, awkward, and uncoordinated
- Controls skeletal muscles to maintain balance
- Coordinates incoming sensory information and acts in other ways to complement and assist various functions of the cerebrum

Diencephalon

The **diencephalon** (literally, "between brain") is the part of the brain located between the cerebrum and the midbrain (mesencephalon). Although the diencephalon consists of several structures located around the third ventricle, the main ones are the **thalamus** and **hypothalamus.** The diencephalon also includes the **optic chiasma,** the **pineal gland,** and several other small but important structures.

THALAMUS

The **thalamus** is a dumbbell-shaped mass of gray matter made up of many nuclei. As Figures 14-10 and 14-13 show, each *lateral mass* of the thalamus forms one lateral wall of the third ventricle. Extending through the third ventricle, and thus joining the two lateral masses of the thalamus, is the *intermediate mass.* Two important groups of nuclei that make up the thalamus are the *geniculate bodies*, located in the posterior region of each lateral mass. The geniculate bodies play a role in processing auditory and visual input.

Large numbers of axons conduct impulses into the thalamus from the spinal cord, brainstem, cerebellum, basal nuclei, and various parts of the cerebrum. These axons terminate in thalamic nuclei, where they synapse with neurons whose axons conduct impulses out of the thalamus to virtually all areas of the cerebral cortex. Thus the thalamus serves as the major relay station for sensory impulses on their way to the cerebral cortex.

The thalamus performs the following primary functions:

- Plays two parts in the mechanism responsible for sensations
  1. Impulses from appropriate receptors, on reaching the thalamus, produce conscious recognition of the crude, less critical sensations of pain, temperature, and touch
  2. Neurons whose dendrites and cell bodies lie in certain nuclei of the thalamus relay all kinds of sensory impulses, except possibly olfactory, to the cerebrum
- Plays a part in the mechanism responsible for emotions by associating sensory impulses with feelings of pleasantness and unpleasantness
- Plays a part in the arousal or alerting mechanism
- Plays a part in mechanisms that produce complex reflex movements

HYPOTHALAMUS

The **hypothalamus** consists of several structures that lie beneath the thalamus and form the floor of the third ventricle and the lower part of its lateral walls. Prominent among the structures composing the hypothalamus are the *supraoptic nuclei*, the *paraventricular nuclei*, and the *mamillary bodies.* The supraoptic nuclei consist of gray matter located just above and on either side of the *optic chiasma.* The optic chiasma is the X-shaped junction of the optic tracts and optic nerves. The paraventricular nuclei of the hypothalamus are named for their location, which is close to the wall of the third ventricle. The midportion of the hypothalamus gives rise to the **infundibulum,** the stalk leading to the posterior lobe of the *pituitary gland (neurohypophysis).* The posterior part of the hypothalamus consists mainly of the mamillary bodies (see Figure 14-13, *inset*), which are involved with the olfactory sense (smell).

The hypothalamus is a small but functionally important area of the brain. It weighs little more than 7 grams (¼ oz), yet it performs many functions of the greatest importance both for survival

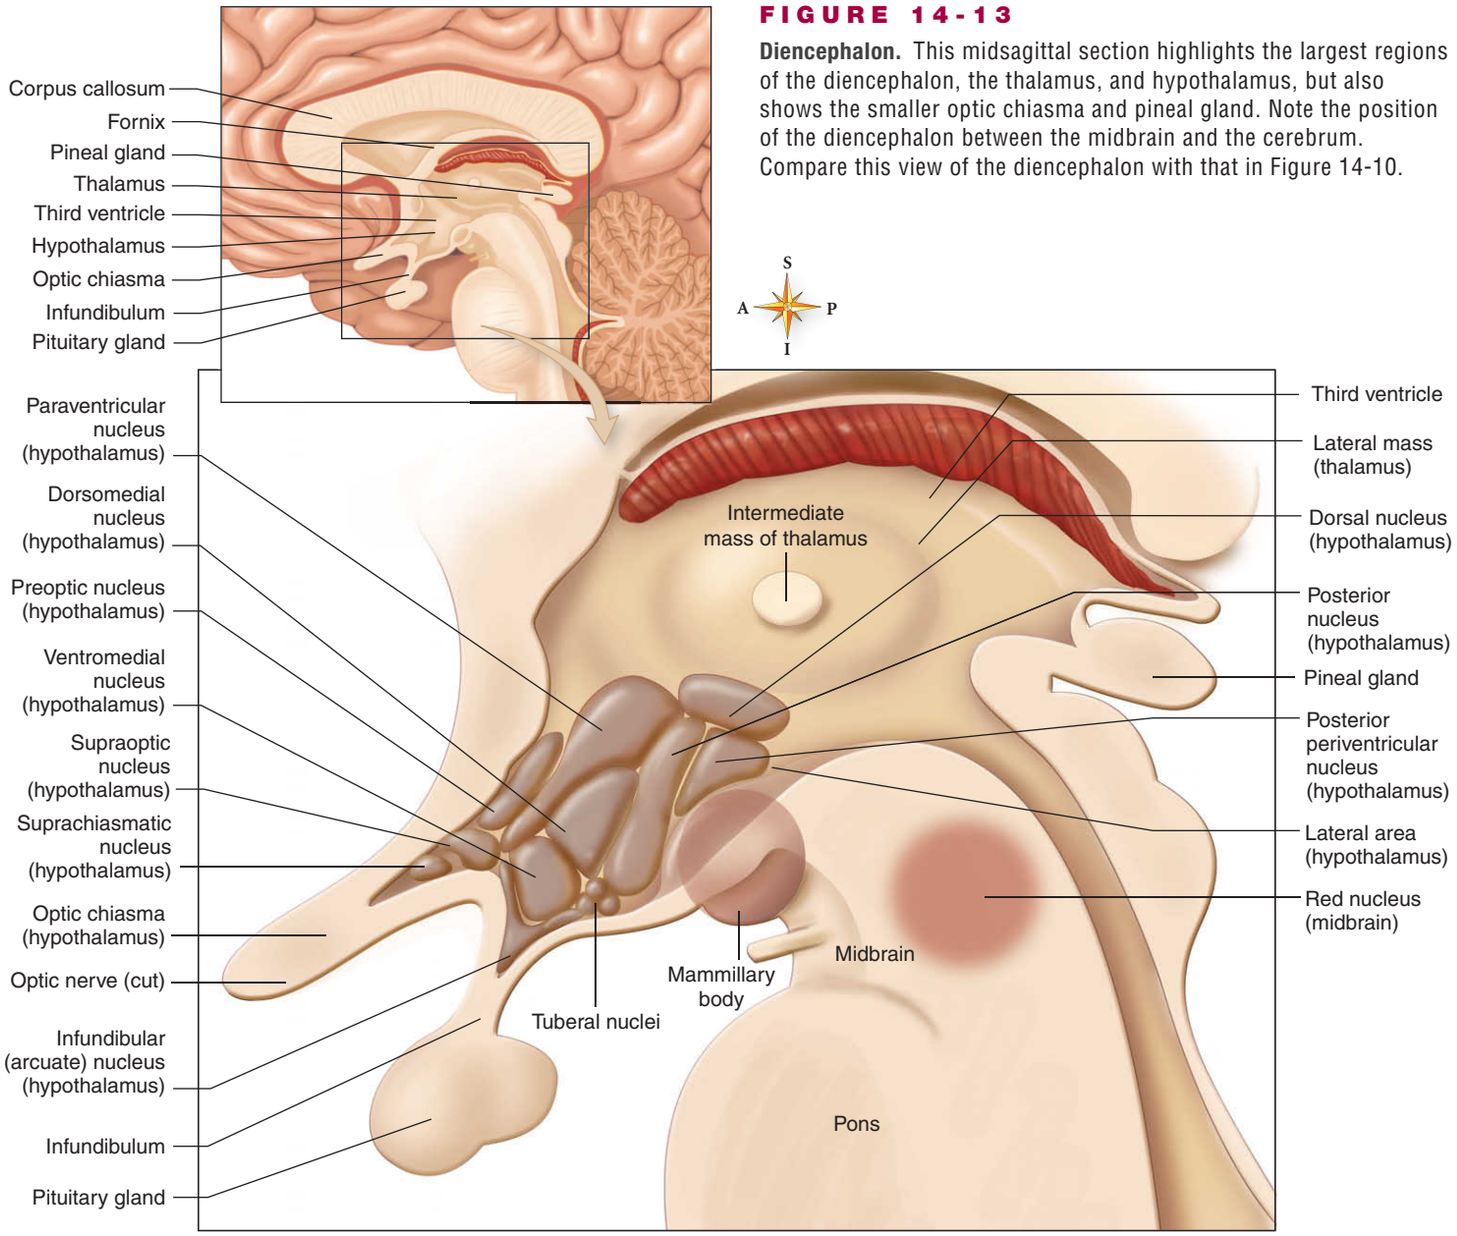

FIGURE 14-13

Diencephalon. This midsagittal section highlights the largest regions of the diencephalon, the thalamus, and hypothalamus, but also shows the smaller optic chiasma and pineal gland. Note the position of the diencephalon between the midbrain and the cerebrum. Compare this view of the diencephalon with that in Figure 14-10.

and for the enjoyment of life. For instance, it functions as a link between the psyche (mind) and the soma (body). It also links the nervous system to the endocrine system. Certain areas of the hypothalamus function as pleasure centers or reward centers for the primary drives such as eating, drinking, and sex. The following list briefly summarizes hypothalamic functions.

- The hypothalamus functions as a higher autonomic center or, rather, as several higher autonomic centers. By this we mean that axons of neurons whose dendrites and cell bodies lie in nuclei of the hypothalamus extend in tracts from the hypothalamus to both parasympathetic and sympathetic centers in the brainstem and cord. Thus impulses from the hypothalamus can simultaneously or successively stimulate or inhibit few or many lower autonomic centers. In other words, the hypothalamus serves as a regulator and coordinator of autonomic activities. It helps control and integrate the responses made by autonomic (visceral) effectors all over the body.
- The hypothalamus functions as the major relay station between the cerebral cortex and lower autonomic centers. Tracts conduct impulses from various centers in the cortex to the hypothalamus. Then, by way of numerous synapses in the hypothalamus, these impulses are relayed to other tracts that conduct them on down to autonomic centers in the brainstem and cord and also to spinal cord somatic centers (anterior horn motor neurons). Thus the hypothalamus functions as the link between the cerebral cortex and lower centers—hence between the psyche and the soma. It provides a crucial part of the route by which emotions can express themselves in changed bodily functions. It is the

all-important relay station in the neural pathways that makes possible the mind's influence over the body—sometimes, unfortunately, even to the profound degree of producing psychosomatic disease. The positive benefits of this mind-body link are the dramatic influences our conscious mind can have in healing the body of various illnesses.

- Neurons in the supraoptic and paraventricular nuclei of the hypothalamus synthesize the hormones released by the posterior pituitary gland (neurohypophysis). Because one of these hormones affects the volume of urine excreted, the hypothalamus plays an indirect but essential role in maintaining water balance (see Chapters 31 and 32).
- Some neurons in the hypothalamus have endocrine functions. Their axons secrete chemicals, *releasing hormones*, into blood, which circulate to the anterior pituitary gland. Releasing hormones control the release of certain anterior pituitary hormones—specifically growth hormone and hormones that control hormone secretion by sex glands, the thyroid gland, and the adrenal cortex (discussed in Chapter 19). Thus indirectly the hypothalamus helps control the functioning of every cell in the body.
- The hypothalamus plays an essential role in maintaining the waking state. Presumably it functions as part of an arousal or alerting mechanism. Clinical evidence of this is that somnolence (sleepiness) characterizes some hypothalamic disorders.
- The hypothalamus functions as a crucial part of the mechanism for regulating appetite and therefore the amount of food intake. Experimental and clinical findings indicate the presence of an "appetite center" in the lateral part of the hypothalamus and a "satiety center" located medially. For example, an animal with an experimental lesion in the ventromedial nucleus of the hypothalamus consumes tremendous amounts of food. Similarly, a human with a tumor in this region of the hypothalamus may eat insatiably and gain an enormous amount of weight.
- The hypothalamus functions as a crucial part of the mechanism for maintaining normal body temperature. Hypothalamus neurons whose fibers connect with autonomic centers for vasoconstriction, dilation, and sweating and with somatic centers for shivering constitute heat-regulating centers. Marked elevation of body temperature often characterizes injuries or other abnormalities of the hypothalamus.

PINEAL GLAND

Although the thalamus and hypothalamus account for most of the tissue that makes up the diencephalon, there are several smaller structures of importance. For example, the *optic chiasma* is a region where the right and left *optic nerves* cross each other before entering the brain—exchanging fibers as they do so. The resulting bundles of fibers are called the *optic tracts*. Various small nuclei just outside the thalamus and hypothalamus, collectively referred to as the **epithalamus**, are also included among the structures of the diencephalon. One of the most intriguing of the epithalamic structures is the *pineal gland* or *pineal body* (formerly known as the *epiphysis*).

As Figures 14-10 and 14-13 show, the pineal gland is located just above the corpora quadrigemina of the midbrain. Its name comes from the fact that it resembles a pine nut.

The functions of the pineal gland are still not completely understood. However, we do know that the tiny pineal gland is an important part of the body's biological clock mechanism. The body's **biological clock** depends partly on the pineal gland varying its secretion of the hormone **melatonin.** Melatonin is a *hormone* because it is a molecule released into the blood to regulate functions elsewhere in the body—a concept we will explore further in Chapters 18 and 19. However, melatonin is in fact simply an altered form of the neurotransmitter serotonin.

As Figure 14-14 shows, changing light levels throughout the day and night (circadian) cycle trigger

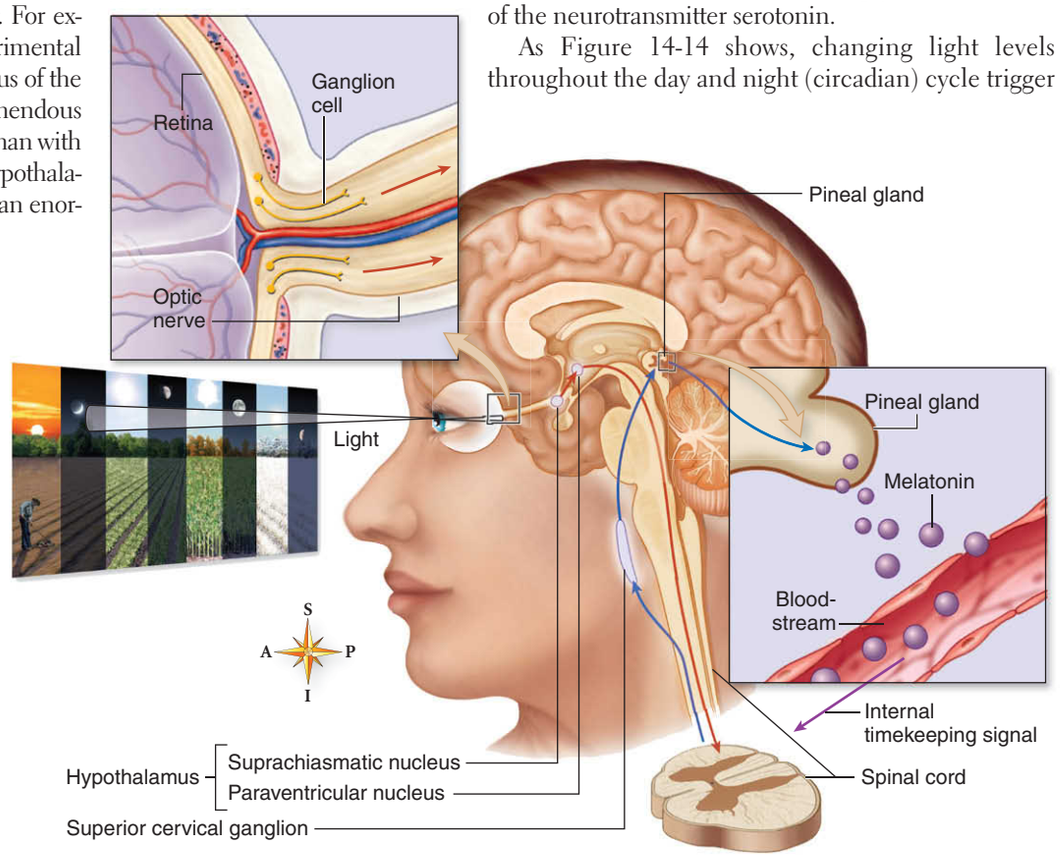

FIGURE 14-14

Role of pineal gland in timekeeping. Changing external levels of light are detected by special receptors in the retina of the eye called *ganglion cells* (see Chapter 17), and the information is relayed to the suprachiasmatic nucleus (SCN) of the hypothalamus. When light levels decrease, signals from the SCN increase, triggering the paraventricular nucleus and a pathway of nervous system signals that eventually result in the release of increased amounts of melatonin from the pineal gland. The changing levels of melatonin throughout the day serve as an internal timekeeping signal.

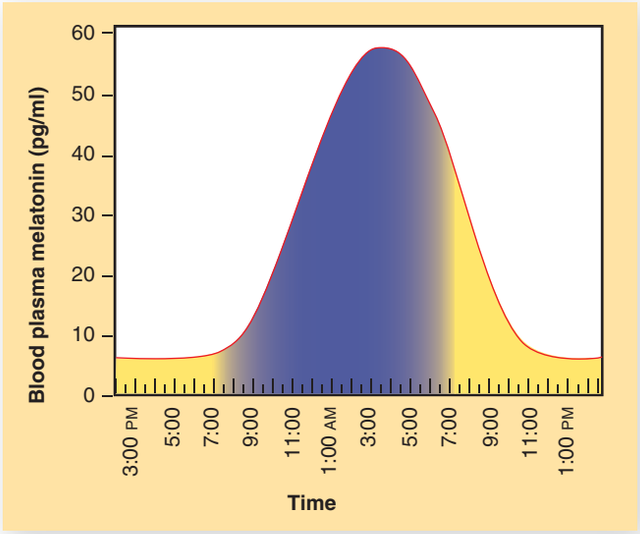

FIGURE 14-15

Melatonin. Graph comparing typical blood melatonin levels throughout the day. Sunlight suppresses melatonin secretion during the day. As the sun goes down, however, melatonin levels begin to rise—dropping again sharply when the sun comes up.

changes in the rate of melatonin secretion. When sunlight levels are high, melatonin secretion decreases (Figure 14-15). When light levels are low, melatonin levels increase proportionally. The changing levels of blood melatonin during the day synchronize various body functions with each other and with external stimuli. This kind of biological clock mechanism is called a daily or *circadian* clock. Melatonin is often called the "timekeeping hormone"—but because high blood levels of melatonin signal the body that it is time to sleep, it is also called the "sleep hormone."

When a person travels to another time zone, or when the seasons change, the altered sunlight patterns cause corresponding time shifts to the melatonin cycle. Likewise, often subtle changes occur in each melatonin cycle depending on how much moonlight (reflected sunlight) is present each evening. Thus the body can sometimes tell what time of the (lunar) month it is—a mechanism that may help regulate the female reproductive cycle.

12. What is the pineal gland's primary function?

Structure of the Cerebrum

CEREBRAL CORTEX

The **cerebrum,** the largest and uppermost division of the brain, consists of two halves, the right and left **cerebral hemispheres.** The surface of the cerebrum—called the *cerebral cortex*—is made up of gray matter only 2 to 4 mm (roughly 1/12 to 1/6 inch) thick. But despite its thinness, the cortex has six layers, each composed of millions of axon terminals synapsing with millions of dendrites and cell bodies of other neurons.

If one uses a little imagination, the surface of the cerebral cortex looks like a group of small sausages. Each "sausage" is actually a **convolution,** or gyrus. Names of some of these are the *precentral gyrus*, *postcentral gyrus*, *cingulate gyrus*, and *hippocampal gyrus (hippocampus)*.

Between adjacent gyri lie either shallow grooves called *sulci* or deeper grooves called *fissures* (Box 14-5). Fissures, as well as a few, largely imaginary boundaries, divide each cerebral hemisphere into five *lobes.* Four of the lobes are named for the bones that lie over them: **frontal lobe, parietal lobe, temporal lobe,** and **occipital lobe** (Figure 14-16). A fifth lobe, the **insula** *(Reil island)*, lies hidden from view in the lateral fissure. The lobes are highlighted in Figure 14-16. The insula can also be seen in the photographs in Box 14-3 (p. 430).

Names and locations of prominent cerebral fissures are as follows (see Figure 14-16):

Longitudinal fissure: the deepest groove in the cerebrum; divides the cerebrum into two hemispheres

Central sulcus (Rolando fissure): groove between the frontal and parietal lobes

Lateral fissure (Sylvius fissure): a deep groove between the temporal lobe below and the frontal and parietal lobes above; island of Reil lies deep in the lateral fissure

Parietooccipital sulcus: groove that separates the occipital lobe from the parietal lobe

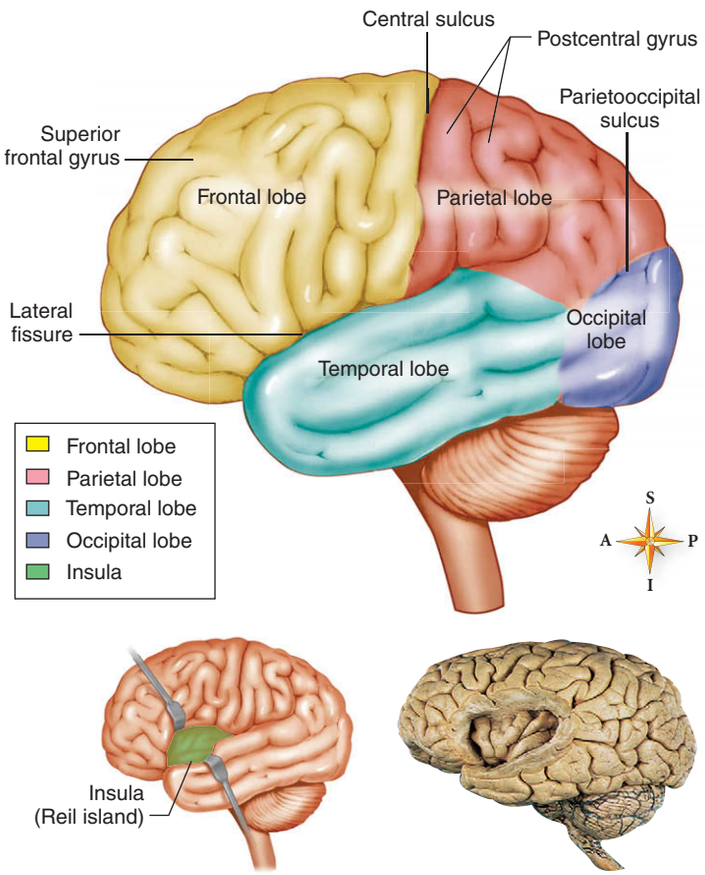

FIGURE 14-16

Box 14-5 | FYI

Brain Wrinkles

One of the first things that people notice about the brain is the very wrinkled appearance of the two largest regions of the brain: the cerebellum and cerebrum (Figure 1). Wrinkling of the skin is associated with aging and degeneration, but the wrinkles in the surfaces of these two brain regions provide great advantages. If you could flatten out the gray matter gyri (folia) of the cerebellar cortex and the gray matter gyri (convolutions) of both cerebral hemispheres, the advantages become clear. As Figure 2 shows, the surface area of these brain structures is much larger than it first appears. The fractal-like wrinkling of these brain surfaces allows more gray matter to be packed into the small space of the cranial cavity than would be the case if the brain were smooth surfaced. Thus many times more "computing power" is available to the cerebellum and cerebrum—enabling them to perform their very complex functions.

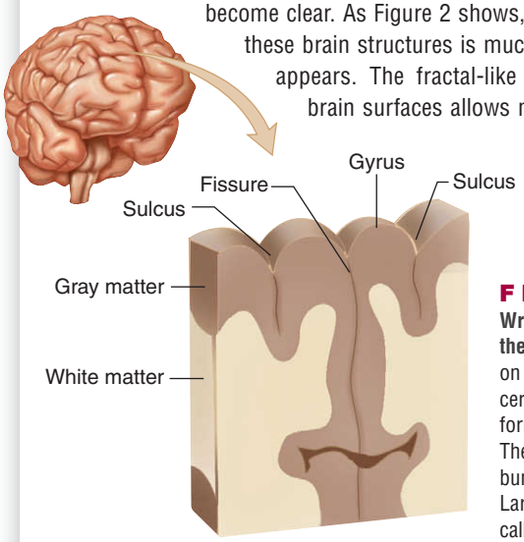

FIGURE 1
Wrinkles and grooves of the brain. Gray matter on the surface of the cerebrum is folded to form bumps or gyri. The valleys between the bumps are called *sulci*. Larger sulci are often called *fissures*.

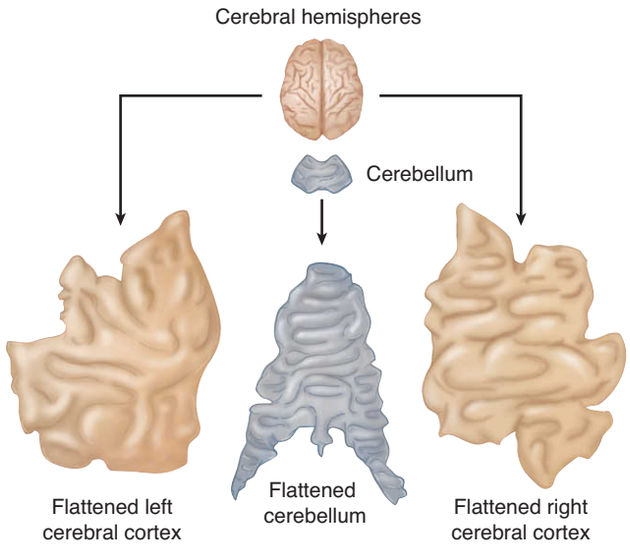

FIGURE 2
Surface area of the cerebellum and cerebrum. The gray matter on the surface of the cerebellum (gray) and the cerebrum (tan) is larger than it first appears because it is highly folded.

CEREBRAL TRACTS AND BASAL NUCLEI

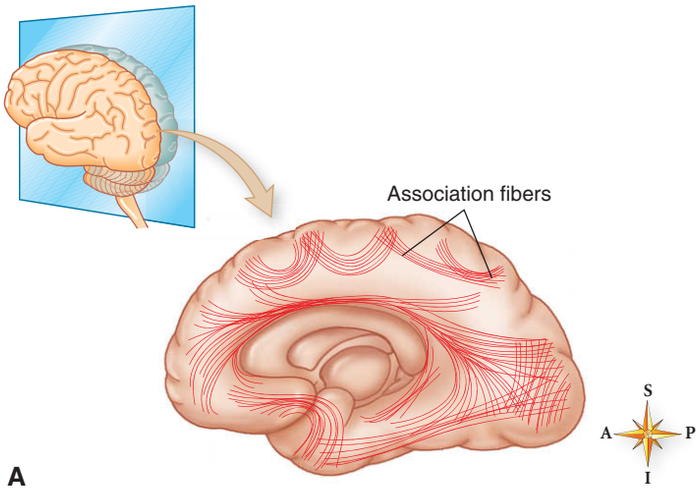
Beneath the cerebral cortex lies the large interior of the cerebrum. It is mostly white matter made up of numerous tracts. Tracts that make up the cerebrum's internal white matter are of three types: projection tracts, association tracts, and commissural tracts (Figure 14-17). *Projection tracts* are extensions of the ascending, or sensory, spinothalamic tracts and descending, or motor, corticospinal tracts. *Association tracts* are the most numerous of cerebral tracts; they extend from one convolution to another in the same hemisphere. *Commissural tracts,* in contrast, extend from a point in one hemisphere to a point in the other hemisphere. Commissural tracts compose the **corpus callosum** (prominent white curved structure seen in Figure 14-9) and the anterior and posterior commissures.

All of the connections within the human cortex to the rest of the brain—the human **connectome**—are currently being mapped out. This massive, international effort hopes to generate better understanding of the complex functions of the human brain.

A few islands of gray matter lie deep inside the white matter of each hemisphere. Collectively these are called **basal nuclei** (or historically, *basal ganglia*). Basal nuclei, seen in Figure 14-18, include the following masses of gray matter in the interior of each cerebral hemisphere:

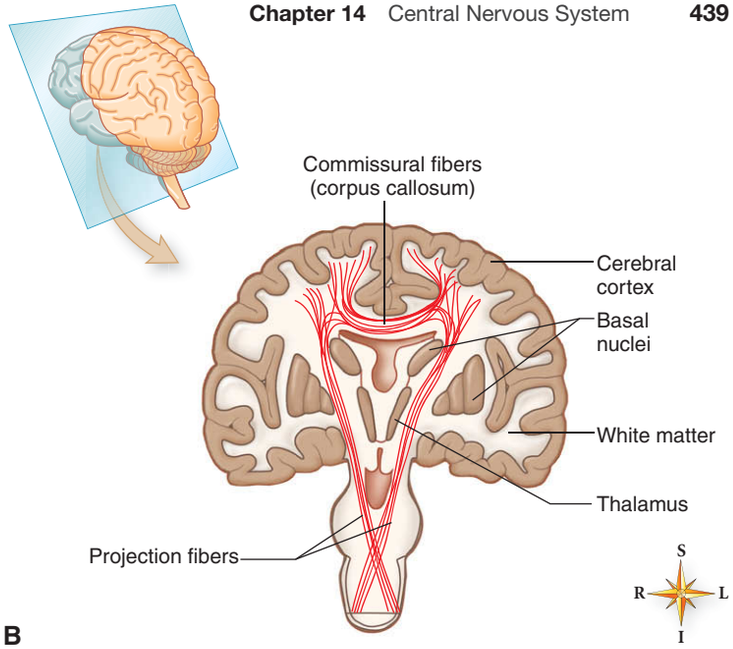
Caudate nucleus: observe the curving "tail" shape of this basal nucleus

Lentiform nucleus: so named because of its lenslike shape; note in Figure 14-18 that the lentiform nucleus consists of two structures, the putamen and the pallidum; the putamen lies lateral to the pallidum (also called the *globus pallidus*)



Amygdaloid nucleus: observe the location of this almond-shaped structure at the tip of the caudate nucleus (also called the *amygdala*, literally "almond")

A structure associated with the basal nuclei is the **internal capsule.** It is a large mass of white matter located, as Figure 14-18 shows, between the caudate and lentiform nuclei and between the lentiform nucleus and thalamus. The caudate nucleus, internal capsule, and lentiform nucleus constitute the corpus striatum, a term that means "striped body."



Researchers are still investigating the exact functions of the basal nuclei, but we already know that this part of the cerebrum plays an important role in regulating voluntary motor functions. For example, most of the muscle contractions involved in maintaining posture, walking, and performing other gross or repetitive movements seem to be initiated or modulated in the basal nuclei (Box 14-6). The basal nuclei may also play a role in thinking and learning.

UNIT 3

Box 14-6 | HEALTH matters

Parkinson Disease

The importance of the basal nuclei in regulating voluntary motor functions is made clear in cases of **Parkinson disease (PD).** Normally, neurons that lead from the substantia nigra to the basal nuclei secrete dopamine. Dopamine inhibits the excitatory effects of acetylcholine produced by other neurons in the basal nuclei. Such inhibition by *dopaminergic* (dopamine-producing) neurons produces a balanced, restrained output of muscle-regulating signals from the basal nuclei. In PD, however, neurons leading from the substantia nigra degenerate and thus do not release normal amounts of dopamine. Without dopamine, the excitatory effects of acetylcholine are not restrained, and the basal nuclei produce an excess of signals that affect voluntary muscles in several areas of the body. Over-stimulation of postural muscles in the neck, trunk, and upper limbs produces the syndrome of effects that typify this disease: rigidity and tremors of the head and limbs; an abnormal, shuffling gait; absence of relaxed arm-swinging while walking; and a forward tilting of the trunk.

Functions of the Cerebral Cortex

FUNCTIONAL AREAS OF THE CORTEX

During the past few decades, research scientists in various fields—neurophysiology, neurosurgery, neuropsychiatry, and others—have added mountains of information to our knowledge about the brain. However, new questions come faster than answers, and a clear, complete understanding of the brain's mechanisms still eludes us. Perhaps it always will. Perhaps the capacity of the human brain falls short of the ability to fully understand its own complexity.

We do know that certain areas of the cortex in each hemisphere of the cerebrum engage predominantly in one particular function—at least on the average. Differences between genders and among individuals of both genders are not uncommon. The fact that many cerebral functions have a typical location is known as the concept of cerebral localization. The fact that localization of function varies from person to person, and even at different times in an individual's life when the brain has sustained damage, is called **cerebral plasticity.**

The function of each region of the cerebral cortex depends on the structures with which it communicates. For example, the postcentral gyrus (Figures 14-19 and 14-20) functions mainly as a general somatic sensory area. It receives impulses from receptors activated by heat, cold, and touch stimuli. The precentral gyrus, on the other hand, functions chiefly as the somatic motor area (see Figures 14-19 and 14-20). Impulses from neurons in this area descend over motor tracts and eventually stimulate somatic effectors, the skeletal muscles. The transverse gyrus of the temporal lobe serves as the primary auditory area. The primary visual areas are in the occipital lobe. It is important to remember that no part of the brain functions alone. Many structures of the central nervous system must function together for any one part of the brain to function normally.

Sometimes, specific functional areas of the cortex are labeled with numbers (1 through 47) called *Brodmann areas (BAs)*. They are named for Korbinian Brodmann, a German neurologist who in 1908 first proposed a numbered map of the cortex based on the organizational pattern of neurons in different regions. We have learned that structure and function are related, so it is no surprise that Brodmann's structural approach has proven to have functional applications.

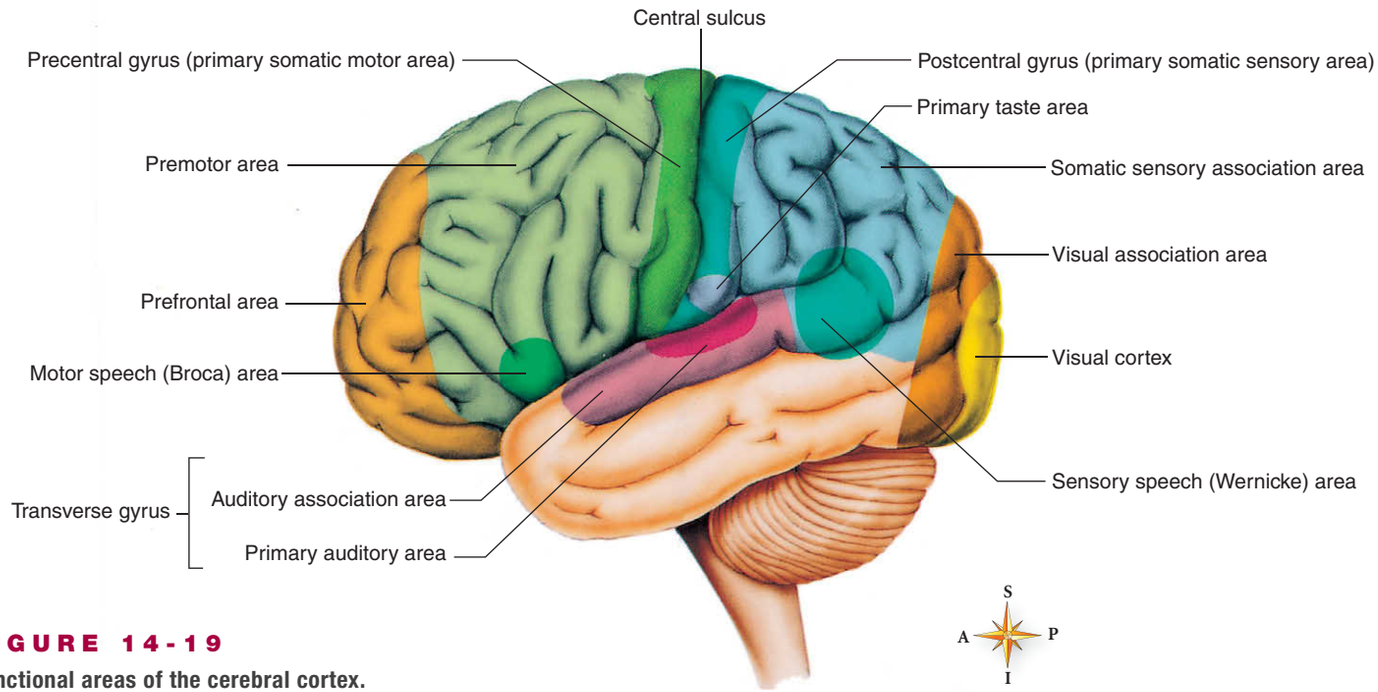

FIGURE 14-19

Functional areas of the cerebral cortex.

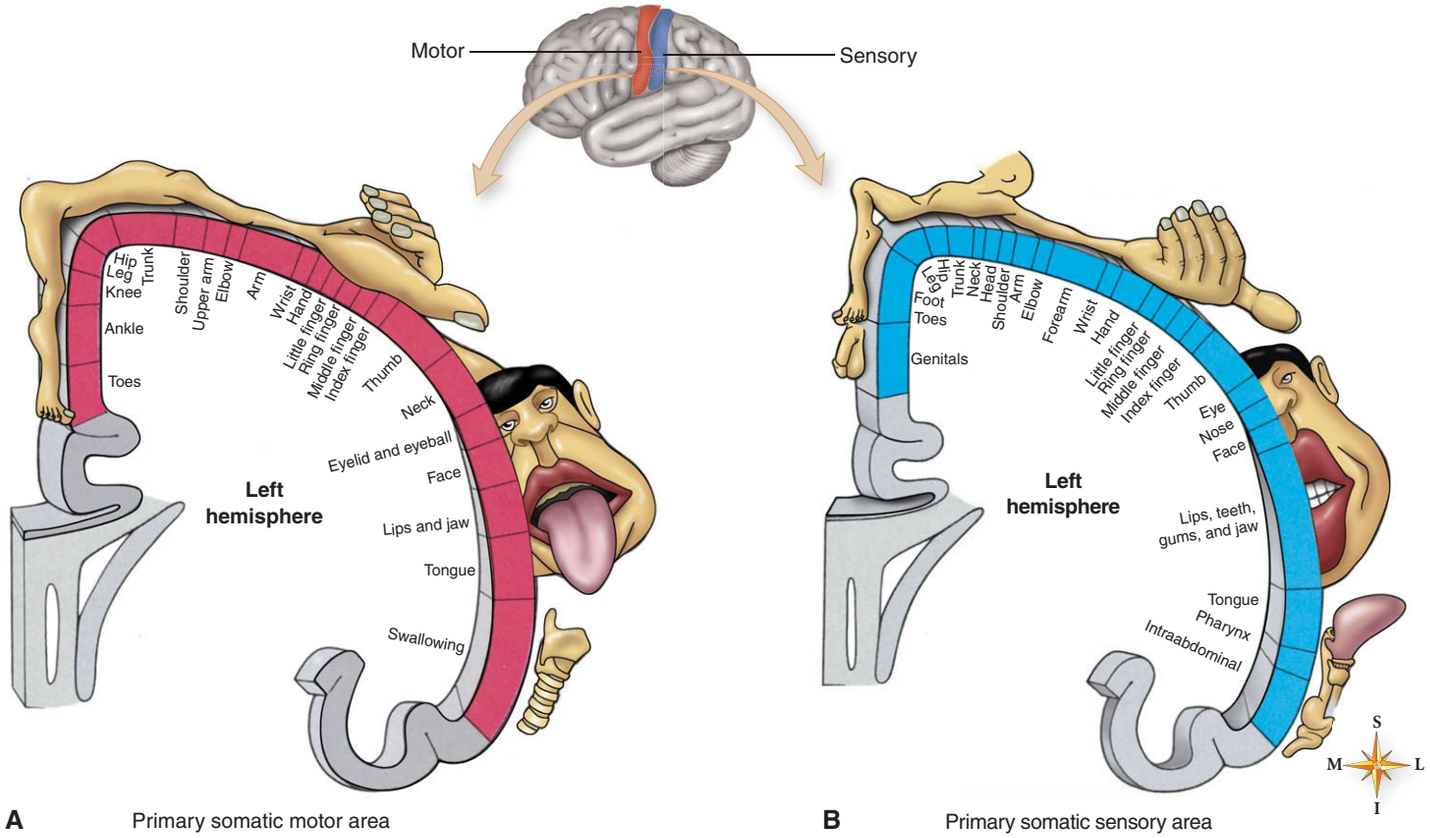

FIGURE 14-20

Primary somatic sensory (A) and motor (B) areas of the cortex. The body parts illustrated here show which parts of the body are "mapped" to specific areas of each cortical area. The exaggerated face indicates that more cortical area is devoted to processing information to and from the many receptors and motor units of the face than for the leg or arm, for example.

Images of the brain that help us understand the relationship between structure and function can be produced in many ways. These brain-imaging techniques can be used to discover new concepts of brain function and also to assess structural and functional problems in individual patients. Box 14-7 describes one important method for visualizing brain activity. Explore other fascinating brain imaging techniques in ***Brain Studies*** online at ***A&P Connect.***

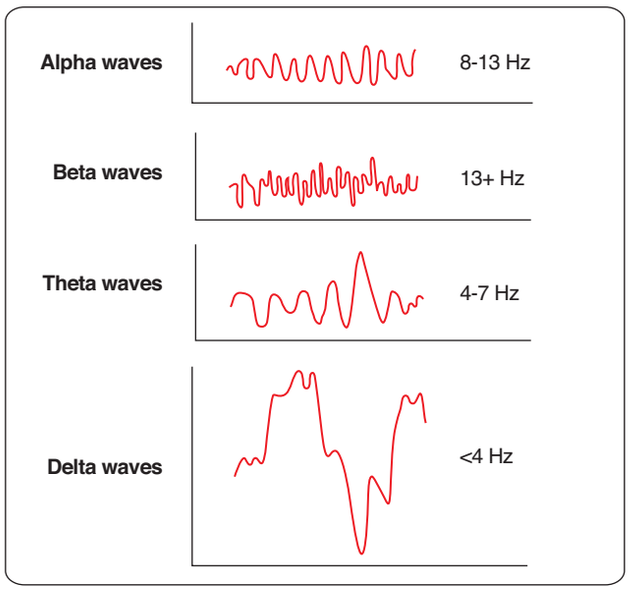
evolve

SENSORY FUNCTIONS OF THE CORTEX

Various areas of the cerebral cortex are essential for normal functioning of the somatic, or "general," senses, as well as the so-called "special" senses. The somatic senses include sensations of touch, pressure, temperature, body position (proprioception), and similar perceptions that do not require complex sensory organs. The special senses include vision, hearing, and other types of perception that require complex sensory organs, for example, the eye and the ear.

As stated earlier, the postcentral gyrus serves as a primary area for the general somatic senses. As Figure 14-20, A, shows, sensory fibers carrying information from receptors in specific parts of the body terminate in specific regions of the somatic sensory area. In

Box 14-7 | DIAGNOSTIC study



The Electroencephalogram (EEG)

Cerebral activity goes on as long as life itself. Only when life ceases (or moments before) does the cerebrum cease its functioning. Only then do all its neurons stop conducting impulses. Proof of this has come from records of brain electrical potentials known as **electroencephalograms,** or **EEGs.** These records are usually made from data detected by a number of electrodes placed on different regions of the scalp; they are records of wave activity—*brainwaves* (parts *A* and *B* of the figure).

Four types of brainwaves are recognized based on frequency and amplitude of the waves. Frequency, or the number of wave cycles per second, is usually referred to as *hertz* (Hz, from Hertz, a German physicist). Amplitude means voltage. Listed in order of frequency from fastest to slowest, brainwaves are designated as *beta, alpha, theta,* and *delta. Beta waves* have a frequency of more than 13 Hz and a relatively low voltage. *Alpha waves* have a frequency of 8 to 13 Hz and a relatively high voltage. *Theta waves* have both a relatively low frequency—4 to 7 Hz—and a low voltage. *Delta waves* have the slowest frequency—less than 4 Hz—but a high voltage. Brainwaves vary in different regions of the brain, in different states of awareness, and in abnormal conditions of the cerebrum.

Fast, low-voltage beta waves characterize EEGs recorded from the frontal and central regions of the cerebrum when an individual is awake, alert, and attentive, with eyes open. Beta waves predominate when the cerebrum is busiest, that is, when it is engaged with sensory stimulation or mental activities. In short, beta waves are "busy waves." Alpha waves, in contrast, are "relaxed waves." They are moderately fast, relatively high-voltage waves that dominate EEGs recorded from the parietal lobe, occipital lobe, and posterior parts of the temporal lobes when the cerebrum is idling, so to speak. The individual is awake but has eyes closed and is in a relaxed, nonattentive state. This state is sometimes called the "alpha state." When drowsiness descends, moderately slow, low-voltage theta waves appear. Theta waves are "drowsy waves." "Deep sleep waves," on the other hand, are known as delta waves. These slowest brainwaves characterize the deep sleep from which one is not easily aroused. For this reason, deep sleep is referred to as slow-wave sleep.

Physicians use electroencephalograms (EEGs) to help localize areas of brain dysfunction, to identify altered states of consciousness, and often to establish death. Two flat EEG recordings (no brainwaves) taken 24 hours apart in conjunction with no spontaneous respiration and total absence of somatic reflexes are criteria accepted as evidence of brain death.

A

other words, the cortex contains a sort of "somatic sensory map" of the body. Areas such as the face and hand have a proportionally larger number of sensory receptors, so their part of the somatic sensory map is larger. Likewise, information regarding vision is mapped in the visual cortex, and auditory information is mapped in the primary auditory area (see Figure 14-19).

The cortex does more than just register separate and simple sensations, however. Information sent to the primary sensory areas is in turn relayed to the various sensory association areas, as well as to other parts of the brain. There the sensory information is compared and evaluated. Eventually, the cortex integrates separate bits of information into whole perceptions.

Suppose, for example, that someone put an ice cube in your hand. You would, of course, see it and sense something cold touching your hand. But also you would probably know that it was an ice cube because you would perceive a total impression compounded of many sensations such as temperature, shape, size, color, weight, texture, and movement and position of your hand and arm.

Discussion of somatic sensory pathways begins on p. 448. The special senses are discussed in Chapter 17.

MOTOR FUNCTIONS OF THE CORTEX

Mechanisms that control voluntary movements are extremely complex and imperfectly understood. It is known, however, that for normal movements to take place, many parts of the nervous system—including certain areas of the cerebral cortex—must function.

The precentral gyrus, that is, the most posterior gyrus of the frontal lobe, constitutes the primary somatic motor area (see Figures 14-19 and 14-20, *B*). A secondary motor area lies in the gyrus immediately anterior to the precentral gyrus. Neurons in the precentral gyrus are said to control individual muscles, especially those that produce movements of distal joints (wrist, hand, finger, ankle, foot, and toe movements). Notice in Figure 14-20 that the primary somatic motor area is mapped according to the specific areas of the body it controls. Neurons in the premotor area just anterior to the precentral gyrus are thought to activate groups of muscles simultaneously.

Motor pathways descending from the cerebrum through the brainstem and spinal cord are discussed on pp. 449–450. Autonomic motor pathways are discussed in Chapter 16.

INTEGRATIVE FUNCTIONS OF THE CORTEX

"Integrative functions" is a murky term. Even more obscure, however, are the neural processes it designates. They consist of all events that take place in the cerebrum between its reception of sensory impulses and its sending out of motor impulses. Integrative functions of the cerebrum include consciousness and mental activities of all kinds. Consciousness, use of language, emotions, and memory are the integrative cerebral functions that we shall discuss—but only briefly.

Consciousness

Consciousness may be defined as a state of awareness of one's self, one's environment, and other humans. Very little is known about the neural mechanisms that produce consciousness. We do know, however, that consciousness depends on excitation of cortical neurons by impulses conducted to them by a network of neurons known as the *reticular activating system*. The **reticular activating system (RAS)** consists of centers in the brainstem's *reticular formation* that receive impulses from the spinal cord and relay them to the thalamus and from the thalamus to all parts of the cerebral cortex (Figure 14-21). Both direct spinal reticular tracts and collateral fibers from the sensory tracts (spinothalamic, lemniscal, auditory, and visual) relay impulses over the reticular activating system to the cortex. Without continual excitation of cortical neurons by reticular activating impulses, an individual is unconscious and cannot be aroused. Here, then, are two current concepts about the reticular activating system: (1) it functions as the arousal or alerting system for the cerebral cortex, and (2) its functioning is crucial for maintaining consciousness. Drugs known to depress the reticular activating system decrease alertness and induce sleep.

Barbiturates, for example, produce these effects. On the other hand, amphetamine, a drug known to stimulate the cerebrum and to enhance alertness and produce wakefulness, probably acts by stimulating the reticular activating system.

Certain variations in the levels or state of consciousness are normal. All of us, for example, experience different levels of wakefulness. At times, we are highly alert and attentive. At other times, we are relaxed and nonattentive. All of us also experience different levels of sleep.

In addition to the various normal states of consciousness, altered states of consciousness also occur under certain conditions. Anesthetic

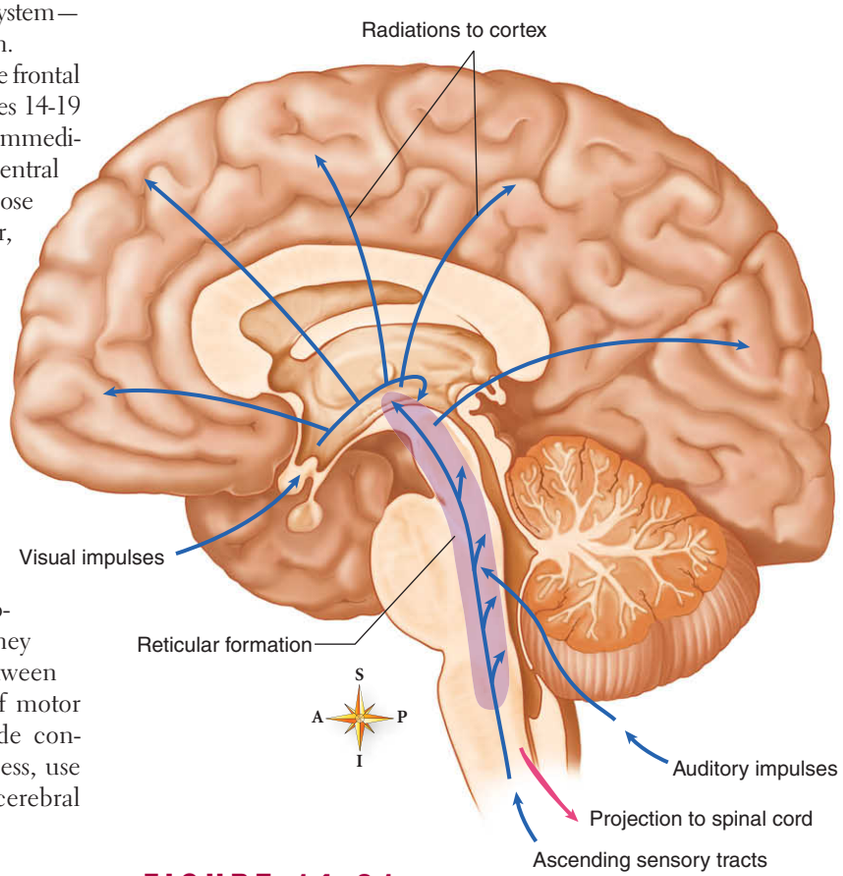

FIGURE 14-21

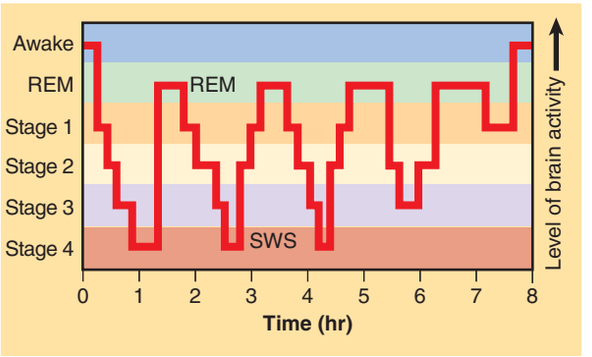

Reticular activating system (RAS). Consists of centers in the brainstem's *reticular formation* plus fibers that conduct to the centers from below and fibers that conduct from the centers to widespread areas of the cerebral cortex. Functioning of the RAS is essential for regulating levels of consciousness.

drugs produce an altered state of consciousness, namely, *anesthesia*. Disease or injury of the brain may produce an altered state called **coma.**

Peoples of various cultures have long been familiar with an altered state called *meditation*. Meditation is a waking state but differs markedly in certain respects from the usual waking state. According to some, meditation is a "higher" or "expanded" level of consciousness. This higher consciousness is accompanied, almost paradoxically, by a high degree of both relaxation and alertness. With training in meditation techniques and practice, an individual can enter the meditative state at will and remain in it for an extended period of time.

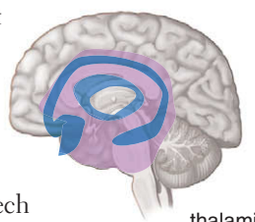
Sleep is a fascinating and mysterious process that we are just beginning to understand. What we do understand is that sleep involves changes in the level of brain activity, as seen in the figure. Shortly after falling asleep, we fall into a deep **slow-wave sleep (SWS)** characterized by slow electroencephalogram (EEG) waves. Approximately every 90 minutes or so, brain activity increases during a dream stage called **rapid eye movement (REM) sleep.** Learn more about the sleep cycle in ***Sleep*** online at ***A&P Connect.***



Sleep Stages

evolve

Language

Language functions consist of the ability to speak and write words and the ability to understand spoken and written words. Certain areas in the frontal, parietal, and temporal lobes serve as speech centers—as crucial areas, that is, for language functions. The left cerebral hemisphere contains these areas in about 90% of the population; in the remaining 10%, either the right hemisphere or both hemispheres contain them.

Lesions in speech centers give rise to language defects called *aphasias*. For example, with damage to an area in the inferior gyrus of the frontal lobe (Broca's area, see Figure 14-19), a person becomes unable to articulate words but can still make vocal sounds and understand words heard and read.

Box 14-8 discusses a newly discovered class of neurons that may help us learn and use language.

Box 14-8 | FYI

Mirror Neurons

A special functional class of neurons called *mirror neurons* exist in the cortex. These neurons exhibit action potentials both when we experience something ourselves and also when someone else does. In other words, certain circuits in our cortex become active whether we perform an action or whether we observe someone else doing so—thus enabling the brain to "mirror" the activity of another person's brain. Although much more is yet to be learned about the so-called *mirror-neuron system,* it seems clear that the action of these neurons may explain how humans are able to learn spoken language; interpret complex body language; empathize with the feelings of others; and learn to walk, write, or ride a bicycle.

Emotions

Emotions—both the subjective experiencing of them and the objective expression of them—involve functioning of the cerebrum's **limbic system.** The name *limbic* (Latin for "border or fringe") suggests the shape of the cortical structures that make up the system. They form a curving border around the corpus callosum, the structure that connects the two cerebral hemispheres.

Look now at Figure 14-22. Here on the medial surface of the cerebrum lie most of the structures of the limbic system. They are the cingulate gyrus and the hippocampus (the extension of the hippocampal gyrus that protrudes into the floor of the inferior horn of the lateral ventricle). These limbic system structures have primary connections with various other parts of the brain, notably

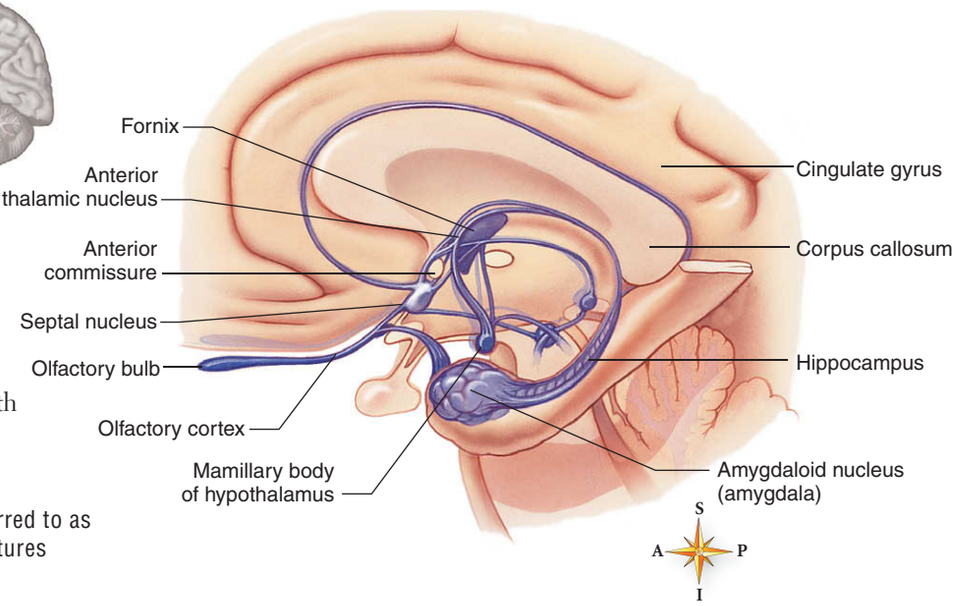


FIGURE 14-22

Structures of the limbic system. Sometimes referred to as "the emotional brain," this network of brain structures functions as we experience emotions.

the thalamus, fornix, septal nucleus, amygdaloid nucleus (the tip of the caudate nucleus, one of the basal nuclei), and the hypothalamus. Some physiologists therefore include these connected structures as parts of the limbic system.

The limbic system (or to use its more descriptive name, the *emotional brain*) functions in some way to make us experience many kinds of emotions—anger, fear, joy, sadness, surprise, and disgust, for example. To bring about the normal expression of emotions, parts of the cerebral cortex other than the limbic system must also function. Considerable evidence exists to indicate that limbic activity without the modulating influence of the other cortical areas may bring on the attacks of abnormal, uncontrollable rage suffered periodically by some unfortunate individuals.

Memory

Memory is one of our major mental activities. The cortex is capable of storing and retrieving both *short-term memory* and *long-term memory*. Short-term memory involves the storage of information over a few seconds or minutes. Short-term memories can be somehow consolidated by the brain and stored as long-term memories that can be retrieved days—or even years—later.

Both short-term memory and long-term memory are functions of many parts of the cerebral cortex, especially of the temporal, parietal, and occipital lobes. Findings by Dr. Wilder Penfield, a noted Canadian neurosurgeon, first gave evidence of this almost 100 years ago. He electrically stimulated the temporal lobes of epileptic patients undergoing brain surgery. They responded, much to his surprise, by recalling in the most minute detail songs and events from their past.

Such long-term memories are believed to consist of some kind of structural changes in the synapses of the cerebral cortex, as you learned in Chapter 13 (see p. 404). Repeated impulse conduction over a given neuronal circuit produces the synaptic change. Two possible changes are an increase in the number of presynaptic axon terminals or an increase in the number of receptor proteins in the postsynaptic neuron's membrane. Other possible changes involve changes in the average concentrations of neurotransmitters at certain synapses or changes in the functions of astrocytes. All of these changes somehow facilitate impulse transmission at the synapses.

More recent data suggests that different kinds of memories may be stored in different ways. Some memories are perhaps stored by way of changes at synapses and some by changes in the neurons themselves. For example, some neurons have been shown to react only when a specific person is seen or mentioned—thus somehow acting as a "recognition neuron" for the particular individual who is recognized.

Many research findings indicate that the cerebrum's limbic system—the "emotional brain"—plays a key role in memory. To mention one role, when the hippocampus (part of the limbic system) is removed, the patient loses the ability to recall new information. Your own personal experience substantiates a relationship between emotion and memory.

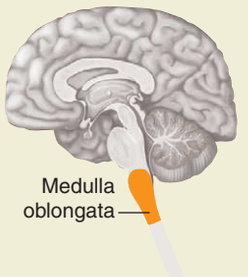
15. Where is the primary somatic motor area of the cerebral cortex? Where is the primary somatic sensory area?
16. What does the reticular activating system have to do with alertness?
17. What is the function of the limbic system?

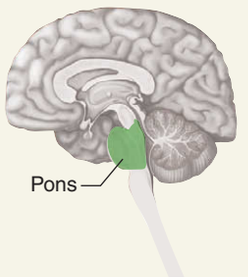
TABLE 14-3 Summary of CNS Structures and Functions

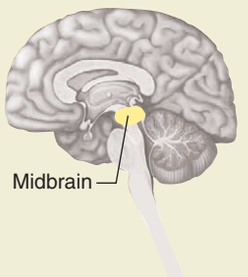
REGION	STRUCTURE*	FUNCTION*
Spinal cord 	Elongated cylinder extending from the brainstem through the foramen magnum of the skull; gray matter interior surrounded by white matter; 31 pairs of spinal nerves attached by dorsal and ventral nerve roots	Integration of simple, subconscious spinal reflexes; conduction of nerve impulses
Gray matter	Numerous synapses and interneurons arranged into anterior, lateral, and posterior gray columns linked by a gray commissure	Integration of spinal reflexes and filtering of information going to higher centers (as in gated pain control)
White matter	Myelinated nerve tracts arranged into anterior, lateral, and posterior white columns (funiculi)	Ascending tracts conduct sensory information to higher CNS centers; descending tracts conduct motor information from higher CNS centers

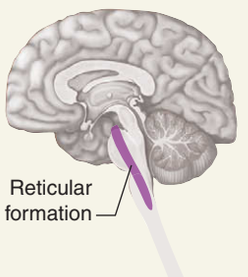
(continued)

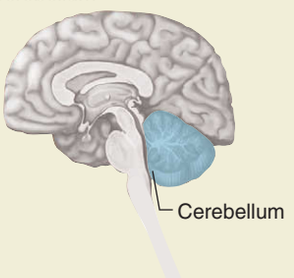
TABLE 14-3 Summary of CNS Structures and Functions *(continued)*

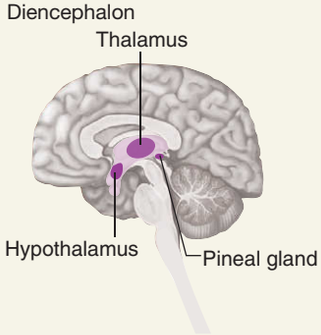


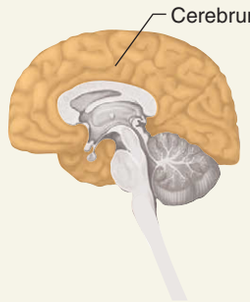


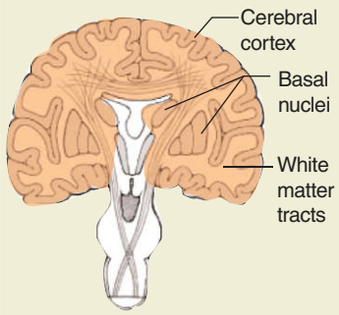












REGION	STRUCTURE*	FUNCTION*
Brainstem	Extends inferiorly from diencephalon to foramen magnum of skull, where it meets the spinal cord; central gray matter nuclei surrounded and connected by white matter tracts; 10 of the 12 pairs of cranial nerves attached here	Subconscious integration of basic vital functions
Medulla oblongata 	Inferior region of brainstem between the spinal cord and the pons	Integration of cardiac, vasomotor (vessel muscle), respiratory, digestive and other reflexes
Pons 	Intermediate region of brainstem between the medulla and the midbrain	Integration of numerous autonomic reflexes mediated by cranial nerves V, VI, VII, and VIII (see Chapters 15, 16) and respiration
Midbrain 	Superior region of the brainstem between the pons and the diencephalon	Integration of numerous cranial nerve reflexes, such as eye movements, pupillary reflex, ear (sound muffling) reflexes
Reticular formation 	Roughly cylindrical network of nerve pathways and centers extending through the brainstem and into the diencephalon	Operates the reticular activating system (RAS) that regulates state of consciousness
Cerebellum 	Roughly spherical structure attached at the posterior of the brainstem; wrinkled gray matter cortex, branched network of white fibers inside (arbor vitae), and several small gray nuclei	Coordinates many functions of cerebrum, including planning and control of skilled movements, posture, balance, coordination of sensory information relating to body position and movement

TABLE 14-3 Summary of CNS Structures and Functions *(continued)*

REGION	STRUCTURE*	FUNCTION*
Diencephalon 	Brain region in the central part of the brain, between the cerebrum and brainstem (midbrain); made up of various gray-matter nuclei	Numerous coordinating and integrating functions
Thalamus	Large ovoid of gray matter, divided into two large lateral masses connected by an intermediate mass	Crude sensations, coordination of sensory information relayed to cerebrum; involved in emotional response to sensory information; involved in arousal; general processing of information to/from cerebrum
Hypothalamus	Numerous gray-matter nuclei clustered below the thalamus	Integration/coordination of many autonomic reflexes, hormonal functions; involved in arousal, appetite, thermoregulation
Pineal gland	Single nucleus of neuroendocrine tissue posterior to the thalamus	Produces melatonin, a timekeeping hormone, as part of the body's biological clock
Cerebrum 	Largest, most superior region of brain; divided into right and left hemispheres, connected by the corpus callosum	Complex processing of sensory and motor information; complex integrative functions
Cerebral cortex 	Highly wrinkled gray-matter surface of the cerebrum; divided into five major lobes per hemisphere; functionally mapped based on concept of localization	Higher-level processing of sensory and motor information, including conscious sensation and motor control; complex integrative functions such as consciousness, language, memory, emotions
Cerebral tracts	White-matter tracts connect various regions of the cortex with each other and with inferior CNS structures	Conduction information between CNS areas to facilitate complex processing and integration
Basal nuclei	Gray-matter nuclei deep in the cerebrum	Integration and regulation of conscious motor control, especially posture, walking, other repetitive movements; possible roles in thinking and learning

*Summary only; see chapter text and figures for detailed descriptions of structure and function.
CNS, Central nervous system.

SOMATIC SENSORY PATHWAYS IN THE CENTRAL NERVOUS SYSTEM

For the cerebral cortex to perform its *sensory* functions, impulses must first be conducted to its sensory areas by way of relays of neurons referred to as *sensory pathways*. Most impulses that reach the sensory areas of the cerebral cortex have traveled over at least three pools of sensory neurons. We shall designate these as *primary sensory neurons*, *secondary sensory neurons*, and *tertiary sensory neurons* (Figure 14-23).

Primary sensory neurons of the relay conduct from the periphery to the central nervous system. Secondary sensory neurons conduct from the cord or brainstem up to the thalamus. Their dendrites and cell bodies are located in spinal cord or brainstem gray matter. Their axons ascend in ascending tracts up the cord, through the brainstem, and terminate in the thalamus. Here they synapse with dendrites or cell bodies of tertiary sensory neurons (see Figure 14-23). Tertiary sensory neurons conduct from the thalamus to the postcentral gyrus of the parietal lobe, the somaticosensory area. Bundles of axons of tertiary sensory neurons form thalamocortical tracts. They extend through the portion of cerebral white matter known as the *internal capsule* to the cerebral cortex (see Figure 14-23).

For the most part, sensory pathways to the cerebral cortex are crossed pathways. This means that each side of the brain registers sensations from the opposite side of the body. Look again at Figure 14-23. The axons that *decussate* (cross from one side to the other) in these sensory pathways are which sensory neurons: primary, secondary, or tertiary? Usually it is the axon of a secondary sensory neuron that decussates at some level in its ascent to the thalamus. Thus general sensations of the right side of the body are predominantly experienced by the left somatic sensory area. General sensations of the left side of the body are predominantly experienced by the right somatic sensory area.

Two sensory pathways conduct impulses that produce sensations of touch and pressure, namely, the *medial lemniscal system* and the *spinothalamic pathway* (see Figure 14-23). The medial lemniscal system consists of the tracts that make up the posterior white columns of the cord (the fasciculi cuneatus and gracilis) plus the *medial lemniscus*, a flat band of white fibers extending through the medulla, pons, and midbrain. (The term *lemniscus* literally means "ribbon," referring to this tract's flattened shape.)

The fibers of the medial lemniscus, like those of the spinothalamic tracts, are axons of secondary sensory neurons. They originate from cell bodies in the medulla, decussate, and then

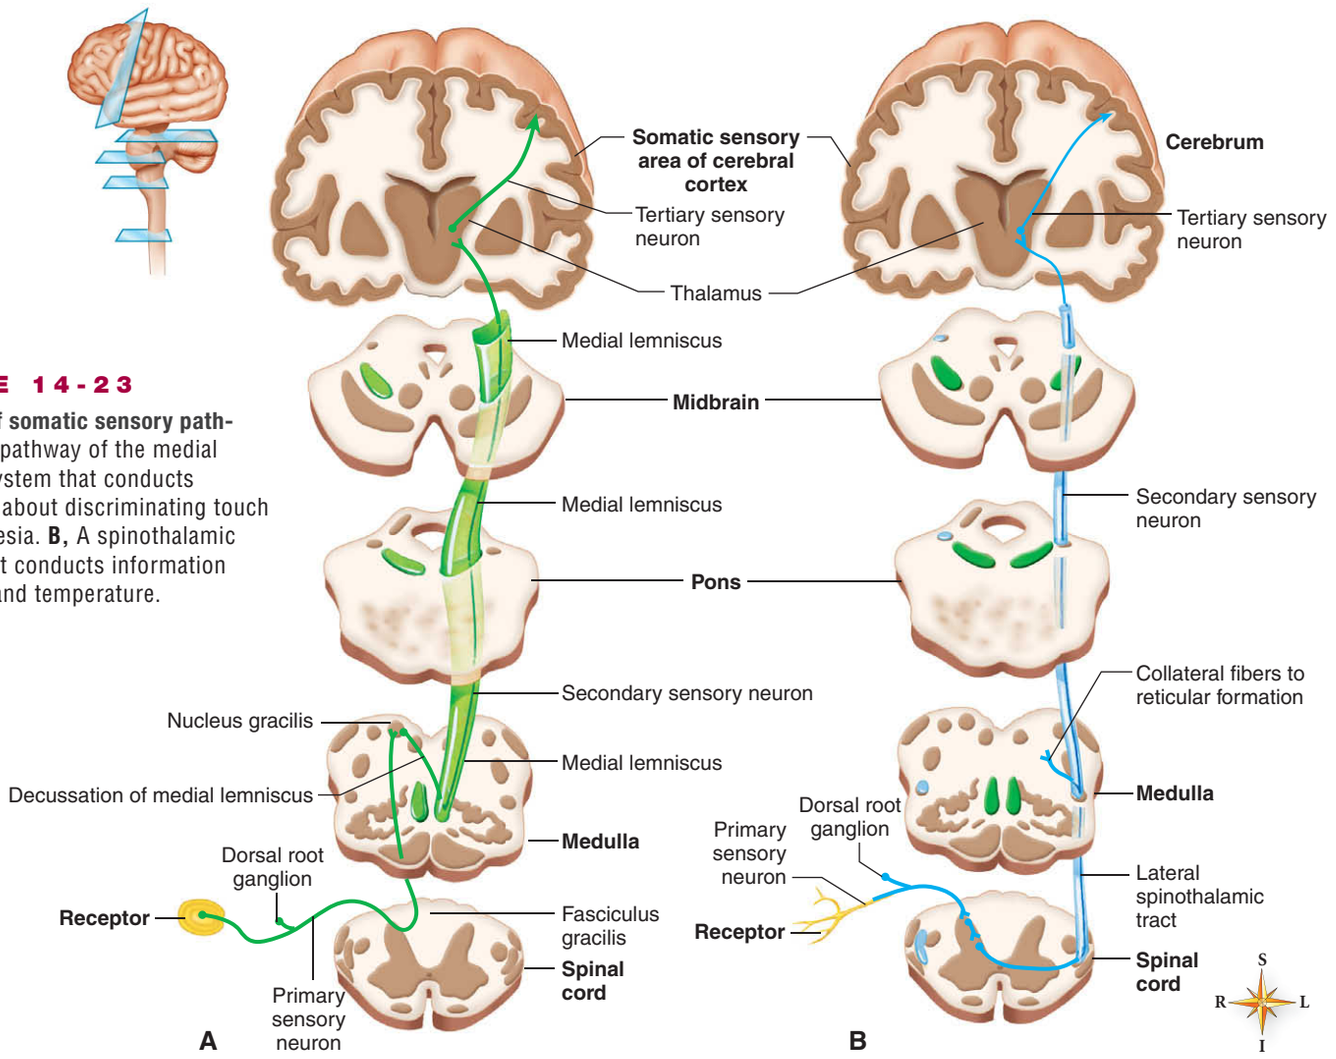


FIGURE 14-23

Examples of somatic sensory pathways. A, A pathway of the medial lemniscal system that conducts information about discriminating touch and kinesthesia. **B,** A spinothalamic pathway that conducts information about pain and temperature.

extend upward to terminate in the thalamus on the opposite side. The function of the medial lemniscal system is to transmit impulses that produce our more discriminating touch and pressure sensations, including *stereognosis* (awareness of an object's size, shape, and texture), precise localization, two-point discrimination, weight discrimination, and sense of vibrations. The sensory pathway for kinesthesia (sense of movement and position of body parts) is also part of the medial lemniscal system.

Crude touch and pressure sensations are functions of the **spinothalamic pathway.** Knowing that something is touching the skin is a crude touch sensation, whereas knowing its precise location, size, shape, or texture involves the discriminating touch sensations of the medial lemniscal system.

18. Over how many afferent neurons does somatic sensory information usually pass?
19. Explain why stimuli on the left side of the body are perceived by the right side of the cerebral cortex.

SOMATIC MOTOR PATHWAYS IN THE CENTRAL NERVOUS SYSTEM

For the cerebral cortex to perform its *motor* functions, impulses must be conducted from its motor areas to skeletal muscles by relays of neurons referred to as *somatic motor pathways.* Somatic motor pathways consist of motor neurons that conduct impulses from the central nervous system to somatic effectors, that is, skeletal muscles. Some motor pathways are extremely complex and not at all clearly defined. Others, notably spinal cord reflex arcs, are simple and well established. You read about those in Chapter 13.

Look now at Figure 14-24. From this diagram you can derive a cardinal principle about somatic motor pathways—the *principle of the final common path.* It is this: only one final common path (namely, each single motor neuron from the anterior gray horn of the spinal cord) conducts *impulses* to a specific motor unit within a skeletal muscle. Axons from the anterior gray horn are the only ones that terminate in skeletal muscle cells. This principle of the final common path to skeletal muscles has important practical implications. For example, it means that any condition that makes anterior horn motor neurons unable to conduct impulses also

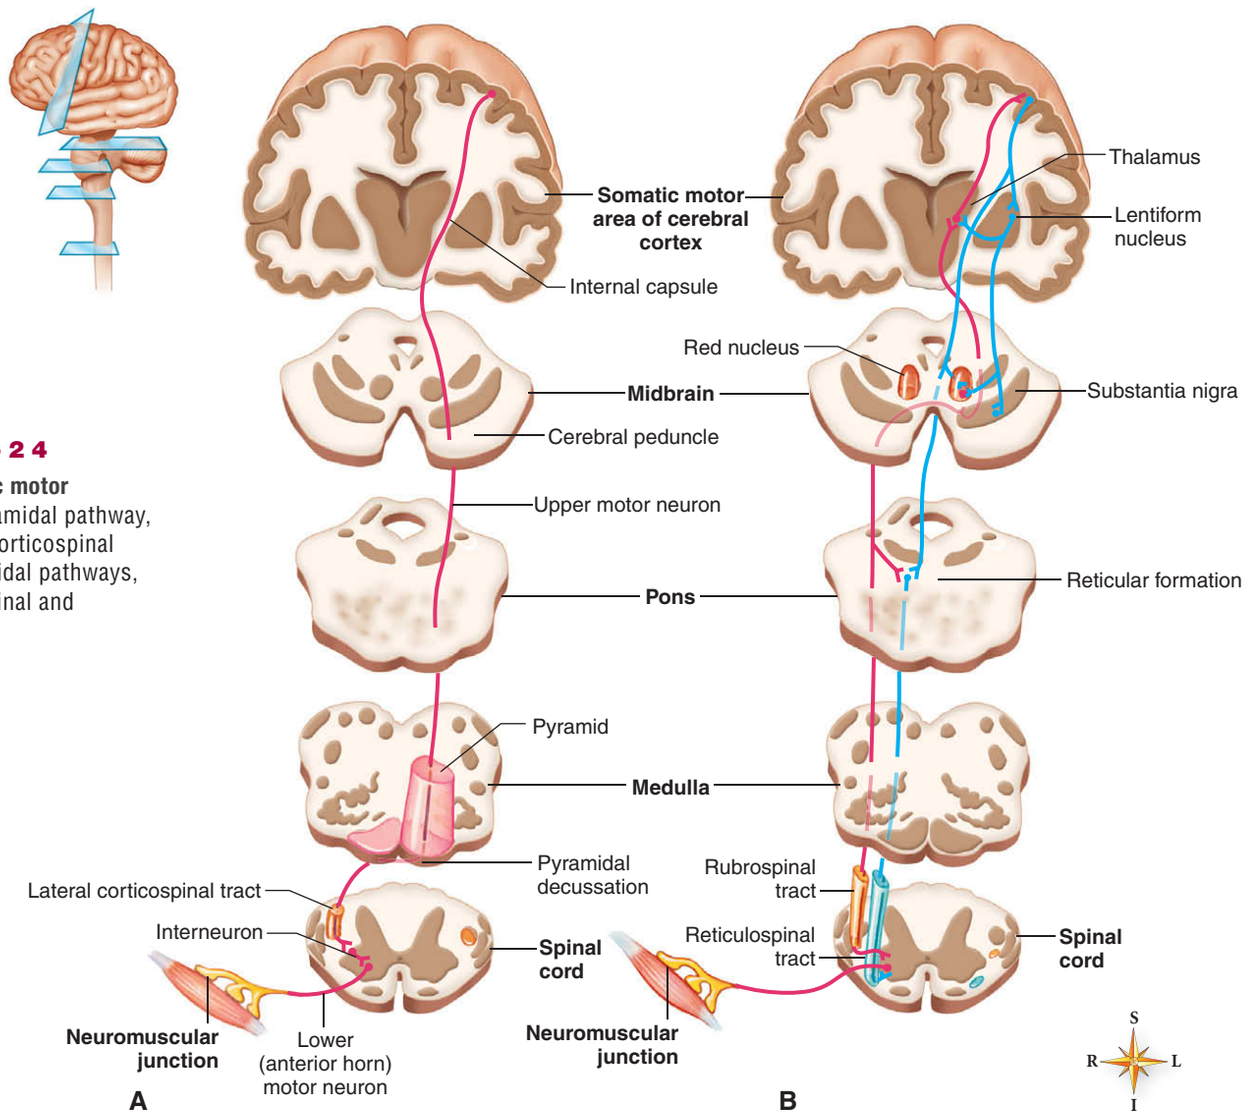

FIGURE 14-24

Examples of somatic motor pathways. A, A pyramidal pathway, through the lateral corticospinal tract. **B,** Extrapyramidal pathways, through the rubrospinal and reticulospinal tracts.

makes skeletal muscle cells supplied by these neurons unable to contract. They cannot be willed to contract nor can they contract reflexively. They are, in short, so flaccid that they are paralyzed. Most well known of the diseases that produce flaccid paralysis by destroying anterior horn motor neurons is *poliomyelitis*. Numerous somatic motor paths conduct impulses from motor areas of the cerebrum down to anterior horn motor neurons at all levels of the cord.

Two methods are used to classify somatic motor pathways—one based on the location of their fibers in the medulla and the other on their influence on the lower motor neurons. The first method divides them into pyramidal and extrapyramidal tracts. The second classifies them as facilitatory and inhibitory tracts.

Pyramidal Tracts

Pyramidal tracts are those whose fibers come together in the medulla to form the pyramids, hence their name (see Figure 14-24, A). Because axons composing the pyramidal tracts originate from neuron cell bodies located in the cerebral cortex, they also bear another name—*corticospinal tracts*. About three fourths of their fibers decussate (cross over from one side to the other) in the medulla. After decussating, they extend down the spinal cord in the crossed corticospinal tract located on the opposite side of the spinal cord in the lateral white column.

About one fourth of the corticospinal fibers do not decussate.

Instead, they extend down the same side of the spinal cord as the cerebral area from which they came. One pair of uncrossed tracts lies in the anterior white columns of the cord, namely, the anterior corticospinal tracts. The other uncrossed corticospinal tracts form part of the lateral corticospinal tracts.

About 60% of corticospinal fibers are axons that arise from neuron cell bodies in the precentral (frontal lobe) region of the cortex. About 40% of corticospinal fibers originate from neuron cell bodies located in postcentral areas of the cortex, areas classified as sensory; now, more accurately, they are often called *sensorimotor areas*.

Relatively few corticospinal tract fibers synapse directly with anterior horn motor neurons. Most of them synapse with interneurons, which in turn synapse with anterior horn motor neurons. All corticospinal fibers conduct impulses that depolarize resting anterior horn motor neurons. The effects of depolarizations occurring rapidly in any one neuron add up, or summate. Each impulse, in other words, depolarizes an anterior horn motor neuron's resting potential a little bit more. If sufficient numbers of impulses impinge rapidly enough on a neuron, its potential reaches the threshold level. At that moment the neuron starts conducting impulses—it is stimulated.

Stimulation of anterior horn motor neurons by corticospinal tract impulses results in stimulation of individual muscle groups (mainly of the hands and feet). Precise control of their contractions is, in short, the function of the corticospinal tracts. Without stimulation of anterior horn motor neurons by impulses over corticospinal fibers, willed movements cannot occur. This means that paralysis results whenever pyramidal corticospinal tract conduction is interrupted. For instance, the paralysis that so often follows **cerebrovascular accidents** (CVAs, or strokes) comes from pyramidal neuron injury—sometimes of their cell bodies in the motor areas, sometimes of their axons in the internal capsule (see Figure 14-24).

Extrapyramidal Tracts

Extrapyramidal tracts are much more complex than pyramidal tracts. They consist of all motor tracts from the brain to the spinal cord anterior horn motor neurons except the corticospinal (pyramidal) tracts. Within the brain, extrapyramidal tracts consist of numerous relays of motor neurons between motor areas of the cortex, basal nuclei, thalamus, cerebellum, and brainstem. In the cord, some of the most important extrapyramidal tracts are the reticulospinal tracts.

Fibers of the *reticulospinal tracts* originate from cell bodies in the reticular formation of the brainstem and terminate in gray matter of the spinal cord, where they synapse with interneurons that synapse with lower (anterior horn) motor neurons. Some reticulospinal tracts function as facilitatory tracts and others as inhibitory tracts. Summation of these opposing influences determines the lower motor neuron's response. It initiates impulse conduction only when facilitatory impulses exceed inhibitory impulses sufficiently to decrease the lower motor neuron's negativity to its threshold level.

Conduction by extrapyramidal tracts plays a crucial part in producing our larger, more automatic movements because extrapyramidal impulses bring about contractions of groups of muscles in sequence or simultaneously. Such muscle action occurs, for example, in swimming and walking and, in fact, in all normal voluntary movements.

Conduction by extrapyramidal tracts plays an important part in our emotional expressions. For instance, most of us smile automatically at things that amuse us and frown at things that irritate us. It is extrapyramidal, not pyramidal, impulses that produce the smiles or frowns.

Axons of many different neurons converge on, that is, synapse with each anterior horn motor neuron (see Figure 14-24). Hence many impulses from diverse sources—some facilitatory and some inhibitory—continually bombard this final common path to skeletal muscles. Together the added, or summated, effect of these opposing influences determines lower motor neuron functioning. Facilitatory impulses reach these cells by way of sensory neurons (whose axons, you will recall, lie in the posterior roots of spinal nerves), pyramidal (corticospinal) tracts, and extrapyramidal facilitatory reticulospinal tracts. Impulses over facilitatory reticulospinal fibers facilitate the lower motor neurons that supply extensor muscles. At the same time, they reciprocally inhibit the lower motor neurons that supply flexor muscles. Hence facilitatory reticulospinal impulses tend to increase the tone of extensor muscles and decrease the tone of flexor muscles.

Inhibitory impulses reach lower motor neurons mainly by way of inhibitory reticulospinal fibers that originate from cell bodies located in the *bulbar inhibitory area* in the medulla. They inhibit the lower motor neurons to extensor muscles (and reciprocally stimulate those to flexor muscles). Hence inhibitory reticulospinal impulses tend to decrease extensor muscle tone and increase flexor muscle tone; note that these effects are opposite from those of facilitatory reticulospinal impulses.

The set of coordinated commands that control the programmed muscle activity mediated by extrapyramidal pathways is often called a **motor program.** Traditionally, the primary somatic motor areas of the cerebral cortex were thought to be the principal organizer of motor programs sent along the extrapyramidal pathway. That view has been replaced by the concept illustrated in Figure 14-25. This newer concept holds that motor programs result from the interaction of several different centers in the brain. Apparently, many voluntary motor programs are organized in the basal nuclei and cerebellum—perhaps in response to a willed command by the cerebral cortex. Impulses that constitute the motor program are then channeled through the thalamus and back to the cortex, specifically to the primary motor area. From there, the motor program is sent down to the inhibitory and facilitatory regions of the brainstem. Signals from the brainstem then continue on down one or more spinal tracts and out to the muscles by way of the lower (anterior horn) motor neurons. All along the way, neural connections among the various motor control centers allow refinement and adjustment of the motor program.

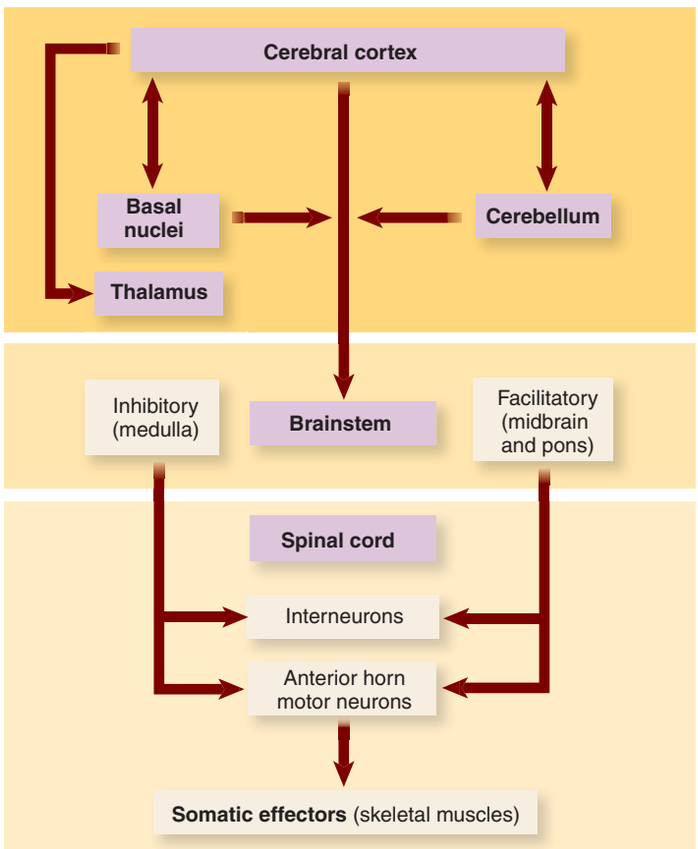

FIGURE 14-25

Concept of extrapyramidal motor control. Programmed movements result from a set of impulses called a *motor program.* The motor program organized in the basal nuclei and cerebellum in response to a command from the cortex is sent back to the primary motor control area of the cortex. From there, it is sent to the brainstem and then on through the spinal cord to the skeletal muscles. All along the motor pathway, the motor program can be refined by various components of this complex pathway.

Box 14-9 | HEALTH matters

Signs of Motor Pathway Injury

Injury of upper motor neurons (those whose axons lie in either pyramidal or extrapyramidal tracts) produces symptoms frequently referred to as "pyramidal signs," notably a spastic type of paralysis, exaggerated deep reflexes, and a positive Babinski reflex (see p. 483). Actually, pyramidal signs result from interruption of both pyramidal and extrapyramidal pathways. The paralysis stems from interruption of pyramidal tracts, whereas the spasticity (rigidity) and exaggerated reflexes come from interruption of inhibitory extrapyramidal pathways.

Injury to lower motor neurons produces symptoms different from those of upper motor neuron injury. Anterior horn cells or lower motor neurons, you will recall, constitute the final common path by which impulses reach skeletal muscles. This means that if they are injured, impulses can no longer reach the skeletal muscles they supply. This, in turn, results in the absence of all reflexes and willed movements produced by contraction of the muscles involved. Unused, the muscles soon lose their normal tone and become soft and flabby (flaccid). In short, absence of reflexes and flaccid paralysis are the chief "lower" motor neuron signs.

If all this sounds complicated and confusing, imagine what it must be like to be a neurobiologist trying to figure out how all this works! In fact, scientists working in this field admit that they have not worked out all the details of the extrapyramidal circuits—or exactly how they control muscle activity. However, the model shown in Figure 14-25 summarizes the current notion that it is a complex, interactive process.

Knowing about all these motor pathways helps us understand and treat injuries and disorders that affect motor functions. Box 14-9 discusses some of the clinical signs of motor pathway injury.

| QUICK CHECK |

20. What is the "principle of final common path" as it pertains to somatic motor pathways?
21. Distinguish between pyramidal and extrapyramidal pathways.

Cycle of LIFE

Central Nervous System

If the most obvious *structural* changes over the life span are the overall growth and then degeneration of the skeleton and other body parts, then the most obvious *functional* changes are the development and then degeneration of the complex integrative capacity of the central nervous system.

Although the development of the brain and spinal cord begins in the womb, further development beyond the time of birth is required. The lack of development of the CNS in a newborn is evidenced by lack of the more complex integrative functions, such as

language, complex memory, comprehension of spatial relationships, and complex motor skills such as walking. As childhood proceeds, one can easily see evidence of the increasing capacity of the CNS for complex function. A child learns to use language, to remember both concrete and abstract ideas, to walk, and even to behave in ways that conform to the norms of society. By the time a person reaches adulthood, most, if not all, of these complex functions have become fully developed. We use them throughout adult life to help us maintain internal stability in an unstable external world.

As we enter very late adulthood, the tissues of the brain and spinal cord may degenerate. If they do degenerate—and they may not—the degree of change varies from one individual to the next. In some cases, the degeneration is profound—or it occurs in a critical part of the brain—and an older person becomes unable to communicate, to walk, or to perform some other complex functions. In many cases, however, the degeneration produces milder effects, such as temporary lapses in memory or fumbling with certain very complex motor tasks. As our understanding of this process increases, we are finding ways to avoid entirely such changes associated with aging.

the BIG picture

The Central Nervous System and the Whole Body

The central nervous system is the ultimate regulator of the entire body. It serves as the anatomical and functional center of the countless feedback loops that maintain the relative constancy of the internal environment. The CNS directly or indirectly regulates, or at least influences, nearly every organ in the body.

The intriguing thing about the way in which the CNS regulates the whole body is that it is able to integrate, or bring together, literally millions of bits of information from all over the body and make sense of it all. The CNS not only makes sense of all this information but also compares it with previously stored memories and makes decisions based on its own conclusions about the data. The complex integrative functions of human language, consciousness, learning, and memory enable us to adapt to situations that less complex organisms could not. Thus our wonderfully complex CNS is essential to our survival.

MECHANISMS of DISEASE

DISORDERS OF THE CENTRAL NERVOUS SYSTEM

Destruction of Brain Tissue

Injury or disease can destroy neurons. A common example is the destruction of neurons of the motor area of the cerebrum that results from a cerebrovascular accident (CVA). A CVA, or *stroke*, is a hemorrhage from or cessation of blood flow through cerebral blood vessels. When this happens, the oxygen supply to portions of the brain is disrupted and neurons cease functioning. If the lack of oxygen is prolonged, the neurons die. If the damage occurs in a motor control area of the brain (see Figures 14-19 and 14-20), a person can no longer voluntarily move the parts of the body controlled by the affected area or areas. Because motor neurons cross over from side to side in the brainstem (see Figure 14-24), flaccid paralysis appears on the side of the body opposite the side of the brain on which the CVA occurred. The term *hemiplegia* refers to paralysis (loss of voluntary muscle control) of one whole side of the body.

One of the most common crippling diseases that appears during childhood, **cerebral palsy,** also results from damage to brain tissue. Cerebral palsy involves permanent, nonprogressive damage to motor control areas of the brain. Such damage is present at birth or occurs shortly after birth and remains throughout life. Possible causes of brain damage include prenatal infections or diseases of the mother; mechanical trauma to the head before, during, or after birth; nerve-damaging poisons; reduced oxygen supply to the brain; and other factors. The resulting impairment to voluntary muscle control can manifest in various ways. Many people with cerebral palsy exhibit **spastic paralysis,** a type of paralysis characterized by involuntary contractions of affected muscles. In cerebral palsy, spastic paralysis often affects one entire side of the body (**hemiplegia**), both legs (**paraplegia**), both legs and one arm (**triplegia**), or all four extremities (**quadriplegia**).

Dementia

Various degenerative diseases can result in destruction of neurons in the brain. This degeneration can progress to adversely affect memory, attention span, intellectual capacity, personality, and motor control. The general term for this syndrome is **dementia.**

Alzheimer disease (AD) is characterized by dementia. Its characteristic lesions develop in the cortex during the middle to late adult years. Exactly what causes dementia-producing lesions to develop in the brains of individuals with Alzheimer disease is not

known. There is strong evidence that this disease has a genetic basis—at least in some families. A current theory is that more than one of the handful of different genes associated with AD has to be abnormal before AD occurs. Other evidence indicates that environmental factors may have a role. Because the exact cause of Alzheimer disease is still not known, development of an effective treatment has proven difficult. Currently, people diagnosed with this disease are treated by helping them maintain their remaining mental abilities and looking after their hygiene, nutrition, and other aspects of personal health management. A few drugs such as memantine HCl (Namenda) and donepezil (Aricept) are available to slow down the progression of AD or lessen the severity of some of the symptoms.

Huntington disease (HD) is an inherited disease characterized by chorea (involuntary, purposeless movements) that progresses to severe dementia and death. The initial symptoms of this disease first appear between ages 30 and 40 years, with death generally occurring by age 55 years. The gene responsible for Huntington disease causes the body to make the protein *huntingtin* incorrectly. In brain cells, the abnormal form of huntingtin apparently clings to molecules too tightly and thus prevents normal function.

Acquired immune deficiency syndrome (AIDS), caused by HIV (human immunodeficiency virus) infection, can also cause dementia. The immune deficiency characteristic of AIDS results from HIV infection of white blood cells that are critical to the proper function of the immune system (see Chapter 24). However, HIV also infects neurons and can cause progressive degeneration of the brain—resulting in dementia.

Diseases caused by prions, pathogenic protein molecules, can also cause dementia. For example, *bovine spongiform encephalopathy*, also known as BSE or "mad cow disease," is a degenerative disease of the central nervous system caused by prions that convert normal proteins of the nervous system into abnormal proteins, causing loss of nervous system function, including dementia. **Variant Creutzfeldt-Jakob disease (vCJD)** is another prion disease that similarly reduces brain function, causing dementia. These diseases have caused alarm occasionally when animal brains (the tissue that carries prions to other organisms) were fed to other animals in the human food chain, increasing the risk of infecting large numbers of humans. The mechanism of prion disease was outlined in Chapter 1, p. 26.

Seizure Disorders

Some of the most common nervous system abnormalities belong to the group of conditions called *seizure disorders*. These disorders are characterized by **seizures**—sudden bursts of abnormal neuron activity that result in temporary changes in brain function. Seizures may be very mild, causing subtle changes in the level of consciousness, motor control, or sensory perception. On the other hand, seizures may be quite severe—resulting in jerky, involuntary muscle contractions called *convulsions* or even unconsciousness.

Recurring or chronic seizure episodes constitute a condition called **epilepsy.** Although some cases of epilepsy can be traced to specific causes such as tumors or chemical imbalances, most epilepsy is idiopathic (of unknown cause). Epilepsy is often treated with anticonvulsive drugs such as *phenobarbital*, *phenytoin*, or *valproic acid* that block neurotransmitters in affected areas of the brain. By thus blocking synaptic transmission, such drugs inhibit the explosive bursts of neuron activity associated with seizures. With proper medication, many people with epilepsy lead normal lives without the fear of experiencing uncontrollable seizures. Even those who have not responded well to drug therapies often have gained some relief from surgeries that cut or destroy areas of the brain prone to severe seizures.

Diagnosis and evaluation of epilepsy or any seizure disorder often rely on **electroencephalography** (see Box 14-7, p. 442). As Figure 14-26 illustrates, a normal EEG shows the moderate rise and fall of voltage in various parts of the brain, but a seizure manifests as an explosive increase in the size and frequency of voltage fluctuations. Different classifications of epilepsy are based on the location or locations and the duration of these changes in brain activity.

CASE study

After several days of a pounding headache, Polai went to the university clinic, hoping for some aspirin. But after she explained her symptoms, instead of being sent home with aspirin, she was sent to the hospital for a lumbar puncture (also called a *spinal tap*) to determine whether she had contracted meningitis. In this procedure, a needle is inserted into the lumbar region to obtain a sample of cerebrospinal fluid.

1. In what order will the needle pierce the meninges?
   a. Pia mater, arachnoid mater, dura mater
   b. Arachnoid mater, pia mater, dura mater
   c. Dura mater, arachnoid mater, pia mater
   d. Dura mater, pia mater, arachnoid mater

2. Where exactly will the cerebrospinal fluid be drawn from?
   a. Epidural space
   b. Subdural space
   c. Epiarachnoid space
   d. Subarachnoid space

Anyone performing a spinal tap must be extremely careful. If the needle goes past its mark, it could puncture the posterior portion of the spinal cord. One of the tracts in this region is the fasciculi gracilis.

3. The transmission of what type of information would be affected if the fasciculi gracilis were damaged?
   a. Discriminating touch
   b. Crude touch
   c. Voluntary movement
   d. Coordination of posture and balance

One possible (though rare) complication of meningitis (inflammation of the meninges) could be a spread of the bacteria to the cerebellum.

4. Which of the following is NOT a function of the cerebellum?
   a. Coordinates skilled movement
   b. Controls language
   c. Helps control posture
   d. Controls balance

COVERINGS OF THE BRAIN AND SPINAL CORD

A. Two protective coverings (Figure 14-2)
   1. Outer covering is bone; cranial bones encase the brain, and vertebrae encase the spinal cord (Figure 14-1)
   2. Inner covering is the meninges; the meninges of the cord continue inside the spinal cavity beyond the end of the spinal cord

B. Meninges—three membranous layers (Figure 14-3)
   1. Dura mater—strong, white fibrous tissue; outer layer of meninges and inner periosteum of the cranial bones; has three important extensions
      a. Falx cerebri
         (1) Projects downward into the longitudinal fissure between the two cerebral hemispheres
         (2) Dural sinuses—function as veins, collecting blood from brain tissues for return to the heart
         (3) Superior sagittal sinus—one of several dural sinuses
      b. Falx cerebelli—separates the two hemispheres of the cerebellum
      c. Tentorium cerebelli—separates the cerebellum from the cerebrum
   2. Arachnoid mater—delicate, spiderweb-like layer between the dura mater and pia mater
   3. Pia mater—innermost, transparent layer; adheres to the outer surface of the brain and spinal cord; contains blood vessels; beyond the spinal cord, forms a slender filament called *filum terminale*, at level of sacrum, blends with dura mater to form a fibrous cord that disappears into the periosteum of the coccyx
   4. Several spaces exist between and around the meninges
      a. Epidural space—located between the dura mater and inside the bony covering of the spinal cord; contains a supporting cushion of fat and other connective tissues (virtually absent around brain because dura is continuous with periosteum of bone)
      b. Subdural space—located between the dura mater and arachnoid mater; contains lubricating serous fluid
      c. Subarachnoid space—located between the arachnoid and pia mater; contains a significant amount of cerebrospinal fluid (CSF)

CEREBROSPINAL FLUID

A. Functions
   1. Provides a supportive, protective cushion
   2. Reservoir of circulating fluid, which is monitored by the brain to detect changes in the internal environment

B. Fluid spaces
   1. Cerebrospinal fluid—found within the subarachnoid space around the brain and spinal cord and within the cavities and canals of the brain and spinal cord
   2. Ventricles—fluid-filled spaces within the brain; four ventricles within the brain (Figure 14-4)
      a. First and second ventricles (lateral)—one located in each hemisphere of the cerebrum
      b. Third ventricle—thin, vertical pocket of fluid below and medial to the lateral ventricles
      c. Fourth ventricle—tiny, diamond-shaped space where the cerebellum attaches to the back of the brainstem

C. Formation and circulation of cerebrospinal fluid (Figure 14-5)
   1. Occurs by separation of fluid from blood in the choroid plexuses
      a. Fluid from the lateral ventricles seeps through the interventricular foramen (of Monro) into the third ventricle
      b. From the third ventricle, fluid goes through the cerebral aqueduct into the fourth ventricle
      c. From the fourth ventricle, fluid goes to two different areas
         (1) Some fluid flows directly into the central canal of the spinal cord
         (2) Some fluid leaves the fourth ventricle through openings in its roof and goes into the cisterna magna, a space that is continuous with the subarachnoid space
      d. Fluid circulates in the subarachnoid space and then is absorbed into venous blood through the arachnoid villi

SPINAL CORD

A. Structure of the spinal cord (Figure 14-6)
   1. Lies within the spinal cavity and extends from the foramen magnum to the lower border of the first lumbar vertebra
   2. Oval-shaped cylinder that tapers slightly from above downward
   3. Two bulges, one in the cervical region and one in the lumbar region
   4. Anterior median fissure and posterior median sulcus are two deep grooves; anterior fissure is deeper and wider
   5. Nerve roots
      a. Fibers of dorsal nerve root
         (1) Carry sensory information into the spinal canal
         (2) Dorsal root ganglion—cell bodies of unipolar, sensory neurons make up a small region of gray matter in the dorsal nerve root
      b. Fibers of ventral nerve root
         (1) Carry motor information out of the spinal cord
         (2) Cell bodies of multipolar, motor neurons are in the gray matter of the spinal cord
   6. Interneurons are located in the spinal cord's gray matter core
   7. Spinal nerve—a single mixed nerve on each side of the spinal cord where the dorsal and ventral nerve roots join together
   8. Cauda equina—bundle of nerve roots extending (along with the filum terminale) from the conus medullaris (inferior end of spinal cord) (Figure 14-7)
   9. Gray matter
      a. Columns of gray matter extend the length of the cord
      b. Consists predominantly of cell bodies of interneurons and motor neurons
      c. In transverse section, looks like an H with the limbs being called the *anterior*, *posterior*, and *lateral horns of gray matter*; crossbar of H is the *gray commissure*
   10. White matter
      a. Surrounds the gray matter and is subdivided in each half on the cord into three funiculi: anterior, posterior, and lateral white columns
      b. Each funiculus consists of a large bundle of axons divided into tracts
      c. Names of spinal tracts indicate the location of the tract, the structure in which the axons originate, and the structure in which they terminate

B. Functions of the spinal cord
   1. Provides conduction routes to and from the brain
      a. Ascending tracts—conduct impulses up the cord to the brain
      b. Descending tracts—conduct impulses down the cord from the brain
      c. Bundles of axons compose all tracts
      d. Tracts are both structural and functional organizations of nerve fibers
         (1) Structural—all axons of any one tract originate in the same structure and terminate in the same structure
         (2) Functional—all axons that compose one tract serve one general function
      e. Important ascending (sensory) tracts (Figure 14-8)
         (1) Lateral spinothalamic tracts—crude touch, pain, and temperature
         (2) Anterior spinothalamic tracts—crude touch, pressure
         (3) Fasciculi gracilis and cuneatus—discriminating touch and conscious kinesthesia
         (4) Spinocerebellar tracts—subconscious kinesthesia
         (5) Spinotectal—touch related to visual reflexes
      f. Important descending (motor) tracts (Figure 14-8)
         (1) Lateral corticospinal tracts—voluntary movements on opposite side of the body
         (2) Anterior corticospinal tracts—voluntary movements on same side of body
         (3) Reticulospinal tracts—maintain posture during movement

(4) Rubrospinal tracts—transmit impulses that coordinate body movements and maintenance of posture
(5) Tectospinal tracts—head and neck movements during visual reflexes
(6) Vestibulospinal tracts—coordination of posture and balance

g. Spinal cord—reflex center for all spinal reflexes; spinal reflex centers are located in the gray matter of the cord

BRAIN

A. One of the largest organs in the adult body—1.4 kg
1. Almost 100 billion neurons and as many glia
2. Most new neurons are produced before and shortly after birth
3. Synapses are made and broken throughout life

B. Structure of the brainstem (Figures 14-9 and 14-10)
1. Medulla oblongata
a. Lowest part of the brainstem
b. Part of the brain that attaches to spinal cord, located just above the foramen magnum
c. A few centimeters in length and separated from the pons above by a horizontal groove
d. Composed of white matter and a network of gray and white matter called the *reticular formation network*
e. Pyramids—two bulges of white matter located on the ventral side of the medulla; formed by fibers of the pyramidal tracts
f. Olive—oval projection located lateral to the pyramids
g. Nuclei—clusters of neuron cell bodies located in the reticular formation
2. Pons
a. Located above the medulla and below the midbrain
b. Composed of white matter and reticular formation
3. Midbrain
a. Located above the pons and below the cerebrum; forms the midsection of the brain
b. Composed of white tracts and reticular formation
c. Extending divergently through the midbrain are cerebral peduncles; conduct impulses between the midbrain and cerebrum
d. Corpora quadrigemina—landmark in midbrain
(1) Made up of two inferior colliculi and two superior colliculi
(2) Forms the posterior, upper part of the midbrain that lies just above the cerebellum
(3) Inferior colliculus—contains auditory centers
(4) Superior colliculus—contains visual centers
e. Red nucleus and substantia nigra—clusters of cell bodies of neurons involved in muscular control

B. Functions of the brainstem
1. Performs sensory, motor, and reflex functions
2. Spinothalamic tracts—important sensory tracts that pass through the brainstem
3. Fasciculi cuneatus and gracilis and spinoreticular tracts—sensory tracts whose axons terminate in the gray matter of the brainstem
4. Corticospinal and reticulospinal tracts—two of the major tracts present in the white matter of the brainstem
5. Nuclei in medulla—contain reflex centers
a. Of primary importance—cardiac, vasomotor, and respiratory centers
b. Nonvital reflexes—vomiting, coughing, sneezing, and so on
6. Pons—contains reflexes mediated by fifth, sixth, seventh, and eighth cranial nerves and pneumotaxic centers that help regulate respiration
7. Midbrain—contains centers for certain cranial nerve reflexes

C. Structure of the cerebellum (Figure 14-11)
1. Second largest part of the brain—contains more neurons than the rest of the nervous system
2. Located just below the posterior portion of the cerebrum; transverse fissure separates these two parts of the brain
3. Gray matter makes up the cortex, and white matter predominates in the interior
4. Arbor vitae—internal white matter of the cerebellum; distinctive pattern similar to the veins of a leaf
5. Cerebellum has numerous sulci and delicate, parallel gyri (folia)
6. Consists of the cerebellar hemispheres and the vermis
7. Internal white matter—composed of short and long tracts
a. Shorter tracts—conduct impulses from neuron cell bodies located in the cerebellar cortex to neurons whose dendrites and cell bodies compose nuclei located in the interior of the cerebellum
b. Longer tracts—conduct impulses to and from the cerebellum; fibers enter or leave by way of three pairs of peduncles
(1) Inferior cerebellar peduncles—composed chiefly of tracts into the cerebellum from the medulla and cord
(2) Middle cerebellar peduncles—composed almost entirely of tracts into the cerebellum from the pons
(3) Superior cerebellar peduncles—composed principally of tracts from dentate nuclei in the cerebellum through the red nucleus of the midbrain to the thalamus
8. Dentate nuclei
a. Important pair of cerebellar nuclei, one of which is located in each hemisphere
b. Nuclei connected with thalamus and with motor areas of the cerebral cortex by tracts
c. By means of the tracts, cerebellar impulses influence the motor cortex, and the motor cortex influences the cerebellum

D. Functions of the cerebellum
1. Cerebellum compares the motor commands of the cerebrum with the information coming from proprioceptors in the muscle; impulses travel from the cerebellum to both the cerebrum and muscles to coordinate movements to produce the intended action (Figure 14-12)
2. General functions
a. Acts with cerebral cortex to produce skilled movements by coordinating the activities of groups of muscles

b. Controls skeletal muscles to maintain balance
c. Controls posture; operates at subconscious level to smooth movements and make movements efficient and coordinated
d. Processes sensory information; complements and assists various functions of the cerebrum

E. Diencephalon (Figure 14-13)
1. Located between the cerebrum and the midbrain
2. Consists of several structures located around the third ventricle: thalamus, hypothalamus, optic chiasma, pineal gland, and several others
3. Thalamus
a. Dumbbell-shaped mass of gray matter made up of many nuclei
b. Each lateral mass forms one lateral wall of the third ventricle
c. Intermediate mass—extends through the third ventricle and joins the two lateral masses
d. Geniculate bodies—two of the most important groups of nuclei comprising the thalamus; located in posterior region of each lateral mass; play role in processing auditory and visual input
e. Serves as a major relay station for sensory impulses on their way to the cerebral cortex
f. Performs the following primary functions:
(1) Plays two parts in mechanism responsible for sensations
(a) Impulses produce conscious recognition of the crude, less critical sensations of pain, temperature, and touch
(b) Neurons relay all kinds of sensory impulses, except possibly olfactory, to the cerebrum
(2) Plays part in the mechanism responsible for emotions by associating sensory impulses with feeling of pleasantness and unpleasantness
(3) Plays part in arousal mechanism
(4) Plays part in mechanisms that produce complex reflex movements
4. Hypothalamus
a. Consists of several structures that lie beneath the thalamus
b. Forms floor of the third ventricle and lower part of lateral walls
c. Prominent structures found in the hypothalamus
(1) Supraoptic nuclei—gray matter located just above and on either side of the optic chiasma
(2) Paraventricular nuclei—located close to the wall of the third ventricle
(3) Mamillary bodies—posterior part of hypothalamus, involved with olfactory sense
d. Infundibulum—the stalk leading to the posterior lobe of the pituitary gland
e. Small but functionally important area of the brain, performs many functions of greatest importance for survival and enjoyment
f. Links mind and body
g. Links nervous system to endocrine system
h. Summary of hypothalamic functions
(1) Regulator and coordinator of autonomic activities
(2) Major relay station between the cerebral cortex and lower autonomic centers; crucial part of the route by which emotions can express themselves in changed bodily functions
(3) Synthesizes hormones secreted by posterior pituitary and plays an essential role in maintaining water balance
(4) Some neurons function as endocrine glands
(5) Plays crucial role in arousal mechanism
(6) Crucial part of mechanism regulating appetite
(7) Crucial part of mechanism maintaining normal body temperature
5. Pineal gland
a. Located just above the corpora quadrigemina of the midbrain
b. Involved in regulating the body's biological clock (Figure 14-14)
c. Produces melatonin as a "timekeeping hormone"
(1) Melatonin is made from the neurotransmitter serotonin
(2) Melatonin levels increase when sunlight is absent; decrease when sunlight is present, thus regulating the circadian (daily) biological clock (Figure 14-15)
(3) Melatonin is the "sleep hormone"

F. Structure of the cerebrum
1. Cerebral cortex
a. Largest and uppermost division of the brain; consists of right and left cerebral hemispheres; each hemisphere is divided into five lobes (Figure 14-16)
(1) Frontal lobe
(2) Parietal lobe
(3) Temporal lobe
(4) Occipital lobe
(5) Insula (island of Reil)
b. Cerebral cortex—outer surface made up of six layers of gray matter
c. Gyri—convolutions; some are named: precentral gyrus, postcentral gyrus, cingulate gyrus, and hippocampal gyrus
d. Sulci—shallow grooves
e. Fissures—deeper grooves, divide each cerebral hemisphere into lobes; four prominent cerebral fissures
(1) Longitudinal fissure—deepest fissure; divides cerebrum into two hemispheres
(2) Central sulcus (fissure of Rolando)—groove between frontal and parietal lobes
(3) Lateral fissure (fissure of Sylvius)—groove between temporal lobe below and parietal lobes above; island of Reil lies deep in lateral fissure
(4) Parietooccipital sulcus—groove that separates occipital lobe from parietal lobes
2. Cerebral tracts and basal nuclei
a. Cerebral tracts make up cerebrum's white matter; there are three types (Figure 14-17)

(1) Projection tracts—extensions of the sensory spinothalamic tracts and motor corticospinal tracts
(2) Association tracts—most numerous cerebral tracts; extend from one convolution to another in the same hemisphere
(3) Commissural tracts—extend from one convolution to a corresponding convolution in the other hemisphere; compose the corpus callosum and anterior and posterior commissures

b. Connectome—entire network of neural connections in the brain
c. Basal nuclei
(1) Structure—islands of gray matter located deep inside the white matter of each hemisphere (Figure 14-18); include the following:
(a) Caudate nucleus
(b) Lentiform nucleus—consists of putamen and pallidum
(c) Amygdaloid nucleus
(2) Function—regulation of voluntary (conscious) motor control related to posture, walking, and other repetitive movements; possible roles in thinking and learning
d. Corpus striatum—composed of caudate nucleus, internal capsule, and lentiform nucleus

G. Functions of the cerebral cortex
1. Functional areas of the cortex—certain areas of the cerebral cortex engage in predominantly one particular function (Figures 14-19 and 14-20)
a. Postcentral gyrus—mainly general somatic sensory area; receives impulses from receptors activated by heat, cold, and touch stimuli
b. Precentral gyrus—chiefly somatic motor area; impulses from neurons in this area descend over motor tracts and stimulate skeletal muscles
c. Transverse gyrus—primary auditory area
d. Occipital lobe—primary visual areas
2. Sensory functions of the cortex
a. Somatic senses—sensations of touch, pressure, temperature, proprioception, and similar perceptions that require complex sensory organs
b. Cortex contains a "somatic sensory map" of the body
c. Information sent to primary sensory areas is relayed to sensory association areas, as well as to other parts of the brain
d. The sensory information is compared and evaluated, and the cortex integrates separate bits of information into whole perceptions
3. Motor functions of the cortex
a. For normal movements to occur, many parts of the nervous system must function
b. Precentral gyrus—primary somatic motor area; controls individual muscles
c. Secondary motor area—in the gyrus immediately anterior to the precentral gyrus; activates groups of muscles simultaneously
4. Integrative functions of the cortex

H. Consciousness (Figure 14-21)
1. State of awareness of one's self, one's environment, and other humans
2. Depends on excitation of cortical neurons by impulses conducted to them by the reticular activating system
3. Two current concepts about the reticular activating system
a. Functions as the arousal system for the cerebral cortex
b. Its functioning is crucial for maintaining consciousness

I. Language
1. Ability to speak and write words and ability to understand spoken and written words
2. Speech centers—areas in the frontal, parietal, and temporal lobes
3. Left cerebral hemisphere contains speech centers in approximately 90% of the population; in the remaining 10%, contained in either the right hemisphere or both
4. Aphasias—lesions in speech centers

J. Emotions (Figure 14-22)
1. Subjective experiencing and objective expressing of emotions involve functioning of the limbic system
2. Limbic system—also known as the "emotional brain"
a. Most structures of limbic system lie on the medial surface of the cerebrum; they are the cingulate gyrus and hippocampus
b. Have primary connections with other parts of the brain, such as the thalamus, fornix, septal nuclei, amygdaloid nucleus, and hypothalamus

K. Memory
1. One of our major mental activities
2. Cortex is capable of storing and retrieving both short- and long-term memory
3. Temporal, parietal, and occipital lobes are among the areas responsible for short- and long-term memory
4. Structural changes in the neural pathways of the cerebral cortex store long-term memories
5. Limbic system plays a key role in memory

SOMATIC SENSORY PATHWAYS IN THE CENTRAL NERVOUS SYSTEM

A. For the cerebral cortex to perform its sensory functions, impulses must first be conducted to the sensory areas by sensory pathways (Figure 14-23)
B. Three main pools of sensory neurons
1. Primary sensory neurons—conduct impulses from the periphery to the central nervous system
2. Secondary sensory neurons
a. Conduct impulses from the cord or brainstem to the thalamus
b. Dendrites and cell bodies are located in the gray matter of the cord and brainstem
c. Axons ascend in ascending tracts up the cord and through the brainstem, terminating in the thalamus, where they synapse with dendrites or cell bodies of tertiary sensory neurons

3. Tertiary sensory neurons
   a. Conduct impulses from thalamus to the postcentral gyrus of the parietal lobe
   b. Bundle of axons of tertiary sensory neurons form the thalamocortical tracts
   c. Extend through the internal capsule to the cerebral cortex

C. Sensory pathways to the cerebral cortex are crossed
D. Two sensory pathways conduct impulses that produce sensations of touch and pressure
   1. Medial lemniscal system
      a. Consists of tracts that make up the fasciculi cuneatus and gracilis, and the medial lemniscus
      b. Axons of secondary sensory neurons make up medial lemniscus
      c. Functions—transmit impulses that produce discriminating touch and pressure sensations and kinesthesia
   2. Spinothalamic pathway—functions are crude touch and pressure sensations

SOMATIC MOTOR PATHWAYS IN THE CENTRAL NERVOUS SYSTEM

A. Impulse conduction
   1. For the cerebral cortex to perform its motor functions, impulses are conducted from its motor areas to skeletal muscles by somatic motor pathways
   2. Pathways consist of motor neurons that conduct impulses from the central nervous system to skeletal muscles; some motor pathways are extremely complex, and others are very simple
   3. Principle of the final common path—cardinal principle about somatic motor pathways; only one final common path, the motor neuron from the anterior gray horn of the spinal cord, conducts impulses to skeletal muscles
   4. Two methods used to classify somatic motor pathways: pyramidal and extrapyramidal tracts (Figure 14-24)

B. Pyramidal tracts—also known as *corticospinal tracts*
   1. Approximately three quarters of the fibers decussate in the medulla and extend down the cord in the crossed corticospinal tract located on the opposite side of the spinal cord in the lateral white column
   2. Approximately one quarter of the fibers do not decussate but extend down the same side of the spinal cord as the cerebral area from which they came

C. Extrapyramidal tracts—much more complex than pyramidal tracts
   1. Consist of all motor tracts from the brain to the spinal cord anterior horn motor neurons except the corticospinal tracts
   2. Within the brain, consist of numerous relays of motor neurons between motor areas of the cortex, basal nuclei, thalamus, cerebellum, and brainstem
   3. Within the spinal cord, some important tracts are the reticulospinal tracts
   4. Conduction by extrapyramidal tracts plays a crucial part in producing large, automatic movements
   5. Conduction by extrapyramidal tracts plays an important part in emotional expressions
   6. Motor program—set of coordinated commands that control the programmed motor activity mediated by extrapyramidal pathways (Figure 14-25)

CYCLE OF LIFE: CENTRAL NERVOUS SYSTEM

A. Development and degeneration of CNS—most obvious functional change over the life span
B. Development of brain and spinal cord begins in the womb
C. Lack of development in the newborn is evidenced by lack of complex integrative functions
   1. Language
   2. Complex memory
   3. Comprehension of spatial relationships
   4. Complex motor skills
D. Complex functions develop by adulthood
E. Late adulthood—tissues degenerate
   1. Profound degeneration—unable to perform complex functions
   2. Milder degeneration—temporary memory lapse or difficulty with complex motor tasks

THE BIG PICTURE: THE CENTRAL NERVOUS SYSTEM AND THE WHOLE BODY

A. Central nervous system—ultimate regulator of the body; essential to survival
B. Able to integrate bits of information from all over the body, make sense of it, and make decisions

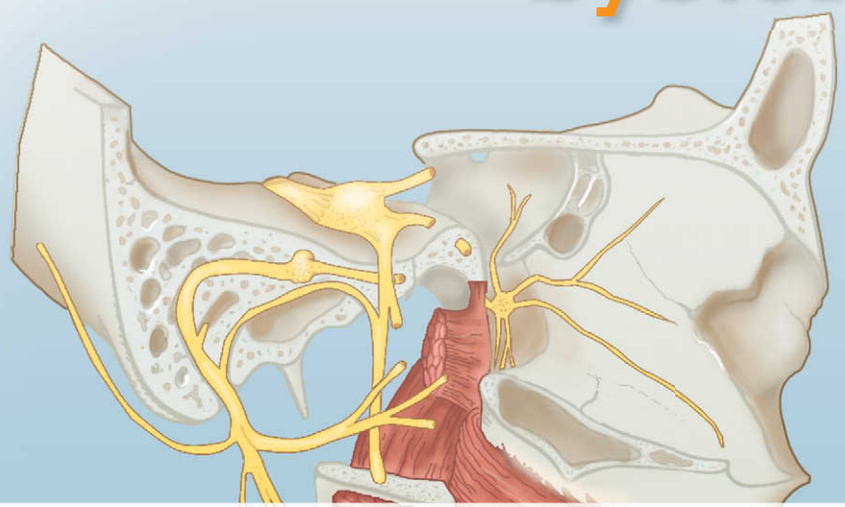
REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. What term refers to the membranous covering of the brain and cord? What three layers compose this covering?
2. What are the large fluid-filled spaces within the brain called? How many are there? What do they contain?
3. Describe the formation and circulation of cerebrospinal fluid.
4. Describe the structure and general functions of the spinal cord.
5. List the major components of the brainstem, and identify their general functions.
6. Describe the general functions of the cerebellum.
7. Describe the general functions of the thalamus.
8. Describe the general functions of the hypothalamus.
9. Describe the general functions of the cerebrum.
10. What general functions does the cerebral cortex perform?
11. Define consciousness. Name the normal states, or levels, of consciousness.

12. Name some altered states of consciousness.
13. Identify the following kinds of brainwaves according to their frequency, voltage, and the level of consciousness in which they predominate: alpha, beta, delta, theta.
14. Locate the dendrite, cell body, and axon of primary, secondary, and tertiary sensory neurons.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Explain what the term *reflex center* means. Is an interneuron necessary for a reflex center? Explain your answer.
2. Explain briefly what is meant by the arousal or alerting mechanism.
3. Some people claim meditation has a wide range of benefits. What benefits can be supported by scientific evidence?
4. If a researcher discovered that a substantial reduction in neurotransmitter concentration caused difficulty in forming memory, what theory of memory formation would be refuted?
5. In Chapter 13, an action potential was explained in terms of electrical activity. Explain the process of measuring that activity to differentiate the types of brainwaves.
6. A person having an absence of any reflex and a person having exaggerated deep tendon reflexes are showing signs of different motor pathway injuries. Using these symptoms as the basis, explain the motor pathway that was damaged and what other symptoms each person might have.
7. Compare pyramidal tract and extrapyramidal tract functions.
8. A patient with a brain infection can be diagnosed by culturing cerebrospinal fluid. The greatest concentration of the disease-causing organism can be drawn from the fluid as soon as it leaves the brain at the level of the third or fourth vertebra. Why would this be an unwise place to take the sample? Where would a better location be? Explain your answer.

Peripheral Nervous System

[*crani-* **skull,** *-al* **relating to**]

continued on p. 483

In Chapter 14, you learned about the structure and function of the central nervous system (CNS). In this chapter we explore the nerve pathways that lead to and from the CNS, which together make up the peripheral nervous system (PNS). The PNS is made up of the 31 pairs of spinal nerves that emerge from the spinal cord, the 12 pairs of cranial nerves that emerge from the brain, and all the smaller nerves that branch from these "main" nerves.

Recall from earlier discussions that afferent *fibers carry information into the CNS. Afferent fibers, part of the sensory nervous system, help us maintain homeostasis by sensing changes in our internal or external environment—providing the feedback necessary to keep the body functioning normally. Afferent fibers belonging to the somatic sensory or special sensory nervous system feed back information regarding changes detected by receptors in the skin, skeletal muscles, and special sense organs. Afferent fibers belonging to the autonomic nervous system (ANS) feed back information regarding the effects of autonomic control of the viscera.*

Recall also that efferent *fibers carry information away from the CNS. Efferent fibers may belong to the somatic nervous system (SNS) that regulates skeletal muscles, allowing us to survive by defending ourselves, getting food, or performing other essential tasks. Efferent fibers may, on the other hand, belong to the ANS. Autonomic regulation controls smooth and cardiac muscle and glands in ways that help us maintain homeostasis of the internal environment.*

The first sections of this chapter explore concepts regarding the structure and function of the spinal and cranial nerves. The last portion of the chapter is devoted to discussion of the peripheral elements of the SNS, with an emphasis on efferent (motor) pathways. Chapter 16 then picks up the story, emphasizing efferent pathways of the ANS. Finally, Chapter 17 explores major concepts of sensation via the afferent pathways.

This study of peripheral nerve pathways clarifies and expands the understanding of the nervous system gained in previous chapters. It also serves as a foundation for understanding important clinical applications (Box 15-1).

Box 15-1 | HEALTH matters

Peripheral Neuropathy

The term **peripheral neuropathy** tells you exactly what it signifies: disease of the peripheral nerves. The term is used to designate many different diseases with many different causes—but all involve damage to peripheral nerves. These disorders can also be called *peripheral neuritis.* If many nerves are involved, peripheral neuropathy can also be called *polyneuropathy* or *polyneuritis.* Probably the most common cause of peripheral nerve damage in the United States and Europe is diabetes mellitus (see ***Diabetes Mellitus*** online at ***A&P Connect***), affecting some 17 million people. But additional causes include other metabolic problems such as kidney disease, injuries such as sports mishaps, poisoning as in drug neurotoxicity and alcohol abuse, infections such as in *leprosy (Hansen disease; Mycobacterium leprae)* or shingles (see Box 15-3, p. 472), and genetic mutations such as *Leber hereditary optic neuropathy* (see Chapter 37, p. 1142).

SPINAL NERVES

Thirty-one pairs of **spinal nerves** are connected to the spinal cord. They have no special names but are merely numbered according to the level of the vertebral column at which they emerge from the spinal cavity (Figure 15-1). Although there are only seven cervical vertebrae, there are eight cervical nerve pairs (C1 through C8), twelve thoracic nerve pairs (T1 through T12), five lumbar nerve pairs (L1 through L5), five sacral nerve pairs (S1 through S5), and one coccygeal pair of spinal nerves. The first pair of cervical nerves emerges from the cord in the space above the first cervical vertebra, and the eighth cervical nerve emerges between the last cervical vertebra and the first thoracic vertebra. Thus nerve pair C1 passes between the skull and vertebra C1, nerve pair C2 passes between vertebrae C1 and C2, nerve pair C3 passes between vertebrae C2 and C3, and so on. All the thoracic nerves pass out of the spinal cavity horizontally through the intervertebral foramina below their respective vertebrae.

Lumbar, sacral, and coccygeal nerve roots, on the other hand, descend from their point of origin at the lower end of the spinal

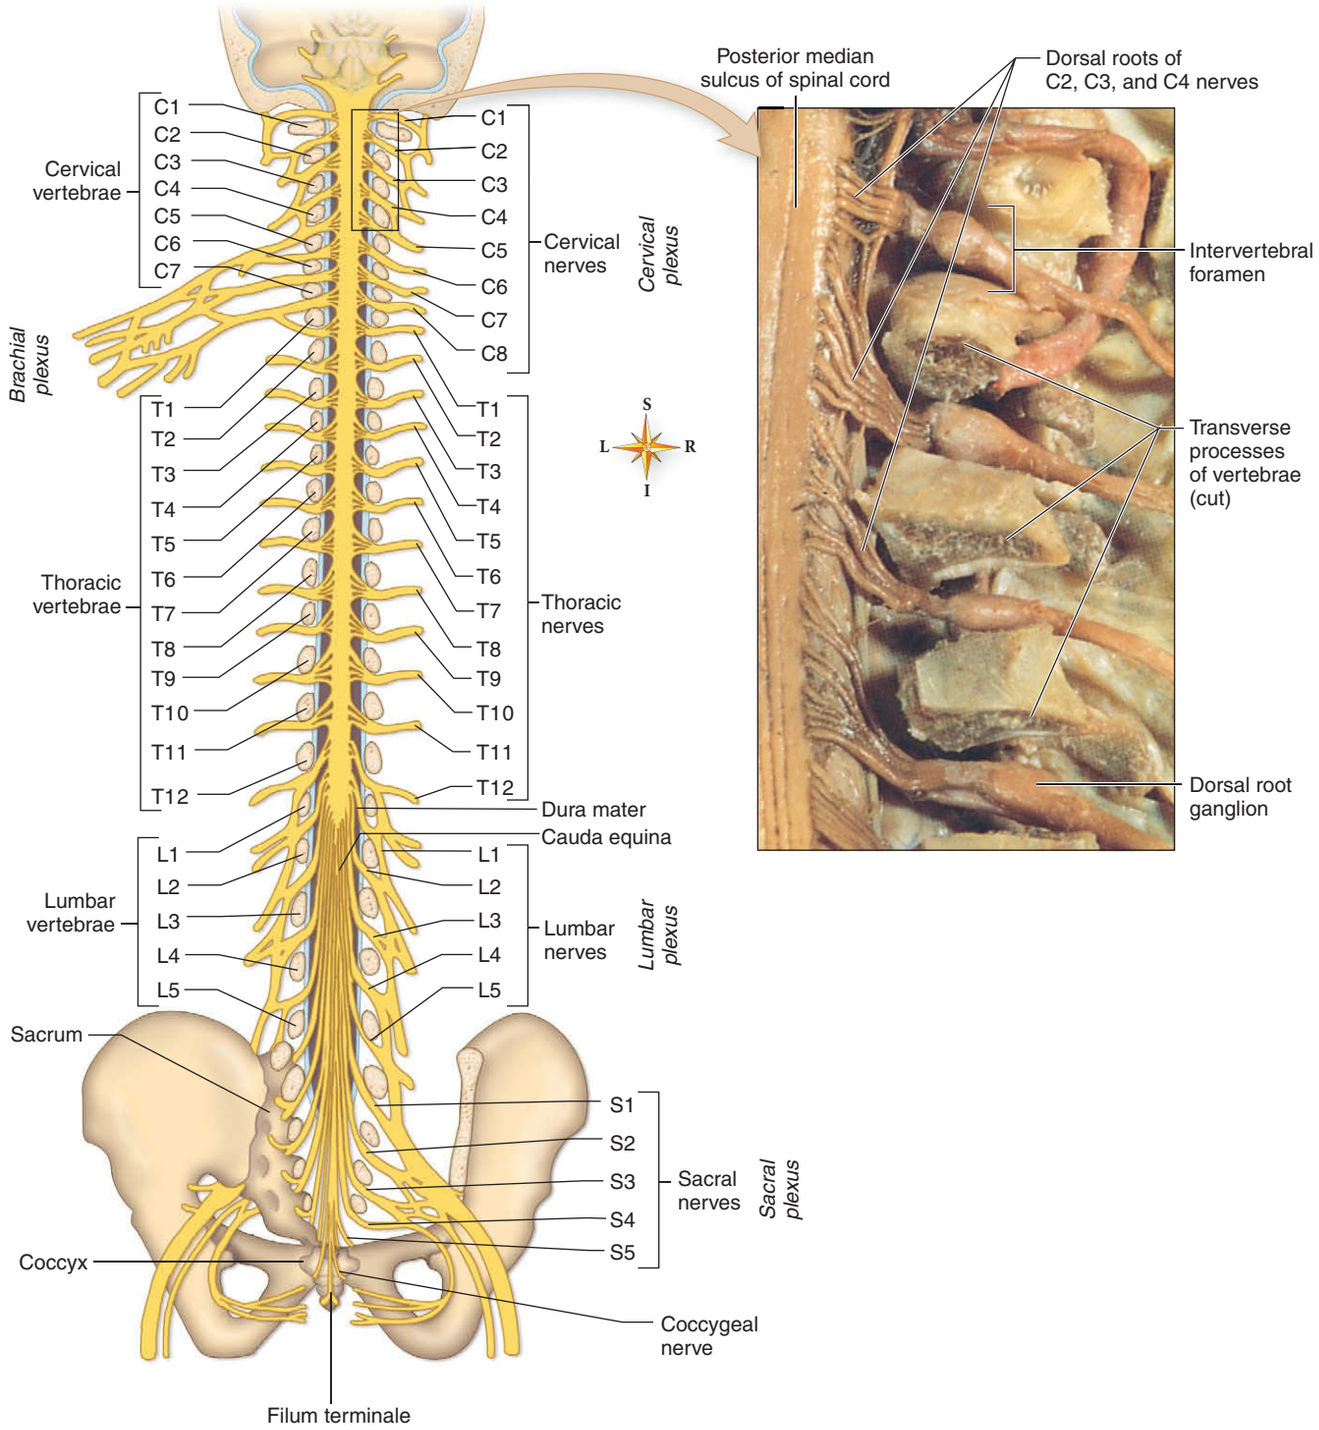

FIGURE 15-1

Spinal nerves. Each of 31 pairs of spinal nerves exits the spinal cavity from the intervertebral foramina. The names of the vertebrae are given on the left and the names of the corresponding spinal nerves on the right. Note that after leaving the spinal cavity, many of the spinal nerves interconnect to form networks called *plexuses.* The inset shows a dissection of the cervical region, showing a posterior view of cervical spinal nerves exiting intervertebral foramina on the right side.

cord (which terminates at the level of the first lumbar vertebra) before reaching the intervertebral foramina of their respective vertebrae, through which the nerves then emerge. This gives the lower end of the cord, with its attached spinal nerve roots, the appearance of a horse's tail. In fact, it bears the name **cauda equina,** which is the Latin equivalent for "horse's tail" (see Figure 15-1).

Structure of Spinal Nerves

Each spinal nerve attaches to the spinal cord by means of two short roots, a **ventral** (anterior) **root** and a **dorsal** (posterior) **root.** The dorsal root of each spinal nerve is easily recognized by a swelling called the dorsal root **ganglion,** or *spinal ganglion* (Figure 15-2). The roots and dorsal ganglia lie within the spinal cavity, as Figure 15-2 shows.

As described in Chapter 14, the ventral root includes motor neurons that carry information from the CNS and toward effectors (muscles and glands). Recall that in each somatic motor pathway, a single motor fiber stretches from the anterior gray horn of the spinal cord, through the ventral root, and on through the spinal nerve toward a skeletal muscle. Autonomic fibers, which also carry motor information toward effectors, may also pass through the ventral root to become part of a spinal nerve. The dorsal root of each spinal nerve includes sensory fibers that carry information from receptors in the peripheral nerves. The dorsal root ganglion contains the cell bodies of the sensory neurons. Because all spinal nerves contain both motor and sensory fibers, they are designated as **mixed nerves.**

Soon after each spinal nerve emerges from the spinal cavity, it forms several large branches, each of which is called a **ramus** (*plural*, rami). As Figure 15-2 shows, each spinal nerve splits into a distinct **dorsal ramus** and **ventral ramus.** The dorsal ramus supplies somatic motor and sensory fibers to several smaller nerves. These smaller nerves, in turn, innervate the muscles and skin of the posterior surface of the head, neck, and trunk. The structure of the ventral ramus is a little more complex. Autonomic motor fibers split away from the ventral ramus, heading toward a ganglion of the *sympathetic chain*. There, some of the autonomic fibers synapse with autonomic neurons that eventually continue on to autonomic effectors by way of *splanchnic nerves* (see Figure 15-2). However, some fibers synapse with autonomic neurons whose fibers rejoin the ventral ramus. The two thin rami formed by this splitting away, then rejoining, of autonomic fibers are together called the *sympathetic rami*. Motor (autonomic and somatic) and sensory fibers of the ventral rami innervate muscles and glands in the extremities (arms and legs) and in the lateral and ventral portions of the neck and trunk.

Nerve Plexuses

The ventral rami of most spinal nerves—all but nerves T2 through T12—subdivide to form complex networks called **plexuses.** As Figure 15-1 shows, there are four major pairs of plexuses: the cervical plexus, the brachial plexus, the lumbar plexus, and the sacral plexus. Table 15-1 summarizes important information about these major plexuses.

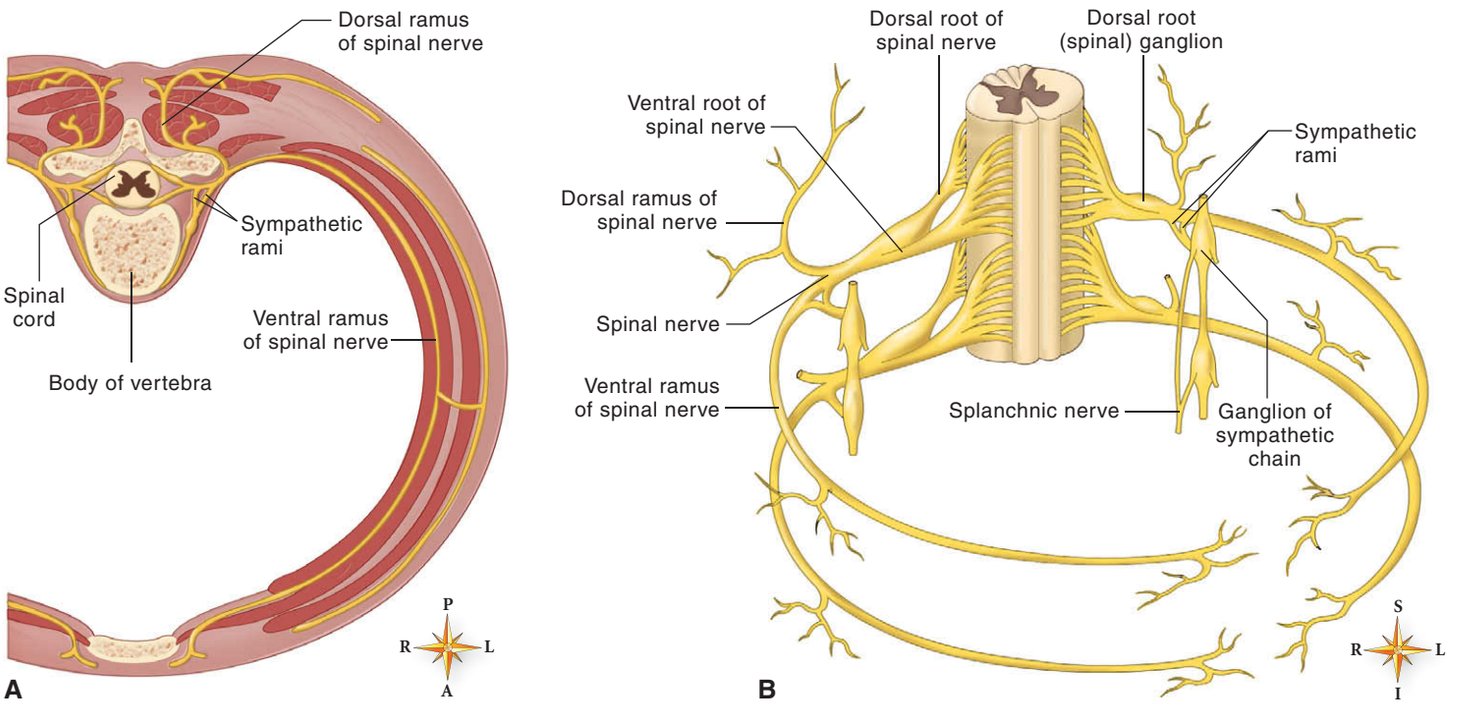

FIGURE 15-2

Rami of the spinal nerves. Note that ventral and dorsal roots join to form a spinal nerve. The spinal nerve then splits into a *dorsal ramus* (plural, *rami*) and *ventral ramus*. The ventral ramus communicates with a chain of sympathetic (autonomic) ganglia by way of a pair of thin sympathetic rami. **A,** Superior view of a pair of thoracic spinal nerves. **B,** Anterior view of several pairs of thoracic spinal nerves.

TABLE 15-1 Spinal Nerves and Peripheral Branches

SPINAL NERVES	PLEXUSES FORMED FROM ANTERIOR RAMI	SPINAL NERVE BRANCHES FROM PLEXUSES		PARTS SUPPLIED
Cervical 1, 2, 3, 4	Cervical plexus	Lesser occipital		Sensory to back of head, front of neck, and upper part of shoulder; motor to numerous neck muscles
		Greater auricular		
		Cutaneous nerve of neck		
		Supraclavicular nerves		
		Branches to muscles		
		Phrenic nerve		Diaphragm
Cervical 5, 6, 7, 8	Brachial plexus	Suprascapular and dorsoscapular		Superficial muscles* of scapula
		Thoracic nerves, medial and lateral branches		Pectoralis major and minor
Thoracic (or Dorsal) 1	No plexus formed; branches run directly to intercostal muscles and skin of thorax	Long thoracic nerve		Serratus anterior
		Thoracodorsal		Latissimus dorsi
2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12		Subscapular		Subscapular and teres major muscles
		Axillary (circumflex)		Deltoid and teres minor muscles and skin over deltoid
		Musculocutaneous		Muscles of front of arm (biceps brachii, coracobrachialis, brachialis) and skin on outer side of forearm
		Ulnar		Flexor carpi ulnaris and part of flexor digitorum profundus; some muscles of hand; sensory to medial side of hand, little finger, and medial half of fourth finger
		Median		Rest of muscles of front of forearm and hand; sensory to skin of palmar surface of thumb, index, and middle fingers
		Radial		Triceps muscle and muscles of back of forearm; sensory to skin of back of forearm and hand
		Medial cutaneous		Sensory to inner surface of arm and forearm
Lumbar 1, 2, 3, 4, 5	Lumbosacral plexus	Iliohypogastric	Sometimes fused	Sensory to anterior abdominal wall
		Ilioinguinal		Sensory to anterior abdominal wall and external genitalia; motor to muscles of abdominal wall
		Genitofemoral		Sensory to skin of external genitalia and inguinal region
		Lateral femoral cutaneous		Sensory to outer side of thigh
Sacral 1, 2, 3, 4, 5		Femoral		Motor to quadriceps, sartorius, and iliacus muscles; sensory to front of thigh and medial side of leg (saphenous nerve)
		Obturator		Motor to adductor muscles of thigh
		Tibial† (medial popliteal)		Motor to muscles of calf of leg; sensory to skin of calf of leg and sole of foot
		Common peroneal (lateral popliteal)		Motor to evertors and dorsiflexors of foot; sensory to lateral surface of leg and dorsal surface of foot
		Nerves to hamstring muscles		Motor to muscles of back of thigh
		Gluteal nerves		Motor to buttock muscles and tensor fasciae latae
		Posterior femoral cutaneous		Sensory to skin of buttocks, posterior surface of thigh, and leg
		Pudendal nerve		Motor to perineal muscles; sensory to skin of perineum
Coccygeal 1	Coccygeal plexus	Anococcygeal nerves		Sensory to skin overlying coccyx

*Although nerves to muscles are considered motor, they do contain some sensory fibers that transmit proprioceptive impulses.
†Sensory fibers from the tibial and peroneal nerves unite to form the medial cutaneous (or sural) nerve that supplies the calf of the leg and the lateral surface of the foot. In the thigh the tibial and common peroneal nerves are usually enclosed in a single sheath to form the *sciatic nerve,* the largest nerve in the body with a width of approximately ¾ inch (2 cm). About two thirds of the way down the posterior part of the thigh, it divides into its component parts. Branches of the sciatic nerve extend into the hamstring muscles.

The term *plexus* is the Latin word for "braid." This is an apt name for a structure in which fibers of several different rami join together to form individual nerves. Each individual nerve that emerges from a plexus contains all the fibers that innervate a particular region of the body. In fact, the destination of each nerve serves as a basis for its name (see Table 15-1). Because spinal nerve fibers are thus rearranged according to their ultimate destination, the plexus reduces the number of nerves needed to supply each body part. And because each body region is innervated by fibers that originate from several adjacent spinal nerves, damage to one spinal nerve does not mean a complete loss of function in any one region.

CERVICAL PLEXUS

The **cervical plexus,** shown in Figure 15-3, is found deep within the neck. Ventral rami of the first four cervical spinal nerves (C1 through C4), along with a branch of the ventral ramus of C5, exchange fibers in the cervical plexus. Individual nerves emerging from this plexus innervate the muscles and skin of the neck, upper shoulders, and part of the head. Also exiting this plexus is the **phrenic nerve,** which innervates the diaphragm (Box 15-2). Two cranial nerves, the accessory nerve (XI) and the hypoglossal nerve (XII), receive small branches that emerge from the cervical plexus.

BRACHIAL PLEXUS

The **brachial plexus,** shown in Figure 15-4, is found deep within the shoulder. It passes from the ventral rami of spinal nerves C5 through T1, beneath the clavicle (collarbone), and toward the arm. Individual nerves that emerge from the brachial plexus innervate the lower part of the shoulder and the entire arm.

LUMBAR PLEXUS

Another spinal nerve plexus is the **lumbar plexus,** which is formed by the intermingling of fibers from the first four lumbar nerves

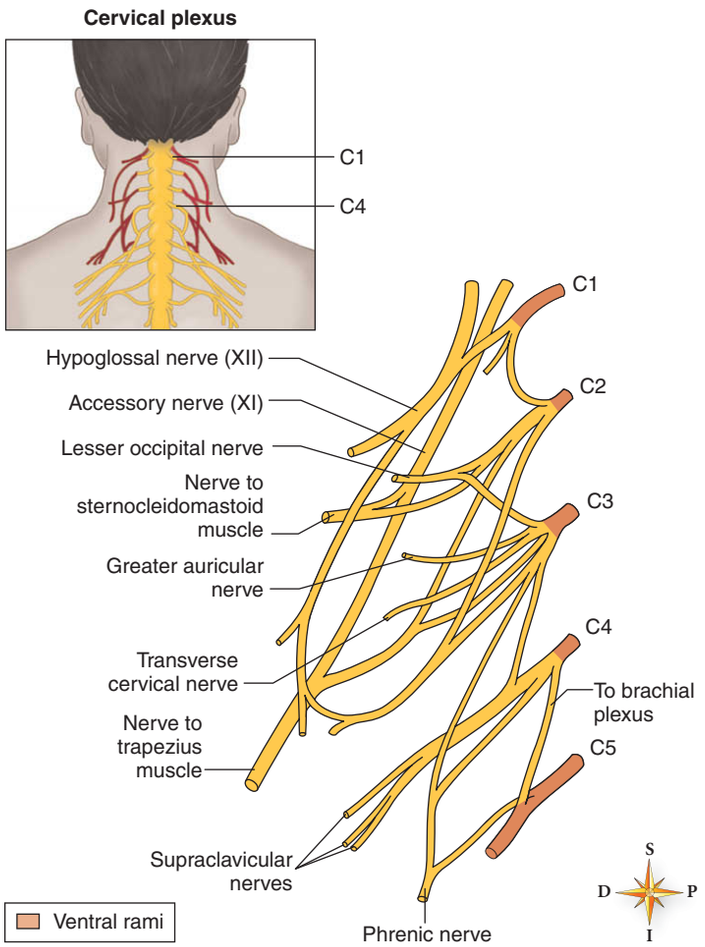

FIGURE 15-3

Cervical plexus. Ventral rami of the first four cervical spinal nerves (C1 through C4) exchange fibers in this plexus found deep within the neck. Notice that some fibers from C5 also enter this plexus to form a portion of the phrenic nerve.

Box 15-2 | HEALTH matters

Phrenic Nerves

The right and left **phrenic nerves,** whose fibers come from the cervical plexus, are of considerable clinical interest because they supply the diaphragm muscle. Contraction of the diaphragm permits inspiration, and relaxation of the diaphragm permits expiration. If the neck is broken in a way that severs or crushes the spinal cord above this level, nerve impulses from the brain can no longer reach the phrenic nerves, and therefore the diaphragm stops contracting. Unless artificial respiration of some kind is provided, the patient dies of respiratory paralysis as a result of the broken neck. Any disease or injury that damages the spinal cord between the third and fifth cervical segments may paralyze the phrenic nerve and, therefore, the diaphragm.

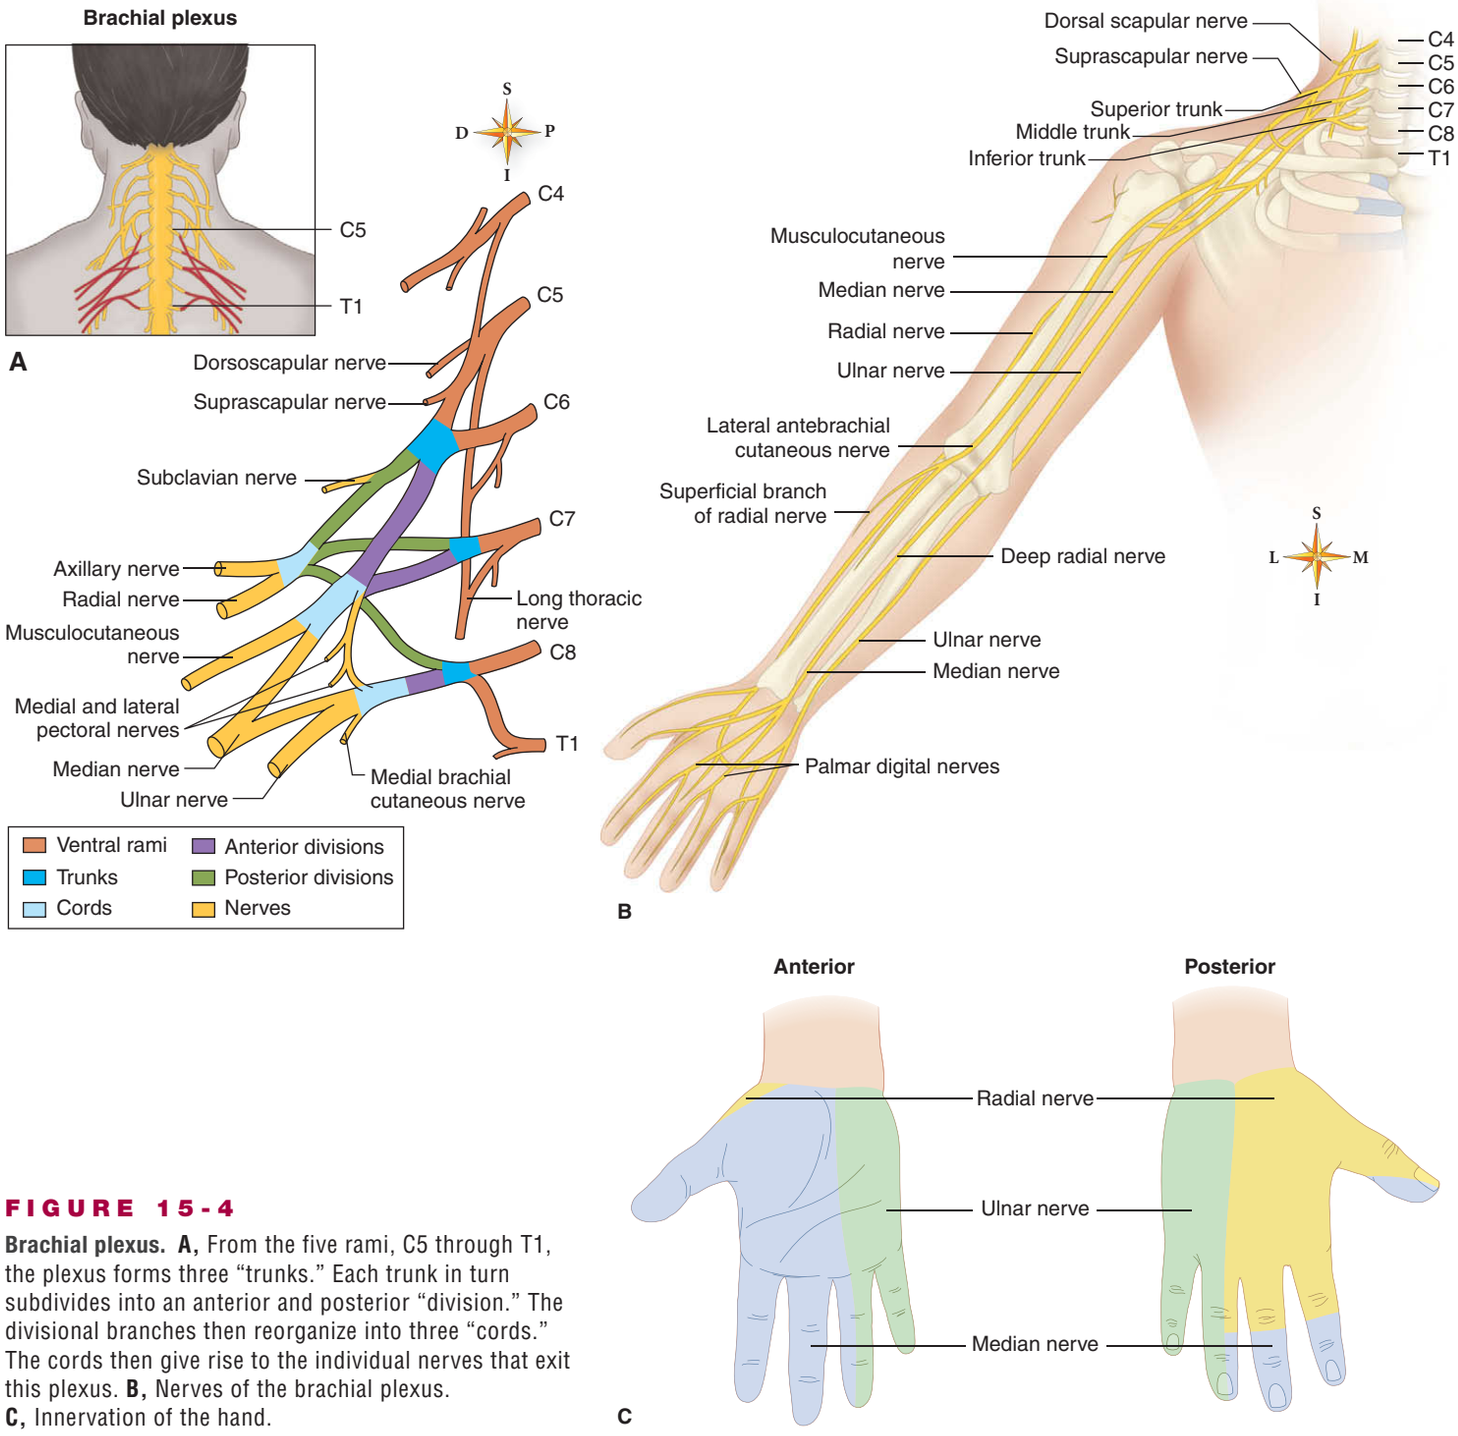

FIGURE 15-4

Brachial plexus. A, From the five rami, C5 through T1, the plexus forms three "trunks." Each trunk in turn subdivides into an anterior and posterior "division." The divisional branches then reorganize into three "cords." The cords then give rise to the individual nerves that exit this plexus. **B,** Nerves of the brachial plexus. **C,** Innervation of the hand.

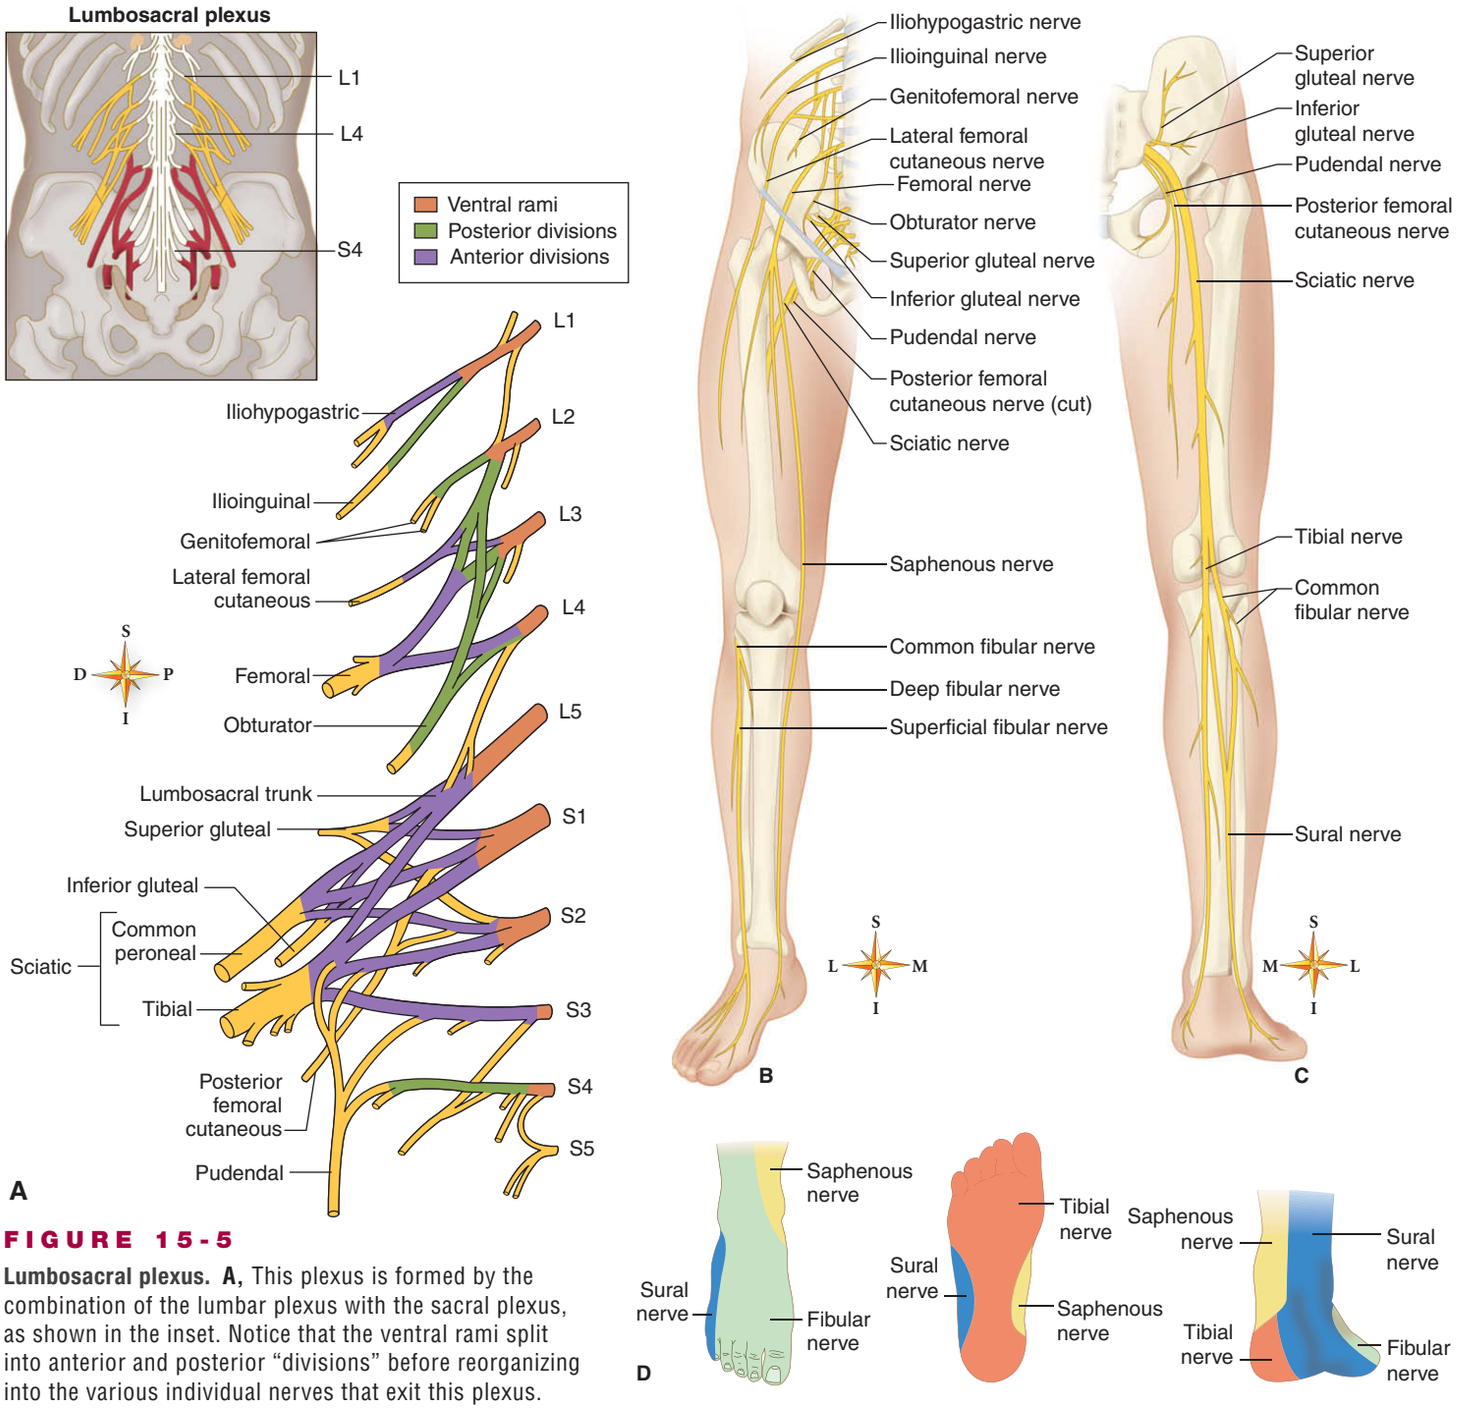

FIGURE 15-5

Lumbosacral plexus. A, This plexus is formed by the combination of the lumbar plexus with the sacral plexus, as shown in the inset. Notice that the ventral rami split into anterior and posterior "divisions" before reorganizing into the various individual nerves that exit this plexus. **B,** Anterior view of lumbosacral plexus nerves. **C,** Posterior view of lumbosacral plexus nerves. **D,** Innervation of the foot and ankle.

(Figure 15-5). This network of nerves is located in the lumbar region of the back near the psoas muscle. The large femoral nerve is one of several nerves emerging from the lumbar plexus. It divides into many branches supplying the thigh and leg.

SACRAL PLEXUS AND COCCYGEAL PLEXUS

Fibers from the fourth and fifth lumbar nerves (L4 and L5) and the first four sacral nerves (S1 through S4) form the **sacral plexus.** It lies in the pelvic cavity on the anterior surface of the piriformis muscle. Because of their close proximity and overlap of fibers, the lumbar and sacral plexuses are often considered together as the *lumbosacral* plexus (see Figure 15-5). Among other nerves that emerge from the sacral plexus are the tibial and common peroneal nerves. In the thigh, they form the largest nerve in the body, the great **sciatic nerve.** It pierces the buttocks and runs down the back of the thigh. Its many branches supply nearly all the skin of the leg, the posterior thigh muscles, and the leg and foot muscles. *Sciatica,* or neuralgia of the sciatic nerve, is a fairly common and very painful condition.

The last sacral spinal nerve (S5), along with a few fibers from S4, joins with the coccygeal nerve to form a small *coccygeal plexus.* Thin anococcygeal nerves arising from this plexus supply the skin that lies over the coccyx bone.

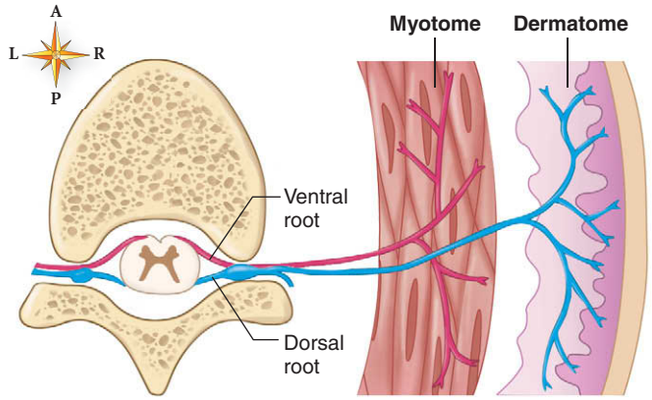

FIGURE 15-6

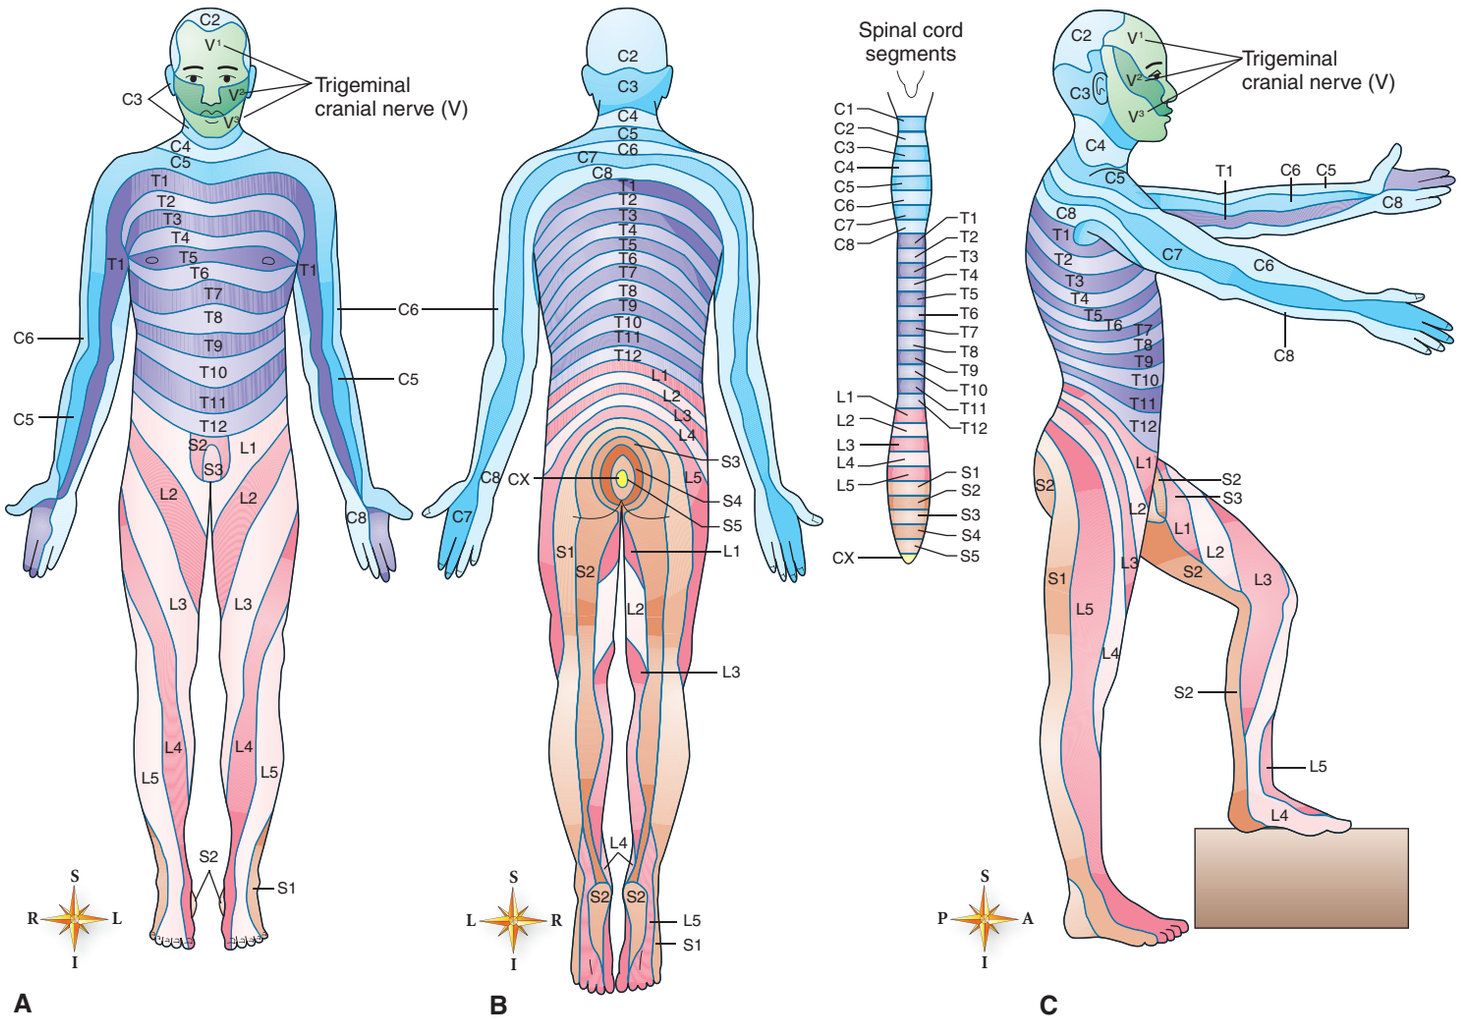
Segmental distribution of spinal nerves. A dermatome is a region of skin supplied by afferent (sensory) fibers of a given spinal nerve. A myotome is a region of skeletal muscle innervated by efferent (motor) fibers of a given spinal nerve. Spinal nerves at different segments of the spinal cord innervate different sets of dermatomes and myotomes.

Dermatomes and Myotomes

At first glance the distribution of spinal nerves does not appear to follow an ordered arrangement, but detailed mapping of the skin surface has revealed a close relationship between the spinal origin of each spinal nerve and the region of the body it innervates. Knowledge of the segmental arrangement of spinal nerves and the region of the body innervated by each segment has proved useful to health professionals. For instance, one can identify the site of spinal cord or nerve abnormality by locating the corresponding area of the body insensitive to a pinprick. Each skin surface area supplied by sensory fibers of a given spinal nerve is called a **dermatome,** a name that means "skin section" (Figures 15-6 and 15-7).

The body maps in Figure 15-7 show sharp boundaries between sensory dermatomes, but there is actually quite a bit of overlap between adjacent dermatomes. Overlap of dermatomes results from differences in the way various types of sensory receptors are distributed in the skin. Dermatome maps help us to better understand



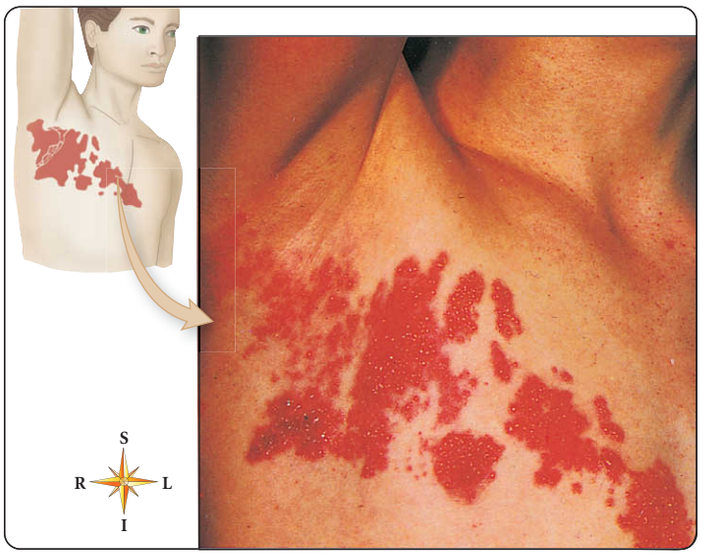


FIGURE 15-7

Dermatome distribution of spinal nerves. **A,** The front of the body's surface. **B,** The back of the body's surface. **C,** The side of the body's surface. The inset shows the segments of the spinal cord connected with each of the spinal nerves associated with the sensory dermatomes shown. *T,* thoracic segments and spinal nerves; *L,* lumbar segments and spinal nerves; *S,* sacral segments and spinal nerves.

Box 15-3 | HEALTH matters

Herpes Zoster

Herpes zoster, or **shingles,** is a unique viral infection that almost always affects the skin of a single dermatome. It is caused by the varicella zoster virus of chickenpox. About 3% of the population will suffer from shingles at some time in their lives. In most cases the disease results from reactivation of the varicella virus. The virus most likely travels through a cutaneous nerve and remains dormant in a dorsal root ganglion for years after an initial episode of chickenpox. If the body's immunological protective mechanism becomes diminished, as in the elderly or as a result of stress, or because of radiation therapy or immunosuppressive drugs, the virus may reactivate. If this occurs, the virus will travel over the sensory nerve to the skin of a single dermatome. The figure shows involvement of dermatome T4 in a 13-year-old boy. The result is a painful eruption of red swollen plaques or vesicles that eventually rupture and crust before clearing in 2 to 3 weeks. In severe cases, extensive inflammation, hemorrhagic blisters, and secondary bacterial infection may lead to permanent scarring. In most cases of shingles, the eruption of vesicles is preceded by 4 to 5 days of preeruptive pain, burning, and itching in the affected dermatome. Unfortunately, an attack of herpes zoster does not confer lasting immunity. Many individuals have three or more episodes in a lifetime.

cutaneous sensation, discussed later in Chapter 17, and also certain conditions that appear on the skin, such as shingles (Box 15-3).

A **myotome** is a skeletal muscle or group of muscles that receives motor axons from a given spinal nerve. There is some overlap among myotomes also. Thus some skeletal muscle organs may be innervated by motor axons from more than one spinal nerve. Figure 15-8 shows examples of how myotomes relate to specific movements of the body.

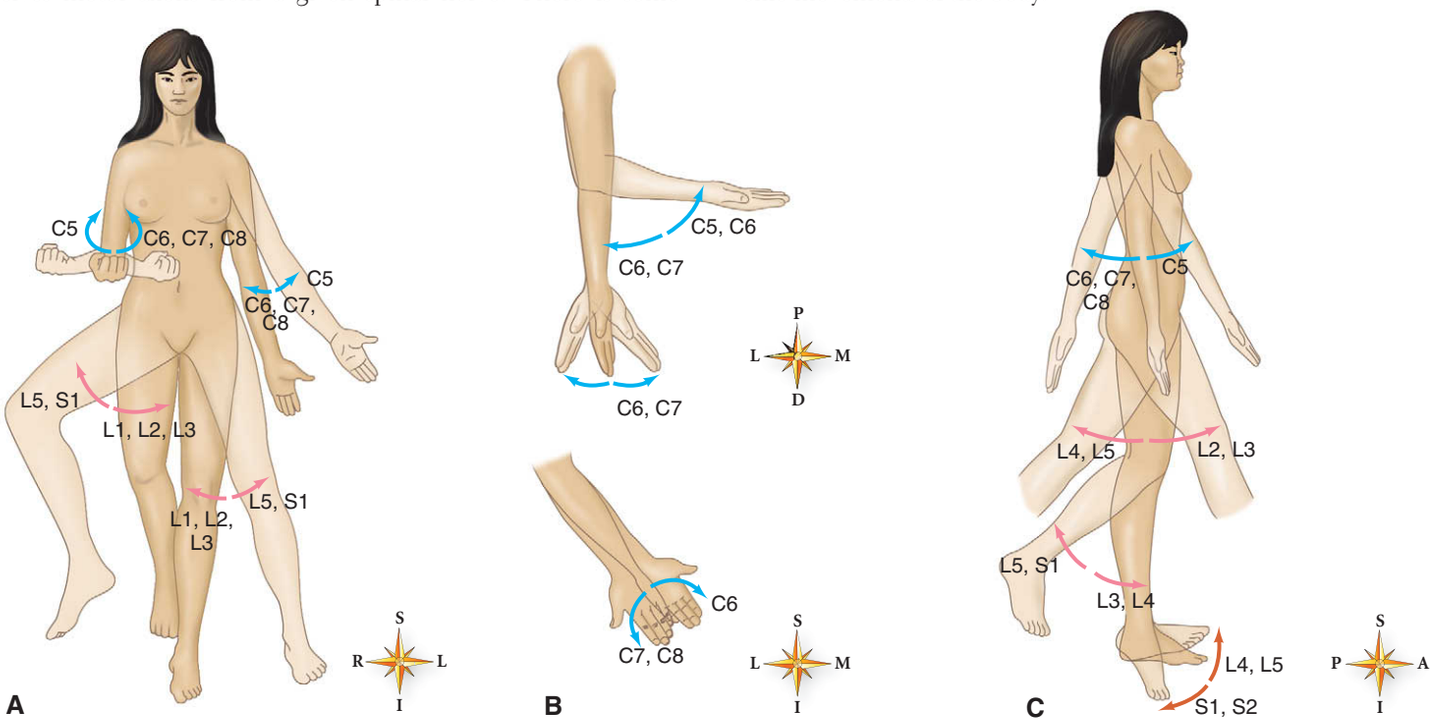

FIGURE 15-8

Myotomes and body movement. Myotomes are skeletal muscles innervated by one or more given spinal nerves. These examples show which spinal nerves innervate the skeletal muscles that produce the movements indicated by the arrows. **A,** Rotation and abduction/adduction of arm and hip. **B,** Flexion/extension of hand and wrist; pronation/supination of hand. **C,** Flexion/extension/hyperextension of arm, hip, knee; dorsiflexion and plantar flexion of foot. *C,* Cervical spinal nerves; *L,* lumbar spinal nerves; *S,* sacral spinal nerves.

CRANIAL NERVES

Twelve pairs of **cranial nerves** connect to the undersurface of the brain (Figure 15-9), mostly on the brainstem. Cranial nerves pass through small foramina (holes) in the cranial cavity of the skull, allowing them to extend to or from their peripheral destinations. Both names and numbers identify the cranial nerves. Their names suggest either their distribution—where they extend to (or from). For example, the optic nerve extends from the eye, carrying visual information. Their numbers indicate the order in which they connect to the brain from anterior to posterior. Roman numerals are most often used for cranial nerves, sometimes with the acronym CN (for "cranial nerve"). For example, the optic nerve is also known as *cranial nerve II* or *CN II*. Less frequently, Arabic numerals are used, as in CN 2.

As with all nerves, cranial nerves are made up of bundles of axons. **Mixed cranial nerves** contain axons of sensory and motor neurons. **Sensory cranial nerves** consist of sensory axons only, and **motor cranial nerves** consist mainly of motor axons. Cranial nerves classified as "motor nerves" contain a small number of sensory fibers. These sensory fibers are *proprioceptive* fibers that carry information regarding tension in the muscles controlled by the motor fibers of the same motor nerve. Table 15-2 lists the name, number, and functional classification of each of the 12 pairs of cranial nerves. Details of the structure and function of each

TABLE 15-2 Names, Numbers, and Functional Classifications of Cranial Nerves

NAME*	NUMBER	FUNCTIONAL CLASSIFICATION†
Olfactory	I	Sensory
Optic	II	Sensory
Oculomotor	III	Motor
Trochlear	IV	Motor
Trigeminal	V	Mixed
Abducens	VI	Motor
Facial	VII	Mixed
Vestibulocochlear	VIII	Sensory
Glossopharyngeal	IX	Mixed
Vagus	X	Mixed
Accessory	XI	Motor
Hypoglossal	XII	Motor

*The first letter of each word in the following sentence correlates with the first letter of the name of each of the cranial nerves, in the correct order, I to XII: **O**n **O**ld **O**lympus' **T**iny **T**ops, **A** **F**riendly **V**iking **G**rew **V**ines **A**nd **H**ops. Many anatomy students find that using this sentence, or one like it, helps in memorizing the names and numbers of the cranial nerves.

†The following sentence is a memory aid for learning the functional classification of each cranial nerve: **S**ome **S**ay '**M**arry **M**oney,' **B**ut **M**y **B**rothers **S**ay '**B**ad **B**usiness, **M**arry **M**oney.' In this sentence, **S** indicates *sensory,* **M** indicates *motor,* and **B** indicates *both* sensory and motor (mixed).

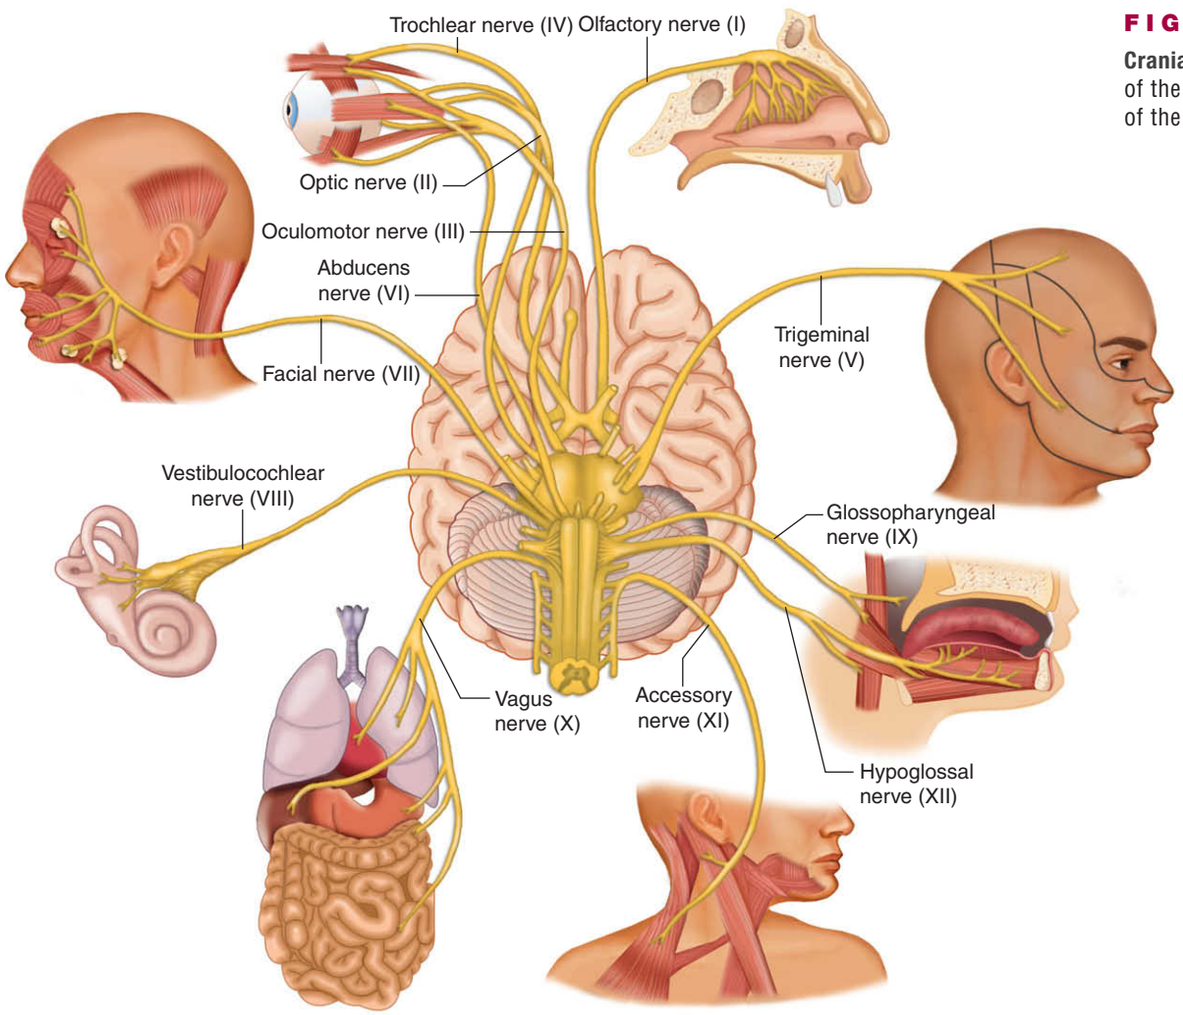

FIGURE 15-9
Cranial nerves. Ventral surface of the brain showing attachment of the cranial nerves.

cranial nerve are described in Table 15-3 and in the paragraphs that follow.

| QUICK CHECK |

1. How many pairs of spinal nerves are there? Can you name them?
2. What is a plexus? Name the four major pairs of plexuses.
3. What is a dermatome? A myotome?

Olfactory Nerve (I)

The **olfactory nerves** are composed of axons of neurons whose dendrites and cell bodies lie in the nasal mucosa, high up along the septum and superior conchae (turbinates). Axons of these neurons form about 20 small bundles of fibers that pierce each cribriform plate and terminate in the olfactory bulbs (see Figure 17-6, p. 514). Here they synapse with the second pool of olfactory neurons, whose axons compose the olfactory tracts. The olfactory nerves carry information about the sense of smell.

| A&P CONNECT |

Although you will not find it in most introductory anatomy texts, there is an additional pair of cranial nerves not found in the classic list of twelve. The **terminal nerve,** or cranial *nerve zero,* is a very thin nerve located near each olfactory nerve. Why is it often missing from the list? Why is it called nerve "zero?" And why are some scientists calling it the "sex nerve?" Check out ***Nerve Zero*** online at ***A&P Connect*** to find out!

evolve

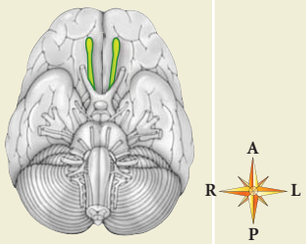
Optic Nerve (II)

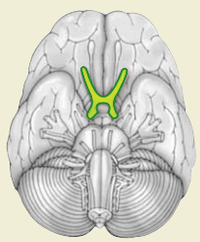
Axons from the innermost layer of sensory neurons of the retina compose the second pair of cranial nerves. They are called **optic nerves** because they carry visual information from the eyes to the brain. After entering the cranial cavity through the optic foramina, the two optic nerves unite to form the *optic chiasma*, in which some of the fibers of each nerve cross to the opposite side and continue in the *optic tract* of that side (see Figure 17-31, p. 533). Thus each optic nerve contains fibers only from the retina of the same side, whereas each optic tract has fibers in it from both retinas, an important fact in interpreting certain visual disorders.

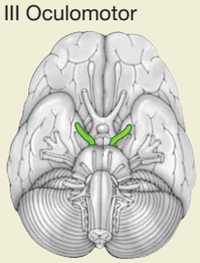
Most of the optic tract fibers terminate in the thalamus (in the portion known as the *lateral geniculate nucleus*). From here a new relay of fibers runs to the visual area of the occipital lobe cortex. A few optic tract fibers terminate in the superior colliculi of the midbrain, where they synapse with motor fibers to the external eye muscles (cranial nerves III, IV, VI).

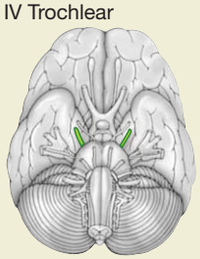
Oculomotor Nerve (III)

Fibers of each **oculomotor nerve** originate from cells in the oculomotor nucleus in the ventral part of the midbrain and extend to the various external eye muscles, with the exception of the superior oblique and the lateral rectus. Autonomic fibers are also present in the oculomotor nerves. They extend to the intrinsic muscles of the eye, which regulate the amount of light entering the eye and aid in focusing on near objects.







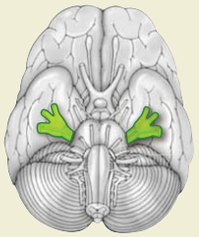


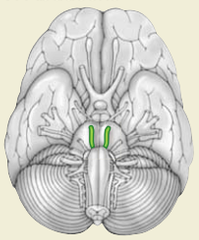
Yet a third group of fibers is found in the third cranial nerves. These are sensory fibers from proprioceptors in the eye muscles.

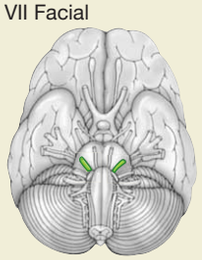
Trochlear Nerve (IV)

Motor fibers of each **trochlear nerve** have their origin in cells in the midbrain, from which they extend to the superior oblique muscles of the eye. The name *trochlear*, from a Greek word meaning "pulley," refers to the fact that the superior oblique muscles of the eye pass through a pulleylike ligament (see Figure 17-20, p. 526). Afferent fibers from proprioceptors in these muscles are also contained in the trochlear nerves.

TABLE 15-3 Structure and Function of the Cranial Nerves







☐ sensory (afferent) ☐ motor (efferent)

	SENSORY FIBERS			MOTOR FIBERS		
NERVE	**RECEPTORS**	**CELL BODIES**	**TERMINATION**	**CELL BODIES**	**TERMINATION**	**FUNCTIONS**
I Olfactory 	Nasal mucosa	Nasal mucosa	Olfactory bulbs (new relay of neurons to olfactory cortex)			Sense of smell
II Optic 	Retina (proprioceptive)	Retina	Nucleus in thalamus (lateral geniculate); some fibers terminate in superior colliculus of midbrain			Vision
III Oculomotor 	External eye muscles except superior oblique and lateral rectus	Trigeminal ganglion	Midbrain (oculomotor nucleus)	Midbrain (oculomotor nucleus)	External eye muscles except superior oblique and lateral rectus; autonomic fibers terminate in ciliary ganglion and then to ciliary and iris muscles	Eye movements, regulation of size of pupil, accommodation (for near vision), proprioception (muscle sense)
IV Trochlear 	Superior oblique (proprioceptive)	Trigeminal ganglion	Midbrain	Midbrain	Superior oblique muscle of eye	Eye movements, proprioception

(continued)

TABLE 15-3 Structure and Function of the Cranial Nerves *(continued)*

□ sensory (afferent) □ motor (efferent)

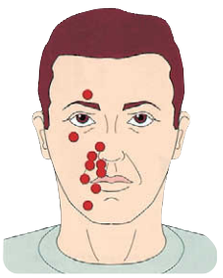
	SENSORY FIBERS			MOTOR FIBERS		
NERVE	**RECEPTORS**	**CELL BODIES**	**TERMINATION**	**CELL BODIES**	**TERMINATION**	**FUNCTIONS**
V Trigeminal 	Skin and mucosa of head, teeth	Trigeminal ganglion	Pons (sensory nucleus)	Pons (motor nucleus)	Muscles of mastication	Sensations of head and face, chewing movements, proprioception
VI Abducens 	Lateral rectus (proprioceptive)	Trigeminal ganglion	Pons	Pons	Lateral rectus muscle of eye	Abduction of eye, proprioception
VII Facial 	Taste buds of anterior two thirds of tongue	Geniculate ganglion	Medulla (nucleus solitarius)	Pons	Superficial muscles of face and scalp; autonomic fibers to salivary and lacrimal glands	Facial expressions, secretion of saliva and tears, taste

(continued on page 492)

Trigeminal Nerve (V)

The fifth pair of cranial nerves is called **trigeminal nerves** because they each split into three large branches. The name trigeminal means "three pairs." The three branches of each pair are the *ophthalmic nerve*, *maxillary nerve*, and *mandibular nerve* (Figure 15-10).

Sensory neurons in all three branches of the trigeminal nerve carry afferent impulses from the skin and mucosa of the head and from the teeth to cell bodies in the trigeminal ganglion (lodged in the petrous part of the temporal bone). Fibers extend from the ganglion to the main sensory nucleus of the fifth cranial nerve situated in the pons. Some of the sensory pathways carry information from the mouth about the texture and temperature of food. The so-called *trigeminal senses* that contribute to the flavor of foods are discussed further in Chapter 17. Damage to some of the sensory pathways of the trigeminal nerve could lead to trigeminal neuralgia (Box 15-4).



Motor fibers of the trigeminal nerve originate in the trifacial motor nucleus located in the pons just medial to the sensory

Box 15-4 | HEALTH matters

Trigeminal Neuralgia

Compression, inflammation, or degeneration of the fifth cranial nerve, the trigeminal nerve, may result in a condition called **trigeminal neuralgia,** or *tic douloureux* (tic doo-loo-ROO). This condition is characterized by recurring episodes of intense stabbing pain, or *neuralgia,* radiating from the angle of the jaw along a branch of the trigeminal nerve (see the figure).

Treatment with the drug carbamazepine (Tegretol) provides relief in most cases. If drugs do not provide relief, surgical methods may be used. The most drastic method of pain reduction is removal of the trigeminal ganglion on the posterior portion of the nerve (see Figure 15-10). This large ganglion contains the cell bodies of the nerve's afferent fibers. After such an operation, the patient's face, scalp, teeth, and conjunctiva on the side treated show anesthesia (loss of sensation). Therefore, special care, such as wearing protective goggles and irrigating the eye frequently, is prescribed. The patient is also instructed to visit the dentist regularly because he or she can no longer experience a toothache—a warning of diseased teeth.

Pain zones in trigeminal neuralgia.

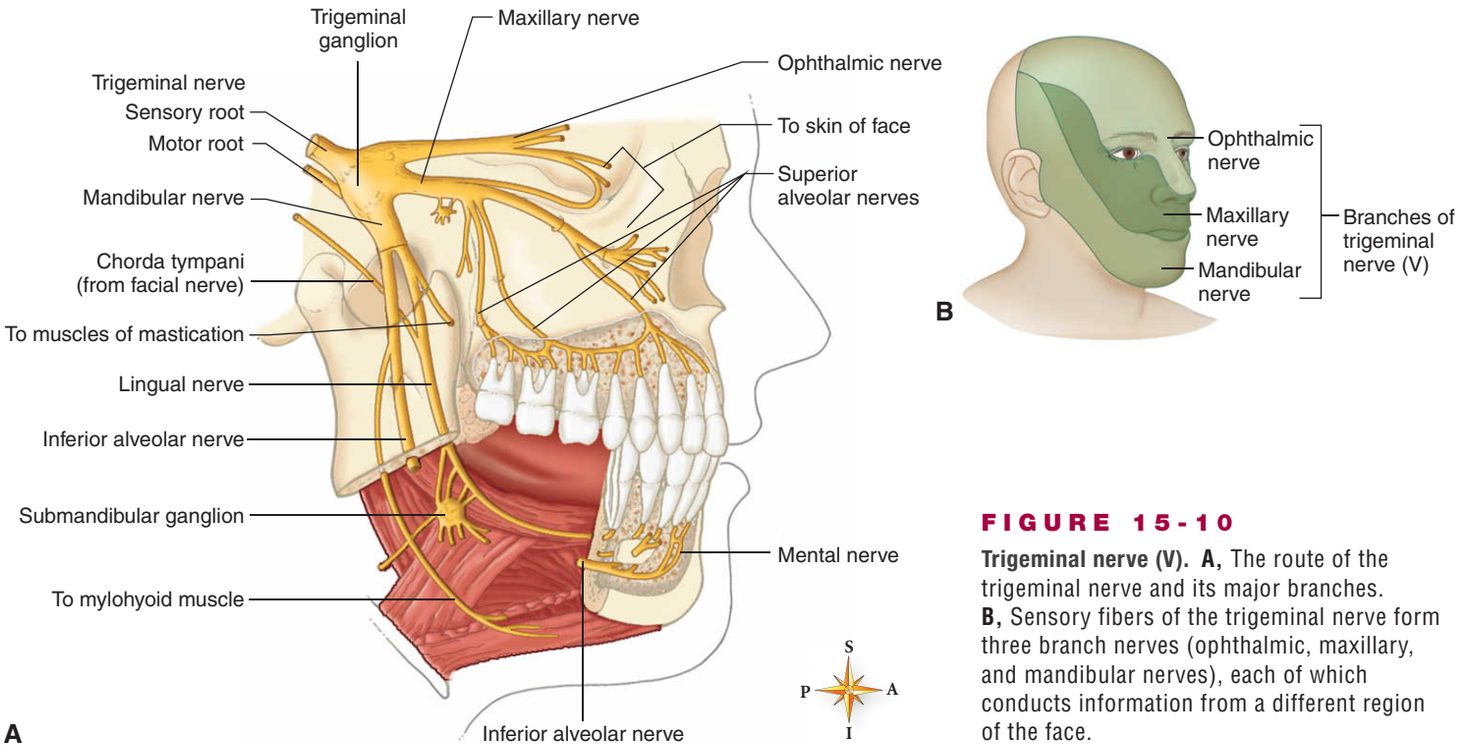


FIGURE 15-10

Trigeminal nerve (V). A, The route of the trigeminal nerve and its major branches. **B,** Sensory fibers of the trigeminal nerve form three branch nerves (ophthalmic, maxillary, and mandibular nerves), each of which conducts information from a different region of the face.

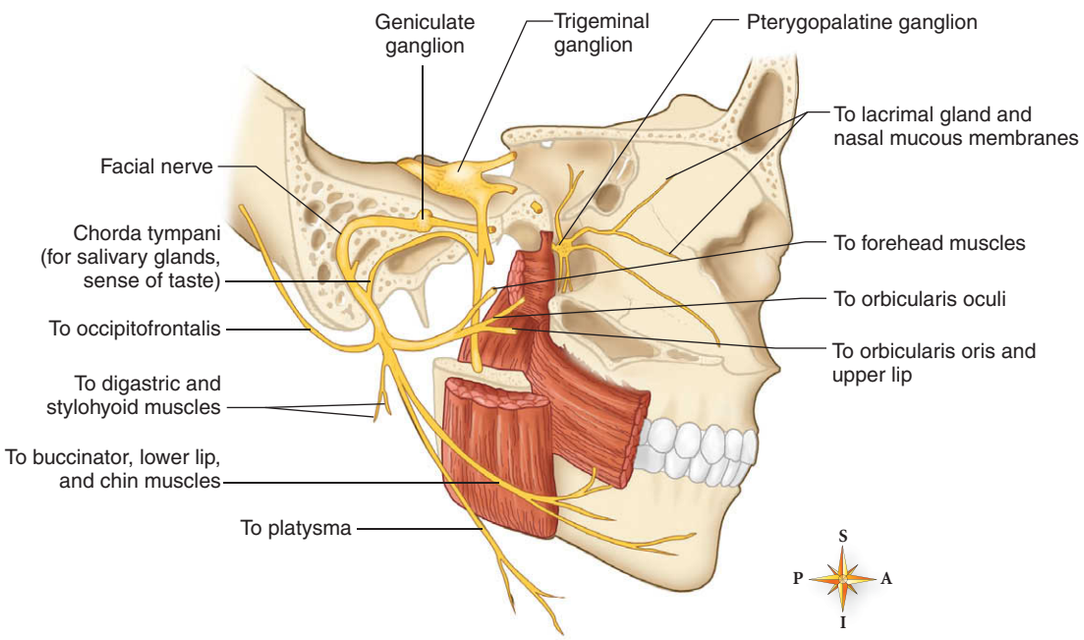
nucleus. These motor fibers run to the muscles of mastication by way of the mandibular nerve.

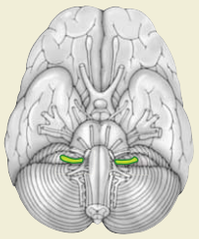
Abducens Nerve (VI)

Each **abducens nerve** is a motor nerve with fibers originating from a nucleus in the pons in the floor of the fourth ventricle and extending to the lateral rectus muscles of the eyes (see Figure 17-20, p. 526). The lateral rectus muscle *abducts* the eye to which it is attached, hence the name *abducens* for this nerve. The sixth cranial nerve also contains some afferent fibers from proprioceptors in the lateral rectus muscles.

Facial Nerve (VII)

The motor fibers of the **facial nerve** arise from a nucleus in the lower part of the pons, from which they extend by way of several branches to the superficial muscles of the face and scalp (Figure 15-11). Efferent autonomic fibers of the facial nerve extend to the submaxillary and sublingual salivary glands, as well as to the lacrimal (tear) glands. Sensory fibers from the taste buds of the anterior two thirds of the tongue run in the facial nerve to cell bodies in the geniculate ganglion, a small swelling on the facial nerve, where it passes through a canal in the temporal bone. From the ganglion, fibers extend to a nucleus in the medulla.





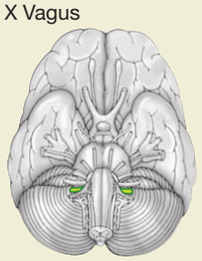


FIGURE 15-11

Facial nerve (VII). Artist's interpretation of the location of the various branches of the facial nerve.

TABLE 15-3 Structure and Function of the Cranial Nerves *(continued)*

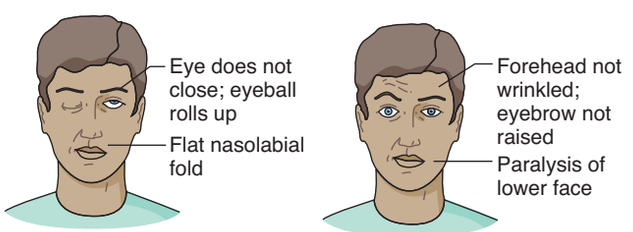
□ sensory (afferent) □ motor (efferent)

	SENSORY FIBERS			MOTOR FIBERS		
NERVE	**RECEPTORS**	**CELL BODIES**	**TERMINATION**	**CELL BODIES**	**TERMINATION**	**FUNCTIONS**
VIII Vestibulocochlear						
Vestibular branch	Semicircular canals and vestibule (utricle and saccule)	Vestibular ganglion	Pons and medulla (vestibular nuclei)			Balance or equilibrium sense
Cochlear (auditory) branch	Spiral (Corti) organ in cochlear duct	Spiral ganglion	Pons and medulla (cochlear nuclei)			Hearing
IX Glossopharyngeal 	Pharynx; taste buds and other receptors of posterior one third of tongue	Jugular and petrous ganglia	Medulla (nucleus solitarius)	Medulla (nucleus ambiguus)	Muscles of pharynx	Sensations of tongue, swallowing movements, secretion of saliva, aid in reflex control of blood pressure and respiration
	Carotid sinus and carotid body	Jugular and petrous ganglia	Medulla (respiratory and vasomotor centers)	Medulla at junction of pons (nucleus salivatorius)	Otic ganglion and then to parotid salivary gland	
X Vagus 	Pharynx, larynx, carotid body, thoracic and abdominal viscera	Jugular and nodose ganglia	Medulla (nucleus solitarius), pons (nucleus of fifth cranial nerve)	Medulla (dorsal motor nucleus)	Ganglia of vagal plexus and then to muscles of pharynx, larynx, and autonomic fibers to thoracic and abdominal viscera	Sensations and movements of organs supplied; e.g., slows heart, increases peristalsis, contracts muscles for voice production

(continued on page 480)

Vestibulocochlear Nerve (VIII)

The **vestibulocochlear nerve** has two distinct divisions: the *vestibular nerve* and the *cochlear nerve* (see Figure 17-12, p. 519). Both are sensory.



Fibers from the semicircular canals in the inner ear run to the vestibular ganglion (in the internal acoustic meatus). Here, the neurons' cell bodies are located, and from them, fibers extend to the vestibular nuclei in the pons and medulla. Together, these fibers constitute the *vestibular nerve*. Some of its fibers run to the cerebellum. The vestibular nerve transmits impulses that result in sensations of equilibrium.

The *cochlear nerve* consists of peripheral axon fibers starting in the organ of Corti in the cochlea of the inner ear. They have their cell bodies in the spiral ganglion in the cochlea, and their central axon fibers terminate in the cochlear nuclei located between the medulla and pons. Conduction by the cochlear nerve results in sensations of hearing. Damage to this nerve can cause deafness (Box 15-5). Because of its role in hearing, the eighth cranial nerve is sometimes still called the *auditory* or *acoustic* nerve.

Box 15-5 | HEALTH matters

Cranial Nerve Damage

Severe head injuries often damage one or more of the cranial nerves, producing symptoms that reflect loss of the functions mediated by the affected nerve or nerves. For example, injury of the sixth cranial nerve causes the eye to turn in because of paralysis of the abducting muscle of the eye. Injury of the eighth cranial nerve, on the other hand, produces deafness. Injury to the facial nerve results in a poker-faced expression and a drooping of the corner of the mouth from paralysis of the facial muscles.

Signs of damage to the facial nerve (VII).

Glossopharyngeal Nerve (IX)

Both sensory and motor fibers compose the **glossopharyngeal nerve.** This nerve supplies fibers not only to the tongue and pharynx (throat), as its name implies, but also to other structures (Figure 15-12). One is the carotid sinus. The carotid sinus plays an important part in the control of blood pressure. Sensory fibers, with their receptors in the pharynx and posterior one third of the tongue, have their cell bodies in the jugular (superior) and petrous (inferior) ganglia. These are located, respectively, in the jugular foramen and the petrous part of the temporal bone. The ganglia fibers extend to a nucleus in the medulla.

The motor fibers of the ninth cranial nerve originate in another medullary nucleus and run to muscles of the pharynx. Also present in this nerve are autonomic fibers that originate in a nucleus at the junction of the pons and medulla. These fibers run to the otic ganglion, from which postganglionic fibers extend to the parotid gland.

Vagus Nerve (X)

The **vagus nerve** contains both sensory and motor fibers. The name vagus means "wanderer" and aptly describes this nerve with many widely distributed branches. Its sensory fibers supply the pharynx, larynx, trachea, heart, carotid body, lungs, bronchi, esophagus, stomach, small intestine, and gallbladder (Figure 15-13). Cell bodies attached to these sensory fibers lie in the jugular and nodose ganglia, which are located, respectively, in the jugular foramen and just inferior to it on the trunk of the nerve. The sensory axons terminate in the medulla and in the pons. Somatic motor fibers of the vagus travel to the pharynx and larynx (voice box), where they control muscles involved in swallowing.

Most motor fibers of the vagus nerve are autonomic (parasympathetic) fibers. They originate in cells in the medulla and extend to various autonomic ganglia. From there, the fibers run to muscles of the pharynx, larynx, and thoracic and abdominal organs, where they control heart rate and other "visceral" activities.

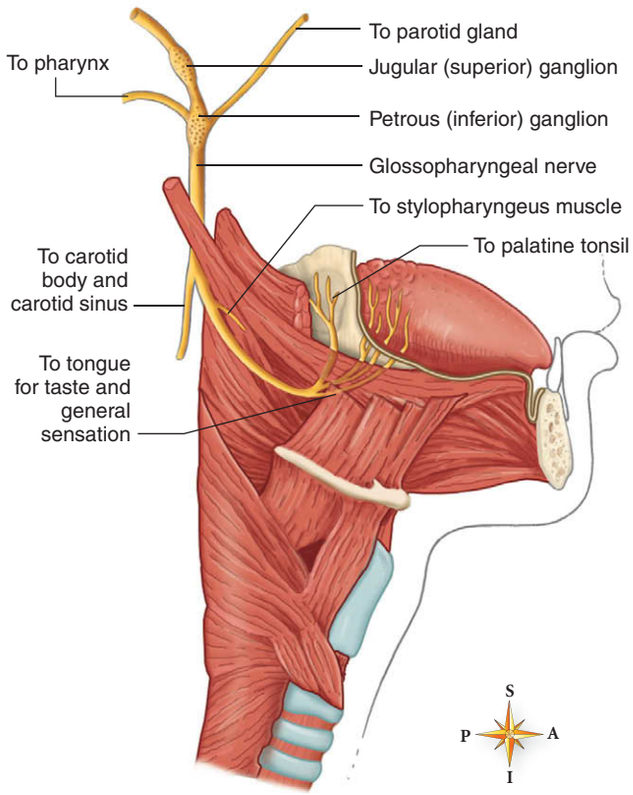


FIGURE 15-12

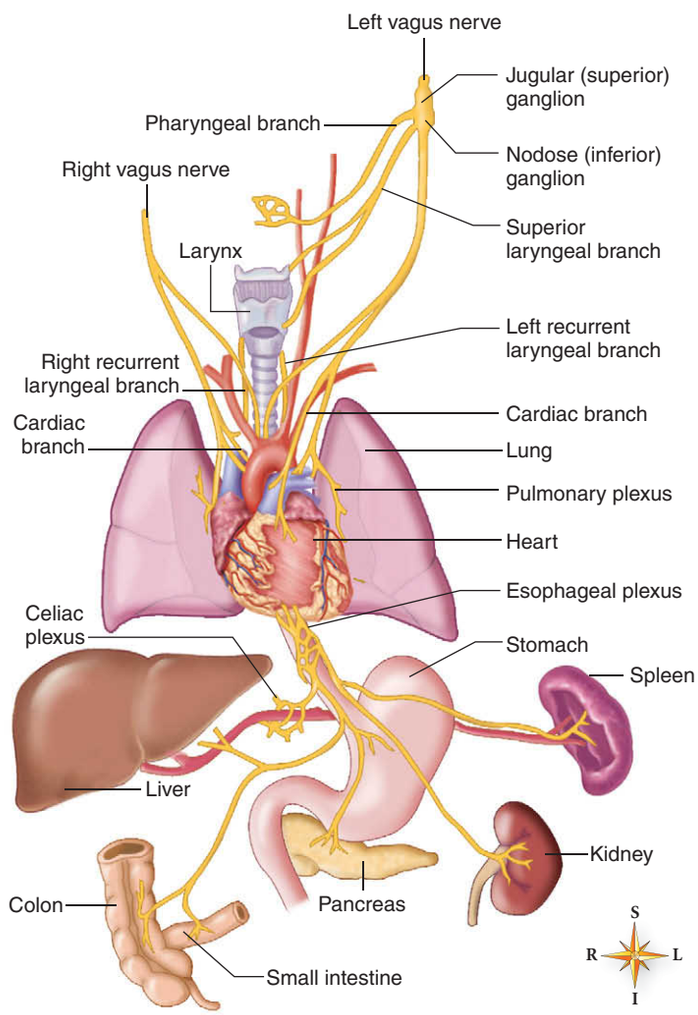
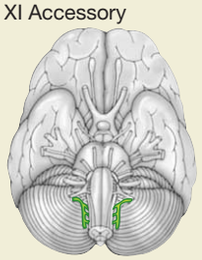
Glossopharyngeal nerve (IX). As its name implies (*glosso-*, "tongue"; *-pharyng-*, "throat"), the ninth cranial nerve supplies fibers to the tongue and throat. It is a mixed nerve that carries both sensory and motor fibers.





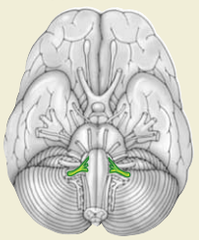


FIGURE 15-13

Vagus nerve (X). The vagus nerve is a mixed cranial nerve with many widely distributed branches—hence the name *vagus,* which is the Latin word for "wanderer."

TABLE 15-3 Structure and Function of the Cranial Nerves *(continued)*

☐ sensory (afferent) ☐ motor (efferent)

	SENSORY FIBERS			MOTOR FIBERS		
NERVE	**RECEPTORS**	**CELL BODIES**	**TERMINATION**	**CELL BODIES**	**TERMINATION**	**FUNCTIONS**
XI Accessory 	Trapezius and sternocleidomastoid (proprioceptive)	Upper, cervical ganglia	Spinal cord	Anterior gray column of first five or six cervical segments of spinal cord	Trapezius and sternocleidomastoid muscle	Shoulder movements, turning movements of head, proprioception
XII Hypoglossal 	Tongue muscles (proprioceptive)	Trigeminal ganglion	Medulla (hypoglossal nucleus)	Medulla (hypoglossal nucleus)	Muscles of tongue and throat	Tongue movements, proprioception

Accessory Nerve (XI)

The **accessory nerve** is a motor nerve historically considered to be an "accessory" to the vagus nerve. In a very few individuals, some of its fibers originate in cells in the medulla and join the fibers of the vagus nerve. However, we now know that in most people, all the fibers of this nerve originate in the upper cervical region (C1-C5) of the spinal cord—and none of the fibers originate in the brain. From there, they extend to the trapezius and sternocleidomastoid muscles (Figure 15-14).

The accessory nerve is still classified as a cranial nerve because it passes into the foramen magnum and then through the cranial cavity, where it exits by way of the jugular foramen. Like the other cranial nerves, this cranial nerve also exits the cranial cavity.

Because of its spinal origin, the eleventh cranial nerve was formerly called the *spinal accessory nerve.*

Hypoglossal Nerve (XII)

Motor fibers with cell bodies in the hypoglossal nucleus of the medulla compose the twelfth cranial nerve. They supply the muscles of the tongue (see Figure 15-9). The **hypoglossal nerve** also contains sensory fibers from proprioceptors in muscles of the tongue. The name *hypoglossal* means "under the tongue."

Table 15-3 summarizes the main facts about the distribution and function of each of the cranial nerve pairs.

| QUICK CHECK |

4. List the names and numbers of the 12 pairs of cranial nerves.
5. Identify the primary function of each pair of cranial nerves.
6. Distinguish between a motor nerve, sensory nerve, and mixed nerve.

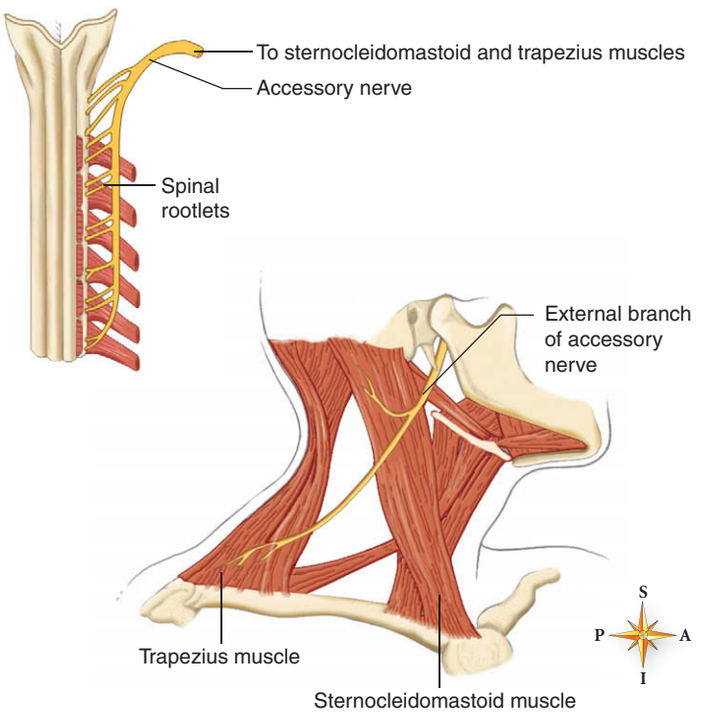

FIGURE 15-14

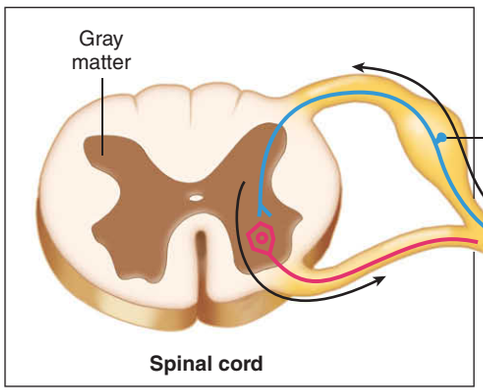
Accessory nerve (XI). This cranial nerve is an "accessory" to the vagus nerve because some of its fibers join the vagus nerve before traveling on to the viscera, pharynx, and larynx. Fibers that originate in the cervical spinal segments travel through an external nerve branch to the trapezius and sternocleidomastoid muscles of the neck.

SOMATIC MOTOR NERVOUS SYSTEM



Divisions of the Peripheral Nervous System

Recall from Chapter 13 that the PNS includes all the nervous pathways *outside* the brain and spinal cord (see Figure 13-2, p. 382). Thus the entire PNS includes the fibers present in the cranial nerves, the spinal nerves, and all their individual branches. Although many of these nerves are *mixed nerves*—containing both sensory and motor fibers—it is often convenient to consider the PNS as having two functional divisions: the sensory (afferent) division and the motor (efferent) division. In this chapter, we concentrate on some essential details of the somatic motor division of the PNS—the *somatic motor nervous system*. Then in Chapter 16 we move on to discuss the efferent pathways of the *autonomic nervous system*. Details of the sensory division of the PNS are discussed in Chapter 17.

BASIC PRINCIPLES OF SOMATIC MOTOR PATHWAYS

The somatic motor nervous system includes all the voluntary motor pathways outside the CNS. That is, it involves the peripheral pathways to the skeletal muscles, which are the *somatic effectors*. Recall from Chapter 14 that all these pathways operate according to the principle of *final common path*. This means that all the somatic motor pathways involve a single motor neuron whose axon stretches from the cell body in the CNS all the way to the effector innervated by that neuron. For fibers that originate in the spinal cord, this means that the axon extends from the anterior gray horn, through the ventral nerve root, and out to a skeletal muscle.

Another important principle of somatic motor pathways was mentioned in Chapter 12, when we were discussing the function of skeletal muscles. This principle states that the axon of the last somatic motor neuron—also called the *anterior horn neuron* or *lower motor neuron*—stimulates effector cells by means of the neurotransmitter **acetylcholine.** This fact will have added importance later when we compare the somatic motor nervous system with the ANS.

Because the basic plan of the somatic motor pathways was discussed in Chapter 14, and the effect of acetylcholine on the somatic effectors (skeletal muscles) has already been outlined in Chapter 11, we will end our discussion of the somatic motor division of the PNS with a brief review of the concept of the reflex arc and how it relates to peripheral motor pathways.

SOMATIC REFLEXES

Nature of a Reflex

The action that results from a nerve impulse passing over a reflex arc is called a **reflex** (see Figure 13-10, p. 390). In other words, a reflex is a predictable response to a stimulus. It may or may not be conscious. Usually the term is used to mean only involuntary responses rather than those directly willed. If the center of a reflex arc is in the brain, the response it mediates is called a **cranial reflex.** If the center of a reflex arc is in the spinal cord, the response is called a **spinal reflex.**

A reflex consists of either muscle contraction or glandular secretion.

Somatic reflexes are contractions of skeletal muscles. Impulse conduction over somatic reflex arcs—arcs whose motor neurons are somatic motor neurons (i.e., anterior horn neurons or lower motor neurons)—produces somatic reflexes.

Autonomic (visceral) reflexes consist of contractions of smooth or cardiac muscle or secretion by glands. Visceral reflexes are mediated by impulse conduction over autonomic reflex arcs, the motor neurons of which are autonomic neurons (discussed later).

The following paragraphs describe only somatic reflexes.

Somatic Reflexes of Clinical Importance

Clinical interest in reflexes stems from the fact that they deviate from normal in certain diseases. Therefore the testing of reflexes is a valuable diagnostic aid. The following reflexes are frequently tested: knee jerk, ankle jerk, plantar reflex, corneal reflex, and abdominal reflex.

Knee Jerk Reflex

The **knee jerk reflex,** or *patellar reflex*, is an extension of the leg in response to tapping of the patellar ligament (Figures 15-15 and

FIGURE 15-15

Patellar reflex. Neural pathway involved in the patellar (knee jerk) reflex.

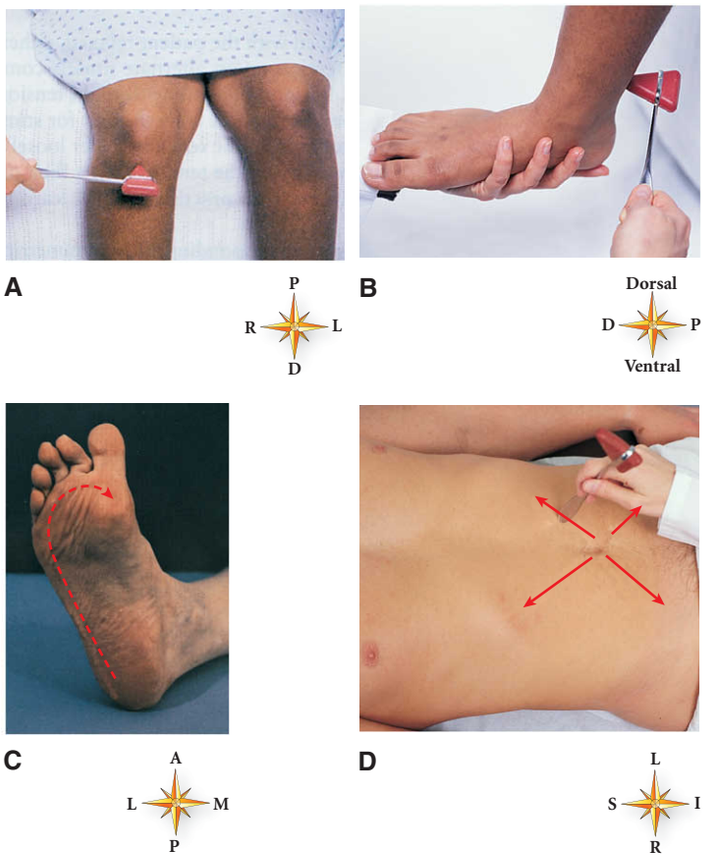


FIGURE 15-16

Common clinical reflex tests. A, Knee jerk reflex. **B,** Ankle jerk reflex. **C,** Plantar reflex showing the Babinski sign (arrow shows path of stimulation along plantar surface). **D,** Abdominal reflexes (one of several ways to test this type of reflex). As an object is moved away from umbilicus and toward the side, the rectus abdominis muscles pull the umbilicus toward the stroked side.

15-16, A). The tap stretches the ligament, pulling on the patella and the tendon of the quadriceps femoris muscles and thereby stimulates muscle spindles (receptors) in the muscle and initiates conduction over the following two-neuron reflex arc:

- Sensory neurons

  Peripheral axon fibers—in femoral and second, third, and fourth lumbar nerves

  Cell bodies—second, third, and fourth lumbar ganglia

  Central axon fibers—in posterior roots of second, third, and fourth lumbar nerves; terminate in these segments of the spinal cord; synapse directly with lower motor neurons

- Reflex center—synapses in anterior gray column between axons of sensory neurons and dendrites and cell bodies of lower motor neurons
- Motor neurons

  Dendrites and cell bodies—in spinal cord anterior gray column

  Axons—in anterior roots of second, third, and fourth lumbar spinal nerves and femoral nerves; terminate in quadriceps femoris muscle

The knee jerk can be classified in various ways as follows:

- As a *spinal cord reflex*—because the center of the reflex arc (which transmits the impulses that activate the muscles producing the knee jerk) lies in the spinal cord gray matter
- As a *segmental reflex*—because impulses that mediate it enter and leave the same segment of the cord
- As an *ipsilateral reflex*—because the impulses that mediate it come from and go to the same side of the body (a *contralateral reflex*, on the other hand, would trigger a response on the opposite side of the body)
- As a *stretch reflex* or *myotatic reflex* (from the Greek *mys-*, "muscle," *-tasis*, "stretching")—because of the kind of stimulation used to evoke it
- As an *extensor reflex*—because it is produced by extensors of the leg (muscles located on the anterior surface of the thigh, which extend the leg)
- As a *deep reflex*—because of the deep location (in muscle) of the receptors stimulated to produce this reflex (as opposed to *superficial reflexes*—those elicited by stimulation of receptors located in the skin or mucosa)

When testing a patient's reflexes, a physician interprets the test results on the basis of what is known about the reflex arcs that must function to produce normal reflexes.

To illustrate, suppose that a patient has been diagnosed as having poliomyelitis. During the examination the physician finds that she cannot elicit the knee jerk when she taps the patient's patellar tendon. She knows that the poliomyelitis virus attacks anterior horn motor neurons. She also knows the information previously related about which spinal cord segments contain the reflex centers for the knee jerk. On the basis of this knowledge, therefore, she deduces that in this patient the poliomyelitis virus has damaged the second, third, and fourth lumbar segments of the spinal cord. Do you think that this patient's leg would be paralyzed, that he would be unable to move it voluntarily? What neurons would not be able to function that must function to produce voluntary contractions?

Ankle Jerk Reflex

Ankle jerk reflex, or *Achilles reflex*, is an extension (plantar flexion) of the foot in response to tapping of the Achilles tendon (Figure 15-16, *B*). As with the knee jerk, it is a tendon reflex and a deep reflex mediated by two-neuron spinal arcs. The centers for the ankle jerk lie in the first and second sacral segments of the cord.

Plantar Reflex

The **plantar reflex** consists of a curling under of all the toes (plantar flexion) plus a slight turning in and flexion of the

anterior part of the foot in response to stimulation of the outer edge of the sole.

The **Babinski sign,** however, is an extension of the great toe, with or without fanning of the other toes, in response to stimulation of the outer margin of the sole of the foot (Figure 15-16, *C*). Normal infants, up until they are about 1½ years old, exhibit this Babinski sign. At about 18 months, corticospinal fibers have become fully myelinated and the Babinski sign becomes suppressed. A Babinski sign after this age is abnormal and is one of the pyramidal signs (see Box 14-9, p. 429). It is interpreted to mean destruction of pyramidal tract (corticospinal) fibers.

Corneal Reflex

The **corneal reflex** is blinking in response to the cornea being touched. It is mediated by reflex arcs with sensory fibers in the ophthalmic branch of the fifth cranial nerve, centers in the pons, and motor fibers in the seventh cranial nerve.

Abdominal Reflex

The **abdominal reflex** occurs when the umbilicus moves in response to stroking the side of the abdomen (Figure 15-16, *D*). It is mediated by arcs with sensory and motor fibers in the ninth to twelfth thoracic spinal nerves and centers in these segments of the cord. It is classified as a superficial reflex. A decrease in this reflex or its absence occurs in lesions involving pyramidal tract upper motor neurons. It can, however, be absent without any pathological condition—in pregnancy, for example.

| QUICK CHECK |

7. What are the somatic effectors?
8. State the principle of final common path as it applies to the somatic motor nervous system.
9. Explain how the knee jerk reflex can be both a stretch reflex and a spinal reflex.

the BIG picture

Peripheral Nervous System and the Whole Body

The peripheral nervous system is made up of all the afferent nervous pathways coming into the CNS and all the efferent pathways going out of the CNS. After reviewing all the major spinal and cranial nerves, including their major branches, we turned our attention to the efferent somatic pathways. The next chapter (16) will continue the story by picking up with the efferent autonomic pathways. We will finally finish the story of the nervous system with the peripheral afferent (sensory) pathways in Chapter 17.

The peripheral motor pathways are simply those nervous pathways that lead from the integrator (CNS) to the effectors. The somatic motor pathways lead to skeletal muscle effectors, allowing them to carry information that regulates how and when our voluntary muscles contract. This allows us to move our skeleton and accomplish many of the tasks that promote survival and make life productive and enjoyable. Somatic motor pathways also control our breathing—a topic we will explore in later chapters. Less obviously—but just as importantly—somatic motor pathways are directly involved in producing heat with our skeletal muscles.

CASE study

The store was only two blocks away. Tomasina was in such a hurry, and it was so close, she didn't think she really needed to rummage through the garage for her bike helmet. She jumped on her bike and peddled quickly toward the store. From out of nowhere, a car sped by—too close to the side of the road—and clipped Tomasina with the side mirror, knocking her to the ground, banging her head sharply on the curb. When she regained consciousness, Tomasina was in the hospital. She was told some tests would be conducted to see whether her cranial nerves had been affected by the head injury.

1. In one of the tests, Tomasina was asked to stick out her tongue. Which cranial nerve was being tested?
   a. Glossopharyngeal
   b. Hypoglossal
   c. Vagus
   d. Trigeminal
2. In a second test, Tomasina's hearing was evaluated. What cranial nerve is involved in the sense of hearing?
   a. Accessory
   b. Vagus
   c. Vestibulocochlear
   d. Trochlear
3. Tomasina was having difficulty focusing her eyes and following the doctor's finger on command. Which of the following cranial nerves does not control eye movement?
   a. Optic
   b. Oculomotor
   c. Trochlear
   d. Abducens
4. The nurse touched a series of swabs with different tastes to the front portion of Tomasina's tongue—sugar, salt, lemon juice, and dissolved aspirin. Which cranial nerve was the nurse testing?
   a. Glossopharyngeal
   b. Olfactory
   c. Trigeminal
   d. Facial

SPINAL NERVES

A. Overview
1. Thirty-one pairs of spinal nerves are connected to the spinal cord (Figure 15-1)
2. No special names; numbered by level of vertebral column at which they emerge from the spinal cavity
   a. Eight cervical nerve pairs (C1 through C8)
   b. Twelve thoracic nerve pairs (T1 through T12)
   c. Five lumbar nerve pairs (L1 through L5)
   d. Five sacral nerve pairs (S1 through S5)
   e. One coccygeal nerve pair
3. Lumbar, sacral, and coccygeal nerve roots descend from point of origin to the lower end of the spinal cord (level of first lumbar vertebra) before reaching the intervertebral foramina of the respective vertebrae, through which the nerves emerge
4. Cauda equina—describes the appearance of the lower end of the spinal cord and its spinal nerves as a horse's tail

B. Structure of spinal nerves
1. Each spinal nerve attaches to spinal cord by a ventral (anterior) root and a dorsal (posterior) root
2. Dorsal root ganglion—swelling in the dorsal root of each spinal nerve
3. All spinal nerves are mixed nerves
4. Ramus
   a. One of several large branches formed after each spinal nerve emerges from the spinal cavity (Figure 15-2)
   b. Dorsal ramus—supplies somatic motor and sensory fibers to smaller nerves that innervate the muscles and skin of the posterior surface of the head, neck, and trunk
   c. Ventral ramus
      (1) Structure is more complex than that of dorsal ramus
      (2) Autonomic motor fibers split from the ventral ramus and head toward a ganglion of the sympathetic chain
      (3) Some autonomic fibers synapse with neurons that continue on to autonomic effectors through splanchnic nerves; others synapse with neurons whose fibers rejoin the ventral ramus
      (4) Sympathetic rami—splitting and rejoining of autonomic fibers
      (5) Motor and sensory fibers innervate muscles and glands in the extremities and lateral and ventral portions of neck and trunk

C. Nerve plexuses
1. Plexuses—complex networks formed by the ventral rami of most spinal nerves (not T2 through T12) subdividing and then joining together to form individual nerves
2. Each individual nerve that emerges contains all the fibers that innervate a particular region of the body
3. In plexuses, spinal nerve fibers are rearranged according to their ultimate destination, reducing the number of nerves needed to supply each body part
4. Four major pairs of plexuses
   a. Cervical plexus (Figure 15-3)
      (1) Located deep within the neck
      (2) Made up of ventral rami of C1 through C4 and a branch of the ventral ramus of C5
      (3) Individual nerves emerging from cervical plexus innervate the muscles and skin of the neck, upper shoulders, and part of the head
      (4) Phrenic nerve exits the cervical plexus and innervates the diaphragm
   b. Brachial plexus (Figure 15-4)
      (1) Located deep within the shoulder
      (2) Made up of ventral rami of C5 through T1
      (3) Individual nerves emerging from brachial plexus innervate the lower part of the shoulder and the entire arm
   c. Lumbar plexus (Figure 15-5)
      (1) Located in the lumbar region of the back in the psoas muscle
      (2) Formed by intermingling fibers of L1 through L4
      (3) Femoral nerve exits the lumbar plexus, divides into many branches, and supplies the thigh and leg
   d. Sacral plexus and coccygeal plexus (Figure 15-5)
      (1) Located in the pelvic cavity in the anterior surface of the piriformis muscle
      (2) Formed by intermingling of fibers from L4 through S4
      (3) Tibial, common peroneal, and sciatic nerves exit the sacral plexus and supply nearly all the skin of the leg, posterior thigh muscles, and leg and foot muscles

D. Dermatomes and myotomes (Figure 15-6)
1. Dermatome—region of skin surface area supplied by afferent (sensory) fibers of a given spinal nerve (Figure 15-7)
2. Myotome—skeletal muscle or muscles supplied by efferent (motor) fibers of a given spinal nerve (Figure 15-8)

CRANIAL NERVES (TABLES 15-2 AND 15-3)

A. Overview
1. Twelve pairs of cranial nerves connect to the brain, mostly the brainstem (Figure 15-9)
2. Identified by name (determined by either distribution or function) or number (order in which they emerge, anterior to posterior) or both
3. Made up of bundles of axons

a. Mixed cranial nerve—axons of sensory and motor neurons
b. Sensory cranial nerve—axons of sensory neurons only
c. Motor cranial nerve—mainly axons of motor neurons and a small number of sensory fibers (proprioceptors)

B. Olfactory nerve (I)
1. Composed of axons of neurons whose dendrites and cell bodies lie in nasal mucosa and terminate in olfactory bulbs
2. Carries information about sense of smell

C. Optic nerve (II)
1. Composed of axons from the innermost layer of sensory neurons of the retina
2. Carries visual information from the eyes to the brain

D. Oculomotor nerve (III)
1. Fibers originate from cells in the oculomotor nucleus and extend to some of the external eye muscles
2. Efferent autonomic fibers are also present, which extend to the intrinsic muscles of the eye to regulate amount of light entering eye and aid focusing on near objects
3. Sensory fibers from proprioceptors in the eye muscles are also present

E. Trochlear nerve (IV)
1. Motor fibers originate in cells of the midbrain and extend to the superior oblique muscles of the eye
2. Also contains afferent fibers from proprioceptors in the superior oblique muscles of the eye

F. Trigeminal nerve (V) (Figure 15-10)
1. Has three branches: ophthalmic nerve, maxillary nerve, and mandibular nerve
2. Sensory neurons carry afferent impulses from skin and mucosa of head and teeth to cell bodies in the trigeminal ganglion
3. Motor fibers originate in trifacial motor nucleus and extend to the muscles of mastication through the mandibular nerve

G. Abducens nerve (VI)
1. Motor nerve with fibers originating from a nucleus in the pons on the floor of the fourth ventricle and extending to the lateral rectus muscles of the eye
2. Contains afferent fibers from proprioceptors in the lateral rectus muscles

H. Facial nerve (VII)
1. Motor fibers originate from a nucleus in lower part of pons and extend to superficial muscles of the face and scalp (Figure 15-11)
2. Autonomic fibers extend to submaxillary and sublingual salivary glands
3. Also contains sensory fibers from taste buds of anterior two thirds of the tongue

I. Vestibulocochlear nerve (VIII)
1. Two distinct divisions that are both sensory: vestibular nerve and cochlear nerve
2. Vestibular nerve fibers originate in the semicircular canals in inner ear and transmit impulses that result in sensations of equilibrium
3. Cochlear nerve fibers originate in the organ of Corti in the cochlea of the inner ear and transmit impulses that result in sensations of hearing

J. Glossopharyngeal nerve (IX)
1. Composed of sensory, motor, and autonomic nerve fibers
2. Supplies fibers to tongue, pharynx, and carotid sinus (Figure 15-12)

K. Vagus nerve (X)
1. Composed of sensory and motor fibers with many widely distributed branches
2. Sensory fibers supply pharynx, larynx, trachea, heart, carotid body, lungs, bronchi, esophagus, stomach, small intestine, and gallbladder (Figure 15-13)
3. Somatic motor fibers innervate the pharynx and larynx and are mostly autonomic fibers

L. Accessory nerve (XI)
1. Motor nerve that was once thought to be an "accessory" to the vagus nerve
2. Innervates the trapezius, and sternocleidomastoid muscles (Figure 15-14)

M. Hypoglossal nerve (XII)
1. Composed of motor and sensory fibers
2. Motor fibers innervate the muscles of the tongue
3. Contains sensory fibers from proprioceptors in muscles of the tongue

SOMATIC MOTOR NERVOUS SYSTEM

A. Two functional divisions of the peripheral nervous system (PNS)
1. Afferent (sensory) division
2. Efferent (motor) division
a. Somatic motor nervous system (SNS)
b. Autonomic nervous system (ANS) efferent pathways; ANS is discussed in Chapter 16

B. Basic principles of somatic motor pathways
1. Somatic nervous system—includes all voluntary motor pathways outside the central nervous system
2. Somatic effectors—skeletal muscles

C. Somatic reflexes
1. Nature of a reflex
a. Reflex—action that results from a nerve impulse passing over a reflex arc; predictable response to a stimulus
(1) Cranial reflex—center of reflex arc is in the brain
(2) Spinal reflex—center of reflex arc is in the spinal cord
b. Reflex consists of either muscle contraction or glandular secretion
(1) Somatic reflex—contraction of skeletal muscles
(2) Autonomic (visceral) reflex—either contraction of smooth or cardiac muscle or secretion by glands
2. Somatic reflexes of clinical importance—reflexes deviate from normal in certain diseases, and reflex testing is a valuable diagnostic aid (Figure 15-16)
a. Knee jerk reflex (also known as *patellar reflex*)—extension of the leg in response to tapping the patellar

ligament; tendon and muscles are stretched, stimulating muscle spindles and initiating conduction over a two-neuron reflex arc (Figure 15-15); may be classified in several different ways
  (1) Spinal cord reflex—center of reflex arc located in spinal cord gray matter
  (2) Segmental reflex—mediating impulses enter and leave at same cord segment
  (3) Ipsilateral reflex—mediating impulses come from and go to the same side of the body
  (4) Stretch or myotatic reflex—result of type of stimulation used to evoke reflex
  (5) Extensor reflex—produced by extensors of the leg
  (6) Deep reflex—result of deep location of receptors stimulated to produce reflex
- b. Ankle jerk reflex (also known as *Achilles reflex*)—extension of the foot in response to tapping the Achilles tendon
  (1) Tendon reflex and deep reflex mediated by two-neuron spinal arcs
  (2) Centers lie in first and second sacral segments of the cord
- c. Plantar reflex—plantar flexion of all toes and a slight turning in and flexion of the anterior part of the foot in response to stimulation of the outer edge of the sole; compare to Babinski sign (below)
  (1) Babinski sign—extension of great toe, with or without fanning of other toes, in response to stimulation of outer margin of sole of foot
  (2) Present in normal infants until approximately 1½ years of age and then becomes suppressed when corticospinal fibers become fully myelinated
  (3) In humans older than 1½ years of age, a positive Babinski reflex is one of the pyramidal signs indicating destruction of corticospinal (pyramidal tract) fibers; compare to the normal adult plantar reflex (above)
- d. Corneal reflex—winking in response to the cornea being touched; mediated by reflex arcs with sensory fibers in the ophthalmic branch of the fifth cranial nerve, centers in the pons, and motor fibers in the seventh cranial nerve
- e. Abdominal reflex—drawing in of the abdominal wall in response to stroking the side of the abdomen; superficial reflex; mediated by arcs with sensory and motor fibers in T9 through T12 and centers in these segments of the cord; decreased or absent reflex may involve lesions of pyramidal tract upper motor neurons

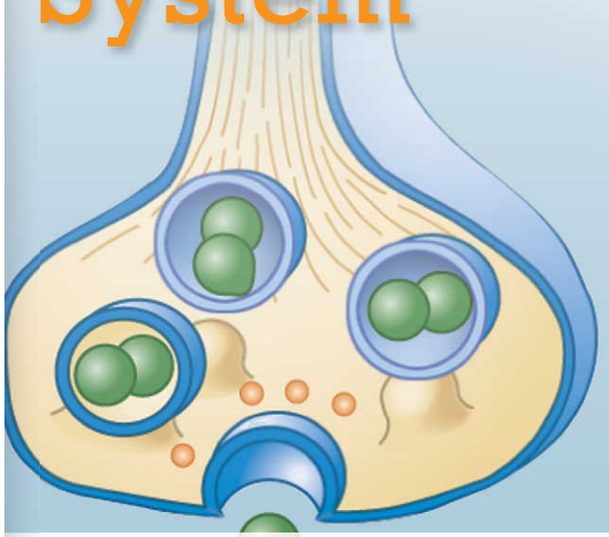
THE BIG PICTURE: THE PERIPHERAL NERVOUS SYSTEM AND THE WHOLE BODY

A. The peripheral nervous system is made of all the afferent nervous pathways coming into the CNS and all the efferent pathways going out of the central nervous system
B. Peripheral efferent (motor) pathways are pathways that lead from the integrator central nervous system to the effectors; allow the central nervous system to communicate regulatory information to the nervous effectors in the body
D. Somatic motor pathways regulate skeletal movements needed for survival, breathing, and heat production

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Identify the direction of the information carried by the ventral root of a spinal nerve.
2. Define mixed nerves.
3. Identify the areas innervated by the individual nerves emerging from the cervical plexus.
4. Explain the concept of a dermatome.
5. Explain the correlation between a myotome and a specific movement of the body.
6. Which cranial nerves transmit impulses that result in vision? In eye movement?
7. Which cranial nerves transmit impulses that result in hearing? In taste sensations?
8. What pathways are found in the somatic motor nervous system?
9. Describe what happens when the fifth cranial nerve is compressed.
10. Describe the condition of shingles.



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Can you distinguish between the reflexes that cause cardiac muscle to react and those that cause skeletal muscles to react?
2. An adult has an extension of the great toe and the fanning of the other toes in response to stimulation of the outer margin of the sole of the foot. Why is this a concern, and where would the problem most likely be?
3. A single reflex can be classified in several ways. What example can you find that would show this? In what ways can this reflex be classified?
4. Can you predict the respiratory consequences of an injury that damaged the spinal cord between the third and fifth cervical segments? What specific mechanism would cause these consequences?

The Big Picture: Autonomic Nervous System and the Whole Body, 501

Case Study, 502

In Chapter 15, we explored the efferent (motor) pathways of the somatic nervous system (SNS) that regulates skeletal muscles, allowing us to survive by defending ourselves, getting food, or performing other essential tasks. This chapter continues the story by exploring the efferent pathways of the autonomic nervous system (ANS).

Autonomic regulation operates below the conscious level to control smooth and cardiac muscle, glands, and other tissues. Such regulation helps us maintain homeostasis of the internal environment and deal with threats to that stability.

OVERVIEW OF THE AUTONOMIC NERVOUS SYSTEM

Role of the Autonomic Nervous System

The **autonomic nervous system (ANS)** is a subdivision of the nervous system that regulates involuntary effectors (Figure 16-1). Because it controls involuntary effectors, we can think of the autonomic system as our system of subconscious regulation of body functions.

It is the ANS that carries efferent signals to the autonomic, or *visceral*, effectors—cardiac muscle, smooth muscle, glandular epithelia, and adipose and other tissues (Box 16-1). Some autonomic pathways connect to the skeletal muscles, which are ordinarily considered somatic effectors. In skeletal muscles, subconscious autonomic stimulation helps prevent fatigue during intense exercise—it does not directly control muscle contractions.

The major functions of the ANS are heartbeat regulation, smooth muscle contraction, glandular secretion, and metabolism regulation in ways that maintain homeostatic balance or respond to threats to that balance. Recall from the previous chapter that **autonomic (visceral) reflexes** can produce these effects over a visceral reflex pathway, which you can see illustrated as a simple reflex arc in Figure 16-1.

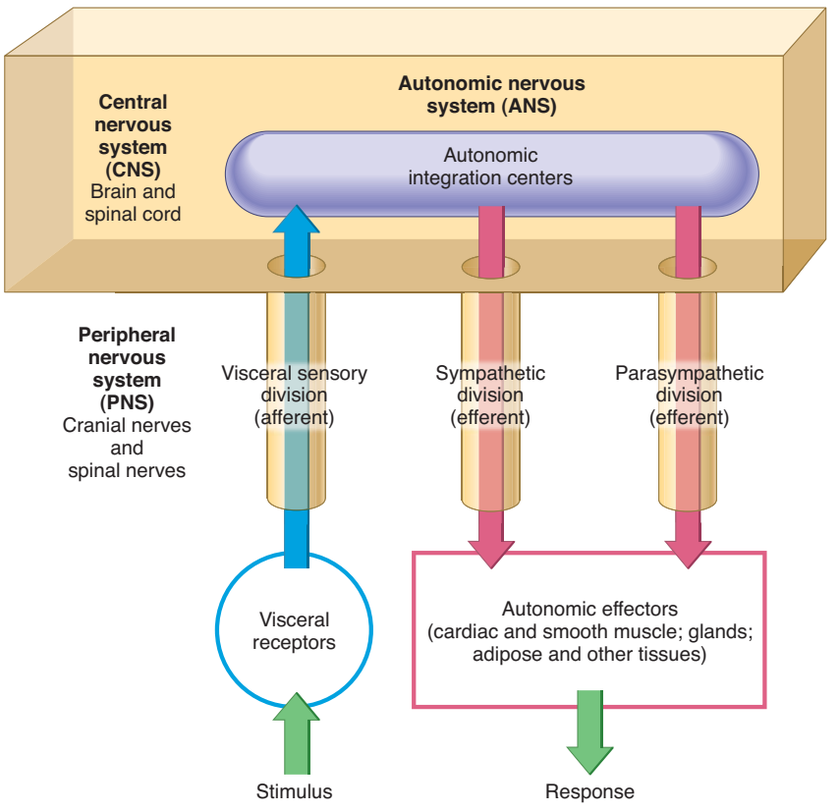

FIGURE 16-1

Organization of the autonomic nervous system. Note the simple arc pattern to information flow in the diagram. Compare to Figure 13-2 on p. 392 to see how this part of the nervous system fits into the big picture of nervous regulation.

Box 16-1 | Autonomic Effector Tissues and Organs

Adipose tissue
Kidneys
Skeletal muscle*

*Skeletal muscle is primarily a somatic effector, but sympathetic fibers help regulate contractility of skeletal muscle during intense exercise to avoid fatigue.

Divisions of the Autonomic Nervous System

Although the ANS also includes sensory (afferent) pathways that provide the feedback necessary to regulate effectors, we will emphasize the motor (efferent) pathways in this chapter. Sensory functions as a whole are discussed in the next chapter.

The ANS has two efferent divisions: the **sympathetic division** and the **parasympathetic division.** The sympathetic division consists of neural pathways that are separate from the parasympathetic pathways.

As you can see in Figure 16-2, however, even though the two divisions follow separate pathways, many autonomic effectors are *dually innervated.* That is, many autonomic effectors receive input from both sympathetic and parasympathetic pathways.

In dually innervated effectors, the effects of the two systems are often antagonistic: one inhibits the effector and the other stimulates the effector. This is similar to the antagonistic effects of an accelerator and brake in a vehicle. The opposing influences allow a dually innervated effector to be controlled with remarkable precision. Such antagonism also allows a dually innervated effector to participate in timed events, such as the sexual response, in which effectors must be stimulated and then rapidly inhibited (or vice versa) in a specific timed sequence.

Some autonomic effectors are *singly innervated*, receiving input from only the sympathetic division.

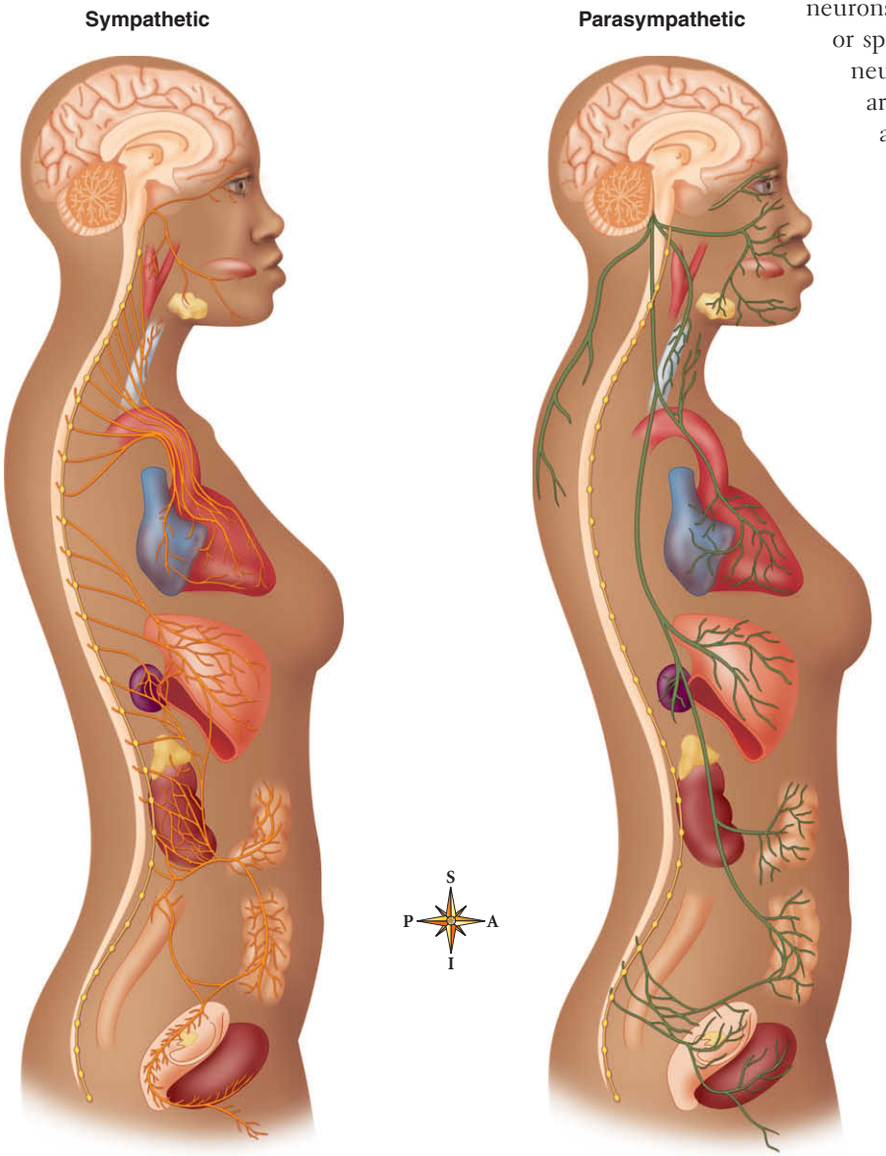

FIGURE 16–2

Divisions of the autonomic nervous system. Note that although the sympathetic pathways are separate from the parasympathetic pathways, most autonomic effectors are innervated by both pathways.

STRUCTURE OF THE AUTONOMIC NERVOUS SYSTEM

Basic Plan of Autonomic Pathways

Each efferent autonomic pathway, whether sympathetic or parasympathetic, is made up of autonomic nerves, ganglia, and plexuses. These structures, in turn, are made up of efferent autonomic neurons. They conduct impulses away from the brainstem or spinal cord to autonomic effectors. As with all efferent neurons, efferent autonomic neurons function in reflex arcs. Thus as with somatic motor regulation, efferent autonomic regulation ultimately depends on feedback from the sensory pathways.

A relay of two autonomic neurons conducts information from the central nervous system (CNS) to the autonomic effectors. The first is called a **preganglionic neuron**—an awkward name but a descriptive one. Preganglionic neurons conduct impulses from the brainstem or spinal cord to an autonomic **ganglion,** locating them *before* the ganglion—thus *pre*ganglionic. Within an autonomic ganglion, the preganglionic neuron synapses with a second efferent neuron. Because this second neuron conducts impulses away from the ganglion and to the effector, it is called the **postganglionic neuron.**

As you can see in Figure 16-3, A, this plan fundamentally differs from the efferent pathways of the somatic motor nervous system. Conduction to somatic effectors requires only one efferent neuron, the somatic motor neuron that originates in the anterior gray horn of the spinal cord. Conduction to autonomic effectors, however, requires a sequence of two efferent neurons from the CNS to the effector. Essential features of the somatic motor pathways and autonomic efferent pathways are further compared and contrasted in Table 16-1.

Structure of the Sympathetic Pathways

SYMPATHETIC PREGANGLIONIC NEURONS

Sympathetic preganglionic neurons begin within the spinal cord. Specifically, they have their dendrites and cell bodies within the lateral gray horns of the thoracic and lumbar segments of the spinal cord (see Figure 16-3, A). For this reason, the sympathetic division has also been called the *thoracolumbar division.*

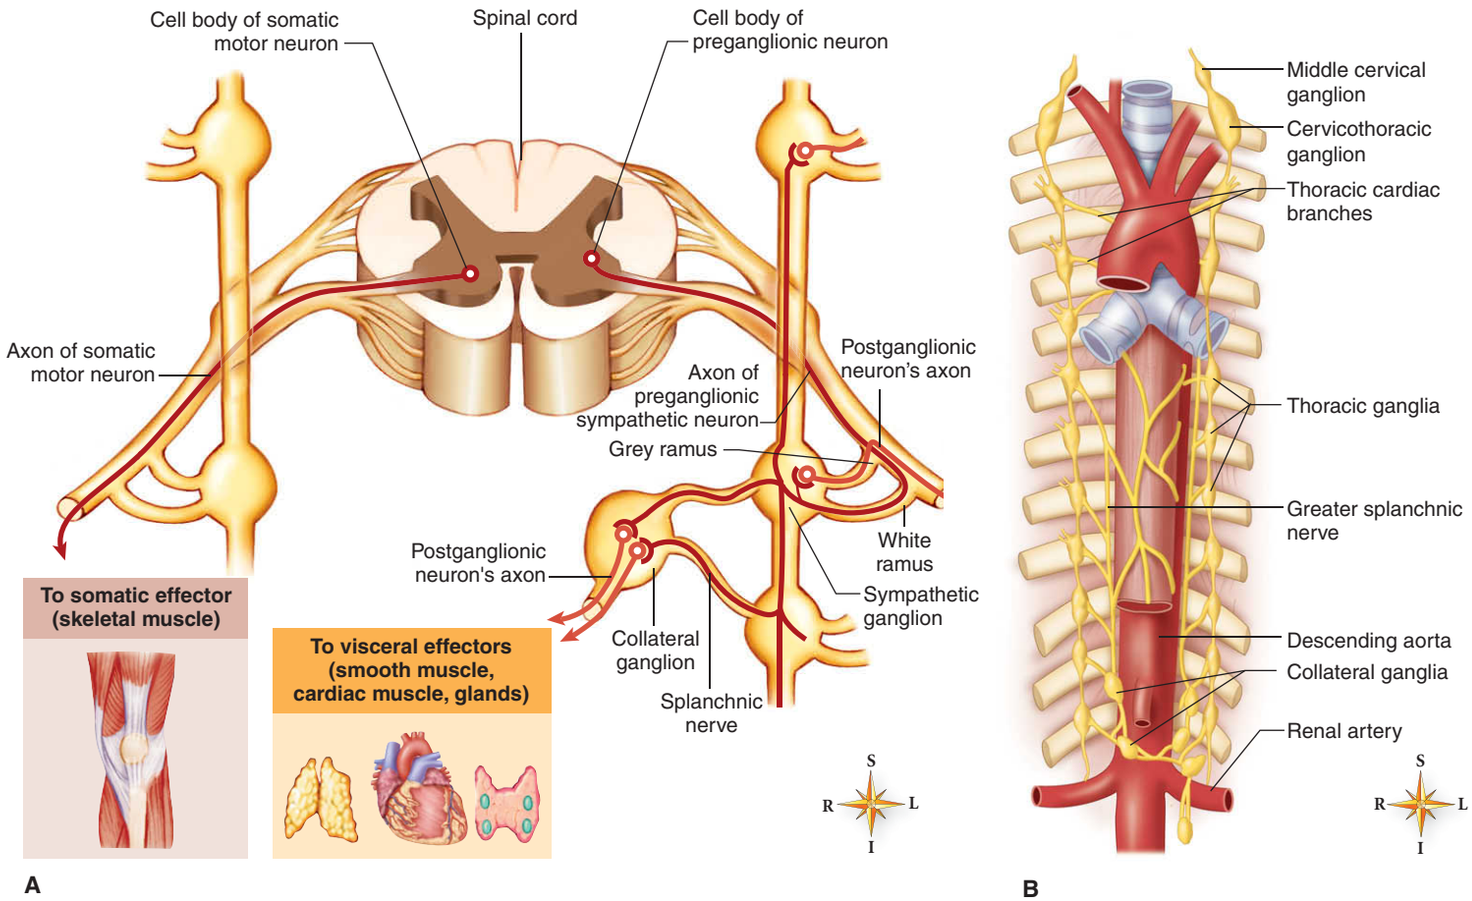

FIGURE 16-3

Diagram of autonomic conduction paths. A, The left side of the diagram shows that one somatic motor neuron conducts impulses all the way from the spinal cord to a somatic effector. Conduction from the spinal cord to any visceral effector, however, requires a relay of at least two autonomic motor neurons—a preganglionic and a postganglionic neuron, shown on the right side of the diagram. **B,** Sketch showing a portion of the left and right sympathetic chain or trunk.

Most of the ganglia of the sympathetic division lie along either side of the anterior surface of the vertebral column (see Figure 14-3, p. 423). Both gray rami and white rami are sympathetic rami. Sympathetic axon collaterals bridge the gap between adjacent ganglia that lie on the same side of the vertebral column. This arrangement forms a structure that resembles a chain of beads (see Figure 16-3, *B*). Thus the linked ganglia are often referred to as the *sympathetic chain ganglia*, or the **sympathetic trunk.**

Each chain runs from the second cervical vertebra in the neck all the way down to the level of the coccyx. There are usually 22 sympathetic chain ganglia on each side of the vertebral column: three cervical, eleven thoracic, four lumbar, and four sacral. Axons of sympathetic preganglionic neurons leave the cord by

TABLE 16-1 Comparison of Somatic Motor and Autonomic Pathways

FEATURE	SOMATIC MOTOR PATHWAYS	AUTONOMIC EFFERENT PATHWAYS
Direction of information flow	Efferent	Efferent
Number of neurons between CNS and effector	One (somatic motor neuron)	Two (preganglionic and postganglionic)
Myelin sheath present	Yes	Preganglionic: yes Postganglionic: no
Location of peripheral fibers	Most cranial nerves and all spinal nerves	Most cranial nerves and all spinal nerves
Effector innervated	Skeletal muscle (voluntary)	Smooth and cardiac muscle, glands, and adipose and other tissues (involuntary)
Neurotransmitter	Acetylcholine	Acetylcholine or norepinephrine

CNS, Central nervous system.

way of the ventral roots of the thoracic and first four lumbar spinal nerves. From there, they split away from other spinal nerve fibers by means of a small branch called the *white ramus*. The white ramus gets its name from the fact that most of the sympathetic preganglionic fibers within it are myelinated axons. Note in Figure 16-3 that the sympathetic preganglionic axon extends through the white ramus to a sympathetic chain ganglion.

If we trace the axon inside the sympathetic chain ganglion, we see that the preganglionic fiber may branch along any of three paths:

1. It can synapse with a sympathetic postganglionic neuron.
2. It can send ascending or descending branches through the sympathetic trunk to synapse with postganglionic neurons in other chain ganglia.
3. It can pass through one or more ganglia without synapsing.

Preganglionic neurons that pass through chain ganglia without synapsing continue on through **splanchnic nerves** to other sympathetic ganglia (see Figures 16-3 and 16-4). These **collateral ganglia,** or *prevertebral ganglia*, are pairs of sympathetic ganglia located a short distance from the spinal cord. The collateral ganglia are named for nearby blood vessels. For example, the *celiac ganglion* (also called the *solar plexus*) is a large ganglion that lies next to the celiac artery just below the diaphragm. Other examples include the *superior mesenteric ganglion* and the *inferior mesenteric ganglion*, each located close to the beginning of an artery of the same name.

Some of the preganglionic fibers that enter the celiac ganglion do not synapse there but continue on to the central portion (medulla) of the *adrenal gland*. Within the adrenal medulla, they synapse with modified postganglionic neurons. These modified postganglionic cells are actually endocrine cells that release hormones (mostly epinephrine) into the bloodstream. These chemical messengers may reach the various sympathetic effectors, where they enhance and prolong the effects of sympathetic stimulation.

SYMPATHETIC POSTGANGLIONIC NEURONS

Most of the sympathetic postganglionic neurons have their dendrites and cell bodies in the sympathetic chain ganglia or collateral ganglia.

Some postganglionic axons return to a spinal nerve by way of a short branch called the *gray ramus*, so named because most postganglionic fibers are unmyelinated (see Figure 16-3). Once in the spinal nerve, the postganglionic fibers are distributed with other nerve fibers to the various sympathetic effectors. On the other hand, some postganglionic fibers are distributed to sympathetic effectors by way of separate autonomic nerves. The course of postganglionic fibers through these autonomic nerves is complex, involving the redistribution of fibers in autonomic plexuses before they reach their respective destinations.

In the sympathetic division, preganglionic neurons are relatively short, and postganglionic neurons are relatively long.

The axon of any one sympathetic preganglionic neuron synapses with many postganglionic neurons, and these frequently terminate in widely separated organs. This anatomical fact partially explains a well-known physiological principle—sympathetic responses are usually widespread, involving many organs—not just one.

| QUICK CHECK |

1. Do autonomic pathways follow the principle of final common path?
2. Why is the sympathetic division of the ANS also known as the *thoracolumbar division?*
3. Describe the path generally taken by an impulse along a sympathetic pathway from the CNS to an autonomic effector.

Structure of the Parasympathetic Pathways

PARASYMPATHETIC PREGANGLIONIC NEURONS

Parasympathetic preganglionic neurons have their cell bodies in nuclei in the brainstem or in the lateral gray columns of the sacral cord. For this reason, the parasympathetic division has also been called the *craniosacral division*.

Axons of parasympathetic preganglionic neurons are contained in cranial nerves III, VII, IX, and X and in some pelvic nerves. They extend a considerable distance before synapsing with postganglionic neurons. For example, at least 75% of all parasympathetic preganglionic fibers travel in the *vagus nerve* (X) for a distance of 30 cm (1 foot) or more before synapsing with postganglionic fibers in **terminal ganglia** near effectors in the chest and abdomen (Figure 16-4 and Table 16-2).

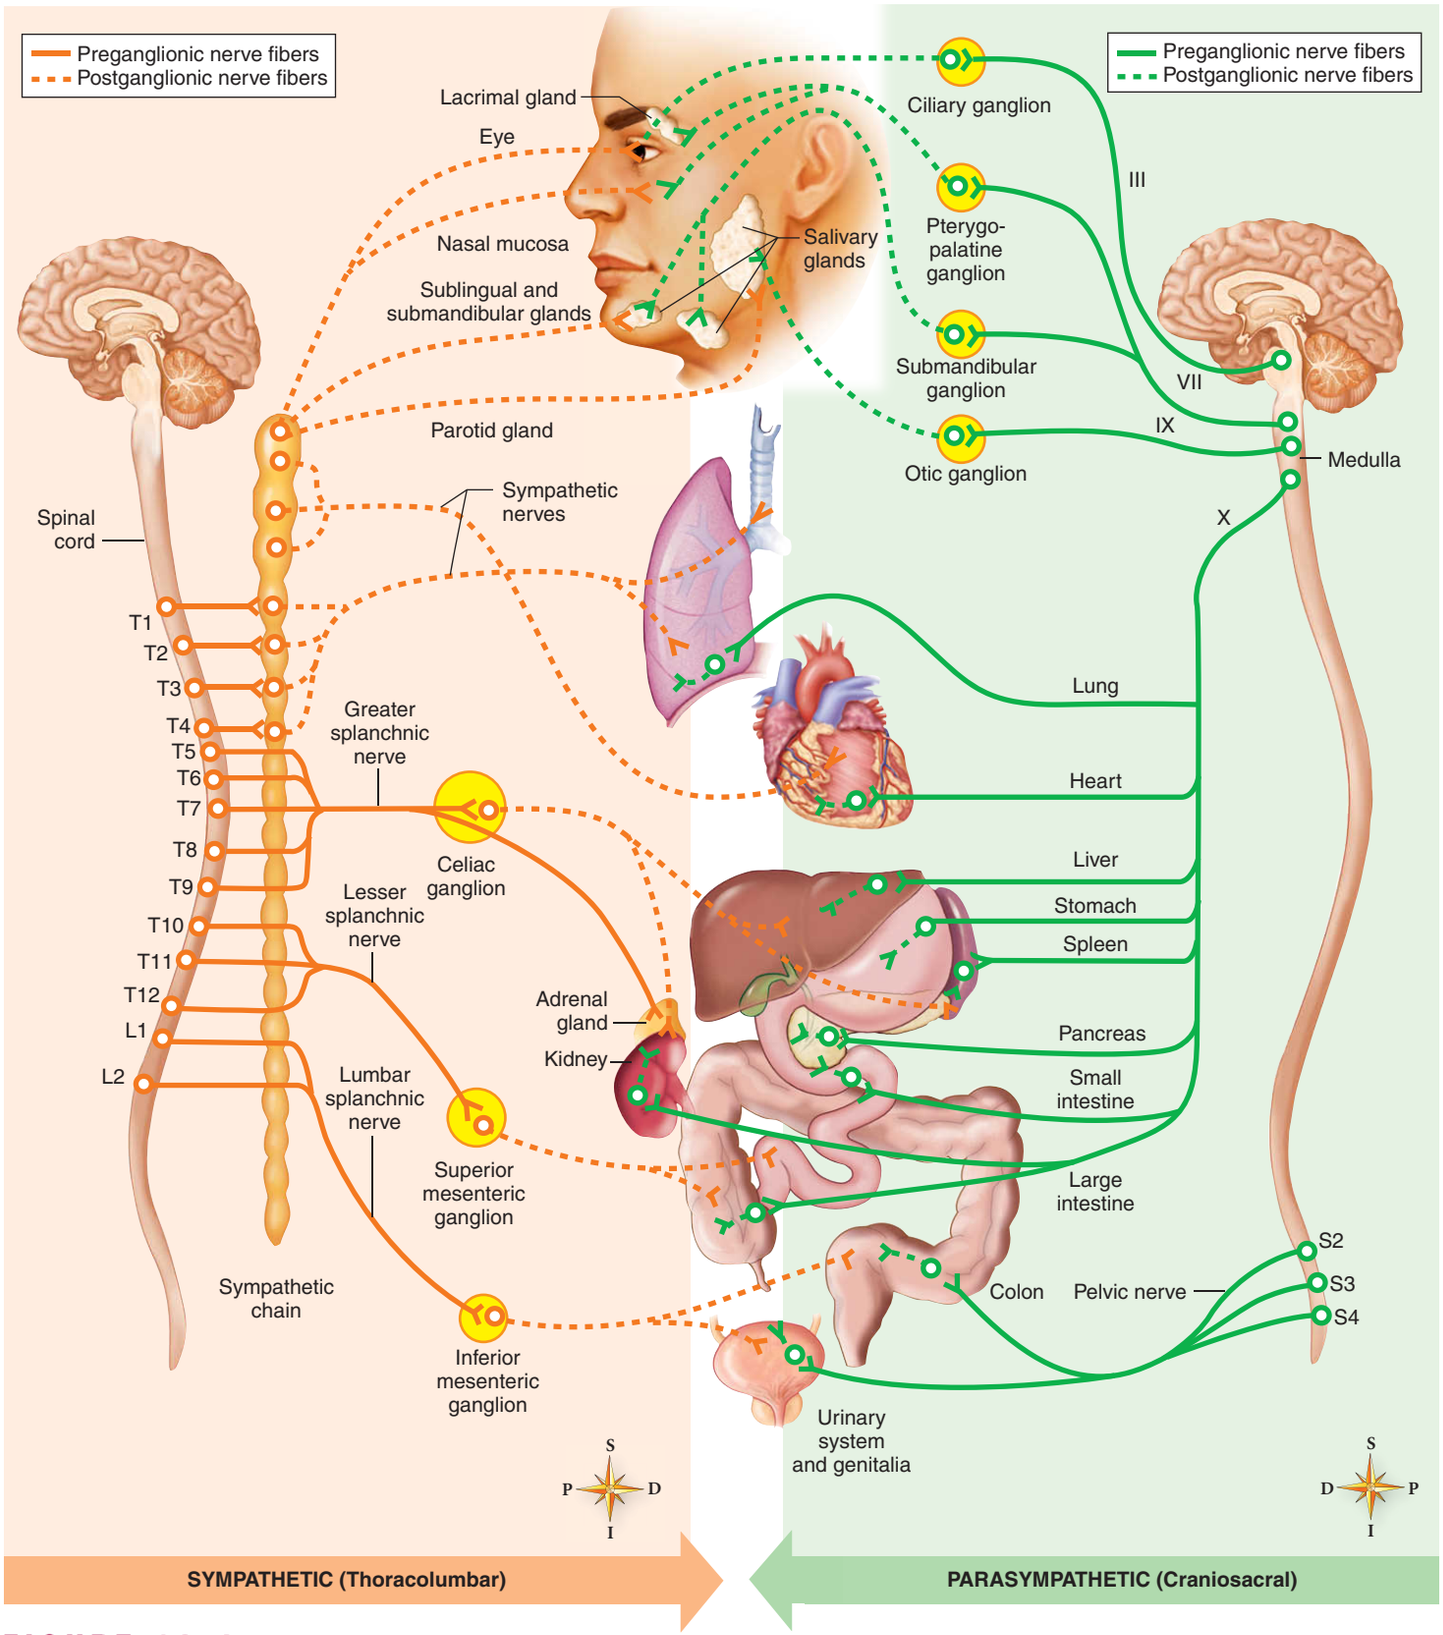

FIGURE 16-4

Major autonomic pathways.

TABLE 16-2 Comparison of Structural Features of the Sympathetic and Parasympathetic Pathways

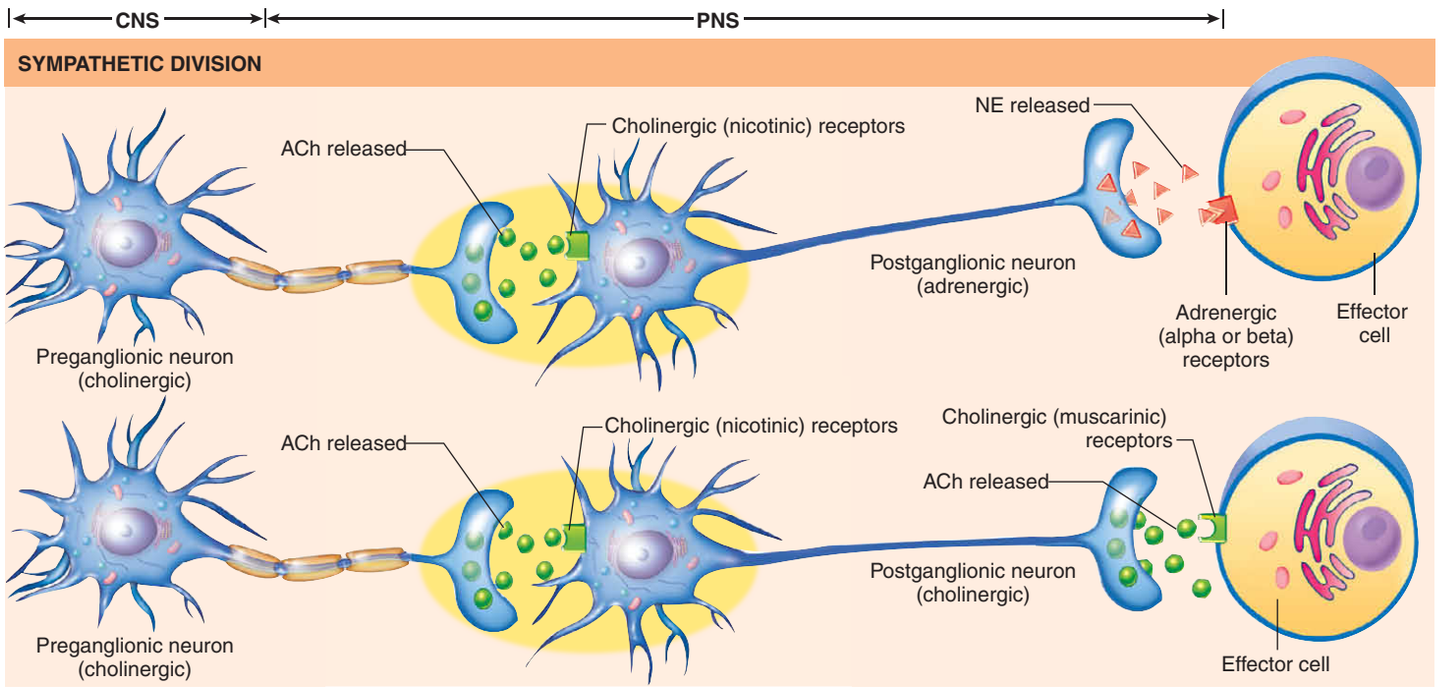
NEURONS	SYMPATHETIC PATHWAYS	PARASYMPATHETIC PATHWAYS
Preganglionic Neurons		
Dendrites and cell bodies	In lateral gray columns of thoracic and first two or three lumbar segments of spinal cord	In nuclei of brainstem and in lateral gray columns of sacral segments of cord
Axons	In anterior roots of spinal nerves to spinal nerves (thoracic and first four lumbar), to and through white rami to terminate in sympathetic ganglia at various levels or to extend through sympathetic ganglia, to and through splanchnic nerves to terminate in collateral ganglia	From brainstem nuclei through cranial nerve III to ciliary ganglion From nuclei in pons through cranial nerve VII to sphenopalatine or submaxillary ganglion From nuclei in medulla through cranial nerve IX to otic ganglion or through cranial nerves X and XI to cardiac and celiac ganglia, respectively
Distribution	Short fibers from CNS to ganglion	Long fibers from CNS to ganglion
Neurotransmitter	Acetylcholine	Acetylcholine
Ganglia	Sympathetic chain ganglia (22 pairs); collateral ganglia (celiac, superior, inferior mesenteric)	Terminal ganglia (in or near effector)
Postganglionic Neurons		
Dendrites and cell bodies	In sympathetic and collateral ganglia	In parasympathetic ganglia (e.g., ciliary, sphenopalatine, submaxillary, otic, cardiac, celiac) located in or near visceral effector organs
Receptors	Cholinergic (nicotinic)	Cholinergic (nicotinic)
Axons	In autonomic nerves and plexuses that innervate thoracic and abdominal viscera and blood vessels in these cavities In gray rami to spinal nerves, to smooth muscle of skin, blood vessels, and hair follicles, and to sweat glands	In short nerves to various visceral effector organs
Distribution	Long fibers from ganglion to widespread effectors	Short fibers from ganglion to single effector
Neurotransmitter	Norepinephrine (many); acetylcholine (few)	Acetylcholine

CNS, Central nervous system.

PARASYMPATHETIC POSTGANGLIONIC NEURONS

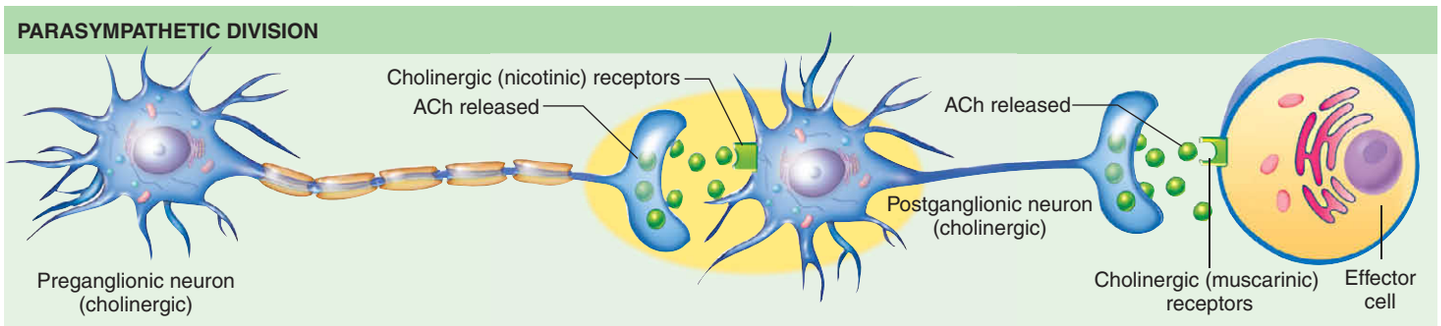
Parasympathetic postganglionic neurons have their dendrites and cell bodies in parasympathetic ganglia. Unlike sympathetic ganglia that lie near the spinal column, parasympathetic ganglia lie near or embedded in autonomic effectors.

For example, note the ciliary ganglion in Figure 16-4. This and the other ganglia shown near it are parasympathetic ganglia located in the skull.



In a parasympathetic ganglion, preganglionic axons synapse with postganglionic neurons that send their short axons into the nearby autonomic effector. A parasympathetic preganglionic neuron therefore usually synapses with postganglionic neurons to a single effector. For this reason, parasympathetic stimulation frequently involves response by only one organ. Sympathetic stimulation, on the other hand, usually evokes responses by numerous organs.

Autonomic Neurotransmitters and Receptors



Axon terminals of autonomic neurons release either of two neurotransmitters: **norepinephrine** (**NE**) or **acetylcholine** (**ACh**). Axons that release norepinephrine are known as *adrenergic fibers.* Axons that release acetylcholine are called *cholinergic fibers.* Autonomic cholinergic fibers are the axons of preganglionic sympathetic neurons and of both preganglionic and postganglionic parasympathetic neurons. This leaves the axons of postganglionic sympathetic neurons as the only autonomic adrenergic fibers, and as you can see in Figure 16-5, not all of these are adrenergic. Sympathetic postganglionic axons to sweat glands and some blood vessels are cholinergic fibers.

NOREPINEPHRINE AND ITS RECEPTORS

Norepinephrine affects visceral effectors by first binding to *adrenergic receptors* in their plasma membranes. The adrenergic

A

B

FIGURE 16-5

Locations of neurotransmitters and receptors of the autonomic nervous system. In all pathways, preganglionic fibers are cholinergic, secreting acetylcholine *(ACh),* which stimulates nicotinic receptors in the postganglionic neuron. Most sympathetic postganglionic fibers are adrenergic **(A),** secreting norepinephrine *(NE),* thus stimulating alpha or beta adrenergic receptors. A few sympathetic postganglionic fibers are cholinergic, stimulating muscarinic receptors in effector cells **(B).** All parasympathetic postganglionic fibers are cholinergic **(C),** stimulating muscarinic receptors in effector cells.

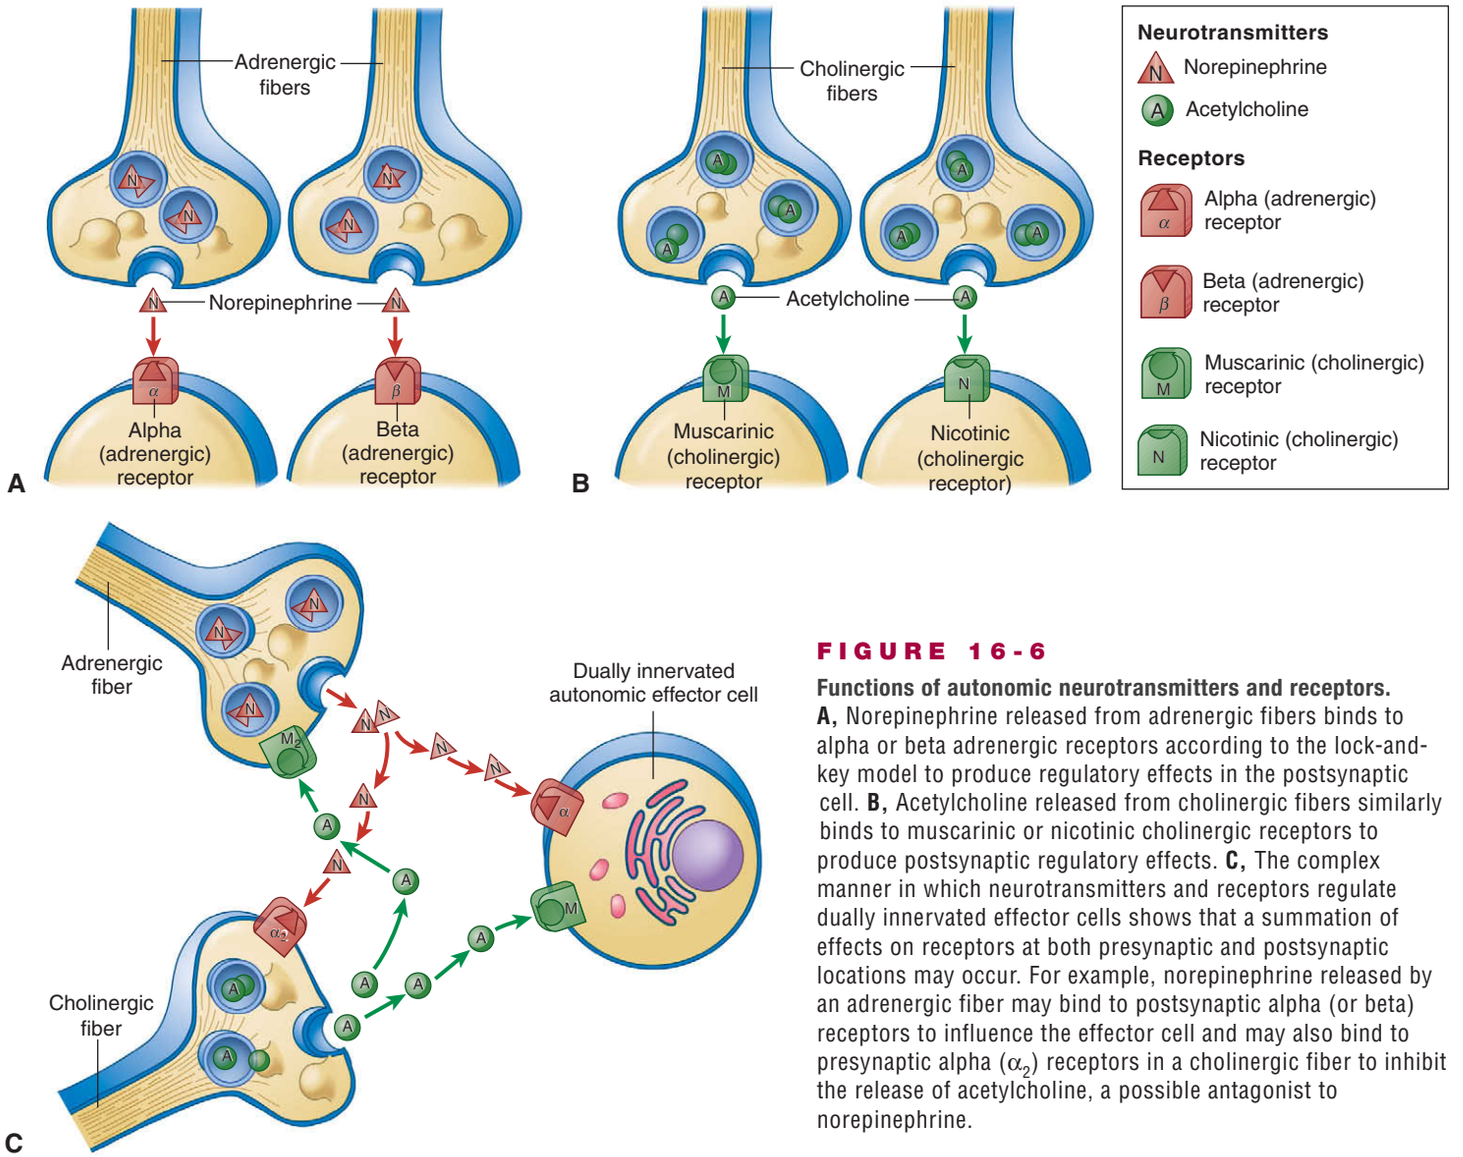


FIGURE 16-6

Functions of autonomic neurotransmitters and receptors. **A,** Norepinephrine released from adrenergic fibers binds to alpha or beta adrenergic receptors according to the lock-and-key model to produce regulatory effects in the postsynaptic cell. **B,** Acetylcholine released from cholinergic fibers similarly binds to muscarinic or nicotinic cholinergic receptors to produce postsynaptic regulatory effects. **C,** The complex manner in which neurotransmitters and receptors regulate dually innervated effector cells shows that a summation of effects on receptors at both presynaptic and postsynaptic locations may occur. For example, norepinephrine released by an adrenergic fiber may bind to postsynaptic alpha (or beta) receptors to influence the effector cell and may also bind to presynaptic alpha (α_2) receptors in a cholinergic fiber to inhibit the release of acetylcholine, a possible antagonist to norepinephrine.

receptors are of two main types, one named **alpha (α) receptors** and the other named **beta (β) receptors** (Figure 16-6, *A*). Different subtypes of alpha and beta receptors, such as alpha-1 (α_1), alpha-2 (α_2), beta-1 (β_1), and beta-2 (β_2), exist among cells that have adrenergic receptors.

The binding of norepinephrine to alpha receptors in the smooth muscle of blood vessels has a stimulating effect on the muscle that causes the vessel to constrict. The binding of norepinephrine to beta receptors in smooth muscle of a different blood vessel produces opposite effects. It inhibits the muscle, causing the vessel to dilate. But the binding of norepinephrine to beta receptors in cardiac muscle has a stimulating effect that results in a faster and stronger heartbeat.

Epinephrine released by the sympathetic postganglionic cells in the adrenal medulla also stimulates the adrenergic receptors, enhancing and prolonging the effects of sympathetic stimulation. Because epinephrine has a greater effect on some beta receptors than norepinephrine, effectors with a large proportion of these beta receptors are more sensitive to epinephrine.

All these facts point to an important principle about nervous regulation: the effect of a neurotransmitter on any postsynaptic cell is determined by the characteristics of the receptor and not by the neurotransmitter itself. This principle has been given due consideration in development of therapies that affect autonomic functions (Box 16-2).

The actions of norepinephrine and epinephrine are terminated in two ways. Most of the neurotransmitter molecules are taken back up by the synaptic knobs of postganglionic neurons, where they are broken down by the enzyme *monoamine oxidase (MAO)*. The remaining neurotransmitter molecules are eventually broken down by another enzyme, *catechol-O-methyl transferase (COMT)*. Both of these mechanisms are very slow compared with the rapid deactivation of acetylcholine by acetylcholinesterase. This fact partly explains why adrenergic effects often linger for some time after stimulation has ceased.

Box 16-2 | HEALTH matters

Beta Blockers

Drugs that bind to beta receptors, and thus block the binding of norepinephrine and epinephrine, are informally called **beta blockers.** Propranolol (Inderal) is one of nearly a dozen beta blockers used to treat irregular heartbeats and hypertension (high blood pressure). Beta blockers achieve their therapeutic effects by preventing the increased rate and strength of the heart's pumping action triggered by sympathetic stimulation. For patients who also have had a previous heart attack (myocardial infarction), these drugs possibly have the added benefit of preventing further attacks.

ACETYLCHOLINE AND ITS RECEPTORS

Acetylcholine binds to *cholinergic receptors.* The two main types of cholinergic receptors are **nicotinic (N) receptors** and **muscarinic (M) receptors** (Figure 16-6, *B*). Nicotinic receptors derive their name from the fact that they were first discovered when nicotine, a drug, was shown to bind to them. Muscarinic receptors are named for the fact that their discovery came about when it was shown that muscarine, a toxin from mushrooms, binds to them. Like the adrenergic receptors, cholinergic receptors have subtypes such as nicotinic-1 (N_1), nicotinic-2 (N_2), muscarinic-1 (M_1), muscarinic-2 (M_2), and muscarinic-3 (M_3).

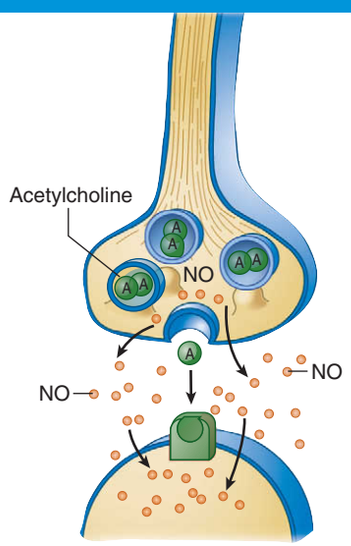
In the ganglia of both autonomic divisions, acetylcholine binds to nicotinic receptors in the membranes of postganglionic cells. Acetylcholine, released by all parasympathetic postganglionic cells and the few sympathetic postganglionic cells that are cholinergic, binds to muscarinic receptors in the membranes of effector cells. As mentioned previously, the action of acetylcholine is quickly terminated by its being hydrolyzed by the enzyme *acetylcholinesterase.*

Figure 16-6, *C,* shows the complex manner in which neurotransmitters and receptors may function at a synapse with a dually innervated autonomic effector cell. Norepinephrine released from a sympathetic adrenergic fiber binds to alpha (or beta) receptors of the effector cell, producing adrenergic (sympathetic) effects. As the figure also shows, norepinephrine may also bind to alpha (α_2) receptors in the presynaptic membrane of a nearby cholinergic (parasympathetic) fiber. This inhibits that fiber's release of the antagonistic neurotransmitter, acetylcholine. Likewise, acetylcholine released from cholinergic fibers may bind to muscarinic (M_2) receptors in the presynaptic membranes of nearby adrenergic fiber. This inhibits the release of acetylcholine's antagonist, norepinephrine.

Autonomic pathways also use additional neurotransmitters to supplement norepinephrine and acetylcholine, further enhancing the complexity of autonomic regulation (Box 16-3).

Because of this complexity of function, the effector cell can be controlled with great precision by balancing the effects of sympathetic and parasympathetic stimulation in various ways.

| QUICK CHECK |



4. Describe the pathway taken by an impulse traveling along a parasympathetic pathway.
5. What is the difference between a cholinergic fiber and an adrenergic fiber? Between a cholinergic receptor and an adrenergic receptor?
6. Name the two major types of cholinergic receptors and the two major types of adrenergic receptors.

Box 16-3 | FYI

Nonadrenergic-Noncholinergic Transmission

Research clearly shows that many neurotransmitters besides norepinephrine and acetylcholine bind to autonomic receptors. Thus a concept of **nonadrenergic-noncholinergic (NANC) transmission** has evolved. Substances that research shows to be involved in NANC transmission across peripheral autonomic synapses include nitric oxide (NO), gamma-aminobutyric acid (GABA), adenosine triphosphate (ATP), neuropeptide Y, vasoactive intestinal peptide (VIP), luteinizing hormone–releasing hormone (LHRH), and others. A theory of autonomic transmission called **co-transmission** states that all or most postganglionic fibers release either norepinephrine or acetylcholine along with NANC transmitters or modulators and that each substance combines with postsynaptic or presynaptic receptors to produce regulatory effects.

Discoveries in autonomic co-transmission have led to a number of therapeutic breakthroughs. One of the better known of these discoveries is the drug sildenafil citrate (Viagra) used to treat **erectile dysfunction** (ED) in males. During the male sexual response, co-transmission of NO in the parasympathetic nerves helps relax smooth muscles in the blood vessels—thus increasing blood flow to the penis. This drug enhances that effect by reducing the natural breakdown of NO in blood vessels of the penis.

Nonadrenergic-noncholinergic (NANC) transmission. In this example, nitric oxide *(NO)* is released from a cholinergic fiber along with acetylcholine *(A).*

FUNCTIONS OF THE AUTONOMIC NERVOUS SYSTEM

Overview of Autonomic Function

The ANS as a whole functions to regulate autonomic effectors in ways that tend to maintain or quickly restore homeostasis. Both sympathetic and parasympathetic divisions are *tonically active*. That is, they continually conduct impulses to autonomic effectors. They often exert opposite, or antagonistic, influences on them. We can call this concept the *principle of autonomic antagonism*.

If sympathetic impulses tend to stimulate an effector, parasympathetic impulses tend to inhibit it. Doubly innervated effectors continually receive both sympathetic and parasympathetic impulses. Summation of the two opposing influences determines the dominating or controlling effect. For example, continual sympathetic impulses to the heart tend to accelerate the heart rate whereas continual parasympathetic impulses tend to slow it. The actual heart rate is determined by whichever influence dominates. To find other examples of autonomic antagonism, examine Table 16-3.

TABLE 16-3 Autonomic Functions

AUTONOMIC EFFECTOR	EFFECT OF SYMPATHETIC STIMULATION (neurotransmitter: norepinephrine unless otherwise stated)	EFFECT OF PARASYMPATHETIC STIMULATION (neurotransmitter: acetylcholine)
Cardiac Muscle	Increased rate and strength of contraction (beta receptors)	Decreased rate and strength of contraction
Smooth Muscle of Blood Vessels		
Skin blood vessels	Constriction (alpha receptors)	No effect
Skeletal muscle blood vessels	Dilation (beta receptors)	No effect
Coronary blood vessels	Constriction (alpha receptors) Dilation (beta receptors)	Dilation
Abdominal blood vessels	Constriction (alpha receptors)	No effect
Blood vessels of external genitalia	Constriction (alpha receptors)	Dilation of blood vessels causing erection
Smooth Muscle of Hollow Organs and Sphincters		
Bronchioles	Relaxation (dilation)	Constriction
Digestive tract, except sphincters	Decreased peristalsis	Increased peristalsis
Sphincters of digestive tract	Contraction	Relaxation
Urinary bladder	Relaxation	Contraction
Urinary sphincters	Contraction	Relaxation
Reproductive ducts	Constriction	Relaxation
Eye		
Iris	Contraction of radial muscle; dilated pupil	Contraction of circular muscle; constricted pupil
Ciliary	Relaxation; accommodates for far vision	Contraction; accommodates for near vision
Hairs (arrector pili muscles)	Contraction produces goose pimples, or piloerection (alpha receptors)	No effect
Glands		
Sweat	Increased sweat (neurotransmitter, acetylcholine)	No effect
Lacrimal	No effect	Increased secretion of tears
Digestive (salivary, gastric, etc.)	Decreased secretion of saliva; not known for others	Increased secretion of saliva
Pancreas, including islets	Decreased secretion	Increased secretion of pancreatic juice and insulin
Liver	Increased glycogenolysis (beta receptors); increased blood sugar level	No effect
Adrenal medulla*	Increased epinephrine secretion	No effect
Adipose	Increased lipolysis	No effect
Skeletal muscle*	During intense exercise, regulates contractility to prevent fatigue (beta receptors)	No effect

*Sympathetic preganglionic axons terminate in contact with secreting cells of the adrenal medulla. Thus the adrenal medulla functions, to quote someone's descriptive phrase, as a "giant sympathetic postganglionic neuron."
**Skeletal muscle is primarily a somatic effector but during intense exercise, subconscious autonomic stimulation also occurs.

The ANS does not function autonomously as its name suggests. It is continually influenced by impulses from the so-called autonomic centers. These are clusters of neurons located at various levels in the brain whose axons conduct impulses directly or indirectly to autonomic preganglionic neurons. Autonomic centers function as a hierarchy in their control of the ANS (Figure 16-7). Highest ranking in the hierarchy are the autonomic centers in the cerebral cortex, for example, in the frontal lobe and limbic system (structures near the medial surface of the cerebrum that form a border around the corpus callosum). Neurons in these centers send impulses to other autonomic centers in the brain, notably in the hypothalamus. Then neurons in the hypothalamus send either stimulating or inhibiting impulses to parasympathetic and sympathetic preganglionic neurons located in the lower autonomic centers of the brainstem and cord.

You may be wondering why the name *autonomic system* was ever chosen if the system is really not autonomous. Originally the term seemed appropriate. The autonomic system seemed to be self-regulating and independent of the rest of the nervous system. Common observations furnished abundant evidence of its independence from cerebral control, from direct control by the will, that is. Later, however, even this was found to be not entirely true. Some rare and startling exceptions were discovered. For example, a man in a brightly lighted amphitheater can change the size of his pupils from small, constricted dots (normal response to bright lights) to widely dilated circles. It is also possible to will the smooth muscle of the hairs on the arms to contract, producing gooseflesh. Box 16-4 discusses how this knowledge can be used in therapy.

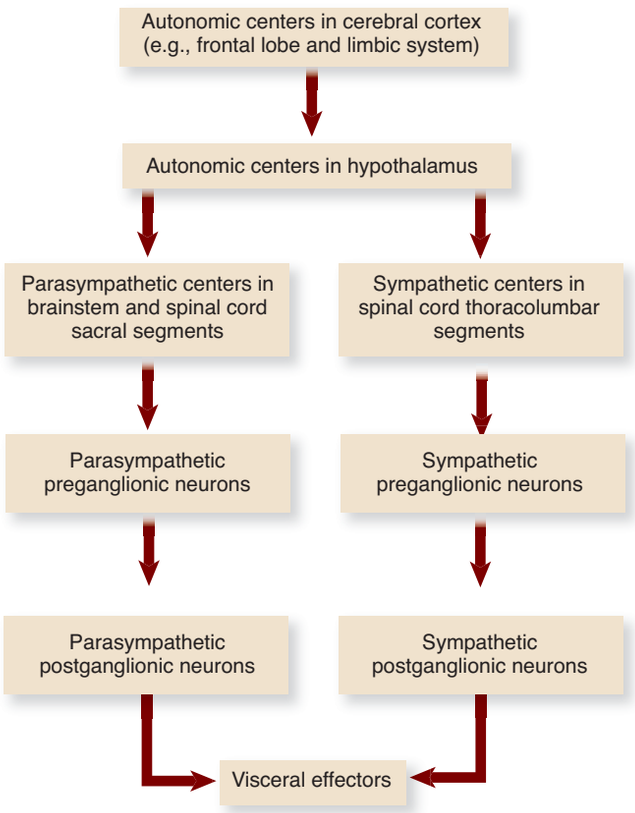


FIGURE 16-7

Central nervous system hierarchy that regulates autonomic functions.

Functions of the Sympathetic Division

Under ordinary, resting conditions the sympathetic division can act to maintain the normal functioning of doubly innervated autonomic effectors. It does this by opposing the effects of parasympathetic impulses to these structures. For example, by counteracting parasympathetic impulses that tend to slow the heart and weaken its beat, sympathetic impulses function to maintain the heartbeat's normal rate and strength.

The sympathetic division also serves another important function under usual conditions. Because only sympathetic fibers innervate the smooth muscle in blood vessel walls, sympathetic impulses function to maintain the normal tone of this muscle. By so doing, the sympathetic system plays a crucial role in maintaining blood pressure under usual conditions.

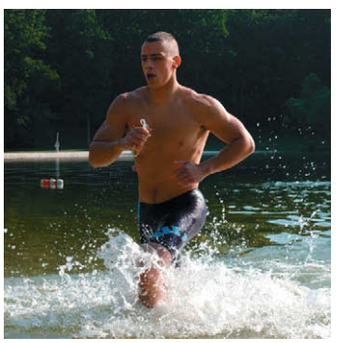
The major function of the sympathetic division, however, is that it serves as an "emergency" system. When we perceive that the homeostasis of the body might be threatened—that is, when we are under physical or psychological stress—outgoing sympathetic signals increase greatly. In fact, one of the very first steps in the body's complex defense mechanism against stress is a sudden and marked increase in sympathetic activity. This brings about a group of responses that all go on at the same time. Together they make the body ready to expend maximum energy and thus to engage in the maximum muscular exertion needed to deal with the perceived threat—as, for example, in running or fighting. Walter B. Cannon coined the descriptive and now famous phrase the "**fight-or-flight" reaction** as his name for this group of sympathetic responses.

Box 16-4 | FYI

Biofeedback

We now know that individuals can learn to control specific autonomic effectors if two conditions are fulfilled. First, they must be informed that they are achieving the desired response, and second, they must be rewarded for it. Various kinds of **biofeedback** instruments have been developed to provide these conditions. For example, a biofeedback instrument that detects slight temperature changes has been used with patients who suffer from migraine headaches. (Migraine headaches initially involve distention of blood vessels in the head.) The instrument is attached to the hands and emits a high sound each time the blood vessels in the hand dilate. The reward for these patients is a lessening of the migraine pain—presumably because of the shunting of blood away from the head to the hands.

TABLE 16-4 Summary of the Sympathetic "Fight-or-Flight" Reaction



RESPONSE	ROLE IN PROMOTING ENERGY USE BY SKELETAL MUSCLES
Increased heart rate	Increased rate of blood flow, thus increased delivery of oxygen and glucose to skeletal muscles
Increased strength of cardiac muscle contraction	Increased rate of blood flow, thus increased delivery of oxygen and glucose to skeletal muscles
Dilation of coronary vessels of the heart	Increased delivery of oxygen and nutrients to cardiac muscle to sustain increased rate and strength of heart contractions
Dilation of blood vessels in skeletal muscles	Increased delivery of oxygen and nutrients to skeletal muscles
Increased stimulation at neuromuscular junctions and increased ion pump activity in skeletal muscles	Increased availability of ACh at the neuromuscular junction and more efficient restoration of resting ion balance in muscle fibers both reduce fatigue in skeletal muscles
Constriction of blood vessels in digestive and other organs	Shunting of blood to skeletal muscles to increase oxygen and glucose delivery
Contraction of spleen and other blood reservoirs	More blood discharged into general circulation, causing increased delivery of oxygen and glucose to skeletal muscles
Dilation of respiratory airways	Increased loading of oxygen into blood
Increased rate and depth of breathing	Increased loading of oxygen into blood (indirect effect)
Increased sweating	Increased dissipation of heat generated by skeletal muscle activity
Increased conversion of glycogen into glucose	Increased amount of glucose available to skeletal muscles
Increased breakdown of stored fats	Increased amount of fatty acids and glycerol available to skeletal muscles

Read Table 16-4 to find many of the fight-or-flight physiological changes. Some particularly important changes for maximum energy expenditure by skeletal muscles are faster, stronger heartbeat, dilated blood vessels in skeletal muscles, and dilated bronchi. Stimulation of glycogenolysis (breakdown of stored glycogen) and lipolysis (breakdown of stored fat) increases available blood levels of glucose, fatty acids, and related nutrients that can be used for energy in muscle cells. Stimulation of the medulla of each adrenal gland triggers its secretion of epinephrine and some norepinephrine. These hormones reinforce and prolong effects of the norepinephrine released by sympathetic postganglionic fibers. The sympathetic system can also directly affect skeletal muscle function (Box 16-5).

The fight-or-flight reaction is a normal response in times of stress. Without such a response, we might not be able to resist or retreat from something that actually threatens our well-being. However, chronic exposure to stress can lead to dysfunction of sympathetic effectors—and perhaps even to the dysfunction of the ANS itself. Some current concepts regarding the effects of chronic stress are discussed in Chapter 25.

Box 16-5 | SPORTS and FITNESS

Sympathetic Stimulation of Skeletal Muscle

We learned in the previous chapter that skeletal muscles are somatic effectors that respond to acetylcholine from somatic motor neurons by contracting. We learned that such motor control is ordinarily conscious, voluntary control. However, there are sympathetic adrenergic fibers that extend into every skeletal muscle of the body.

For a long time we thought that the sole function of adrenergic fibers in skeletal muscle tissue was to innervate the arterioles and thus regulate blood flow during exercise or stress. Later we found beta receptors in skeletal muscle that also respond during exercise and stress. One adrenergic effect in skeletal muscle fibers is to speed up the sodium-potassium pumps that maintain the ion concentration gradients needed to produce action potentials. These pumps may fail to keep up with the barrage of action potentials during intense exercise and thus produce a temporary inability to contract efficiently—producing physiological fatigue (see Box 12-5 on p. 363).

Adrenergic effects on the somatic motor neurons at the neuromuscular junction during intense exercise can trigger the release of additional acetylcholine and thus also help prevent or overcome fatigue.

Clearly, skeletal muscle contractions are directly controlled by somatic motor stimulation. But sympathetic stimulation can enhance skeletal muscle function to avoid fatigue during intense activity.

Functions of the Parasympathetic Division

The parasympathetic division is the dominant controller of most autonomic effectors most of the time. Under quiet, nonstressful conditions, more impulses reach autonomic effectors by cholinergic parasympathetic fibers than by adrenergic sympathetic fibers. If the sympathetic division dominates during times that require fight-or-flight, then the parasympathetic division dominates during the in-between times of "rest-and-repair."

Acetylcholine, the neurotransmitter of the parasympathetic system, tends to slow the heartbeat but acts to promote digestion and elimination. For example, it stimulates digestive gland secretion. It also increases peristalsis by stimulating the smooth muscle of the digestive tract. Can you identify other parasympathetic effects in Table 16-3?

| QUICK CHECK |

7. What is the principle of autonomic antagonism? Give an example.
8. Name the responses that occur in the fight-or-flight reaction. How does each of these prepare the body to expend a maximum amount of muscular energy?
9. Which division of the ANS is the dominant controller of autonomic effectors when the body is at rest?

the BIG picture

Autonomic Nervous System and the Whole Body

As you know, the main role of the nervous system as a whole is to detect changes in the internal and external environment, to evaluate those changes in terms of their effect on homeostatic balance, and to regulate effectors accordingly. The autonomic efferent pathways lead to the cardiac muscle effectors, smooth muscle effectors, glandular effectors, and other effectors. Such regulation not only helps us maintain our homeostatic balance, it can also react rapidly when that balance is threatened.

Because the autonomic pathways communicate with endocrine glands, endocrine effectors throughout the body can also be regulated through nervous mechanisms. Every major organ of the body is thus influenced, directly or indirectly, by autonomic output. Although the CNS is an overall controller of the major homeostatic functions of the body, the autonomic pathways are the means to exert that control.

CASE study

Tim was hiking in the Ozark Mountains when he decided to take some time to rest at the top of a bluff with a beautiful view of the river below. Soon he was dozing. After waking from a restful nap, he saw a mountain lion less than a hundred feet from him! The lion was not looking in his direction. In fact, it took no interest in Tim and simply walked away into the thick forest atop the bluff. Despite the restful nap, Tim noticed that his heart was now racing!

1. Which statement is true, given the circumstance in which Tim found himself?
   a. The racing heart resulted from a day of intense exercise including climbing the bluff.
   b. Increased heart rate is abnormal, given that Tim was well rested.
   c. Tim experienced a normal reaction to a threat.
   d. Tim is hallucinating because there are no mountain lions in the Ozarks.
   e. Tim experienced the rest-and-repair response.
2. What triggered Tim's reaction when he saw the mountain lion?
   a. Sympathetic stimulation of the heart
   b. Parasympathetic stimulation of the heart
   c. Somatic motor stimulation of the heart
   d. Both sympathetic and parasympathetic stimulation of the heart
3. What other effect(s) did Tim likely experience besides a rapid heart rate? (choose all that apply)
   a. Increased rate of breathing
   b. Sweating
   c. Slower pulse
   d. Twitching of the ears
   e. Increased digestive activity
4. Which neurotransmitter produced the effects Tim experienced?
   a. Serotonin
   b. Dopamine
   c. Acetylcholine
   d. Norepinephrine
5. Which type of organ was primed for maximum efficiency by Tim's reactions?
   a. Synovial joints
   b. Skeletal muscles
   c. Smooth muscles
   d. Kidneys
   e. Digestive organs
6. Which type of effects did Tim's body experience?
   a. Adrenergic
   b. Dopaminergic
   c. Cholinergic
   d. Anaphylactic

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

OVERVIEW OF THE AUTONOMIC NERVOUS SYSTEM

A. Role of the autonomic nervous system (ANS)
   1. Contains afferent (sensory) and efferent (motor) components (Figure 16-1)
      a. Efferent components of ANS are emphasized in this chapter
      b. Sensory concepts of the ANS are discussed in Chapter 17
   2. Carries fibers to and from the autonomic effectors (Box 16-1)
   3. Major function—to regulate heartbeat, smooth muscle contraction, glandular secretions, and metabolic functions to maintain homeostasic balance and react to threats to that balance

B. Divisions of the autonomic nervous system
   1. Two efferent divisions—sympathetic division and parasympathetic division
   2. Sympathetic division consists of neural pathways that are separate from parasympathetic pathways (Figure 16-2)
   3. Many autonomic effectors are dually innervated, which allows remarkably precise control of effector

STRUCTURE OF THE AUTONOMIC NERVOUS SYSTEM

A. Basic plan of efferent autonomic pathways (Figure 16-3)
   1. Each pathway is made up of autonomic nerves, ganglia, and plexuses, which are made of efferent autonomic neurons
   2. All autonomic neurons function in reflex arcs; called *autonomic reflexes* or *visceral reflexes*
   3. Efferent autonomic regulation ultimately depends on feedback from sensory receptors
   4. Relay of two efferent autonomic neurons conducts information from central nervous system to autonomic effectors
      a. Preganglionic neuron—conducts impulses from the central nervous system to an autonomic ganglion
      b. Postganglionic neuron—efferent neuron with which a preganglionic neuron synapses within autonomic ganglion

B. Structure of the sympathetic pathways
   1. Sympathetic chain ganglia (sympathetic trunk)
      a. Most sympathetic division ganglia lie along either side of the anterior surface of the vertebral column; joined with the other ganglia located on the same side
      b. Each chain runs from the second cervical vertebra to the level of the coccyx
      c. Usually 22 sympathetic chain ganglia on each side of vertebral column: three cervical, eleven thoracic, four lumbar, and four sacral
   2. Thoracolumbar division
      a. Sympathetic preganglionic neurons have dendrite and cell bodies in lateral gray horns of the thoracic and lumbar segments of the spinal cord
      b. Axons leave the cord by way of the ventral roots of the thoracic and first four lumbar spinal nerves; split away from other spinal nerve fibers by means of the white ramus; extend to a sympathetic chain ganglion
   3. Preganglionic fiber may take one of three paths once inside the sympathetic chain ganglion
      a. Synapse with sympathetic postganglionic neuron
      b. Send ascending or descending branches through the sympathetic trunk to synapse with postganglionic neurons in other chain ganglia
      c. Pass through one or more chain ganglia without synapsing
   4. Sympathetic postganglionic neurons
      a. Dendrites and cell bodies are mostly in sympathetic chain ganglia or collateral ganglia
      b. Gray ramus—short branch by which some postganglionic axons return to a spinal nerve
   5. In the sympathetic division, preganglionic neurons are relatively short, and postganglionic neurons are relatively long
   6. Axon of one sympathetic preganglionic neuron synapses with many postganglionic neurons, terminating in widely spread organs (Figure 16-4)

D. Structure of the parasympathetic pathways
   1. Parasympathetic preganglionic neurons—cell bodies are located in nuclei in the brainstem or lateral gray columns of the sacral cord; extend a considerable distance before synapsing with postganglionic neurons
   2. Parasympathetic postganglionic neurons—dendrites and cell bodies are located in parasympathetic ganglia, which are embedded in or near autonomic effectors
   3. Parasympathetic postganglionic neurons synapse with postganglionic neurons that each lead to a single effector (Figure 16-4)

E. Autonomic neurotransmitters and receptors (Figures 16-5 and 16-6)
   1. Axon terminal of autonomic neurons releases either of two neurotransmitters: norepinephrine or acetylcholine
   2. Adrenergic fibers—release norepinephrine; axons of postganglionic sympathetic neurons
   3. Cholinergic fibers—release acetylcholine; axons of preganglionic sympathetic neurons and of preganglionic and postganglionic parasympathetic neurons
   4. Norepinephrine affects visceral effectors by first binding to one of two types of adrenergic receptors in plasma membranes: alpha receptors or beta receptors
      a. Binding of norepinephrine to alpha receptors in smooth muscle of blood vessels is stimulating, causing the vessels to constrict
      b. Binding of norepinephrine to beta receptors in smooth muscle of blood vessels is inhibitory, causing blood vessels to dilate; in cardiac muscle, has stimulating effect
   5. Epinephrine also stimulates adrenergic receptors, enhancing and prolonging effects of sympathetic stimulation
   6. Effect of a neurotransmitter on any postsynaptic cell is determined by characteristics of the receptors, not by the neurotransmitter
   7. Termination of actions of norepinephrine and epinephrine
      a. Monoamine oxidase (MAO)—enzyme that breaks up neurotransmitter molecules taken back up by the synaptic knobs
      b. Catechol-O-methyl transferase (COMT)—enzyme that breaks down the remaining neurotransmitter
   8. Acetylcholine binds to two types of cholinergic receptors: nicotinic receptors and muscarinic receptors
   9. Termination of action of acetylcholine is by the enzyme acetylcholinesterase
   10. Autonomic neurotransmitters and receptors may influence different types of presynaptic and postsynaptic receptors at synapses with dually innervated effectors; this summation of effects increases precision of control

FUNCTIONS OF THE AUTONOMIC NERVOUS SYSTEM

A. Overview of autonomic function
   1. Autonomic nervous system functions to regulate visceral effectors in ways that tend to maintain or quickly restore homeostasis
   2. Sympathetic and parasympathetic divisions are tonically active, often exerting antagonistic influences on visceral effectors

3. Dually innervated effectors continually receive both sympathetic and parasympathetic impulses, and the summation of the two determines the controlling effect

B. Functions of the sympathetic division
   1. Under resting conditions can act to maintain the normal functioning of doubly innervated autonomic effectors
   2. Sympathetic impulses function to maintain normal tone of the smooth muscle in blood vessel walls
   3. Major function of sympathetic division is that it serves as an "emergency" system—the "fight-or-flight" reaction (review Table 16-4)

C. Functions of the parasympathetic division (review Table 16-3)
   1. Dominant controller of most autonomic effectors most of the time
   2. Acetylcholine—slows heartbeat and acts to promote digestion and elimination

THE BIG PICTURE: THE PERIPHERAL NERVOUS SYSTEM AND THE WHOLE BODY

A. The autonomic nervous system maintains homeostatic balance and can react rapidly to threats to that balance

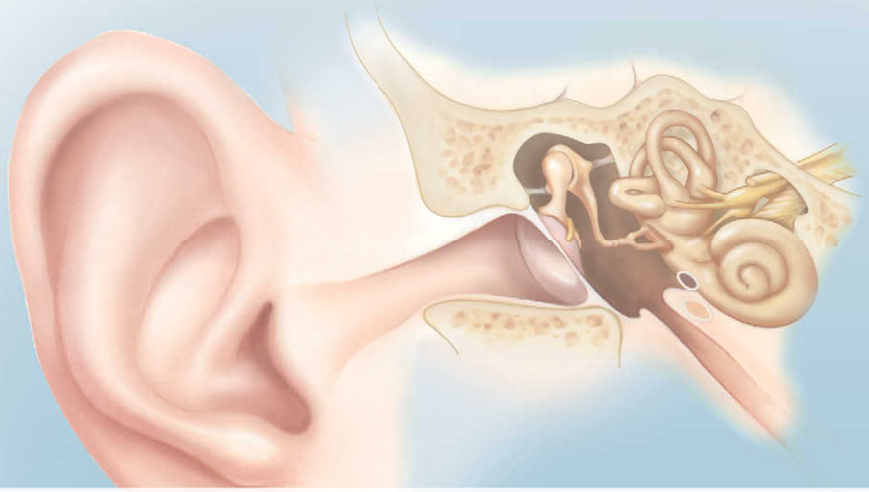
B. Every major organ is influenced, directly or indirectly, by autonomic nervous system output

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Describe an autonomic preganglionic neuron.
2. Identify the paths that a nerve signal may take once it is inside the sympathetic chain ganglion.
3. Differentiate between the sympathetic preganglionic and postganglionic neurons in terms of length.
4. How do parasympathetic ganglia differ from sympathetic ganglia in terms of location?
5. Describe the actions of norepinephrine. How are these actions terminated?
6. Describe the responses caused by acetylcholine release. How are these actions terminated?
7. Name the main types of adrenergic and cholinergic receptors.
8. Which efferent division of the autonomic nervous system is the dominant controller of most autonomic effectors most of the time?

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. What is the distinction between the reflexes that cause cardiac muscle to react and those that cause skeletal muscles to react?
2. Using the control of the speed of a car as an example, explain dual innervation in the autonomic nervous system.
3. What distinguishes the function of autonomic transmitters from that of receptors? How do they regulate dually innervated effector cells?
4. Based on what you know, explain why the autonomic nervous system is not an "automatic" nervous system with little control from the higher brain centers.
5. There are reports of people performing almost superhuman feats of strength when under great stress. Specifically, what is happening in the body that would allow this to happen?
6. The drug propranolol (Inderal) blocks the effect of a portion of the sympathetic nervous system. To what class of drugs does propranolol (Inderal) belong, and what are its therapeutic effects?
7. Can you identify substances (other than acetylcholine and norepinephrine) that respond to receptors for the autonomic nervous system? What name is given to this group of substances, and what is their most likely role?

Sense Organs

continued on p. 537

The body has millions of sense organs. They fall into two main categories: general sense organs and special sense organs. Of these, by far the most numerous are the general sense organs, or receptors. Receptors function to produce the general, or somatic, senses (e.g., touch, temperature, pain) and to initiate various reflexes necessary for maintaining homeostasis. Special sense organs function to produce the special senses (vision, hearing, balance, taste, smell), and they too initiate reflexes important for homeostasis. In this chapter we begin with a description of receptors and follow with information related to the special senses.

SENSORY RECEPTORS

Sense organs called **sensory receptors** make it possible for the body to respond to stimuli caused by changes occurring in our external or internal environment. This function is crucial to survival. The abilities to see and hear, for example, may provide the necessary warning to help us avoid injury from dangers in our external environment. Internal sensations ranging from pain and pressure to hunger and thirst help us maintain homeostasis of our internal environment.

Receptor Response

The general function of receptors is to respond to stimuli by converting them to nerve impulses. Receptors are often described as the sensitive dendritic endings or "end organs" of sensory neurons. As a rule, different types of receptors respond to different types of stimuli. Heat receptors, for example, do not respond to light or stretch stimuli.

When an adequate stimulus acts on a receptor, a local potential develops in the receptor's membrane. This **receptor potential** is a graded response, graded to the strength of the stimulus (see Chapter 13, p. 395). When a receptor potential reaches a certain threshold, it triggers an action potential in the sensory neuron's axon. These impulses then travel over sensory pathways to the brain and spinal cord, where they are interpreted as a particular **sensation,** such as heat or cold, or they initiate some type of reflex action, such as withdrawal of a limb from a painful stimulus.

Certain sensory impulses terminating in the brainstem may affect so-called "vital sign" reflexes that help regulate heart or respiratory rate. Others may end in the thalamus or cerebral cortex where they trigger imprecise or "crude" sensation awareness (thalamus) or very precise and specific awareness of not only a specific type of sensation but also its exact location and level of intensity (cerebral cortex).

Receptors often exhibit a functional characteristic known as adaptation. **Adaptation** refers to the process by which the magnitude of the receptor potential decreases over time in response to a continuous stimulus (Figure 17-1). As a result, the rate of impulse conduction by the sensory neuron's axon also decreases. So too does the intensity of the resulting sensation. A familiar example of adaptation is feeling the touch of your clothing when you first put it on and then soon not sensing it at all. Touch receptors adapt rapidly. In contrast, the proprioceptors in our muscles, tendons, and joints adapt slowly. As long as stimulation of them continues, they continue sending impulses to the brain.

If we not only remain aware of a particular sensation over time, but also interpret what that sensation means in a larger context, the process is called **perception.** Although we may have no conscious perception of certain sensory inputs, they often play a critical role in maintaining homeostasis. Examples might include our ability to sense and respond to changing levels of blood glucose and carbon dioxide—but not at a conscious level.

Distribution of Receptors

Receptors responsible for the **special senses** of smell, taste, vision, hearing, and equilibrium are grouped into localized areas (such as nasal mucosa or the tongue) or into complex organs such as the eye and ear. The **general sense organs,** on the other hand, consist of microscopic receptors widely distributed throughout the body

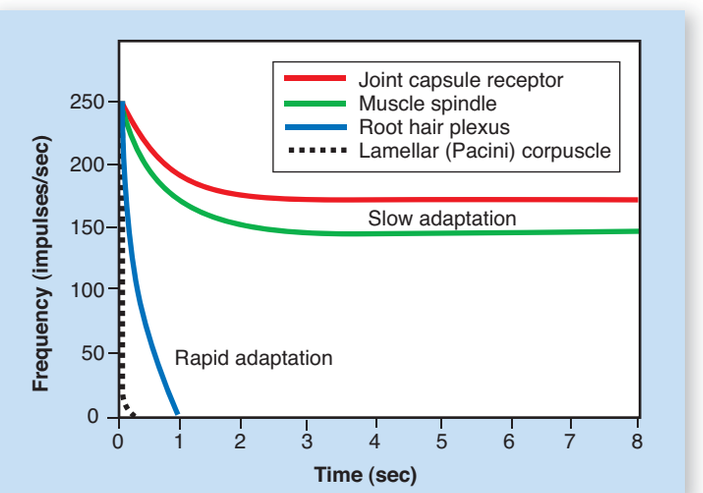

FIGURE 17-1

Adaptation of sensory receptors. In the presence of a continuous stimulus, the rate (frequency) of impulses declines quickly in rapidly adapting receptors of the skin where the initial stimulus, representing a *change,* is valuable information. However, continued sensation from the skin may be distracting. In slow-adapting joint and muscle receptors, the rate of impulses instead declines gradually and levels off to a constant, moderately high level. Thus information about body position is continually sent to the central nervous system. (Specific receptor types are discussed later in this chapter.)

in the skin, mucosa, connective tissues, muscles, tendons, joints, and viscera.

Sensations produced by the receptors of general sense organs are often called the *somatic senses*. The distribution of general sense receptors is not uniform in all areas. In some, it is very dense; in others, it is sparse. The skin covering the fingertips, for instance, contains many more receptors to touch than does the skin on the back. A simple procedure, the **two-point discrimination test,** demonstrates this fact. A subject reports the number of touch points felt when an investigator touches the skin simultaneously with two points of a compass. If the skin on the fingertip is touched with the compass points barely ⅛ inch apart, the subject senses them as two points. If the skin on the back is touched with the compass points this close together, they will be felt as only one point. Unless they are 1 inch or more apart, they cannot be discriminated as two points. Why this difference? Because touch receptors are so densely distributed in the fingertips that two points very close to each other still stimulate two different receptors—they are sensed as two points.

The situation is quite different in the skin on the back. There, touch receptors are so widely scattered that two points have to be at least 1 inch apart to stimulate two receptors and be felt as two points.

CLASSIFICATION OF RECEPTORS

Receptors can be classified according to (1) their location in the body, (2) the particular stimulus that causes them to respond, and (3) their structure.

Classification by Location

Three groups or classes of receptors can be identified by their location:

1. Exteroceptors
2. Viscероceptors (or interoceptors)
3. Proprioceptors

Exteroceptors, as the name implies, are located on or very near the body surface and respond most frequently to stimuli that arise external to the body itself. Receptors in this group are sometimes called *cutaneous receptors* because of their placement in the skin. However, the special sense organs, which are described later in the chapter, are also classified as exteroceptors. Examples of exteroceptors include those that detect pressure, touch, pain, and temperature.

Viscероceptors (interoceptors) are located internally, often within the substance of body organs (viscera), and when stimulated provide information about the internal environment. They are activated by stimuli such as pressure, stretching, and chemical changes that may originate in diverse internal organs, such as the major blood vessels, intestines, and urinary bladder. Viscероceptors are also involved in mediating sensations such as hunger and thirst.

Proprioceptors are a special type of viscероceptor. They are less numerous and generally more specialized than other internally placed receptors, and their location is limited to skeletal muscle, joint capsules, and tendons. Proprioceptors provide us with information about body movement, orientation in space, and muscle stretch.

Activation of two types of proprioceptors, called *tonic* and *phasic* proprioceptors, allows us to orient our body in space and provides us with positional information about specific body parts while at rest or during movement. The firing of the nonadapting tonic proprioceptors allows us to locate, for example, our arm, hand, or foot at rest without having to look. Phasic proprioceptors are rapidly adapting receptors, so they are triggered only when there is a change in position. Phasic proprioceptors therefore permit us to feel the changing position of our body parts during continuous movement.

Classification by Stimulus Detected

Receptors are frequently classified into six categories based on the types of stimuli that activate them:

1. **Mechanoreceptors**—activated by mechanical stimuli that in some way "deform" or change the position of the receptor, resulting in the generation of a receptor potential. Examples include pressure applied to the skin or to blood vessels or pressure caused by stretch or pressure in muscle, tendon, or lung tissue.
2. **Chemoreceptors**—activated by either the amount or the changing concentration of certain chemicals. Our senses of taste and smell depend on chemoreceptors. Some chemoreceptors in the body also detect the concentration of specific chemicals such as carbon dioxide (CO_2) and blood glucose.
3. **Thermoreceptors**—activated by changes in temperature.
4. **Nociceptors**—activated by intense stimuli of any type that results in tissue damage. The cause may be a toxic chemical, intense light, sound, pressure, or heat. The sensation produced is one of pain.
5. **Photoreceptors**—found only in the eye. Photoreceptors respond to light stimuli if the intensity is great enough to generate a receptor potential.
6. **Osmoreceptors**—concentrated in the hypothalamus and sense levels of osmotic pressure in body fluids. They are important in detecting changes in concentration of electrolytes (osmolarity) in extracellular fluids and in stimulating the hypothalamic thirst center.

Classification by Structure

Regardless of their location or how they are activated, the general (somatic) sensory receptors may be classified anatomically as either of the following:

- Free nerve endings
- Encapsulated nerve endings

Refer often to Table 17-1 as you read about the general sensory receptors that are described in the following paragraphs.

FREE NERVE ENDINGS

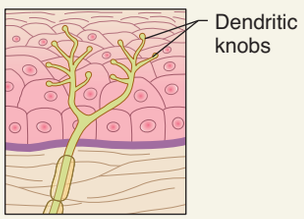
Free nerve endings are the simplest, most common, and most widely distributed sensory receptors. They are located both on the surface of the body (exteroceptors) and in the deep visceral organs (viscero ceptors). These slender sensory fibers often terminate in small swellings called *dendritic knobs*.

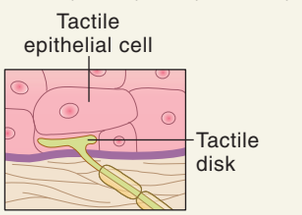
Pain Sensations

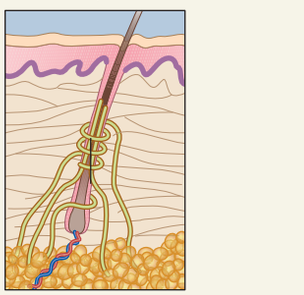
The term **nociceptor** is used to describe the free nerve endings that serve as the primary sensory receptors for pain. Nerve fibers that carry pain impulses from nociceptors to the brain can be divided into two types—**acute** or **fast (A) pain** fibers and **chronic** or **slow (B) pain** fibers.

A fibers are concentrated in the skin, mucous membranes, and other superficial areas. Fast pain is sometimes described as a sharp "take your breath away" type of pain associated with superficial injury or trauma. If you have ever slammed your finger while closing a car door you have experienced this type of fast or **somatic pain.**

The type of deep or **visceral pain** that develops more slowly over time and travels over B fibers is often described as dull or aching. It originates in deeper body (visceral) structures and can be severe if caused by conditions such as intestinal obstruction or passage of a kidney stone or gallstone.







It is important to stress that in responding to powerful stimuli of any kind, including chemical or thermal burns, intense light, sound, or pressure, the generation of a receptor potential in free nerve endings most often results in the sensation of pain—often the first indication of injury or disease.

Brain tissue is unique in that it lacks the type of nociceptors that transmit sensations of pain and is therefore incapable of sensing painful stimuli. Just the opposite is true of many deep visceral organs, in which the presence of free nerve endings makes pain one of the few sensations that can be evoked.

Pain is experienced differently by different people. Many factors cause this—many of which are unknown. Certainly the brain's filtering and processing of sensory information plays a large part. Box 17-1 describes a common phenomenon in which visceral pain is perceived as external pain.

Pain is a "bad news/good news" type of sensation. The bad news, of course, is its relationship to disease and injury. The good news is the important role pain plays in alerting us to threats in our environment. Pain expert Paul Brand often called pain "the

TABLE 17-1 Classification of Somatic Sensory Receptors
