Salpingitis isthmica nodosa. Glands infiltrate the wall in a circumferential and swirling manner around the central lumen in the fallopian tube. The glands are mostly rounded, and some are cystically dilated. Occasional glands show mild contour irregularities. Some glands contain blood within the lumens. Closer magnification will show glands lined by a single layer of bland tubal epithelium

[89, 104, 149, 183, 206]. A rare complication that we have seen is rupture of a deep diverticulum through the serosa, with subsequent mild intra-abdominal bleeding and pelvic pain.

Ectopic Pregnancy

An ectopic pregnancy occurs when the developing blastocyst implants at a site other than the endometrium of the fundus or lower uterine segment. Because more than 95% of ectopic pregnancies occur in the fallopian tube, the terms ectopic pregnancy and tubal pregnancy are nearly synonymous. However, implantation on both tubal fimbriae and ovary or in the interstitial segment of the fallopian tube (intramural pregnancy) or cornu, abdominal cavity, cervix, or retroperitoneum also may occur, in descending order of frequency [29]. Hepatic, diaphragmatic, and splenic pregnancies are extremely rare [56].

Etiology

The mechanisms responsible for ectopic pregnancy are largely unknown, but any disease process that alters the normal tubal anatomy seems to increase the frequency. Although delay in entering the uterine cavity may

predispose the blastocyst to tubal nidation, experimentally delayed conceptuses in rabbit, guinea pig, and mouse oviducts degenerate and fail to implant. However, ectopic pregnancy is reported uncommonly in nonhuman primates. As many as 88% and 43% of carefully studied tubes with an ectopic pregnancy will show chronic salpingitis and salpingitis isthmica nodosa, respectively [89]. Ultrastructural studies have demonstrated that the mucosa of fallopian tubes in women with ectopic pregnancies have lower numbers of ciliated cells compared with women who have intrauterine pregnancies [234]. Risk factors for ectopic pregnancy are (in descending order of magnitude) prior ectopic pregnancy, prior tubal surgery, smoking (>20 cigarettes/day), pelvic inflammatory disease, multiple spontaneous abortions (>3), increasing age (>40 years), prior medically induced abortion, infertility (>1 year), multiple sexual partners (>5), and previous intrauterine contraceptive device (IUD) use [27].

Clinical Features

Currently, ectopic pregnancy accounts for 1–2% of clinically known pregnancies [3, 70, 232]. Simultaneous ectopic and intrauterine implantations (heterotopic pregnancy) used to occur in 1 in 30,000 pregnancies decades ago; however, the frequency now can be as high as 0.75–1% of pregnancies after undergoing assisted reproductive technology [92, 150]. The classic presentation of ectopic pregnancy includes amenorrhea with subsequent vaginal bleeding and/or abdominal pain. Tubal rupture is associated with intra-abdominal hemorrhage. The frequency of left- versus right-sided ectopic tubal pregnancies is similar, but they are slightly more common on the right [29, 30]. Rare cases are bilateral.

Serial serum beta-human chorionic gonadotropin (β-hCG) measurements and transvaginal ultrasonography are important parts of the clinical evaluation. Management typically consists of either surgery (salpingectomy or salpingostomy) or medical therapy (methotrexate). Incomplete removal of trophoblastic tissue may result in persistent ectopic pregnancy, which occurs in 2-11% and 4-20% of cases after laparotomy with salpingostomy and laparoscopic salpingostomy, respectively [70, 79]. These figures are similar to the frequency of failure with systemic methotrexate therapy. In some cases, persistent ectopic pregnancy may be a result of spillage of gestational tissue from disruption/morcellation of the specimen after salpingostomy or salpingectomy. In such instances, the lesional tissue may be found as nodules/implants on pelvic, omental, or uterine serosal surfaces [39, 63].

Pathologic Features

The unruptured tubal pregnancy is characterized grossly by a somewhat irregular elongated dilatation of the tube, with a blue discoloration caused by hematosalpinx (\bigcirc *Fig.* 11.16). Within the tube, most ectopic pregnancies are found in the ampulla (\sim 80%), isthmus (12%), and fimbriae (5%) [29].

Nearly two thirds of cases contain a grossly or microscopically identifiable embryo. Chorionic villi usually are found in the blood-filled and dilated tubal lumen and, in 75% of cases, appear viable. Implantation is deeper and more apt to be associated with a viable pregnancy when the placentation occurs on the mesosalpingeal side of the tube as compared with the anti-mesosalpingeal side [121]. The extra-villous intermediate trophoblast of the conceptus penetrates deep in the tubal wall. On occasion, this proliferation may exhibit diffuse sheet-like architecture, which can raise concern for a gestational trophoblastic neoplasm or hydatidiform mole [33, 211]; however, this appearance is within the range of proliferation that can be encountered in ectopic pregnancies (> Fig. 11.17). Perhaps because of the limited ability of the endosalpingeal stroma to undergo decidualization, and analogous to a placenta increta, the chorionic villi invade muscularis and then serosa [181]. Another major difference compared with uterine implantation is the failure of tubal trophoblast to differentiate into chorion frondosum and chorion laeve [196], but a gestational sac can be seen [181]. Vascular changes in mid-sized tubal arteries adjacent to ectopic pregnancies are similar to those found in the vessels near uterine implantations, with invasion by intermediate trophoblast, proliferation of the vascular intima, and accumulation of foam cells in the intima.

Fig. 11.16

Ectopic pregnancy. External view of dilated fallopian tube containing an ectopic pregnancy. The cross section will show a hemorrhagic cut surface

Exuberant intermediate trophoblast proliferation in an ectopic pregnancy. The sheet-like architecture and atypical epithelioid cells should not be mistaken for a gestational trophoblastic neoplasm or hydatidiform mole. Chorionic villi are present on the left side of the photograph

Chronic salpingitis is found in nearly half the patients, with a reported range of 29–88% [89]. Salpingitis isthmica nodosa may also be present. Arias-Stella reaction can be seen in the fallopian tube mucosa [159]. Clear cell hyperplasia has been reported [230].

The clinicopathologic features of extratubal ectopic pregnancy vary according to the site [173]. Cornual or interstitial pregnancies may expand up to about 12 weeks, when rupture may lacerate one of the uterine arteries as well as the entire side of the uterus. Cervical ectopic pregnancy presents with bleeding similar to an incomplete abortion. Because of the nature of the cervical tissue underlying placental implantation, control of bleeding may be difficult. Ovarian pregnancy is clinically similar to tubal pregnancy, including frequent preoperative rupture. More than half the patients in one series had a history of previous reproductive tract disease or infertility [90]. Macroscopic examination typically reveals a hemorrhagic mass replacing the ovary. Pathologic criteria for ovarian pregnancy have been proposed as follows: (1) the tube must be intact and separate from the ovary; (2) the gestational sac must occupy the normal position of the ovary; (3) the gestational sac must be connected to the uterus by the utero-ovarian ligament; and (4) ovarian tissue must be demonstrated within the wall of the sac [90]. Pathologic documentation of ovarian tissue within the pregnancy may be difficult or impossible if treatment consists of conservative resection or if the pregnancy has extensively replaced the ovarian tissue.

Sequelae

The natural history of tubal ectopic pregnancy includes spontaneous expulsion from the fimbriated end (tubal abortion), as well as embryonal death and involution of the conceptus. Typically, however, continued growth of the trophoblast leads to increasing dilatation and weakening of the muscularis, with rupture at about the eighth week. About 25% of tubal pregnancies have ruptured by the time of diagnosis [69]. Hemorrhage due to rupture may be massive, and ectopic pregnancy is a major cause of maternal mortality during pregnancy. Rare ectopic pregnancies have proceeded to term with fetal viability.

In grossly normal fallopian tubes, chorionic villi or placental site nodules may be found, indicative of a prior unsuspected ectopic pregnancy [111, 168]. A subset of tubal pregnancies forms a mass that, with involution of trophoblast and reestablishment of the menstrual cycle, may present problems in differential diagnosis. This convoluted, blood-filled tube (including organization, variable inflammation, and adhesions), often with involved ipsilateral ovary, may simulate a tumor or an endometrioma. Most, but not all, patients will have detectable serum β -hCG. Extensive microscopic sampling of this so-called chronic ectopic pregnancy may be required to demonstrate trophoblastic tissue, which may consist of nonviable chorionic villi [231]. In more advanced pregnancy, death of the fetus with retention in the extrauterine location may be followed by calcification of the fetus (lithopedion) or both membranes and fetus (lithokelyphopedion).

Polyps

Polyps of the fallopian tube have been classified as tumors in the WHO Classification of fallopian tube neoplasms and in other textbooks on gynecologic pathology; however, they are included in the non-neoplastic section of this chapter for conceptual purposes. They are found in approximately 1-3% of women undergoing hysterosalpingography for infertility and may cause proximal tubal occlusion [50, 71]. Their causality of and relationship with infertility has been debated in the literature. They are typically small and preferentially occur in the intramural segment of the fallopian tube, particularly at the tubal ostium. Polyps are frequently bilateral. Although they are removed for microscopic examination only rarely, histologically they are of endometrioid type and resemble endometrial polyps [145]. Given that endometriosis of the tubal mucosa is found in some patients, it is possible

that tubal polyps might represent a microscopic form of polypoid endometriosis.

Infertility

Most of the diseases discussed in this chapter may result in sufficient anatomic distortion to cause tubal infertility. In contrast, purely physiologic tubal dysfunction is not well defined but may be illustrated by the immotile cilia of Kartagener's syndrome that can lead to reduced fertility only 3 of 12 women in one series succeeded in becoming pregnant [5]. Paratubal or fimbrial adhesions secondary to endometriosis, prior pelvic inflammatory disease, or appendicitis may interfere with normal tubal motility and ovum pick-up. For a detailed discussion of the pathophysiology of fallopian tube cilia in various diseases in relation to infertility, the reader is referred elsewhere [147]. Obliterative fibrosis (possibly secondary to inflammation within the uterus) or polyps at the uterine tubal ostium may lead to obstruction at the uterotubal junction [76, 139].

Issues Related to Sterilization Procedures

Sterilization by interference with tubal function involves procedures designed to damage or obstruct the mucosa or lumen of the fallopian tube by surgical removal of a segment of the tube (bilateral partial salpingectomy), rings/clamps, electrocoagulation, intratubal chemical methods (e.g., silicone plugs and methylcyanoacrylate), or intratubal mechanical devices (e.g., Essure system) [62, 223]. Tubal resection should be confirmed by histologic demonstration of a cross section of the fallopian tube including the entire lumen. On occasion, histologic sections may only show fibromuscular/fibrovascular tissue without fallopian tube mucosa. Such cases may represent pelvic ligaments or vessels that were clinically mistaken for a fallopian tube. In order to completely evaluate those cases, it may be necessary to cut deeper levels from the paraffin block, including the possibility of re-orienting and re-embedding the tissue in the block so as to entirely cut through it and find a fallopian tube lumen. The above protocol also applies to cases in which a fallopian tube is definitely present histologically but for which a complete cross section of the lumen is not seen on the H&E slide.

In women who were initially treated by surgical resection, spontaneous re-anastomosis or fistula formation, which may lead to fertilization and ectopic or intrauterine pregnancy, are common mechanisms of sterilization failure [221]. To identify the cause of failure of tubal sterilization procedures, careful gross examination of the specimen, occasionally specimen salpingography, longitudinal orientation of the tubal segment in the paraffin block, and meticulous sectioning techniques may be necessary.

Salpingitis

Salpingitis consists of three major types: acute, chronic, and granulomatous/histiocytic. On occasion, some cases will have mixed features, but this section is arranged according to the predominant histologic appearance.

Acute Salpingitis

Acute salpingitis is a purulent inflammatory process usually secondary to the passage of bacteria from the cervix and uterine cavity into the tubal lumen [137, 154]. It is the pathologic correlate of the clinical entity, pelvic inflammatory disease. It typically occurs in young, sexually active, and reproductive-age women. Important risk factors include patterns of sexual behavior and contraceptive use.

Grossly, the fallopian tube is enlarged and edematous (\bigcirc *Fig.* 11.18). The serosa is erythematous and may be covered with fibrinopurulent exudates. Pus may also fill the lumen. Histologically, the fallopian tube lumen,

Fig. 11.18

Fallopian tube with acute salpingitis. The tube is enlarged with a dilated lumen and erythematous mucosa. The wall is edematous and thickened. Other examples may contain pus in the lumen

Acute salpingitis. (a) The mucosa shows distorted architecture and abundant inflammation, including pus in the overlying lumen. (b) The inflammatory component is mixed but mostly composed of abundant neutrophils

mucosa, and wall contain neutrophils, fibrinous debris, and ulceration (\triangleright *Fig. 11.19*). Edema and lymphocytes may be present as well. Mucosal hyperplasia and distortion can be seen. The histologic appearance varies according to the severity and phase of the disease. The appearance may also vary somewhat based on the specific causative microbial agent, as discussed below. Significant fallopian tube-specific sequelae include infertility and ectopic pregnancy.

It is not clear if organisms are carried upward by sperm or trichomonads as vectors or whether some form of passive transport is in effect [120]. The bacteria implicated in acute salpingitis appear to be from two sources: sexual transmission and lower genital tract flora. Although *Neisseria gonorrhoeae* and *Chlamydia trachomatis* have been considered the most common causative organisms, meticulous bacteriologic studies indicate that most cases are polymicrobial and that anaerobic bacteria, especially *Bacteroides* species and peptostreptococci, frequently are present, as well as aerobes such as *Escherichia coli*. The presence of serum antibodies against gonococcal pili in some of these women, however, suggests that gonococci may initiate the process, only to be supplanted by anaerobes. The role of mycoplasmas in acute salpingitis is controversial, and viruses do not appear to be etiologic. However, Herpes simplex virus infection involving the mucosa of a prolapsed tube with mixed acute and chronic inflammation has been reported [141].

The gonococcus gains access to the tube most readily at the time of menstruation. This situation corresponds to the typical clinical presentation in which the onset of acute pain occurs a few days after menses. The onset of non-gonococcal, non-chlamydial acute salpingitis is not, however, clearly related to the recent onset of menses [227]. Elegant in vitro studies by Ward et al. [237] have clarified the likely initial steps in gonococcal infection, and the molecular mechanisms involved have been reviewed elsewhere [67, 147]. N. gonorrhoeae perfused through the lumen of cultured whole tubes attach only to non-ciliated cells. Within 3 h, microvilli from the cells appear to embrace the gonococci and adhere to them. The bacteria then penetrate both the cells and intercellular junctions, with cell lysis and sloughing. Adjacent ciliated cells are also destroyed but are not invaded directly. Gonococcal lipopolysaccharide and gonococcal-induced tumor necrosis factor-alpha and various other cytokines cause much of the epithelial damage [148, 156], and the degree of pathogenicity likely depends on the bacterial as well as the host genome [11]. After cell lysis, the bacteria penetrate the subepithelial connective tissue. In vivo, this process is considerably modified by the host response.

N. gonorrhoeae spreads via the epithelial surface and thus causes mucosal damage. A brisk diapedesis of granulocytes from capillaries into the mucosa and lumen occurs, and there is vascular engorgement and edema of all tubal layers. As the lumen fills with granulocytes and cellular debris, and as the tube distends, pus may be seen dripping from the fimbriated end in patients undergoing laparoscopy. In severe cases, transudation of plasma proteins results in a fibrinous exudate on the serosal surface, which is erythematous because of vascular dilatation. The cell necrosis, distension of the tube, and focal peritonitis account for the symptoms of abdominal and pelvic pain. Over time, repeated infections result in recurrent symptoms as well as the anatomic changes of chronic salpingitis, discussed below.

Chlamydia trachomatis is cultured frequently from the cervix, uterus, and fallopian tubes in women with acute salpingitis [131, 151]. It is thought that the damage of the fallopian tube by *Chlamydia* is due to the 60-kDa chlamydial heat shock protein (hsp60), as well as other various cytokines [147]. The histologic appearance of tubes removed during the acute or subacute phase of chlamydial salpingitis is virtually identical to that caused by the gonococcus. There is an initial transmural and mucosal infiltration of neutrophils with an intraluminal exudate. Subsequently, there is a lymphoplasmacytic response with variable numbers of residual granulocytes. Chlamydial inclusion bodies have been identified within the epithelial cells [240]. On occasion, the lymphofollicular response may be so florid as to suggest lymphoma [236].

As a result of acute salpingitis (usually in the context of gonococcal or chlamydial disease), fibrinous adhesions develop between the fallopian tube serosa and surrounding peritoneal surfaces. Peritoneal inflammation may be widespread, and thin so-called violin-string adhesions may form between the liver and the anterior abdominal wall as part of the Fitz-Hugh–Curtis syndrome.

In severe cases of acute salpingitis (as well as with chronic or granulomatous salpingitis) with involvement of the ovary regardless of the specific microorganism, both the ovary and the tube are attached to one another by adhesions and create a mass in the form of a tubo-ovarian abscess (**>** *Fig. 11.20*). Tubo-ovarian abscesses can be unilateral or

bilateral. Histologically, the inflammatory component may be predominantly composed of neutrophils or contain a mixture of neutrophils, lymphocytes, histiocytes, and plasma cells. Widespread necrosis is common. The background fallopian tube and ovarian parenchyma will be markedly distorted, and abundant fibrous and edematous stroma may be present. Although N. gonorrhoeae and C. trachomatis are common bacterial causes of acute salpingitis, they are isolated in culture only rarely from tuboovarian abscesses. Both aerobic and anaerobic cultures of any tubo-ovarian abscess should be obtained in the operating room or laboratory. Prior treatment with antibiotics possibly may eliminate culturable organisms, but anaerobes are commonly isolated. E. coli, Bacteroides fragilis, and other Bacteroides species, Peptostreptococcus, Peptococcus, and aerobic streptococci are the most commonly found organisms [136]. Typically, these infections are polymicrobial.

Another organism that can result in tubo-ovarian abscess is *Actinomyces israelii*, which is part of the indigenous female genital tract flora [184]. Actinomycotic infections of the tube are associated with intrauterine contraceptive devices (IUDs) (see Chap. 7, Benign Diseases of the Endometrium) [60]. Anaerobic culture is necessary to permit growth of *Actinomyces israelii*. Microscopically, fragments of gram-positive filaments and sulfur granules may be recognized within pus. Pseudoactinomycotic radiate granules should not be mistaken for the sulfur granules of actinomycosis [24, 192].

Fig. 11.20

Tubo-ovarian abscess. In this case, bilateral tubo-ovarian abscesses are composed of fibroinflammatory masses, and the ovary and fallopian tube on each side are attached to one another by adhesions. The cut surface will show distorted fibrous tissue with edema, hemorrhage, and necrosis

Fig. 11.21

Physiologic salpingitis. A mild amount of acute inflammation is present within the vascular spaces in the mucosa. Other cases may have mild acute inflammation within the mucosal epithelium or lamina propria An asymptomatic form of acute salpingitis ("physiologic salpingitis") is seen in tubes removed during postpartum ligation. Beginning about 5 h after delivery and present up to 7–10 days later, a small number of acute or mixed acute and chronic inflammatory cells are found in the mucosa or lumen of 10% or more of specimens (\bigcirc *Fig. 11.21*). Attempts to culture aerobic or anaerobic bacteria have been almost uniformly unsuccessful. The process may be secondary to the trauma of delivery or intrauterine tissue necrosis and is apparently of no clinical significance.

Chronic Salpingitis

As a result of acute salpingitis, the proximity of the ovary to the fimbriae allows multiple tubo-ovarian adhesions to form, which may also cause occlusion of the tubal ostium. If the fimbriae close before the ovary is involved as part of a tubo-ovarian abscess, the inflamed and dilated tube can form a pyosalpinx full of acute and chronic inflammatory cells. When acute salpingitis resolves, the acute and most of the chronic inflammatory cells gradually disappear, and the patient is left with either a severely scarred tube in the form of chronic salpingitis or a hydrosalpinx. *C. trachomatis* DNA has even been detected in fallopian tubes in a subset of cases that contained only chronic salpingitis [103]. Thus, the finding of chronic salpingitis may imply previous pelvic inflammatory disease in some patients.

In chronic salpingitis, the mucosal plicae are often adherent to one another secondary to surface fibrin deposition from acute salpingitis. This may be focal or extensive. If it is severe enough, the bases of the fimbriae may coalesce in the center with the fimbriae radiating outward, or the tips of the fimbriae may adhere blocking the lumen and causing a blunted end - the so-called clubbed tube (**)** Fig. 11.22). Healing and organization in the non-fimbriated portions of the tube also lead to permanent bridging between folds. Classically, this results in so-called follicular salpingitis (**)** Fig. 11.23); however, that term is a misnomer as it suggests a pattern of inflammation characterized by lymphoid follicles. In chronic salpingitis, plicae may retain much of their size and shape, but plasma cells, lymphocytes, or both are still present in the mucosa (> Fig. 11.24). Often the height of the folds appears reduced, and the plicae may become blunted and have fibrous stroma. Therefore, the once orderly pattern of the mucosa becomes distorted. The mucosa may also be hyperplastic.

Hydrosalpinx is characterized by obliteration of the fimbriated end and dilation of the tube, usually

Fig. 11.22

Clubbed tube. The fimbriated end is closed because of fimbrial adhesions, creating a blunted end

 Fig. 11.23
Follicular salpingitis. The plicae are adherent to one another, creating follicle-like spaces in the setting of chronic salpingitis

the ampullary and infundibular portions (\bigcirc Fig. 11.25). If the ovary is first involved by tubo-ovarian adhesions, the ovary may be compressed by the dilated tube. Because a luminal communication usually can be demonstrated between dilated and non-dilated portions of the tube, the etiology of the dilatation can be obscure. The dilated tube can become cystic and filled with serous fluid, and the wall is generally white, thin, and translucent with occasional fibrous adhesions on the external surface. The muscle wall is either thin and atrophic or replaced by fibrous tissue. Most of the epithelial lining consists of low-cuboidal cells, but an occasional plica may persist with columnar epithelium containing histologically normal

546

ciliated and secretory cells (\bigcirc *Fig. 11.26*). A few lymphocytes may be found in the wall of the hydrosalpinx but are more commonly absent.

Granulomatous/Histiocytic Salpingitis and Foreign Bodies

Granulomatous and histiocytic inflammation of the fallopian tube may result from infection by a number of different organisms or be induced by a variety of noninfectious processes, some of which include tissue reactions due to microscopic foreign bodies.

Pseudoxanthomatous/Xanthogranulomatous Salpingitis

Pseudoxanthomatous salpingitis (variably referred to as "pigmentosis tubae") is characterized by lipofuscin- and hemosiderin-laden macrophages within the lamina

Fig. 11.24

Chronic salpingitis. (a) Fibrotic and blunted plicae. (b) The distorted plicae show the lamina propria filled with lymphocytes and plasma cells

propria of the mucosa of the fallopian tube, including distension of the plicae, and is associated with endometriosis (\bigcirc *Fig. 11.27*) [45, 78, 101, 164, 215]. The tubes may be enlarged and edematous, with the mucosa having a dark brown polypoid gross appearance. Despite the association with endometriosis, this process also might result from salpingitis with associated bleeding [45, 215]. It has been suggested that pseudoxanthomatous salpingitis should be distinguished from xanthogranulomatous salpingitis because of the latter's association with pelvic inflammatory disease and lack of association with

Fig. 11.25 Hydrosalpinx. The fallopian tube is massively dilated, producing a large cystic mass

Fig. 11.26

Hydrosalpinx. Most of the dilated fallopian tube contains a thin wall and atrophic mucosa. Residual small plicae are present. Note the smooth muscle within the wall

Pseudoxanthomatous salpingitis. The plicae are expanded and distorted due to sheets of histiocytes with eosinophilic cytoplasm in the lamina propria. This should not be mistaken for decidualization

Fig. 11.28 Granulomatous salpingitis due to tuberculosis. Noncaseating granulomas are present in the mucosa. Note calcifications and multinucleated giant cells. Other cases

may contain caseating granulomas

endometriosis [78]. In contrast with pseudoxanthomatous salpingitis, xanthogranulomatous salpingitis has mucosa which is usually grossly yellow and purulent, macrophages which are foamy (as opposed to the dark brown macrophages in pseudoxanthomatous salpingitis), and other types of inflammatory cells, including multinucleated giant cells [78, 133]. A potentially related lesion that has been described in the tube is xanthelasma [41].

Tuberculous Salpingitis

Mycobacterium tuberculosis historically has been the predominant etiologic agent of granulomatous salpingitis. The frequency of tuberculous salpingitis in women studied for tubal causes of infertility ranges from much less than 1% in the USA to nearly 40% in India [178]. Twenty percent of women who die of tuberculosis have tubal involvement [208]. Primary infection of the genitalia, as by coitus with a partner with genitourinary tuberculosis, is extremely rare. Secondary spread via a hematogenous route, usually from a primary pulmonary infection, is the usual route of infection. For unclear reasons, the bloodborne organism prefers the tubes rather than other parts of the female genital tract. The primary pulmonary lesion may not be radiologically evident, but extrapulmonary involvement of the peritoneum, kidneys, or other sites may be present. Lymphatic spread from primary intestinal tuberculosis or direct spread from the urinary bladder or gastrointestinal tract may occur. Tubal involvement is usually bilateral. Although the earliest pathologic lesions

are microscopic, with advancing disease the tube increases in diameter and may become nodular, mimicking salpingitis isthmica nodosa. In the more common adhesive form of the disease, multiple dense adhesions may form between the tube and ovary, and the fimbriae and ostium may be obliterated [93]. With the exudative form of disease, progressive distension mimics bacterial pyosalpinx. Hematosalpinx, hydrosalpinx, tubo-ovarian abscesses, or a so-called frozen pelvis may be found late in the disease process [178]. In either form, serosal tubercles may be present.

In early disease, microscopic lesions are mucosal based with a typical granulomatous reaction of epithelioid histiocytes and lymphocytes arranged in a nodular configuration. Multinucleated giant cells are often seen, and focal or massive central caseation may be present (> Fig. 11.28). Immunosuppression can modify cellular immunity to a point where granulomas fail to form, and with this clinical information, the mere finding of acute and chronic inflammatory cells should lead to consideration of staining for acid-fast organisms. From the mucosa, extension to the muscularis and serosa may occur. As the tubercles enlarge and coalesce, they may erode through the mucosa and discharge their contents into the tubal lumen, and the tube may then become dilated. The mucosal inflammatory reaction leads to progressive scarring, with plical distortion and agglutination. Calcification can occur in areas of fibrosis. Because tubercles may not be present in a given section, the presence of caseation,

fibrosis, or calcification in a tube may be the only histologic finding that suggests the need for more thorough evaluation. Notable mucosal distortion may result in hyperplasia mimicking carcinoma.

There are several complications of tuberculous salpingitis. Alteration in function is expected, and sterility is almost universal because of the common bilaterality of the disease. Because of repeated seeding of the endometrium from the infected tubes, the mycobacterial culture and the histologic finding of endometrial granulomas on curettage are diagnostically useful (see **>** Chap. 7, Benign Diseases of the Endometrium).

Parasitic Salpingitis

Pinworm (Oxyuriasis) The pinworm, *Enterobius vermicularis*, may migrate up the female genital tract, embed in the tube, and cause an inflammatory reaction. The tube can be involved with the ovary as a tubo-ovarian abscess, or a fibrous nodular area may be present. Acute and chronic inflammatory cells may be found together with eosinophils and portions of a gravid female worm. Ova can be released into the tissue, where they provoke a granulomatous reaction (\bigcirc *Fig. 11.29*), but identification of ova can be obscured by calcification and granulomas.

Schistosomiasis (Bilharziasis) Although tubal schistosomiasis may be one of the more common causes of granulomatous salpingitis worldwide, it is rare in the USA. In Africa, the fallopian tube is involved by schistosomiasis in

Fig. 11.29

Granulomatous salpingitis due to pinworm. This caseating granuloma contains abundant eosinophils. A pinworm egg (*arrow*) is present within the necrotic zone 22% of all infected women [84]. The ova of *Schistosoma haematobium* are most common, but *Schistosoma mansoni* eggs may be present in some women. Gross findings appear to be related to fibrosis surrounding the ova, producing a nodular or fibrotic tube. Histologically, the inflammatory reaction is typically granulomatous and may contain eosinophils, neutrophils, plasma cells, lymphocytes, and macrophages, including multinucleated giant cells. Some granulomas may be present within the stroma of the plicae and produce plical expansion. Ectopic pregnancy has been reported as occurring synchronously with tubal schistosomiasis in some patients.

Other Parasites Where the condition is common, hydatid disease secondary to *Echinococcus granulosus* infection may involve the female genital tract, including the adnexa. Cysticercosis (*Taenia solium*) also has been described in the tube [2]. Other rare parasites that have been reported in the fallopian tube include *Entamoeba histolytica* (amebiasis). Liesegang rings should not be mistaken for parasites [46].

Fungal Salpingitis

Other fungi that rarely can cause tubo-ovarian abscesses or granulomatous salpingitis include *Blastomyces dermatitidis*, *Coccidioides immitis*, *Candida*, and *Aspergillus*. These may be secondary to hematogenous spread or disseminated disease.

Sarcoidosis

Sarcoidosis of the tube is rare [25]. Histologically, noncaseating granulomas may be seen in the mucosa. Culture, histochemical stains, and clinical information are necessary to exclude other granulomatous diseases.

Crohn's Disease

Crohn's disease of the ileum, colon, or appendix may secondarily involve the tube and ovary to produce a granulomatous salpingitis and tubo-ovarian abscess. Noncaseating granulomas can involve the entire thickness of the tubal muscularis as well as the mucosa. The mucosa may exhibit hyperplasia with reactive atypia [32]. Fistulas from bowel to tube also can occur.

Other Types of Granulomatous/Histiocytic Lesions and Foreign Bodies

Malakoplakia has rarely been reported in the fallopian tube. Some vasculitides have a granulomatous pattern

(see **Vasculitis** section below) [20]. Foreign body granulomas due to starch and talc, as well as pulse granulomas [197] can occur in the tube. In order to detect some foreign bodies, granulomatous or histiocytic reactions should be examined under polarized light. Extruded keratin from endometrioid carcinomas with squamous differentiation of the endometrium or ovary can produce keratin granulomas on the serosa or fimbriated end of the tube, as well as within the tubal lumen [124]. It should be noted, however, that not all foreign bodies produce a significant granulomatous or histiocytic response. Gelatin microsphere embolization particles (Embospheres[®]/ EmboGold[®]) used in uterine artery embolization for treatment of uterine leiomyomas may sometimes be found in the fallopian tubes or ovaries because of the vascular anastomosis between the uterine and ovarian arteries [123]. In the fallopian tube, these particles are typically found within arterial lumens in the outer wall of the tube or para-tubal locations. They usually elicit only a mild lymphocytic response with rare multinucleated giant cells as opposed to the marked multinucleated giant cell reaction with a granulomatous or histiocytic component seen with other foreign bodies.

Torsion, Prolapse, and Intussusception

Among the various anatomic displacements of the tube, torsion is the most common. The usual predisposing factor is cystic enlargement of the ipsilateral ovary. A benign ovarian cyst or tumor is present in the majority of patients, but in a minority, a malignant ovarian tumor is the cause. Para-ovarian cysts also are associated with torsion. Tubal enlargement secondary to hydrosalpinx or pyosalpinx, or previous gynecologic surgery (especially sterilization), are additional etiologies, but torsion may occur in the absence of apparent adnexal disease [22]. The typical patient is in the reproductive years, occasionally pregnant, and complains of the sudden onset of lower abdominal pain. At operation, the adnexa on one side is twisted, usually once or twice. Venous outflow is compromised early, and the resulting congestion may lead to arterial compression. The adnexa often are enlarged, edematous, and dark and show hemorrhagic infarction. If surgical intervention is prompt, the tube may be preserved. Asymptomatic or undiagnosed torsion can occur.

Tubal prolapse into the vagina may occur rarely as a complication of vaginal or abdominal hysterectomy (see ≥ Chap. 3, Diseases of the Vagina) [195]. Clinically, this is characterized by dyspareunia, vaginal bleeding/discharge, or abdominal pain beginning a few days to several years after hysterectomy. However, some women may be asymptomatic. On clinical examination, an excrescence is seen in the vaginal vault, suggestive of granulation tissue or carcinoma. Fimbriae may be apparent grossly. Severe acute and chronic inflammation can be present microscopically, and papillary architecture or pseudogland formation by the tubal epithelium can mimic adenocarcinoma. Due to admixed granulation tissue, it may be difficult to recognize the lesional tissue as a distorted segment of fallopian tube; however, close scrutiny should reveal papillae lined by benign tubal epithelium. Depending on the specific differential diagnosis, immunohistochemical staining for WT-1, ER/PR, CK7, CK20, p16, and/or Ki-67 may be of help.

Intussusception of the tube is rare. In one case, a paraovarian cyst was engulfed by the end of the tube, and the fimbriated end was pulled into the ampulla [4].

Congenital Anomalies

Structural congenital anomalies of the fallopian tube are rare. Diethylstilbestrol (DES) use during pregnancy was discontinued decades ago, but surgical specimens from patients who were born during the DES era may still be examined today. *In utero* exposure to DES produces shortened, sacculated, and convoluted fallopian tubes. The fimbriae are constricted, and the os is pinpoint [54]. The mucosa may be absent, or when it is present, the plicae do not develop [199].

Tubal duplication and accessory fallopian tubes are uncommon, but the latter occur more frequently [23, 47, 51, 83]. Absence of various segments of the fallopian tube (also variably referred to as atresia, hypoplasia, or interruption), absence of the ampullary muscularis, and complete absence of the tube have been described. These may be unilateral or bilateral, and they can occur with or without uterine anomalies, such as unicornuate or bicornuate uterus (reviewed in Nawroth et al. [167]).

Vasculitis

The fallopian tube can be involved by vasculitis as part of localized or systemic disease, and involvement of the tube is less frequent compared with other sites within the gynecologic tract. Vasculitis involving the female genital

tract can be of polyarteritis nodosa or giant cell arteritis types, but the former is more common [82, 105]. Either one or multiple arterioles/small arteries may be involved. Clinical correlation is needed to determine whether or not vasculitis is localized to the gynecologic tract; however, it is uncommon for patients with vasculitis involving the female genital tract to have either a previous diagnosis of systemic disease or subsequent development of systemic disease [82, 105].

Neoplasms of the Fallopian Tube

The neoplasms arising in the fallopian tube include benign and malignant types, but malignant tumors are more common than benign ones; however, both are infrequent. They are commonly mistaken for chronic salpingitis or pyosalpinx, both preoperatively and during the operative procedure itself. Many benign tumors are small enough to be incidental findings at laparotomy. The WHO Classification of fallopian tube tumors is listed in O *Table 11.1*. Most of these are nonspecific histologic types since the same ones can be seen in other gynecologic sites, especially the ovary.

Benign Neoplasms

Adenomatoid Tumor

Adenomatoid tumor (benign mesothelioma) is the most frequent type of benign tubal tumor. Previously reported lymphangiomas probably represent examples of this entity. They are usually only 1–2 cm in diameter, appearing as a nodule beneath the tubal serosa, and are yellow or white-gray on cross section. Rare cases are bilateral. Similar lesions may be found in the uterus, culde-sac, or ovary (see O Chap. 10, Mesenchymal Tumors of the Uterus). Their origin is presumed to be from the cells of the serosal mesothelium. A fortuitous section may demonstrate a connection between serosa and tumor, but usually the serosa covers the lesion.

Microscopically, the tumor may be large enough to displace the tubal lumen eccentrically and may grow into the supporting stroma of the luminal folds in an infiltrating manner. Multiple, small, slit-like, or ovoid tubules proliferate through the muscular wall of the fallopian tube; however, the stroma may be fibrous or hyalinized (> Fig. 11.30). Foci of chronic inflammation can also be present. A single layer of low-cuboidal or flattened epithelial-like cells, which contain abundant eosinophilic cytoplasm with variably sized vacuoles and round and bland nuclei line the tubules. Mitotic figures are rare. The tubules may be empty or contain pale fluid. Infarction may occur in adenomatoid tumor. When it occurs, and when marked, there is the potential for confusion with other lesions, such as adenocarcinoma, because of the obscured junction between adenomatoid tumor and non-neoplastic tissue, pseudoinfiltration, solid patterns in viable tumor, and reactive atypia [218].

Histochemical studies have shown Alcian blue-positive, hyaluronidase-digestible material in the cells and spaces; however, this material may be absent after routine processing for histologic sections. No significant glycogen or intracellular epithelial mucin is present, as might be found in a tumor of müllerian origin. Immunohistochemically, tumors express mesothelial markers (WT-1, calretinin, CK5/6, D2-40) and are usually negative for epithelial-specific markers (Ber-EP4, B72.3, MOC-31, ER, PR). Electron microscopic studies also support a mesothelial origin for these lesions. Clinically, they are asymptomatic, and recurrences after adequate excision are rare.

The most important lesion to be considered in the differential diagnosis, particularly at the time of frozen section, is metastatic signet ring cell carcinoma. Clinical data such as prior history of a carcinoma (some primary tumors may be occult, and such a history will not be known), extra-fallopian tube tumor seen intraoperatively (especially if multifocal), bilaterality, and histologic presence of a combination of glands, papillae, and solid sheets of tumor help favor a diagnosis of carcinoma. Nuclear atypia and mitotic activity should raise suspicion for carcinoma, but some signet ring cell carcinomas may lack these features. A source of confusion may be the presence of the Alcian blue-positive, hyaluronidase-digestible material within the lumens of the tubules in adenomatoid tumor. At the time of intraoperative consultation, this material resembles epithelial-type mucin on H&E frozen section slides; however, it is lost during routine processing and, as a result, is not present in permanent H&E sections.

Fig. 11.30

Adenomatoid tumor. (a) Nodular configuration in the wall of the fallopian tube. (b) Diffuse proliferation of tubules that infiltrate the myosalpinx. Foci of chronic inflammation are also present. (c) The tubules are lined by a single layer of flat eosinophilic cells with cytoplasmic vacuoles and bland nuclei. The lumens of the tubules are empty. An intraluminal thin cytoplasmic strand, which can be focally seen in some cases, is present (*arrow*)

Fallopian tube papilloma. Abundant papillae with complex branching resemble the plicae of normal fallopian tube. Closer magnification will show the same type of epithelium seen in normal fallopian tube

After frozen section analysis, immunohistochemical stains specific for mesothelial and epithelial markers will help aid distinction.

Epithelial Tumors

Papilloma is rare [87]. It is composed of an intraluminal mass with an "adenomatous" and very complex papillary proliferation. At low power, the proliferation resembles an exaggerated pattern of tubal mucosa with fine stromal fibrovascular cores, and the quantity of papillae is much greater than in the normal fallopian tube (> Fig. 11.31). At higher power, the epithelium resembles normal fallopian tube mucosa, including the presence of ciliated and secretory cells. The nuclei are bland, and mitotic activity is not seen. In our anecdotal experience, fallopian tube papilloma diffusely expresses ER and WT-1, and the Ki-67 proliferation index is low. Because of the complex papillary proliferation, this tumor may be confused with atypical proliferative (borderline) serous tumor, low-grade serous carcinoma, or a villoglandular variant of endometrioid carcinoma. Although very complex, the orderly degree of papillary branching of papilloma is in contrast to a greater degree of complexity and hierarchical papillary branching with cellular stratification and tufting of atypical proliferative (borderline) serous tumor. The fine micropapillary tufting, associated psammoma bodies, and stromal invasion of low-grade serous carcinoma are

Fig. 11.32

Metaplastic papillary tumor. The tumor is small and characteristically located within the lumen of the fallopian tube. It contains a limited number of medium-sized papillae. Closer magnification will show papillae lined by columnar to cuboidal cells that have abundant, dense, and eosinophilic cytoplasm with nuclei, which are bland or have, at most, mild atypia. Only a limited degree of stratification is present

not seen in papilloma. At low power, papilloma can resemble a villoglandular endometrioid carcinoma, but closer examination at high power shows endosalpingeal cell types and an absence of endometrioid differentiation. Furthermore, squamous metaplasia, endometriosis, and foci with solid growth would favor endometrioid carcinoma.

Metaplastic papillary tumor is rare and found as an incidental finding in the lumen of the fallopian tube during the postpartum period [19, 119, 203]. It is of microscopic size and composed of broad papillae lined by stratified and tufted epithelium with cells showing abundant eosinophilic cytoplasm (\bigcirc *Fig.* 11.32). The nuclei do not exhibit malignant features. It is not clear whether this lesion is a papillary metaplastic proliferation or small atypical proliferative (borderline) serous tumor associated with pregnancy. Regardless, the behavior appears benign.

Cystadenomas have been reported but are rare. Although the topic of whether or not atypical proliferative (borderline) tumors are benign has been debated in the literature, these tumors are included in the benign neoplasms section of this chapter for simplicity. Rare atypical proliferative (borderline) serous, endometrioid, and clear cell tumors of the fallopian tube have been reported. The literature is too limited to predict their outcome; however, behavior similar to their ovarian counterparts would be anticipated. Atypical proliferative (borderline) mucinous tumors have been described, but such cases should be rigorously evaluated to exclude the likely possibility that they represent secondary involvement of the fallopian tubes from a non-ovarian site.

Leiomyoma and Adenomyoma

Leiomyoma is the most common mesenchymal tumor of the fallopian tube; however, these tumors are much less common than uterine leiomyomas. They are usually small and grossly and microscopically similar to those found in the uterus and other gynecologic sites, and they can undergo similar degenerative changes. Rarely, benign glands and smooth muscle may be so intimately involved in a tumor that a diagnosis of adenomyoma may be warranted; however, these may arguably represent endometriosis with smooth muscle metaplasia ("endomyometriosis") or the so-called uterine-like mass.

Other Benign Mesenchymal and Mixed Epithelial–Mesenchymal Tumors

Although adenofibromas producing clinical masses are uncommon, those of microscopic size are not infrequent. In one consecutive series of fallopian tubes unassociated with tubo-ovarian malignancy or inflammatory disorders, and in which all tubal tissue was submitted for histologic examination, adenofibromas were found in 30% of cases [26]. In that study, the majority were <0.3 cm in size, and only a small subset were >1 cm. All arose in the fimbria. Some may be synchronously associated with an ovarian adenofibroma. Histologically, fallopian tube adenofibromas resemble their ovarian counterparts, with admixed epithelial and mesenchymal components () Fig. 11.33). The epithelial component may contain papillary clefting and is frequently cystic or composed of small round tubules. Most tumors are of serous histologic type, but a minority of the tumors are of endometrioid type [7]. The mesenchymal component is hypercellular, densely fibrotic, or hyalinized. In lesions <0.1 cm in size, an epithelial component may be absent, and the diagnosis of an early adenofibroma may be suggested because of a patch of cellular spindled stroma with a subepithelial arrangement.

Fig. 11.33

Adenofibroma. Note the biphasic architecture with cellular fibromatous stroma and round glands lined by a single layer of bland cuboidal epithelium. Other cases may be predominantly composed of round and blunted papillae with cleft-like architecture or have an abundant component of tubules

Cystadenofibroma, hemangioma, lipoma, chondroma, angiomyofibroblastoma, angiomyolipoma, and neural tumors are rare but have been reported. Their microscopic appearances are similar to their counterparts elsewhere in the body.

Teratoma

Tubal teratomas are rare. Clinically, a patient with a tubal teratoma usually is nulliparous and in the fourth decade. Grossly, the tumors are located most frequently in the lumen, often attached by a pedicle to the inner tubal wall. They may, however, be intramural or attached to the serosa. On section, they are more often cystic than solid and may be small (1-2 cm in diameter) or large (10-20 cm in diameter). As with their ovarian counterparts, ectodermal, mesodermal, and endodermal tissues are represented by mature elements. Most are in the form of a dermoid cyst. Rare teratomas consisting entirely of mature thyroid tissue have been described in the tube of women without clinical hyperthyroidism. Only rare cases of immature teratoma of the fallopian tube have been reported, including a mixed germ cell tumor in which one of the components was an immature teratoma [144]. Although ovarian teratomas appear to originate from abnormally developing ova, the pathogenesis of fallopian tube teratomas is unclear.

Malignant Neoplasms

Carcinoma

The history of the discovery and evolution about knowledge of carcinoma of the fallopian tube during the nineteenth and twentieth centuries has been reviewed elsewhere [244] and will not be repeated here. In the recent past, "carcinoma *in situ*" of the fallopian tube was considered uncommon since the majority of patients with fallopian tube carcinoma presented with advanced stage disease. Therefore, at the time of presentation, most tumors were of bulky size, and patients had symptomatic disease. Over the last several years, early tubal carcinomas (i.e., those that are commonly of microscopic size and clinically occult) have become diagnosed more frequently due to complete histologic examination of all fallopian tube tissue from prophylactic bilateral salpingooophorectomy specimens.

Clinical Features

Primary adenocarcinoma of the tube is uncommon, and it has been estimated to account for 0.7–1.5% of invasive malignancies of the gynecologic tract [21, 190]. However, the true frequency is difficult to determine, partly because some fallopian tube carcinomas might be misclassified as "ovarian" (*see below*). The incidence of fallopian tube carcinoma is 0.41 per 100,000 women in the USA [222].

Tumors with "carcinoma in situ"/intraepithelial carcinoma and small tumors with microscopic invasion are usually asymptomatic and more commonly seen as occult findings in prophylactic bilateral salpingo-oophorectomy specimens (see Occult Disease in > Prophylactic Bilateral Salpingo-Oophorectomy Specimens section below for details regarding clinical presentation). They may be occasionally detected when tumor cells exfoliate into the fallopian tube lumen and are then found in endometrial or endocervical biopsies/curettages or Pap smears. In such instances, a fallopian tube origin may not be clinically evident at first (and sometimes not even grossly evident at the time of hysterectomy), and further clinical evaluation is needed to eventually identify the true origin in the tube. Likewise, in rare cases, occult invasive tubal carcinoma may present as a distant metastasis (e.g., malignant pleural effusion or metastatic carcinoma of unknown primary site in a supraclavicular lymph node).

Most women with symptomatic tumors are between 50 and 80 years of age, with the mean age in large studies ranging from 56 to 63 years [8, 98, 202, 222]. Tubal malignancies in women younger than age 40 years are

very uncommon. Ninety percent of patients are white, non-Hispanic. A substantial proportion of women are nulliparous or have a previous history of infertility or pelvic inflammatory disease. Some patients have had a previous malignancy, usually breast carcinoma. A small percentage of patients have a synchronous tumor in another gynecologic site. The most common symptoms and signs are abnormal uterine bleeding/vaginal discharge, abdominal/pelvic mass, abdominal distention, and abdominal pain; however, a small subset of cases will be detected as an incidental finding as part of another gynecologic disorder [8, 17, 185]. Between 5% and 14% of women have ascites at the time of presentation [17, 66]. The classic symptom complex hydrops tubae profluens (intermittent colicky abdominal pain relieved by sudden discharge of watery fluid per vagina) is only present in a very small percentage of patients. Serum CA-125 is elevated in most but not all patients. Some patients have an elevated serum β-hCG level, which has been attributed to ectopic production. A subset of patients have tumor in endometrial biopsies/curettages or Pap smears. Because of the rarity of fallopian tube carcinoma, as well as the clinical presentation that simulates an ovarian tumor, a correct preoperative diagnosis of fallopian tube carcinoma is uncommon. Rare patients can have an associated paraneoplastic syndrome [153, 213].

In symptomatic cases, women with *BRCA*-associated tumors present at an age slightly younger than those with sporadic tumors, and both patient groups have similar clinicopathologic features; however, information in the literature is too limited to make definitive conclusions regarding prognostic differences [38, 143].

FIGO Stage

The staging system for fallopian tube carcinoma is that of the International Federation of Gynecology and Obstetrics (FIGO), which is primarily based on surgical pathology findings. Tubal intraepithelial carcinoma (TIC) represented stage 0 disease prior to the Seventh Edition of the AJCC Cancer Staging Manual; however, stage 0 no longer exists in the current system. With stage I tumors, disease is confined to the fallopian tube (\bigcirc *Fig.* 11.34). Involvement of other pelvic sites represents stage II, and with stage III, tumor involves the peritoneum outside of the pelvis. Finally, distant metastases are classified as stage IV. Details are listed in \bigcirc *Table 11.2.*

The staging terminology for cases with TIC and only positive washings is unclear. Some clinicians consider this scenario FIGO stage 0 (prior staging system) while other authors have designated this stage IC. As TIC can be associated with disease on ovarian or peritoneal surfaces

(especially, since many TICs are located in the fimbriated end of the tube and, therefore, have direct access to the peritoneal cavity), one can speculate whether TICs with only positive washings should be considered greater than stage 0 (prior staging system).

It has been suggested that intraluminal masses without invasion qualify as neither stage 0 (prior staging system) nor stage IA [8]. Also, because of observed differences in prognosis for stage I fallopian tube carcinomas with different depths of invasion into the wall (similar to other abdominal/pelvic organs with a muscular wall), it has been recommended that the FIGO stage should be modified since such cases are not appropriately represented by the current version of the FIGO staging system. Alvarado-Cabrero et al. have proposed that stage I cases should be divided into substages IA-0 (intraluminal masses without invasion into lamina propria), IA-1 (invasion into lamina propria but not muscularis), and IA-2 (invasion of muscularis) [8]. As it has also been suggested that carcinomas in the fimbriated end without invasion have a worse prognosis than carcinomas invading the wall of the tube because of direct access to the peritoneal cavity, it has been proposed that the FIGO system should be modified since the former are not represented by the current version [7, 8]. This proposed stage would be designated I(F).

The majority of patients with symptomatic disease have advanced stage disease at presentation (stage >I). In the largest clinicopathologic study using hospital-based cases by Baekelandt et al., the distribution of stage was as follows: stage 0 (6%) (prior staging system), stage I (27%),

Table 11.2

International Federation of Gynecology and Obstetrics (FIGO) staging system for fallopian tube carcinoma^a

Stage l	Growth limited to fallopian tubes
	IA: Growth limited to one tube with extension into submucosa ^b and/or muscularis but not penetrating serosal surface; no ascites
	IB: Growth limited to both tubes with extension into submucosa and/or muscularis but not penetrating serosal surface; no ascites
	IC: Tumor either Stage IA or Stage IB with extension through or onto tubal serosa or with positive ascites/peritoneal washings
Stage II	Growth involving one or both fallopian tubes with pelvic extension
	IIA: Extension and/or metastases to uterus and/or ovaries
	IIB: Extension to other pelvic tissues
	IIC: Tumor either Stage IIA or IIB and with positive ascites/peritoneal washings
Stage III	Tumor involving one or both fallopian tubes with peritoneal implants outside pelvis and/or positive retroperitoneal or inguinal lymph nodes. Superficial liver metastasis equals stage III. Tumor appears limited to true pelvis but with histologically proven malignant extension to small bowel or omentum
	IIIA: Tumor grossly limited to true pelvis with negative lymph nodes but with histologically confirmed microscopic involvement of abdominal peritoneal surfaces
	IIIB: Tumor involving one or both tubes with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Lymph nodes are negative
	IIIC: Abdominal implants >2 cm in diameter and/ or positive retroperitoneal or inguinal lymph nodes
Stage IV	Growth involving one or both fallopian tubes with distant metastases. If pleural effusion is present, tumor cells must be present to be Stage IV. Parenchymal liver metastasis equals Stage IV

From Pettersson with slight modifications [186]

^a Stage 0 does not exist in the 7th Edition of the AJCC Cancer Staging Manual

^b "Submucosa" is interpreted as meaning lamina propria

stage II (22%), stage III (35%), and stage IV (12%) [17]. These results are similar to those of other large hospitalbased or population-based studies, which have found the percentage of stage I cases to be 30–56% [96, 98, 202, 222]. The true stage distribution of all fallopian tube carcinomas in the general population is difficult to determine because of the existence of two patient populations, which are usually not included together in the same studies – patients with asymptomatic tumors (i.e., occult tubal carcinomas in prophylactic bilateral salpingo-oophorectomy specimens from women with an increased genetic risk for carcinoma) and those with symptomatic tumors (i.e., women with bulky tumors and advanced stage disease who may not be suspected of having an increased genetic risk for carcinoma).

Intraoperative and Gross Features

Bilaterality is infrequent (3-13% of cases) [8, 17, 98, 222]. The average tumor size is 5 cm (range, 0.2–10 cm) [8]. The fallopian tube is dilated in slightly over one half of cases, which intraoperatively can be mistaken for a hydrosalpinx, hematosalpinx, or pyosalpinx [8]. The tumor can appear as one or more yellow to tan nodules or a mass that fills the lumen (\bigcirc *Fig. 11.35*). Hemorrhage or necrosis is frequent. Most tumors are within the tubal portion (usually the distal two thirds), but a small percentage is located in the fimbriated end.

Histologic Features

Intraepithelial Carcinoma Noninvasive carcinomas of the fallopian tube have traditionally been considered "carcinoma *in situ.*" With recognition of early carcinomas

Fig. 11.35

Fallopian tube carcinoma. The cut surface is slightly heterogeneous, nodular, irregular, and yellow-tan. For comparison, the structure at the upper left is the ovary uninvolved by tumor without invasion of underlying fallopian tube stroma in prophylactic bilateral salpingo-oophorectomy specimens, the term tubal intraepithelial carcinoma (TIC) has become popular in recent years. Given the ability of TIC to spread beyond the fallopian tube without invasion of underlying stroma (*see below*), the term carcinoma *in situ* should be abandoned because it implies that there is no potential for metastasis.

Histologically, TIC is the earliest morphologically recognizable form of carcinoma. It is characterized by absence of invasion of underlying fallopian tube stroma and the presence of cytologic abnormalities that result in the fallopian tube epithelium appearing darker than adjacent normal epithelium at low-power magnification (> Fig. 11.36). In cases with invasive carcinoma in the same tube, TIC may be found directly adjacent to invasion. TIC may occur as a single focus or multifocally. The lesional epithelium is typically flat, but some degree of stratification may be seen. The luminal border may be straight or exhibit variable amounts of irregular contours and hobnail morphology. With increased stratification, small tufts of detached cells can be found within the tubal lumen. At high-power magnification, the lesional cells lack cilia and show variable combinations of nuclear enlargement, increased nuclear-to-cytoplasmic ratios, hyperchromasia or irregular chromatin distribution, loss of polarity, prominent nucleoli, and mitotic figures (> Fig. 11.37). Nuclei may be oval or columnar but are frequently round.

The lesional cells of TIC show secretory cell differentiation [140]. Also, they cytologically resemble the cells of high-grade serous carcinoma. For these reasons, as well as what is known about the pathogenic relationship between TIC and invasive high-grade serous carcinoma (*see below*), most TICs should be considered as being of serous histologic type. Therefore, the diagnostic terms "tubal serous intraepithelial carcinoma" and "tubal intraepithelial carcinoma" should usually be considered synonymous. However, rare endometrioid TICs have been reported [113].

Before diagnosing an incidental lesion as TIC in a routine specimen, it is necessary to submit all remaining fallopian tube tissue for histologic examination as invasive carcinoma can be of small size.

Tubal dysplasias have been described in the literature, and the clinical significance of such lesions is unclear. Furthermore, standardized criteria and terminology, as well as reproducibility studies, have not been published. Accordingly, use of the diagnostic term "dysplasia" is discouraged. For worrisome atypical mucosal lesions of the fallopian tube which do not entirely qualify as TIC based on a combination of histologic and immunohistochemical

Serous tubal intraepithelial carcinoma (STIC). (a) STIC is composed mostly of a flat proliferation of cells. However, at low-power magnification, STIC is visible because of the thicker and darker epithelium (*arrowheads*) compared with adjacent normal tubal epithelium (*arrow*). (b) Abrupt transition between STIC and normal tubal epithelium

features (*see below*), one option for handling such problematic cases is to use a descriptive diagnosis with a comment that the lesion is concerning for but not sufficiently diagnostic of TIC.

Invasive Carcinoma Some otherwise conventionalappearing high-grade serous carcinomas within the lumen of the fallopian tube may be small without enlargement of the fallopian tube and lack invasion of the underlying tubal stroma. Such morphology in occasional cases can overlap with the upper morphologic limit of TIC, especially when the latter shows an increased degree of stratification. In such cases, the diagnostic threshold

Fig. 11.37

Serous tubal intraepithelial carcinoma (STIC). (a) The lesional cells can be hyperchromatic with high nuclear-tocytoplasmic ratios, stratification, and loss of polarity (*upper half of photograph*), or they may show enlarged and round nuclei with vesicular chromatin, nucleoli, and mitotic figures (*lower half of photograph*). (b) Comparison between normal tubal epithelium (*upper half of photograph*) and STIC (*lower half of photograph*)

between TIC versus a small intraluminal high-grade serous carcinoma without invasion of underlying fallopian tube stroma is subjective and varies between authors [113, 244]. However, some authors have suggested that intraluminal masses without invasion qualify as neither stage 0 (prior staging system) nor stage IA (*see FIGO Stage above*) [8].

Some invasive carcinomas may be of small volume. As these may not be clinically evident, and in order to assess the possibility of the fallopian tube being a primary site of occult disease, it is important to submit all remaining fallopian tube tissue from grossly unremarkable tubes for histologic examination in women presenting with metastatic high-grade adenocarcinoma of unknown primary site.

The histologic types and appearances of invasive fallopian tube carcinoma are similar to its ovarian counterparts. In the largest clinicopathologic study using hospital-based cases, the distribution of histologic types was as follows: serous (80%), adenocarcinoma, not otherwise specified (10%), endometrioid (7%), clear cell (2%), mucinous (2%), and mixed serous-mucinous (1%) [17]. Most fallopian tube carcinomas are poorly differentiated, and well-differentiated tumors are very uncommon. Standardized grading schemes for fallopian tube carcinoma have not been implemented. However, we apply the same grading schemes as used for the ovary (i.e., low-versus high-grade for serous, FIGO uterine criteria for endometrioid, etc.).

The majority, if not all, tubal serous carcinomas are histologically indistinguishable from high-grade serous carcinomas of the ovary and include broad papillae with epithelial stratification, irregular slit-like spaces with micropapillary tufting, invasion by solid nests of variable size or sheets of tumor cells, necrosis, and psammoma bodies (\bigcirc *Fig.* 11.38) [8]. The nuclei are high grade, characterized by nuclear enlargement, hyperchromasia or irregular chromatin distribution with prominent nucleoli, irregular nuclear membranes, and abundant mitotic figures. TIC may be found adjacent to invasive carcinoma.

Most endometrioid carcinomas are grade 2 or 3, but some are grade 1 [166, 194]. They may resemble conventional endometrioid carcinomas as seen in the endometrium, including squamous differentiation and villoglandular architecture, but oxyphilic types, sex cordlike appearances, and spindled epithelial cells may be seen. In some cases, associated endometriosis is present. Benign stromal osseous metaplasia can be seen in a minority of cases. Almost one half of cases have an appearance resembling female adnexal tumor of wolffian origin (FATWOlike type) [53, 166]. Independent primary endometrioid carcinomas can synchronously arise in the fallopian tube and uterus [49].

Clear cell and transitional cell carcinomas resemble those seen in the ovary [8, 130]. Other rare histologic types include undifferentiated, small cell neuroendocrine, lymphoepithelioma-like, mixed serous-transitional cell, squamous cell, adenosquamous, hepatoid, glassy cell, and giant cell carcinomas [8, 10, 42, 99]. Mucinous carcinomas with a synchronous endocervical adenocarcinoma have been described, but such cases should be rigorously evaluated to exclude the likely possibility that they represent secondary involvement of the fallopian tubes from

G Fig. 11.38

Invasive high-grade serous carcinoma. (a) Complex papillae with stratified epithelium producing irregular slit-like spaces and small epithelial tufts. (b) The nuclei are highgrade with abundant mitotic figures. Note enlarged nuclei with vesicular chromatin and nucleoli. In other cases, the nuclei may be hyperchromatic rather than vesicular

the endocervix. Unlike the ovary, low-grade serous carcinomas typically are not seen in the fallopian tube.

Immunohistochemical Features

Although some cases of TIC may be diagnosed solely on histologic features without the need for immunohistochemistry, immunostains are helpful in establishing the diagnosis in problematic cases. TIC diffusely and strongly expresses p53 (\bigcirc *Fig.* 11.39); however, 21% of TICs did not overexpress p53 in one study [217]. The Ki-67 proliferation index is usually markedly elevated (\bigcirc *Fig.* 11.39). In one study, the mean Ki-67 labeling index was 72% (range: 40–95%) [113]. Also, p16, which is diffusely and

Immunohistochemical features of serous tubal intraepithelial carcinoma. (a) H&E. (b) Diffuse expression of p53. (c) Elevated Ki-67 proliferation index. (d) Diffuse expression of p16

strongly expressed in endometrial serous carcinomas and many ovarian high-grade serous carcinomas, is occasionally expressed with a strong diffuse pattern in TIC in our experience. Of note, the diffuse patterns of expression of p53 and p16 show nearly all lesional cells being positive as opposed to a patchy pattern of staining in which substantial numbers of both negative and positive cells are present.

Invasive high-grade serous carcinomas usually show diffuse expression of WT-1. It should be noted, however, that expression is not restricted to invasive carcinomas, as normal fallopian tube epithelium and TIC also show WT-1 expression. Expression of ER and PR is variable. Although most cases overexpress p53, the exact extent of expression has not been adequately detailed in the literature. Immunohistochemical data are limited for endometrioid carcinomas, but in our experience, WT-1 and p53 can be diffusely expressed in some cases.

Treatment and Prognosis

Tumor usually spreads in an intraperitoneal, lymphatic, and hematogenous manner. At presentation, lymph node metastases are frequent, the lymph node groups most frequently involved are those in para-aortic and pelvic sites, and inguinal and supraclavicular lymph nodes can be involved as well; however, lymph node metastases may be present even when it appears that the tumor is limited to the tube [8, 17, 55, 59, 127, 128].

In the largest studies of fallopian tube carcinoma, patients have been treated in various fashions, but the most important prognostic factor is stage [8, 17, 98, 185, 198, 202]. The overall 5-year survivals for fallopian tube carcinoma for all stages combined range from 43% to 56% between studies [17, 96, 202]. In the largest clinicopathologic study using hospital-based cases, the 5-year survivals were as follows: stage 0 (88%) (prior staging system), stage I (73%), stage II (37%), stage III (29%), and
stage IV (12%) [17]. These 5-year survivals are similar to those of other large studies [96, 98, 161, 185, 202]. It is also noteworthy that stage 0 disease (prior staging system) does not guarantee a cure, as the 5-year survivals for stage 0 (prior staging system) range from 75% to 91% between studies [17, 66, 209]. However, these studies do not provide details specifying whether the entire fallopian tube was submitted for histologic examination in those cases in order to exclude microscopic invasion (i.e., stage IA). For details regarding behavior of stage 0 cases (prior staging system) in the context of prophylactic bilateral salpingo-oophorectomy specimens, see the respective section below.

Alvarado-Cabrero et al. showed that subcategorization of stage I cases based on depth of invasion was prognostically significant [8]. In their study, patients with substages IA/B-0 (intraluminal masses without invasion into lamina propria) and IA/B-1 (invasion into lamina propria but not muscularis) had a better diseasefree survival than those with substage IA-2 (invasion of muscularis), which was a statistically significant difference. They also demonstrated that patients with stage I(F) (carcinomas in the fimbriated end without invasion) had a poorer survival than those with substages IA/B-0 and IA/B-1, as well as that the survival for stage I(F) was similar to stages IA-2 and IC. These aspects have not been extensively studied in the literature. Two other studies also showed that differences in depth of invasion in the wall of the fallopian tube in stage I cases were prognostically significant while another study demonstrated that it was not [14, 17, 185].

Presence/amount of residual disease after surgery is a poor prognostic factor [17, 185, 202]. Closure of the fimbriated end (hydrosalpinx-like, hematosalpinx-like, or pyosalpinx-like gross appearance) has been shown to be a favorable prognostic factor on univariate but not multivariate analysis [8, 17]. Disagreement exists between studies regarding whether or not histologic grade, vascular invasion, age, or ascites is prognostically significant [8, 17, 98, 185, 202]. Histologic type has not been shown to be of prognostic importance [8, 17].

Treatment of fallopian tube carcinoma should consist of cytoreductive surgery and combination platinum/ taxane chemotherapy, and as response to this chemotherapy regimen is analogous to that in patients with ovarian carcinoma, fallopian tube carcinoma should be treated similarly to ovarian carcinoma [17, 161, 177, 198]. In patients with a pre-chemotherapy elevated serum CA-125 level, this marker can be used to monitor disease for response and progression. In the study by Baekelandt et al., the median progression-free survival for the entire cohort was 32 months [17]. In that study, patients were not postoperatively treated in a uniform fashion. In a study of patients who received postoperative combination platinum/taxane chemotherapy, carcinoma recurred in 74% of patients with stage III or IV disease by 33 months [161]. In the study by Baekelandt et al., the pelvis was the most common site of recurrence, followed by upper abdomen, retroperitoneal lymph nodes, liver, pleura, vagina, lungs, supraclavicular lymph nodes, groin lymph nodes, brain, bone, breast, and adrenal gland in descending order [17].

Given the association of fallopian tube carcinoma with germline *BRCA* mutations, genetic counseling should be considered for all new diagnoses of fallopian tube carcinoma. For treatment and prognosis of occult fallopian tube carcinoma in prophylactic bilateral salpingo-oophorectomy specimens, see the respective section below.

Occult Disease in Prophylactic Bilateral Salpingo-Oophorectomy Specimens

At least 10% of ovarian carcinomas are hereditary rather than sporadic, and approximately 90% of the former have mutations of the BRCA1 or BRCA2 gene. Carriers of germline BRCA1 and BRCA2 mutations have 39-62% and 11-27% lifetime risks for ovarian carcinoma, respectively, and those risks (cumulative risk) increase over time from ages 40 to 80 years [9, 72, 75, 126]. Women with such mutations are also at risk for peritoneal and fallopian tube carcinoma. The exact proportion of fallopian tube carcinomas that is hereditary is not clear; however, 16-43% of patients with tubal carcinoma have shown BRCA germline mutations [16, 38, 143]. Given the significant risk of ovarian carcinoma for patients with BRCA mutations, prophylactic salpingo-oophorectomy recommended by age 40 years, and such surgical procedures have been shown to significantly reduce the risk of pelvic carcinoma [1, 117]. This risk is not reduced to 0% since a small percentage of patients subsequently develop peritoneal carcinomas.

● *Table 11.3* highlights important features of patients with carcinomas detected in prophylactic salpingo-oophorectomy specimens. The frequency of finding a malignancy of the ovary, fallopian tube, or peritoneum during surgery or in the surgical specimen varies from 0% to 14% between studies. However, among 1,662 patients from 13 studies, carcinoma is found in 4% of cases (mean). The majority of carcinomas are primary tumors in the fallopian tube or ovary, but a very small proportion is due to primary peritoneal carcinomas or metastatic breast carcinoma in the ovary. Comparing just carcinomas in the fallopian tube and ovary, more are found in the tube compared with the ovary (64% versus 36%, respectively).

The percentage of carcinomas in the tube is even greater when considering only studies that submitted all tubal tissue (81% fallopian tube versus 19% ovary). Some of the earliest studies on occult carcinoma in prophylactic specimens did not remove the fallopian tube, and data from those studies are not presented here.

The mean age of patients with fallopian tube carcinoma is 53 years, which is slightly older than that of the

entire cohort undergoing prophylactic surgery (mean, 47 years). The mean age of *BRCA2* mutation-positive patients with fallopian tube carcinoma (59 years) is slightly older than that of *BRCA1* mutation-positive patients (50 years) [34, 72, 73, 95, 134, 135, 155, 158, 174, 176, 187, 191]. The proportion of patients with *BRCA1* mutations who undergo surgery is essentially twice that of those with mutations of *BRCA2*. Three percent and 2% of patients with *BRCA1* and *BRCA2* mutations, respectively, had carcinoma of the fallopian tube in the surgical specimen.

The vast majority of these carcinomas are occult, being of microscopic size and not seen intraoperatively. Most are either "carcinoma *in situ*"/intraepithelial carcinoma or invasive high-grade serous carcinoma, and in some cases TIC is found adjacent to the invasive carcinoma. Frequently, the carcinoma is located in the fimbriated end [6, 35, 73, 95, 157, 176, 187, 217]. A small proportion of carcinomas are of endometrioid histologic type. Clear cell carcinoma has been reported but is rare [95].

The invasive fallopian tube carcinomas are of variable stage but frequently stage I. Issues of interest are the behavior for cases with only TIC (+/− positive washings) and whether such patients should be treated with chemotherapy. **>** *Table 11.4* lists features of patients with TIC in prophylactic bilateral salpingo-oophorectomy specimens. Only a limited number of such cases have been reported, and the available follow-up in many is short. Of the reported cases in the literature, some have been treated with chemotherapy, including those in which the peritoneal washings were negative for tumor. Based on the few cases with available follow-up, these do not appear to behave aggressively, but more cases with longer follow-up are needed.

Since many of the invasive fallopian tube carcinomas are occult and of small volume, an important question is whether the behavior of such cases is similar to symptomatically detected carcinomas that have bulky disease. The behavior of carcinomas (other than "carcinoma *in situ*"/ intraepithelial carcinoma) in prophylactic bilateral salpingo-oophorectomy specimens is listed in **?** *Table 11.5*. Stage IA tumors in prophylactic specimens with available follow-up in the literature have not shown aggressive behavior; however, too few cases have been reported, and Fallopian tube "carcinoma in situ"/intraepithelial carcinoma in prophylactic bilateral salpingo-oophorectomy specimens:^a pathologic features, treatment, and outcome

the available follow-up is short. Advanced-stage tumors in prophylactic specimens show potential for aggressive behavior.

A portion of the fallopian tube (chiefly, the intramural segment) remains in the uterus after prophylactic bilateral salpingo-oophorectomy. In one study, it was shown that the segment of fallopian tube remaining in the hysterectomy specimen after prophylactic bilateral salpingooophorectomy had a median length of 1.2 cm (range: 0.6–1.5 cm) [85]. Despite the fact that not all tubal mucosa is removed during the prophylactic procedure, the risk for development of carcinoma in the remaining tube is probably minimal since (1) tubal carcinomas are not frequently found in the intramural segment, (2) follow-up studies of women after prophylactic bilateral salpingooophorectomy show a low frequency of subsequent pelvic carcinoma (in one study, the estimated risk of peritoneal carcinoma at 20 years after prophylactic surgery was only 4% [72]), and (3) most occult tubal carcinomas arise in the fimbriated end. Details regarding handling of prophylactic bilateral salpingo-oophorectomy specimens are provided in the section on **O** Gross Examination above.

Pathogenesis, Including Molecular Features

Serous Carcinoma Gene expression profiles of fallopian tube and ovarian serous carcinomas have been shown to be similar, implying that tumorigenesis in both organs shares related molecular pathways [229]. *p53* has been identified as an important gene in the development of fallopian tube carcinoma. Mutations have been observed in serous carcinoma, but the frequency differs between studies [97, 245]. *p53* mutations have been detected in early stage carcinoma and TIC, suggesting that mutation of this gene is an early event in carcinogenesis [140, 245].

Opinions regarding the role of *HER-2/neu* in the pathogenesis of fallopian tube carcinoma vary. One study did not detect amplification in any cases and concluded that this gene does not play a role in pathogenesis [224]. However, overexpression has been shown in other studies. One study in particular demonstrated a correlation between overexpression and advanced stage, suggesting that *HER-2/neu* may be involved in tumor progression [169]. *K-ras* mutations are frequent [160]. This finding is of interest, as mutations of *K-ras* are infrequent in

ovarian high-grade serous carcinoma; therefore, further study is warranted.

DNA cytometry and molecular genetic studies have shown that fallopian tube carcinomas are aneuploid and have a high degree of chromosomal instability, characterized by multiple gains and losses of genetic material at various loci on all chromosomes [102, 170, 182, 219]. One study demonstrated that epithelial atypia/dysplasia of the fallopian tube and TIC in risk-reducing prophylactic specimens contained chromosomal abnormalities, which implies that chromosomal instability is an early event in the pathogenesis of serous carcinoma [204]. The results of molecular genetic studies have also suggested multiple potential candidate oncogenes involved in the development of fallopian tube carcinoma [170, 219, 229].

An important molecular event involved in the development of hereditary fallopian tube carcinoma is germline mutation of *BRCA1* or *BRCA2*. These tumor suppressor genes are located on chromosomes 17 and 13, respectively. They are normally involved in transcriptional regulation of gene expression, cell cycle control, and recognition/ repair of DNA damage. *BRCA*-associated carcinomas appear to follow the "2-hit model" of tumorigenesis, as seen in other organs (i.e., patients inherit a germline *BRCA* mutation [first hit], and with somatic loss of the wild-type allele [second hit], carcinoma develops).

In one report of two patients with a BRCA1 germline mutation and serous carcinoma of the fallopian tube, both patients showed loss of the wild-type BRCA1 allele in the tumors [246]. In another report, a patient with a BRCA1 germline mutation and dysplasia of the fallopian tube exhibited loss of the wild-type BRCA1 allele [188]. Two patients in a third report had BRCA1 germline mutations and serous carcinoma of the fallopian tube, and loss of heterozygosity at multiple loci was observed on chromosome 13q, indicating that this chromosomal arm may contain tumor suppressor genes involved in the evolution of hereditary fallopian tube carcinoma [115]. Furthermore, the small number of samples of histologically normal fallopian tube epithelium from women with BRCA mutations that were analyzed in one study showed that the gene expression profile during the luteal phase of the menstrual cycle more closely resembled that of serous carcinoma compared with histologically normal samples

from the follicular phase [229]. These findings suggest that the hormonal milieu during the menstrual cycle might play a role in carcinogenesis for women with *BRCA* mutations.

The pathogenesis of invasive high-grade serous carcinoma of the fallopian tube appears to begin with TIC as the first histologically identifiable lesion in this pathway. However, a precursor lesion of TIC has recently been proposed - the p53 signature [113, 140]. This lesion is composed of histologically normal mucosal epithelium and characterized by immunohistochemical overexpression of p53, which has been defined as a linear extent of ≥ 12 consecutive secretory cells showing strong expression (according to this definition, intervening p53-negative ciliated cells are allowed) (> Fig. 11.40). In one study, 57% of p53 signatures contained a p53 mutation [140]. p53 signatures, however, have a low Ki-67 proliferation index. The mean Ki-67 proliferation index in one study was 3% (range: 0-30%) [113]. They show evidence of DNA damage, as manifested by immunohistochemical expression of γ -H2AX [113, 140]. When present, p53 signatures are usually located in the fimbriated end of the tube, and their frequency in women with BRCA mutations is similar to that of controls (10-38% versus 17-33%, respectively); however, p53 signatures are more frequent and multifocal in tubes with TIC [74, 140, 217].

A model has been suggested linking the p53 signature with TIC in which the p53 signature is the earliest step in the pathogenesis of fallopian tube carcinoma [113]. This is supported by the following: (1) p53 signatures are more common in tubes with TIC; (2) the p53 signature preferentially occurs in the same portion of the tube as TIC (fimbriated end); (3) both the p53 signature and TIC are thought to arise from the secretory cell; (4) the p53 signature, like TIC, shows p53 overexpression, p53 mutations, and evidence of DNA damage; (5) direct continuity of the p53 signature with TIC has been reported (including an identical p53 mutation in both components in one case [140]); (6) lesions histologically and immunohistochemically (Ki-67) intermediate between the p53 signature and TIC have been described; and (7) identical p53 mutations in a p53 signature and peritoneal serous carcinoma in one case have been reported [37]. In this model, the fallopian tube mucosa in the fimbriated end undergoes injury, and as a result, the secretory cell experiences DNA damage with overaccumulation of p53 protein (p53 signature). With the development of a p53 mutation, along with further cell proliferation and malignant transformation in a very small subset of women, the p53 signature then evolves into TIC. Although the p53 signature would be a common lesion in the general population regardless of BRCA status, it would, therefore, be in this

Fig. 11.40

p53 signature. (a) The tubal mucosa lacks morphologic features of intraepithelial carcinoma. (b) p53 expression is diffuse in three small segments of the mucosa (*arrows*), corresponding to (a). (c) The Ki-67 proliferation index is low in the three segments of diffuse p53 expression shown in (b). If these foci of diffuse p53 expression represented intraepithelial carcinoma, then the Ki-67 proliferation index would have been much higher (*compare with* **)** *Fig. 11.39c*)

setting that further molecular alterations would allow for the possible development of a malignant clone with the potential to transform into TIC. Women without BRCA mutations can have a p53 signature, but it is possible that germline mutations of BRCA act as a promoter for the development of TIC [74]. It should also be noted that TIC and invasive carcinoma may arise independently of a BRCA mutation. In one study, the frequency of TIC in women with a BRCA mutation was not statistically different from that of controls (8% versus 3%, respectively) [217]. At this stage of growth, the TIC is of microscopic size, but with continued cell proliferation and growth of the tumor, malignant tumor cells eventually exfoliate into the peritoneal cavity (or proximally along the lumen of the tube) or infiltrate underlying tubal stroma in the form of invasive high-grade serous carcinoma. Progressive tumor growth eventually results in increasing tumor stage and volume of disease, peritoneal spread, and metastases, including involvement of lymph nodes.

Some evidence suggests that chronic salpingitis could be an etiology and that serous carcinomas may develop on a background of atrophy [57]. Unlike the ovary, serous carcinomas of the fallopian tube do not appear to follow a dualistic model as proposed for the ovary. Thus, a low-grade pathway, in which serous adenofibroma/ cystadenofibroma evolves into atypical proliferative (borderline) serous tumor/noninvasive micropapillary (lowgrade) serous carcinoma and then invasive low-grade serous carcinoma, typically is not seen in the fallopian tube.

Endometrioid Carcinoma As endometrioid carcinoma can evolve from endometriosis and atypical proliferative (borderline) endometrioid tumors in the ovary, these pathways are plausible in the fallopian tube. In one study of 26 endometrioid carcinomas of the fallopian tube, 23% of cases were associated with adjacent endometriosis [166]. In that study, direct continuity between carcinoma and endometriosis was not observed, but that does not exclude the possibility that carcinoma arose from endometriosis and obliterated any direct connection between the two. Although the fallopian tube is not an uncommon location for endometriosis, atypical (proliferative) borderline tumors occur only rarely in this anatomic site [7].

Differential Diagnosis

Non-neoplastic Lesions Pseudocarcinomatous hyperplasia can histologically simulate carcinoma because of cribriform architecture, pseudoinvasion of the muscularis, papillae within lymphatics, and subserosal mesothelial hyperplasia (**○** *Fig. 11.11*) [43]. Patients with hyperplasia are usually premenopausal while those with carcinoma are typically postmenopausal. The tube can be enlarged in hyperplasia but does not show a mass on cross section unlike most cases of carcinoma; thus, the epithelial proliferation in hyperplasia is a microscopic finding. In contrast with carcinoma, hyperplasia usually exhibits a low mitotic index, absence of solid architecture, and a substantially lesser degree of nuclear atypia and nucleolar prominence. Acute or chronic salpingitis is usually present in hyperplasia, but some carcinomas can have an inflammatory component.

Determination of Site of Origin of Serous Carcinoma: Distinction from Ovarian/Peritoneal Primary Origin Traditionally, when carcinoma involves both the fallopian tube and ovary, the ovary has been considered the primary site given the much more frequent occurrence of primary ovarian carcinomas compared with fallopian tube primaries. Similarly, in the context of what would be conventionally considered a primary peritoneal carcinoma, involvement of the fallopian tube would generally be thought to represent secondary disease. Previously, criteria have been proposed for determining fallopian tube origin for tumors synchronously involving the tube and ovary. These criteria of Hu et al. (and subsequently modified by Sedlis) are as follows: (1) tumor arises from the endosalpinx, (2) histology of the tumor resembles tubal mucosa, (3) transition from benign to malignant epithelium, and (4) size of the fallopian tube tumor is larger than the ovarian tumor [106, 212]. As will be seen below, these criteria are nonspecific and unreliable.

It has been suggested that a subset of cases which appear to represent a primary ovarian or peritoneal highgrade serous carcinoma may actually be fallopian tube in origin. The finding of a synchronous TIC, in the setting of a synchronous ovarian or peritoneal high-grade serous carcinoma, has been proposed as indicating a fallopian tube origin [113, 125]. Lines of evidence supporting this include the following: (1) the fimbriated end of the tube is the preferred site of TIC; (2) the fimbriated end of the tube is in close proximity to the ovarian surface/peritoneal cavity; (3) intraepithelial carcinoma in the ovary or peritoneum is a rare finding; (4) early serous carcinomas in prophylactic bilateral salpingo-oophorectomy specimens from women with BRCA mutations (i.e., women who are at an increased risk for "ovarian" carcinoma) are commonly found in the fallopian tube (especially the fimbriated end) without disease in the ovary; (5) identical p53 mutations have been reported in TIC and synchronous ovarian/peritoneal high-grade serous carcinomas; and (6) identical p53 mutations in a p53 signature (see Pathogenesis, Including Molecular Features section above) and peritoneal serous carcinoma in one case have prima been reported [37].

It is possible that a small fallopian tube carcinoma can exfoliate cells onto the ovary or peritoneum, and preferential tumor growth in these secondary sites may overgrow the fallopian tube and obliterate any clues to a true fallopian tube origin in cases that do not initially appear as having arisen from the fallopian tube. Thus, the true frequency of "ovarian" carcinomas that really originated in the tube may be underestimated. In one study of consecutively accessioned pelvic serous carcinomas by Kindelberger et al. in which all fallopian tube tissue was submitted for histologic examination, 48% of cases initially interpreted as ovarian in origin contained a TIC, suggesting that a significant proportion of "ovarian" carcinomas could be of fallopian tube origin [125]. In that study, identical p53 mutations were identified in the TIC and corresponding ovarian carcinoma in five of five cases tested. Interestingly, cases with a dominant mass in the ovary have a low frequency of TIC (11%) whereas TIC is much more common (45%) in cases in which involvement of the ovary did not create a dominant mass [201]. In a study by Carlson et al., nearly half of cases that would have originally been classified as primary peritoneal serous carcinoma contained a TIC [37]. In that study, identical p53 mutations were identified in the TIC and corresponding peritoneal carcinoma in four of four cases tested.

Three possibilities may exist for cases with high-grade serous carcinoma in the ovary/peritoneum and TIC: (1) the fallopian tube is the primary lesion with secondary involvement of the ovary/peritoneum; (2) the ovary/peritoneum is the primary site with secondary involvement of the fallopian tube in the form of intraepithelial spread; and (3) both sites may be independent primaries. In cases where the primary site cannot be determined, this distinction usually will not be critical since most cases will typically be high stage, and the treatment and prognosis for a high-grade serous carcinoma simultaneously involving these sites will be similar regardless of which site is designated the primary origin [17, 161].

Determination of Site of Origin of Serous Carcinoma: Distinction from Endometrial Primary Origin Endometrial serous intraepithelial carcinoma (EIC) has been observed in association with TIC [114]. We have encountered cases of synchronous TIC and uterine malignant müllerian mixed tumor (MMMT) with a component of serous carcinoma. In these situations, the relationship between the fallopian tube and uterine tumors is not clear. Three possibilities may also exist, similar to that mentioned above: (1) the fallopian tube is the primary lesion with secondary involvement of the uterus; (2) the uterus is the primary site with secondary involvement of the fallopian tube; and (3) both sites may be independent primaries.

Other Fallopian Tube and Paratubal Neoplasms Because of the admixture of spindle cells in the epithelial component in some endometrioid carcinomas, the differential diagnosis can include malignant müllerian mixed tumor (MMMT). In general, the epithelial and mesenchymal components of MMMT, while admixed, do not show a histologic transition as opposed to the gradual transition between endometrioid glands and spindle cells in endometrioid carcinoma, and the latter has more of an orderly growth than MMMT. The degree of nuclear atypia and mitotic activity is greater in MMMT. The presence of malignant heterologous tissues would favor MMMT.

Endometrioid carcinomas with a female adnexal tumor of wolffian origin-like (FATWO-like) growth pattern can be confused with FATWO. Location within the lumen of the fallopian tube typically favors carcinoma since FATWO is usually in a paratubal location, but rare FATWOs can arise within the wall of the tube (see section ▶ Wolffian Adnexal Tumor ("Female Adnexal Tumor of Probable Wolffian Origin"; FATWO) below); however, the latter is predominantly within the muscularis as opposed to mostly occupying the lumen as in an endometrioid carcinoma. Villoglandular architecture, squamous differentiation, and endometriosis would favor carcinoma. Also, carcinoma contains larger, more conventional-appearing endometrioid glands. The degree of glandular confluence and nuclear atypia are usually greater in carcinoma than FATWO. The latter typically has more of an admixture of patterns, including open or closed tubules and sieve-like, solid, and spindled architecture; however, these features can be seen in FATWO-like endometrioid carcinomas. Calretinin is often positive in FATWO but occasionally may be negative; however, most carcinomas are negative. Carcinomas would be expected to express CK7, EMA, ER, and PR and be negative for inhibin. FATWO occasionally expresses CK7 and inhibin. ER, PR, and EMA are frequently negative in FATWO, but expression may occasionally be seen.

Sarcomas and Mixed Epithelial–Mesenchymal Tumors

Pure sarcomas of the tube may occur, and the mesenchymal component of mixed epithelial–mesenchymal tumors can be sarcomatous. Mixed epithelial–mesenchymal neoplasms in which the mesenchymal component is malignant and the epithelial component is benign are designated adenosarcoma whereas those in which both components are malignant are classified as malignant müllerian mixed tumor (MMMT; carcinosarcoma).

Pure sarcomas may be histologically subtyped if sufficient differentiation is present. Leiomyosarcomas are perhaps the most common type and may arise from the tube or broad ligament [110]. However, some may actually represent gastrointestinal stromal tumors arising outside of the gastrointestinal tract [77]. Other gynecologic-specific sarcomas, such as primary endometrioid stromal sarcoma arising in the tube, are rare [40]. Chondrosarcoma, malignant fibrous histiocytoma, and embryonal rhabdomyosarcoma have been described.

There are only a small number of tubal MMMTs in the literature, most of which are individual case reports [36, 77, 109]. Nearly all women are postmenopausal. They may have watery or bloody vaginal discharge and abdominal pain with signs of peritoneal spread. Grossly, the tumors distend the tube, and by the time of discovery, the majority of women have a pelvic mass with spread to adjacent pelvic and abdominal structures. The ovary must be identified clearly to rule out an origin in that organ. The grossly dilated tube when opened reveals an irregular mucosal surface with areas of necrosis and hemorrhage. Microscopically, distinct carcinoma and sarcoma components should be identifiable and intimately admixed with one another. The histologic appearance (**)** Fig. 11.41) is essentially identical to MMMTs of the uterus and ovary. Malignant glandular or squamous foci (or both) lie in an atypical mitotically active spindle or round cell background of sarcoma. In about half the cases, the sarcoma component may consist only of malignant elements homologous to the tube, such as smooth muscle or stromal

 Fig. 11.41
 Malignant müllerian mixed tumor. Intimate admixture of malignant epithelial and mesenchymal components

cells, but commonly there are foci of malignant cartilage, osteosarcoma, or rhabdomyosarcoma. Areas of TIC may be present adjacent to the main tumor mass, especially in the fimbriated end [36, 81]. The histology of metastases from MMMTs may be composed of carcinoma, sarcoma, or a mixture of both. The main tumor in the differential diagnosis of MMMT is a poorly differentiated endometrioid carcinoma with spindle cell features (see above section on Differential Diagnosis of Carcinoma). MMMT of the fallopian tube behaves aggressively, but prognosis is dependent on stage. Given that the experience is limited with tubal MMMT and that patients have been treated variably in the literature, standardized current treatment recommendations are not available. Other biphasic malignant tumors, such as adenosarcoma, are rare.

Metastatic Tumors/Secondary Involvement

Secondary involvement of the fallopian tube by carcinoma is much more common than primary tubal carcinoma, and metastatic carcinomas involving the tube are usually of ovarian or endometrial origin; however, metastases from the endocervix occur as well. Metastatic gynecologic or non-gynecologic carcinomas involving the pelvis typically involve the tubal serosal surface. Secondary involvement of the serosa in the form of implants from an ovarian atypical proliferative (borderline) serous tumor or by disseminated peritoneal adenomucinosis in the clinical syndrome of pseudomyxoma peritonei can occur too. In addition, lymphatic metastases may involve the mucosa or muscularis. Low-grade endometrial stromal sarcoma may involve the tubes by the extension of worm-like tongues of tumor along tubal lymphatics. Hematogenous metastases from breast carcinomas or other extra-pelvic tumors also may occur. Rarely, displaced benign endometrial tissue can be seen in the veins of the fallopian tube and should not be mistaken for metastatic carcinoma. On occasion, squamous carcinoma of the uterine cervix may spread in an in situ manner to involve the endometrial cavity, tubes, and even the ovarian surface [189]. The presence of tumor in the lumen of the fallopian tube in cases of endometrial serous carcinoma with metastases in the peritoneum (without myoinvasion or lymph-vascular space invasion in the uterus) suggests that the tubal lumen serves as a conduit for tumor spread [220]. In primary ovarian carcinoma, luminal groups of tumor cells may implant onto endosalpingeal surfaces and simulate TIC or early invasive primary tubal carcinoma. The distinction of fallopian tube versus ovarian origin for serous carcinoma is discussed in the above section on differential diagnosis of carcinoma.

Lymphoma

Primary tubal lymphoma is rare and is associated almost invariably with simultaneous involvement of the ipsilateral ovary [233]. Undifferentiated carcinoma and other small round blue cell tumors must be ruled out with appropriate immunohistochemical stains. For details, see O Chap. 21, Hematologic Neoplasms.

Gestational Trophoblastic Disease of the Fallopian Tube

Trophoblastic tubal lesions are exceedingly uncommon. Patients have risk factors for ectopic pregnancy such as prior salpingitis and tubal occlusion [165]. The clinical presentation of a tubal hydatidiform mole or choriocarcinoma is similar to that of a tubal ectopic pregnancy; thus, rarely, an apparent ectopic pregnancy will prove to be a mole or choriocarcinoma. Hydatidiform moles usually occur as isolated growths but may be associated with intrauterine pregnancy. The histologic appearance resembles complete or partial moles as seen in the uterus. However, tubal moles are frequently overdiagnosed because ectopic pregnancies in the fallopian tube commonly have an exuberant extra-villous trophoblastic proliferation [33, 211]. Intraoperatively, the appearance of a tubal choriocarcinoma may be that of a large, hemorrhagic, and fleshy mass mostly destroying the tube. Histologically, the malignant trophoblastic proliferation resembles uterine choriocarcinoma. Response to modern chemotherapy in general has been excellent. Lesions of intermediate trophoblast, including placental site nodule, placental site trophoblastic tumor, and epithelioid trophoblastic tumor, are rare (see Ochap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions) [18, 111, 168, 179, 225].

Paratubal Lesions

Adrenal Rests

If a careful search is made, adrenal cortical rests may be found in the broad ligament in more than 20% of women. They lie adjacent to the ovarian vein and just beneath the peritoneum. Grossly, they appear as yellow nodules, but they may be obscured by fat. Medullary tissue is absent, but microscopically all three cortical layers are recognizable (\bigcirc *Fig. 11.42*). This accessory tissue may hypertrophy secondary to adrenal destruction or may, rarely, give rise to a functional or nonfunctional cortical adenoma [207, 239].

Fig. 11.42

Adrenal rests. They typically show similar cortical architecture and cells types as seen in the adrenal gland

Paratubal Cysts

Paratubal cysts can be small or large. They have been classified based on their presumed origin: paramesonephric (müllerian), mesothelial, or mesonephric (wolffian). Differentiation may be difficult because of compression and atrophy of the lining cells. Those of paramesonephric type are the most common. In one study of paratubal cysts, 76% were paramesonephric, 24% were mesothelial, and none of the cysts were mesonephric [205]. The hydatid of Morgagni is by far the most common paramesonephric cyst. Grossly, it is attached to one of the fimbriae (> Fig. 11.3). It is ovoid or round, 2–10 mm in diameter, and contains clear serous fluid surrounded by a thin translucent wall. Microscopically, it is lined by epithelium resembling fallopian tube mucosa (including ciliated and non-ciliated cells), may have small epithelial-covered plicae projecting into the lumen, and may contain a thin smooth muscle wall (> Fig. 11.43). However, the cells lining the cyst can be flattened. Mesothelial cysts typically are lined by cuboidal or flattened cells and have a thin wall containing fibrous stroma. They lack the ciliated cells and thin plicae seen in paramesonephric cysts. Based on the available literature, it is not entirely clear what the specific histologic features of mesonephric cysts are.

Common differential diagnostic problems, which are usually of no clinical importance, are distinguishing a hydatid cyst of Morgagni from a serous cystadenoma and hydrosalpinx. In some cases, distinction from a serous cystadenoma may not be possible; however, hydatid cysts frequently contain a smooth muscle wall while the wall of a serous cystadenoma contains more fibromatous stroma than is typically seen in a hydatid cyst. Thin fallopian tubelike plicae, if present, favor a hydatid cyst rather than cystadenoma. In cases where the fallopian tube cannot be clearly discerned, distinction of a hydatid cyst from hydrosalpinx in which the fallopian tube is markedly distorted might be impossible since both can contain a thin smooth muscle wall and thin plicae lined by epithelium resembling that of the fallopian tube.

Wolffian Adnexal Tumor ("Female Adnexal Tumor of Probable Wolffian Origin"; FATWO)

This small group of distinctive tumors is described as located either within the leaves of the broad ligament, the mesosalpinx, or in the ovarian hilus (these tumors are also discussed in **O** Chap. 17, Nonspecific Tumors of the Ovary Including Mesenchymal Tumors) [58, 116]. However, rare tumors can arise within the wall of the fallopian tube without growth in the lumen (**O** *Fig. 11.44*). Patients range in age from 19 to 83 years (mean ranges from 42 to 45 years between studies). Either they have abdominal pain and a palpable mass, or the tumor is discovered as an incidental finding. The tumor is typically unilateral and localized without disseminated disease. The lesions measure from 0.8 to 20 cm in greatest dimension (mean, 6 cm) and are solid and lobulated with gross encapsulation. The cut surface is gray-yellow or tan,

Fig. 11.43

Paratubal cyst. The cyst is thin and lined by bland tubal epithelium as seen in normal fallopian tubes. Focal residual plicae may be present and the consistency may be firm, rubbery, or friable. Cysts or calcification may be present.

The microscopic appearance is variable. The tumors usually show a combination of growth patterns, including tubular (open or solid tubules), cystic, diffuse/ solid, lobulated, sieve-like/retiform, and adenomatoid (**)** *Fig. 11.45*). The tubal lumens and sieve-like spaces frequently contain eosinophilic, colloid-like material. The cells are cuboidal, flat, and/or spindled and have scant cytoplasm. The nuclei are typically bland, and the mitotic index is usually low. The stroma is either fibrous or hyalinized. FATWO typically expresses pan-cytokeratin and CD10. Calretinin, low molecular weight cytokeratin (CAM5.2), and androgen receptor are often positive but

Fig. 11.44

Female adnexal tumor of wolffian origin (FATWO) in nonclassic location. (a) The tumor is located within the wall of the fallopian tube rather than in a paratubal site but is not intraluminal. (b) The tumor exhibits the same architectural patterns seen in paratubal locations

Fig. 11.45

Female adnexal tumor of wolffian origin (FATWO). (a) Open tubules. (b) Closed elongated tubules (note focally hyaline stroma). (c) Sieve-like pattern

occasionally may be negative. Expression of calretinin is usually diffuse. Tumors occasionally express CK7 and inhibin. Expression of CK7 is typically focal while the pattern with inhibin is variable, but the latter can be focal too. ER, PR, and EMA are frequently negative but expression may be seen on occasion. CK20 is typically negative.

Patients have been treated surgically, usually with a benign outcome. Malignant behavior is uncommon and includes multiple local recurrences and fatal metastases [31, 52]. It is difficult to predict which cases will exhibit malignant behavior. The tumors that demonstrate malignant behavior generally have nuclear atypia and mitotic activity; however, bland histology has been noted in some FATWOs that exhibit malignant behavior.

The differential diagnosis includes the FATWO-like variant of tubal endometrioid carcinoma (see above section on **>** Differential Diagnosis of **>** Carcinoma). Many of the histologic and immunohistochemical features of FATWO overlap with those of Sertoli cell tumor; however, the admixture of multiple growth patterns (particularly cystic architecture with a sieve-like pattern) and cell types in FATWO is generally greater than that is typically seen in Sertoli cell tumor, and sex cord-stromal tumors are rare in extra-ovarian sites.

Papillary Cystadenoma Associated with Von Hippel–Lindau Disease

These epithelial tumors are rare and characteristically arise in the broad ligament [15, 86, 129, 238]. Most of them are thought to be of mesonephric origin, but a müllerian origin has been suggested in one case [238]. In some cases, patients have a known history of the autosomal dominant disorder, von Hippel-Lindau disease; however, in other cases, the tumor in the broad ligament may be the first manifestation of the disease. Patients range in age from the third to fifth decades of life. Tumors may be unilateral or bilateral. They vary in size and are composed of cysts that contain a complex papillary proliferation (> Fig. 11.46). The papillae are generally short and blunted. The stroma of the papillae varies in cellularity and may be hyalinized or fibrous. The papillae are usually lined by a single layer of low-cuboidal, non-ciliated cells that have eosinophilic or clear cytoplasm, but ciliated cells have been reported in one case [238]. The nuclei are bland, and the tumors are mitotically inactive. These tumors typically lack epithelial stratification and psammoma bodies. They are thought to be benign.

The importance of diagnosing this tumor (or suggesting it as a diagnostic possibility in ambiguous cases) is because of the association with von Hippel–Lindau disease (and, hence, various tumors of other organs, including renal cell carcinoma) and to not confuse it with other histologically similar neoplasms that do not have this association. The

G Fig. 11.46

Papillary cystadenoma associated with von Hippel–Lindau disease. Cysts contain a complex papillary proliferation. The papillae are short and blunted. Closer magnification will show papillae lined by a single layer of cuboidal, nonciliated cells with bland nuclei and clear to eosinophilic cytoplasm

differential diagnosis includes cystadenofibromas of müllerian type with prominent papillary architecture that are not associated with von Hippel-Lindau disease. Those generally contain papillae which are much larger and less complex and contain cilia. They should also have areas which appear more conventionally adenofibromatous, including distinctive cleft-like architecture. Histologic overlap can also occur with atypical proliferative (borderline) serous tumor, but this tumor exhibits a hierarchical degree of papillae branching with epithelial stratification (including cellular tufts), ciliated cells, and psammoma bodies. Papillary cystadenomas associated with von Hippel-Lindau disease that are predominantly of clear cell type can mimic metastatic renal cell carcinoma [15]. In contrast with the latter, papillary cystadenoma diffusely expresses CK7 and is negative for RCC marker. CD10 is usually negative, but expression can be seen in some cases.

Other Paratubal/Para-ovarian and Pelvic Ligament Lesions

Atypical proliferative (borderline) tumor occurs more commonly in the broad ligament and paratubal/paraovarian locations compared with carcinoma. Most of the atypical proliferative (borderline) tumors are of serous type [12]. These patients range in age from 19 to 67 years (mean, 32 years). The tumors are typically unilateral, and they range in size from 1 to 13 cm. They are usually confined to the broad ligament and histologically similar to their ovarian counterparts. The behavior appears to be favorable. Primary carcinoma of the broad ligament is rare [13]. Many of the patients are relatively young, and the tumors are usually unilateral. Some are associated with pelvic endometriosis. In most cases, disease is limited to the broad ligament. Various histologic types have been described, including endometrioid and clear cell.

Most mesenchymal tumors in paratubal/para-ovarian locations and pelvic ligaments are leiomyomas. Criteria for classification of benign, atypical, and malignant smooth muscle tumors in paratubal/para-ovarian locations have not been developed; however, some authors have advocated using the same criteria as used for uterine locations [122, 138]. It should be noted that criteria have been suggested for classifying smooth muscle tumors in the ovary [142]. For additional details regarding extra-uterine smooth muscle tumors, see **3** Chap. 22, Soft Tissue Lesions Involving the Female Reproductive Organs. Sarcomas (leiomyosarcoma being the most common one) are rare.

Other primary lesions, some of which are rare, that may occur in paratubal/para-ovarian locations and pelvic ligaments include endometriosis, uterus-like mass, ectopic hilus cell nests, benign epithelial tumors (including serous cystadenoma and Brenner tumor; cystadenofibromas are occasional, usually incidental findings), adenomyoma, benign mesenchymal tumors (including lipoma, benign mesenchymoma, neurofibroma, and schwannoma), sex cord-stromal tumors (including fibroma, thecoma, and steroid cell tumor), ependymoma, teratoma, pheochromocytoma, carcinoid, perivascular epithelioid cell tumor (PEComa), malignant mesenchymal tumors (including extra-skeletal Ewing's sarcoma/PNET, adenosarcoma, endometrioid stromal sarcoma, rhabdomyosarcoma, "mixed mesenchymal sarcoma," liposarcoma, and alveolar soft part sarcoma), yolk sac tumor, and choriocarcinoma [138]. Various gynecologic and non-gynecologic tumors may secondarily involve paratubal/para-ovarian locations and pelvic ligaments. Such mesenchymal gynecologic tumors in particular include intravenous leiomyomatosis, diffuse uterine leiomyomatosis, cotyledenoid dissecting leiomyoma ("Sternberg tumor"), uterine leiomyosarcoma, and endometrial stromal sarcoma.

Artifacts and Normal Findings

Nonneoplastic lesions of the ovary frequently form a pelvic mass and are often associated with abnormal hormonal manifestations, thus potentially mimicking an ovarian neoplasm on clinical examination, at operation, or on pathologic examination. Many occur in the reproductive years and may be associated with infertility. Their proper recognition is, therefore, important to allow appropriate, usually conservative therapy, thereby avoiding unnecessary oophorectomy. This chapter begins with a very brief overview of the embryology and gross anatomy of the normal ovary, and key aspects of normal ovarian histology are featured in the discussion of relevant nonneoplastic lesions.

Embryology and Gross Anatomy

Embryology

During the development of both male and female human embryos, primordial germ cells migrate from the yolk sac to the urogenital ridges via the hindgut approximately 3 weeks post fertilization. In the absence of sex-determining region Y, the germ cells are incorporated into a proliferating mass of surface epithelial cells. From the second to the early third trimester, this thickened cortical mass of proliferating epithelial and germ cells divides into small groups demarcated by strands of stromal tissue extending from the medulla to the cortex. The small groups of germ cells and epithelial cells are further subdivided into primordial follicles composed of single germ cells surrounded by a layer of epithelial cells, the primitive granulosa cells. Interstitial (Leydig) cells develop within the stroma of the secondtrimester female gonad, but most of these cells degenerate by term. The few found in the hilum of the adult ovary are called hilus cells. Early epithelial proliferations, which in males contribute to the connection between the sex cords and the mesonephric tubules, undergo degeneration in gonads destined to become ovary, leaving a few tubular remnants in the ovarian hilum, the rete ovarii.

Gross Anatomy

The newborn ovary is a tan, elongated, and flat structure that lies above the true pelvis. It may have a lobulated appearance with irregular edges [162]. Its approximate dimensions are $1.3 \times 0.5 \times 0.3$ cm, and its weight is less than 0.3 g [162]. The ovary enlarges, increases in weight 30-fold, and changes in shape throughout infancy and childhood, and at puberty, has the size and shape of an adult ovary and lies within the true pelvis.

Adult ovaries are ovoid, approximately $3-5 \times 1.5-3 \times 0.6-1.5$ cm, and weigh 5–8 g. Their size and weight, however, vary considerably depending on their content of follicular derivatives. Their pink-white exterior in early reproductive life is usually smooth but becomes increasingly convoluted thereafter. Thin-walled, fluid-filled cystic follicles and bright yellow corpora lutea may be partially visible from the external aspect. Three poorly defined zones are discernible on the sectioned surface: an outer cortex, an inner medulla, and the hilus. Follicular structures (cystic follicles, corpora lutea, and corpora albicantia) are usually visible in the cortex and medulla [28].

After the menopause, the ovaries typically shrink to a size approximately one half their size during the reproductive era. Their size varies considerably, however, depending on their content of ovarian stromal cells and the number of unresorbed corpora albicantia. Most postmenopausal ovaries have a shrunken, gyriform, external appearance, but some have a smooth surface. The sectioned surface is usually firm and predominantly solid, although occasional cysts several millimeters in diameter (inclusion cysts) may be visible within the cortex. Small white scars (corpora albicantia) are typically present within the medulla. Thick-walled blood vessels may be appreciable within the medulla and hilus [28].

In the adult, the ovaries lie on either side of the uterus close to the lateral pelvic wall, behind the broad ligament and anterior to the rectum. Each ovary is attached along its anterior (hilar) margin by a double fold of peritoneum, the mesovarium, to the posterior aspect of the broad ligament. Each ovary is also attached at its medial pole to the ipsilateral uterine cornu by the ovarian (uteroovarian) ligament and from the superior aspect of its lateral pole to the lateral pelvic wall by the infundibulopelvic (suspensory) ligament.

The blood supply of the ovary is derived from anastamoses formed by the ovarian artery, a branch of the aorta, and the ovarian branch of the uterine artery. Approximately ten arterial branches from this arcade penetrate the ovarian hilus and course through the medulla, becoming markedly coiled and branched [166]. At the corticomedullary junction, the medullary arteries and arterioles form a plexus from which smaller, straight cortical arterioles arise and penetrate the cortex in a radial fashion. These cortical arterioles branch and anastomose, forming sets of interconnecting vascular arcades that give rise to dense capillary networks within the theca layers of the ovarian follicles [166]. The veins within the ovary accompany the arteries and become large and tortuous in the medulla. The veins join together in the hilus, forming a plexus that drains into the ovarian veins [166]; the left

and right ovarian veins drain into the left renal vein and the inferior vena cava, respectively. Ovarian lymphatics originate predominantly within the theca layers of the follicles, and traverse the ovarian stroma to form a plexus at the hilus. Efferent lymphatics enter the mesovarium and form the subovarian plexus with branches from the fallopian tube and uterine fundus. Leaving the plexus, they pass along the free border of the infundibulopelvic ligament enmeshed with the ovarian veins and drain into the upper paraaortic lymph nodes at the level of the lower pole of the kidney [158]. Accessory channels can bypass the subovarian plexus, passing through the broad ligament to the internal iliac, external iliac, and interaortic lymph nodes, or via the round ligament to the iliac and inguinal lymph nodes [158]. When the pelvic and paraaortic lymph nodes are extensively replaced by tumor, retrograde lymphatic flow may provide a rare route of tumor spread to the ovaries.

Congenital Lesions and Ectopic Tissues

Absent Ovary

In phenotypic females, absence of both ovaries usually is associated with an abnormal karyotype and a syndrome of gonadal dysgenesis. In such cases, bilateral streak gonads or a unilateral streak gonad and a contralateral intraabdominal testis are usually found. However, rare cases of truly agonadal individuals have been reported, usually with a karyotype that is 46XY, but rarely, 46XX [152]. Rare patients with ataxia telangiectasia have had no evidence of ovarian tissue at laparotomy.

Rarely, one ovary may be absent in an otherwise normal woman, usually representing an incidental finding at operation or postmortem examination. Associated findings frequently include agenesis or malformation of the ipsilateral fallopian tube, round ligament, kidney, or ureter, alone or in various combinations. The differential diagnosis includes: (1) ectopic ovary, which may lie at the level of the liver, close to the kidney, within the omentum [152], or within an inguinal hernia and (2) adnexal torsion with atrophy or autoamputation.

Lobulated, Accessory, and Supernumerary Ovary

Examples of lobulated, accessory, and supernumerary ovary are among the rarest of gynecologic abnormalities. A lobulated ovary is a normally situated ovary divided by one or several fissures into two or more lobes. The lobes may be completely separate or connected by fibrous tissue or ovarian stroma; rarely both ovaries may be affected. A closely related anomaly is an accessory ovary, a structure containing normal ovarian tissue located in the vicinity of a normal, eutopic ovary with which it has a direct or ligamentous attachment. A supernumerary ovary is a similar structure but located at some distance from, and not connected to, a eutopic ovary [65]. It may be pelvic, attached to the uterus, bladder, or pelvic walls, or retroperitoneal, within the omentum, periaortic area, or mesentery, or inguinal. In most cases, the accessory or supernumerary ovary is less than 1 cm in size, and smaller examples may go unrecognized at operation or autopsy; they are multiple and bilateral in some cases [65]. The ectopic ovarian tissue possesses the functional potential, as evidenced by persistent menses after bilateral oophorectomy, as well as the pathologic potential of normal ovaries. The presence of a supernumerary ovary therefore is one histogenetic mechanism for ovarian-type tumors in extraovarian sites. This derivation is even more likely for nonepithelial tumors such as a granulosa-theca tumors within the broad ligament, which are unlikely to have a mesothelial or secondary müllerian origin (> Chap. 13, Diseases of the Peritoneum).

Lobulated and accessory ovary are closely related embryonically. The former results from lobulation of the ovarian anlage, whereas the latter presumably develops from a slightly separated part of the otherwise normally developing and migrating ovarian anlage. Pathogenetic theories for supernumerary ovary include aberrent migration of part of the gonadal ridge after incorporation of the germ cells or, alternatively, arrest of some of the migrating germ cells in an ectopic location with inductive transformation of the surrounding tissue into ovarian stroma. As many as one third of patients with lobulated ovaries, accessory ovary, and supernumerary ovary have other congenital genitourinary abnormalities.

Adrenal Cortical Rests

Although accessory adrenal cortical tissue frequently is observed within the wall of the fallopian tube and the broad ligament, it is an extremely rare finding in the ovary [199]. The adrenal rests are typically yellow, spherical, and encapsulated nodules several millimeters in size (\bigcirc *Fig. 12.1*). Adrenal cortical ectopia in these sites can be explained by the close proximity of the anlage of the adrenal cortex to the gonadal ridge during embryonic development. Ovarian adrenal cortical rests may be the

Fig. 12.1 Adrenal cortical rest within mesovarium

origin of occasional steroid cell tumors of the ovary that resemble adrenal cortical tissue in both their histologic appearance and endocrine manifestations.

Uterus-Like Ovarian Mass

Approximately ten reported examples of a uterus-like ovarian mass have been reported [150, 165, 190]. They have occurred in adult and occasionally early adolescent females (11-50 years of age) and were characterized by a central cavity lined by endometrial tissue and a thick wall of smooth muscle [150]. Additional findings have included an elevated CA-125 level (two cases), an associated breast carcinoma (two cases), and a contiguous endometrioid adenocarcinoma (one case). Although the lesion can be explained on the basis of an ovarian endometriotic cyst with smooth muscle metaplasia of its stromal component (endomyometriosis; see **O** Chap. 13, Diseases of the Peritoneum), in some cases it may may be caused by a congenital malformation of the ipsilateral müllerian duct, an origin supported by the presence of congenital abnormalities of the urinary tract in three of the reported cases. In several other cases, however, residual ovarian parenchyma was identified at the periphery of the mass.

Splenic–Gonadal Fusion

Splenic–gonadal fusion (**)** *Fig. 12.2*) is an extremely rare anomaly resulting from the fusion of the anlage of both

■ Fig. 12.2 Splenic-gonadal fusion. A nodule of splenic tissue is contiguous with the surface of the ovary

organs during embryonic development. The male/female ratio is 9:1. Three examples have been described in newborn female infants, two of which were associated with partially undescended ovaries, as well as other, multiple, congenital anomalies [163]. All three cases were of the continuous type in which a cord-like structure connected the spleen to the left ovary or surrounding structures. In one of these cases, several intraovarian splenic nodules were found. A case of discontinuous splenic-gonadal fusion has been reported in a 19-year-old woman with no other apparent congenital abnormalities [126]. In an additional case, a 44-year-old woman had a septate uterus and a cluster of splenic nodules surrounding the otherwise normal left ovary; multiple adhesions made it difficult to ascertain if a splenic-ovarian cord was present [7]. The differential diagnosis in the discontinuous cases is with traumatic splenosis. Affected women usually have a history of trauma, and at laparotomy, splenic nodules are widely dispersed throughout the peritoneal cavity (> Chap. 13, Diseases of the Peritoneum).

Prostatic Tissue

One case of ovarian ectopic prostatic tissue has been reported in a 70-year-old woman, postulated to arise from hilar mesonephric rests [192]. Prostatic tissue has also been described in mature cystic teratomas (> Chap. 16, Germ Cell Tumors of the Ovary).

Infections

Common Bacterial Infections

Pelvic inflammatory disease (PID) of bacterial origin accounts for most ovarian infections in the western world. Although some studies have indicated that the presence of an intrauterine device (IUD) increases the risk of infection, other studies have shown that when the number of sexual partners are controlled for, IUDs do not increase the risk of PID [89]. Ovarian involvement by PID is almost always secondary to salpingitis and typically takes the form of a tuboovarian abscess (> Fig. 12.3), which usually is bilateral. The typical clinical manifestations are abdominal or pelvic pain, and, less often, fever, vaginal discharge or bleeding, and urinary symptoms [101]. An adnexal mass is palpable, demonstrable with imaging techniques, or visible at laparoscopy. A history of an acute infectious episode is present in only one third to one half of patients, suggesting that the subclinical infections are common [101]. A mixed flora with a preponderance of anaerobic organisms is typically recovered from the contents of the abscess [101]. With resolution, the only sequelae may be tuboovarian fibrous adhesions, but occasionally a healed abscess becomes a cyst.

A unilateral or bilateral ovarian abscess without tubal involvement is much rarer than a tuboovarian abscess. The former usually is secondary to direct or lymphatic spread of organisms from a nongynecologic pelvic inflammatory process, such as diverticulitis, appendicitis, inflammatory bowel disease, or postoperative pelvic infection. Rarely, an ovarian abscess is the result of a blood-borne infection. The external ovarian surface in such cases often is unremarkable, and the process may not be apparent until the organ is sectioned. Uncommonly, rupture of an ovarian or tuboovarian abscess leads to secondary peritonitis or, rarely, fistulas involving the colon, bladder, or vagina [191].

Milder, chronic, or recurrent forms of ovarian involvement by PID may take the form of a chronic perioophoritis, with periovarian and tuboovarian adhesions; sclerocystic ovarian changes may also be present. Rarely, a chronic ovarian abscess may result in a tumorlike mass, variably designated ovarian xanthogranuloma, xanthogranulomatous oophoritis, or inflammatory pseudotumor. The involved ovary in such cases is replaced by a solid or cystic, yellow, lobulated mass (\bigcirc *Fig. 12.4*), characterized microscopically by foamy histiocytes admixed with multinucleated giant cells, plasma cells, fibroblasts, neutrophils, foci of necrosis, and fibrosis (\bigcirc *Fig. 12.5*). Several additional examples of pseudotumorous xanthogranulomatous inflammation with a more diffuse involvement of the adnexa have been described [98].

Rare Bacterial Infections

Actinomycosis

Pelvic actinomyces infection is uncommon and usually represents a complication of an IUD, although most cases of IUD-related PID are nonactinomycotic [131, 179]. Almost 85% of cases have occurred in women who

Fig. 12.3 Tuboovarian abscess. Lining consists of inflammatory debris with subjacent granulation tissue

Fig. 12.4 Ovarian xanthogranuloma, sectioned surface

have had an IUD in place for 3 or more years [179], and the infection may be more common in women using plastic, rather than copper, IUDs. There is a high likelihood of subsequent sterility [179].

The adnexal involvement usually is unilateral, with destructive, often multiple, abscesses involving the ovary and fallopian tube (> Chap. 11, Diseases of the Fallopian Tube and Paratubal Region) that may clinically mimic a pelvic malignancy [4]. Rarely, the characteristic actinomycotic (sulfur) granules are grossly visible within the abscess cavities. Microscopic examination typically reveals a nonspecific inflammatory response composed predominantly of neutrophils and foamy histiocytes sometimes admixed with lymphocytes and plasma cells. A specific diagnosis can be made only by finding the sulfur granules within the inflammatory exudate, but numerous blocks may be necessary to find them. The granules are composed of circumscribed rounded masses of basophilic, grampositive, and argyrophilic bacteria growing as branching filaments with a characteristic radial or palisading pattern at the periphery of the granule (**>** Fig. 12.6). A silver stain or fluorescent antibody stain may facilitate their detection [156], and negative modified acid-fast staining aids in the distinction from nocardia [161]. A diagnosis of actinomycosis may be made before salpingo-oophorectomy in some cases by finding the granules within endometrial curettings or cervico-vaginal smears. In one study, almost 90% of patients with actinomyces demonstrated by the latter method were found to have a tubo-ovarian abscess [22]. Sulfur granules should be distinguished from noninfectious, pseudoactinomyocotic radiate granules, which may be encountered in endometrial samples as

Fig. 12.6 Actinomycosis of ovary. A colony of actinomyces (sulfur granule) is surrounded by a purulent exudate

a tisssue response to intrauterine devices (**>** Chap. 7, Benign Diseases of the Endometrium) [161].

Tuberculosis

Tuberculous oophoritis is uncommon and usually secondary to tuberculous salpingitis (Chap. 11, Diseases of the Fallopian Tube and Paratubal Region). The tubes are almost always involved in tuberculosis of the female genital tract, but the ovarian parenchyma is affected in only 10% of cases [143]. Unilateral or bilateral adnexal masses, in some cases accompanied by an elevated CA-125 level, may clinically simulate an ovarian tumor. On macroscopic inspection, the ovaries are typically adherent to the tubal ampullae. Grossly visible caseation is rare. On histologic examination, the tuberculosis is typically confined to the cortex. In cases in which the ovary is enlarged, granulomas on the adjacent peritoneum may simulate metastatic ovarian cancer at operation [51, 143].

Malacoplakia

Of approximately 25 reported cases of gynecologic malacoplakia, only 4 have involved the ovary [27, 92]. Friable, yellow, focally hemorrhagic, and necrotic masses involve one or both ovaries and the ipsilateral fallopian tube. In one case, the process also involved contiguous portions of the small and large bowel, simulating a malignant ovarian tumor at operation [92]. Histologic examination reveals the typical features of malacoplakia

Fig. 12.7

Malacoplakia of ovary. Mixed inflammatory infiltrate with epithelioid histiocytes, some containing Michaelis–Guttman bodies, shown at higher magnification in right image

(**>** *Fig. 12.7*). Organisms (*Escherichia coli* and/or *Entero-coccus faecalis*) were demonstrated by culture in two of the cases [27, 92].

Leprosy

Although leprosy rarely involves the female genital tract, the ovary is the most commonly involved gynecologic site [19]. In one well-documented case, microscopic examination of the grossly normal ovaries revealed numerous vacuolated histiocytes within the ovarian stroma that contained *Mycobacterium leprae*. In chronic forms of leprous oophoritis, a chronic inflammatory cell infiltrate and fibrosis are seen, and bacilli usually are demonstrable.

Syphilis

For unknown reasons, syphilitic involvement of the ovary is very rare. Luetic oophoritis has been described in congenital, secondary, and tertiary forms of the disease. The pathology of these various stages is similar to those in extraovarian sites.

Parasitic Infections

Parasitic infestations of the ovary are extremely rare in most parts of the world. Ovarian schistosomiasis, however, is

■ Fig. 12.8 Ovarian involvement by *Enterobius vermicularis*. Note numerous and characteristically flat ova

common in endemic areas; the fallopian tube is typically also involved [111]. Patients usually have lower abdominal pain, a pelvic mass, and occasionally irregular menses and infertility. The typical operative findings are an enlarged tube and ovary, numerous adhesions, and scattered peritoneal nodules that may simulate the implants of a malignant tumor. On histologic examination, granulomas, often containing eosinophils, surround schistosoma ova. Dense fibrosis frequently is seen in the later stages of the disease. We have seen an ovarian endometriotic cyst containing schistosoma ova, similar to a reported case of schistosomiasis involving intestinal endometriosis [1].

Ovarian involvement by *Enterobius vermicularis* usually is an incidental operative finding on the external surface, or, rarely, within the ovary [125, 159]. In several cases, there has been simultaneous involvement of the pelvic peritoneum, simulating a metastatic tumor [159]. The granulomas, which may undergo caseation and contain eosinophils, surround the adult female worms and ova (\bigcirc *Fig. 12.8*) [125]. The worms probably reach the peritoneal cavity by migration from the perineum through the lumen of the genital tract.

Rare cases of ovarian echinococcosis have been described [219]. In one of them, a typical hydatid cyst 12 cm in diameter involved the ovary.

Viral Infections

Oophoritis secondary to cytomegalovirus (CMV) can occur as an incidental finding in surgical or autopsy specimens in immunosuppressed patients, usually as part of a generalized infection [212]. On macroscopic examination, the ovaries are usually of normal size but contain foci of superficial cortical hemorrhagic necrosis several millimeters in size. Microscopic examination reveals foci of coagulative necrosis, with variable numbers of neutrophils, nuclear debris, and hemorrhage, as well as lymphocytes, plasma cells, and vascular dilatation in the surrounding stroma. Ovarian stromal and endothelial cells, even at a distance from the necrotic foci, contain typical intranuclear and occasional intracytoplasmic inclusion bodies. Immunohistochemical staining for CMV may facilitate the diagnosis in some cases [212], and intranuclear and intracytoplasmic herpes-type viral particles have been found on ultrastructural examination.

Mumps oophoritis as a clinical entity occurs much less commonly than mumps orchitis; clinical evidence of the lesion occurs in 5% of females with mumps. The pathology of the acute stage has not been well described. It is postulated that germ cell depletion secondary to mumps oophoritis may result in premature menopause and possibly an increased risk of ovarian cancer [39].

In view of the frequency of human papillomavirus (HPV) infection in the lower female genital tract, it is perhaps surprising that histologically documented examples of HPV infection of the ovary are exceptionally rare. We are aware of only one report in which HPV 16 DNA was detected by polymerase chain reaction (PCR) analysis with E6 and E7 primers in synchronous ovarian and cervical squamous cell carcinoma in situ lesions, the former presumably arising in an endometriotic cyst [112]. Lai et al. have found HPV-16 or HPV-18 DNA sequences by PCR in five of ten histologically normal ovaries [100].

Fungal Infections

Fungal infections of the ovary are extremely rare, even in patients with disseminated mycoses. Extremely rare examples of tuboovarian abscess due to *Blastomyces dermatitidis* have been reported [132]. In one case, the abscesses were bilateral and associated with miliary nodules involving the pelvic peritoneum, probably secondary to hematogenous spread from the lungs, while in another case, the infection was sexually transmitted.

Seven of 11 patients with coccidioidomycosis of the upper female genital tract had tuboovarian and peritoneal involvement; 2 of the 7 had concomitant coccidioidal endometritis [23]. One case of tuboovarian abscess caused by Aspergillus has been reported in an IUD user [94]. Rupture of the abscess led to generalized peritonitis.

Noninfectious Inflammatory Disorders

A variety of noninfectious, typically granulomatous, inflammatory disorders may involve the ovary. In addition, granulomas may be seen rarely in autoimmune oophoritis (page 35).

Foreign Body Granulomas

A variety of foreign materials may evoke a granulomatous reaction on the ovarian and extraovarian peritoneal surfaces, potentially mimicking a malignant tumor at operation. Examples include suture material, lipid material used in hysterosalpingographic contrast material, crystalline material such as talc, and keratin (> Figs. 12.9 and ≥ 12.10) from cystic teratomas and the squamous elements of endometrial and ovarian endometrioid adenocarcinomas (peritoneal and ovarian keratin granulomas are discussed in more detail in **O** Chap. 13, Diseases of the Peritoneum) [120]. A foreign body reaction also occurs in response to starch granules from surgical gloves, starchcontaining douche fluid, and lubricants. An 8-cm mass mimicking a primary ovarian tumor was due to a florid granulomatous reaction to oxidized cellulose (SurgicelTM) [60]. Rarely, the starch granulomas are of the tuberculoid type, with or without caseous necrosis, and mimic tuberculosis on microscopic examination. Granulomatous oophoritis is occasionally a response to bowel contents

Fig. 12.12 Gallstone implanted on ovarian surface

Fig. 12.11

Postcautery carbon pigment granuloma in ovary. Note black carbon pigment. Palisading histiocytes are seen at the bottom and right

that reach the ovary via a coloovarian fistula [61]. Foreign body-type granulomas containing brown to black carbon pigment have been described in the ovary secondary to laser or electrocautery treatment (\bigcirc *Fig.* 12.11) [201]. Implantation of gallstones on the peritoneum and ovarian surface ("ovarian cholelithiasis," \bigcirc *Fig.* 12.12; see also Fig. 13.3) may occur as a complication of laparoscopic cholecystectomy. It is also discussed in (\bigcirc Chap. 13, Diseases of the Peritoneum, page 3).

Necrobiotic (Palisading) Granulomas

Necrobiotic granulomas have been encountered in the ovary, usually as an incidental microscopic finding [91, 120, 201]. In most cases, there is a history of an operation or cauterization involving the same ovary months to years earlier. The granulomas can be multiple and occasionally bilateral. A central zone of fibrinoid necrosis or hyalinization is usually surrounded by palisading, sometimes multinucleated, histiocytes and variable numbers of other inflammatory cells including lymphocytes, plasma cells, and eosinophils; a fibrous pseudocapsule forms in some of the cases (> Fig. 12.13). Brown to black carbon pigment (as already noted) is typically present in multinucleated giant cells in postcautery palisading granulomas [201]. The differential diagnosis of palisading granulomas includes the other ovarian granulomas discussed in this chapter as well as necrotic pseudoxanthomatous nodules of endometriosis (Chap. 13, Diseases of the Peritoneum).

Granulomas Secondary to Systemic Diseases

In rare cases of ovarian involvement by sarcoidosis, the sarcoid granulomas were usually an incidental microscopic finding; in one case, findings of an elevated CA-125, an adnexal mass, and pelvic lymphadenopathy were clinically suspicious for malignancy [151]. Patients with systemic sarcoidosis may have involvement of other gynecologic sites or paraaortic lymph nodes. The finding of sarcoid-like granulomas in the ovary should alert the

Fig. 12.13 Isolated palisading granuloma of ovary

 Fig. 12.14
 Cortical granuloma. Circumscribed collection of lymphocytes, spindle cells, and an occasional multinucleated giant cell lie within the ovarian stroma

pathologist to the possibility of a rare dysgerminoma with a granulomatous reaction sufficiently extensive to obscure the malignant tumor cells. Crohn's disease is another rare cause of granulomatous oophoritis, usually caused by direct extension of the inflammatory process from the bowel [120]. The ipsilateral fallopian tube is also involved in most cases. Although not strictly granulomatous, mucicarminophilic histiocytosis can occasionally involve the ovary (S Chap. 13, Diseases of the Peritoneum).

Cortical Granulomas

Cortical granulomas are common, incidental, microscopic findings within the ovarian cortex. The granulomas are spherical, well circumscribed, 100-500 µm in diameter, and are composed of spindle cells, epithelioid cells, lymphocytes, and, in some, multinucleated giant cells; occasional anisotropic fat crystals also may be seen (> Fig. 12.14) [77, 120]. Hughesdon suggested that the granulomas become fibrotic with time, potentially accounting for at least some of the spherical, cloud-like, hyaline scars commonly encountered in the cortical stroma of postmenopausal women [77]. These scars resemble corpora fibrosa but usually are distinguishable from the latter by their more superficial location within the cortex, greater cellularity, weaker eosinophilia, and the presence of a reticulin framework [77]. It also has been suggested that hyaline scars may represent foci of atrophic stromal endometriosis, luteinized stromal cells, or ectopic decidua [77].

The frequency of cortical granulomas appears to be related to age. They are not usually encountered before the age of 30 years, but Hughesdon found active lesions in 40% of women over the age of 40 years; the number of lesions per cross section of ovary increased in successive decades [77]. The clinical significance, if any, of cortical granulomas is unknown. Possible associations with ovarian stromal hyperplasia, endometrial carcinoma, or both have been suggested but not demonstrated consistently.

Surface Proliferative Lesions

The Surface Epithelium, Inclusion Glands and Cysts, and Metaplasias

The normal ovarian surface epithelium consists of a single, focally pseudostratified layer of modified mesothelial cells. The cells vary from flat to cuboidal to columnar, and several types may be seen in different areas of the same ovary. Squamous metaplasia of the surface epithelium has been recently described in patients on long-term peritoneal dialysis [76]. The surface cells are separated from the underlying stroma by a distinct basement membrane. In oophorectomy specimens, the epithelium is almost always denuded as a result of handling by the surgeon and pathologist, as well as drying artifact as a result of delayed fixation. Preserved epithelium is usually confined to sulci and areas protected by surface adhesions. The surface epithelial cells are immunoreactive for cytokeratin, Ber-EP4, calretinin, desmoplakin, vimentin, and receptors for estrogen, progesterone, and epidermal growth factor receptors, but not desmin [47, 102].

Surface epithelial inclusion (SEI) glands and their cystic counterparts, SEI cysts, arise from cortical invaginations of the ovarian surface epithelium that have lost their connection with the surface. SEI glands and cysts can be found in ovaries from females of all ages, including fetuses, infants, and adolescents [16, 18]. With advancing age, their frequency increases to the extent that they are common in the late-reproductive and postmenopausal age groups.

SEI cysts may be visible on gross inspection of the ovary () Fig. 12.15), although most SEI glands and cysts are appreciable only on microscopic examination; cysts greater than 1 cm in diameter are designated a cystadenoma (O Chap. 14, Surface Epithelial Tumors of the Ovary). SEI glands and cysts are usually multiple, scattered singly or in small clusters throughout the superficial cortex (> Fig. 12.16); less commonly, they extend into the deeper cortical or medullary stroma. They are typically lined by a single layer of columnar cells that in postmenopausal patients is often ciliated, mimicking tubal (endosalpingeal) epithelium. Psammoma bodies may be seen within the cysts and the adjacent stroma (> Fig. 12.16) and, rarely, within cervicovaginal Papanicolaou smears [108]. Similar glands, with or without associated psammoma bodies, encountered on the ovarian surface, within periovarian adhesions, and elsewhere on the peritoneum and in the omentum, are designated endosalpingiosis () Chap. 13, Diseases of the Peritoneum).

Less commonly, the lining of the glands and cysts consists of other müllerian cell types (endometrioid, mucinous) or nonspecific, flat, cuboidal, or columnar cells; rarely, apocrine metaplasia may be seen within a SEI cyst. An Arias–Stella-like reaction has been described within SEI glands in pregnant patients [18]. One study found that hyperplastic and metaplastic changes within SEI glands are more common in women with polycystic ovarian disease or endometrial carcinoma, suggesting a possible hormonal basis for these changes (\bigcirc *Fig.* 12.17) [167]. A rare pseudoneoplastic alteration in SEI glands is a striking vacuolar, presumably hydropic, cytoplasmic change of the lining cells. In such cases, abundant clear cytoplasm displaces the nucleus, potentially mimicking signet-ring cell carcinoma, especially when the cells proliferate to form solid nests (\bigcirc *Fig.* 12.18). Awareness of this phenomenon, additional sectioning (if necessary) to

Fig. 12.16

Epithelial inclusion glands and small cysts, lined by a single layer of columnar cells. Psammoma bodies are present within an occasional gland or cyst but are mostly in the adjacent stroma

Fig. 12.18 Vacuolar change within surface epithelial inclusion glands. The change results in solid nests within the ovarian stroma simulating signet-ring cells

demonstrate a relation to inclusion glands, and negative staining for mucin facilitate the diagnosis.

SEI glands and cysts are likely the site of origin for most common epithelial tumors of the ovary. Several studies have found that patients with ovarian carcinoma have an increased number of SEI cysts (or surface epithelial invaginations, their precursors) in the contralateral ovary compared to controls [128, 205]. Additional support for this hypothesis is provided by the occasional presence of dysplastic changes within their linings [42, 183] as well as immunoreactivity for a variety of ovarian epithelial tumor markers including WT-1, epithelial membrane antigen, CA-125, CA-19-9, CEA, human chorionic gonadotropin (hCG), and placental alkaline phosphatase [17, 26, 79, 188]. SEI cysts are distinguished from cystadenomas by their smaller size (see earlier). The differential diagnosis also includes other unilocular ovarian cysts.

Mesothelial Proliferations

Proliferation of mesothelial cells on the ovarian surface, within periovarian fibrous adhesions or elsewhere on the pelvic peritoneum, is usually a response to pelvic inflammation but also occurs in response to ovarian tumors and endometriosis. Florid examples may be associated with complex glandular and papillary proliferations of mesothelial cells that may exhibit mild to moderate atypia (\bigcirc *Fig. 12.19*). Such a process may simulate stromal invasion in a borderline ovarian tumor (\bigcirc *Fig. 12.20*) or simulate a metastatic carcinoma, primary serous surface

Fig. 12.19

Mesothelial proliferation on ovarian surface. Mesothelial cells, growing in papillary pattern, are admixed with lymphocytes. The mesothelial cells exhibit mild nuclear pleomorphism and occasional multinucleation

Fig. 12.20 Mural mesothelial hyperplasia within the wall of an ovarian serous borderline tumor

carcinoma, or malignant mesothelioma. This subject is discussed in more detail in O Chap. 13, Diseases of the Peritoneum.

Surface Stromal Proliferations

Nodular, polypoid, and papillary stromal projections from the ovarian surface are a common incidental microscopic finding in women of late-reproductive and postmenopausal age. These projections are composed of ovarian stroma, exhibiting varying degrees of hyalinization covered

Fig. 12.21 Ovarian surface stromal proliferation. Papillary and nodular stromal proliferation involves ovarian surface

by a single layer of surface epithelium (\bigcirc *Fig.* 12.21). Detachment of these structures may give rise to "collagen balls" occasionally found in peritoneal washings [214]. Surface stromal proliferations are typically 1–3 mm in maximal dimension and do not exceed 1 cm, the arbitrary dividing line between this type of proliferation and a serous surface papilloma.

Nonneoplastic Lesions of the Follicular and Stromal Elements

This section describes the wide spectrum of nonneoplastic lesions that arise from the ovarian follicles and stroma. Many of them are secondary to ovarian stimulation by pituitary or chorionic gonadotropins and may be associated with excessive production of estrogens, androgens, or both. Although most nonneoplastic proliferations of Leydig cells are not of stromal origin, these lesions are most conveniently discussed in this section.

Solitary Follicle Cysts and Corpus Luteum Cysts

Solitary follicle cysts and corpus luteum cysts are nonneoplastic lesions derived from their normal counterparts.

For details regarding normal folliculogenesis, the reader is referred elsewhere, but a brief overview is provided here [28]. Normal follicular maturation begins during the luteal phase and continues throughout the follicular phase of the next cycle. Each month, usually

only one developing follicle is dominant and achieves ovulation. The other developing follicles undergo atresia, and continued shrinkage and hyalinization of an atretic follicle produces the corpus fibrosum, a small scar consisting of a wavy strand of hyaline tissue. In the absence of fertilization, the collapsed ovulatory follicle becomes the corpus luteum of menstruation (CLM), a 1.5- to 2.0-cm round structure with a festooned contour and a center filled with a gray, focally hemorrhagic coagulum, and a color that changes during the luteal phase from brown to orange-yellow as it acquires more lipid. Occasionally, the CLM is cystic, but this feature is more characteristic of the corpus luteum of pregnancy (which may be indistinguishable from the CLM but is usually larger and bright yellow). During a period of several months, the CLM involutes by progressive fibrosis and shrinkage, with conversion to a corpus albicans. Most corpora albicantia and corpora fibrosa are resorbed.

Clinical Features

Solitary follicle cysts (FCs) are most common in nonpregnant women of reproductive age, particularly around the menarche and menopause. FCs may also occur during fetal life, in newborns, throughout childhood, and rarely after the onset of the menopause [104, 198]. Solitary or multiple FCs can be a component of the McCune– Albright syndrome (polyostotic fibrous dysplasia, cutaneous melanin pigmentation, and endocrine organ hyperactivity), as discussed later, and postpubertal women with cystic fibrosis may be predisposed to the development of solitary FCs [186]. Corpus luteum cysts (CLCs) usually occur during the reproductive era but rarely are found in neonates or follow sporadic ovulation in a postmenopausal woman.

The proportion of FCs and CLCs associated with clinical manifestations is unknown, because many are incidentally discovered by pelvic ultrasononography, laparoscopy, or laparotomy. Patients with clinically evident FCs and CLCs typically have either a palpable adnexal mass or manifestations related to increased estrogen production that may include isosexual precocity or pseudoprecocity, menstrual disturbances including amenorrhea and postmenopausal bleeding, or endometrial hyperplasia. A CLC is the most common finding in the ovarian remnant syndrome (see page 39). An uncommon clinical presentation of FCs and CLCs is rupture, which may cause abdominal pain, hemoperitoneum [67], and rarely exsanguination. Rupture is more likely to occur in patients receiving anticoagulant therapy or in those with bleeding diatheses [210]. Additionally, FCs occurring in utero or during the neonatal period may be complicated by adnexal torsion as well as hemorrhage and rupture; most regress during the first 4 months of life.

Gross Findings

Solitary follicle cysts (FCs) and corpus luteum cysts (CLCs) are thin walled and unilocular, ranging from 3 to 8 cm in diameter, although larger examples occur rarely (**>** *Fig. 12.22*), especially during pregnancy and the puerperium (see following). They usually have smooth surfaces and thin walls. CLCs are characterized by the presence of a convoluted yellow lining (**>** *Fig. 12.23*). The contents of FCs and CLCs vary from serous or serosanguineous fluid to clotted blood.

Fig. 12.23 Corpus luteum cyst. Note the convoluted yellow lining

Microscopic Findings

FCs are lined by an inner layer of granulosa cells that may be focally denuded and an outer layer of theca interna cells (\bigcirc *Fig. 12.24a*). The cells in either layer may be luteinized. Distinction between the two layers can be facilitated by a reticulin stain, which reveals dense reticulum surrounding the theca cells but sparse or absent reticulum in the granulosa layer (\bigcirc *Fig. 12.24b*). CLCs exhibit a convoluted lining composed of large luteinized granulosa cells

Fig. 12.24

Follicle cyst. (a) Lining consists of an inner layer of granulosa cells and an outer layer of theca interna cells. (b) Distinction between the two layers is enhanced with a reticulin stain, showing a reticulum network within the theca interna layer and an absence of reticulin within the granulosa layer

and an outer layer of smaller luteinized theca interna cells, with a prominent inner layer of connective tissue (\triangleright *Fig. 12.25*). CLCs associated with pregnancy typically have characteristic hyaline bodies and calcific foci within the granulosa cells. Focal infarction of a CLC, possibly secondary to inadequate hCG production, has been encountered in association with tubal pregnancy. Involution of FCs and CLCs usually leads to the formation of corpora fibrosa and corpora albicantia, respectively; rarely, the latter may be cystic.

A rare type of solitary FC, designated "large solitary luteinized follicle cyst of pregnancy and the puerperium" with distinctive clinical and pathologic features, occurs during pregnancy and the puerperium and is presumably related to hCG stimulation [29]. Patients present with a palpable adnexal mass (most commonly at the first postpartum visit) or are found to have a unilateral ovarian cyst at cesarean section. No endocrine disturbances have been reported to date. On gross inspection, the cyst resembles a typical FC except for its large size (median diameter 25 cm). On microscopic examination, the cyst is lined by one to many layers of luteinized granulosa and theca cells that are usually indistinguishable. Nests of luteinized cells may be embedded within the fibrous tissue of the cyst wall. The cells have abundant vacuolated to eosinophilic cytoplasm, vary considerably in size and shape, and in all the reported cases have exhibited focal marked nuclear

Fig. 12.25
 Corpus luteum cyst. A prominent inner layer of connective tissue is present

pleomorphism and hyperchromasia; mitotic figures have been absent (**>** *Fig.* 12.26).

Pathogenesis

The pathogenesis of some FCs is probably related to abnormalities in the release of anterior pituitary gonadotropins, such as a failure of the normal preovulatory luteinizing hormone surge. FCs occurring in females with abnormalities in gonadotropin release can be multiple, bilateral, recurrent, and in some cases are accompanied by corpora lutea and the possibility of pregnancy. Other FCs appear to be autonomous and do not recur following removal. Girls with the McCune–Albright syndrome and precocious

Fig. 12.26

Large solitary luteinized follicle cyst of pregnancy and puerperium. (a) Luteinized cells with abundant eosinophilic to clear cytoplasm line a cyst (*upper*) and lie within its fibrous wall (*lower*). Note focal nuclear atypicality. (b) Higher-power view of lining cells showing marked nuclear hyperchromasia and atypicality puberty secondary to a FC may have elevated gonadotropin levels, whereas in others with this syndrome, the FCs appears to be mediated by a gonadotropin-independent mechanism [211]. Treatment with low-dose phasic oral contraceptives [24], gonadotropin-releasing hormone analogues [14], and tamoxifen [33] may also stimulate the development of FCs.

Clinical Behavior and Treatment

Most cases of FC and CLC regress spontaneously within 2 months; observation of small ovarian cysts in women of reproductive age is justifiable for this period. Regression in some cases can be accelerated by administration of a high-dose, combined estrogen–progestogen preparation. FCs associated with isosexual pseudoprecocity can sometimes be treated by cyst puncture; others may require surgical removal. Persistence of a cyst suggests that it is neoplastic, and in these cases laparotomy or laparoscopy is necessary.

Differential Diagnosis of Solitary Follicle Cysts

Solitary cysts of follicular origin should be distinguished on microscopic examination from other solitary unilocular ovarian cysts. Cysts otherwise identical to FCs and CLCs but less than 3 cm in diameter are generally regarded as physiologic, that is, cystic follicles and cystic corpora lutea, respectively. A simple cyst is of unknown origin because its lining has disappeared, was destroyed by rubbing or dessication after its removal, or because the lining consists of a thin layer of nonspecific epithelial-like cells. Additional sections may reveal theca lutein cells in its wall or foci of serous, endometrioid, or another type of epithelial lining, allowing a more specific diagnosis. Even a rare cystic struma ovarii may be misdiagnosed as a simple cyst if inconspicuous follicles in its wall are overlooked or not sampled.

Cysts of surface epithelial origin that are usually small, incidental microscopic findings are designated inclusion cysts. Otherwise, similar cysts measuring more than 1 cm are considered neoplastic and designated serous, endometrioid, or mucinous cystadenoma, depending on the nature of their lining (② Chap. 14, Surface Epithelial Tumors of the Ovary). Epidermoid cysts are those lined exclusively by mature squamous epithelium and are considered either monodermal teratomas or of surface epithelial origin [142, 217]. The finding of Walthard nests in the walls of some of these cysts favor the latter origin in at least some cases [217]. Endometriotic cysts are readily distinguishable by their characteristic lining of endometrial epithelium and stroma and pigmented histiocytes within their walls (**>** Chap. 13, Diseases of the Peritoneum). Solitary FCs should also be distinguished from those of rete origin that are located within the hilus (see page 40) [174].

Differentiating large FCs from unilocular cystic granulosa cell tumors of either the adult or juvenile type (Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations) may be difficult, especially if such a tumor has an orderly arrangement of granulosa and theca cells in its wall. Cystic granulosa cell tumors, however, are usually considerably larger than FCs, and the two cell types usually have a more disorderly pattern that may include obvious penetration of the cyst wall. In contrast to the large solitary luteinized FC of pregnancy, cystic granulosa cells tumors rarely have cells with bizarre nuclei.

Hyperreactio Luteinalis

Hyperreactio luteinalis (HL) is characterized by bilateral ovarian enlargement caused by the presence of multiple luteinized follicle cysts secondary to hCG stimulation [129].

Clinical Features

Hyperreactio luteinalis most commonly occurs with disorders resulting in high levels of hCG such as hydatidiform moles, choriocarcinoma, fetal hydrops (usually secondary to Rh sensitization but rarely of nonimmunologic type), and multiple gestations. Sixty percent of cases unassociated with gestational trophoblastic disease (GTD), however, have accompanied a singleton pregnancy. The frequency of HL in women with GTD ranges from 10% to 50% depending on whether it is detected by clinical examination or sonography. The presence of HL in these patients may indicate an increased risk for persistent or metastatic GTD (• Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions) [129]. Rarely, HL has been preceded by the polycystic ovary syndrome (PCOS) [15].

HL can be detected as a pelvic mass during any trimester, at cesarean section, or rarely during the puerperium. Symptoms are usually absent, but hemorrhage into the cysts may cause abdominal pain. Rarely, the involved ovary undergoes torsion or rupture, sometimes with intraabdominal bleeding, which can be fatal. In contrast to patients with the ovarian hyperstimulation syndrome (see following), ascites is rare. In patients with HL accompanying GTD, HL is detected at the time of the diagnostic curettage or during the postoperative follow-up period [157]. In approximately 15% of cases unassociated with trophoblastic disease, there has been virilization of the patient but not the female infant [15]. Plasma testosterone levels have been elevated in these patients as well as nonvirilized patients with trophoblastic disorders, with the levels proportional to the degree of ovarian enlargement.

Pathological Findings

On macroscopic examination, multiple, usually bilateral, thin-walled cysts cause moderate to massive ovarian enlargement (up to 35 cm) (\bigcirc *Fig. 12.27*). The cysts are filled with clear or hemorrhagic fluid. Microscopic examination reveals FCs with prominent luteinization of the theca interna cells and, in some cases, the granulosa cells (\bigcirc *Fig. 12.28*). Occasionally, the latter have bizarre nuclei. There is usually marked edema of the theca layer and the intervening stroma; the latter frequently contains luteinized stromal cells.

Pathogenesis

Because HL occasionally occurs in patients with otherwise normal pregnancies and normal hCG levels, and because

Fig. 12.27 Hyperreactio luteinalis. Multiple thin-walled follicle cysts are present within the cortex

HL does not occur in all women with high hCG levels, factors other than the latter likely play a role in the pathogenesis of HL. An increased ovarian sensitivity to hCG in patients with the disorder has been suggested [21]. One study found elevated levels of other hormones, specifically progesterone, prolactin, and estradiol, in patients with HL and GTD, possibly implicating these hormones in the pathogenesis or maintenance of HL [148].

Clinical Behavior and Treatment

The cysts of HL typically involute during the puerperium, but occasionally regression is incomplete until 6 months postpartum. In exceptional cases, the cysts regress spontaneously during pregnancy. In cases associated with

Fig. 12.28

Hyperreactio luteinalis. Fluid-filled, thin-walled follicle cysts (a), lined by granulosa and theca layers, both of which exhibit marked luteinization and shown at higher magnification in (b)
trophoblastic disease, gradual regression typically occurs 2–12 weeks after uterine evacuation, but occasionally the cysts persist for months or even enlarge after the hCG level has returned to normal [129, 157]. Operative treatment of HL is needed only to remove infarcted tissue, control hemorrhage, or reduce ovarian size to diminish androgen production in virilized patients. Rarely, HL recurs in subsequent pregnancies.

Differential Diagnosis

Lack of knowledge of the gross appearance of the enlarged ovaries of hyperreactio luteinalis and their resultant misinterpretation as cystic ovarian tumors occasionally leads to an unwarranted bilateral oophorectomy. If doubt exists, a frozen section examination of the cyst wall should solve the problem. Rarely, pregnancy luteomas coexist with HL, heightening the suspicion of a neoplastic process on gross examination.

Ovarian Hyperstimulation Syndrome

An iatrogenic form of HL, the ovarian hyperstimulation syndrome (OHS), occurs in a variable proportion of women undergoing ovulation induction, typically after the administration of follicle-stimulating hormone (FSH) followed by hCG, or rarely clomiphene alone [68]. The frequency of OHS has varied widely in the literature; it has been suggested that some degree of the syndrome exists in all patients undergoing ovulation induction, with a frequency of 0.5-5% for severe forms [86]. OHS occurs only after ovulation, is more severe in patients who conceive, and is particularly prone to occur if the ovaries were polycystic before the institution of therapy. Several cases of spontaneous OHS unassociated with ovulation induction have been reported, usually in the setting of high hCG levels, for example, with molar or multiple gestations [3, 49, 86]. There have been several reports of OHS occurring in association with severe hypothyroidism, usually in pregnant but occasionally in nonpregnant patients [49]. Careful selection of patients and regulation of drug dosage by monitoring estrogen levels and ovarian size have reduced the frequency of OHS. Current evidence has identified hCG to be a potent inducer of vascular endothelial growth factor; the latter is thought to have a major role in the increased vascular permeability associated with severe OHS [124, 209]. Recently, a mutation in the FSH receptor was found to be associated with recurrent, familial OHS [193].

In severe cases, the ovaries become massively enlarged, and ascites, sometimes with hydrothorax, (acute Meigs' syndrome) develops as a result of increased serosal permeability. Elevation of serum estrogens, progesterone, and testosterone typically occurs [68]. Hemoconcentration with secondary oliguria and thromboembolic phenomena is a life-threatening complication. High plasma levels of renin, aldosterone, and antidiuretic hormone may occur [68]. Patients usually respond to conservative therapy, such as cyst aspiration under ultrasonic guidance, and the cysts usually regress within 6 weeks. Operative intervention is only necessary in the rare instance of cyst torsion or rupture. Histologic examination of the ovaries reveals changes identical to those seen in HL, with the additional finding of one or more corpora lutea.

Rare Disorders Characterized by Multiple Follicle Cysts

Depending on the method of detection, as many as 75% of girls with juvenile hypothyroidism have multicystic ovaries [105, 168]. Rarely, the ovarian enlargement may be the presenting sign leading to a diagnosis of hypothyroidism. The clinical features, in addition to ovarian enlargement and manifestations of hypothyroidism, include varying degrees of sexual precocity in more than half the patients and galactorrhea. The sexual precocity and galactorrhea appear to be caused by increased secretion of pituitary gonadotropins and prolactin, respectively. A similar clinical picture can occur rarely in adults. Histologic examination, which has been performed in only a few cases, has revealed FCs, some with luteinization of the theca interna layer. In two cases, a depletion of primordial follicles was also noted. Treatment with thyroxin has resulted in regression of the hypothyroidism, the ovarian cysts, and sexual precocity, and a decline in the elevated gonadotropin and prolactin levels.

Multiple, bilateral FCs associated with estradiol production have been described in infants born before the 30th week of gestation [184]. The cysts, which are secondary to elevated levels of FSH and luteinizing hormone (LH), appear at a postconception age that slightly precedes the expected time of delivery. It is postulated that marked prematurity is associated with relative insensitivity of the hypothalamus and anterior pituitary to negative feedback by estradiol.

Congenital deficiency of 17-hydroxylase, an enzyme required for both cortisol and estrogen synthesis, results in low estrogen levels and secondarily elevated levels of FSH and LH [202]. The rare patients with this disorder have

congenital adrenal hyperplasia, hypokalemia, hypertension, primary amenorrhea, absence of sexual maturation, and ovarian enlargement due to multiple, bilateral FCs. A late onset of the disorder can mimic idiopathic hirsutism or polycystic ovary syndrome (PCOS).

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is an idiopathic disorder, which can have a signifcant impact on the health of affected women, with respect to potential reproductive, metabolic, cardiovascular, and neoplastic sequelae [50, 103, 144]. It is characterized by inappropriate gonadotropin secretion, chronic anovulation, hyperandrogenism, increased peripheral conversion of androgens to estrogens, and sclerocystic ovaries. Many patients also have abnormal glucose tolerance and hyperinsulinemia. The current clinical spectrum of PCOS is broader than that initially defined by Stein and Leventhal in 1935 (as the Stein-Leventhal syndrome), and as is discussed here, PCOS may be the result of multiple potential etiologies and be associated with variable clinical presentations [50, 144]. Some patients with PCOS have the HAIR-AN syndrome of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN), a syndrome discussed after the section on stromal hyperthecosis, a closely related disorder that overlaps both clinically and pathologically with PCOS.

Clinical Features

PCOS has been estimated to affect 5-10% of the female population [93], making it the most common endocrinopathy in women of reproductive age [58]. The clinical diagnosis of PCOS can be challenging, as presenting signs and symptoms are heterogeneous. Recently, an international consensus group has provided updated diagnostic criteria, requiring at least two of the following: oligomenorrea/amenorrhea, hyperandrogenism/ hyperandrogenemia, and polycystic ovaries on ultrasonography; other possible medical diagnoses must also be excluded [204]. Notably, the diagnosis of PCOS can be made in the absence of polycystic ovaries [50]. The affected women are typically in their third decade with a history of dysfunctional uterine bleeding related to anovulatory cycles and typically of peripubertal onset, or less commonly, secondary amenorrhea as well as subfertility or infertility; 80% exhibit evidence of hyperandrogenism, usually in the form of hirsutism [58, 202]. A significant proportion of women with PCOS are overweight or

obese, which can exacerbate the underlying metabolic and reproductive abnormalities [50]. In addition to hirsutism, cutaneous manifestations include acne, androgenetic alopecia, and acanthosis nigricans (> HAIR-AN syndrome) [103]. Hyperinsulinemia, insulin resistance, and impaired glucose tolerance are present in the majority of patients, particularly in those who are obese, although these features may not appear until later in life [50, 144]. Frank virilization (clitoromegaly, deep voice, temporal baldness, male habitus) is rare, and if of sudden onset, suggests stromal hyperthecosis or a virilizing ovarian tumor rather than PCOS. The ovaries may or may not be palpably enlarged. Pelvic ultrasonography may help in establishing the diagnosis, as discussed below. Patients with PCOS have an increased risk for cardiovascular disease secondary to obesity, impaired glucose tolerance, and in some cases, hypertension and dyslipidemias [50].

Studies indicate that PCOS has a strong familial component and may be the most common endocrinopathy causing familial hirsutism. Single-gene mutations may rarely be implicated, but more likely the syndrome is multigenic; candidate genes involved in regulation of the hypothalamic–pituitary–ovarian axis are the major focus in current studies, including microarray analysis of target tissues [46, 50, 215].

Manifestations of unopposed estrogenic stimulation that occur in a significant proportion of patients include endometrial hyperplasia or, in approximately 1% of patients, endometrial carcinoma. The tumors typically occur in obese patients under the age of 40; conversely, up to one quarter of patients with endometrial carcinoma under 40 have PCOS [37]. The tumors are almost always grade 1 endometrioid adenocarcinomas that are confined to the endometrium or invade the myometrium superficially [37]. The carcinomas are rarely, if ever, fatal, and many are reversible with progesterone therapy or by ovulation induction () Chap. 8, Precursor Lesions of Endometrial Carcinoma and O Chap. 9, Endometrial Carcinoma). A wide variety of extrauterine tumors have also been described in patients with PCOS, but their association is probably coincidental [37]. One study, however, has found a 2.5-fold-increased risk of epithelial ovarian cancer in women with PCOS [177].

Gross Findings

Both ovaries, or rarely only one, are typically rounded and two to five times the normal size; the ovarian volume can be three times that of control subjects [107]. Occasionally, however, the ovaries may be of normal size. Superficial 598

cortical cysts are usually visible beneath the white ovarian surface. Examination of the sectioned ovarian surface reveals a thickened, white, capsule-like superficial cortex and numerous subjacent cysts, typically of similar size and usually less than 1 cm in diameter (**>** *Fig. 12.29*). There is usually a central zone of stroma with only rare or no stigmata of ovulation (corpora lutea or albicantia).

Ovarian tissue from patients with PCOS is rarely encountered, as treatment by ovarian wedge resection is no longer used. Polycystic ovaries are defined ultrasonographically by the presence of 12 or more follicles measuring 2–9 mm in diameter or increased ovarian volume (>10 cm³) [9]. The typical gross or ultrasonographic ovarian morphology, however, is unnecessary to make the diagnosis of PCOS, and in the absence of the typical clinical findings, is not diagnostic of the syndrome (\bigcirc Differential Diagnosis) [202].

Microscopic Findings

The superficial cortex is fibrotic and hypocellular, resembling a capsule (\bigcirc *Fig. 12.30a*) and may contain prominent thick-walled blood vessels [78]. Tongues of similarly fibrotic stroma may extend from the superficial cortex into the deeper cortex and medulla. The cysts are attric cystic follicles and have an inner lining of several layers of nonluteinized, focally exfoliated granulosa cells. There is a prominent outer layer of luteinized theca interna cells (\bigcirc *Fig. 12.30b*), giving rise to the term follicular

Fig. 12.29 Polycystic ovary disease. Superficial cortical fibrosis and multiple cystic follicles are present

hyperthecosis, but other studies have found that cystic follicles in women with PCOS differ from those in normal women only in their increased number [107]. Maturing follicles up to midantral stage and atretic follicles exhibiting prominent luteinization of the theca interna may be twice as numerous as in normal ovaries [78]. Primordial follicles are normal in number and appearance [78]. As noted, stigmata of prior ovulation are typically absent, but corpora lutea have been described in as many as 30% of otherwise typical cases of PCOS [78]. The deeper cortical and medullary stroma may have as much as a fivefold increase in volume. The stroma contains luteinized stromal cells in 80% of cases and, less commonly, foci of smooth muscle [78]. Nests of ovarian hilus (Leydig) cells may be more numerous in patients with PCOS than in age-matched controls.

Fig. 12.30

Polycystic ovary disease. (a) Multiple cystic follicles lie beneath the superficially fibrotic cortex. (b) A cystic follicle is lined by nonluteinized granulosa cells and an outer, thicker layer of luteinized theca interna cells

Pathophysiology

The pathophyiology of PCOS is complex, and the initiating factor(s) is (are) not yet completely understood [202]. A cardinal finding is an elevation of the serum level of LH or an elevated LH:FSH ratio; of note, documentation of abnormal gonadotropin levels is not required for the diagnosis of PCOS in routine clinical practice, since their release is pulsatile and concentrations vary throughout the menstrual cycle [50]. LH stimulates the follicular theca interna cells to produce androstenedione, which is converted peripherally, primarily within adipose tissue, to estrone (E1), and to a lesser extent, testosterone. More importantly, ovarian follicular production of testosterone is also increased, leading to the small increases in serum testosterone concentrations that are present in PCOS. Estradiol (E₂) levels remain normal or low normal, resulting in an elevated E1/E2 ratio. Elevated E1 levels, and in some patients an increased secretion of inhibin, a nonsteroidal peptide produced by granulosa cells [200], inhibit secretion of FSH. An elevated LH:FSH ratio is thus a characteristic finding in PCOS. Ovarian estrogen production in PCOS is markedly diminished, probably a result of inactivity of the FSH-dependent aromatase system within the granulosa cells. Inadequate intrafollicular estrogen synthesis, increased intrafollicular androgens, and an elevated LH:FSH ratio result in cessation of follicle growth at the midantral stage, anovulation, and sclerocystic ovaries.

A number of interlinked factors potentially play a role in initiating or perpetuating PCOS. According to Taylor [202], "there are correlations between gonadotropin secretion, insulin secretion, and androgen secretion across the spectrum of patients with PCOS such that it remains impossible to determine the primary etiologic factor in the vast majority of patients." Obesity-related factors including hyperestronemia due to conversion of androstenedione to E_1 and hyperinsulinemia play a role in the pathogenesis of PCOS, and the increase in obesity in the United States has been postulated as an explanation for the reported increased incidence of PCOS [50]. An estimated 20-30% of patients with PCOS have adrenal androgen excess, as manifested by an elevated androgen dehydroepiandrosterone sulfate (DHES) and abnormal adrenal androgen responses to ACTH [169, 216]. The increased adrenal androgens can lead to hyperestronemia and consequently an elevated LH:FSH ratio. Although some investigators believe that the adrenal abnormalities (which may include late-onset congenital adrenal hyperplasia) are a primary disturbance, others have concluded that they are secondary to the hormonal milieu of PCOS [25].

Insulin resistance and hyperinsulinemia are present in most obese and nonobese women with PCOS, although these features tend to be more severe in the former group [140]. Despite peripheral insulin resistance, ovarian tissues remain responsive to insulin in women with PCOS. Insulin appears to amplify LH action, enhancing production of estradiol and progesterone from the follicular granulosa cells and possibly contributing to the arrest of follicle growth [64]. As discussed later (> HAIR-AN syndrome), insulin and insulin-like growth factor stimulate proliferation of ovarian stromal cells and their production of androgen. Hyperinsulinemia thus can increase circulating androgen levels (and by peripheral conversion, estrone) in patients with PCOS. The resultant hyperandrogenism may in turn increase insulin resistance.

Hyperprolactinemia is present in approximately 15–25% of patients with PCOS, but recent evidence indicates that they are distinct entities, with galactorrhea a feature of hyperprolactinemia but not PCOS; in one recent study, elevated plasma prolactin levels were attributable to pituitary adenomas and drug-related effect in 19% and 23% of cases, respectively [50, 54].

Differential Diagnosis

PCOS is a clinicopathologic syndrome, and the finding of polycystic ovaries with little or no evidence of prior ovulation does not warrant the diagnosis per se in the absence of the usual clinical findings. Polycystic ovaries that resemble those of PCOS are seen occasionally in prepubertal children and in otherwise normal girls during the first few years after the onset of puberty. Similarly, ultrasonographic studies have revealed that ovulating women with minor evidence of hyperandrogenism, but without menstrual irregularity, can have polycystic ovaries similar to those of patients with overt clinical manifestations except that the ovaries also contain corpora lutea and albicantia [160]. Thus, the boundary between the clinical syndrome of PCOS and normality is not clear cut.

Although PCOS does not cause a problem in differential diagnosis with a neoplasm for the pathologist, the clinical manifestations may suggest the possibility of an androgenic or estrogenic ovarian tumor, particularly in the exceptional cases in which the disease coexists with a nonfunctioning ovarian neoplasm. In some cases, in which the associated ovarian tumor is capable of function, such as a Sertoli–Leydig cell tumor, it may be difficult to determine which lesion was responsible for the endocrine manifestations.

The differential diagnosis includes a wide variety of other disorders that result in abnormal gonadotropin release, chronic anovulation, and sclerocystic ovaries. Sclerocystic ovaries are a nonspecific morphologic expression of chronic anovulation in the premenopausal patient and can accompany (1) adrenal lesions such as Cushing's syndrome, congenital adrenal hyperplasia (most commonly 21-hydroxylase or 11-beta-hydroxylase deficiency), and virilizing adrenal tumors; (2) primary hypothalamicpituitary disorders; and (3) ovarian lesions that produce excessive quantities of estrogens or androgens, including sex cord-stromal tumors, steroid cell tumors, and nonneoplastic lesions such as Leydig cell hyperplasia and stromal hyperthecosis. As previously noted, the latter overlaps both clinically and pathologically with PCOS, and the two disorders may represent opposite poles of a single disease spectrum. Sclerocystic ovaries have also been described in patients with autoimmune oophoritis [10], after long-term use of oral contraceptives, in association with periovarian adhesions, and after long-term androgen therapy in female to male transsexuals [149]. An association between a PCOS-like syndrome and the use of the antiepileptic drug valproate has been found [80].

Stromal Hyperplasia and Stromal Hyperthecosis

Normal, spindle-shaped stromal cells, which have scant cytoplasm and resemble fibroblasts, are typically arranged in whorls or a storiform pattern within a dense reticulum network and a variable amount of collagen, which is most abundant in the superficial cortex. Stromal cells are typically immunoreactive for CD56, WT-1, vimentin, and estrogen and progesterone receptors [8, 69, 122]. In many women of late-reproductive and postmenopausal age, there is a decrease in stromal volume and cellularity, with an increase in collagen. A variety of other cells may be found within the ovarian stroma, most of which are probably derived from the spindle-shaped stromal cells, including luteinized stromal cells, enzymatically active stromal cells, decidual cells, endometrial stromal-type cells (stromal endometriosis, "ovarian stromatosis") (> Chap. 13, Diseases of the Peritoneum), smooth muscle cells, fat cells, stromal Leydig cells, and rare cells of neuroendocrine or APUD (amino precursor uptake and decarboxylation) type [28]. Stromal hyperplasia (SH) is characterized by varying degrees of proliferation of the ovarian stromal cells. Stromal hyperthecosis (HT) refers to the presence of luteinized cells within the stroma at a distance from the follicles; it is usually accompanied by at least a moderate degree of SH.

Clinical Features

The clinical manifestations are variable. Moderate to severe SH is most commonly encountered in women in their sixth and seventh decades and has been documented in more than one third of autopsied patients in this age group [194]. Similar degrees of SH are found less commonly in patients in the eighth decade, suggesting that it may be a reversible process. A strong negative association with parity was found in one study [194]. SH of moderate to severe degree may be found in women with disorders associated with androgenic or estrogenic manifestations including endometrial carcinoma, obesity, hypertension, and glucose intolerance, but these findings are less frequent and less obtrusive than in HT.

HT is most frequent in patients in the sixth to ninth decades. Some familial cases of HT have been reported [84]. The process has been documented in one third of autopsied patients over the age of 55, and exhaustive microscopic sampling may reveal that rare luteinized stromal cells are even more common in this age group [28]. In postmenopausal women, HT is usually mild and of doubtful clinical significance.

Clinically florid examples of HT are more common in patients in the younger reproductive age group, although rare cases occur in adolescents and postmenopausal patients [109]. The findings include marked virilization, obesity, hypertension, hyperinsulinemia, and decreased glucose tolerance. In addition, a small subset of women with HT (or occasionally PCOS) have the HAIR-AN syndrome (see following). The clinical picture of HT typically evolves gradually, but occasionally there is an abrupt onset, potentially suggesting the presence of an androgenic tumor, especially if the process is unilateral and associated with ovarian enlargement. Less commonly, the clinical findings are more characteristic of PCOS. In some patients with HT, especially postmenopausal women, estrogenic findings predominate and may include endometrial hyperplasia or even well-differentiated adenocarcinoma [109, 135, 176, 194]. Conversely, women with endometrial hyperplasia or carcinoma in some studies have had a high frequency of HT on microscopic examination of their ovaries [135, 176]. HT-related virilization has been present in two cases of placental site trophoblastic tumor, and in one case it was the presenting manifestation of the tumor [133, 138].

Gross Findings

SH and HT are almost invariably bilateral, and the ovaries range from normal size to 8 cm in maximum dimension, thus potentially mimicking an ovarian neoplasm [109]. The sectioned surfaces are usually solid, firm, homogenous, and white to yellow (\bigcirc *Fig.* 12.31). In cases of nodular hyperthecosis, multiple yellow nodules may be appreciable. In premenopausal women, sclerocystic changes similar to those seen in PCOS may also be present [78]. HT rarely coexists with a neoplasm, usually a stromal luteoma, which may also have hormone-secreting potential [180].

Microscopic Findings

In both SH and HT, a variable degree of nodular or diffuse cortical and medullary proliferation of ovarian stromal cells is present (**)** *Fig. 12.32a*). A mild degree of SH cannot be reliably distinguished from the normal appearance. Follicular derivatives may lie within the hyperplastic stroma but may be rare or absent in advanced cases (**)** *Fig. 12.32b*). The stromal cells in SH are plumper than normal postmenopausal ovarian stromal cells, and have oval to fusiform, vesicular nuclei, and, frequently, cytoplasmic lipid. The luteinized stromal cells of HT are more common in the medulla but may also be present in the cortex. They appear as single cells, small nests, or nodules of polygonal cells with abundant eosinophilic to vacuolated cytoplasm, containing variable amounts of lipid (**)** *Fig. 12.33*). The

Fig. 12.31 Stromal hyperplasia and stromal hyperthecosis. Solid, homogeneous, yellow sectioned surface

round nucleus of the luteinized cells typically has a central small nucleolus. As noted, in premenopausal women including those with the HAIR-AN syndrome, sclerocystic changes characteristic of PCOS are also commonly present. In cases of HT accompanying the HAIR-AN syndrome (see following), edema and fibrosis of the ovarian stroma, rather than SH, are frequently a prominent change [117].

Other ovarian findings occasionally encountered in HT include an increased number of atretic follicles, small stromal nodules of metaplastic smooth muscle, hilus cell hyperplasia, hilus cell tumors, stromal luteomas, and thecomas [170, 181, 196, 220]. SH in the absence of HT has also been associated with thecomas [220]. Some cases of HT may be associated with massive ovarian edema.

Fig. 12.33

Stromal hyperthecosis. (a) A nest of luteinized stromal cells is present within the ovarian stroma. (b) Calretinin immunostain highlights luteinized stromal cells

Histochemical analyses have shown that nonluteinized and luteinized stromal cells and cells transitional in appearance between the two have oxidative activity important in steroid hormone production [182]. The luteinized cells were immunoreactive for cytochrome P-450-17-alpha, which catalyzes androgen synthesis, in approximately 50% of the cases of SH in one series [176]. Luteinized stromal cells are also immunoreactive for inhibin, calretinin (**)** *Fig. 12.33*), testosterone, estradiol, and follicle-stimulating hormone (FSH) [109, 121, 135, 154].

Pathophysiology

In vitro and in vivo studies have shown that ovaries with SH secrete more androstenedione, estrone, and estradiol than normal ovaries [43]. Similar studies using ovarian tissue from patients with HT [136] as well as in vivo

studies in these patients have shown, respectively, markedly increased production rates and serum levels of ovarian testosterone, dihydrotestosterone, and androstenedione, usually in the male range [109]. As already noted, immunohistochemical staining for various enzymes involved in the conversion of cholesterol to steroid hormones in cases of HT has been consistent with androgen synthesis not only in the luteinized stromal cells characteristic of the disorder but also in the adjacent spindleshaped stromal cells [176]. As in PCOS, the predominant estrogen in patients with SH and HT is estrone, derived predominantly from peripheral aromatization of ovarian androgens, resulting in an increased estrone/estradiol ratio [176].

Unlike patients with PCOS, most premenopausal patients with HT have normal gonadotropin levels [84]. That gonadotropins may play a role in SH and HT, however, is suggested by (1) elevated LH levels in occasional premenopausal women with HT and most postmenopausal patients with SH and HT; (2) immunoreactivity for FSH and LH receptors within ovarian stromal cells [139]; (3) in vitro incubation studies showing that FSH and LH stimulate proliferation of the ovarian stroma of pre- and postmenopausal women [194]; (4) studies showing that androgen production by the ovarian stromal cells in patients with and without HT is enhanced by LH [43, 136]; (5) the often prominent stromal luteinization during pregnancy; (6) cases of symptomatic HT complicating pregnancy and trophoblastic disease [133, 138]; and (7) the increase in pituitary amphophils in some cases of severe HT [109]. As noted, insulin resistance and hyperinsulinemia occur in as many as 90% of patients with HT and likely play a role in the pathogenesis of the stromal luteinization in these patients (> HAIR-AN syndrome) [137].

Differential Diagnosis

In contrast to a fibroma, SH is almost always bilateral and is characterized by cells with smaller nuclei, scanty collagen, and nodules that commonly coalesce. The lesion is distinguished from a low-grade endometrioid stromal sarcoma by the spindle shape of its cells and by an absence of mitotic figures and regularly distributed arterioles.

The differential diagnosis of HT includes other nonneoplastic and neoplastic solid proliferations of luteinized cells, most of which are also virilizing. The nonneoplastic category includes pregnancy luteoma and Leydig cell hyperplasia (discussed elsewhere in this chapter) and the neoplasms include luteinized thecoma and steroid cell tumors (Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). These neoplasms, in contrast to HT, are almost always unilateral and typically form distinct tumors or nodules appreciable on gross examination. Luteinized stromal cells, histologically similar to those present in HT, may also be encountered within the nonneoplastic stroma of a variety of benign and malignant ovarian tumors, including primary surface epithelial and germ cell tumors as well as metastatic tumors, that is, "tumors with functioning stroma" (Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations).

Clinical Behavior and Treatment

In contrast to patients with PCOS, those with HT usually exhibit little or no response to clomiphene treatment [84]. Many patients require bilateral oophorectomy to halt progressive virilization. Such treatment may also result in disappearance of hypertension and abnormalities in glucose tolerance. More recently, successful treatment of HT has been achieved with gonadotropin-releasing hormone (GnRH) agonists [195].

HAIR-AN Syndrome

In addition to the common occurrence of insulin resistance and hyperinsulinemia in patients with HT, some patients with HT have the HAIR-AN syndrome, a syndrome estimated to occur in as many as 5% of all women with hyperandrogenism [11, 48, 115]. The syndrome consists of hyperandrogenism (HA), typically of early, sometimes premenarcheal, onset; insulin resistance (IR); and acanthosis nigricans (AN) [11]. Striking degrees of masculinization are present in some patients with the HAIR-AN syndrome and may be disproportionate to the degree of hyperandrogenism [48]. Some patients have a normal glucose tolerance whereas others have symptomatic diabetes [85].

The syndrome has been most frequently described in patients with PCOS, although it appears likely that most, if not all, such patients also have HT [48, 117]. Unusual histologic findings in patients with HT and the HAIR-AN syndrome have included prominent follicular atresia, large numbers of degenerating oocytes, medullary stromal fibrosis, and numerous small nests of granulosa cells forming Call–Exner bodies [115]. Dermoid cysts and stromal luteoma have been rarely described in patients with the HAIR-AN syndrome in association with HT, sclerocystic ovaries, or both.

The typical laboratory findings include hyperinsulinemia and increased production rates and elevated serum levels of testosterone and androstendione [48]. In some patients, the severity of the insulin resistance is proportional to the testosterone elevation. Proposed mechanisms of insulin resistance have included a decreased number or functional capacity of insulin receptors, which may be associated with obesity, or in other cases, genetic alterations in the structure of the receptors (type A); antiinsulin receptor antibodies that decrease insulin receptor affinity for insulin and which are often associated with autoimmune diseases (type B); and postreceptor defects in insulin action or clearance (type C) [12, 85].

It has been postulated that the primary defect in the HAIR-AN syndrome is insulin resistance leading to hyperinsulinemia and the other findings in the syndrome. Thus, any cause of insulin resistance leading to hyperinsulinemia can produce the HAIR-AN syndrome. The hyperandrogenism itself may increase the severity of the insulin resistance, and thus a self-perpetuating cycle that increases in severity may result [11]. The acanthosis nigricans is probably an epiphenomenon secondary to the hyperandrogenism, hyperinsulinemia, or both.

Bilateral oophorectomy in patients with the HAIR-AN syndrome decreases hyperandrogenism but usually does not ameliorate insulin resistance [115, 137]. Gonadotropin suppression with oral contraceptives has been successful in decreasing ovarian androgen production in some patients. Marked improvement of acanthosis nigricans may follow correction of the hyperandrogenism.

Massive Edema and Ovarian Fibromatosis

Tumor-like enlargement of one, or occasionally, both ovaries secondary to an accumulation of edema fluid within the ovarian stroma is referred to as massive ovarian edema. Over 100 cases of this disorder have been reported [141, 171, 218]. A rarer lesion designated ovarian fibromatosis [218], characterized by diffuse ovarian fibrosis, is closely related to massive edema and is therefore considered in this section.

Clinical Features

Patients with massive edema are typically young, with a mean age of 21 years (range, 6–37 years) and have

abdominal or pelvic pain, menstrual irregularities, and abdominal distension. The pain may be of several years duration or have a sudden onset and mimic the pain of acute appendicitis. Androgenic manifestations are present in approximately 20% of patients and are nearly always associated with the presence of luteinized stromal cells. Of these, two thirds are masculinized and the rest exhibit only hirsutism [218]. Serum testosterone has been elevated in some cases. Rare patients have had estrogenic manifestations, manifested by isosexual pseudoprecocity [141, 171, 218]. Pelvic examination typically reveals a palpable adnexal mass, which in 70% of cases has been rightsided. Abdominal exploration reveals unilateral involvement in 90% of cases, and in approximately half the patients, partial or complete torsion of the involved ovary. In one patient, the contralateral ovary had a twisted pedicle and was infarcted. Intraperitoneal fluid is not usually present, although rare patients have had an associated Meigs' syndrome. Rare cases of ovarian edema secondary to lymphatic permeation by metastatic cervical carcinoma have also been reported [95].

Patients with ovarian fibromatosis have ranged in age from 13 to 39 years, with an average of 25 years [218]. Clinical manifestations include menstrual abnormalities or amenorrhea, abdominal pain, and rarely hirsutism or virilization. The majority of patients have a palpable adnexal mass. Occasionally, the ovarian enlargement is an incidental finding late in pregnancy or during cesarean section. In some cases, the involved ovary was found twisted on its pedicle at the time of operation. The endocrine manifestations, including, in several cases, infertility, disappear after oophorectomy, indicating that the lesion produces steroid hormones.

Gross Findings

The involved ovary in massive edema is enlarged, soft, and fluctuant, ranging from 5.5 to 35 cm in maximum dimension (mean, 11.5 cm). The heaviest ovary weighed 2,400 g [218]. The ovary has a shiny, white, smooth exterior as a result of a white and fibrotic superficial cortex and a sectioned surface that is edematous or gelatinous and exudes watery fluid (\bigcirc *Fig. 12.34*). Occasional superficial FCs may be present. The ipsilateral fallopian tube may also be edematous.

In ovarian fibromatosis, there is usually complete or almost complete ovarian involvement by a fibromatous process [218]. In 20% of cases, the process is bilateral. The ovaries are 8–14 cm in maximum dimension with white and typically smooth or lobulated external surfaces. The cut surfaces are firm, white to gray, and solid except for the presence of cystic follicles in one third of cases (\triangleright *Fig.* 12.35).

Microscopic Findings

The striking finding on low magnification in massive edema is marked, diffuse, stromal edema that separates and sometimes involves the follicular structures but typically spares the superficial cortex (\bigcirc *Fig.* 12.36). The latter is usually thickened and fibrotic. Higher magnification

reveals spindle-shaped ovarian stromal cells separated by abundant pale-staining fluid that focally may impart a microcystic appearance. In nonedematous areas, the stroma has the appearance of normal stroma, hyperplastic stroma, or ovarian fibromatosis [218]. In approximately 40% of cases, foci of luteinized cells are present (**>** *Fig. 12.37*). Associated nonspecific findings include vascular and lymphatic dilatation within the ovary and occasionally the mesosalpinx, focal necrosis, extravasated erythrocytes, hemosiderin-laden macrophages, and mast cells [171, 218]. The contralateral ovary is normal in more than 75% of cases; in the rest, it is enlarged and edematous, or is nonedematous but altered by stromal hyperthecosis or sclerocystic changes.

 Fig. 12.39
Ovarian fibromatosis. Fibrotic ovarian stroma surrounds a preantral follicle

Ovarian fibromatosis is characterized by a fibromatoid proliferation of collagen-producing spindle cells (\bigcirc *Fig. 12.38*) that typically surrounds normal follicular structures and thickens the superficial cortex (\bigcirc *Fig. 12.39*) [218]. In most cases of fibromatosis, the process is diffuse but it may be localized, and occasionally it is confined to or predominantly involves the cortex ("cortical fibromatosis"). The process varies from moderately cellular fascicles of spindle cells with a focal storiform pattern to relatively acellular bands of dense collagen. Small foci of uninvolved ovarian stroma are usually present. In rare cases, luteinized cells are seen within the lesion or the adjacent nonfibrotic stroma. Minor foci of

stromal edema and microscopic foci of sex cord elements within the fibromatous tissue, alone or in combination, have been encountered in occasional cases [218].

Pathogenesis

The pathogenesis of massive edema is thought to be intermittent torsion of the ovary on its pedicle, causing partial obstruction of venous and lymphatic drainage. Torsion is observed in half the cases of massive edema, and a few cases of massive edema have been reported in association with obstruction of ovarian lymphatics secondary to metastatic carcinoma within pelvic and paraaortic lymph nodes [95, 218]. Luteinization of the ovarian stromal cells is considered a secondary phenomenon.

In at least some cases, massive edema likely occurs in an ovary with an underlying stromal proliferation, either fibromatosis or stromal hyperthecosis, that enlarges the ovary, promoting torsion with subsequent edema [218]. This interpretation is supported by the clinical similarities and pathologic overlap between massive edema and ovarian fibromatosis. Young and Scully suggest that massive edema is simply ovarian fibromatosis following torsion and accumulation of edema fluid [218]. Similarly, some examples of massive edema in which luteinized stromal cells are present in the same ovary and in the contralateral, edematous or nonedematous ovary may represent cases of stromal hyperthecosis in which one or both ovaries have undergone torsion.

Rather than accepting that fibromatosis is a precursor of massive edema, Russell and Farnsworth [173] hypothesized that the fibromatoses described by Young and Scully represent the "burned-out" stage of a reactive fibroblastic proliferation that at one end of the spectrum is represented by massive edema and at the other by a variety of highly cellular fibroblastic tumor-like lesions.

Differential Diagnosis

The differential diagnosis of massive edema includes ovarian neoplasms that may exhibit an edematous or myxoid appearance, most commonly fibroma, but also sclerosing stromal tumor, Krukenberg tumor, luteinized thecoma associated with sclerosing peritonitis, and the rare ovarian myxoma. Recognition of massive edema is therefore of great importance to prevent unnecessary oophorectomy in a young female. Fibromatosis also may be confused with a fibroma, or if sex cord-like nests are prominent, a Brenner tumor. Massive edema and fibromatosis are distinguished from a neoplasm by the presence of follicular derivatives visible on both macroscopic and microscopic examination. A neoplasm may be surrounded by a rim of normal ovarian tissue in contrast to massive edema and fibromatosis, which usually diffusely involve the ovarian tissue. Additionally, ovarian fibromas occur in an older age group and are hormonally inactive, and Krukenberg tumors, in contrast to massive edema and fibromatosis, are characterized by signet-ring cells. Finally, the sex cordlike nests in fibromatosis are distinguishable from those of a Brenner tumor in their number, shape, and cell type.

Clinical Behavior and Treatment

Although most of the reported patients with massive edema have been successfully treated by oophorectomy, the condition should be managed conservatively, especially if the patient is young, because there is a strong likelihood that the condition will resolve. After an intraoperative frozen section of a wedge biopsy to exclude a neoplasm, an ovarian suspension procedure should be performed, with fixation of the involved ovary.

Pregnancy Luteoma

Pregnancy luteoma is a distinctive, nonneoplastic lesion of pregnancy, characterized by solid proliferations of luteinized cells, resulting in tumor-like ovarian enlargement that regresses during the puerperium [145].

Clinical Features

The patients are usually in their third or fourth decades, are multiparous in 80% of the cases, and a similar proportion are black. Most patients are asymptomatic, and the ovarian enlargement is discovered incidentally at cesarean section or postpartum tubal ligation. Rarely, a pelvic mass is palpable or obstructs the birth canal. In approximately 25% of cases, hirsutism or virilization appears or worsens during the latter half of pregnancy. Seventy percent of female infants born to virilized mothers are born with clitoromegaly and labial fusion. Plasma testosterone and other androgens may reach levels 70 times normal in virilized patients; increased values have also been demonstrated in nonvirilized patients [134]. Androgen levels in the infants may be increased but are usually lower than maternal levels or normal [134]. Regression of the luteomas usually begins within days after delivery and is

complete within several weeks. Simultaneously, elevated androgen levels decrease rapidly, usually normalizing within 2 weeks postpartum. In rare cases, pregnancy luteomas occur in consecutive pregnancies. The diagnosis is made by excisional biopsy and frozen section examination of one nodule.

Gross Findings

Pregnancy luteomas are solid, fleshy, circumscribed, red to brown nodules ranging from microscopic up to 20 cm in diameter (median, 6.6 cm) (**>** *Fig. 12.40*) [145]. Hemorrhagic foci are common. The lesions are multiple in almost half the cases and bilateral in at least one third. A separate corpus luteum of pregnancy may also be visible. Examination of the ovaries days to weeks postpartum reveals brown puckered scars.

Microscopic Findings

The lesions are composed of sharply circumscribed, rounded masses of cells (\bigcirc *Fig.* 12.41), that are also occasionally arranged in a trabecular or follicular pattern, the latter associated with spaces containing colloid-like material (\bigcirc *Fig.* 12.42a). The cells are intermediate in size between the luteinized granulosa cells and luteinized theca cells of adjacent follicles and have abundant eosinophilic cytoplasm that contains little or no stainable lipid and central nuclei (\bigcirc *Fig.* 12.42b). The nuclei may vary slightly in size and are hyperchromatic; nucleoli may be

Fig. 12.40 Pregnancy luteoma. Multiple, solid, circumscribed, reddishbrown and hemorrhagic nodules replace the normal parenchyma

prominent. Mitotic figures may range up to seven per ten high-power fields, with an average of two or three, and may be atypical [145]. Less common features include focal balloon-like cytoplasmic degeneration and colloid droplets similar to those seen in the corpus luteum of pregnancy. The stroma is scanty, and reticulin fibrils surround groups of cells. Examination of lesions removed postpartum shows shrunken aggregates of degenerating lipidfilled luteoma cells with pyknotic nuclei, infiltration by lymphocytes, and fibrosis.

Pathogenesis

Pregnancy luteomas most likely arise from hCG-induced proliferations of luteinized ovarian stromal cells. Some authors, however, have favored origin from luteinized follicular granulosa and theca cells [145]. The exclusive occurrence of the lesion in pregnancy suggests a role for hCG in its pathogenesis, and augmentation of steroidogenesis by pregnancy luteomas in response to hCG, both in vitro and in vivo, supports this interpretation. However, the rarity of pregnancy luteomas in association with gestational trophoblastic disease, which is typically accompanied by very high levels of hCG, and the almost exclusive recognition of the lesions during the third trimester when hCG levels are lower than earlier in pregnancy, indicate that hCG is not the only factor in their development. The occasional history of hirsutism, sometimes familial, antedating the pregnancy suggests that a preexistent endocrinopathy, such as stromal hyperthecosis or PCOS, may predispose to the development of the lesion in some patients.

Differential Diagnosis

When pregnancy luteomas are multiple, intraoperative inspection may suggest nodules of metastatic tumor. Such a diagnosis can usually be excluded by frozen section examination of one of the nodules, but the distinction may be difficult if the patient has a history or clinical evidence of an oxyphilic malignant tumor such as a malignant melanoma. When the luteoma is a single nodule, the microscopic differential diagnosis includes a number of lesions composed of luteinized cells occurring during pregnancy. However, the typical gross appearance of the pregnancy luteoma readily distinguishes it from a large solitary luteinized follicle cyst of pregnancy and puerperium, hyperreactio lueinalis, and corpus luteum of pregnancy. Solid primary neoplasms composed partially or entirely of luteinized cells such as granulosa tumors, thecomas, and steroid cell tumors may occur during pregnancy and enter the differential diagnosis. Such tumors are almost always unilateral and solitary compared to the more frequent bilaterality and multinodularity of the pregnancy luteoma. The partly luteinized group, that is, luteinized granulosa cell tumors and luteinized thecomas, contain typical nonluteinized foci and usually have denser reticulum patterns and more abundant intracellular lipid than seen in pregnancy luteoma. Entirely luteinized tumors belonging to the steroid cell category may closely resemble pregnancy luteoma histologically. Features favoring a steroid cell neoplasm include a dense reticulum pattern, intracellular lipid, lipochrome pigment, and in Leydig cell tumors, a hilar location and the presence of Reinke crystals (> Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). Differentiation of a solitary pregnancy luteoma from a lipid-poor steroid cell tumor may be impossible, but such a lesion in a pregnant woman is generally considered a pregnancy luteoma until proven otherwise.

Clinical Behavior and Treatment

Because the pregnancy luteoma is a benign, self-limited condition, no treatment is required.

Granulosa Cell Proliferations of Pregnancy

General and Pathologic Features

Granulosa cell proliferations that simulate small neoplasms have been encountered as incidental findings in the ovaries of pregnant women [31]. The older literature documented the presence of similar lesions in the ovaries of nonpregnant women, and we have encountered them in the ovary of a newborn that also contained a corpus luteum. The lesions in pregnant women are usually multiple and lie within atretic follicles, which are typically enveloped by a thick layer of luteinized theca cells. The granulosa cells may be arranged in solid, insular, microfollicular () Fig. 12.43), or trabecular patterns, mimicking similar patterns in clinically evident granulosa cell tumors. In one case, a solid tubular pattern was identical to that seen in some Sertoli cell tumors. The granulosa cells typically contain scanty cytoplasm and grooved nuclei, resembling the cells of the adult-type granulosa cell tumor and in the case with a sertoliform pattern, the cells contained moderate amounts of finely vacuolated cytoplasm, suggesting the presence of lipid. In one case, there were large nodules of luteinized granulosa

Fig. 12.43

Granulosa cell proliferations of pregnancy mimicking a small granulosa cell tumor. The proliferations are within the center of an atretic follicle and are surrounded by the luteinized cells of the theca interna. (a) The proliferating cells form an irregular island containing Call-Exner formations. (b) In a different case, the granulosa cells form

small nests and contain nuclear grooves

cells with variably sized, round, nongrooved nuclei, resembling pregnancy luteomas except for their obvious origin in granulosa cells and the larger size of their cells.

Differential Diagnosis

The differential diagnosis in most of the cases is with a small granulosa or Sertoli cell tumor. Although similar proliferations have been previously interpreted as small tumors, the frequency of the lesions during pregnancy suggests an unusual nonneoplastic response to the hormonal milieu, possibly to the FSH-like property of hCG. The microscopic size of the lesions, their multifocality, and their confinement to atretic follicles support this interpretation.

Leydig Cell Hyperplasia

Leydig cells typically occur in the ovarian hilus, where they are also referred to as hilus cells and can be found in virtually all adult ovaries, typically intermingled with nonmyelinated nerves. Rarely, Leydig cells occur in nonhilar locations, either within the ovarian stroma or in extraovarian sites such as the lamina propria or adventitia of the fallopian tube [74]. Stromal (nonhilar) Leydig cell hyperplasia, in which Reinke crystal-containing Leydig cells are present within the ovarian stroma, is much less common than hilar Leydig cell hyperplasia. One recent report documented bilateral stromal Leydig cell hyperplasia in a postmenopausal woman who presented with virilization; hilus cell hyperplasia was absent [203].

Stromal Leydig cells are likely the origin of the rare Leydig cell tumors encountered within the ovarian stroma (Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). In one such case, there was also bilateral hilar Leydig cell hyperplasia and bilateral hilar Leydig cell tumors [196]. Stromal Leydig cells have also been rarely encountered within the nonneoplastic stroma of a variety of ovarian neoplasms and cysts, including mucinous and serous cystadenomas, Brenner tumors, struma ovarii, and strumal carcinoid tumors [175].

Hilar Leydig cell hyperplasia is difficult to define because hilus cell nests are typically widely separated and cannot be quantitated adequately without sectioning both ovaries extensively. Also, hilus cell proliferation can occur physiologically as a result of elevated hCG or LH levels, such as during pregnancy and after the menopause (> Fig. 12.44) [28]. In such cases, the proliferation is often mild and generally not accompanied by a clinical endocrine disturbance, although such proliferations may account for at least some of the hirustism that is frequently observed during pregnancy. Severe degrees of hyperplasia, often associated with virilization, may occur in both pregnant and nonpregnant women. In some cases, elevated serum testosterone levels have been documented [41]. Hilus cell hyperplasia is characterized by an increased number of cells in a nodular or, less commonly, a diffuse arrangement, increased cell size, the presence of mitotic figures, cellular and nuclear pleomorphism, hyperchromasia, and multinucleation; crystals of Reinke may or may not be apparent by light microscopy (**▷** *Figs.* 12.44 and **◇** 12.45) [196].

Hilar Leydig cell hyperplasia may be associated with other ovarian lesions, including stromal hyperplasia, stromal hyperthecosis, stromal Leydig cell hyperplasia, rete cysts () Miscellaneous Lesions), and hilus cell neoplasia

Fig. 12.44

Hilar Leydig cell hyperplasia in a postmenopausal woman. (a) Nodular proliferation of hilar Leydig cells; (b) The hilus cells have abundant eosinophilic cytoplasm. No crystals are seen in this field, but spherical hyaline globules are present (*lower right*), likely representing crystal precursors

• Fig. 12.45 Hilar Leydig cell hyperplasia. Some nuclei are enlarged and hyperchromatic. Many crystals are seen in this field

[196]. One case of hilus cell hyperplasia has been associated with the resistant ovary syndrome and other cases have been associated with gonadal dysgenesis [83]; in both disorders, LH levels are elevated. From a pathologic point of view, the distinction between a large hyperplastic nodule of hilus cells and a hilus cell tumor is arbitrary; we diagnose neoplasia when the nodule is more than 1 cm in diameter.

Ovarian "Tumor" of the Adrenogenital Syndrome

One ovarian example of this lesion has been reported [5]. A 36-year-old woman with congenital adrenal hyperplasia presented with an abrupt aggravation of her virilizing symptoms, relieved by bilateral salpingo-oophorectomy. Ovarian or paraovarian soft brown masses were present in both adnexae, which on microscopic examination were identical to the testicular tumor of the adrenogenital syndrome [5].

Ovarian Stromal Metaplasias Including Decidual Reaction

The ovarian stromal cell has the potential to differentiate, presumably by a process of metaplasia, into a variety of other mesenchymal cell types, most commonly decidua, but rarely smooth muscle, fat, and bone.

Ovarian Decidual Reaction

An ectopic decidual reaction may be encountered within the ovarian stroma as an isolated finding or as part of a more widespread decidual transformation of the subperitoneal pelvic mesenchyme (> Chap. 13, Diseases of the Peritoneum) [20]. As in other sites of the secondary müllerian system, an ovarian decidual reaction usually represents a response of the indigenous stromal cells to the hormonal milieu of pregnancy. Ectopic decidua may be seen as early as the ninth week of gestation and is present in almost all ovaries at term. Less commonly, the decidua is associated with trophoblastic disease, in patients treated with progestagens, in the vicinity of a corpus luteum, and in association with hormonally active neoplastic and nonneoplastic lesions of the ovaries and adrenal glands [20, 146]. Prior ovarian radiation may be a predisposing factor by increasing the sensitivity of the stromal cells to hormonal stimulation [146]. Foci of ectopic decidua occasionally may occur within the ovaries

of pre- and postmenopausal women with no obvious cause [146].

The decidual foci are usually seen only microscopically but in some cases, may be visible on macroscopic examination as variably sized, soft, tan to hemorrhagic nodules, or patches. The decidual cells typically occur singly, as small nodules, or confluent sheets in the superficial cortical stroma and the ovarian surface, often within periovarian adhesions (> Fig. 12.46). The cells are indistinguishable from eutopic decidua on light microscopic and ultrastructural examination. Smooth muscle cells, probably derived from submesothelial fibroblasts or the ovarian stroma, may be admixed. A rich vascular network of distended capillaries and a sprinkling of lymphocytes are typically found within the decidual foci. Focal nuclear pleomorphism and hyperchromasia, sometimes in association with hemorrhagic necrosis, should not be misinterpreted as evidence of a malignant tumor. Occasionally, ectopic decidual cells may have vacuoles and eccentric nuclei simulating signet-ring cells [32]. The bland appearance of most of the nuclei, the absence of mitotic figures, the PAS negativity of the vacuolar contents, and the association with pregnancy should facilitate the correct diagnosis. Ectopic decidua in postpartum patients may undergo hyalinization.

Rarer Ovarian Stromal Metaplasias and Calcification

Foci of metaplastic smooth muscle (**>** *Fig. 12.47a*) may be rarely encountered in the ovarian stroma of otherwise

Fig. 12.46 Ectopic decidua. Small nodules of decidual cells involving ovarian surface adhesions

normal ovaries, within hyperplastic ovarian stroma (as in stromal hyperthecosis or polycystic ovaries), or within the walls of nonneoplastic or neoplastic cysts [78, 181]. Foci of mature fat have been described as a rare incidental histologic finding within the superficial ovarian stroma in obese women (\bigcirc *Fig. 12.47b*) [75]. Heterotopic bone formation in the ovary in the absence of an ovarian neoplasm is also unusual, typically occurring within periovarian adhesions or the walls of endometriotic cysts but rarely within otherwise normal ovaries [189].

In one case, extensive idiopathic calcification resulted in a stony hard consistency of both ovaries, which were of normal size [30]. Microscopic examination showed numerous spherical, laminated, calcific foci without accompanying epithelial cells (\bigcirc *Fig.12.48*). This process must be distinguished from a serous borderline tumor or carcinoma with confluent psammoma bodies, in which at least occasional neoplastic epithelial cells should be

Fig. 12.47

Ovarian stromal metaplasia. (a) Foci of smooth muscle are separated by ovarian stromal cells. (b) A focus of adipose tissue lies within the ovarian stroma, surrounded by epithelial inclusion glands

Fig. 12.48

Idiopathic ovarian calcification. Numerous spherical, laminated, and calcific foci without accompanying epithelial cells occupy the ovarian stroma. Both ovaries were stony hard on gross examination

identified, and from a "burned-out" gonadoblastoma replaced by laminated calcified masses. In cases of the latter type, the patient almost always has evidence of abnormal gonadal development and Y-chromosome material in her karyotype as well as residual typical gonadoblastoma in the same or contralateral gonad.

Disorders of Ovarian Failure

Premature ovarian failure (POF) or premature menopause is a result of a variety of disorders that lead to the onset of amenorrhea and infertility before the age of 35 years, or according to others, 40 years [164, 172, 206]. POF is uncommon, affecting an estimated 1% of women under the age of 40 [87] and accounting for only 4–10% of patients with secondary amenorrhea [172]. The ovarian failure is usually permanent, but occasionally it is reversible, at least temporarily, as manifested by subsequent ovulation and even conception [164, 206].

Patients with POF typically have a 46XX karyotype, normal secondary sexual characteristics, and secondary amenorrhea, although rarely prepubertal ovarian failure causes primary amenorrhea or oligomenorrhea and incompletely developed secondary sexual features. POF, therefore, probably represents a continuum in which individuals may be affected at any age before the expected age of menopause [164]. In contrast to patients with POF, patients with gonadal dysgenesis usually have an abnormal karyotype, streak gonads or abdominal testes, primary amenorrhea, ambiguous internal and external genitalia, and somatic abnormalities. The absence or decline in follicular activity in patients with POF typically results in low serum estrogen levels, often accompanied by estrogen withdrawal symptoms. Because of the failure of negative feedback, the low estrogen levels lead to elevated levels of pituitary gonadotropins, a feature that differentiates POF from central causes of amenorrhea related to hypothalamic or pituitary dysfunction.

Although three histologic patterns have been recognized, specifically premature follicular depletion (true premature menopause), resistant ovary syndrome, and autoimmune oophoritis, it is not known with certainty if each represents a distinct disorder or a nonspecific morphologic manifestation of a number of different disorders [172].

Premature Follicular Depletion

This disorder is characterized by ovaries that are typically small on gross inspection, resembling streak gonads. On microscopic examination, there is premature follicular depletion, with the ovaries resembling normal peri- or postmenopausal ovaries with complete, or nearly complete, absence of primordial and developing follicles [172]. Follicles in varying stages of atresia and stigmata of prior ovulation are typically present, excluding a streak gonad.

Postulated pathogenetic mechanisms include a decreased number of ovarian germ cells at birth, acceleration of normal follicular atresia, or prepubertal or postpubertal destruction of germ cells. With respect to the last, there is strong evidence, including the presence of antiovarian antibodies, autoimmune disorders, or both, implicating immune factors in a substantial proportion of women with POF. As some or all these cases likely represent an end stage of autoimmune oophoritis, they are considered further in that section (see page 35) [172]. Additionally, postnatal destruction of germ cells may be caused by cytotoxic drugs or radiation (O Ovarian Changes Secondary to Cytotoxic Drugs and Radiation) and mumps oophoritis (> Viral Infections). Because mumps oophoritis is probably clinically occult in the majority of cases, it may be a more frequent cause of premature menopause, including familial cases, than is generally suspected.

The occurrence of familial cases of POF, in a pattern consistent with an autosomal dominant mode of inheritance [119], implicates genetic factors in some cases; familial POF may account for 12–28% of cases of this disorder [87]. Occasional patients with an otherwise typical presentation have had chromosomal abnormalities, usually 47XXX, pure or mosaic, but occasionally 45XO/46XX [207]. In some familial cases, the affected women were 46XX but had an interstitial deletion of the long arm of the X chromosome [96]. A proportion of these patients have fragile X syndrome, with a premutation in the *FMR1* gene found in 14% of cases [187]. Some authors, however, exclude cases with chromosomal abnormalities from the category of POF so that it includes only "chromosomally competent" patients.

The presence of galactosemia in some patients with POF suggests that it may play a pathogenetic role. Approximately two thirds of females with galactosemia in one study had POF [90]. In many such patients dietary treatment of galactosemia had been delayed. One galactosemic patient with POF had the pattern of the resistent ovary syndrome (see following) on ovarian biopsy, but in a series of galactosemic patients who were not biopsied, some patients had severely atrophic ovaries, suggesting premature follicular depletion [52]. Similarly, experimental studies indicate that galactose or its metabolites may interefere with normal prenatal oogenesis. Depletion of primordial follicles has been described in several women with ataxia telangiectasia, which may be related to their severe immunosuppression or to their athymic state [57].

Resistant Ovary Syndrome

This rare syndrome, also known as Savage syndrome, is found in approximately 20% of patients with POF and characterized by primary or secondary amenorrhea, endogenous hypergonadotropinemia, and resistance to exogenous gonadotropins, often in massive doses [116, 172]. The resistance to endogenous and exogenous gonadotropins may be relative or absolute, episodic or chronic.

The ovaries typically have a normal prepubertal or adult appearance on macroscopic inspection. Microscopic examination reveals an appropriate number of normalappearing primordial follicles but a complete, or nearly complete, absence of developing follicles. Atretic follicles and stigmata of prior ovulation may be present. In occasional patients, the space normally occupied by the ovum in some of the atretic follicles contains calcified material. In another case, numerous abnormal preantral follicles were found that contained multiple nodules of basement membrane material [116]. A histologic pattern similar to that in the resistant ovary syndrome occurs in morbid obesity, Cushing's syndrome, and hypogonadotropic ovarian failure secondary to hypothalamic– pituitary dysfunction. The pathogenesis of this disorder is not yet established, but a possible deficiency of FSH and LH receptors within the ovary, the presence of antibodies to these receptors, or a postreceptor defect have been postulated. An IgG-like substance that alters FSH receptors and thereby impairs binding of this hormone was present in the serum of several patients with associated myasthenia gravis [52]. In another patient with the resistent ovary syndrome, lupus erythematosus appeared while the ovarian failure was evolving, and a serum antibody specific for the FSH receptor was found [116]. In another study, circulating autoimmune antibodies to thyroglobulin and smooth muscle were found in some patients [172]. As noted earlier, one patient with the resistent ovary syndrome had galactosemia [172].

Autoimmune Oophoritis

Clinical and Pathogenetic Features

Approximately 25 cases of autoimmune oophoritis have been documented pathologically [10, 106, 172, 185]. The patients, who have ranged in age from 17 to 48 years (mean, 31), typically present with oligomenorrhea or amenorrhea, or symptoms relating to multiple follicular cysts, including pelvic pain, adnexal torsion, or estrogenic manifestations, such as abnormal bleeding, and in one case endometrial adenocarcinoma [10, 106]. Most patients have steroid cell antibodies in their sera; Addison's disease, Hashimoto's thyroiditis, or Sjogren's disease have been additionally present in some cases [10, 53]. The Addison's disease may arise at the same time or subsequent to the ovarian failure and is associated at least in some cases with a lymphocytic adrenalitis. The steroid cell antibodies, which are rare in the general population, belong to a group of antibodies reactive with a range of antigens in steroidproducing cells. They are typically reactive against adrenal cortex, but in some cases also to theca interna, corpus luteum, thyroid epithelium and thyroglobulin, parathyroid cells, gastric parietal cells, and thymocytes, alone or in combination [40, 172].

There is also evidence supporting a role for cellmediated immune mechanisms in the pathogenesis of autoimmune oophoritis. Studies have shown expression of major histocompatibility class II antigens by granulosa cells in autoimmune oophoritis, a phenomenon inducible by interferon gamma, a product of activated T cells [72]. Additionally, there have been reports of occasional patients with POF, including some with documented autoimmune oophoritis, in whom menses and ovulation resumed after administration of corticosteroids [38]. All the foregoing observations suggest that a complex immune process with an interplay of humoral and cellular mechanisms is involved in the pathogenesis of autoimmune oophoritis [185].

Autoimmune oophoritis is almost certainly more common than the small number of histologically documented cases would suggest. In two studies of women with POF who were not biopsied or in whom a biopsy revealed an afollicular pattern, two thirds [153] and 90% [127] of patients, respectively, had some evidence of autoimmune phenomena with immunologic testing. In a third study, some women with POF had a decreased ratio of inducer/ helper lymphocytes to suppressor/cytotoxic lymphocytes as well as a decreased concentration of serum IgA, suggesting a mild suppression of immune competence [57]. Similarly, as many as one half of patients with POF in some series have or subsequently develop one or more associated autoimmune disorders; an average figure calculated from the literature is 20% [97]. Addison's disease or thyroid disease (Hashimoto's thyroiditis, Grave's disease) is the most common of these disorders and is typically accompanied or preceded by the presence of steroid cell antibodies [36]. Conversely, as many as 25% of patients with idiopathic Addison's disease may have POF, the latter usually preceding the former by several, but occasionally many, years [97]. Other autoimmune diseases that occur less commonly in these patients include rheumatoid arthritis, hypoparathyroidism, myasthenia gravis, diabetes mellitus, atrophic gastritis, pernicious anemia, hemolytic anemia, idiopathic thrombocytopenia purpura, alopecia, vitiligo, and sicca syndrome [36, 97]. POF occurs frequently in patients with two or more such diseases (polyglandular endocrinopathy) [97].

Additionally, a subgroup of patients with POF have chronic mucocutaneous candidiasis or chronic vaginal candidiasis, suggesting a defect in T-cell function, possibly secondary to circulating antibodies against T lymphocytes demonstrable in some of these patients [118]. Patients with these two types of candidiasis also frequently have anti-Candida, antithymocyte, and antiovarian antibodies, suggesting a shared antigen on these cells [118].

A partial genetic basis is suggested by a family history of an autoimmune disease in approximately one fifth of patients who have both POF and an autoimmune disease. Similarly, a prevalence of certain HLA antigens has been found in some patients with autoimmune endocrine disease [208].

The foregoing findings suggest that a substantial proportion of patients with the histologic pattern of premature follicular depletion likely represent an end stage of autoimmune oophoritis that is no longer recognizable on histologic examination.

Gross Findings

On gross examination, the ovaries may be small or normal in size, but in one third of cases one or both are enlarged by multiple follicular cysts, potentially simulating cystic neoplasms [10, 106]. The cysts are more common in the earlier phases of the disease and are likely caused by elevated gonadotropin levels. Small ovaries presumably reflect a late- or end stage of the disorder, after complete destruction of the follicles.

Microscopic Findings

The cardinal feature of autoimmune oophoritis on microscopic examination is a folliculotropic lymphoid infiltrate that affects developing follicles with a theca layer, corpora lutea, and atretic follicles (> Fig. 12.49). The intensity of the infiltrate increases with the degree of follicular maturation. The theca interna layer is typically more intensely infiltrated than the granulosa layer and may be focally destroyed; the granulosa layer may be focally disrupted with sloughing of its cells. The inflammatory infiltrate consists predominantly of lymphocytes and plasma cells, but eosinophils, histiocytes, and, rarely, sarcoid-like granulomas are also present, and may predominate [10]. Primordial follicles are typically present but uninvolved. Additionally, perivascular and perineural lymphoid infiltrates may be found in the hilus, and in some such cases, there has been an absence of Leydig cells, suggesting destruction of the latter by the inflammatory process [63]. Nonspecific findings have included the presence of abnormal "dysplastic" follicles, follicle cysts (as noted earlier), and superficial cortical fibrosis [10]. Immunophenotyping of the inflammatory infiltrate has revealed, variously, B and T lymphocytes, polyclonal plasma cells, macrophages, and natural killer cells [63, 106].

Vascular Lesions

Ovarian Hemorrhage

Rupture of a normal corpus luteum or a corpus luteum cyst may occasionally result in hemorrhage and, rarely, fatal hemoperitoneum. Although hemorrhage may occur

Fig. 12.49

Autoimmune oophoritis. (a) A maturing follicle is infiltrated by mononuclear inflammatory cells. (b) Corpus luteum partially destructed by intense lymphoplasmacytic infiltrate

Fig. 12.50

Ovarian hemorrhage. Ovary from a patient being treated with anticoagulation therapy is replaced by a large hematoma

in otherwise normal women, it is observed more often in women receiving anticoagulant therapy (**2** *Fig. 12.50*) [67]. The right ovary is the source of the hemorrhage in almost two thirds of patients, and the clinical manifestations frequently resemble acute appendicitis [67].

Ovarian Torsion and Infarction

Ovarian or adnexal torsion is most frequently a complication of an underlying ovarian lesion, usually a nonneoplastic cyst, abscess, or benign tumor but occasionally a malignant neoplasm [71]. Torsion of a normal ovary occurs rarely, especially in infants or children but also in adults. Bilateral adnexal torsion, synchronous or asynchronous, has been reported.

The patients present with clinical findings similar to those of acute appendicitis or with recurrent episodes of abdominal pain; occasionally, an adnexal mass is palpable. Laparotomy reveals a swollen, hemorrhagic, and in some cases, infarcted, tuboovarian mass twisted on its pedicle. Where possible, detorsion is advocated, rather than oophorectomy, to preserve ovarian function [147]. In rare cases, the torsion and infarction may be asymptomatic, and autoamputation can result in a mass, which is occasionally calcified, lying free in the peritoneal cavity or attached to adjacent structures. The differential diagnosis in such cases, as noted earlier (**2** Congenital Lesions and Ectopic Tissues), is with congenital unilateral absence of the ovary and tube.

It is crucial to examine thoroughly any hemorrhagic infarcted ovarian mass to exclude a neoplasm. A search should be made for viable foci at the periphery of the lesion, and the necrotic tissue should be scrutinized for shadows of neoplastic cells.

Ovarian Vein Thrombophlebitis

Ovarian vein thombosis or thrombophlebitis is an uncommon but potentially fatal disorder that most often occurs postpartum but may follow pelvic operations or pelvic trauma or complicate other pelvic disorders such as pelvic inflammatory disease [213]. Patients usually present with fever and lower abdominal pain and an abdominal mass, almost always on the right side. The clinical picture may simulate acute appendicitis or pyelonephritis. The marked right-sided predominance in the puerperal cases is explained on the basis of retrograde venous flow in the left ovarian vein during the puerperium, protecting that side from bacterial spread from the uterus. Sonography, computed tomography (CT), and magnetic resonance imaging studies may be useful in establishing the diagnosis preoperatively, thus avoiding unnecessary laparotomy, as the mainstays of treatment are anticoagulation and antibiotic therapy [44].

If surgery is undertaken, the involved ovarian vein will be markedly enlarged and the thrombus usually extends to the inferior vena cava on the right or to the renal vein on the left. Rarely, one or both of the latter structures are also thrombosed. There is marked edema and inflammation of the surrounding retroperitoneal tissues. The ipsilateral ovary is usually congested but not infarcted, although asymptomatic bilateral ovarian infarction in a postpartum patient secondary to massive pelvic venous thrombosis has been reported. Some cases may be associated with the ovarian vein syndrome (**>** Rare Vascular Lesions).

Rare Vascular Lesions

Giant cell arteritis can rarely involve the female genital tract, including the ovaries [2, 13, 114]. The patients are almost invariably postmenopausal, and some patients with ovarian involvement have had systemic manifestations, such as a history of polymyagia rheumatica or temporal arteritis, an elevated erythrocyte sedimentation rate (ESR), or both. Less commonly, the arteritis is an incidental microscopic finding in an asymptomatic patient. Treatment is probably unnecessary in this group of patients, but they should be followed carefully, including repeated determinations of the ESR [13, 114]. Rare examples of vasculitis of polyarteritis nodosa type involving the ovaries or ovarian hilus have also been reported (> Fig. 12.51). Rarely, the finding is a reflection of systemic involvement, but usually polyarteritis in the female genital tract (typically the cervix) is an isolated finding without systemic manifestations on follow-up [2, 56, 59].

A rare cause of retroperitoneal hemorrhage is rupture of an ovarian artery or vein, typically during pregnancy or the puerperium [62]. In some cases, the rupture represents a complication of an aneurysm of the ovarian artery.

Varicosities of the ovarian vein, almost always on the right side, may occur in pregnant or parous women and cause ipsilateral ureteric compression and pyelonephritis, constituting the so-called ovarian vein syndrome. Ovarian arteriovenous fistulas have been reported as a rare complication of gynecologic surgery.

Ovarian Pregnancy

Up to 1–3% of all ectopic pregnancies are ovarian [66, 81]. The diagnosis of ovarian pregnancy should be restricted to cases in which there is no involvement of the fallopian tube. There is an increased frequency of ovarian pregnancy in patients with an intrauterine contraceptive device. The typical clinical presentation is severe pain with hemoperitoneum, and at laparotomy and on gross pathologic examination, the enlarged hemorrhagic ovary may mimic a hemorrhagic neoplasm (\odot *Fig. 12.52*). In a minority of the cases, gross identification of an embryo is indicative of the diagnosis, and in other cases, microscopic examination is diagnostic. One placental site nodule of the ovary has been described in a 61-year-old

Fig. 12.51 Vasculitis of polyarteritis nodosa type in a postmenopausal woman. Three ovarian hilar vessels are involved in this field. Polyarteritis also involved the uterine cervix in this case

■ Fig. 12.52 Ovarian pregnancy. A nodule of hemorrhagic placental tissue protrudes from the ovarian surface (*lower right*)

woman, presumably representing the remnants of an old ovarian pregnancy [6]. Distinction between an ovarian pregnancy and the very rare examples of primary ovarian gestational trophoblastic disease (Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions) is made by applying criteria similar to those used in the uterus.

Ovarian Changes Secondary to Metabolic Diseases

Amyloidosis may rarely involve the ovaries, usually as an incidental microscopic finding in patients with systemic amyloidosis (**>** *Fig. 12.53*) [35]. There are several reports of tumor-like ovarian enlargement secondary to systemic or presumably localized amyloidosis [130].

Rare cases of ovarian enlargement secondary to involvement by systemic storage disorders (lipidoses, mucopolysaccharidoses) have been reported [45]. In such cases, the stored material is typically within macrophages, allowing histologic distinction from a steroid cell tumor or foci of fat within the ovarian stroma. An autopsy study in patients with diabetes mellitus revealed atrophic and fibrotic changes in the ovaries more frequently than in ovaries from control patients, although the differences were not statistically significant [55].

In contrast to frequent testicular involvement in hemochromatosis, in which hemosiderin is typically seen within walls of testicular blood vessels, pathologic changes in the

 Fig. 12.53
Ovarian amyloidosis. Amyloid involves the ovarian stroma and vessels

ovary secondary to this disorder appear to be rare or nonexistent.

Ovarian Changes Secondary to Cytotoxic Drugs and Radiation

Cytotoxic Drugs

Cytotoxic drugs may cause a variety of histologic changes in the ovaries of prepubertal and postpubertal patients, including focal or diffuse cortical fibrosis, impaired follicular maturation, and a reduction or depletion in follicle numbers [34, 73, 113]. Some studies have shown a direct correlation between the severity of these changes and the duration of the chemotherapy, the number of drugs, and malnourishment of the patients. These morphologic findings are consistent with clinical observations of diminished ovarian endocrine function or ovarian failure in some of these patients [178]. The risk of ovarian failure appears to be greater in patients who received higher doses and in whom treatment is begun after the age of 25 [34, 178]. In rare cases, the ovarian failure has reversed after cessation of the therapy.

Radiation

The ovary is among the most radiosensitive of organs. Relatively low doses of radiation (500–600 R) to the ovaries cause complete or nearly complete disappearance of primordial and developing follicles, fibrosis of the ovarian stroma, and vascular sclerosis in more than 90% of patients (\bigcirc *Fig.* 12.54) [34, 73]. Follow-up studies of both children and adults who received pelvic radiation have shown that ovarian failure occurs in the majority of such patients [73, 197]. The ovarian stroma appears to be more radioresistant than the follicles and may continue to secrete androgens after radiation [82].

Miscellaneous Lesions

Ovarian Remnant Syndrome

Ectopic, accessory, and supernumerary ovary (**O** Congenital Lesions and Ectopic Tissues) should be distinguished from examples of the ovarian remnant syndrome (ORS), which is also known as the ovarian implant syndrome [88, 99, 110, 155]. The ORS should in turn be distinguished from the residual ovary syndrome, in which pelvic symptoms originate from ovaries preserved at the time of

Fig. 12.54 Radiation changes. Blood vessels are hyalinized, and the ovarian stroma is fibrotic

Fig. 12.55 Ovarian remnant syndrome. A corpus luteum cyst is surrounded by congested fibroadipose tissue

hysterectomy [99]. Patients with ORS have a history of a presumably total bilateral oophorectomy but present with findings related to the presence of residual ovarian tissue. The oophorectomy in such cases was often complicated by dense adhesions that are usually caused by endometriosis, pelvic inflammatory disease, a previous pelvic operation, inflammatory bowel disease, or combinations thereof. Clues to the diagnosis in patients who have had bilateral oophorectomy are premenopausal FSH, LH, and estradiol levels, an absence of menopausal symptoms, and a lack of atrophic changes on cervicovaginal smears.

Within weeks to months, but occasionally years, after the oophorectomy, women with ORS usually present with chronic or cyclic pelvic pain and, in about half the cases, a palpable pelvic mass. Ultrasonography or computed tomographic (CT) scanning may aid preoperative detection of nonpalpable symptomatic remnants [155], and stimulation of the residual ovarian tissue with clomiphene citrate therapy can facilitate their intraoperative localization [88]. Reoperation typically reveals a 3- to 4-cm cystic mass, covered by dense adhesions on the pelvic side wall, or less commonly, the mesentery; bilateral ovarian remnants rarely have been encountered. Obstruction or compression of the ureter, the colon, the small intestine, or the bladder may occur [155]. Pathologic examination usually reveals one or several follicular or corpus luteum cysts within a remnant of ovarian tissue surrounded by chronically inflamed fibrous tissue (> Fig. 12.55). Less common findings have included endometriosis, benign neoplasms, or normal ovarian tissue. Excision of the remnants may be difficult and require multiple operations.

Rete Cysts

The rete ovarii, the ovarian analogue of the rete testis, which is present in the hilus of all ovaries, consists of a network of anastomosing branching tubules with intraluminal polypoid projections, lined by an epithelium that varies from flat to cuboidal to columnar. Solid cords of similar cells may also be seen. The rete is surrounded by a cuff of spindle cell stroma morphologically similar to, but discontinuous from, the ovarian stroma. The rete lies adjacent to and may communicate with mesonephric tubules within the mesovarium. The rete epithelium may undergo transitional metaplasia.

Occasional hilar cysts originate from the rete, and small tumor-like proliferations of the rete have been referred to as rete adenomas. Rete cysts are typically located in the ovarian hilus, and in one series, the cysts had a mean diameter of 8.7 cm (range, 1-24 cm) [174]. Most are unilocular, although occasionally they are multilocular. Rete cysts typically are lined by a single layer of nonciliated epithelium that varies from flat to cuboidal to columnar. In addition to their hilar location, clues to the origin of the cysts are an irregular contour of their inner surface with small crevice-like outpouchings and a wall that often contains bundles of smooth muscle and hyperplastic hilus cells (**)** Fig. 12.56). A lesion interpreted as adenomatous hyperplasia of the rete ovarii has been reported, which formed a 3-mm nodule in the ovarian hilus of a 43-yearold woman. The lesion consisted of a poorly circumscribed proliferation of benign appearing tubules with scanty fibromuscular stroma, merging with the normal rete [70].

Fig. 12.56

Rete cyst. The lining is composed of a single layer of flattened cells which line crevices. Note smooth muscle and nests of Leydig cells in the wall

Fig. 12.57

Artifactual displacement of granulosa cells. Nests of granulosa cells occupy an artifactual space in the ovarian stroma (*bottom*). Note adjacent cystic follicle (*top*) with detached granulosa cells similar to those in the stroma

Artifacts and Normal Findings

The granulosa cells of normal follicles can be artifactually introduced into tissue spaces or vascular channels during sectioning (**>** *Figs. 12.57* and **>** *12.58*). This finding, especially when the displaced cells are shrunken or crushed, is occasionally misinterpreted as small cell carcinoma [123]. Awareness of this artifact, the bland nuclear features of the cells, and their similarity to cells lining nearby follicles are

Fig. 12.58 Displaced luteinized granulosa cells in ovarian lymphatics

helpful clues to the correct diagnosis. Granulosa cells that appear to be deposited on the surface of the ovary secondary to follicle rupture may be misinterpreted as mesothelial cells and when numerous, may even suggest the possible diagnosis of a mesothelioma. Immunohistochemical staining for inhibin may confirm their presence in difficult cases.

Normal findings that may be misinterpereted as neoplastic include the occasionally highly mitotic granulosa cells and the theca externa cells of the normal developing follicle. Similarly, the corpus luteum of late pregnancy and the puerperium may contain numerous calcific deposits; we have encountered one case in which their presence in a patient with a history of a serous borderline tumor was misinterpreted as recurrent tumor.

Lesions that can involve the ovary, but which are more appropriately discussed in O Chap. 13, Diseases of the Peritoneum, include mucicarminophilic histiocytosis and infarcted appendix epiploica.

This chapter considers the wide range of nonneoplastic and neoplastic lesions that involve the peritoneum, and in some cases the retroperitoneal lymph nodes, of females. The first half of the chapter covers inflammatory lesions, tumor-like lesions (including mesothelial hyperplasia), mesothelial neoplasms, miscellaneous primary tumors, and metastatic tumors. The final half of the chapter is devoted to a large group of lesions that exhibit müllerian differentiation on microscopic examination and share a potential origin from the secondary müllerian system, the prototypical example of which is endometriosis.

Inflammatory Lesions

Acute Peritonitis

Acute diffuse peritonitis, characterized by a serosal fibrinopurulent exudate, is most commonly associated with a perforated viscus, and is usually bacterial or chemical (bile or gastric or pancreatic juice) in origin. The lipases in pancreatic juice typically produce fat necrosis. Spontaneous bacterial peritonitis occurs most often in children and in adults who are immunocompromised or have cirrhosis of the liver [242]. Rare infectious causes of acute peritonitis include Candida [15], Actinomycetes, and amoebas [111]. Recurrent attacks of acute peritonitis are an almost constant feature of familial Mediterranean fever (recurrent polyserositis; periodic disease) [220]. Localized acute peritonitis may be associated with infection (or infarction) of specific organs, as in pelvic inflammatory disease.

Granulomatous Peritonitis

A variety of infectious and noninfectious agents can cause granulomatous peritonitis. The peritoneum may be studded with nodules, which can mimic disseminated tumor at operation. The diagnosis rests on the histologic, and in some cases, microbiologic, identification of the causative agent.

Infectious

Tuberculous peritonitis, which is increasing in frequency, particularly among immunosuppressed patients, may be secondary to spread from a focus within the abdominopelvic cavity or be a manifestation of miliary spread [122]. The granulomas are characterized by caseous necrosis and Langhans type giant cells; mycobacteria may be demonstrated by acid-fast stains or immunofluorescence methods. Rarely, granulomatous peritonitis is a complication of fungal infections, including histoplasmosis, coccidioidomycosis, and cryptococcosis, and parasitic infestations, including schistosomiasis, oxyuriasis, echinococcosis, ascariasis, and strongyloidiasis.

Noninfectious

Foreign material, typically recognizable on histologic examination, can elicit a granulomatous reaction on the peritoneum. Starch granules from surgical gloves, douche fluid, and lubricants typically incite a granulomatous and fibrosing peritonitis; in occasional cases, the inflammatory reaction may be of tuberculoid type with caseous necrosis [162]. The periodic acid–Schiff (PAS) positive starch granules exhibit a characteristic Maltese-cross configuration under polarized light. Talc was once an important cause of granulomatous and fibrosing peritonitis because of its use as a lubricant on surgical gloves, and talc-induced peritonitis has also been described in drug abusers. Other iatrogenic causes of granulomatous peritonitis include cellulose and cotton fibers from surgical pads and drapes, microcrystalline collagen hemostat (Avitene) [175], and oily materials such as hysterosalpingographic contrast medium, which can be associated with a lipogranulomatous reaction. In one described case, a foreign body reaction to SurgicelTM resulted in a pelvic mass that mimicked recurrent ovarian cancer [63].

Contamination of the peritoneal cavity by bowel contents, including vegetable matter, food-derived starch, and barium sulfate, can produce a peritoneal foreign body reaction. Sebaceous material and keratin from ruptured dermoid cysts typically evoke an intense granulomatous, lipogranulomatous, and fibrosing peritoneal inflammatory reaction that may mimic a neoplasm at operation (\triangleright *Fig. 13.1*). Granulomatous inflammation to keratin derived from uterine and ovarian endometrioid carcinomas with squamous differentiation is discussed later in \triangleright Tumor-Like Lesions.

Spillage of amniotic fluid at cesarean section, with its content of vernix caseosa (keratin, squames, sebum, and lanugo hair) and meconium (bile, pancreatic, and intestinal secretions), produces a granulomatous peritonitis [86]. Meconium peritonitis caused by bowel perforation in utero can also be a problem in newborn infants. In contrast to vernix caseosa peritonitis, calcification rather than granulomatous inflammation dominates the microscopic picture, which in some cases is associated with striking radiographic findings. In boys, the process may

Fig. 13.1 Lipogranulomatous peritonitis due to ruptured ovarian dermoid cyst

involve the tunica vaginalis and result in a tumor-like scrotal mass [79]. Rare cases of meconium peritonitis are associated with disseminated intravascular spread of the meconium.

Granulomatous peritonitis has also been described secondary to Crohn's disease, sarcoidosis, and Whipple's disease. Necrotizing peritoneal granulomas have been described following diathermy ablation of endometriosis (> Fig. 13.2) [37]. Necrotic pseudoxanthomatous nodules of endometriosis, which can resemble necrotic granulomas, are described on page 28.

Granulomatous inflammation can occur in the peritoneum secondary to spillage of bile or gallstones during laparoscopic cholecystectomy, with subsequent implantation of gallstones on peritoneal surfaces, including the ovaries ("ovarian cholelithiasis"; see also O Chap. 12, Nonneoplastic Lesions of the Ovary, Fig. 12.12) [238]. The embedded gallstones may cause abdominal pain, be associated with a foreign body granulomatous reaction and fibrosis or act as a nidus for infection; the reddishbrown, pigmented lesions visible at laparoscopy can mimic endometriosis [146]. Cholesterol crystals and bile pigment may be identifiable within the foreign body giant cells (**>** Fig. 13.3). Positive Fouchet's staining for bile and awareness of the history of a previous cholecystectomy will facilitate the correct diagnosis.

Nongranulomatous Histiocytic Lesions

The peritoneum can be occasionally involved by histiocytic infiltrates rather than discrete granulomas.

Peritoneal granuloma secondary to diathermy ablation for endometriosis. Histiocytes surround a necrotic center containing wisps of brown pigment

peritoneum. Note the rim of foreign body giant cells and surrounding fibrosis. Laparoscopic cholecystectomy had been performed 18 months earlier

Ceroid- and lipid-rich histiocytes involving the peritoneum and omentum can be secondary to endometriosis [49] or can occur in association with a peritoneal decidual reaction [244]. Peritoneal lesions consisting of pigmentladen histiocytes have been referred to as peritoneal melanosis. Reported cases of melanosis have usually been associated with ovarian dermoid cysts, sometimes with preoperative rupture [108]; association with a serous

cystadenoma has also been reported. At laparotomy, focal or diffuse, tan to black, peritoneal staining, or similarly pigmented, tumor-like nodules are encountered within the pelvis and in the omentum. Some of the cysts within the ovarian tumors exhibit pigmentation of their contents and lining. On histologic examination, the ovarian and peritoneal pigmentation consists of pigment-laden histiocytes within a fibrous stroma (> Fig. 13.4). In at least three of the reported cases and in a fourth case we have encountered, gastric mucosa was prominent within an otherwise typical dermoid cyst. No obvious source for the pigment could be identified in most of the cases; Jaworski et al. demonstrated the pigment to have neither the histochemical features of melanin nor hemosiderin, but was rich in iron, and postulated that the pigment was derived from hemorrhage secondary to peptic ulceration of gastric mucosa [108]. These cases of benign peritoneal melanosis should obviously be distinguished from metastatic malignant melanoma, a distinction that is straightforward because of the bland nuclear features and absence of mitotic figures of the pigmented histiocytes.

Nonpigmented histiocytes can occasionally occur as a nonspecific peritoneal inflammatory response in the form of nodular, plaque-like, or more extensive aggregates that may appear as small grossly visible peritoneal nodules at operation, or more commonly as a microscopic finding. Histologically, the aggregates are composed of a monotonous population of histiocytes with moderate amounts of pale eosinophilic cytoplasm; the nuclei may be reniform and/or contain a groove, reminiscent of Langerhans-type histiocytes (\bigcirc *Fig* 13.5). We are aware of one such case from a patient with a granulosa cell tumor in which the histiocytes were initially misinterpreted microscopically as metastatic granulosa cell tumor. Admixed mesothelial cells may also be present ("nodular histiocytic/mesothelial hyperplasia"). A recent report has described a diffuse histiocytic proliferation of the pelvic peritoneum associated with endocervicosis [199]. In these cases, immunohistochemical staining for CD68 and cytokeratin can aid the distinction of histiocytes from mesothelial cells (\bigcirc *Fig.* 13.5).

Mucicarminophilic histiocytosis is characterized by histiocytes that contain polyvinylpyrrolidone (PVP), a substance that has been used as a blood substitute [124]. These cells can be found in many sites, both within and outside the female reproductive organs, including the ovary, the pelvic lymph nodes, and the omentum. The histiocytes have vacuolated basophilic to lavender

Fig. 13.4 Peritoneal melanosis. Histiocytes are laden with brown pigment

■ Fig. 13.5 Nodule of histiocytes involving the peritoneal surface. (a) The cells have moderate pale eosinophilic cytoplasm, some with reniform nuclei. (b) Positive immunostaining of histiocytes with CD68

cytoplasm and an eccentric nucleus, an appearance that may suggest the diagnosis of signet-ring cell adenocarcinoma (\bigcirc *Fig. 13.6*). The histiocytes are mucicarminophilic, but in contrast to neoplastic signet-ring cells, are PAS negative; a variety of other stains are also helpful in the differential diagnosis [124].

Peritoneal collections of mucicarmine-positive histiocytes have also been described associated with topical administration of oxidized regenerated cellulose, a hemostatic agent [119]. The cytoplasm of these cells is PAS positive, diastase resistant, CD 68 positive, and S-100 and cytokeratin negative.

Peritoneal Fibrosis

Reactive peritoneal fibrosis, often accompanied by fibrous adhesions, is a common sequela of prior peritoneal inflammation and a frequent complication of a surgical procedure. The fibrosis can on occasion take the form of well-circumscribed fibrous nodules. Some reactive peritoneal fibrous lesions may contain spindle cells that are immunoreactive for vimentin, smooth muscle actin, and cytokeratin, referred to as multipotential subserosal cells by Bolen et al. [20]. Rarely, reactive fibrous proliferations of the peritoneum can form tumor-like nodules, in contrast to the more widespread peritoneal thickening of sclerosing peritonitis. In one case we have seen, three of these nodules, which we refer to as peritoneal fibrous nodules [38], were found in the cul-de-sac in a woman with an ovarian mucinous cystadenocarcinoma. Similar nodules involved the serosal aspect of the tumor. The nodules were composed of moderately cellular fascicles of benign-appearing spindle cells resembling fibroblasts and myofibroblasts that contained occasional mitotic figures. Some of the spindle cells had the immunoprofile of the multipotential subserosal cells noted earlier.

Localized hyaline plaques are a common incidental finding on the splenic capsule and are probably related to splenic congestion [241]. Nonspecific fibrous thickening of the peritoneum may be seen in patients with hepatic cirrhosis and ascites. The designation sclerosing peritonitis has been applied to a clinically significant, potentially fatal lesion that represents a reactive hyperplasia of the submesothelial mesenchymal cells to a variety of stimuli. The first description, by Concato, was that of pearly white thickening of the visceral peritoneum, either as discrete plaques or continuous sheets involving the hepatic, splenic, and diaphragmatic peritoneum. The process often encases the small bowel ("abdominal cocoon"), causing bowel obstruction. Sclerosing peritonitis occurs in an idiopathic form, which most frequently, but not invariably, affects adolescent girls in tropical countries [78]. Known causes include practolol therapy, chronic ambulatory peritoneal dialysis, the use of a peritoneovenous (LeVeen) shunt, bacterial or mycobacterial infection, sarcoidosis, the carcinoid syndrome, familial Mediterranean fever, and fibrogenic foreign materials as seen in drug users. Additionally, sclerosing peritonitis has an enigmatic association with luteinized thecomas of the ovary () Fig. 13.7; see) Chap. 15, Sex Cord-Stromal

■ Fig. 13.6 Mucicarminophilic histiocytosis. Note multiple vacuolated histiocytes, some with a signet-ring-cell appearance

Fig. 13.7 Sclerosing peritonitis associated with bilateral luteinized thecomas of the ovary. Omentum shows surface involvement by cellular, reactive fibrous tissue

Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations) [47, 222]. Some patients with sclerosing peritonitis have been successfully treated utilizing antiestrogens and/or GnRH agonists. Sclerosing peritonitis should be distin-

guished from the rarer "peritoneal encapsulation," a congenital malformation in which an accessory peritoneal membrane encases loops of small bowel in a saclike structure. The latter condition is largely asymptomatic and is usually found incidentally at laparotomy or autopsy. Confusion arises when the two terms are used interchangeably or even together, as in "encapsulating peritonitis."

Reactive nodular fibrous pseudotumor is a term that has been applied to single or multiple lesions ranging up to 6 cm involving the gastrointestinal tract or mesentery in adults; some have been associated with bowel wall infiltration but all have had a benign clinical course [251]. Microscopically, the lesions are composed of a low to moderate cellular proliferation of fibroblasts, collagen, and mononuclear inflammatory cells that are usually sparse. The fibroblastic cells show variable immunoreactivity for vimentin, CD117, muscle specific actin, smooth muscle actin, and desmin, with negative staining for CD34 and ALK-1. Sclerosing mesenteritis (mesenteric panniculitis, mesenteric lipodystrophy) usually occurs as a localized mass in the small bowel mesentery, and is characterized by variable fibrosis, inflammation, and fat necrosis [70].

In occasional cases, it may be difficult to differentiate between markedly reactive peritoneal fibrosis and a desmoplastic mesothelioma lacking frankly sarcomatoid areas, particularly in a small biopsy specimen. These tumors, however, are very rare in the peritoneal cavity, especially in women. Features favoring a diagnosis of mesothelioma include nuclear atypia, necrosis, organized patterns of collagen deposition (fascicular, storiform), and infiltration of adjacent tissues [136].

Rare Types of Peritonitis

Eosinophilic peritonitis is seen rarely in cases of eosinophilic gastroenteritis and the hypereosinophilic syndrome [1]. Isolated cases of eosinophilic ascites have been associated with childhood atopy, peritoneal dialysis, vasculitis, lymphoma or metastatic carcinoma, and ruptured hydatid cysts [1]. Rare cases of peritonitis may be secondary to peritoneal involvement by collagen vascular diseases, including systemic lupus erythematosus and Degos' disease.

Tumor-Like Lesions

Mesothelial Hyperplasia

Hyperplasia of mesothelial cells is a common response to inflammation (including pelvic inflammatory disease), and chronic effusions (> Figs. 13.8 and > 13.9). Hyperplastic lesions may be noted at operation as solitary or multiple small nodules, but more commonly are incidental findings on microscopic examination [36]. Mesothelial hyperplasia often involves the adnexal areas in cases of chronic salpingitis and endometriosis [117] and is occasionally encountered, particularly in the omentum, in association with ovarian tumors [44]. Mesothelial hyperplasia can also occur within the superficial ovarian stroma overlying a borderline epithelial tumor and in such cases can be misinterpreted as invasive tumor (> Fig. 13.10) [44]. Mesothelial hyperplasia may be confined to a hernia sac, and in such cases may be caused by trauma or incarceration [196]. Hyperplastic mesothelial cells occasionally are an incidental microscopic finding within pelvic and intra-abdominal lymph nodes, and in such cases are usually associated with mesothelial hyperplasia of the peritoneum (> Fig. 13.11) [48]. The mesothelial cells may be misinterpreted as metastatic tumor, particularly in a woman with a known primary pelvic tumor. The appearance of the cells on routine stains suggests the correct diagnosis, and can be confirmed by histochemical and immunohistochemical staining (see following).

In florid examples, solid, trabecular, tubular, papillary, or tubulopapillary patterns (\triangleright *Figs.* 13.8 and \triangleright 13.9) and limited degrees of extension of the mesothelial cells into the underlying reactive fibrous tissues or the walls of

An underlying borderline epithelial tumor was present

■ Fig. 13.11 Hyperplastic mesothelial cells within the subcapsular sinus of a pelvic lymph node

ovarian tumors, endometriotic cysts, and peritoneal inclusion cysts (see below) may be seen ("mural mesothelial proliferation"). The cells are often focally disposed in linear, sometimes parallel, thin layers, separated by fibrin or fibrous tissue (**>** *Fig. 13.10*). The mesothelial cells may have cytoplasmic vacuoles containing acid mucin (predominantly hyaluronic acid) or, less commonly, exhibit marked cytoplasmic clearing. Mild to moderate nuclear pleomorphism, mitotic figures, and occasional multinucleated cells may be seen. Psammoma bodies are encountered in occasional cases, and rarely, eosinophilic strap-shaped cells resembling rhabdomyoblasts have been described.

The major differential diagnosis is with peritoneal malignant mesothelioma (PMM). The presence of grossly visible nodules, necrosis, conspicuous large cytoplasmic vacuoles, marked nuclear pleomorphism, and deep infiltration favor PMM over mesothelial hyperplasia [36]. Some of these features, however, such as marked nuclear atypia, are not always present or may be present only focally within a PMM. Immunostains may facilitate the differential diagnosis. Immunoreactivity for p53 [109] and intense cytoplasmic immunoreactivity for epithelial membrane antigen (EMA) [97] are characteristic of the cells of PMM but not hyperplastic mesothelial cells; reactive mesothelial cells, in contrast to PMMs, tend to be desmin-positive [10]. Application of proliferative markers Ki67 and repp86 have recently been shown to be of diagnostic utility in differentiating PMM from reactive mesothelial hyperplasia (approximately 25% versus 5% labeling index, respectively) [232]. Despite these differential features, in occasional cases the distinction between a hyperplastic and malignant mesothelial lesion may be
difficult or impossible, particularly in a biopsy specimen. If the lesion in question is a PMM, follow-up usually reveals its nature within several months because of its typical rapid growth. In contrast, an atypical mesothelial proliferation occasionally persists for years without an apparent cause. An apparently benign, otherwise typical mesothelial proliferation, however, occasionally precedes the appearance of a PMM [36]. Some cases of "atypical mesothelial hyperplasia" evolving into PMM, however, likely represent PMM ab initio [173].

The differential diagnosis of mesothelial hyperplasia also includes borderline serous tumors of primary peritoneal or ovarian origin. Grossly visible ovarian or peritoneal tumor, columnar cells with or without cilia, the presence of intracellular or extracellular neutral mucin, and numerous psammoma bodies all favor a serous tumor. Immunohistochemical markers for epithelial differentiation (see section on PMM) may also be of value in the differential diagnosis.

Peritoneal Inclusion Cysts

Peritoneal inclusion cysts typically occur in the peritoneal cavity of women in the reproductive age group [145, 197]. Rarely, they occur in males and in the pleural cavity. Unilocular peritoneal inclusion cysts are usually incidental findings at laparotomy in the form of single or multiple, small, thin-walled, translucent, unilocular cysts that may be attached or lie free in the peritoneal cavity. Occasionally, they may involve the round ligament simulating an inguinal hernia [95]. The cysts have a smooth lining, and contents that vary from yellow and watery to gelatinous. Although most of these unilocular mesothelial cysts are probably reactive in origin, some of those located in the mesocolon, mesentery of the small intestine, retroperitoneum, and splenic capsule may be developmental [197].

Multilocular peritoneal inclusion cysts (MPICs) may form large bulky masses (**?** *Fig. 13.12*); these lesions have also been referred to as benign cystic mesotheliomas, inflammatory cysts of the peritoneum, or postoperative peritoneal cysts. MPICs are usually associated with clinical manifestations, most commonly lower abdominal pain, a palpable mass, or both. They are usually adherent to pelvic organs and may simulate a cystic ovarian tumor on clinical examination, at laparotomy [145], or even on pathologic examination; the upper abdominal cavity, the retroperitoneum, or hernia sacs may also be involved [197]. Unlike the smaller unilocular cysts, the septa and walls of MPICs may contain considerable amounts of

Fig. 13.12 Peritoneal inclusion cyst. Multilocular cystic mass consists of thin-walled cysts with a smooth lining

fibrous tissue. Their contents may resemble those of the unilocular cysts or be serosanguineous or bloody.

On microscopic examination, MPICs are typically lined by a single layer of flat to cuboidal, occasionally hobnail-shaped, mesothelial cells with generally bland nuclear features, although a degree of reactive atypia is not infrequent (> Figs. 13.13 and > 13.14). The lining cells occasionally form small papillae and cribriform patterns or undergo squamous metaplasia. In some cases, mural proliferations of typical or atypical mesothelial cells arranged singly, as gland-like structures or nests (**)** Figs. 13.15 and **)** 13.16) [145], or in patterns resembling those in adenomatoid tumors may be encountered. Occasional vacuolated mesothelial cells in the stroma may simulate signet-ring cells [197]. The septa typically consist of a loose, fibrovascular connective tissue with a sparse inflammatory infiltrate. In some cases, marked acute and chronic inflammation, abundant fibrin, broad bands of granulation and fibrous tissue, and evidence of recent and remote hemorrhage are present in the cyst walls. The mesothelial cells are typically immunoreactive for calretinin, and some cases are positive for estrogen (ER), progesterone receptors (PR), or both [208].

A history of a prior abdominal operation, pelvic inflammatory disease, endometriosis, or combinations thereof was present in 84% of patients in one series [197], suggesting a role for inflammation in the pathogenesis of the cysts. An inflammatory pathogenesis is also supported by the occurrence of cases in which the

Fig. 13.13

Multilocular peritoneal inclusion cyst (MPIC). Cystic spaces are lined by a single layer of flat mesothelial cells and are separated by thin fibrous septa

■ Fig. 13.14 Multilocular peritoneal inclusion cyst. Cystic spaces are lined by cells with mild reactive nuclear atypia

dividing line between florid adhesions associated with inflammation and a MPIC may be difficult. With rare exceptions, there has been no association with asbestos exposure. Follow-up examinations have not disclosed malignant behavior in cases that we consider MPICs, but in as many as one half of these, the lesions have recurred from months to many years postoperatively [197]. It is likely, however, that at least some of these "recurrences" are the result of newly formed postoperative adhesions. Some patients have responded favorably to treatment with GnRH agonists or tamoxifen [208]. For these reasons – although accepting that low-grade cystic mesotheliomas

Fig. 13.16 Multilocular peritoneal inclusion cyst with mural mesothelial proliferation. High power view showing benign-appearing mesothelial cells forming small nests and lining small tubules

occur rarely (see page 12) – we prefer the designation multilocular peritoneal inclusion cyst to benign cystic mesothelioma for such lesions, until there is convincing evidence for their neoplastic nature.

Aside from the contentious problem of their distinction from "true" cystic mesotheliomas (see page 12), MPICs are confused most often with multilocular cystic lymphangiomas. In contrast to MPICs, the latter typically occur in children, more frequently in boys. In addition, they are usually extrapelvic, being almost always localized to the mesentery of the small intestine, omentum, mesocolon, or retroperitoneum. Their contents may be chylous, and on histologic examination lymphoid aggregates and smooth muscle, which are rare findings in MPICs, are typically present within their walls. In problematic cases, immunohistochemical stains are useful in distinguishing endothelial from mesothelial cells. Another lesion that merits consideration in the differential diagnosis of MPICs is the rare multicystic adenomatoid tumor. In contrast to MPICs, the latter typically involve the myometrium, contain foci of typical adenomatoid tumor, and lack prominent numbers of inflammatory cells. A detailed discussion of other lesions in the differential diagnosis of MPICs has been presented elsewhere [197].

Splenosis

Splenosis, which results from implantation of splenic tissue, is typically an incidental finding at laparotomy or autopsy months to years after splenectomy for traumatic splenic rupture [27]. A few to innumerable, red-blue, peritoneal nodules, ranging from punctate to 7 cm in diameter, are scattered widely throughout the abdominal cavity and, less commonly, over the pelvic cavity. The intraoperative appearance may mimic endometriosis, benign or malignant vascular tumors, or metastatic cancer.

Trophoblastic Implants

Implants of trophoblast on the pelvic or omental peritoneum may complicate the operative treatment of tubal pregnancy [29, 66, 194, 233]. The implants are more likely to occur in cases managed by laparoscopy (1.9% of cases) than those managed by laparotomy (0.6% of cases) and are more likely to occur after salpingotomy than salpingectomy. The clinical presentation in such cases includes an initial decline in the serum human chorionic gonadotropin (hCG) level after removal of the ectopic pregnancy, followed by a rising level, abdominal pain, and in some cases intra-abdominal hemorrhage. Microscopic examination of the implants reveals viable trophoblastic tissue that may include chorionic villi. Some lesions resemble a placental site nodule or plaque (**>** *Fig. 13.17*).

Peritoneal Keratin Granulomas

Peritoneal granulomas that form in response to implants of keratin derived from neoplasms of the female reproductive tract may be confused with metastatic tumor

Fig. 13.17 Placental site plaque of the peritoneum

Fig 13.18 Peritoneal keratin granuloma

[121]. The tumors are most commonly endometrioid carcinomas with squamous differentiation originating in the endometrium or ovary, or, rarely, squamous cell carcinomas of the cervix or atypical polypoid adenomyomas of the uterus. The granulomas consist of laminated deposits of keratin, sometimes with ghost squamous cells, surrounded by foreign body giant cells and fibrous tissue (see Fig. 13.18; see also O Chap. 12, Nonneoplastic Lesions of the Ovary, Figs. 12.9 and 12.10). Follow-up data on these patients suggest that the granulomas have no prognostic significance, although they should be thoroughly sampled by the gynecologist and carefully examined microscopically to exclude the presence of viable tumor. The differential diagnosis includes peritoneal granulomas in response to keratin derived from other sources, as discussed earlier in this chapter.

Appendices epiploicae may undergo torsion and infarction [239]. Subsequent calcification can result in a hard tumor-like mass that may be found attached or loose in the peritoneal cavity. In the late stages, these structures are typically composed of layers of hyalinized connective tissue surrounding a central necrotic and calcified zone in which infarcted adipose tissue is usually recognizable (\bigcirc *Fig. 13.19*).

Mesothelial Neoplasms

Adenomatoid Tumor

This benign tumor of mesothelial origin, adenomatoid tumor, rarely arises from extragenital peritoneum, such as the omentum or mesentery, but is much more commonly encountered within the fallopian tube and myometrium (see O Chap. 10, Mesenchymal Tumors of the Uterus, and O Chap. 11, Diseases of the Fallopian Tube and Paratubal Region), and, in the male, the epididymis.

Well-Differentiated Papillary Mesothelioma

Well-differentiated papillary mesotheliomas (WDPMs) of the peritoneum are uncommon lesions [62, 88]. Eighty percent of the cases have occurred in women, who are

Fig 13.19 Infarcted appendix epiploica

usually of reproductive age; occasional patients are postmenopausal. WDPMs are usually an incidental finding at operation, but rare cases have been associated with abdominal pain or ascites. Occasional patients, including two who were sisters, have had possible exposure to asbestos [62].

At laparotomy and on gross examination, WDPMs may be solitary but are usually multiple, and appear as gray to white, firm, papillary or nodular lesions measuring less than 2 cm in diameter. The omental and pelvic peritoneum are typically involved; several examples have also been encountered on the gastric, intestinal, or mesenteric peritoneum. Microscopic examination reveals fibrous papillae covered by a single layer of flattened to cuboidal mesothelial cells (> Fig. 13.20) with occasional basal vacuoles; the nuclear features are bland, and mitotic figures are rare or absent. Uncommon patterns include tubulopapillary, adenomatoid-like, branching cords, or solid sheets. The stroma of some tumors may be extensively fibrotic. Multinucleated stromal giant cells and psammoma bodies are encountered in occasional cases. When multiple lesions are present, they should each be sampled histologically as lesions with the appearance of a WDPM may rarely be associated with others that have the appearance of malignant mesothelioma and progressive disease [88]. The diagnosis of WDPM should be strictly reserved for tumors with bland nuclear features and no evidence of invasion.

With the exception of one case that appeared to evolve into a diffuse malignant mesothelioma, follow-up studies suggest that most WDPMs are benign. Occasional examples, however, have persisted for as many as 29 years [62].

Fig 13.20
Well-differentiated papillary mesothelioma (WDPM).
Fibrous papillae are lined by a single layer of uniform, flat to cuboidal, mesothelial cells

Several patients with WDPM have died, although the adjuvant therapy used in such cases possibly was a contributory factor [62].

Low-Grade Cystic Mesothelioma

Although we believe that most multilocular cystic mesothelial lesions are MPICs, we have seen very rare cases of what appear to be bona fide multicystic mesotheliomas. In contrast to MPICs, the cysts are lined, at least focally, by markedly atypical mesothelial cells, and the tumors may contain areas of conventional malignant mesothelioma on histologic examination.

Malignant Mesothelioma

Clinical Features

Peritoneal malignant mesotheliomas (PMMs) are much less common than similar tumors in the pleural cavity, and account for only 10–20% of all mesotheliomas [9, 12, 88, 118]. These tumors are particularly rare in women, in whom most malignant papillary neoplasms of the peritoneum are extraovarian papillary serous carcinomas (see Secondary Müllerian System).

About two thirds of the patients with PMM are male, usually middle aged or elderly; occasional PMMs occur in young adults or children. The patients typically present with nonspecific manifestations, including abdominal discomfort and distension, digestive disturbances, and weight loss. Ascites is present in the majority of cases, and cytologic examination of the ascitic fluid may be diagnostic of PMM in some cases. The diagnosis, however, usually requires laparotomy or laparoscopy and biopsy. PMMs may rarely present within a hernia or hydrocele sac, as a retroperitoneal, umbilical, intestinal, or pelvic tumor, or as cervical or inguinal lymphadenopathy [229]. Rarely there is prominent ovarian involvement, the intraoperative appearance mimicking that of a primary ovarian tumor with peritoneal spread [52].

More than 80% of the patients in one large series had a history of asbestos exposure, but most of them were identified because of an occupational exposure to asbestos. In contrast, two series of PMMs in women found no association with a history of asbestos exposure [88, 118]. Asbestos fibers, however, have been identified with special techniques in some of these women [96]. Aside from asbestos, radiation, chronic inflammation, organic chemicals, and nonasbestos mineral fibers may be etiologic agents in some cases.

Most males with PMMs reported in the literature survived less than 2 years after diagnosis, although there have been occasional long-term survivors. A recent study of PMMs in women [118], however, found that 40% of the patients survived longer than 4 years. Increasing nuclear and nucleolar size has been shown to correlate with shorter survival in epithelial tumors [31]. The histopathological subtype (see below) is of prognostic significance, as biphasic PMMs are associated with a much shorter survival than pure epithelial tumors [31]; deciduoid mesotheliomas are usually rapidly fatal [214]. Two recent studies have identified a number of favorable prognostic factors including an age less than 60 years, low nuclear grade, low mitotic count, minimal residual disease after cytoreduction, and an absence of deep invasion [75, 163]. Localized mesotheliomas, although very uncommon, may also be associated with a better prognosis.

Pathologic Findings

At laparotomy, the visceral and parietal peritoneum are diffusely thickened or extensively involved by nodules and plaques. The viscera are often encased by tumor (**>** *Fig. 13.21*) and may be invaded, although local invasion and metastases to lymph nodes, liver, lungs, and pleura are less frequent than in association with carcinomas with comparable degrees of peritoneal involvement. Significant degrees of invasion or metastatic involvement of abdominal viscera, however, may be encountered at autopsy, such as transmural invasion of bowel wall or massive replacement of the pancreas. Some tumors incite

Fig 13.21

Peritoneal malignant mesothelioma (PMM). The tumor encases loops of bowel (Courtesy of J. Prat, M.D., Barcelona, Spain) a striking desmoplastic reaction. As noted earlier, rare PMMs form localized solitary masses.

The typical histologic features (**)** *Figs. 13.22–13.25*) are identical to malignant mesotheliomas involving the pleura. Most tumors are composed of epithelial cells arranged in tubulopapillary and solid patterns; areas of necrosis may be present. There is usually evidence of invasion of subperitoneal tissues, such as the omentum. As already noted, intra-abdominal lymph nodes may be involved. The tumor cells usually retain some resemblance to mesothelial cells, with a cuboidal shape and

eosinophilic cytoplasm. Usually there are mild to moderate degrees of nuclear atypicality and variably prominent nucleoli. Mitotic figures usually are present but are not numerous. Rare tumors with an exclusively solid pattern of polygonal cells with abundant eosinophilic cytoplasm and prominent nucleoli ("deciduoid" PMMs) (\bigcirc *Fig.* 13.26), with one exception, have arisen in the peritoneum [214]. Two thirds of such tumors have occurred in females, some of whom were adolescents or young adults. Biphasic and sarcomatoid PMMs occur, but are less common than their pleural counterparts, accounting for only 5 of

Fig 13.22 Peritoneal malignant mesothelioma. Papillary pattern

Fig 13.25 Peritoneal malignant mesothelioma. The cells are cuboidal or polygonal, with eosinophilic cytoplasm and moderate nuclear atypia

Fig 13.26

Peritoneal malignant mesothelioma. Solid growth pattern composed of cells with abundant eosinophilic cytoplasm (deciduoid PMM)

75 PMMs in one recent study [12]. Psammoma bodies are present in approximately one third of cases, but are usually less prominent than in serous neoplasms. Occasional tumors contain a prominent inflammatory infiltrate, such as a dense lymphocytic infiltrate with lymphoid follicles, granulomas, or large numbers of foamy lipid-rich histiocytes. Some tumors consisting predominantly of cells with clear cytoplasm, rich in glycogen or occasionally lipid, have also been reported [168]. The immunohistochemical (see next section) and ultrastructural features of PMMs are similar to their pleural counterparts.

Differential Diagnosis

The differential diagnoses of PMM with atypical mesothelial hyperplasia (see **>** Mesothelial Hyperplasia) and of desmoplastic PMM versus reactive fibrosis (see **>** Peritoneal Fibrosis) have been previously discussed. Another frequently problematic lesion in the differential diagnosis is adenocarcinoma with diffuse peritoneal involvement, including metastatic adenocarcinomas (see **>** Metastatic Tumors) and adenocarcinomas of primary peritoneal origin (see **>** Lesions of the Secondary Müllerian System). Features favoring a diagnosis of PMM include a prominent tubulopapillary pattern, polygonal cells with moderate amounts of eosinophilic cytoplasm, only mild to moderate nuclear atypia, a paucity of mitotic figures, and the presence of acid mucin (alcianophilic material) rather than neutral (PASD) mucin.

PMMs usually lack immunoreactivity for a variety of "epithelial" antigens, including carcinoembryonic

antigen, B72.3, Leu-M1 (CD 15), MOC-31, CA 19–9, S-100 protein, Ber-EP4, and placental alkaline phosphatase. Positive immunoreactivity for MOC-31, Ber-EP4, and estrogen receptors favors serous carcinoma; positive staining with calretinin, cytokeratin 5/6, podoplanin, and D2–40 favors PMM, but these markers are less discriminatory as they may be positive in a minor proportion of serous carcinomas [14, 54, 168–170]. Comin has found that an h-caldesmon+/calretinin+/estrogen receptor-/ Ber-EP4– immunophenotype strongly favors PMM over serous carcinoma [54]. However, no single immunohisto-chemical stain is diagnostic in the separation of PMM from adenocarcinoma, and the results of a panel of antibodies should be interpreted in conjunction with the hematoxylin and eosin (H&E) and mucin stains.

"Deciduoid" PMMs must be distinguished from an ectopic decidual reaction involving the peritoneum. Prominent nucleoli, often brisk mitotic activity, and cytokeratin immunoreactivity in the deciduoid tumors exclude an ectopic decidual reaction.

Lin et al. have reported peritoneal epithelioid hemangioendotheliomas or epithelioid angiosarcomas that have mimicked PMM [134]. Features that suggested the diagnosis of PMM in some of the cases included epithelioid cells in a tubulopapillary pattern and the presence of reactive or neoplastic spindle cells resulting in a focal biphasic pattern. Variable degrees of vascular differentiation and immunoreactivity of the neoplastic cells for endothelial antigens (and negative or weak cytokeratin staining) excluded the diagnosis of PMM.

Miscellaneous Primary Tumors

Intra-abdominal Desmoplastic Small Round Cell Tumor

Clinical Features

This rare tumor (desmoplastic small round cell tumor, DSRCT) is of uncertain histogenesis, but it may ultimately prove to be a primitive tumor of mesothelial origin ("mesothelioblastoma") [126, 165–167, 255]. Although most of the tumors are intra-abdominal, similar tumors have also been described in the pleura and rarely at a distance from a mesothelium-lined surface (parotid gland, tentorium, and hand). DSRCTs exhibit a reciprocal translocation [t(11;22) (p13;q12)], resulting in fusion of the EWS1 gene on chromosome 22 and the Wilm's tumor suppressor gene (WT1) on chromosome 11 that appears to be unique for this tumor [165]. This fusion

results in the expression of the EWS/WT1 chimeric transcript detectable by reverse transcriptase polymerase chain reaction (PCR). The EWS/ERG fusion gene characteristic of Ewing's sarcoma/peripheral neuroectodermal tumors has been found in rare DSRCTs, suggesting some overlap between the two groups of tumors.

DSRCTs have a strong male predilection (M:F ratio, 4:1) and are most common in adolescents and young adults (range, 5–76 years) who usually have abdominal distension, pain, and a palpable abdominal, pelvic, or scrotal mass, sometimes in association with ascites. Some patients have had an elevated serum level of CA-125 or neuron-specific enolase (NSE). Laparotomy typically discloses variably sized but usually large, intra-abdominal masses associated with smaller peritoneal "implants" of similar appearance. The tumor is sometimes confined to the pelvis, and prominent involvement of the tunica vaginalis or the ovaries may mimic a primary testicular or ovarian tumor [255]. The retroperitoneum is involved in some cases. One tumor appeared to originate within the liver.

After initial treatment (debulking and postoperative chemotherapy, irradiation, or both), there may be an initial response, but more than 90% of patients die of tumor progression. The bulk of the tumor tends to remain within the peritoneal cavity, although extraabdominal metastases occur in some patients.

Pathologic Findings

On gross examination, the tumors, which may reach 40 cm in maximal dimension, have smooth or bosselated outer surfaces and firm to hard, gray-white, focally myxoid, and necrotic sectioned surfaces. Direct invasion of intra-abdominal or pelvic viscera may occur.

Microscopic examination reveals sharply circumscribed aggregates of small epithelioid cells delimited by a cellular desmoplastic stroma (**)** Fig. 13.27). The aggregates vary from tiny clusters (or even single cells) to rounded or irregularly shaped islands. Other common features include rounded rosette-like or gland-like spaces, peripheral palisading of basaloid cells in some of the nests, and central necrosis with or without calcification. The tumor cells are typically uniform with scanty cytoplasm and indistinct cell borders (> Fig. 13.28), although tumor cells with eosinophilic cytoplasmic "inclusions" and an eccentric nucleus, resulting in a rhabdoid appearance, are frequently also present. Small to medium-sized, round, oval, or spindle-shaped hyperchromatic nuclei have clumped chromatin and nucleoli that are usually inapparent. Mitotic figures and single necrotic cells are numerous.

Fig 13.27

Intra-abdominal desmoplastic small round cell tumor (DSRCT). The cellular nests of tumor are sharply circumscribed and separated by a fibrous stroma. Focal necrosis of the tumor is seen

Architectural features noted in a minority of cases, which can occasionally predominate and lead to diagnostic problems, include tubules, glands (sometimes with luminal mucin), cysts, papillae, anastomosing trabeculae, cords of cells mimicking lobular breast carcinoma, adenoid cystic-like foci, and only a sparse desmoplastic stroma. Cytologic features noted in a minority of cases, which can occasionally predominate, include spindle cells, cells with abundant eosinophilic or clear cytoplasm, which may create a biphasic pattern, signet-ring-like cells, and cells with marked nuclear pleomorphism [166]. Invasion of vascular spaces, especially lymphatics, is a common feature. Lymph nodes are occasionally involved by tumor.

Immunohistochemical and Ultrastructural Findings

The usual immunoreactivity for epithelial (low molecular weight cytokeratins, epithelial membrane antigen [EMA]), neural/neuroendocrine (neuron-specific enolase [NSE], CD57/Leu-7), and muscle (desmin) markers, as well as vimentin, suggests divergent differentiation. Desmin and vimentin immunoreactivity is typically paranuclear and globular and is particularly intense in the rhabdoid cells. Immunoreactivity for other antigens has been present in a variable proportion of cases, including Wilms' tumor protein (WT1), Leu-M1 (CD 15), S-100, B72.3, CA-125, MIC-2 protein, actin (MSA, SMA), desmoplakin, CD 99, MOC-31, NB84, Ber-EP4, chromogranin, and synaptophysin, but not HBA 71 (Ewing's sarcoma/PNET antigen) [126, 167, 258]. The stroma is typically immunoreactive for vimentin and muscle specific actin.

Ultrastructural variability suggests a range of differentiation. Cell junctions have varied from scant and primitive to more prominent ones including intermediate, desmosomal, and tight types. Paranuclear intermediate cytoplasmic filaments and basal lamina surrounding the nests of tumor have been prominent features in most of the cases [167].

Differential Diagnosis

The typical age of the patient, the absence of an extraperitoneal primary tumor, the distribution of the tumor, and its typical microscopic features and immunoprofile facilitate the distinction from other malignant small blue cell tumors in most cases. Identification of the unique reciprocal translocation is diagnostic in problem cases.

Solitary Fibrous Tumor

Although once referred to as fibrous mesotheliomas, these tumors are now designated solitary fibrous tumors and are believed to originate from submesothelial fibroblasts [23, 254]. The clinical and pathologic features are similar to their much more common pleural counterparts, including immunoreactivity for CD34 and lack of immunoreactivity for cytokeratin, an immunoprofile that is useful in distinguishing these tumors from desmoplastic mesotheliomas [23]. Typical tumors are clinically benign. One peritoneal solitary fibrous tumor that was focally sarcomatous was clinically malignant [82].

Inflammatory Myofibroblastic Tumor

Day et al. reviewed the features of seven cases of abdominal "inflammatory pseudotumor," [61] a lesion that has also been referred to as plasma cell granuloma or, more recently, inflammatory myofibroblastic tumor [182]. Various anatomical locations have been reported but most tumors arise in the lung, mesentery, omentum, or retroperitoneum. The abdominal lesions are typically encountered in patients younger than 20 years of age, often in the first decade, who present with a mass, fever, growth failure or weight loss, hypochromic anemia, polyclonal thrombocytosis, and hypergammaglobulinemia. Laparotomy typically reveals a solid mesenteric mass that on microscopic examination consists of myofibroblastic spindle cells, mature plasma cells, and small lymphocytes. The spindle cells often show positive cytoplasmic immunoreactivity for ALK-1, with associated chromosomal translocations detected in approximately 50% of cases. Inflammatory myofibroblastic tumors are regarded as neoplasms of low-grade or intermediate biologic behavior, which can be associated with favorable outcome, but have a tendency for local recurrence and generally a low risk of distant metastasis. Coffin et al. recently reported that abdominopelvic tumors had a higher rate of recurrence relative to other anatomical sites and that ALK-negative tumors were more likely to be associated with distant metastases [53].

Calcifying Fibrous Tumor

The rare lesion known as calcifying fibrous tumor, initially considered a pseudotumor, is likely neoplastic, with a predilection for children and young adults but which can occur over a wide age range and in a variety of anatomical sites including the subcutaneous or deep soft tissues and the pleura [159, 217]. In the peritoneum, the calcifying fibrous tumor is usually an incidental finding involving the visceral peritoneum of the small intestine or stomach. The tumors are often small (less than 5 cm) but can be larger and sometimes multiple. Microscopically, they are hypocellular, composed of bland spindle cells, hyalinized collagen, a chronic lymphoplasmacytic

inflammatory infiltrate, and psammomatous or dystrophic calcifications. The spindle cells are typically CD34positive and ALK-negative, the latter regarded as evidence that these lesions are distinct from the inflammatory myofibroblastic tumor; rare cells may show positive staining with muscle actin and desmin [159, 217].

Omental-Mesenteric Myxoid Hamartoma

The omental-mesenteric myxoid hamartoma designation was applied by Gonzalez-Crussi et al. to a lesion in infants characterized by multiple omental and mesenteric nodules composed of plump mesenchymal cells in a myxoid, vascularized stroma [89]. The diagnosis of the referring pathologists was usually that of some type of sarcoma, but the follow-up was uneventful. The lesions may be hamartomatous or a variant of inflammatory myofibroblastic tumor.

Sarcomas

The majority of intra-abdominal sarcomas are of nonperitoneal origin and arise in the retroperitoneum or gastrointestinal tract; they include leiomyosarcomas, liposarcomas, and gastrointestinal stromal tumors, and are not discussed further here. Rarely, malignant vascular tumors may arise from the peritoneum (epithelioid hemangioendothelioma, epithelioid angiosarcoma) and are briefly discussed above in the differential diagnosis with malignant mesothelioma [134].

Gestational Trophoblastic Disease

Rarely, gestational trophoblastic disease (including placental site trophoblastic tumor, hydatidiform mole, and choriocarcinoma) may arise in the peritoneum, presumably secondary to an intra-abdominal pregnancy.

Metastatic Tumors

Peritoneal involvement by metastatic tumor is typically a result of seeding from a primary tumor arising within the abdomen or pelvis, most commonly the ovary. Peritoneal serous tumors in which the ovaries are normal or only minimally involved may arise directly from the peritoneum (see **O** Lesions of the Secondary Müllerian System) or rarely are metastatic from a serous papillary carcinoma of the endometrium or fallopian tube. Other tumors that may be associated with peritoneal seeding include carcinomas of the breast and gastrointestinal tract, especially the colon and stomach, and the pancreas. In such cases, the metastatic tumor may take the form of signet-ring cells widely scattered in a fibrous stroma (\bigcirc *Fig.* 13.29). Occasionally, the signet-ring cells can have relatively bland nuclear features, resulting in a deceptively benign appearance.

Pseudomyxoma Peritonei

Pseudomyxoma peritonei, which is a clinical term referring to the presence of masses of jelly-like mucus in the pelvis and often the abdomen, is usually a result of peritoneal spread from a typically low-grade mucinous

Fig 13.29

Poorly differentiated adenocarcinoma with signet-ring cells involving the peritoneum. (a) Deceptively bland, malignant cells infiltrate omental fat lobules, with an associated desmoplastic stromal reaction. (b) High-power view of signet-ring cells neoplasm, usually originating within the appendix or, less commonly, from a primary tumor elsewhere in the gastrointestinal tract. Ovarian involvement is common in such cases and this topic is discussed in detail in O Chap. 14, Surface Epithelial Tumors of the Ovary, and O Chap. 18, Metastatic Tumors of the Ovary.

Lesions of the Secondary Müllerian System

These peritoneal lesions are characterized by müllerian differentiation on microscopic examination and share an origin from the so-called secondary müllerian system, that is, the pelvic and lower abdominal mesothelium and the subjacent mesenchyme of females [128]. The müllerian potential of this layer is consistent with its close embryonic relation to the müllerian ducts that arise by invagination of the coelomic epithelium. Displacement of coelomic epithelium and subcoelomic mesenchyme during embryonic development could account for the presence of identical lesions within pelvic and abdominal lymph nodes. The origin of many of these lesions, however, is not known with certainty, and other proposed histogenetic mechanisms are discussed where appropriate.

Lesions of the secondary müllerian system include those containing endometrioid, serous, and mucinous epithelium, simulating normal or neoplastic endometrial, tubal, and endocervical epithelium. The metaplastic potential of the pelvic peritoneum also includes differentiation toward cells of transitional (urothelial) type, exemplified most commonly by Walthard nests. Proliferation of the subjacent mesenchyme may accompany epithelial differentiation of the mesothelium or may give rise to a variety of pure mesenchymal lesions composed of endometrial stromal-type cells, decidua, or smooth muscle.

Endometriosis in Usual Sites

Endometriosis is defined as the presence of endometrial tissue outside the endometrium and myometrium. Usually both epithelium and stroma are seen, but occasionally the diagnosis of endometriosis can be made when only one component is present, as discussed below.

Etiology and Pathogenesis

Two theories have been proposed for the pathogenesis of endometriosis: (1) metastases of endometrial tissue to its ectopic location (metastatic theory); and (2) metaplastic development of endometrial tissue at the ectopic site (metaplastic theory). The metastatic theory explains the majority of cases, but a metaplastic origin likely accounts for occasional cases in which metastatic spread of endometrial tissue is unlikely or impossible (see following).

Metastatic Theory

Sampson [205] proposed that endometriosis was caused by reflux of endometrial tissue through the fallopian tubes by a process of retrograde menstruation, with subsequent implantation and growth on peritoneal surfaces. Implantation of menstrual endometrium has also been proposed to explain endometriosis within surgical scars, on traumatized cervical and vaginal mucosa, and within perineal and vulvar scars following vaginal delivery. Passage of refluxed menstrual endometrium from the peritoneal cavity through diaphragmatic defects, diaphragmatic lymphatics, or both may explain pleural endometriosis.

Observations supporting the menstrual implantation hypothesis include the following: (1) endometriotic lesions are most common in areas closest to the tubal ostia and occur in a distribution that appears dependent on gravity and uterine position [104]; (2) lateral predisposition of ovarian endometriomas, which are more commonly left-sided than right-sided, a phenomenon attributed to reduced flow of peritoneal fluid due to the presence of the sigmoid colon in the left pelvis [230] (3) retrograde menstruation through the fallopian tubes is a common physiologic process, occurring in 90% of menstruating women with patent tubes [93]; (4) endometriosis is more common in women with early menarche, heavy menstrual flow, long menstrual flow (greater than 7 days), and frequent menses (cycle less than 27 days); (5) menstrual endometrium is viable, capable of growth in tissue culture and after subcutaneous or intrapelvic injection [65]; (6) endometriosis is more frequent in females with congenital obstruction to menstrual flow [164]; and (7)endometriosis may follow uteropelvic or uteroabdominal wall fistulas in experimental animals and humans.

Although endometriosis in some scars may be a result of menstrual implantation, endometriosis within scars after uterine operations may be secondary to intraoperative implantation of endometrial tissue [34, 224]. Supporting this theory is the greater frequency of scar endometriosis after abdominal hysterotomy than after cesarean section in some studies, consistent with the greater viability of transplanted early-pregnancy endometrium compared to late-pregnancy endometrium. Also, the occurrence of endometriosis within an episiotomy scar is much higher if uterine curettage is performed immediately after delivery than in patients without postdelivery curettage [177].

The presence of endometriosis in distant sites (e.g., lungs, extremities, and brain) is most easily explained by hematogenous spread from the uterus. Similarly, endometriosis within lymph nodes is likely a result of lymphatic spread. Evidence supporting the origin of endometriosis from lymphatic or hematogenous spread includes (1) the presence of normal endometrial tissue within endotheliumlined spaces as an incidental histologic finding within the myometrium, most often associated with adenomyosis; (2) the presence of intraluminal vascular involvement in rare endometriotic lesions; (3) the presence of intravascular or perivascular trophoblastic tissue and "decidua" as an incidental microscopic finding within the lungs of pregnant patients [223]; (4) the occurrence of pulmonary endometriosis almost exclusively in women who have had prior uterine operations that could predispose to the embolization of endometrial tissue; (5) the experimental production of pulmonary endometriosis by intravenous injection of endometrial tissue in rabbits; and (6)the observations that tumor cells, blood, dve, and radiographic material can migrate from the pelvis to the umbilicus by retrograde lymphatic flow.

Metaplastic Theory

The origin of pelvic endometriosis by a process of metaplasia from the pelvic peritoneum is consistent with the putative müllerian potential of this tissue, which, as noted earlier, has been referred to as the secondary müllerian system [128]. Evidence for the metaplastic theory includes (1) the demonstration of endometriosis in subjects in whom metastasis of normally situated endometrium could not occur or is highly unlikely, such as those with Turner's syndrome and pure gonadal dysgenesis who are amenorrheic and have hypoplastic uteri [179], and in males; (2) the experimental induction of peritoneal endometriosis adjacent to millipore filters that contain endometrial tissue but that prevent cellular transfer; (3) the observation that autologous endometrial implants in rabbits degenerate but are associated with the subsequent development of endometriosis in adjacent tissues; and (4)the juxtaposition of endometriosis with other putative metaplastic lesions of the peritoneum, such as diffuse peritoneal leiomyomatosis [91].

Other Etiologic Factors

Endometriosis is an idiopathic disease in most patients, and why only a minority of females are affected despite the common occurrence of retrograde menstruation is unknown. Some potential etiologic factors have been discussed (congenital obstruction, iatrogenic implantation); others are summarized in the following section. Familial and Genetic Factors Several studies concluded that the prevalence of endometriosis is greater in mothers and sisters of women with endometriosis than in the mothers and sisters of their husbands [127, 218]. Lamb et al. calculated the overall risk for first-degree relatives to be 4.9% [127]. Genetic studies suggest a polygenic mode of inheritance (influenced by several different genes) or one that is multifactorial (a result of interaction between genetic and environmental factors). In opposition to the foregoing, Houston et al. [102] concluded that there were methodologic flaws in these studies [127, 218] and that an inherited tendency to endometriosis has not yet been substantiated.

Molecular genetic analysis has elucidated a number of intriguing theories regarding the pathogenesis of endometriosis [24]. By microarray analysis, Wu et al. have shown that in patients with endometriosis, the ectopic and eutopic endometria have different gene expression profiles [247]. Putative endometrial progenitor/stem cells, which are thought to reside in the basalis endometrium and possibly in the bone marrow, have recently been characterized by in vitro and in vivo assays [206]. It has been shown that patients with endometriosis shed significantly more basalis layer during menstruation compared with normal controls, supporting the hypothesis that endometriotic implants develop from endometrial progenitor/stem cells, which are in turn derived from retrograde menstrual flow, known to be higher in women with endometriosis [93, 132, 206].

Hormonal Factors Because endometriosis occurs almost exclusively in women of reproductive age, hormonal factors may play an etiologic role. The rare examples of endometriosis in phenotypic females with gonadal dysgenesis and in males have usually been associated with the use of exogenous estrogens [138, 179]. Similarly, smoking and exercise, which are inversely correlated with endogenous estrogen levels, appear to be protective factors for the development of endometriosis. In a recent large epidemiologic study, factors associated with an increased risk of endometriosis included low body weight, alcohol use, and certain menstrual characteristics (early menarche, short cycle length, and heavy menstrual cycles) [140].

It has been suggested that the progestational milieu of pregnancy may inhibit the development of endometriosis. Many studies have indicated that endometriosis is more likely to occur in women who have delayed pregnancy and is less common in multiparous women [192]. Similarly, in some studies, patients with endometriosis are much less likely to have used oral contraceptives than similar patients without endometriosis. Some studies have found an increased frequency of the luteinized unruptured follicle syndrome (LUFS) in patients with endometriosis. In normal women, the ruptured corpus luteum releases its progesterone-rich fluid into the peritoneal cavity. It has been postulated that this fluid may inhibit implantation and growth of refluxed endometrial fragments at the time of menstruation [123]. In patients with LUFS, a corpus luteum is formed, but rupture and fluid release do not occur, resulting in lowered luteal-phase levels of progesterone in the peritoneal fluid [123]. This local hormonal imbalance may be critical in allowing endometrial cells to implant on the peritoneum. Other studies, however, have shown no difference in the luteal-phase peritoneal fluid hormone values in women with and without endometriosis.

Immune Factors One study has demonstrated a reduced T-lymphocyte-mediated cytotoxicity to autologous endometrial cells and a decreased lymphocyte stimulation response to autologous endometrial antigens in patients with endometriosis [225]. The degree of depressed cellular immunity was directly proportional to the severity of the disease. The authors of this study suggested that certain cell-mediated immune mechanisms that may be operative in limiting the growth of endometriotic tissue may be impaired in patients with endometriosis. Other authors have suggested that the growth of endometriotic implants may be stimulated by activated macrophages. Recent evidence has shown that local production of interleukin-4, a cytokine involved in the Th2 immune response, induces proliferation of endometriotic stromal cells [172]. Cyclo-oxygenase-2, which is involved in the biosynthesis of prostaglandin E2, is highly expressed in ectopic endometria relative to eutopic endometria, and is thought to play a promotory role in the development of endometriosis [13].

Clinical Features

Epidemiologic Factors

The highest risk of the disease has traditionally been considered to be in the upper socioeconomic levels of developed societies, especially among women who delay pregnancy, although, according to Houston, these associations have not been proven statistically [102]. Although endometriosis was once considered to be more common in Caucasians, recent studies showing a similar frequency of the disease in Orientals and blacks cast doubt on this view.

The true prevalence of endometriosis is unknown as many patients are asymptomatic; estimates for the prevalence of the disease in women of reproductive age are 10–15% [147]. Prevalence figures, however, have varied widely, depending on the population studied and the method of diagnosis (clinical, operative, or pathologic). Similarly, a study of the incidence rates of pelvic endometriosis in white females of reproductive age in Rochester, Minnesota (USA), found that the overall incidence of the disease more than doubled (from 108.8 to 246.9 cases per 100,000 person-years) as the definition of a case was extended from histologically confirmed cases to clinically and surgically diagnosed cases [101].

More than 80% of affected patients are in the reproductive age group. In one study, the age-specific incidence rates increased in successive age groups through age 44 and then declined for women 45-49 years [101]. Less than 5% of cases occur in postmenopausal women, and in these patients the disease is frequently not diagnosed premenopausally [115]. Endometriosis can be clinically significant in this age group, with 20-30% of affected patients requiring operative management [115, 189]. In some postmenopausal patients with endometriosis, an association with obesity and endometrial carcinoma has been noted, suggesting that hyperestrinism may play a role, but in other series, a majority of patients have had no obvious exogenous or endogenous source of estrogen [115]. Almost 10% of patients with endometriosis are adolescents [32]. Endometriosis was found at laparoscopy in approximately 50% of teenage patients with dysmenorrhea or chronic pelvic pain in three studies [32]. In some studies, adolescents with endometriosis have a particularly high frequency of a congenital obstruction to menstrual flow.

Symptoms and Signs

The recurrent cyclic menstrual, inflammatory, and fibrotic changes within endometriotic lesions are likely responsible for most of the symptomatology of endometriosis, although there is often no direct relationship between the extent of the disease and the severity of the symptoms [32]. An exception to the foregoing applies to women with deeply infiltrating endometriosis, a clinical term used for patients with deep pelvic pain, usually in the form of severe dyspareunia and dysmenorrhea, which is often associated with rectovaginal lesions or involvement of bowel, ureter, or bladder [56]. One study has shown significant reduction in painful symptoms obtained with complete surgical excision of deep lesions [35]. Hormonal responsiveness of the lesions as judged histologically also does not correlate with symptoms, and microscopic examination of symptomatic endometriosis in postmenopausal patients typically reveals atrophic changes [115]. Age generally does not appear to affect disease severity in most studies [102]. An exception to the foregoing is one study in which women in the age group of 26–52 years had less extensive disease than women 16–25 years of age [192]. A higher frequency of nulliparity in the younger women appeared to account for part of this difference [102]. Another recent study found that endometriosis in postmenopausal patients was morphologically less extensive and less active in appearance relative to endometriosis in premenopausal women, but that the endometriotic foci retained the same immunoprofile by estrogen and progesterone receptor immunostaining [58].

The typical symptoms that are attributed to pelvic endometriosis are acquired dysmenorrhea, lower abdominal, pelvic, and back pain, dyspareunia, irregular bleeding, and infertility. Infertility is present in up to 30% of women with endometriosis, although the putative association between mild endometriosis and infertility has been challenged and remains controversial. The subject of endometriosis-related infertility has been reviewed elsewhere [92, 147] and is not considered in detail here. Potential pathogenetic factors include tubal factors (adhesions, luminal obstruction), ovarian factors (anovulation, luteal-phase dysfunction, LUFS), immune factors (antiendometrial antibodies), peritoneal factors (increased prostaglandins, increased macrophages), and an increased risk of spontaneous abortion.

Pelvic examination may reveal tender nodules in the cul-de-sac and uterosacral ligaments, tender, semifixed, cystic ovaries, and a fixed, retroverted uterus. The rectovaginal septum may also be tender and indurated. The endometriotic lesions frequently enlarge and become more painful during menses. The clinical manifestations also vary according to the site of the endometriosis, as is discussed later in this chapter. As the clinical manifestations of endometriosis are frequently nonspecific, vary widely between patients, and may be absent in a high proportion of patients, a definitive diagnosis requires direct visualization by laparoscopy (or laparotomy) and, ideally, biopsy. Hormonal suppression and surgical ablation remain commonly employed therapeutic modalities, and while treatment of endometriosis is not discussed here, it is important to note that with advances in the understanding of the pathogenesis of endometriosis, future methods may include molecular-targeted drug therapies such as cyclo-oxygenase inhibitors and immunomodulators in an attempt to minimize the need for surgical intervention [24, 92].

Laparoscopic Findings

A number of recent studies have stressed that endometriotic foci, especially early ones, are frequently nonpigmented and may have a wide variety of laparoscopic appearances, including clear, white, and red lesions [107, 137, 226]. Sequential laparoscopic examinations indicate that nonpigmented endometriotic implants eventually evolve into the typical pigmented lesions [107]. Even in patients with laparoscopically typical disease, biopsy may yield only nondiagnostic tissue, and thus, in the opinion of some authors, diagnosis and treatment should not always depend on microscopic confirmation [33]. Other authors have found that 25% of laparoscopically atypical lesions prove to be endometriosis on histological examination, and therefore advocate that all lesions suggestive of endometriosis, both typical and atypical, should be excised if eradication is the surgical objective [3]. In another study, only 50% of all laparoscopic biopsies from clinically suspicious foci were proven microscopically to be endometriosis [240].

Laparoscopically detectable defects or "pockets" involving the pelvic peritoneum are frequently associated with, and likely caused by, endometriosis [193]. In one study, 80% of women with pelvic peritoneal defects had endometriosis, and in another, the endometriotic foci were often located along the edges of the defects [193]. Conversely, 18–28% of women with endometriosis had peritoneal defects [193].

Serum Markers

Levels of CA-125 may be elevated in the serum and peritoneal fluid of patients with endometriosis [74]. The concentrations of serum CA-125 correlate with both the severity and the clinical course of the disease. The serum test has low sensitivity, however, and is not appropriate for general screening purposes. In contrast, CA-125 levels have acceptable sensitivities and very high specificities in populations with a relatively high prevalence of the disease and are useful in monitoring response to treatment.

Antiendometrial antibodies have been found in up to 83% of women with laparoscopically confirmed endometriosis. In one study, the antibody titers in women who had had a good response to hormonal treatment were lower than in those with untreated endometriosis or in whom there had been a poor response to treatment, and in another study, sequential determination of antibody levels showed that they were lowered by hormonal treatment.

Effects of Pregnancy

Although rare cases of endometriosis undergo permanent regression during pregnancy, the ameliorative effect of pregnancy noted in many cases of endometriosis is only temporary. The behavior of endometriosis during pregnancy is extremely variable among different patients and between one pregnancy and another in the same patient. During pregnancy, visible endometriotic lesions frequently undergo initial enlargement, with occasional ulceration and bleeding, followed by shrinkage. In most sites, there is a decrease in the associated pain.

A rare complication of endometriosis during pregnancy is intrapartum or postpartum rupture of the lesion, most probably caused by a softening of the lesion secondary to stromal decidualization, pressure from the expanding uterus, or both. Rupture occurs most frequently in the ovaries or bowel, typically resulting in perforation and an acute abdomen. Rarely, hemoperitoneum, sometimes fatal, is caused by hemorrhage from decidualized endometriotic lesions at term.

Rare Complications

Massive, sometimes serosanguineous, ascites can occur in patients with pelvic endometriosis; a right pleural effusion is also present in one third of such patients [157]. If one or both ovaries are involved, the operative findings may simulate those of an ovarian carcinoma. The pathogenesis of the ascites is not clear. Possible sources include production by endometriotic cysts, irritated peritoneal mesothelial cells, or the ovarian serosa (Meigs-like syndrome). Other rare complications include hemorrhage from an endometriotic cysts, resulting in an acute abdomen.

Gross Features of Peritoneal and Ovarian Endometriosis

The most common anatomical sites of endometriosis are the ovaries, the uterosacral, broad, or round ligaments, the rectovaginal septum and cul-de-sac, and the serosa of the uterus, fallopian tubes, or other pelvic organs (see **7** *Table 13.1*). Less common sites include the serosa of the large bowel, small bowel, and appendix, the mucosa of the female genital tract, the skin, the urinary tract, and pelvic lymph nodes. These sites and other additional rare sites of involvement are discussed separately below.

Depending on their duration and their superficial or deep location in relation to the peritoneal surface, endometriotic foci may appear as punctate, red, blue, brown, or white spots or patches with either a slightly raised or a puckered surface (\bigcirc *Fig.* 13.30). Ecchymotic or brown areas have sometimes been described as "powder burns." The endometriotic foci are frequently associated with dense fibrous adhesions. The lesions may form nodules or cysts or both. Rarely, endometriosis can take the

Table 13.1

Sites of endometriosis

Ovaries Uterine ligaments (uterosacral, round, broad) Rectovaginal septum Cul-de-sac Peritoneum of uterus, tubes, rectosigmoid, ureter, bladder	Large bowel, small bowel, appendix Mucosa of cervix, vagina, and fallopian tubes Skin (scars, umbilicus, vulva, perineum, inguinal region) Ureter, bladder Omentum, pelvic lymph nodes Inguinal (noncutaneous)	Lungs, pleura Soft tissues, breast Bone Upper abdominal peritoneum Stomach, pancreas, liver Urethra, kidney, prostate, paratesticular Sciatic nerve, subarachnoid space, brain

form of polypoid masses that project from the serosal surfaces, into the lumens of endometriotic cysts, or from the mucosa of the bowel (**>** *Fig. 13.31*) or bladder. In some of these cases, there is a history of exogenous estrogen use and hyperplastic changes are found on microscopic examination [176]. This appearance, which we refer to as polypoid endometriosis, can simulate a malignant tumor on clinical, intraoperative, or pathologic examination [155, 176].

Endometriotic cysts (endometriomas) most commonly involve the ovaries, where they can partially or almost completely replace the normal tissue; bilateral

Fig. 13.31 Polypoid endometriosis. A polypoid mass projects from the mucosa of the large bowel

Endometriosis of cul-de-sac. Cystic endometrial glands with a cuff of endometrial stroma are surrounded by fibrous and adipose tissue

Fig. 13.32

Endometriotic cyst of ovary. The cyst has been opened to reveal a focally hemorrhagic lining. Multiple hemorrhagic lesions also involve the uterine serosal surface

involvement occurs in one third to one half of the cases [67]. The cysts rarely exceed 15 cm in diameter; larger examples are more likely to harbor a neoplasm. Endometriotic cysts are commonly covered by dense fibrous adhesions, which may result in fixation to adjacent structures. The cyst walls are usually thick and fibrotic, with a smooth or shaggy, brown to yellow lining (\bigcirc *Fig. 13.32*). The cyst contents typically consist of altered, semifluid or inspissated, chocolate-colored material; rarely, the cyst is filled with watery fluid. Any solid areas in the cyst wall or intraluminal polypoid projections should be sampled histologically to exclude a neoplasm originating in the cyst (see page 37).

Typical Microscopic Findings

Many of the problems and pitfalls encountered in the histological diagnosis of endometriosis have been addressed in detail in a recent comprehensive review [39]. The typical appearance in reproductive age women, in whom the disease is usually diagnosed, is of one or more glands lined by endometrioid epithelium, surrounded by a mantle of densely packed small fusiform cells with scanty cytoplasm and bland cytology, typical of nonneoplastic endometrial stromal cells () Figs. 13.33 and () 13.34). Small blood vessels, which may be engorged, are present and sometimes draw attention to the lesion on low-power examination. When seen in the ovary, the most common site encountered by the surgical pathologist, endometriosis varies from simple to microscopically dilated glands (> *Fig. 13.35*) to grossly recognizable endometriotic cysts. This spectrum is seen at extraovarian sites, although striking cysts are less common to rare, depending on the site. Endometriosis may occur anywhere in the ovary but is most common in the cortex. Sometimes it is very superficial and may occur on the surface as small nodules, irregularly shaped aggregates, or even have a plaque-like configuration (> Fig. 13.35). Surface endometriosis is typically associated with fibrous tissue and inflammatory cells and, if prominent and of significant duration, there may be conspicuous adhesions. Glands, which can sometimes be cystic, may hang off the surface of the ovary, tethered to it by the associated stroma and fibrous tissue. Endometriotic glands in the cortex of the ovaries of perimenopausal or

Fig. 13.34

Endometriosis of cul-de-sac (higher magnification of **Fig. 13.33**). Endometriotic glands are lined by inactive epithelium and surrounded by a thin rim of endometrial stroma

postmenopausal women, or glands that are atrophic for any reason, may be mistaken for inclusion glands and cysts if the often subtle, sometimes barely perceptible, cuffs of stroma are overlooked or obscured by hemorrhage or histiocytes (see \bigcirc *Fig. 13.35*). Immunostaining for CD10 can facilitate the recognition of the stromal cells, particularly when sparse and when glandular epithelium is minimal or absent (\bigcirc *Fig. 13.35c*) [227].

The appearance of endometriotic tissue varies with the extent of its response to the normal hormonal fluctuations of the menstrual cycle and the duration of the process. When the appearances of simultaneous samples of eutopic endometrium and endometriotic foci from reproductive age women are compared, cyclic changes are seen in the endometriosis in 44-80% of the cases, with considerable variability in glandular morphology [149, 252]. When more than one endometriotic focus is examined in the same patient, the appearance of the specimens does not differ significantly from one to another [18]. In most postmenopausal patients, the endometriotic tissue is atrophic with glands, that are occasionally cystic, lined by flattened epithelial cells surrounded by a dense fibrotic stroma with sometimes a barely perceptible tendency for the stroma to be more cellular close to the gland, a feature that may be a diagnostic clue; the appearance is similar to that of simple or cystic atrophy of the endometrium (> Fig. 13.36) [115]. In a minority of cases, however, the endometriotic tissue has an active appearance, with or without the metaplastic and hyperplastic changes that are more commonly present in premenopausal women.

G Fig. 13.35

Subtle endometriosis involving the ovarian surface. (a) The periglandular endometriotic stroma is only focal and less cellular than usual. (b) The periglandular endometriotic stroma is obscured by hemorrhage. In both examples, failure to recognize the endometriotic stroma could result in the diagnosis of endometriosis being missed and the endometriotic glands being misinterpreted as epithelial inclusion glands. (c) Endometrial stromal cells highlighted by positive CD10-immunoreactivity

At the time of menstruation, hemorrhage may occur within the stroma and glandular lumens of endometriotic foci, as well as a secondary inflammatory response consisting predominantly of a diffuse infiltration of histiocytes. The histiocytes typically convert the extravasated red blood cells into glycolipid and granular brown pigment, becoming so-called pseudoxanthoma cells (> Figs. 13.37 and > 13.38) that can replace most or all the endometriotic stroma [49]. Most of the pigment is ceroid (lipofuscin, hemofuscin), and hemosiderin is typically present to a much lesser extent [49]. The amount of pigment in an endometriotic lesion appears to increase with its age, and early lesions are frequently nonpigmented [107]. Variable numbers of lymphocytes and smaller numbers of other inflammatory cells may be present. Large numbers of neutrophils with microabscess formation should raise the possibility of secondary bacterial infection [210].

As already mentioned, a common manifestation of ovarian endometriosis is striking cystification resulting in an endometriotic cyst. The epithelial and stromal lining of an endometriotic cyst frequently becomes attenuated, and the former may be reduced to a single layer of cuboidal cells that may retain some endometrial characteristics but which are often devoid of specific features. In such circumstances, recognition of the cyst as endometriotic may only be possible if a rim of subjacent endometrial stroma persists. Commonly, the cyst lining of endometrial epithelium and stroma is totally lost, and replaced by granulation tissue, dense fibrous tissue containing

■ Fig. 13.36 Endometriosis in a postmenopausal woman. The glands are cystic, atrophic, and separated by a fibrous stroma

fibroblasts with particularly small nuclei, and variable numbers of pseudoxanthoma cells (presumptive endometriosis) (**?** *Fig. 13.38*). In some "old" endometriotic cysts, ossification, calcification, and old luminal blood clot can produce striking gross and microscopic appearances. The epithelial cells lining endometriotic cysts are often focally large and cuboidal with abundant eosinophilic cytoplasm and large atypical nuclei (**?** *Fig. 13.39*) [39, 212]. The significance of such nuclear atypia is unclear. Although it may be reactive, cells with these features may merge with clear cell adenocarcinomas and endocervical-like mucinous borderline tumors (EMBLTs) [83, 200, 201]. When this atypia is an isolated finding in an endometriotic cyst, however, the follow-up is typically uneventful [212].

Endometriosis that involves smooth muscle in the uterine ligaments or the walls of hollow viscera differs significantly in its appearance from that of endometriosis

Fig. 13.37

Lining of ovarian endometriotic cyst. (a) The lining consists of cystically dilated endometrial glands and numerous pigment-laden histiocytes within the subjacent stroma. (b) Endometriotic surface epithelial lining with underlying, lightly pigmented histiocytes

G Fig. 13.38

Lining of ovarian endometriotic cyst. In this field, the lining consists only of fibrotic granulation tissue and pigmentladen histiocytes (presumptive endometriosis)

Fig. 13.39 Lining of ovarian endometriotic cyst. The epithelial cells show notable nuclear atypia

in the ovaries and the peritoneal surfaces. In the former, there is typically a striking proliferation of the indigenous smooth muscle, often resulting in a firm, solid, tumor-like mass. The appearance is similar to that of adenomyosis with secondary striking myometrial hypertrophy.

Unusual Microscopic Findings

Metaplastic Glandular Changes

Metaplastic changes similar to those occurring in eutopic endometrial glands have been described in endometriotic glands [84]. These changes include ciliated, eosinophilic,

Fig. 13.40 Mucinous metaplasia in endometriosis

hobnail, and, rarely, squamous and mucinous metaplasia (**>** *Fig. 13.40*); the latter may be characterized by the presence of endocervical-type cells or, less often, goblet cells. In one study of ovarian endometriosis [84], there was a significant association between the presence of metaplasia in the endometriosis and a synchronous ovarian epithelial cancer. Additionally, all four endocervical-like mucinous borderline tumors (EMBLTs) in the same study were associated with foci of ovarian endometriosis that exhibited both mucinous metaplasia and hyperplasia. In some cases of endometriosis, the distinction between papillary mucinous metaplasia and an early EMBLT may be arbitrary.

Unusual Hormonal Changes

Endometriotic tissue usually exhibits striking progestational changes (**>** *Fig. 13.41*) during pregnancy or progestin therapy. In such cases, examination reveals a decidual reaction with atrophy of the endometrial glands, which are small and lined by cuboidal or flattened epithelial cells (**>** *Fig. 13.41a*). In pregnancy the glands can rarely exhibit the Arias–Stella reaction (**>** *Fig. 13.41b*), optically clear nuclei, or both. Necrosis of the decidual cells, foci of marked stromal edema, and infiltration by lymphocytes are additional findings in patients receiving progestational agents. Inactive or atrophic changes similar to those that are seen typically in the endometriotic foci of postmenopausal patients may be present in premenopausal patients treated with hormones [161]. Additionally, endometriotic foci often disappear or are replaced by fibrous tissue after danazol therapy.

Hyperplastic Glandular Changes

A variety of hyperplastic and atypically hyperplastic changes similar to those occurring in the endometrium

have been described in endometriotic glands, sometimes related to an endogenous or exogenous estrogenic stimulus (\bigcirc *Fig. 13.42*) [83, 205, 249] or tamoxifen therapy [142, 209]. Hyperplastic changes are particularly common in cases of polypoid endometriosis [176]. It is logical to conclude that such atypical changes have a malignant potential similar to those in the endometrious, and indeed, rare cases of hyperplastic endometriosis have preceded the development of an adenocarcinoma in the same area or have coexisted with carcinoma in the same specimen (\bigcirc *Fig. 13.42*; see also \bigcirc *Fig. 13.56*, later in this chapter) [125].

Stromal Changes

The endometriotic stroma may also undergo metaplasia, typically smooth muscle metaplasia, which is encountered

Fig. 13.41

Pregnancy-induced changes within endometriosis. (a) The endometriotic gland is atrophic, and the stroma exhibits marked decidual transformation. (b) The endometriotic glands exhibit the Arias–Stella reaction most often within the walls of ovarian endometriotic cysts but occasionally elsewhere (**>** *Fig. 13.43*) [80, 81, 211]. Extensive amounts of smooth muscle within the endometriotic stroma can result in "endomyometriosis" or uterus-like masses, which have been described within an obturator lymph node, the ovary, the small bowel, the broad ligament, and lumbosacral region, and in males, in the scrotum [174, 191, 257]. In some cases, a uterus-like mass in the region of the ovary may possibly represent a congenital malformation rather than an unusual

Fig. 13.42

Hyperplasia within endometriosis. Endometriotic glands exhibit architectural and cytologic atypia. Endometrioid carcinoma was found elsewhere in the specimen (see **)** *Fig. 13.56*)

 Fig. 13.43
Endometriosis with smooth muscle metaplasia.
Endometriotic glands and stroma surrounded by extensive, metaplastic smooth muscle

manifestation of endometriosis [188]. Occasional cases of endometriosis can elicit a striking periglandular myxoid [40] (\bigcirc *Fig.* 13.44) or elastotic [46] response (\bigcirc *Fig.* 13.45), which in both situations can focally obliterate the endometriotic stroma. In two cases, extensive myxoid change in endometriosis was misinterpreted as pseudomyxoma peritonei and/or metastatic adenocarcinoma, one at the time of frozen section [40, 94].

Fig. 13.44

Endometriosis with prominent myxoid stroma. A small endometriotic gland with a periglandular rim of endometriotic stroma is surrounded by loose fibrous tissue and pools of acellular mucin. This appearance was misinterpreted as pseudomyxoma peritonei on frozen section examination

Fig. 13.45

Endometriosis with prominent elastotic stroma. Large masses of elastic tissue replace the normal endometriotic stroma. (Elastic tissue stain) Anatomical location and hormonal factors appear to be predisposing factors, as there is a propensity for myxoid change to occur in endometriosis of the skin or superficial soft tissues, and also during pregnancy or the puerperium; the latter situation may be further confounded by the presence of decidual change of the stromal cells [39].

Stromal Endometriosis

Some cases of endometriosis are characterized by an absence or rarity of glands, so-called stromal endometriosis [21, 46, 51]; the same term was used in the older literature to refer to what is now designated low-grade endometrial stromal sarcoma (ESS). Stromal endometriosis is most commonly encountered in the ovary, where it is typically an incidental microscopic finding within the ovarian stroma ("benign stromatosis"). There is usually no associated pelvic endometriosis, and the process likely represents a metaplastic response of the ovarian stromal cells. A disproportionate number of cases of stromal endometriosis are seen within the superficial stroma of the uterine cervix (see page 30) [51]. Endometriosis involving the pelvic peritoneum can take the form of multiple small nodules of endometriotic stroma in which endometriotic glands are absent or rare, a finding referred to as micronodular stromal endometriosis [21, 46]. (> Fig. 13.46). As noted above, immunostaining for CD10 may be of assistance in confirming the presence of endometriotic stromal cells, but this marker is less useful in cases of stromal endometriosis involving the cervix, as normal cervical stroma may be strongly CD10-positive [143].

Necrotic Pseudoxanthomatous Nodules

Occasionally, ovarian and extraovarian endometriosis take the form of "necrotic pseudoxanthomatous nodules," which typically occur in postmenopausal women [49]. Multiple nodules can be attached to the peritoneum or, less commonly, lie free in the peritoneal cavity. When associated with enlargement of one or both ovaries, the intraoperative findings can mimic those of carcinoma with peritoneal spread. The nodules are characterized by a central zone of necrosis surrounded by pseudoxanthoma cells, often in a palisaded arrangement, hyalinized fibrous tissue, or both (> Fig. 13.47). Typical endometriotic glands and stroma are sparse or absent within the nodules and their immediate vicinity, but foci of recognizable endometriosis are usually present in the ovaries. The typical postmenopausal age group of the patient and the appearance of the nodules suggest that they represent end-stage or burned-out foci of endometriosis that should be distinguished from other necrotic peritoneal and ovarian granulomas, as well as necrotic tumor, on histologic examination.

A central area of necrosis is surrounded by pseudoxanthoma cells and an outer zone of fibrous tissue

Rare Miscellaneous Findings

Rare examples of endometriosis have been encountered in intimate association with foci of peritoneal leiomyomatosis, glial implants of ovarian teratomas, and nodules of splenosis. Perineural and vascular invasion can occur rarely in otherwise typical, benign endometriotic lesions, findings that may incorrectly suggest the diagnosis of malignancy [198].

Liesegang rings are eosinophilic, acellular, ringlike structures composed of periodic precipitation zones from colloidal solutions that are supersaturated in vitro or in vivo. They are typically encountered within necrotic, inflamed, or fibrotic tissues and have been found on microscopic examination within endometriotic cysts (\bigcirc *Fig.* 13.48) [180]. These structures have been confused with, and should be distinguished from, parasites and foreign material on histologic examination [50].

Microscopic examination of the fallopian tubes in patients with endometriosis has revealed nonspecific chronic salpingitis in as many as one third of cases [59]. A less common lesion, so-called pseudoxanthomatous salpingitis or pseudoxanthomatous salpingiosis, characterized by infiltration of the tubal mucosa by pseudoxanthoma cells, is almost always associated with pelvic endometriosis [49, 59].

Ultrastructural, Histochemical, and Steroid Receptor Studies

Endometriotic glands typically exhibit ultrastructural features that represent a response, but an incomplete one, to the prevailing hormonal milieu of the particular phase of

Fig. 13.48Liesegang rings in an endometriotic cyst

the menstrual cycle. In contrast to eutopic endometrial glands, it is usually not possible to date the glands precisely within the secretory phase because of marked interglandular and intraglandular variability. Ultrastructural examination of endometriotic tissue following danazol treatment shows either arrest of the endometriotic glandular epithelium in the early proliferative phase or disorganization of the epithelial cells with atrophic changes.

Estrogen (ER) and progesterone receptors (PR) are present in endometriotic glands and stroma but usually in lower concentrations than in eutopic endometrium [25]. In a variable number of cases, one or both receptors are absent. Moreover, the normal variation in the quantity of both receptors exhibited by eutopic endometrium during the menstrual cycle is diminished or absent within foci of endometriosis [131]. Differences in receptor concentrations between eutopic endometrium and endometriotic epithelium in response to danazol have also been noted. No correlation has been found between receptor levels and severity of symptoms.

In summary, the findings of these studies are consistent with the incomplete and variable hormonal response of endometriotic foci observed on microscopic examination. They indicate a greater degree of autonomy of endometriotic tissue from the mechanisms controlling eutopic endometrium and may explain the failure of hormonal therapy in some patients [148].

Differential Diagnosis

Endometriosis may be accompanied by, and should be distinguished from, endosalpingiosis, which is characterized by glands lined by benign tubal-type epithelium, unassociated with endometrial stroma or the usual histiocytic inflammatory reaction of endometriosis (see **)** Endosalpingiosis). A misdiagnosis of endosalpingiosis or, if in the ovary, an epithelial inclusion gland (see **)** Chap. 12, Nonneoplastic Lesions of the Ovary) is likely when the endometriotic stroma is sparse or obscured by hemorrhage (see **)** *Fig.* 13.35).

Necrotic pseudoxanthomatous nodules should be distinguished from other ovarian and peritoneal necrotic nodules, such as infectious granulomas and isolated palisading granulomas of the ovary (see O Chap. 12, Nonneoplastic Lesions of the Ovary), and as noted earlier, peritoneal granulomas related to diathermy [37]. Such lesions, in addition to having characteristic features, lack the numerous pseudoxanthoma cells that are typical of endometriotic lesions.

Rare low-grade endometrial stromal sarcomas (ESSs) contain numerous benign-appearing or atypical endometrial

glands, to the extent that confusion with endometriosis may occur [42]. Indeed, it is likely that at least some cases referred to as aggressive endometriosis are examples of ESS with prominent glandular differentiation [42]. These tumors, however, in contrast to typical endometriosis, contain foci of more typical ESS devoid of glands, and in some cases, prominent mitotic activity of the stromal cells, sex-cord-like elements, and prominent vascular invasion.

A diagnosis of adenosarcoma was initially considered in some cases of polypoid endometriosis. Adenosarcomas, in contrast to polypoid endometriosis, are characterized by a stromal component that usually exhibits dense periglandular cellularity, atypia (albeit mild in many cases), intraglandular papillae, and increased mitotic activity.

Cervical and Vaginal Endometriosis

Superficial endometriosis of the uterine cervix is more common than is generally appreciated [11, 51, 85]. The predilection for sites of trauma and the usual absence of associated pelvic endometriosis suggest implantation as the most likely pathogenetic mechanism. The condition may be an incidental finding in an asymptomatic patient or be associated with premenstrual or postcoital spotting or menorrhagia. The solitary or multiple lesions typically involve the ectocervix; endocervical lesions have been described only rarely. The endometriotic foci appear as friable, ecchymotic streaks, patches, nodules, or cysts measuring from 1 mm to 2 cm in diameter. Rare lesions have been puckered secondary to fibrosis within the lesion, or papillary, simulating a carcinoma. In patients who have had a recent cone biopsy or extensive cautery, the entire transformation zone may be involved [105]. Before menses, the lesions typically enlarge and change from bright red to blue; during menses they may rupture, leaving an irregular ulcer. Because a punch biopsy may yield nondiagnostic tissue due to the size of the lesion (which is frequently small), tissue crushing, and fragmentation, aspiration cytology may be useful in establishing the diagnosis. Cervical endometriosis may be the source of abnormal gland cells identified on cervicovaginal smears [231].

On histologic examination, the endometriotic focus is usually confined to the superficial lamina propria (\bigcirc *Fig. 13.49*). The diagnosis can be missed when the endometriotic stromal component is sparse or obscured by edema, hemorrhage, or inflammatory cells [11]. In such cases, the endometriotic glands, particularly when they show atypia or mitotic activity, can be misinterpreted as endocervical glandular dysplasia, adenocarcinoma in situ, or even invasive adenocarcinoma (\bigcirc *Fig. 13.50*). As

 Fig. 13.49
Superficial cervical endometriosis. Endometriotic glands and surrounding stroma lie beneath squamous epithelium

previously noted, only endometrial stroma (stromal endometriosis) is found in occasional cases of superficial cervical endometriosis, even after serial sectioning (**>** *Fig. 13.51*) [51].

In contrast to superficial cervical endometriosis, deep cervical endometriosis is usually an extension of cul-de-sac involvement in association with more widespread pelvic endometriosis. It may be palpable as deep, firm nodules or cysts in the posterior wall of the cervix [85]. The diagnosis is made by biopsy or pathologic examination of the hysterectomy specimen. The differential diagnosis includes downgrowth of adenomyosis from the uterine corpus.

Superficial vaginal endometriosis, which typically involves the vault, is rarer than cervical endometriosis but is similar to the latter macroscopically, both in its predilection for involving sites of prior trauma and in its lack of associated pelvic endometriosis [85]. Deep vaginal endometriosis is more common, is typically associated with pelvic endometriosis, and appears as nodular or polypoid masses involving the posterior vaginal fornix (\bigcirc *Fig.* 13.52) [85]. The differential diagnosis of vaginal endometriosis, particularly of the superficial type, includes vaginal adenosis of the tuboendometrial variety; the latter, however, lacks endometrial stroma and the characteristic inflammatory response of endometriosis. Endometriosis of the vulva is discussed in a subsequent section (see \bigcirc Cutaneous Endometriosis).

Fig. 13.50

Superficial endometriosis of the uterine cervix. The endometriotic glands show cellular stratification and mitotic figures. If the scanty endometriotic stroma and histiocytes had not been appreciated, these glands may have been misinterpreted as endocervical glandular adenocarcinoma in situ

Fig. 13.51

Stromal endometriosis of uterine cervix. A cellular sheet of hemorrhagic, endometriotic stroma lies below the exocervical squamous epithelium

Fig. 13.52 Polypoid endometriosis of vagina

In a recent study of vaginal endometrioid adenocarcinoma, a strong association with vaginal endometriosis was found, with the latter present in 14 of 18 cases [221]. As the vagina is a common site for recurrence of endometrial adenocarcinomas, identification of endometriosis is an important observation in establishing a vaginal origin [39, 221].

Tubal Endometriosis

The term "tubal endometriosis" has been applied to at least three different unrelated lesions of the fallopian tube. The most common type is serosal or subserosal endometriosis, typically associated with endometriosis elsewhere in the pelvis; the myosalpinx is usually not involved.

Endometrial tissue may extend directly from the uterine cornu and replace the mucosa of the interstitial and isthmic portions of the tube in as many as 25% and 10% of women in the general population, respectively [39]. This finding is considered to represent a normal morphologic variation, although in some cases the ectopic endometrial tissue may give rise to intratubal polyps [60]. In occasional cases, the endometrial tissue may occlude the tubal lumen, that is, intraluminal endometriosis ("endometrial colonization") (\triangleright *Fig.* 13.53); involvement may be bilateral. Intraluminal endometriosis is typically unassociated with endometriosis elsewhere. The disorder accounts for 15– 20% of tubal-related infertility; it may also be associated with tubal pregnancy.

The third type of endometriosis involving the fallopian tube has been designated postsalpingectomy endometriosis. It occurs in the tip of the proximal tubal

stump, typically 1–4 years following tubal ligation [195]. It is closely related to, and may be associated with, salpingitis isthmica nodosa. The lesion is analogous to uterine adenomyosis, consisting of endometrial glands and stroma extending from the endosalpinx into the myosalpinx and frequently to the serosal surface. Hysterosalpingography or India ink injection of the specimen may show tuboperitoneal fistulous tracts; postligation pregnancies are a rare complication. Postsalpingectomy endometriosis has been documented in 20–50% of tubes examined following ligation. The frequency of this complication is increased with the electrocautery method of ligation, with short proximal stumps, and with increasing postligation intervals.

Intestinal Endometriosis

Intestinal involvement has been documented in as many as 37% of patients with endometriosis undergoing laparotomy [245], although the average frequency appears to be approximately 12%. In the majority of such cases, the involvement is confined to the serosa or subserosa and is unassociated with clinical manifestations referable to the intestinal tract. In contrast, from 0.7% to 2.5% of patients with endometriosis require bowel resection for symptomatic lesions [187]. In some series, as many as half the patients with symptomatic intestinal endometriosis have no extraintestinal involvement; the endometriotic nature of the intestinal lesions in such cases is more likely to be unrecognized preoperatively or at the time of laparotomy. Misdiagnosis is also common in postmenopausal patients because of a decreased index of suspicion, even though the intestine is one of the more common sites of clinically significant endometriosis in this age group [115]. As many as 7% of patients with symptomatic intestinal endometriosis are postmenopausal.

Intestinal sites of involvement include, in descending order of frequency, the rectum and sigmoid, the appendix, the terminal ileum, the cecum, and other parts of the large and small bowel, including Meckel's diverticulum [250]. In one large study [187], 15% of patients had more than one site of involvement. The presenting symptoms include, alone or in combination, acute or chronic abdominal pain, diarrhea, constipation, hematochezia, and decrease in stool caliber. Although the frequently catamenial nature of the symptoms may suggest the correct diagnosis, the clinical presentation can mimic acute appendicitis, bowel obstruction due to adhesions or a hernia, a neoplasm, or even inflammatory bowel disease. Endoscopic and radiographic studies typically demonstrate an extramucosal stenosing lesion; endoscopic biopsies are usually of no diagnostic value.

Endometriosis of the rectosigmoid area is usually a solitary lesion, involving a segment several centimeters in length, whereas ileal involvement is frequently multifocal and may involve segments of bowel up to 45 cm in length [250]. On gross examination, the segment of bowel is indurated and often angulated by a poorly defined, usually noncircumferential mass; the serosal surface may be puckered and covered by adhesions. Sectioning typically reveals a firm, gray-white, solid, mural mass, the bulk of which represents markedly thickened muscularis propria; the latter often has a radiating fanlike appearance. Small cystic spaces containing altered blood may be seen but are uncommon. In contrast to a primary adenocarcinoma, the overlying mucosa is usually intact, despite the high frequency of symptomatic bleeding in some series of patients. However, rare cases of polypoid endometriosis have involved the intestinal mucosa; such lesions can grossly mimic an adenocarcinoma (see > Fig. 13.31) [176]. On microscopic examination of symptomatic intestinal endometriosis, islands of endometriotic tissue are typically scattered throughout the hyperplastic muscularis propria, with or without involvement of other layers (> Fig. 13.54) [250].

A complication of intestinal endometriosis is perforation, which is usually associated with pregnancy; a marked decidual reaction is typically seen with the endometriotic stroma in such cases. Other complications include

Fig. 13.54 Colonic endometriosis. A nest of endometriotic glands and stroma lie in the muscularis propria

volvulus, intussusception, acute appendicitis, appendiceal mucocele, intramural hematoma, and the development of a malignant neoplasm (see below) [155, 249].

Urinary Tract Endometriosis

Urinary tract involvement has been documented at laparotomy in from 16% to 20% of patients with endometriosis [192, 245]. In most of these cases, the endometriosis is found on the serosa of the urinary bladder or that overlying the ureter and is without local clinical manifestations. Similarly, high-volume intravenous urography has demonstrated subtle, clinically insignificant abnormalities in 15% of women with proven pelvic endometriosis before therapy. In contrast, only 0.5–1% of patients with endometriosis have clinically significant urinary tract involvement; approximately 30% of such patients ultimately require nephrectomy for a hydronephrotic or nonfunctioning kidney. Most reported cases of urinary tract endometriosis have involved the urinary bladder or the ureters (with approximately equal frequency); the kidneys and the urethra are involved much less commonly. Urinary tract involvement is usually associated with endometriosis elsewhere in the pelvis, although the symptoms relating to the urinary tract may be the initial or sole manifestations of the disease in such patients [223]. In some series, however, as many as half the patients with ureteral involvement have disease restricted to the ureter and the adjacent uterosacral ligament [110]. Patients with renal endometriosis typically do not have endometriosis elsewhere, suggesting an embolic, likely blood-borne, origin.

From one third to one half of the affected patients are over 40 years of age and almost 5% of the patients are postmenopausal, some of whom had received estrogen replacement therapy. A preoperative diagnosis may be suspected by the catamenial nature of the symptoms, which include suprapubic or flank pain, frequency, urgency, dysuria, and hematuria; chills and fever secondary to a urinary tract infection have been the presenting symptoms in occasional cases. A tender suprapubic or flank mass may be palpable. Many patients, however, particularly those with ureteric involvement, have nonspecific manifestations or present with a silent obstructive uropathy, occasionally complicated by hypertension, renal failure (in cases of bilateral involvement), or both [110, 223]. In patients with bladder involvement, urography may reveal a filling defect; a stricture in the lower ureter with hydroureter and hydronephrosis or a nonfunctioning kidney is the typical urographic finding in those with ureteral involvement. All seven patients with ureteral endometriosis in one recent study had hydroureter, in most cases accompanied by hydronephrosis, two with superimposed pyelonephritis [4]. Endoscopy may confirm vesical or even ureteral involvement, and the lesions may exhibit catamenial enlargement, darkening, and bleeding. Endoscopy and biopsy, however, are often nondiagnostic [223].

Symptomatic endometriosis of the bladder is usually a result of mural involvement, and the lesions are typically located on the trigone, the floor of the bladder, or low on the posterior wall [223]. Involvement is rarely confined to the lateral walls, the dome, or the ureterovesical junction. Gross examination typically reveals a solitary, blue, red, gray, or brown multicystic mass that thickens the wall and sometimes projects into the bladder lumen; the lesions have ranged from several millimeters to 14 cm in diameter. The mucosa is usually intact, but occasionally may be ulcerated and bleeding, particularly during menses. Histologic examination reveals fibrosis and proliferation of the muscularis around the foci of endometriosis; the lamina propria was also involved in 60% of the cases in one study [223]. Obstruction of both ureteric orifices, vesicocolic fistula, and malignant transformation have been rare complications.

With rare exceptions, endometriosis of the ureter is confined to its lower one third, usually involving a segment less than 2 cm in length that lies 2-5 cm from the ureterovesical junction; involvement has been bilateral in approximately 10% of the cases [4, 223]. Six of seven cases in the study cited above involved the left ureter only [4]. Ureteral endometriosis has been traditionally divided into extrinsic and intrinsic forms, although this distinction has not been possible in many of the reported cases because the affected segment of ureter was not removed for microscopic examination. Also, it is likely that at least some intrinsic cases were initially of extrinsic type. In the latter, endometriosis of the uterosacral ligament or ureteral adventitia causes ureteral luminal narrowing by compression, fibrosis, or both; in some such cases, there is transmural scarring of the ureter. Intrinsic involvement is characterized by endometriotic tissue within a typically hyperplastic and fibrotic muscularis; in some cases, the lamina propria is also involved. Mucosal involvement rarely takes the form of a polypoid mass projecting into the lumen [223].

On gross examination, endometriosis of the kidney is typically a solitary, well-circumscribed, hemorrhagic, solid and cystic mass that focally replaces the renal parenchyma; the lesions in the ten reported cases have measured from 1.5 to 13 cm in diameter. In occasional cases, polypoid masses have projected into the renal pelvis. Foci of smooth muscle have been found admixed with the endometriotic tissue on microscopic examination in some of the cases.

Only rare cases of urethral endometriosis have been described [59]. In one, a caruncle-like nodule projected from the urethral orifice in a 38-year-old woman with dysuria. In others, a 24-year-old woman with dysuria and dyspareunia was found to have endometriosis in the wall of a large urethral diverticulum, and a 35-year-old woman with left lower abdominal pain had endometriosis involving a left mid-urethral diverticulum as well as a vaginal endometriotic cyst.

Cutaneous Endometriosis

The majority of the reported cases of cutaneous endometriosis have occurred within surgical scars [34, 100, 113, 153, 224], or rarely within needle tracts; the remainder are spontaneous. Both types are associated with pelvic endometriosis in only a minority of cases [34, 224].

Because scar-related endometriosis typically occurs after operations on the uterus or fallopian tubes, the site most commonly involved is the lower abdominal wall; the umbilicus is involved less commonly. Similarly, most cases of endometriosis of the lower vagina, vulva, Bartholin's gland, perineum, and perianal region involve areas of obstetric or surgical trauma, most commonly episiotomy scars [34, 85, 177, 224]. The overall frequency of post-Cesarean scar endometriosis was 0.08% in one recent study, and the authors hypothesized that an increased risk of incisional endometriomas may result from failure to close the parietal and visceral peritoneum with sutures [153]. Scar-related cases occur less commonly after nongynecologic procedures, such as an appendectomy or inguinal hernia repair [224]. Spontaneous cutaneous endometriosis typically involves the umbilicus [224] and, less commonly, the inguinal [224] and perianal regions.

The most common symptoms are those relating to a cutaneous mass or nodule that, in the scar-related cases, appears weeks to years following surgery [100, 224]; the average postoperative interval from the time of Cesarean section in the study cited above was 3.2 years [153]. A catamenial increase in size and tenderness, and occasionally bleeding from the lesion, suggest the diagnosis. Patients with perianal lesions may have involvement of the external sphincter producing anorectal pain and irritation simulating an anal fistula, abscess, or thrombosed hemorrhoid. Umbilical endometriosis may simulate an umbilical hernia on physical examination. The lesions occasionally recur following excision; the recurrence rate of 445 cases of abdominal wall endometriosis after surgical excision was 4.3% [100].

On clinical examination, the lesions are firm, solitary nodules, varying up to 6-12 cm in diameter, and pink to brown to blue-black depending on the age of the lesion and the depth within the skin. The cut surface of the scarrelated lesions is typically gray-white, with or without focal areas of recent or old hemorrhage [34]. On microscopic examination, the endometriosis may involve the dermis () Fig. 13.55), the subcutis, or both [224] and, in occasional cases, underlying skeletal muscle. Metaplastic glandular and stromal changes may be present, similar to those observed in endometriotic lesions elsewhere, most commonly tubal metaplasia, in addition to oxyphilic, hobnail, mucinous, and papillary syncytial metaplasia [113]. In one study, which evaluated 71 cases of cutaneous and superficial soft tissue endometriosis, smooth muscle metaplasia was found in one third of cases, and 25% of lesions showed reactive epithelial atypia [113]. There is typically no continuity between the cutaneous and

Fig. 13.55 Cutaneous endometriosis. Endometriotic foci are present within the dermis

peritoneal lesions in patients with associated pelvic endometriosis.

The association of abdominal scar-related endometriosis and episiotomy scar-related endometriosis with uterine operations and episiotomies, respectively, suggests implantation of endometrial tissue as the most likely pathogenesis. The risk of implantation appears to be much higher after hysterotomy than after cesarean section or vaginal delivery, suggesting that the decidua of late pregnancy has a reduced ability to implant. When curettage is performed immediately after vaginal term delivery, however, the frequency of endometriosis in the episiotomy scar becomes much higher [177]. In nonpregnant patients, implantation of endometrium during endometrial curettage or spontaneous implantation of menstrual endometrium has also been implicated in occasional cases of scar-related endometriosis. Lymphatics have been demonstrated between the pelvis and umbilicus that may explain cases of spontaneous endometriosis in the latter site.

Inguinal Endometriosis

Noncutaneous inguinal endometriosis, secondary to involvement of the extraperitoneal portion of the round ligament, occurs in less than 1% of patients with endometriosis [26]. The usual presentation is that of a painful, typically right-sided, hernia-like inguinal mass, with catamenial exacerbation in some cases. In approximately one third of the reported cases, an inguinal hernia may also be present. The lesion can impinge on the pubic tubercle and mimic arthritis, bursitis, or tendinitis. Rarely, endometriosis in the inguinal region has also been described in inguinal or femoral hernia sacs or the canal of Nuck [190].

Endometriosis of Lymph Nodes

Lymph node involvement by endometriosis is uncommon, and many examples reported as such, particularly in the older literature, are lymph nodes involved by benign müllerian (usually endosalpingiotic) glands devoid of an endometrial stromal component. The involved lymph nodes may be visibly or palpably enlarged at operation. On microscopic examination, in contrast to glandular inclusions, endometriotic foci are characterized by a more central location within the node, an endometrial stromal component, and the frequent presence of erythrocytes and pseudoxanthoma cells. Endosalpingiosis and endometriosis may coexist, however, in the same lymph node. As in other sites, decidual transformation of the endometriotic stroma has been encountered during pregnancy. As previously noted, one case of intranodal endomyometriosis has been reported.

Pleuropulmonary Endometriosis

Pathologically documented cases of endometriosis involving the lungs or pleura are rare. Some reported examples interpreted as pulmonary endometriosis have taken the form of microscopic foci of "decidua" found at autopsy in pregnant or recently pregnant women. Most such lesions would likely be interpreted by current criteria as foci of embolic intermediate trophoblast, although one case of bona fide deciduosis of the lung has been documented [77]. Many cases of purported pleuropulmonary endometriosis have been diagnosed solely on the basis of clinical manifestations or in conjunction with nonspecific histologic or cytologic findings. Coverage here is based on the 38 pathologically documented cases of thoracic endometriosis in the literature, 21 of which were pleural and 17 of which were parenchymal [77].

The affected patients are usually in the reproductive age group, although rare patients are postmenopausal. The clinical manifestations of pleural endometriosis usually differ from those associated with parenchymal involvement. In the former, the characteristic presentation is one of recurrent catamenial shortness of breath related to catamenial pneumothorax, typically right sided. Less common presentations include recurrent right-sided, typically hemorrhagic effusions, hemoptysis, or catamenial pain. Chest X-rays usually reveal a pneumothorax, or occasionally, a hemothorax, pleural effusion, or a pleural lesion. Coexistent intra-abdominal endometriosis has been demonstrated in approximately one third of cases, although in another one third of cases, its presence or absence was not confirmed. In contrast, patients with parenchymal endometriosis typically present with catamenial hemoptysis or blood-tinged cough; other patients are asymptomatic and the lesion is an incidental radiographic finding. Chest X-ray typically shows a nodule, infiltrates, or opacification of an entire lobe [77]. Only one patient has had documented peritoneal endometriosis, although in most patients the peritoneum has not been visualized. The majority of patients with parenchymal endometriosis have had prior uterine operations.

Pleural endometriosis is almost invariably confined to the right side; one case with bilateral involvement has been reported. The lesions are typically multiple, dark red or blue nodules or cysts on the diaphragmatic pleura; parietal, visceral, and pericardial pleural surfaces are also affected less commonly. Associated pathologic changes have included diaphragmatic fenestrations in 50% of the cases and occasionally pleural blebs. Parenchymal endometriotic lesions are typically solitary, tan to gray, focally hemorrhagic nodules or thin-walled cysts measuring up to 6 cm in diameter. Several lesions have been subpleural or have involved bronchial walls and lumina. Parenchymal lesions lack the almost exclusively rightsided location of pleural endometriosis; one case had a bilateral miliary distribution. In additional contrast to pleural lesions, associated diaphragmatic fenestrations have not been described.

The clinicopathologic differences between pleural endometriosis and parenchymal endometriosis of the lung suggest that they differ in their histogenesis. The distribution of the parenchymal lesions and their strong association with prior uterine trauma strongly suggest an embolic origin. In contrast, most if not all pleural lesions are likely a result of passage of endometriotic tissue from the peritoneal cavity through diaphragmatic defects or diaphragmatic lymphatics, consistent with the right-sided predominance of both structures. The catamenial pneumothorax in these patients, and in those with catamenial pneumothorax unassociated with pleural endometriosis, may be related to the diaphragmatic defects that allow passage of air from the peritoneal into the pleural cavity. The escape of air from defects in the visceral pleura produced by the endometriotic lesions or from preexistent blebs is another possible explanation for the pneumothorax in these patients. It has been suggested that prostaglandins produced by eutopic endometrium or endometriotic tissue at the time of the menses may predispose to alveolar rupture.

Soft Tissue and Skeletal Endometriosis

Rarely, typical endometriomas have occurred in skeletal muscle or deep soft tissues in distant sites. The presentation is usually that of a mass associated with catamenial pain, tenderness, and enlargement. The involved sites have included the trapezius, extensor carpi radialis, thumb, biceps femoris, thigh, and the knee. A unique endometrioma occurred in the breast of a patient with a 2-year history of catamenial bloody nipple discharge [154]. Rare pelvic endometriotic cysts have eroded lumbar vertebrae, causing catamenial lumbar pain.

Upper Abdominal Endometriosis

Endometriotic implants may occasionally occur on the omentum; omental endometriosis was only one eighth as common as omental endosalpingiosis in one study [259]. Rarely, endometriotic implants may involve the peritoneal surfaces of the liver or the diaphragm. As with pleural diaphragmatic involvement, implants on the peritoneal side of the diaphragm have occasionally been associated with diaphragmatic defects and catamenial pneumothorax. Rare endometriomas of the epigastrium, the tail of the pancreas, and the liver parenchyma have been reported.

Endometriosis of the Nervous System

Approximately 30 cases of endometriosis of the sciatic nerve sheath at the level of the sciatic notch have been described, typically associated with catamenial sciatica [183]. Some cases have been associated with a visible peritoneal evagination attached to the involved portion of the nerve ("pocket sign"). A case of subarachnoid endometriosis of the lumbar spinal cord caused catamenial radicular pain and recurrent subarachnoid hemorrhage [135]. In another case, a cerebral endometrioma was discovered in the parietal lobe of a patient who had a 3-year history of episodic headaches that culminated in a generalized seizure [234].

Endometriosis in Males

Rare examples of endometriosis have been described in men receiving long-term estrogen therapy for prostatic carcinoma. With the exception of one case involving the abdominal wall [138], the sites of involvement have been confined to the genitourinary tract, specifically the urinary bladder, prostate, and paratesticular region [257]. The two paratesticular lesions were endomyometriotic in composition.

Neoplasms Arising from Endometriosis

Recent studies evaluating consecutive cases of endometriosis found that a malignant tumor was associated with ovarian and pelvic endometriosis in 4% and 10% of cases, respectively [185]. However, exact frequencies of malignancy arising from pelvic endometriosis in the general population are not known, as some tumors likely overgrow and obliterate the endometriotic foci from which they arose [155]. Coexistence of endometriosis and a mullerian-type tumor is not definitive evidence that the tumor has arisen from the endometriosis, unless merging of the two lesions is histologically identified. In most cases, the term "endometriosis-associated" tumor is preferable.

For stage I epithelial ovarian cancers, up to 30% have associated ovarian endometriosis, with an even higher frequency for endometrioid and clear cell carcinomas. Studies to determine putative precursor lesions in such cases have shown that hyperplastic changes ("atypical endometriosis," discussed above), similar to those that arise in eutopic endometrium, may occur in endometriotic lesions. Such morphologic findings may be observed in the setting of endogenous or exogenous estrogenic stimuli or tamoxifen therapy (see) Fig. 13.42). Atypical ovarian endometriosis was found in approximately 60% of endometriosis-associated carcinomas, but in only 2% of cases of ovarian endometriosis not associated with carcinoma [83]. Some endometriotic lesions, including atypical endometriosis, and the synchronous carcinoma share similar molecular genetic alterations, including PTEN mutations, loss of heterozygosity

(LOH), and over-expression of p53 and c-erb-2 [185, 186, 203, 204, 207]. Recently, it has been shown that women with carcinomas arising in endometriosis tend to be younger (and premenopausal), obese, and have a history of unopposed estrogens, in comparison to women with uncomplicated endometriosis. Furthermore, endometriosis-associated tumors are more often lower grade and lower stage, and have a better prognosis than similar tumors without associated endometriosis [71]. Approximately 75% of tumors complicating endometriosis arise within the ovary. The most common extraovarian site is the rectovaginal septum; less frequent sites include the vagina, colon and rectum [249], urinary bladder, and other sites in the pelvis and abdomen. In some cases, there is a history of prolonged unopposed estrogen replacement therapy [249]. As previously noted, hyperplastic and metaplastic changes within endometriosis may precede or be found synchronously with the neoplasm. Tumors arising in endometriosis in unusual sites are more likely to be misdiagnosed than similar tumors arising in ovarian endometriosis, such as an endometrioid adenocarcinoma arising in colonic endometriosis being mistaken for a primary colonic adenocarcinoma (see below), an error that could result in inappropriate staging and treatment [249].

Endometrioid carcinoma (Fig. 13.56) is the most common tumor arising within ovarian endometriosis, accounting for almost 75% of such cases. Direct origin of endometrioid carcinoma from endometriotic tissue has been demonstrated in as many as 24% of cases in some

series [155]. At least 90% of the carcinomas arising from extraovarian endometriosis have been of endometrioid type [155]. Rarely, endometrioid tumors arising in ovarian and extraovarian endometriosis may exhibit a benign or borderline adenofibromatous pattern [249]. Endometrioid carcinoma is the most common tumor to arise in intestinal endometriosis; the majority of endometriosis-associated intestinal tumors occur in the rectosigmoid colon, with most of the remainder in the ileum and the cecum [39, 181, 219]. The following features are in favor of endometrioid adenocarcinoma over a primary colonic adenocarcinoma: Atypical gross features, the presence of endometriosis, an absence of mucosal involvement, lower grade nuclei than expected for colonic adenocarcinoma, squamous metaplasia, an absence of dirty necrosis, and a cytokeratin 7+/cytokeratin 20-/CDX2- immunoprofile [39, 114, 219]. Other tumors arising in intestinal endometriosis include endometrioid stromal sarcoma, mullerian adenosarcoma, carcinosarcoma, clear cell carcinoma, squamous cell carcinoma, and mixed germ cell tumor [39].

Clear cell carcinoma (♥ *Figs.* 13.57 and ♥ 13.58) is the second most common tumor originating in endometriosis, accounting for approximately 15% of such cases. In some studies, the frequency of endometriosis coexisting with clear cell carcinoma of the ovary is even higher than with endometrioid carcinoma; pelvic endometriosis has been reported in 24–49% of cases of ovarian clear cell carcinoma [200, 235]. A few examples of clear cell carcinoma arising within extraovarian endometriosis have also

Fig. 13.56
Endometrioid carcinoma arising within endometriosis.

Fig. 13.57 Clear cell carcinoma arising within an endometriotic cyst. Fleshy pale tumor nodules protrude into the cyst lumen

adenofibromas and borderline tumors of endocervical-

been described [2, 98]. A recent study, which utilized the polymerase chain reaction and loss of heterozygosity (LOH) analysis using laser-microdissected tumor tissue, has indicated that ovarian clear cell adenofibroma may be a clonal precursor for clear cell carcinoma, shown by high concordance rates of allelic patterns between clear cell carcinoma and benign and borderline clear cell adenofibromatous components, with 95% of cases showing an identical LOH pattern [248]. Patients with endometriosis-associated clear cell carcinomas of the ovary have also recently been found to have improved progression free and overall survival rates in comparison to those without endometriosis [171].

Ovarian and extraovarian epithelial tumors of other types arising from endometriosis include endometrioid

like and mixed cell type, as well as serous borderline tumors and squamous cell carcinomas [158, 200, 201, 249]. Endometrioid stromal sarcomas (ESSs), malignant mesodermal mixed tumors, and adenosarcomas (both typical and with sarcomatous overgrowth) (> Fig. 13.59) account for approximately 10% and 20% of tumors arising in ovarian and extraovarian endometriosis, respectively [41, 215, 249, 256]. Approximately one quarter of colonic endometriosis tumors arising in are adenosarcomas [219, 250]. In one study, 60% of ESSs apparently arising within the ovary were associated with ovarian endometriosis [256]. Rare examples of yolk sac tumor have arisen in association with endometriosis [202], and in one unique case, a sex cord tumor with annular tubules was intimately associated with endometriosis of the tubal serosa [90].

Peritoneal Endometrioid Lesions Other Than Endometriosis

Benign glands lined by endometrial epithelium (but lacking endometrial stroma) with the peritoneal distribution of endosalpingiosis occasionally occur [128]; some may represent foci of endometriosis in which the stromal component has undergone atrophy. Benign endometrioid peritoneal "implants" lacking an endometrial stromal

Mesodermal adenosarcoma arising in ovarian endometriosis. Low-grade sarcomatous stroma forms periglandular cuffs and intraglandular papillae

component have also been reported in association with a borderline ovarian endometrioid tumor [200]. The peritoneal lesions were interpreted as having arisen directly from the peritoneum.

A variety of extrauterine, extraovarian, pelvic, or retroperitoneal neoplasms of endometrioid type occur in the absence of demonstrable endometriosis. These tumors have generally been considered to arise directly from the mesothelium or submesothelial stroma, or possibly from foci of endometriosis that have been obliterated by the tumor. They have included endometrioid cystadenofibroma and cystadenocarcinoma, endometrioid stromal sarcoma, homologous and heterologous types of malignant mesodermal mixed tumor, and mesodermal adenosarcoma.

Peritoneal Serous Lesions

Serous lesions of the peritoneum include those that are nonneoplastic (endosalpingiosis) and neoplastic, which are morphologically analogous to their ovarian counterparts.

Endosalpingiosis

Clinical Findings

Endosalpingiosis typically refers to the presence of benign glands lined by tubal-type epithelium involving the peritoneum and subperitoneal tissues; the term may also be used to refer to similar glands within retroperitoneal lymph nodes (see **Senign** Intranodal Glands of Müllerian Type). This disorder occurs almost exclusively in females, typically during their reproductive years, with a mean age of 29.7 years in one study [259], although occasional cases have been described in postmenopausal women. Endosalpingiosis is almost always an incidental finding at either the time of operation or more commonly on microscopic examination. Zinsser and Wheeler found endosalpingiosis in 12.5% of surgically removed omenta in a retrospective study, but this figure doubled when omenta were examined more thoroughly in a prospective study [259]. Endosalpingiosis may be detected as multiple fine pelvic calcifications on X-ray examination or as psammoma bodies within cul-de-sac fluid, peritoneal washings [216], the lumen of the fallopian tube, or cervical Papanicolaou smears [116].

An origin from the secondary müllerian system is favored by most investigators, but the association of endosalpingiosis with chronic salpingitis implicates implantation of sloughed tubal epithelium as a possible histogenetic mechanism in some cases [259]. A similar association with serous tumors of borderline malignancy suggests that some endosalpingiotic foci may represent tumor implants that have undergone maturation [141]. Endosalpingiosis in the absence of residual tumor at the time of second-look laparotomy in patients with ovarian epithelial neoplasms does not justify additional treatment [55].

Pathologic Findings

Endosalpingiosis is most commonly encountered on the pelvic peritoneum covering the uterus, fallopian tubes, ovaries, and cul-de-sac [259]. Less frequent sites include the pelvic parietal peritoneum, omentum [259], bladder and bowel serosa, paraaortic area, and skin, including laparotomy scars. Endosalpingiosis is usually inapparent at the time of operation or on gross inspection of the involved tissues but may be visible as multiple, punctate (1–2 mm), white to yellow, opaque or translucent, fluid-filled cysts, which impart a vesicular or granular appearance to the involved surface; rarely larger cysts may be seen [45]. Rare examples of cystic endosalpingiosis have involved the wall of the uterus, resulting in grossly apparent transmural cysts [45].

Microscopic examination reveals multiple, simple glands, often cystically dilated and lined by a single layer of epithelium resembling that of the normal fallopian tube (\bigcirc *Figs.* 13.60 and \bigcirc 13.61). The glands are frequently surrounded by a loose or dense connective tissue stroma that may contain a sparse mononuclear inflammatory cell infiltrate. The glands may exhibit irregular contours, crowding, and intraluminal stromal papillae. The three

Fig. 13.60

Endosalpingiosis. Complex glandular structure lies beneath uterine serosa. Glands are lined by a single layer of benign endosalpingeal epithelium

Fig. 13.61 Endosalpingiosis. Glands within the omentum are lined by benign endosalpingeal epithelium

cell types of the normal fallopian tube epithelium are found in varying numbers: pale ciliated cells, secretory cells, and dark rodlike, intercalated or "peg" cells. The cells have prominent luminal margins, distinct borders, and basal nuclei. Focal cellular pseudostratification may be present. The nuclei have fine chromatin and delicate nuclear membranes and typically lack significant atypia or mitotic activity. Psammoma bodies are frequently present within the lumens or in the adjacent stroma, and, in occasional cases, numerous psammoma bodies are embedded in subserosal connective tissue. Endosalpingiotic glands can rarely extend into the underlying tissues, such as the wall of the appendix or, as noted earlier, the uterus [45]. Staining with the PAS method reveals a basement membrane surrounding each gland and PAS-positive, diastase-resistant material in the apices of the lining cells and within the glandular lumens. Estrogen and progesterone receptors have been identified immunohistochemically within the cells.

The term atypical endosalpingiosis has been applied to endosalpingiotic lesions in which there is cellular stratification, including cellular buds, cribriform patterns, and varying degrees of cellular atypia, occurring in the absence of a serous tumor of borderline malignancy. Such lesions merge histologically with peritoneal serous tumors of borderline malignancy (see next section). Bell and Scully use the latter term if the "lesions composed of tubal-type epithelium exhibit papillarity, tufting, or detachment of cell clusters ... even when they arise on a background of endosalpingiosis." [16] Endosalpingiotic glands should be differentiated from mesonephric remnants, which are common incidental microscopic findings in the region of the fallopian tube. Mesonephric tubules are typically located more deeply than endosalpingiosis and characteristically have a collar of smooth muscle under the epithelial lining, which is typically a single layer of nonciliated, low columnar to cuboidal cells. Rare extraovarian borderline and malignant serous tumors have been shown to arise from endosalpingiosis [28, 144].

Peritoneal Serous Tumors

The full spectrum of serous neoplasms arising within the ovary may also arise directly from the extraovarian peritoneum. These tumors are considered only briefly here because their clinicopathologic features closely resemble those of their ovarian counterparts. Primary peritoneal serous borderline tumors are usually associated with widespread extraovarian peritoneal involvement and normalsized ovaries that are free of disease or which have serosal involvement similar to that involving the extraovarian peritoneum [16, 19]. The most common presenting features in patients with these tumors, who are typically under the age of 35 years (range, 16-67), are infertility and chronic pelvic or abdominal pain. Many cases, however, are discovered incidentally at laparotomy for other conditions. At operation, focal or diffuse miliary granules, fibrous adhesions, or both involve the pelvic peritoneum and omentum and, less commonly, the abdominal peritoneum. Microscopic examination reveals superficial tumor that resembles noninvasive epithelial or desmoplastic implants of borderline serous tumors of ovarian origin. Coexistent endosalpingiosis has been found in 85% of cases. The prognosis of peritoneal serous borderline tumors is favorable; approximately 85% of patients have had no clinically persistent or progressive disease on follow-up. In rare cases, transformation to an invasive low-grade peritoneal serous carcinoma (LGPSC) may occur, although in a proportion of these, the invasive tumor may have been present but not sampled at the time of the initial operation.

Although most primary peritoneal serous carcinomas are high grade (see following paragraph), some have lowgrade nuclear features and are distinguished from peritoneal serous borderline tumors by the presence of invasion. Low-grade peritoneal serous carcinomas (LGPSCs) resemble invasive implants of serous borderline tumors (\triangleright *Fig. 13.62*) [243]. Some may have a micropapillary pattern [68]. They lack high-grade nuclear atypia, invade tissue or lymphovascular spaces or both, and have appreciable solid epithelial proliferation. Peritoneal psammocarcinomas [87, 141, 243] are a subtype of Diseases of the Peritoneum

Fig. 13.62

Low-grade primary papillary serous carcinoma of the peritoneum. (a) The tumor is infiltrating the omental fat.(b) The papillae are lined by tumor cells resembling serous borderline neoplasia. Note the psammoma bodies

LGPSCs with psammoma bodies in most of the tumor nests and absent or rare solid epithelial proliferation (see Chap. 14, Surface Epithelial Tumors of the Ovary); lymphatic invasion is often conspicuous. The average ages of patients in one study were 57 years (LGPSC of usual type) and 40 years (peritoneal psammocarcinomas) [243]. Features present in both tumors are usually abdominal pain, mass, or both, but approximately 40% are incidental findings. Operative and gross findings vary from nodules to adhesions to a dominant mass. Short-term outcomes for LGPSCs and peritoneal psammocarcinomas are favorable, but follow-up is too limited in the reported cases to determine long-term outcomes. These tumors should be distinguished from peritoneal serous borderline tumors, which are very similar except for an absence of invasion. Adequate sampling is necessary to identify invasion, with highest yields of invasive foci in the omentum.

Typical peritoneal serous carcinomas have high-grade nuclear features and have been referred to as serous surface papillary carcinomas, serous papillary carcinomas of the peritoneum, or extraovarian peritoneal serous papillary carcinoma [5, 17, 69, 236]. The typical intraoperative appearance of a primary peritoneal serous carcinoma, with widespread peritoneal tumor associated with ovaries of normal size, may mimic that of a diffuse malignant mesothelioma or peritoneal carcinomatosis associated with an unknown primary tumor. The ovaries are often involved by small surface "implants" but retain their normal size and shape. In some series, the patients have had an average age that is a decade older than patients with similar tumors of ovarian origin. Some tumors have occurred in women who had had bilateral oophorectomy performed as prophylactic treatment for BRCA-related familial ovarian cancer [30], suggesting that some peritoneal serous carcinomas may be a phenotypic variant of familial ovarian cancer [112]. The risk of peritoneal serous carcinoma in BRCA1 mutation carriers is about 4% at 20 years after prophylactic salpingo-oophorectomy [30, 76].

Primary peritoneal serous carcinomas resemble their ovarian counterparts on microscopic and immunohistochemical examination; their distinction from malignant mesothelioma has been previously discussed. Criteria for their separation from primary ovarian serous carcinomas with peritoneal spread have been proposed by the Gynecologic Oncology Group: (1) both ovaries are either normal in size or enlarged by a benign process; (2) in the judgment of the surgeon and the pathologist, the bulk of the tumor is in the peritoneum and the extent of tumor involvement at one or more extraovarian sites is greater than on the surface of either ovary; (3) microscopic examination of the ovaries reveals no tumor, tumor confined to the surface epithelium with no evidence of cortical invasion, tumor involving the ovarian surface and the underlying cortical stroma but less than 5 mm in area, or tumor less than 5 mm in diameter within the ovarian substance, with or without surface involvement; and (4) the histologic and cytologic characteristics of the tumor are predominantly serous and similar or identical to those of ovarian serous papillary adenocarcinomas of any grade. In most series, these tumors have a prognosis similar to that of high-stage ovarian serous carcinomas with a similar volume of residual tumor and similar postoperative treatment [106].

The differential diagnosis includes metastatic serous carcinoma from an occult primary tubal or endometrial

serous carcinoma (see O Chap. 11, Diseases of the Fallopian Tube and Paratubal Region, and O Chap. 9, Endometrial Carcinoma). Peritoneal serous carcinomas, like their ovarian and tubal counterparts but unlike endometrial serous carcinomas, are typically immunoreactive for WT1 [72]. If serous carcinoma involves the tubes or endometrium as well as the peritoneum, it may not be possible, short of clonality studies, to determine if they are independent primaries or if one is metastatic from the other.

Rare extraovarian serous tumors take the form of localized, typically cystic masses, usually within the broad ligament and less commonly within the retroperitoneum. Serous papillary cystadenomas and adenofibromas, serous borderline tumors, and serous carcinomas have been described in these sites [7, 8, 237].

Endocervicosis (including Mullerianosis)

Benign glands of endocervical type involving the peritoneum, so-called endocervicosis, are rare, but examples involving the posterior uterine serosa, cul-de-sac, vaginal apex, outer wall of the uterine cervix, and the urinary bladder have been documented [43, 128, 139, 160, 253]. In the last site, the lesions usually formed tumor-like masses that involved the posterior wall or posterior dome of the bladder in women of reproductive age. On microscopic examination, benign endocervical-type glands were located predominantly within the smooth muscle of the muscularis propria (**>** *Fig.* 13.63) [43, 160]. In several cases, the infiltrative pattern of the glands, mild epithelial atypia, and a reactive periglandular stroma, alone or in combination, resulted in an initial misdiagnosis of well-differentiated adenocarcinoma. In such cases, the absence of a mucosal-based tumor and no more than mild atypia facilitate the diagnosis of endocervicosis, The differential diagnosis also includes mullerianosis, a term applied to lesions composed of an admixture of mullerian glandular epithelia (tubal, endocervical, and endometrioid), sometimes with foci of endometriotic stroma. Examples of mullerianosis have been reported in the urinary bladder, mesosalpinx, and inguinal lymph nodes [133, 252].

Extraovarian Mucinous Tumors

Ovarian-type mucinous neoplasms, in the absence of a primary tumor within the ovary, have been described in extraovarian sites, typically in the retroperitoneum (\bigcirc *Fig.* 13.64) [64, 128, 129, 178]; a single case has been

Fig. 13.63

Endocervicosis of urinary bladder. (a) Benign endocervicaltype glands lie within the muscularis propria. (b) Highpower view of glands with cytologically bland, endocervical-type mucinous epithelium

described in the inguinal region [228]. These tumors form large cystic masses that on histologic examination resemble ovarian mucinous cystadenomas, borderline tumors, or cystadenocarcinomas (> Fig. 13.65); some tumors contain ovarian-type stroma in their walls. Mural nodules, usually consisting of anaplastic carcinoma, similar to those in ovarian mucinous tumors, have been present in several cases [151]. Although it is possible that some of these tumors originate within a supernumerary ovary, the great rarity of the latter, the absence of follicles or their derivatives within the ovarian-like stroma, and the rare occurrence of similar tumors in males strongly support a peritoneal origin. It has been recently suggested that, in some cases of pseudomyxoma peritonei associated with ovarian and appendiceal mucinous tumors, the peritoneal lesions may arise directly from the peritoneum as part of a multifocal neoplastic process [150, 213].

Peritoneal Transitional, Squamous, and Clear Cell Lesions

Nests of transitional (urothelial) epithelium referred to as Walthard nests are commonly present on the pelvic peritoneum in women of all ages, typically involving the serosal surfaces of the fallopian tubes (**>** *Figs. 13.66* and **>** *13.67*), mesosalpinx, and mesovarium [22]. Walthard nests are uncommon on the ovarian surface but may be seen in the hilus, probably originating from the peritoneum of the mesovarium; they are most common on the tubal serosa (see **>** Chap. 11, Diseases of the Fallopian

Fig. 13.67

Walthard nests on fallopian tube serosa. A nest (far left) and multiple cysts are formed or lined by benign transitionaltype cells

Tube and Paratubal Region). Rare extraovarian Brenner tumors have been encountered, most commonly in the broad ligament. In contrast to Walthard nests, squamous metaplasia of the peritoneum is rare; it is usually an incidental microscopic finding but in one case it resulted in tiny, but grossly visible, nodules [156]. Two clear cell carcinomas of apparent peritoneal origin have been reported. One was a localized mass within the sigmoid mesocolon [73] whereas the other diffusely involved the peritoneum [130]; no endometriosis was identified in either case.

Peritoneal Decidual Reaction

Clinical and Operative Findings

An ectopic decidual reaction similar to that seen in the lamina propria of the fallopian tube, cervix, and vagina may also be seen within the submesothelial stroma of the peritoneal cavity. Frequent sites of ectopic decidua include the submesothelial stroma of the fallopian tubes, uterus and uterine ligaments, appendix and omentum, and within pelvic adhesions. Rare sites have included the serosal surfaces of the diaphragm, liver, spleen, and the renal pelvis.

Submesothelial decidua is typically an incidental microscopic finding, but florid lesions may be visible at the time of cesarean section or postpartum tubal ligation as multiple, gray to white, focally hemorrhagic nodules or plaques studding the peritoneal surfaces and simulating a malignant tumor. Several cases have been associated with massive, occasionally fatal, intraperitoneal hemorrhage during the third trimester, labor, or the puerperium. Other rare clinical presentations include abdominal pain, which may simulate that of appendicitis, and hydronephrosis and hematuria secondary to renal pelvic involvement.

Microscopic Findings

Microscopic examination discloses submesothelial decidual cells disposed individually or arranged in nodules or plaques (**>** *Fig. 13.68*). Smooth muscle cells, probably

■ Fig. 13.68 Ectopic decidua beneath pelvic peritoneum. Note the prominent cytoplasmic vacuoles

derived from submesothelial myofibroblasts, may be admixed. The decidual foci are typically vascular and contain a sprinkling of lymphocytes. Focal hemorrhagic necrosis and varying degrees of nuclear pleomorphism and hyperchromasia of the decidual cells may suggest a tumor such as a deciduoid malignant mesothelioma [214], but their bland appearance and mitotic inactivity militate against such a diagnosis. We have seen several cases of an omental decidual reaction in which most of the decidual cells exhibited striking vacuolization with basophilic mucin and an eccentric location of the nucleus. The appearance of the cells raised the possibility of metastatic signet-ring cell carcinoma, but in contrast to the cells of the latter, the vacuoles within the decidual cells contain acid rather than neutral mucin, and their cytoplasm lacks immunoreactivity for cytokeratin.

Diffuse Peritoneal Leiomyomatosis

Diffuse peritoneal leiomyomatosis is a rare disorder characterized by the presence of multiple submesothelial nodules of cytologically benign smooth muscle, frequently associated with uterine leiomyomas and, rarely, ovarian leiomyomas. The nodules are generally considered to arise from multipotential submesothelial mesenchymal cells. This disorder is discussed elsewhere (see **O** Chap. 10, Mesenchymal Tumors of the Uterus).

Benign Intranodal Glands of Müllerian Type

Clinical Features

Benign glands of müllerian type are most commonly encountered within the pelvic and paraaortic lymph nodes of females [99, 120], and less often in inguinal and femoral lymph nodes. Because these glands are almost always incidental microscopic findings in lymph nodes removed in cases of pelvic carcinoma, their reported frequency, which has varied from 2% to 41%, depends on the number of lymph nodes removed and the extent of the histologic sampling. Almost all the patients have been adults, although rare examples have been reported in children. In males, the presence of similar glands has been recorded rarely within lymph nodes in the pelvis, abdomen, and mediastinum. Although typically without clinical or intraoperative manifestations, rare examples of lymph nodes containing müllerian-type glands have been associated with a false-positive lymphangiogram, ureteral obstruction secondary to lymph node enlargement, or visible enlargement at the time of operation.

670

In a number of patients, intranodal glandular inclusions have been accompanied by endosalpingiosis of the peritoneum, salpingitis isthmica nodosa, or acute and chronic salpingitis [120]. Other patients have had coexistent ovarian serous tumors, which have been benign, borderline tumors, or carcinomas [184].

Pathologic Findings

On gross examination, the glands are usually not apparent, although rarely they are recognizable as cysts measuring up to a few millimeters in diameter. The glands are typically located in the periphery of the node, most commonly within its capsule or between the lymphoid follicles in the superficial cortex (\bigcirc *Fig.* 13.69); rarely, they lie free within the subcapsular sinuses [120]. In florid cases, they can be diffusely distributed throughout the lymph node. Intraglandular or periglandular psammoma bodies are commonly present. Intranodal glands may be surrounded by a thin rim of fibrous tissue or abut directly on the surrounding lymphoid cells.

The glands may be round and cystically dilated or exhibit an irregular contour as a result of infolding. They are most commonly lined by a single layer of cuboidal to columnar tubal-type epithelium, with an admixture of ciliated, secretory, and intercalated cell types (\bigcirc *Fig.* 13.70). With special stains, mucin can be demonstrated in the apical portion of the secretory cells and within the gland spaces. The cells have a benign appearance with regular, basally oriented or pseudostratified, oval to round nuclei, fine nuclear chromatin, and

occasional small nucleoli; mitotic figures are typically absent. In rare cases, the cells can exhibit varying degrees of atypia and stratification; the latter can produce an intraglandular cribriform pattern or luminal obliteration by sheets of cells (**>** *Fig. 13.71*). These cases of atypical endosalpingiosis may rarely be the origin of intranodal serous neoplasms (see following).

Examples of intranodal glandular inclusions lined by benign endometrioid epithelium, mucinous epithelium of endocervical or goblet cell type, or metaplastic squamous epithelium have been reported [128, 152].

Fig. 13.70

Endosalpingiotic glands within pelvic lymph node. The glands are lined by benign cells of multiple types, including ciliated cells

Fig. 13.69

Endosalpingiotic glands within pelvic lymph node. The glands are located within and immediately beneath the node capsule as well as deeper within the node

• Fig. 13.71 Atypical endosalpingiotic glands within pelvic lymph node. Some of the glands exhibit luminal obliteration by cells growing in solid and cribriform patterns

Differential Diagnosis

In most cases the distinction between glandular inclusions and metastatic adenocarcinoma is not difficult unless a primary ovarian serous tumor of low malignant potential is present, in which case the distinction may be difficult or impossible. Features favoring a benign diagnosis include a capsular or interfollicular location of the glands, lining cells of multiple types including ciliated forms, a lack of significant cellular atypia and mitotic activity, and an absence of a desmoplastic stromal reaction. Complicating the differential diagnosis is the very rare development of borderline or frankly malignant change in müllerian glandular inclusions in lymph nodes. This diagnosis is suggested in cases in which the intranodal neoplasm merges with foci of atypical endosalpingiosis. Intranodal nests of benign squamous epithelium should not be mistaken for metastatic squamous cell carcinoma. Features favoring a benign diagnosis include bland cytologic features, mitotic inactivity, and, in some cases, an origin within benign glands.

Intranodal Ectopic Decidua

Ectopic decidua unassociated with endometriosis has been described as a rare, incidental microscopic finding in paraaortic and pelvic lymph nodes, usually removed as part of a radical hysterectomy for carcinoma of the cervix in pregnant patients [6, 152, 246]. A subserosal ectopic decidual reaction may be present elsewhere in the pelvis. In some cases, the decidual tissue has been recognized on careful macroscopic examination as tiny, gray, subcapsular nodules. On microscopic examination, the decidual nests typically occupy the subcapsular sinus and superficial cortex () Fig. 13.72), although more central parts of the lymph node may also be involved. The cells appear benign, but may contain occasional bizarre, hyperchromatic nuclei, mimicking metastatic squamous cell carcinoma. The absence of mitotic activity, keratinization, and stromal desmoplasia facilitate the diagnosis. Metastatic squamous cell carcinoma, however, may be present in the same node.

Intranodal Leiomyomatosis

Rare cases of lymph node involvement by mitotically inactive, cytologically benign smooth muscle have been described (**>** *Fig.* 13.73) [57, 103]. Most patients have had concurrent typical uterine leiomyomas or, less commonly, diffuse peritoneal leiomyomatosis [103] or similar

Fig. 13.72

Ectopic decidua within pelvic lymph node. The nodal architecture is focally replaced by sheets of decidualized cells

Fig. 13.73 Benign smooth muscle within pelvic lymph node

nodules within the lungs [57]. In pregnant patients, the process may merge with intranodal decidua [103]. The finding in most cases likely is secondary to lymphatic spread from uterine leiomyomas ("benign metastasizing leiomyoma"; see **2** Chap. 10, Mesenchymal Tumors of the Uterus), but in some cases the intranodal smooth muscle may arise from entrapped subcoelomic mesenchyme or myofibroblastic organization of intranodal decidua. The presence of benign-appearing smooth muscle in a lymph node should also bring into consideration the diagnosis of lymphangioleiomyomatosis. This disorder is usually, but not invariably, associated with pulmonary involvement. Benign intranodal smooth muscle should also be distinguished from metastatic

well-differentiated leiomyosarcoma of uterine origin. Patients with the latter usually have a large uterine mass, and on histologic examination the intranodal tumor is cellular and exhibits evidence of cellular atypicality and mitotic activity.

Epidemiology

Geographic Distribution, Incidence and Mortality

Worldwide, ovarian cancer is the sixth most common cancer in women and the seventh most common cause of cancer death. There are about 204,000 new cases and 125,000 deaths annually [29]. In most Western countries, ovarian carcinoma is the fifth most common malignancy and ranks fourth in cancer mortality. In the Western hemisphere, it accounts for 4% of cancer in women and is the most frequent cause of death due to gynecological cancer. In US women, ovarian cancer ranks ninth in incidence and fifth in mortality, and accounts for 3% of cancers diagnosed and 5% of cancer deaths. It is estimated that in the United States in 2010, there were 21,880 new ovarian cancer cases and 13,850 deaths [137]. Approximately 1.4% of American women will develop ovarian cancer in their lifetime. In general, the disease is more common in industrialized countries where parity is lower, but there are notable exceptions such as Japan which has a low parity and low rate of ovarian cancer. The incidence varies widely among different ethnic groups. The lifetime risk varies widely from 0.45% in Japan to 1.7% in Sweden. Annual incidence rates of ovarian cancer range from less than 5 per 100,000 women in The Gambia, Brazil, Thailand, Algeria, and India, to greater than 13 per 100,000 in the United Kingdom, United States, Germany, and Scandinavia. In the United States, based on SEER (Surveillance, Epidemiology, and End Results (US National Cancer Institute)) data, the rate is 13.5 per 100,000 (2000-2004) [340]. Scandinavia has one of the highest annual incidence rates at greater than 16 per 100,000 women [337]. There has been little change in incidence over the past few decades with a few exceptions: in Korea, the age-standardized incidence increased by 25% from 3.8 to 4.7 per 100,000 from 1993 to 2002 [57], and over the same period, the incidence in Israel decreased by nearly one third from 9.6 to 6.6 per 100,000 [217]. The extent to which changes in diagnostic criteria or calculation methods may account for these changes is unclear. However, in the United States, changing the age-adjustment to the 2000 standard has artificially increased the incidence of ovarian cancer by about 20% [9]. In addition, the incidence of ovarian carcinoma appears to have decreased as peritoneal and tubal carcinomas have increased [110]. This may reflect a recent increase in the awareness of peritoneal and particularly tubal carcinomas among pathologists. Accordingly, relatively small changes in the incidence of ovarian carcinoma are probably due to these

factors. Migration studies have shown that ovarian cancer rates approach those of the place of immigration rather than the place of emigration, suggesting a significant environmental component to ovarian cancer risk.

Ovarian cancer rates vary among different ethnic groups. White women have higher rates than blacks and Asians; in the United States, African-American women have a rate two thirds that of white women, and Asians have a 48% lower death rate than whites [340]. In Israel, Jewish women have a risk eightfold that of non-Jewish women as 1 of 40 Jewish women have a *BRCA1* mutation [184].

Epidemiologic studies of ovarian cancer rely on accurate tumor classification. It has become apparent that a large proportion of mucinous carcinomas involving the ovaries are actually metastatic from elsewhere. The specific association of smoking with ovarian mucinous carcinoma is interesting, since some smoking-associated extraovarian mucinous carcinomas such as pancreatic cancer can mimic primary ovarian mucinous tumors when they metastasize to the ovary. This suggests that misclassification of ovarian mucinous tumors has had an effect on epidemiological studies (see **)** Mucinous Tumors, later in this chapter).

The large volume of literature on atypical proliferative (borderline) tumors belies their low prevalence. Large institutions such as Stanford University [190] and Washington Hospital Center encounter only about three atypical proliferative serous tumors (APSTs) per year in-house. Two general hospitals in Barcelona had fewer than 5 per year combined [262]. Population-based incidence data on borderline tumors are scant; in the United States, the annual incidence is 2.5 per 100,000 (1.5 per 100,000 for serous tumors in white women) [222] and in Sweden, 6.6 per 100,000 (all borderline tumors) [111].

Etiology and Risk Factors

Age

Ovarian cancer rates increase with age. In the United States, the annual incidence steadily increases from less than 3 per 100,000 in women age less than 30, and plateaus at 54 per 100,000 in the 75–79-year age group. In the United States, the median age of women with ovarian cancer is about 63 years at diagnosis, and the median age at death 71 years [340]. In the 40–59-year and 60–79-year age groups, ovarian cancer ranks fourth and fifth, respectively, in cancer deaths in US women [136]. The mean age varies substantially among subgroups, a reflection of differences in hereditary syndromes and differences in the pathogenesis of different types of ovarian carcinoma

Table 14.1

Mean age in subgroups of ovarian cancer (years)

Lynch syndrome II-associated carcinoma	40
Well-differentiated (micropapillary) serous	43–45
carcinoma	
Endometrioid carcinoma arising in endometriosis	50
BRCA1-associated carcinoma	53
FIGO stage I carcinoma	53
Clear cell carcinoma	50–53
Endometrioid carcinoma	55–58
BRCA2-associated carcinoma	59
FIGO stage III high-grade serous carcinoma	59–64
Carcinosarcoma (malignant mixed müllerian tumor (MMMT))	64–66

(**)** *Table 14.1*) (See **)** Morphologic and Molecular Pathogenesis, later in this chapter).

Many studies have shown that age is an independent prognostic factor [106, 377], but these data are difficult to evaluate as there are multiple interacting factors involved. To some extent, age-related prognostic differences are largely explained by higher proportions of low-grade, low-stage, optimally debulked, and Type I tumors (see • Morphologic and Molecular Pathogenesis, later in this chapter) in younger patients, who are also generally healthier than older patients, who are more likely to have a lower performance status, more comorbid conditions, and have a lower likelihood of responding to chemotherapy [8, 350]. Older women are also treated less aggressively than younger women; in the SEER database, over 40% of American women older than 85 years did not receive definitive treatment.

The risk of death in the presence of comorbid conditions is 30–40% higher than those without such conditions [8]. A population-based study in Maryland showed that women aged more than 50 years are more than twice as likely as younger women to die within 30 days after surgery (mortality rates of 2.6% and 1.2%, respectively; p = 0.010) [348]. Accordingly, younger women with invasive ovarian cancer on average do have a more favorable stage distribution and other prognostically favorable features and thus a better prognosis, even when stratified by stage.

Reproductive Factors

Evidence suggests that reproductive factors are important in ovarian cancer risk. Established protective factors include increasing parity and oral contraceptive use [62]. Early menarche and late menopause are significant risk factors. Pregnancies appear to be more strongly protective for endometrioid and clear cell carcinoma as compared to serous carcinoma [166]. High socioeconomic status is associated with an increased ovarian cancer risk and lower fertility. Several recent meta-analyses of hormone replacement therapy and ovarian cancer risk have shown a slightly but significantly elevated risk with odds ratios of 1.1-1.3 [397]. The protective effect of increased parity and oral contraceptive use applies only to non-mucinous tumors. However, as noted earlier, data on mucinous carcinomas of the ovary prior to the mid- to late-1990s are unreliable because a large proportion of apparent primary ovarian mucinous carcinomas have now been recognized to be metastatic (see **>** Mucinous Tumors, later in this chapter, and **O** Chap. 18, Metastatic Tumors of the Ovary).

Surgically induced protective factors include hysterectomy, tubal ligation, and bilateral salpingo-oophorectomy. The mechanism for risk reduction with hysterectomy and tubal ligation is unclear, although both can prevent passage of endometrial tissue via retrograde menstruation, which is one of the proposed mechanisms for the development of endometriosis, and endometriosis is a precursor of some ovarian cancers [345] (See) Endometrioid Carcinoma Arising in Endometriosis, later in this chapter). This mechanism is further supported by the finding that the frequency of clear cell carcinoma is inversely related to tubal ligation to a stronger degree than other cell types, and clear cell carcinoma, among all types of ovarian carcinomas, has the highest association with endometriosis [166, 255, 256]. In addition, hysterectomy and tubal ligation prevent the introduction of a variety of potential environmental carcinogens from entering the peritoneal cavity and thereby coming into contact with tubal and ovarian tissue.

Ovulation and Hormonal Factors

The most commonly cited hormonal mechanism for the etiology of ovarian cancer is the incessant ovulation hypothesis. It was hypothesized that ovulation repeatedly traumatizes the ovarian surface epithelium and thus stimulates proliferation, creating a milieu that predisposes the actively proliferating epithelium to malignant transformation. This hypothesis is supported by epidemiologic observations of a direct correlation between the number of ovulations, i.e., the length of the reproductive years uninterrupted by pregnancies or oral contraceptive use, and the risk of ovarian cancer. Most of these studies report a 50% reduction of ovarian cancer in women who have been on oral contraceptives. Moreover, the longer the duration of usage, the greater is the protective effect. The gonadotropin hypothesis, which is less favored than the incessant ovulation hypothesis, proposes that high levels of circulating gonadotropins increase the risk of ovarian cancer either directly by altering estrogen levels or via mechanisms that cause primary ovarian failure. Another hypothesis proposes that androgen levels are important. At present, no clear-cut hormonal explanation for ovarian carcinogenesis is known.

Inflammation

It has been suggested that inflammation, potentially incited by ovulation-induced surface damage [233], by retrograde menstruation-induced salpingitis [287], or by the introduction of foreign material through the vagina and uterine cavity, plays an important role in ovarian carcinogenesis. Evidence of a proinflammatory microenvironment in endometriosis supports this hypothesis for Type I tumors [95]. High-grade serous carcinomas are associated with chronic salpingitis in 53% of cases, significantly more often than 23% seen with non-serous tumors, lending circumstantial support to this hypothesis [309].

Other Risk Factors

Other potential risk factors have been studied, but associations with ovarian cancer risk are weak or inconclusive. These include body mass index, age at birth of first child, breastfeeding, weight, diet, talc, smoking, certain types of viral infections in childhood, and ionizing radiation. A study of 49,000 women showed a reduction in ovarian cancer risk in postmenopausal women on a low-fat diet, with a hazard ratio of 0.6 [264].

Morphologic and Molecular Pathogenesis

Ovarian carcinogenesis can be divided into two broad phases: malignant transformation and peritoneal dissemination. Until recently, some investigators believed that benign, "borderline," and malignant ovarian tumors reflect sequential steps in malignant transformation, regardless of their type of differentiation (i.e., serous, mucinous, endometrioid, or clear cell). Accordingly, many studies in the cell and molecular biology literature juxtaposed these entities in an attempt to elucidate the events in ovarian carcinogenesis, and often considered the different histological types of ovarian tumors essentially interchangeable. Further, the traditional view of peritoneal dissemination was that carcinoma begins in the ovary, undergoes progressive dedifferentiation from a well to a poorly differentiated tumor, and then spreads through the peritoneal cavity before metastasizing to distant sites. These time-honored views now do not appear to be valid for the majority of ovarian cancers as described below.

A New Model of Ovarian Cancer Pathogenesis

Advances in molecular biology correlated with morphologic studies aimed at investigating the relationship of borderline tumors to invasive carcinoma have shed new light on the pathogenesis of ovarian carcinoma and have challenged many of the time-honored concepts of ovarian neoplasia. These studies have led to the proposal of a new model of carcinogenesis, which has important clinical implications. In addition, recent studies have provided evidence that what has traditionally been regarded as the origin of ovarian carcinoma, namely the surface epithelium, may rather be the fallopian tube in many cases. Accordingly, the view that ovarian cancer begins in the ovary and spreads systematically to the pelvis, abdomen, and then distant sites is being challenged and the concept that ovarian carcinoma, over time, progresses from well to poorly differentiated does not appear to be valid. This section will summarize these new developments in our understanding of ovarian carcinogenesis and are discussed in greater detail in the individual sections on the different cell types later in the chapter.

Mounting clinicopathologic and molecular genetic data have led to the proposal of a new model of ovarian carcinogenesis that reconciles the differing relationships of borderline and malignant tumors that exist among the different cell types of ovarian cancer. This model divides surface epithelial tumors into two broad categories: Type I and Type II, based on their clinicopathologic features and characteristic molecular genetic changes [56, 167, 168, 170]. Type I and Type II refer to tumorigenic pathways and are not histopathologic diagnostic terms (> Fig. 14.1 and **7** Table 14.2). This classification system will undoubtedly continue to evolve, particularly as the molecular changes that characterize the less common types of ovarian carcinomas and the distinction between morphologically overlapping categories (e.g., high-grade serous versus high-grade endometrioid) become more clearly defined.

Fig. 14.1a

Schematic of proposed origin of high-grade serous carcinoma. (a) STIC cells from fimbrial epithelium and occasionally cells from ovarian surface epithelial inclusions via cystadenomas and atypical proliferative serous tumors (APST) can develop into high-grade serous carcinoma (b) STIC cells implanting on ovarian surface

Table 14.2

Type 1 versus type 2 ovarian carcinoma: precursors and molecular features

	Common precursors	Most frequent mutations	Chromosomal instability ^a					
Type I tumors	Type I tumors							
Low-grade serous CA	APST, noninvasive MPSC	KRAS, BRAF	Low					
Low-grade endometrioid CA	Endometriosis	CTNNB1, PTEN	Low					
Clear cell CA ^b	Endometriosis	РІКЗСА	Low					
Mucinous CA	APMT	KRAS	Low					
Type II tumors								
High-grade serous CA	U ^c	TP53	High					
High-grade endometrioid CA	U	TP53	High					
Undifferentiated CA	U	U	U					
Carcinosarcoma	U	TP53	U					

^aLow versus high chromosomal instability refers to comparison between low-grade and high-grade carcinomas within the same histologic type. ^bCriteria for classification of clear cell carcinoma into type I versus type II subsets are uncertain (see text).

^cSome high-grade carcinomas may be associated with tubal intraepithelial serous carcinomas.

APMT, atypical proliferative mucinous tumor; APST, atypical proliferative serous tumor; CA, carcinoma; MPSC, micropapillary serous carcinoma; U, unknown.

Modified with permission of the author [56].

Type I tumors are low grade, relatively indolent neoplasms that arise from well-characterized precursor lesions (atypical proliferative (borderline) tumors and endometriosis), and usually present as large stage I neoplasms. This group includes low-grade serous (invasive micropapillary serous carcinoma (MPSC)), low-grade endometrioid, mucinous, and tentatively clear cell carcinomas. Clear cell carcinoma, although it exhibits most of the features of the Type I tumors such as association with a well-established precursor (endometriosis) and frequent presentation in stage I, is typically high grade unlike the other Type I tumors. Nonetheless, preliminary molecular genetic data show a greater similarity of clear cell carcinoma to Type I as compared to Type II tumors.

Type I tumors often harbor somatic mutations of genes encoding protein kinases including *KRAS*, *BRAF*, *PIK3CA*, and *ERBB2*, as well as other signaling molecules including *PTEN* and *CTNNB1* (β -catenin). The atypical proliferative or borderline serous and mucinous tumors in turn appear to develop from cystadenomas, while the atypical proliferative endometrioid and clear cell tumors arise from endometriosis, typically endometriotic cysts (endometriomas) (**)** *Fig. 14.1b*).

In contrast, Type II tumors, of which the vast majority are high-grade serous carcinomas, are aggressive, highgrade neoplasms from the outset; in the past, they have been said to arise "de novo." Recent data, however, suggest that high-grade serous carcinomas arise from intraepithelial carcinomas, the majority of which have been detected in the tubal fimbriae (see \textcircled Chap. 11, Diseases of the Fallopian Tube and Paratubal Region). At this time it is not clear as to what proportion of high-grade serous carcinomas arise from the tube. More than 75% of Type II carcinomas have *TP53* mutations. Interestingly, the few examples of stage I high-grade serous carcinomas that have been studied have been shown to harbor

G Fig. 14.1b

Schematic of the proposed origin of type I tumors.

Retrograde menstruation leads to the development of endometriosis and atypical proliferative tumors which can give rise to endometrioid and clear cell carcinomas mutations of *TP53* [183]. Therefore, it appears that conventional high-grade serous carcinoma even in its earliest stage of development resembles advanced-stage serous carcinoma at both the morphologic and molecular level. Of further interest has been the detection of *TP53* mutations in tubal intraepithelial carcinomas, and in a recently described putative precursor lesion of tubal intraepithelial carcinoma designated "p53 signature." This lesion appears morphologically normal but overexpresses p53, and can harbor a p53 mutation. These findings highlight the importance of p53 mutation in the early development of high-grade serous carcinoma [149]. These findings have important clinical implications (see **O** Screening and Prevention).

The anatomical progression of ovarian carcinoma is poorly understood. It is generally assumed that carcinoma originates in the ovary, is confined to the ovary for a period of time, and then disseminates to the pelvis, followed by the abdominal cavity before spreading to distant sites. This view underlies the basis of the International Federation of Gynecology and Obstetrics (FIGO) staging system in which tumors confined to the ovary are stage I, those involving the pelvic organs stage II, with involvement of abdominal organs stage III, and when spread occurs to distant sites stage IV (> Table 14.3). There are, however, significant problems with this assumption. Clinicopathologic comparison of stage I with stage III carcinomas shows that stage I tumors are predominantly Type I and non-serous, while stage III tumors are predominantly Type II and most often high-grade serous; furthermore, stage I tumors tend to be significantly larger, an observation that would suggest that ovarian carcinomas get smaller with progression [389].

It is important to recognize that Type II ovarian carcinomas account for the vast majority of ovarian cancer deaths. Most Type II tumors are high-grade serous carcinomas, and, at the time of diagnosis, most are widely disseminated throughout the peritoneum (FIGO stage III and IV), with the largest volume of tumor outside the ovaries. Serous carcinoma and its variants (peritoneal serous carcinoma, carcinosarcoma, undifferentiated carcinoma, and mixed carcinomas with a high-grade serous component) account for 87% of cases of carcinomatosis from ovarian carcinoma and accordingly the vast majority of ovarian cancer deaths [107, 114, 301] (Table 14.4). These data that analyze stage distribution by histologic type suggest that early and advanced stage tumors are fundamentally different diseases, and provide further support for the dualistic model [154, 168, 389].

Like other cancers, ovarian carcinomas arise through a multistep process in which clonal selection acts on

Table 14.3

Carcinoma of the ovary: International Federation of Gynecology and Obstetrics (FIGO) nomenclature (Rio de Janeiro 1988)

Stage I	Growth limited to the ovaries
la	Growth limited to one ovary; no ascites present containing malignant cells. No tumor on the external surface; capsule intact
lb	Growth limited to both ovaries; no ascites present containing malignant cells. No tumor on the external surfaces; capsules intact
lc ^a	Tumor either stage la or lb, but with tumor on surface of one or both ovaries, or with capsule ruptured, or with ascites present containing malignant cells, or with positive peritoneal washings
Stage II	Growth involving one or both ovaries with pelvic extension
lla	Extension and/or metastases to the uterus and/or tubes
llb	Extension to other pelvic tissues
llc ^a	Tumor either stage IIa or IIb, but with tumor on surface of one or both ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings
Stage III	Tumor involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases equals stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum
llla	Tumor grossly limited to the true pelvis, with negative nodes, but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces, or histologic-proven extension to small bowel or mesentery
lllb	Tumor of one or both ovaries with histologically confirmed implants, peritoneal metastasis of abdominal peritoneal surfaces, none exceeding 2 cm in diameter; nodes are negative
lllc	Peritoneal metastasis beyond the pelvis; 2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to allot a case to stage IV; parenchymal liver metastasis equals stage IV

^aTo evaluate the impact on prognosis of the different criteria for allotting cases to stage Ic or IIc; it would be of value to know if rupture of the capsule was spontaneous, or caused by the surgeon; and if the source of malignant cells detected was peritoneal washings, or ascites. From Heintz et al.

cells with somatic mutations and altered gene expression to allow outgrowth of progeny with increasingly aggressive growth properties. The genes mutated in cancer are not selected randomly, but frequently encode proteins that function in highly conserved signaling pathways. Over the past several years, a number of studies have evaluated ovarian epithelial tumors for molecular genetic alterations such as point mutations, gene amplifications, deletions, and translocations. The molecular biology and genetics of ovarian cancer have been recently reviewed [56]. Although a detailed cataloguing of the genetic alterations identified to date in ovarian epithelial tumors is beyond the scope of this chapter, some useful themes have emerged. First, while few if any changes appear to be unique to ovarian cancer, studies have shown that certain alterations appear to be particularly characteristic of specific histological types of ovarian carcinomas. Second, for carcinomas with serous or endometrioid differentiation, specific genetic alterations distinguish low-grade from high-grade carcinomas. Third, identification of shared genetic alterations in some histological types of ovarian carcinomas and their putative precursor lesions has provided useful insights into the pathogenetic pathways leading to ovarian cancer. Details of the molecular biology of the different cell types of ovarian carcinoma are reviewed in their respective sections later in this chapter.

Putative Histopathologic Precursor Lesions

The study of precursors of ovarian carcinoma is difficult because the ovaries are not readily accessible for screening, and ovarian carcinomas typically present in advanced stage, obliterating or rendering unrecognizable any precursor lesion that may have been present. Furthermore, identification of a putative precursor lesion is based on microscopic examination of a complete resection, and therefore the natural history of the lesion cannot be observed. Studies on ovaries removed prophylactically

^aOnly 41 (68%) of stage I tumors were comprehensively staged, including 5 high-grade serous carcinomas.

^bThere were two stage I malignant Brenner tumors. We classify transitional cell carcinomas (TCCs) as serous carcinoma; the remaining seven cases are included under the serous category.

^cFour stage III carcinosarcomas were primary peritoneal tumors.

Percentages under 10% are rounded to the nearest 0.5%. Sum of percentages is not 100% due to rounding.

^dSerous, low grade are invasive carcinomas.

from high-risk women, and normal-appearing ovaries contralateral to stage I carcinomas, have generated conflicting data [312].

Surface Epithelial Dysplasia

Investigators have studied ovarian surface epithelium in the vicinity of carcinomas in an attempt to define the putative entity of "ovarian dysplasia," and have reported atypical cellular and nuclear features that appear more frequently in ovarian surface epithelium near or contralateral to carcinomas in comparison to control ovaries. Much of these data derive from one group of investigators and have not been independently validated [308]. Some investigators have reported that, although not identifiable by light microscopy, subtle nuclear changes identified by image analysis are detectable in the surface epithelium of ovaries prophylactically removed from high-risk women in comparison to controls. In contrast, another group of investigators examined high-risk ovaries under oil immersion and found only subtle atypical features that were not significantly more common in cases than controls [308].

Surface Epithelial Inclusions

The superficial ovarian cortex often contains simple glands and cysts lined by a single layer of flat or nondescript cuboidal epithelium, which often undergoes metaplasia to tubal-type epithelium. These are termed surface epithelial or cortical (formerly "germinal") inclusions, and they are more common in older women (see also Ochap. 12, Non-neoplastic Lesions of the Ovary). Their origin is unknown. Historically they have been considered to arise after post-ovulatory repair of the damaged ovarian surface; however the evidence for this is weak [121]. It has been stated that they arise when invaginations or clefts of the ovarian cortex lined by surface epithelium lose their connection to the surface. However, this circumstantial observation may be based on confusion of tangentially sectioned clefts with inclusions [312]. Conceivably, the origin of inclusions could be the fimbrial epithelium, which is in close apposition with the ovarian surface epithelium [168, 258] (> Fig. 14.1c). Ovarian surface adhesions may also play a role.

Some studies on prophylactic oophorectomy specimens in high-risk women and normal-appearing ovaries contralateral to stage I carcinomas have shown a higher number of these cortical inclusions in comparison to controls, but others have not confirmed these findings. These studies have also evaluated a variety of other features including cortical invaginations (clefts) and surface papillomatosis, and some have found the latter two to be more common in cancer-prone ovaries than in controls, but these findings have not been confirmed by other investigators [258, 312]. Many of these studies have significant drawbacks and are not strictly comparable to one another. For example, the method of quantitation of cortical inclusions and clefts is variable [312].

Endometriosis

Although the precursors of ovarian carcinoma are for the most part unknown, endometriosis is the best documented and most easily recognized precursor. This is because carcinomas arising in endometriosis are Type I tumors, which grow slowly; therefore there is a greater window of opportunity for discovery prior to obliteration of the precursor lesion by the carcinoma. Endometriosis is common and found in 10% of reproductive-age women, but the risk of malignant transformation in an individual patient is very low. Nonetheless, endometriosis is associated with up to about 20% of ovarian cancers and is acknowledged to be the precursor of many endometrioid and clear cell carcinomas and an occasional mucinous carcinoma [392]. Serous carcinomas may be found coincidentally in women with endometriosis, but do not appear to be histogenetically related.

The plausibility of endometriosis as an ovarian cancer precursor is supported by our understanding of endometrial cancer precursors. Atypical endometrial hyperplasia in the uterus is a well-defined precursor of endometrial adenocarcinoma (see O Chap. 8, Precancerous Lesions of the Endometrium), and changes similar to this lesion are occasionally observed in endometriosis. In addition, atypical changes are also seen in endometriosis in the vicinity of endometrioid adenocarcinomas of the ovary, and even more frequently in association with clear cell carcinoma. On occasion, the full morphologic spectrum from

Fig. 14.1c

Schematic of proposed mechanism for the origin of ovarian surface epithelial inclusions from fimbrial epithelium. Epithelial cells from fimbria implant on site of rupture on the ovary where ovulation occurred. These epithelial cells can conceivably invaginate to form a cortical inclusion cyst

endometriosis with hyperplasia to atypical hyperplasia and well-differentiated endometrioid adenocarcinoma can be observed. The risk of neoplastic transformation appears to be low [298]. Further support for the premalignant potential of endometriosis comes from molecular biologic studies that have demonstrated molecular alterations, including LOH in the PTEN gene and microsatellite instability [6, 374], as well as chromosomal aberrations including trisomies and monosomies [159], all indicative of a neoplastic process [351]. Therefore, a significant proportion of endometriotic lesions have the potential to undergo additional genetic changes and malignant transformation. Parenthetically, if ovarian endometriotic cysts were classified as benign epithelial neoplasms, which some certainly are, this would radically change the distribution of ovarian surface epithelial tumors. More specifically, in our series (> Table 14.5), endometriomas would be at least as common as serous cystadenoma and therefore would be the most common benign ovarian neoplasm. Alternatively, since endometriosis is probably of endometrial origin, it can be argued that tumors arising in endometriosis are ultimately not of ovarian origin.

It has been estimated that carcinoma develops in 0.3–3% of cases of endometriosis [6, 336] but this is very

likely an overestimate since a large number of cases of endometriosis never come to biopsy. The true figure is probably closer to 0.3% or lower. Ovarian endometriosis appears to be significantly more likely to undergo malignant transformation than extraovarian endometriosis [336]. As noted earlier, the relative proportion of endometrioid and clear cell carcinomas that are associated with endometriosis is much higher than that for the other cell types.

Further evidence that endometriosis is a precursor of ovarian carcinoma is provided by large studies from Sweden and Japan. In a Swedish study of over 20,000 women hospitalized with endometriosis, after a mean follow-up of 11.4 years, the risk of ovarian cancer in comparison to the control population was 1.9. Patients with a long-standing history of endometriosis (10 years or longer) had a relative risk of 4.2 [308]. In a study in Japan of 6,398 women with endometriosis, the standardized incidence ratio was 9.0 after 17 years of follow-up, with a risk of 13.2 in women diagnosed after age 50 [152]. In the latter study, the mean age at diagnosis of ovarian carcinoma was 51, a reflection of the significantly younger age of women with endometriosis-associated cancers (see > Table 14.1 and "Endometrioid adenocarcinoma associated with endometriosis," later in this chapter).

	Benign (%)	Atypical proliferative (%) ^a	Malignant (%) ^b	Total (%)

Distribution of 1,000 ovarian epithelial tumors by cell type. Washington Hospital Center, 1999–2008

^aAlso referred to as "borderline" tumors, and includes those with intraepithelial carcinoma and/or microinvasion.

^bIncludes peritoneal primaries.

^dIncludes 0.2% proliferative endometrioid tumors.

^eIncludes 0.6% with focal atypia.

fIncludes metaplastic Brenner tumors.

⁹0.5% serous-endometrioid and 0.1% mucinous-endometrioid.

^cIncludes 1.7% with focal atypia.

Benign and Atypical Proliferative Neoplasms

Although the natural history of benign ovarian tumors cannot be observed since they must be completely removed for accurate diagnosis, the observation of morphologically benign areas within carcinomas, and recent molecular data, strongly suggest that borderline tumors are precursors of low-grade serous, endometrioid and mucinous carcinomas (Type I tumors in the dualistic model). The evidence supporting these conclusions is discussed in their respective sections.

Serous Tubal Intraepithelial Carcinoma (STIC) and p53 Signature

It has recently been proposed that the origin of some serous carcinomas is the tubal fimbriae [168, 287]. The fimbriae normally extend over, and are in close contact with, the ovarian surface. As noted earlier, the origin of surface epithelial inclusions is unknown. Reported associations of chronic salpingitis with both ovarian serous tumors and tubal carcinomas [71, 309] suggest the possibility of incorporation of fimbrial epithelium into the ovarian cortex via adhesions or a role of salpingitis in tubal carcinogenesis [258, 287].

The typical fallopian tube carcinoma is a high-grade serous carcinoma and, until recently, was felt to be characterized by a dilated tubal lumen containing grossly obvious tumor. However, a fimbrial carcinoma might not lead to a dilated tubal lumen and could be misinterpreted as ovarian in origin. Epithelial atypia, carcinoma in situ, and small high-grade serous tubal carcinomas have been found in prophylactic specimens from women with BRCA mutations (> Table 14.6). In addition, it is frequently impossible to completely separate the ovary and tube for evaluation in serous carcinoma. All of these observations suggest the possibility that some apparent ovarian cancers are in fact tubal in origin [59, 168, 258, 287]. Carcinoma involving the tubal mucosa is generally regarded as secondary when there is also tumor in the ovary, peritoneum, and/or endometrium [191, 287]; however this is an assumption. Many of the dominant tumorous adnexal masses appear to be paraovarian and/or extensively involve the fallopian tube in a manner consistent with peritoneal or tubal origin. Sometimes the fallopian tube cannot be identified, perhaps in some cases because a large cystic carcinoma is actually an unrecognizable tube filled with carcinoma. The identification of TP53 mutations in TICs as well as in high-grade serous carcinomas provide further support for the tubal origin of many high-grade serous carcinomas (see ● Chap. 11, Diseases of the Fallopian Tube and Paratubal Region).

Meticulous examination of risk-reducing salpingooophorectomy (RRSO) specimens has disclosed occult invasive carcinomas in 3% of cases: 53% ovarian, 39% tubal, and 8% peritoneal (> Table 14.6), and it has been suggested that some apparent primary peritoneal carcinomas after RRSO reflect undetected microscopic ovarian carcinomas [44]. It has also been suggested that some apparent peritoneal carcinomas in women who have undergone oophorectomy but not salpingectomy may reflect metastases from primary tubal carcinomas [88]. Foci of tubal carcinoma in situ and atypical hyperplasia have been reported in RRSO specimens, and the tubal fimbria seems to be a preferred site [42, 43, 149, 212, 287] (See O Chap. 11, Diseases of the Fallopian Tube and Paratubal Region). The reported frequency of occult invasive carcinomas in prophylactic specimens varies widely; 0-12% among 16 series including 1,750 patients (Table 14.6). This wide range could reflect differing thresholds for the diagnosis of tubal carcinoma, particularly carcinoma in situ. In addition, there are several potential sources of bias in these types of studies [151].

In light of the above findings, the search for precursors of Type II ovarian carcinomas has shifted to the fimbriae of the fallopian tubes, where serous tubal intraepithelial carcinomas (STICs) have been identified in association with a high proportion of high-grade serous carcinomas. STICs contain TP53 mutations and are cytologically malignant, but are confined to the tubal epithelium. More recently it has been found that that there are short stretches of morphologically normal tubal epithelium that are immunohistochemically positive for p53, and that have a Ki-67 proliferation index higher than normal tubal epithelium but lower than STICs. A minimum of 12 tubal secretory epithelial cells that are p53 positive has been proposed as a definition for a "p53 signature," which is a candidate for a STIC precursor. p53 signatures have been associated with STICs as well as apparent ovarian serous carcinoma, but are also found in the general population. TP53 mutations have been found in a majority of p53 signatures. These findings have led to the proposal that the p53 signature is the long-sought precursor of a subset of ovarian high-grade serous carcinomas. Much of these data derive from one group of investigators and await confirmation in larger series and by other investigators. Nonetheless, this is an attractive hypothesis that fits much of the data that have hitherto been difficult to reconcile regarding the origin of ovarian cancer. A more comprehensive discussion can be found in O Chap. 11, Diseases of the Fallopian Tube and Paratubal Region.

Some incidental carcinomas that are reported to have involved both ovary and tube were assigned as primary ovarian unless a clear histologic description permitted assignment as a tubal primary or a clear gross description described a dominant tubal mass. Some incidental ovarian surface carcinomas could reflect a peritoneal primary.

The importance of the fimbriae in carcinogenesis is highlighted by a recent study which describes the junction of the peritoneum with the fimbrial epithelium (tubalperitoneal junction (TPJ)) [314]. Since junctions between different types of epithelium are known to be hot spots for carcinogenesis (e.g., the gastroesophageal and anorectal junctions), the presence of the TPJ in and around the fimbriae suggests that this junction is in fact the source of serous carcinomas. That study also found transitional metaplasia to be common and perhaps normal at the TPJ. In light of the above findings, it can be argued that since serous carcinomas are usually of fimbrial origin, endometrioid and clear cell carcinomas are ultimately of endometrial origin, and Brenner and mucinous tumors may also arise in the fimbriae via transitional metaplasia [168], it may be the case that no "ovarian surface epithelial tumors" are of ovarian origin. This would make gonadal stromal and germ cell tumors the only true ovarian (gonadal) tumors, just as in the testis, and is consistent with the fact that men do not have fallopian tubes to give rise to these epithelial tumors.

Familial (Hereditary) Ovarian Cancer

BRCA and Other Genes

At least 10% of ovarian carcinomas arise in the setting of highly penetrant, autosomal dominant genetic predisposition. Hereditary ovarian cancer has been recently reviewed [263, 284]. Three major types of genetic predisposition to ovarian cancer have been identified, including site-specific ovarian cancer, hereditary breast/ovarian cancer, and hereditary non-polyposis colorectal cancer (HNPCC, Lynch syndrome II). Notably, the increased frequency of ovarian cancer in relatives of women with ovarian cancer is not paralleled by an increase among relatives of women with "borderline" or mucinous ovarian tumors.

Site-specific ovarian cancer is recognized in families in which two or more first- or first- and second-degree relatives have ovarian carcinoma. The lifetime risk of ovarian carcinoma is approximately threefold higher in these families than in the general population. This type of hereditary predisposition is currently considered an "ovarian-specific" variant of hereditary breast/ovarian cancer, as no susceptibility gene other than *BRCA1* and *BRCA2* has been identified.

Hereditary breast and ovarian cancer is associated with germline mutations of either BRCA1 or BRCA2. The risk of developing ovarian carcinoma by age 70 years for BRCA1 and BRCA2 carriers is estimated as 40% and 18%, respectively [53]. The BRCA1 and BRCA2 genes map to chromosome 17q and 13q, respectively, and encode proteins that play important roles in DNA repair, cell cycle checkpoint control, protein ubiquitinization, and chromatin remodeling [284]. Germline mutations of these genes include small deletions, insertions, point mutations, and gene rearrangements that typically lead to prematurely truncated protein products. Mutations are widely distributed throughout both genes. Given the genes' large size and the absence of mutational "hotspots," mutation screening based on traditional sequencing approaches is cumbersome and has been largely supplanted by new automated technologies allowing rapid mutation detection. Studies suggest the site of the mutation within these genes may correlate with risk for ovarian cancer. For example, mutations between nucleotides 2,401 and 4,190 in BRCA1 increase the risk of ovarian cancer, but reduce the risk of breast cancer [268]. Mutations involving nucleotides 4,075-6,503 of BRCA2 exon 11 are also associated with increased risk of ovarian cancer, and hence, this region has been referred to as the "ovarian cancer cluster region" [100]. Mutations of BRCA1 and BRCA2 are uncommon in sporadic cases of ovarian carcinomas, but these genes are functionally inactivated in a substantial fraction of cases through allelic deletions and/or silencing due to promoter hypermethylation.

Increased risk for developing ovarian cancer has also been observed in patients affected by HNPCC, and this accounts for about 2% of ovarian cancers [195]. This autosomal dominant syndrome is associated with elevated risk of colon carcinoma without polyposis, endometrial carcinoma, and less frequently, carcinomas of other organs, including the ovary. HNPCC is caused by mutations in genes that encode proteins involved in DNA mismatch repair. Over 70% of individuals with HNPCC harbor germline mutations of *hMSH2* or *hMLH1*, with mutations of *hPMS1*, *hPMS2*, and *hMSH6* being less common. Studies of ovarian carcinomas arising in the setting of HNPCC are rather limited, but in one retrospective series of 80 affected patients including 31 known and 35 presumptive mutation carriers, ovarian cancers were found to arise at an earlier age than sporadic cases and tended to be well or moderately differentiated and relatively low stage (FIGO stage I or II) at diagnosis [373].

Clinicopathologic Features of Familial Ovarian Cancers

Ovarian cancer in women with familial ovarian cancer occurs at a younger age than sporadic ovarian cancer. For BRCA1-associated ovarian cancer, the age at diagnosis is about 53 years, and for Lynch syndrome II, 40 years (Table 14.1). In the largest series with centralized pathology review [375], cancers in BRCA carriers were compared to those in noncarriers. Among 220 women, mutation-associated tumors were of significantly higher grade and stage as compared to non-mutation-associated tumors. No mucinous and no borderline tumors were found in the mutation-associated group. Primary peritoneal carcinoma occurred rarely in both groups. Nearly all mutation-associated tumors appear to be high-grade high-stage serous carcinomas, slightly but significantly different from the distribution in the general population [317]. Despite the unfavorable stage and grade distribution, the prognosis for germline BRCA-mutationassociated familial cases appears to be somewhat better than for sporadic cases. In sporadic ovarian cancer, absent or reduced BRCA1 protein expression is more common in high-stage, high-grade serous carcinomas as compared to low-stage and non-serous carcinomas [352].

Mouse Models of Ovarian Cancer and Implications for Treatment

Genetically engineered mouse (GEM) models of each major subtype of ovarian cancer will undoubtedly prove useful for improving knowledge of ovarian cancer biology and for preclinical testing of signal transduction inhibitors as novel therapeutics. Historically, most animal models of ovarian cancer were based on xenografting human ovarian cancer cells into immunodeficient mice. Such models have limitations, including incomplete recapitulation of tumor–host interactions and inability to replicate early stages of tumor development. Recently described GEM

models of ovarian cancer appear to overcome some weaknesses of the xenograft models as tumors arise orthotopically in immunologically intact animals and more closely mimic the behavior of human ovarian cancers. One approach involves ex vivo genetic modification of primary murine ovarian surface epithelium (MOSE) [249]. In this model, MOSE cells were removed from p53^{-/-} transgenic mice expressing the cell surface avian retroviral receptor (ARR) under the control of the keratin-5 promoter and cultured in vitro for several generations. The cultured MOSE were infected, via the ARR, with replication-competent avian leucosis-derived vectors carrying oncogenes, such as c-MYC, KRAS, or AKT. MOSE cells expressing various combinations of oncogenes were then surgically transplanted under the ovarian bursa of recipient mice. The addition of any two of the oncogenes was sufficient to induce tumor formation when infected cells were injected at subcutaneous, intraperitoneal, or ovarian sites. In another model, a promoter element from the murine Müllerian Inhibitory Substance II Receptor (MISIIR) gene was used to drive expression of SV40 T-Ag (large and small) in MOSE [64]. In this model, approximately 50% of female mice develop bilateral poorly differentiated ovarian carcinomas. Flesken-Nikitin and colleagues used an alternative approach to conditionally inactivate the p53 and Rb tumor suppressors in the mouse ovarian surface epithelium [89]. A single ovarian intrabursal injection of recombinant adenovirus-expressing Cre recombinase (AdCre) in female mice homozygous for conditional (floxed) p53 and Rb alleles led to development of ovarian carcinomas. Mice from all three models develop poorly differentiated papillary carcinomas of the ovary with greatest resemblance to human serous carcinomas. The tumors disseminate intraperitoneally and are frequently accompanied by bloody ascites.

Given the morphological and molecular heterogeneity of ovarian carcinomas described above, a goal for researchers in the field is the development of mouse models that recapitulate each major histological type of ovarian cancer. Toward that end, Dinulescu and colleagues used ovarian bursal injection of AdCre to coordinately activate an oncogenic *KRas* allele and inactivate *Pten* in the MOSE [75]. Although ovarian carcinomas resembling endometrioid adenocarcinomas developed, as described above, *KRAS* mutations in human ovarian endometrioid carcinomas are rather uncommon, and data supporting cooperation between mutant *KRAS* and *PTEN* loss in human tumors are lacking [383]. In light of the data identifying frequent co-occurrence of canonical Wnt and PI3K/Pten/Akt signaling defects in the human tumors, Wu and colleagues employed ovarian bursal injection of AdCre to conditionally inactivate the *Pten* and *Apc* tumor suppressor genes in the ovarian surface epithelium of *Apc*^{flox/flox}; *Pten*^{flox/flox} mice [383]. The injected ovaries uniformly and rapidly developed tumors with similar morphology to human ovarian endometrioid cancers. In addition, the mouse tumors exhibited biological behavior and gene expression patterns similar to their human tumor counterparts with comparable signaling pathway defects. It is expected that mouse models of ovarian cancer will yield new insights into ovarian cancer pathogenesis, particularly with respect to putative precursor lesions and mechanisms by which tumors develop and progress.

Implications for Treatment

Mouse models that faithfully recapitulate their human tumor counterparts may prove especially useful for preclinical testing of novel therapeutics that target specific molecular defects in the tumor cells. Animal models such as this are expected to accelerate the translation of promising new therapies from the laboratory to the clinic. The readily recognizable aberrations of specific signaling pathways in many Type I tumors including low-grade serous carcinomas, low-grade endometrioid carcinomas, and mucinous carcinomas suggest that inhibitors targeting specific components of these pathways may be effective for treating patients with advanced-stage disease that is refractory to current chemotherapy. For example, MEK inhibitors such as CI-1040 and Quercetin from red wine extract deserve consideration as therapeutic agents for patients with lowgrade serous carcinomas [175]. This notion is supported by studies of Pohl et al., who demonstrated that treatment of ovarian serous carcinoma cells harboring KRAS or BRAF mutations with a MEK inhibitor, CI-1040, resulted in significant growth inhibition in vitro as compared to tumor cells with wild-type KRAS and BRAF [259]. Since low-grade serous carcinoma and its presumptive precursor, APST, have a high frequency of mutations in KRAS and BRAF, future clinical trials should help to determine if MEK inhibitors can prolong disease-free interval and overall survival in patients with advanced-stage lowgrade serous carcinomas. Similarly, the observation that growth of murine ovarian carcinomas with PI3K/Pten signaling pathway defects is profoundly inhibited by drugs that target this pathway provides further support for testing such agents in women with disseminated lowgrade (Type I) endometrioid carcinomas.

Finally, the high level of genetic instability that characterizes the majority of ovarian epithelial cancers (i.e., Type II tumors) presents a tremendous challenge with respect to the development of effective screening programs and therapeutic strategies that target the particular molecular defects present in a given patient's tumor. The lack of shared aberrations of cellular signaling pathways (except those mediated by p53) in high-grade serous and endometrioid carcinomas makes it difficult to design target-based therapies for these tumors at present. Clearly, a major goal of ongoing work in the field is to identify additional "hallmark" genetic alterations that characterize the Type II tumors. As our understanding of the molecular pathogenesis of each major type of ovarian carcinoma improves, the design of "personalized" therapeutic regimens based on the particular alterations present in a given patient's tumor may become a reality. It is reasonable to hope that drugs targeting specific molecular defects in tumor cells could be used alone or in combination with existing treatment modalities to substantially improve the clinical outcome for women with ovarian cancer.

Screening and Prevention

Screening Tests

An understanding of the new model of ovarian cancer pathogenesis has important implications for ovarian cancer screening. A presumptive goal of screening should be to detect high-grade serous carcinoma in stage I. Since high-grade serous carcinomas, which account for the vast majority of ovarian cancer deaths, are usually relatively small at their site of origin even when they are widely disseminated, both vaginal ultrasound and serum CA125 lack sufficient sensitivity and specificity to effectively detect them at a curable stage, if one even exists. Screening trials have generally identified stage I non-serous tumors, borderline tumors, nonepithelial tumors, and advancedstage serous carcinomas, with the identification of stage I high-grade serous carcinoma an exceedingly rare event, even in series focusing on high-risk women [214, 359]. In a compilation of some recent series, among over 338,000 women screened, there were only 242 invasive cancers detected, the majority of which were already in advanced stage (> Table 14.7). Over 3,100 women had to be screened to detect each low-stage carcinoma. Furthermore, advanced-stage serous carcinomas have been detected during intervals after a normal screen in several large studies [219], providing further evidence that the time course of

^bSome series grouped stage II with stage I as "low stage."

Atypical proliferative (borderline), germ cell, and stromal tumors are excluded. All invasive carcinomas, including those of tubal or peritoneal origin, are included.

progression of typical ovarian cancer is not amenable to effective screening by transvaginal sonography.

The fact that many ovarian cancer patients in retrospect have had symptoms, sometimes chronic, prior to diagnosis, has led to efforts to develop a symptom index for early diagnosis [10]. Unfortunately, this is unlikely to be effective because the early symptoms of ovarian cancer are too nonspecific and very common. Moreover, the relatively low prevalence of ovarian cancer in the general population makes the development of an effective screen test extremely challenging [127].

In contrast to Type II tumors, only about 20% of ovarian carcinomas are Type I tumors. These appear to grow slowly from benign cystadenomas, atypical proliferative tumors, and endometriomas, which become quite large before undergoing malignant transformation. As a result, most patients with these tumors are diagnosed with large pelvic masses on pelvic examination without the need of ultrasound before the neoplasms have undergone malignant transformation or peritoneal dissemination. This sequence of events with delayed transformation and dissemination accounts for the high proportion of FIGO stage I, low-grade cases among Type I carcinomas (mucinous and endometrioid) as compared to high-grade serous carcinomas.

Prevention

Few data are available regarding prevention of ovarian cancer. In the Nurse's Health Study of over 80,000 women, there was a modest inverse association between caffeine intake and ovarian cancer risk in women not using hormones, while alcohol and smoking had no effect, with the exception of smoking, which increased the risk of mucinous carcinoma [358]. A large review found that smoking doubles the risk of mucinous carcinoma [141]; however, data on mucinous tumors prior to the mid- to late-1990s are unreliable because it is now recognized that most mucinous carcinomas involving the ovary are metastatic (see **)** Epidemiology, earlier in this chapter, and **)** Mucinous Tumors, later in this chapter).

RRSO is often performed in patients at high risk of ovarian cancer. Unfortunately, the reduction in risk is not complete and appears to be only about 95–98%. The risk of primary peritoneal serous carcinoma is significant and estimated at 0.2–0.35% per year after salpingo-oophorectomy [44, 88] with a slightly higher risk for BRCA1 carriers [44]. Nearly all reported cases have occurred within 10 years of prophylactic surgery; however, longer follow-up might reveal a more extended period of increased risk.

Prognostic Factors

The only universally accepted prognostic factors for patients with ovarian cancer are FIGO stage and, in stage IIIC and IV patients, volume of residual disease after surgical staging (with or without debulking). Age is a strong prognostic factor in many studies but may not be independent, as already discussed (see **>** Etiology and Risk Factors; **>** Age, earlier in this chapter). Other factors that may be important but about which there is continued debate include cell type, histopathologic grade, and tumor rupture.

Cell Type and Histologic Grade

The issue of the prognostic importance of cell type and grade is complex because these features are interdependent, making it difficult to analyze them separately. The vast majority of serous and clear cell carcinomas are high grade regardless of the grading system used, while endometrioid and mucinous carcinomas are more often low grade [106, 313].

On reviewing the literature, histologic grade is reported to be a significant prognostic factor in many studies and in literature reviews. However, most of these data are not useful because of the number of different grading systems, the failure to specify which system was used, the lack of uniform pathologic review, and the fact that grade is among the most poorly reproducible observations among pathologists. Two recent large studies with uniform expert pathology review found that grade was not an independent prognostic factor on multivariate analysis: a Canadian population-based study of 575 patients [106], and a review of 1,895 stage III patients from a compilation of Gynecologic Oncology Group (GOG) studies [378].

For all major cell types of ovarian carcinoma, histologic subtype is not an independent prognostic factor when stage is taken into account, with the possible exception of clear cell carcinoma, which historically has portended a very poor outcome. However, many large recent series have not confirmed this [49, 182, 239, 255, 313, 329, 353, 369, 393] (see ♥ Clear Cell Carcinoma, later in this chapter). Some recent large studies suggest that advanced-stage endometrioid carcinomas have a better progression free and overall survival as compared to stage-stratified serous carcinoma [338, 378]. This could reflect a higher proportion of low-grade tumors among the endometrioid carcinomas as noted above.

At present, grading of ovarian carcinoma is clinically important only for stage IA, IB, and IIA patients because chemotherapy can be withheld for low-grade tumors in view of their excellent prognosis when untreated. Stage IA and IB, grade 1 carcinomas have survival rates as high as 97% [106]. However, stage I ovarian cancer is a heterogeneous group with only a small minority being serous carcinomas. Since the decision to treat or not to treat is a binary one, the data suggest that the binary system can be used, with chemotherapy withheld for low-grade stage I, i.e., Type I tumors (see >> High-Grade Serous Carcinoma for further information on grading, later in this chapter). There are insufficient data available to determine whether the binary system is appropriate for nonserous tumors; furthermore, even for serous tumors, only advanced stage cases have been tested.

Stage, Patterns of Spread, and Survival

The most recent version of the FIGO staging of gynecological cancers is shown in **?** *Table 14.3* [119]. FIGO stage is so powerful a predictor of outcome in ovarian cancer that most other putative prognostic factors are of little importance in comparison to stage, with the exception of volume of residual disease after staging and debulking in stages IIIC and IV.

Standard procedures for surgical staging have evolved over the past 3 decades. In the early 1980s, it became clear that approximately one third of ovarian cancer patients with apparent stage I disease (confined to the ovaries) were upstaged at subsequent complete staging laparotomy. The extent of surgical exploration and tissue sampling are currently quite thorough when performed by a gynecological oncologist, but suboptimal staging often still occurs when performed by nonspecialists. Survival rates for the lower stages gradually improved in the 1970s and 1980s as occult advanced-stage tumors were detected and properly categorized.

Comprehensive staging as described later in this chapter ("Treatment"; "Surgery") will generally be sufficient surgical treatment for patients in stages I and II. Patients with advanced-stage disease often require debulking, or cytoreductive surgery, as well. Although cure is uncommon, cytoreductive surgery improves survival. Other benefits include improved patient comfort, reduction in the adverse metabolic consequences due to tumor including enhanced ability to maintain nutrition, enhanced ability to tolerate chemotherapy, and enhanced responsiveness of residual tumor to chemotherapy. Aggressive primary cytoreductive surgery has a low morbidity and mortality rate and is supported by an improved survival rate in multiple studies. The median survival is about 3-4 years or longer after optimal cytoreduction as compared to about 1-2 years after suboptimal cytoreduction. Systematic lymphadenectomy as compared to removal of only clinically suspicious nodes improves progression-free survival by a few months but does not improve overall survival in optimally debulked patients [48, 341]. Many patients with bulky disease cannot be optimally cytoreduced at primary surgery. It has been found that two to three cycles of chemotherapy followed by interval debulking significantly increases the proportion of patients who can be successfully cytoreduced.

Staging takes both surgical and pathological findings into account, hence the term, "surgicopathologic stage." Stage can usually be deduced solely from the histopathologic and cytologic findings. However, limited evidence suggests that dense adhesions of an apparent stage I tumor that require sharp dissection, leaving a raw area following dissection, or when dissection results in tumor rupture, are associated with a prognosis similar to that of a more advanced stage tumor [250]. At present, it is not clear whether upstaging based on dense adhesions is warranted, although one recent study suggests that it is not [299]. This and other problems in assigning stage are summarized in **O** *Table 14.8.*

The stage distribution of ovarian cancer varies by histological type (**2** *Table 14.4*). The highest proportion of FIGO stage I cases is found among Type I tumors. The vast majority of mucinous carcinomas are stage I, as are one-third to one-half of clear cell carcinomas and nearly

Table 14.8

Problems and pitfalls in staging ovarian carcinoma

Problem	Solution
What constitutes ovarian surface involvement?	Tumor cells directly exposed to the peritoneal cavity, generally manifested as exophytic surface papillae
Does slight leakage warrant substage C?	Yes
Does rupture of a benign component of a heterogeneous tumor warrant substage C?	No guidelines or data are available
Does sigmoid colon involvement indicate stage II or III?	ll. The sigmoid colon is a pelvic structure
Does invasion of skeletal muscle of diaphragm, posterior abdominal wall (psoas muscles), or anterior abdominal wall (rectus muscles) warrant stage IV?	No. This is stage III
Does invasion of the diaphragm indicate stage IV?	Invasion through to the pleural surface of the diaphragm or into the parietal pleura warrants stage IV
Does abdominal wall involvement indicate stage III or IV?	Invasion through the anterior rectus sheath, or into subcutis or skin, warrants stage IV
Does splenic parenchymal involvement indicate stage III or IV?	No guidelines are available
Does dense adherence to extraovarian structures warrant upstaging in the absence of histologic confirmation of extraovarian disease?	Unresolved. Practices vary and FIGO guidelines are not clear [299]
Are chest CT and other extra- abdominal evaluations for apparent stage III patients needed to rule out stage IV?	No

half of endometrioid carcinomas. Only 3% of serous carcinomas are diagnosed in stage I. Low-grade serous carcinoma, a Type I tumor, is rarely diagnosed in stage I, although the morphologically noninvasive form of MPSC is somewhat more often diagnosed in stage I. In our series, only 14% of ovarian cancers were stage I, and

Table 14.9

Five-year survival by stage (%), in four continents

IV	18.6	17.9	20.4	11.7	12

one third of these were not comprehensively staged. Fiveyear survival rates by stage are shown in **S** *Table 14.9.*

Stage I ovarian cancer is confined to the ovaries and peritoneal fluid or washings. Tumor rupture or tumor cells in peritoneal washings or ascitic fluid warrant a stage of IC. Ovarian surface involvement by tumor is also considered to reflect stage IC disease. We consider ovarian surface involvement to be present only when tumor cells are exposed to the peritoneal cavity. Thus, surface involvement is characterized by exophytic papillary tumor on the surface of the ovary or on the outer surface of a cystic neoplasm replacing the ovary (> Figs. 14.2 and > 14.3); rarely a smooth ovarian tumor surface will be shown to have an exposed single layer of neoplastic epithelium. Assessment of surface involvement requires careful gross examination and cooperation between the surgeon and the pathologist. Poor prognostic factors in stage I have historically been grade 3, clear cell type, and IC substage (including rupture). However, this is controversial [313, 369]. Several large recent studies have shown that stage IC tumors do not have a poorer outcome than IA, nor does clear cell histology or rupture portend a poor outcome [50, 182, 239, 313, 353]. Occasionally a large ovarian tumor that is stage IB is associated with a contralateral normal size ovary with small tumor foci on the surface suggesting that the latter is metastatic. Among stage I tumors with bilateral involvement, one third have this appearance [313]. Stage IB is quite uncommon and is found in only 1-5% of stage I cases [119, 182, 389]. Data from several studies suggest

Fig. 14.2

Low grade (micropapillary) serous carcinoma. The outer surface displays exophytic papillary excrescences reflecting ovarian surface involvement

Fig. 14.3 Low grade (micropapillary) serous carcinoma. Sectioning reveals papillary excrescences on both inner and outer surfaces (same tumor as Fig. 14.2)

that stage I clear cell carcinoma is more frequently IC as compared to the other cell types [313, 329], possibly because of an increased risk of rupture [353].

Stage II ovarian carcinoma is a small and heterogeneous group, and comprises less than 10% of ovarian cancers, 6.5% in our series. It is defined as extension or metastasis to extraovarian pelvic organs. As such, it includes examples of direct extension to the tubes and pelvic sidewall, as well as metastatic seeding of the pelvic peritoneum, and therefore may include curable tumors that have directly extended to adjacent organs but have not yet metastasized, as well as tumors that have seeded the pelvic peritoneum by metastasis and therefore have a poor prognosis. Of note, the sigmoid colon is within the pelvis, and therefore, sigmoid involvement is stage II (**7** *Table 14.8*). As noted earlier, some "pathologic stage I" tumors are considered "surgical stage II" by many surgeons [299]. Although stage II is subclassified into three substages, these do not separate direct extension from metastasis.

Ovarian cancer most commonly presents in stage III and the vast majority of these (84%) are stage IIIC [119]. These tumors characteristically spread along peritoneal surfaces involving both pelvic and abdominal peritoneum including the omentum, surfaces of the small and large bowel, mesentery, paracolic gutters, diaphragm, and peritoneal surfaces of the liver and spleen. Less often, there is a solitary dominant primary ovarian tumor that directly invades bowel or other abdominal structures without the usual features of peritoneal studding. Ascites is found in two thirds and its presence correlates with suboptimal cytoreduction and a higher number of positive lymph nodes [16]. Metastases to retroperitoneal or pelvic lymph nodes are found in the majority of patients who undergo node sampling or dissection and in up to 78% of advanced-stage patients [117, 135]. Inguinal lymph nodes are less commonly involved. Nodal metastasis indicates stage IIIC even in the absence of peritoneal metastasis. Nodal metastasis without peritoneal metastasis is relatively uncommon and seems to portend a better outcome as compared to stage IIIC patients with bulky abdominal disease, even those who have been optimally cytoreduced [58]. The majority of these have positive para-aortic nodes. Isolated positive pelvic nodes with negative para-aortics is very uncommon (0-3%) [117]. Palpable suspicious nodes are positive in 75% while 32% of nonsuspicious nodes are positive [117]. In node-positive stage IIIC cases, about one fourth of resected lymph nodes are positive. Patients with tumors that otherwise appear to be stage I have lymph node metastases in about 9% of cases; the corresponding figures for stages II, III, and IV are 36%, 55%, and 88%, respectively. Most studies have shown that the number of positive nodes has no prognostic significance [15]. Rarely, inguinal (stage III), or supraclavicular (stage IV) node metastases will be the presenting manifestation of ovarian carcinoma [87].

Bowel involvement is grossly evident in 72% of stage III patients, and 40% require bowel resection [135]. This is manifested as serosal and subserosal involvement that is frequently extensive and often forms large tumorous masses. More than half of patients have multiple bowel segments involved. The rectosigmoid is the most common site and is involved in 80% of those with bowel involvement. Focal invasion of the outer layer of muscularis propria is not uncommon. Invasion into the submucosa or transmural invasion with mucosal ulceration occurs much less often.

Volume of residual disease is an important prognostic factor in most studies, but this applies only to stages IIIC and IV, as stages IIIA and IIIB have low-volume disease by definition (**7** *Table 14.3*). Regrettably, there is no standard definition of optimal versus suboptimal debulking, the latter group being those considered to have high volume of residual disease. Criteria used rely on the size of the largest nodule remaining. Eighty-seven percent of gynecologic oncologists use 0, 0.5, or 1.0 cm as the threshold, with 1.0 cm the most widely used. Most studies show that the complete elimination of macroscopic disease (i.e., a zero threshold) is associated with the most favorable prognosis [83].

Stage IV is defined as distant metastasis and includes patients with parenchymal liver metastases and extraabdominal metastases; 12–21% of patients present in stage IV [119, 300]. A complete extraabdominal evaluation to exclude distant metastases such as CT of the chest and other studies is not required to assign stage III (**)** *Table 14.8*). The median survival for stage IV is 23 months. Liver and lungs/pleurae are the most common metastatic sites, and anterior abdominal wall metastasis including periumbilical skin and subcutis is frequent. A solitary distant metastasis is a favorable prognostic factor as compared to multiple metastases [347].

Lung and pleural metastases have been reported in up to 45% of ovarian cancer patients [347], and respiratory failure is one of the most common clinical causes of death. In one large series, at presentation, 15% of ovarian cancer patients had pulmonary metastases, and an additional 30% developed pulmonary metastases after a mean of 9 months. During the course of the disease, one third of patients had pleural effusions, and three quarters of these contained malignant cells on cytopathological examination. Among patients with pulmonary involvement, malignant pleural effusion is three times as common as solid parenchymal lung metastasis. A few studies have shown that women with malignant pleural effusion do worse than those with other distant metastases. Historically, the 5-year survival has been 6% after pulmonary metastasis; however, this has improved to 17-36% as surgical resection of metastases has been widely performed.

Hepatic metastases have been found in half of ovarian cancer patients at autopsy. The median survival of stage IV patients with liver metastases is about 1 year. With surgical resection of metastases, the survival improves to a median of about 2 years [347]. As with pulmonary metastases, solitary lesions and those resected with a tumor-free margin are associated with a better outcome. In a study of 29 patients with liver metastases, the median time to recurrence in the liver was 29 months. The median survival for those having undergone resection of a solitary nodule was 25 months as compared to 10 months for those with multiple nodules [189].

Anterior abdominal wall metastases frequently involve periumbilical subcutis and skin. Extraperitoneal abdominal wall involvement warranting the stage IV designation occurs when tumor has invaded through the anterior rectus sheath (> Table 14.8). Invasion of the rectus muscle alone is considered stage III. When carcinoma is present in a specimen labeled "abdominal wall," if skin is not present for orientation, review of the operative report or discussion with the surgeon is needed to determine whether a stage IV designation is warranted. The pathology report should be explicit in this regard.

Splenic parenchymal metastases are found in 20% of patients at autopsy. There are no specific guidelines for changing the stage based on splenic parenchymal metastasis and it is not clear whether splenic involvement is an adverse prognostic factor in patients who are otherwise stage IIIC. Among ovarian cancer patients who undergo splenectomy, only about half have splenic metastases [14].

Diaphragmatic metastases are usually confined to the peritoneal surface. On occasion, tumor will invade into or penetrate through the diaphragm and the depth of invasion or extent of involvement may necessitate partial diaphragm resection. Penetration of the parietal pleural surface of the diaphragm warrants designation as stage IV.

As survival rates have improved in the taxane era, previously rare sites of distant metastasis such as bone and brain are being diagnosed more often. Brain metastases are present in 0.1% of patients at presentation [216], and are found in up to 6% of patients at autopsy. CNS recurrence is clinically manifested as carcinomatous meningitis in 4-6% of patients, and the median survival is less than 5 months. About half of patients have multiple brain lesions, and in 30-40%, the brain is the only site of distant metastasis. Among patients who develop brain parenchymal involvement after diagnosis, the median time after diagnosis is about 20 months, and the subsequent survival is less than 6 months [216, 347]. The absence of extracranial metastases is prognostically favorable. Bone metastases occur in 1-2% of patients during the course of the disease and are found in up to 15% at autopsy. The median survival after bone metastasis is diagnosed is 4 months. Interestingly, among women with a history of ovarian carcinoma who present with a breast or axillary mass, one third have metastatic ovarian carcinoma and two thirds have a primary breast carcinoma [142].

Cytopathology

Ovarian epithelial neoplasms are usually evaluated in two types of cytopathological specimens: fine-needle aspirates (FNA) of ovarian cysts and peritoneal fluids (obtained by peritoneal washing or by aspiration of ascitic fluid). Intraoperative smears of ovarian tumors can also be useful adjuncts to, or replacements for, frozen section examination. Once disseminated, ovarian cancers may also be examined in FNA specimens or effusions from sites of distant metastasis. Rarely, the presence of psammoma bodies in a Pap smear will be the first sign of primary or recurrent ovarian or peritoneal serous carcinoma, more commonly when associated with atypical glandular cells of undetermined significance (AGUS) or in older women with symptoms and signs suggesting malignancy [223]. In a review of over 200,000 Pap smears, psammoma bodies were found in six patients, two of whom proved to have ovarian carcinoma [266]. In a review of 138 cases of AGUS, 5 (3.6%) proved to have ovarian cancers [344].

Fine-Needle Aspiration of Ovarian Cysts

FNA may be useful in patients who appear to have inoperable ovarian cancer or who cannot undergo surgery for other reasons. Unsatisfactory specimens from ovarian cyst aspirates are common and limit the usefulness of the procedure.

FNA specimens from most carcinomas are cellular and contain cytologically malignant cells, but accurate subclassification is often difficult and may be impossible based solely on cytologic material. Features useful in subclassification of epithelial neoplasms include psammoma bodies and papillary structures, which suggest serous differentiation, elongated cells, and focal squamous features that suggest endometrioid differentiation and cells with abundant clear, frothy, cytoplasm, and prominent enlarged nucleoli, which suggest clear cell differentiation. Columnar cells with large cytoplasmic vacuoles containing basophilic cytoplasmic mucin suggest mucinous differentiation and, if malignant nuclear features are present, should immediately raise the question of metastatic carcinoma to the ovaries (see) Mucinous Tumors, later in this chapter, and O Chap. 18, Metastatic Tumors of the Ovary). FNA specimens from serous carcinomas are usually very cellular and display malignant cells, singly and in clusters, with nuclear enlargement, hyperchromasia, irregular chromatin clumping, and prominent nucleoli. Bizarre tumor giant cells are common. Mucinous carcinomas yield mucus and high cellularity with single cells, clusters,

and syncytial fragments displaying pleomorphism, coarse chromatin, prominent nucleoli, and vacuolated cytoplasm. Exclusion of metastatic mucinous carcinoma is generally not possible in cytologic material, but if sufficient material is available for immunoperoxidase stains, the differential diagnosis can be narrowed. Cytologic material from endometrioid carcinomas resembles that from serous carcinomas but with scanty, more granular cytoplasm, nuclear crowding, and microacini. Squamous differentiation may be present. Clear cell carcinomas display cells with abundant pale vacuolated cytoplasm. Nuclear features often include pleomorphism and macronucleoli.

FNA of benign epithelial neoplasms usually produces a paucicellular specimen. Most of the material consists of macrophages and lymphocytes with few epithelial cells. The background is generally clean, unless torsion or necrosis has occurred. Benign serous tumors may display cohesive sheets of uniform cells with round to oval nuclei, moderate amounts of cytoplasm with well-defined cell borders, and occasionally cilia. The nuclei have finely granular chromatin and small nucleoli. Cystadenofibromas also may display spindled stromal cells without atypia. Mucinous cystadenomas display tall columnar cells with basal nuclei without atypia and occasionally signet ring-like cells. Since any ovarian tumor more than a few centimeters in diameter requires careful gross examination and directed sampling of different areas, a diagnosis of a benign epithelial neoplasm on FNA is likely to have a significant false-negative rate. Atypical proliferative epithelial tumors of all types may display a degree of cytologic atypia that overlaps with invasive well-differentiated carcinoma, and therefore this distinction requires tissue examination in all cases.

Peritoneal Fluid Cytology

Cytological samples of peritoneal fluid are routinely obtained during staging procedures for ovarian cancer. Washings are performed or ascites aspirated upon entering the peritoneal cavity, prior to surgical manipulation that could dislodge tumor cells. Cytological findings are important in substaging early (FIGO I and II) ovarian cancer; malignant cells in peritoneal washings or ascites warrants assignment of tumors to stage IC or IIC. Cytology is more sensitive in detecting ovarian carcinoma in ascites than in peritoneal washes, as well as in patients with peritoneal metastases measuring >0.5 cm as compared to those with smaller volume disease. Malignant cells are more often present in ascites as compared to washings, and their presence correlates positively with volume of ascites, serous histology, stage, and positive lymph nodes [16]. Peritoneal serous carcinoma more commonly yields positive cytologic specimens as compared to ovarian serous carcinoma [22]. The cytologic features of tumor cells generally resemble those in FNA specimens (see above) but may be more degenerate. The prognosis of patients with stage IC ovarian cancer based on positive peritoneal cytology is poorer than for stages IA and IB. In addition, patients with stage III disease with positive cytology have a poorer prognosis than stage III patients with negative cytology.

Peritoneal lavage is often performed at the time of RRSO in high-risk women. Occult carcinomas can be identified in these cytology specimens. Colgan and associates found malignant cells in 3 of 35 such specimens. One microscopic ovarian surface carcinoma and one in situ tubal carcinoma were found; no carcinoma could be identified in the third patient. Endosalpingiosis was found in 22% [60]. Rarely, malignant cells have been reported in washings at RRSO without an identifiable carcinoma by histology [88], and in two studies, positive cytology specimens led to the discovery of early-stage tubal carcinomas [2, 212].

The main component of benign peritoneal washings is mesothelial cells arranged singly and in sheets. In Papanicolou stains, mesothelial cells appear as round or polygonal cells with dense, cyanophilic cytoplasm and centrally placed, round nuclei with smooth contours and finely granular chromatin. Degenerate and reactive mesothelial cells often display fine or course cytoplasmic vacuolation and a lightly stained perinuclear zone.

The presence of epithelial cells in peritoneal fluid samples from patients with atypical proliferative ("borderline") epithelial ovarian tumors has been highlighted in the past as a problematic area of cytopathology. This problem no longer exists because much more accurate histological subclassification of these neoplasms into benign and malignant types (see Serous Tumors and Mucinous Tumors sections below) renders the peritoneal fluid cytology specimens in the vast majority of these patients who have benign tumors of no importance. The small proportion of patients who have bona fide carcinomas (patients with invasive MPSCs or APSTs with invasive implants) can be substaged based on the presence or absence of epithelial cells resembling the primary ovarian tumor in the cytology specimens. This situation is rarely encountered since most of these latter tumors are stages III and IV.

The most important pitfall in the examination of peritoneal cytology specimens in women involves benign epithelial proliferations. Women with or without cancer can have endometriosis and/or endosalpingiosis involving peritoneal surfaces. These lesions often shed epithelial fragments into peritoneal washings or ascites; in addition, benign fallopian tube epithelium, particularly if salpingitis is present, and benign eutopic endometrial tissue via expulsion through the fallopian tubes may also be shed into the fluid. If the cells in the fluid are not obviously malignant, comparison of the cytologic features of the epithelium in the fluid with those of the tissue sections are essential in arriving at the correct diagnosis. It is also important to be aware of the cytological abnormalities that may be caused by intraperitoneal chemotherapy as well as radiation, as they may mimic malignancy.

Treatment

Surgery

Initial surgical management of ovarian cancer includes staging, which is aimed at defining the extent of disease, and debulking, which is aimed at reducing tumor burden. In addition to removing the primary tumor intact, total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy are performed. Fertility-sparing surgery can be performed in selected young patients. Random peritoneal biopsies including the diaphragm, and para-aortic and often pelvic lymph node sampling are essential unless there is obvious disseminated peritoneal disease.

Comprehensive staging will generally be sufficient surgical treatment for patients in stages I and II. Patients with advanced-stage disease often require debulking, or cytoreductive surgery, as well. Cytoreductive surgery, both primary (at presentation) and secondary (after recurrence), prolongs survival and progression-free interval. The median survival after first recurrence followed by secondary cytoreduction is 2–4 years in optimally cytoreduced patients and about 1 year in suboptimally cytoreduced patients. Patients operated on by gynecological oncologists have superior survival rates as compared to those operated on by general surgeons [79].

Chemotherapy

The survival for patients with stage IA and IB, low-grade tumors is 90% or better, and there is no demonstrable benefit from adjuvant chemotherapy. Stage IC is generally regarded as a negative prognostic indicator, but some recent studies have not confirmed this. It is possible that the inability to demonstrate a prognostic difference between stages IA and IC in recent studies is due to a beneficial effect of chemotherapy on stage IC patients. For low-stage ovarian cancer with prognostic features that are generally considered adverse (high-grade and stages IC and IIA), it is not clear whether adjuvant chemotherapy is superior to no treatment. Although there certainly exists a group of low-stage patients that are cured without any further treatment, identification of this group has been difficult as studies of low-stage patients have evaluated a wide variety of features and many of the results are conflicting [313]. Management options for this group include platinum-based chemotherapy (PBC) with or without a taxane, or no treatment.

Patients with advanced stage (FIGO III and IV) disease benefit from chemotherapy using platinum with or without a taxane. PBC has resulted in a significant improvement in response rate, response duration, time to progression, and overall survival. Long-term survival (>5 years) can be achieved with platinum-based combination chemotherapy in over 50% of patients with stage III smallvolume residual disease. A recent autopsy study analyzing patients treated with PBC found that 49% of all PBCtreated patients had metastases confined to the abdomen as compared to only 16% of those treated with older chemotherapeutic regimens. There was a higher frequency of liver metastases and fewer lung and pleural metastases. It was therefore suggested that PBC can help prevent extraabdominal spread [114]. At present, a platinum compound in combination with paclitaxel is the best first-line chemotherapy for advanced-stage ovarian cancer. Recent data on platinum-based intraperitoneal chemotherapy for first-line treatment of optimally debulked stage III disease have shown about 20% improvement in both progression-free and overall survival [123], with the median survival increasing by about 12 months. An NCI Clinical Announcement in 2006 established a combination of intraperitoneal and intravenous platinum with or without a taxane as standard treatment for optimally debulked stage III patients. However, the optimal regimen is still not clear and significant toxicity issues remain. The advantages of the intraperitoneal route include higher drug concentrations, prolonged tumor exposure, and reduced systemic toxicity [97].

Occasionally, a cytoreductive procedure is abandoned due to unresectable disease or inability of the patient to tolerate the procedure. These patients generally undergo neoadjuvant chemotherapy to reduce the extent of disease or improve performance status, followed by interval debulking surgery. This management does not appear to have an appreciable effect on survival if there is a concerted upfront attempt at cytoreduction. If there is no initial attempt at cytoreduction, the survival is inferior [32, 33, 188].

Second-look laparotomy has no demonstrated effect on survival. In recurrent ovarian cancer, platinum with or without a taxane can be of value. Paclitaxel is active in many patients whose tumors are platinum-resistant.

Other Therapeutic Modalities

Radiation and hormonal therapy may be alternatives in patients who cannot tolerate surgery or chemotherapy. Long-term follow-up of patients who received consolidation radiation therapy and those treated with radiation and melphalan in the 1970s have shown long-term survival rates comparable to those currently treated with PBC; however radiation toxicity rates are high [78, 257]. Hyperthermic intraperitoneal chemotherapy combined with aggressive cytoreduction is used in some centers, but there are no prospective randomized trials demonstrating its efficacy [199].

Up to one third of ovarian cancers have amplification or overexpression of the *HER2/neu* proto-oncogene; however, recent success in treating *HER2*-positive breast cancer with trastuzumab has not been repeated in ovarian cancer [174]. Similarly, immunohistochemical expression of c-kit (CD117) has been variable, but generally low, suggesting that imatinib will not be of value [145]. Amplification and immunoreactivity for EGFR have been reported in 20% and 28% of ovarian cancers, respectively, and clinical responses to gefitinib, an EGFR inhibitor, have been variable but generally low [335]. The VEGF inhibitor, bevacizumab, has shown some activity in ovarian cancer, but the data are preliminary [163]. In vitro drug-resistance assays are sometimes used to guide therapy, more often with recurrent tumor, but data are limited.

Pathology of Ovarian Epithelial Neoplasms

The World Health Organization (WHO) classification of surface epithelial tumors is summarized in **3** *Table 14.10*, and the distribution of ovarian surface epithelial tumors is shown in **3** *Table 14.5*. Ovarian epithelial tumors comprise about half of all ovarian tumors, and account for about 40% of benign tumors and nearly 90% of malignant tumors. A uniform series using standard histologic criteria

Modified from [297]

to assess the distribution of ovarian tumors has not been reported since Russell's review of 1,000 surface epithelial tumors in the late 1970s [308]. We have recently evaluated 1,000 consecutive ovarian surface epithelial tumors accessioned at the Washington Hospital Center from 1999 to 2009 (**2** *Table 14.5*). Although not populationbased, our data on carcinomas are very similar to population-based data from Canada [107] and Sweden [4], with the exception of a somewhat higher frequency of mucinous carcinoma in the latter study.

The apparent cell-type distribution has changed significantly in the past 2 decades as metastatic mucinous carcinomas have been recognized and properly categorized. Primary invasive mucinous carcinoma now appears to be quite uncommon, comprising only 3% of ovarian carcinomas and less than 1% of advanced-stage carcinomas (**>** *Table 14.4*) [104, 301], although they appear to be somewhat more common in Asia with 6.7% found in a recent Thai study [147]. Carcinosarcoma (malignant mixed müllerian tumor - MMMT), previously regarded as a rare primary ovarian tumor, now appears to comprise over 7% of ovarian carcinomas in the United States and 2.5% in Thailand. This apparent increase in frequency may be due to more thorough sampling with the identification of small sarcomatous components in otherwise typical high-grade serous carcinomas.

Accurate pathologic classification is predicated on examination of histological sections that are representative of the entire neoplasm. Intratumoral heterogeneity is a common phenomenon of many sites and it is particularly common in ovarian tumors. Since volume is exponentially related to a spherical tumor diameter, small tumors measuring up to about 5-7 cm can easily be thoroughly sampled, while larger tumors cannot. A 15 cm solid tumor, for example, would require hundreds of sections to achieve the same sampling per unit volume as a 5 cm tumor examined with five sections. Type II tumors, usually high-grade serous carcinoma, are relatively uniform. In contrast, Type I tumors display a wide variety of patterns and degrees of epithelial proliferation in different areas. Although extensive sampling is not generally needed for invasive carcinomas, noninvasive tumors need careful gross examination and directed sampling of papillary, solid, and any unusual areas to make certain that invasive foci are not overlooked. This is particularly important for the atypical proliferative (borderline) endometrioid, mucinous, clear cell, and low-grade serous cell types, i.e., the precursors of Type I carcinomas.

CAP and WHO Recommendations

The College of American Pathologists (CAP) has issued guidelines for the reporting of ovarian cancer [243]. Complete reporting with the CAP cancer checklist requires assessment of ovarian surface involvement and tumor rupture for stages I and II. It is therefore important that the pathologist communicate with the surgeon or review the operative report to provide these data. For advanced stage, the size of the largest peritoneal nodule needs to be assessed, and although this is often evident from the gross pathologic examination, the surgeon's input may be required since the tumor may be incompletely resected. In apparent stage III patients, clinical or pathologic information may be needed to determine whether distant metastases have been diagnosed (stage IV).

The CAP does not recommend any specific grading system. There are features found in the checklist that are not routinely reported: (1) For bilateral tumors, which one is the primary (this is possible in only a small minority of cases); (2) The presence of venous or lymphatic invasion; (3) specimen type (requiring, e.g., distinguishing an omental biopsy, partial omentectomy, and complete omentectomy). Some of the data are considered optional. Required elements include specimen type, specimen integrity, primary site, tumor size, histologic type, grade, and TNM stage. There is a separate CAP checklist for peritoneal tumors [244]. This should not be used for primary peritoneal serous carcinomas as it is incomplete for this purpose. The ovary checklist is more appropriate.

The status of peritoneal implants is required for the reporting of borderline tumors. However, it is not necessary to use the CAP checklist for borderline tumors unless carcinoma (invasive implants or invasive MPSC) is present.

In the most recent edition of the WHO classification of ovarian tumors [297], there are some differences from the classification used in this chapter (> Table 14.10). The most notable difference is division of serous borderline tumors (SBT) into APST (benign) and noninvasive MPSC (low-grade malignant), while WHO uses SBT with micropapillary pattern for the latter tumor. In addition, we do not use the modifiers "cystadeno," "papillary," "surface," "fibroma," and "adeno" for serous carcinomas, as these create multiple different names for the most common type of ovarian cancer. Because of this multiplicity of names, the International Classification of Diseases for Oncology contains at least four different codes for synonyms for serous carcinoma [90]. This leads to confusion in cancer registries as well as difficulties in the interpretation of population-based data. Regarding microinvasion, the WHO recommends a cutoff of 3 mm for microinvasion for APST, whereas we prefer 5 mm for all cell types. The category of intraepithelial carcinoma, which WHO uses for mucinous tumors, we use on rare occasion for endometrioid and clear cell tumors as well. Finally, we require 25% of a second epithelial component for diagnosis of a mixed epithelial tumor, whereas WHO uses 10%.

Serous Tumors

The classification of serous neoplasms of the ovary has been mired in confusion and controversy due to the widely misunderstood intermediate category between benign and malignant. The borderline group has now been successfully subclassified into benign (APST) and low-grade malignant (noninvasive MPSC or APST with invasive peritoneal implants) categories and is therefore no longer needed. The terminology is summarized in **>** Table 14.11.

Serous Cystadenoma and Adenofibroma

Benign serous tumors include cystadenomas, adenofibromas, cystadenofibromas, and surface papillomas. These tumors are common and account for two

Table 14.11

Terminology of serous tumors

Old Terminology	New terminology	
Ovarian		
Serous borderline tumor (SBT)	Atypical proliferative serous tumor (APST)	
Serous tumor of low malignant potential		
Micropapillary serous borderline tumor	Noninvasive micropapillary serous carcinoma (MPSC)	
Well-differentiated serous carcinoma	Low grade (invasive) micropapillary serous carcinoma	
Microinvasion	Microinvasion ^a	
	Microinvasive carcinoma ^b	
Peritoneal		
Noninvasive epithelial implant	Implant ^c	
Noninvasive desmoplastic implant	Implant ^c	
Noninvasive implant with micropapillary pattern	Metastatic low-grade serous carcinoma ^c	
Invasive implant	Metastatic low-grade serous carcinoma ^c	

^aUsual type characterized by small clusters of eosinophilic cells just beneath the surface epithelium.

^cProposed new terminology.

thirds of benign ovarian epithelial tumors and the majority of ovarian serous tumors. They occur in adults of all ages, with reported mean ages varying widely from 40 to 60 years. The symptoms and signs associated with large tumors are nonspecific and most commonly include pelvic pain, discomfort, or an asymptomatic pelvic mass. Tumors measuring 1–3 cm are usually incidental findings. Bilaterality rates are variable depending upon both the thoroughness with which an apparently uninvolved ovary is examined as well as the threshold for diagnosis of a small serous neoplasm. Accordingly, 12–23% of cystadenomas are bilateral.

Benign serous tumors are equally distributed among unilocular cysts, multilocular cysts, and cystadenofibromas [307]. They are composed of cysts filled with clear watery (serous) fluid or thin mucoid material. Occasionally, they contain thicker mucus-like material more typical of mucinous neoplasms. The external surfaces of the cysts are smooth and glistening. Occasionally, papillary excrescences are found on the external surface of the cyst. The tumors vary widely in size up to 30 cm, with a mean of 5–8 cm. The lining of the cyst is either flat or may have a varying number of coarse papillary projections. Such papillary excrescences rarely cover the entire inner surface of the cyst. Adenofibromas are solid neoplasms composed of tough, rubbery tissue with interspersed glandular spaces.

Normal-sized ovaries often have small surface papillary projections with a fibrotic stromal component resembling a microscopic adenofibroma or cystadenofibroma; these have been termed surface papillomas, and when multiple, surface papillomatosis (see **O** Chap. 12, Nonneoplastic Lesions of the Ovaries). In addition, surface epithelial inclusions may become cystically dilated. It has been suggested that a serous neoplasm be diagnosed only if the lesion is >1 cm in diameter. This is arbitrary and therefore unlikely to distinguish neoplastic growth from simple serous cysts or non-neoplastic hyperplasias of the ovarian cortex.

The vast majority of lesions classified as serous cystadenoma display a serous epithelial lining lacking proliferation. In a recent study, only 7% of serous cystadenomas had greater than 1 mm of epithelial proliferation [307]. Accordingly, most serous cystadenomas are not true neoplasms, but rather represent cystically dilated inclusions.

Cystadenomas are lined by pseudostratified, tubaltype epithelium, with the characteristic elongated (secretory cell) and rounded (ciliated cell) nuclei (\bigcirc *Fig.* 14.4). A single layer of flattened to cuboidal cells with uniform basal nuclei is also common. Although the cells often

^bLess common type characterized by micropapillae and or small solid nests of cells surrounded by a space, identical in appearance to invasive low-grade micropapillary serous carcinoma.

Serous cystadenoma with focal proliferation and atypia. Epithelial stratification and tufting are present in less than 10% of this otherwise ordinary serous cystadenoma

produce mucin, which is secreted into the cystic spaces, they do not contain basophilic cytoplasmic vacuoles or granules characteristic of mucinous neoplasms. In large cysts, the epithelium often becomes attenuated. Mitoses and atypia are generally absent. Psammoma bodies are present in the stroma in 15% of cystadenomas. There is a broad spectrum of epithelial proliferation in benign serous tumors, which is manifested by variation in the prominence and complexity of the papillae, from a simple, single layer and blunt papillae to focal epithelial stratification and detachment of cell clusters approaching the degree of proliferation seen in APSTs. Identification of these features in 10% of the tumor separates serous cystadenoma from APST. If these features are focal (<10%), a diagnosis of serous cystadenoma with focal atypia is used (> Fig. 14.5) [7, 310].

The stroma of benign serous tumors can resemble normal ovarian stroma, but is generally more fibrous or edematous. When the stroma is highly cellular and fibrous and forms large solid areas containing scattered glands or thick papillary projections lined by serous epithelium, the tumor is designated an adenofibroma, or if cystic, cystadenofibroma (\bigcirc *Fig.* 14.6). Pseudoxanthoma cells with granular, light-brown cytoplasmic pigment beneath the epithelium can be seen on occasion.

The immunohistochemical profile of serous cystadenoma is similar to that of normal ovarian surface epithelium and tubal epithelium. In addition to positivity with most commonly used epithelial markers, p63 is positive in most cases [260].

Fig. 14.6 Serous cystadenofibroma. Broad fibrous papillae lined by a single layer of tubal-type epithelium protrude into a cyst

A variety of benign cysts may occur in and around the ovary and broad ligament and may simulate serous cystadenomas both grossly and microscopically. Functional ovarian cysts may have a denuded or attenuated lining. Similarly, an endometriotic cyst on occasion will mimic a serous cystadenoma if it lacks hemorrhage, and endometriotic stroma is inconspicuous. Broad ligament cysts, such as hydatid cysts of Morgagni, mesonephric cysts, and mesothelial (peritoneal) cysts, often mimic a serous cystadenoma. Mesonephric cysts are lined by cuboidal cells and are usually surrounded by concentric smooth muscle bundles. Peritoneal cysts are very common, are lined by mesothelial cells, and frequently arise via ovarian surface adhesions. Occasionally, hydrosalpinx will mimic a serous cystadenoma grossly and microscopically. Careful gross examination and discussion with the surgeon helps in the recognition that the apparent cyst represents a dilated fallopian tube.

A recent report indicates that the cells lining the cysts in most serous cystadenomas are polyclonal and therefore non-neoplastic [54]. Unilateral salpingo-oophorectomy or ovarian cystectomy is adequate treatment. Clinical recurrence is uncommon and reflects either incomplete resection or a new primary tumor.

Low Grade Serous Tumors Atypical Proliferative Serous Tumor (APST); Serous Borderline Tumor (SBT)

The "borderline" category of ovarian epithelial tumors was introduced in the early 1970s in order to describe a group of tumors that did not display invasion, but that occasionally appeared to behave in a malignant fashion. Their behavior appeared to be intermediate between benign cystadenomas and frank serous carcinomas. The classification was intended as provisional, but with its continued use over the past 3 decades, the borderline category has become entrenched and regarded as a specific entity. Recent studies have documented a wide histologic spectrum encompassed by the borderline category that correlates with behavior. Tumors at the lower end of the spectrum behave in a benign fashion and display a papillary architecture in which papillae have a hierarchical branching pattern. These tumors are termed "APST." Tumors at the upper end of the spectrum behave like low-grade carcinomas, display a more complex nonhierarchical branching pattern characterized by delicate micropapillae, and are classified as "noninvasive MPSC." APSTs comprise about 50% of atypical proliferative (borderline) ovarian tumors of all histologic types (**)** Table 14.5). The atypical proliferative terminology has been accepted by the WHO since 2000 [90], and was accepted as synonymous with "borderline" at the 2003 Borderline Ovarian Tumor conference, while "low malignant potential" was not recommended at the latter meeting [310].

Clinical Findings

The clinical features of patients with APSTs are similar to those for serous cystadenomas; the mean age is 42 years. The risk factors are similar to those for ovarian cancer with notable exceptions of a higher frequency of infertility and a lower frequency of *BRCA* mutations.

Operative Findings

Thirty-seven percent of APSTs are bilateral in the older literature; the recent Stanford series showed a 55% bilaterality rate [190]. This difference probably reflects more diligent examination of normal-sized ovaries with the identification of small serous proliferations. Exophytic papillae reflecting ovarian surface involvement are common, and are more often found in patients who also have peritoneal implants. Tumors with an exophytic component are associated with implants in 49–69% of cases as compared to 4–27% tumors that are completely intracystic [190, 262].

Gross Findings

APSTs tend to have fine, friable, and exuberant papillary projections in contrast to the smooth-walled cysts of serous cystadenoma. Papillae are nearly always present on the internal surfaces of the cyst, and are present on the external surfaces in up to 70% of cases. The adenofibromatous variant of APST is unusual.

Peritoneal endosalpingiosis in patients with APST is grossly inconspicuous. Noninvasive desmoplastic implants are firm and fibrotic, and are covered by an inflammatory exudate in 20% of cases. Invasive implants (metastatic lowgrade serous carcinoma) resemble typical serous carcinoma, but are often less bulky and more calcified.

Thorough sampling of the primary tumor for histological examination is needed to rule out invasion. Previous recommendations of one section per centimeter of maximum tumor diameter will not identify invasion in a significant minority of cases in which invasion is actually present. Recent data suggest that at least two sections per centimeter are needed to confidently exclude invasion [303] (see) Microinvasion below).

Microscopic Findings

APSTs display extensive epithelial stratification, tufting (budding), and detachment of individual cells and cell clusters in addition to hierarchical branching with successively smaller papillae emanating from the larger, more centrally located papillae (\bigcirc *Figs.* 14.7–14.9). Stratification and budding in at least 10% of the tumor warrants a diagnosis of APST. Complex papillary patterns often display stromal invaginations cut tangentially that must be distinguished from stromal invasion (\bigcirc *Fig.* 14.8).

Focal areas of fusion of the epithelial buds may create a roman bridge or cribriform pattern (**>** *Figs. 14.10* and **>** *14.11*). Similarly, foci of nonhierarchical branching with

Fig. 14.7
Atypical proliferative (borderline) serous tumor (APST).
A complex hierarchical branching pattern is present

G Fig. 14.9

Atypical proliferative (borderline) serous tumor. The stroma is edematous. Detached cell clusters are present between small and large papillae

Fig. 14.8

Atypical proliferative (borderline) serous tumor. Gland-like structures within the stroma reflect tangential sectioning of a complex papillae and are not indicative of invasion

fine elongated micropapillae emanating directly from large central papillae are seen not infrequently (\bigcirc *Fig.* 14.12). When cribriform and/or micropapillary patterns constitute either a 5 mm or greater confluent area, or 10% or greater proportion, the tumor warrants classification as noninvasive MPSC (see "Malignant serous tumors" below).

The cells in APSTs show features of epithelial and occasionally mesothelial differentiation. Ciliated cells resembling fallopian tube epithelium are present in

Fig. 14.10 Atypical proliferative (borderline) serous tumor. Fusion of surface papillae create a roman bridge or cribriform pattern

about one third of tumors. Hobnail-type cells may be present (\triangleright *Figs. 14.11* and \triangleright *14.13*) and occasionally the epithelium becomes attenuated and resembles mesothelium. In addition, cells with abundant eosinophilic cytoplasm and rounded nuclei, occasionally resembling mesothelial cells, may be present, particularly on the tips of the papillae. The nuclei of APSTs resemble those in cystadenomas but tend to display slightly more atypia. Nuclei are basally located and tend to be ovoid or rounded. The chromatin is usually fine and nucleoli are

Atypical proliferative (borderline) serous tumor. Numerous hobnail cells line papillae. Detached cell clusters are present

Fig. 14.12

Atypical proliferative (borderline) serous tumor. A micropapillary architecture is present in less than 10% of the tumor

occasionally prominent (**>** *Figs.* 14.14 and **>** 14.15). Mitoses are not common and rarely exceed four per ten high-power fields (HPF). Psammoma bodies are present in up to half of APSTs.

Occasionally, foci resembling noninvasive desmoplastic peritoneal implants (see **Noninvasive Peritoneal Implants** below) are found on the surfaces of the ovarian tumor. This has been referred to as "autoimplantation." Autoimplants are found on the ovarian surface or between exophytic surface papillae. They are multifocal in two thirds of cases and range from 0.1 to 2.5 cm in size. They have a well-delineated border

Fig. 14.13 Atypical proliferative (borderline) serous tumor. Hobnail cells with abundant eosinophilic cytoplasm are prominent

Fig. 14.14 Atypical proliferative (borderline) serous tumor. Small clusters of cells and small papillae appear detached from the larger papillae

with adjacent tissue. Microscopically they are identical to noninvasive desmoplastic implants. Infarcted tumor papillae are found in about one third of cases. In all advanced-stage cases, noninvasive desmoplastic peritoneal implants are present. Postulated mechanisms for the origin of this lesion include adhesion of the ovarian tumor to desmoplastic implants and infarction of tumor papillae [275]. The term "autoimplant" suggests that such lesions might arise by detachment of papillae from the tumor surface and subsequent reattachment back to itself, but there is no evidence for this phenomenon. This lesion has no known clinical significance.

Fig. 14.15 Atypical proliferative (borderline) serous tumor. There is mild cytologic atypia and small prominent nucleoli

Microinvasion Two distinct types of lesions have been designated "microinvasion" in APSTs. In most published reports, the two types have not been specifically distinguished or correlated with outcome.

Usual Type of Microinvasion (Eosinophilic Type) This type of microinvasion accounts for the vast majority of reported cases. It is characterized by isolated cells and small cell clusters with abundant eosinophilic cytoplasm that appear to be budding from the epithelium into the superficial stromal cores of the papillae (\bigcirc *Figs. 14.16–14.20*). The lesion must be smaller than 5 mm, and can be multiple. The true nature of these eosinophilic cells is not clear. In most cases, they do not evoke a host stromal response and they bear little resemblance to invasive carcinoma. We remain unconvinced that this lesion is a manifestation of invasive carcinoma.

When carefully sought, 10% of reported APSTs contain microinvasion; however, microinvasion was specifically noted in only 1.3% of reported APSTs up to 1999 [305]. However, two recent series suggest that microinvasion may be found in 25% of cases [126, 226], and in one study of APST with noninvasive implants, 56% had microinvasion [326]. A high proportion of APSTs diagnosed during pregnancy show microinvasion [210]. A recent study demonstrated a significant association of microinvasion with papillary infarction [160].

Microinvasive Carcinoma The second type of microinvasion occurs less commonly and is characterized by a haphazard infiltrative pattern of small solid nests of cells and micropapillae, often surrounded by a clear space

Fig. 14.16

Atypical proliferative (borderline) serous tumor with microinvasion. Single cells with abundant eosinophilic cytoplasm are present in the stroma. Note the similarity to eosinophilic cells on the surface of the papillae

and associated with an identifiable stromal response (i.e., desmoplasia; \bigcirc *Figs.* 14.20–14.23). Occasionally the nests display a cribriform pattern. This second pattern of invasion closely resembles primary ovarian invasive low-grade serous carcinomas as well as the peritoneal lesions that have been designated "invasive implants." Accordingly we refer to this second type of microinvasion as "microinvasive carcinoma," because the evidence, albeit limited, indicates that it is a manifestation

Atypical proliferative (borderline) serous tumor with

microinvasion. Eosinophilic cell clusters of about 3–12 cells are surrounded by a space. Compare to cluster of luteinized ovarian stromal cells in the center, which have paler cytoplasm and are not surrounded by a space

Fig. 14.19

Atypical proliferative (borderline) serous tumor with

microinvasion. Single eosinophilic cells and cell clusters in the stroma, adjacent to a noninvasive gland-like structure lined by similar eosinophilic cells with a hobnail pattern. Note psammomatous calcification in the stroma and within the epithelium

of true invasive carcinoma. To qualify as microinvasive carcinoma, the lesion should be smaller than 5 mm. Multiple foci are permitted.

Microinvasion has been associated with a higher frequency of bilaterality, exophytic growth, and peritoneal

■ Fig. 14.21 Atypical proliferative (borderline) serous tumor with microinvasive carcinoma. Small papillae on the *right side* are surrounded by spaces and display an infiltrative pattern

implants [262]. Recent evidence suggests that the identification of microinvasion or microinvasive carcinoma is a clue that further sampling might disclose more extensive invasion. A minimum of two sections per centimeter of maximum tumor diameter are needed to maximize detection of occult invasion [303].

The clear space surrounding most nests and micropapillae, and occasionally surrounding single cells

Atypical proliferative (borderline) serous tumor with

microinvasive carcinoma. A large papilla occupies the *right* half of the photograph and contains both micropapillae and macropapillae surrounded by spaces and display an infiltrative pattern. This focus is about 5 mm, and is therefore at the boundary between APST with microinvasive carcinoma and invasive low-grade serous carcinoma

■ Fig. 14.23 Atypical proliferative (borderline) serous tumor with microinvasive carcinoma. Invasive papillae of varying sizes, from micropapillae surrounded by spaces on the *right* side, to a single macropapillae on the *left*

and small clusters, have generally been considered artifactual due to tissue retraction. However, recent work using a lymphatic endothelium-specific antibody, D2-40, has demonstrated that many of these spaces represent lymphatics and therefore lymphatic invasion [289]. Among 20 SBT (19 APST and 1 noninvasive MPSC) with microinvasion, 60% had lymphatic invasion as compared to none of 20 (18 APST and 2 noninvasive MPSC) without microinvasion. In this study, lymphatic invasion correlated with microinvasion but not with age, stage, autoimplantation, micropapillary architecture, or pattern/extent of microinvasion.

Clinical Behavior and Treatment A review of 94 patients with microinvasion reported up to 1999 showed 100% survival [305]. More recently, Longacre and associates found that microinvasion was a significant predictor of survival on univariate but not multivariate analysis [190, 210]. Although more data are needed, from the standpoint of prognosis and patient management, microinvasion does not appear to have any clinical relevance. On the other hand, limited data suggest that microinvasive carcinoma is associated with a higher risk of recurrence [210]. Whether or not staging is needed for a woman with microinvasive carcinoma is unclear. There are no data at present suggesting that follow-up or any treatment will influence recurrence or survival.

Associated Peritoneal Lesions: Endosalpingiosis and "Implants" APSTs are often associated with serous lesions involving the peritoneum. Endosalpingiosis, or benign glandular inclusions, are found in 40% of patients. At present, 40% of reported APSTs are associated with peritoneal implants in contrast to 25% in the pre-1980 literature [305]. However, in population-based and hospital-based material, the figure is closer to 10–20% [17, 68, 252, 380], suggesting a referral bias to large specialized centers in favor of tumors with implants as compared to those without. In the Stanford study, 59% had implants [190]. Among those with implants, about three fourths were noninvasive, and one fourth were invasive. It is important to note that the origin of peritoneal "implants" is unknown and the purported mechanism of "detachment and implantation" is an assumption (see > Pathogenesis of Peritoneal Implants below).

Endosalpingiosis Endosalpingiosis, or benign glandular inclusions, may involve the peritoneal surfaces in patients with or without benign or malignant serous ovarian tumors (see **O** Chap. 13, Diseases of the Peritoneum). These glands typically are lined by simple columnar epithelium, often displaying tubal-type differentiation. The epithelium may display minor degrees of cytologic atypia and form simple papillary structures [209] (**O** *Fig. 14.24*); psammoma bodies are sometimes present

and may persist after degeneration of the associated epithelial structures. Mitotic figures are absent.

Noninvasive Peritoneal Implants Among women with APSTs, 31% (78% of all patients with implants) have peritoneal epithelial lesions that display a degree of proliferation beyond that usually seen in endosalpingiosis, but that lack features of invasion. These have been designated "noninvasive implants" and have two morphological forms: epithelial and desmoplastic. Some patients have both types of noninvasive implants.

Epithelial implants are papillary and resemble the ovarian APST to some extent (\bigcirc *Figs.* 14.25–14.29). The cores of the papillae have fibrovascular support, and the epithelial cells resemble those in endosalpingiosis. Thus, mild atypia is often present, but mitoses are usually absent (\bigcirc *Figs.* 14.28 and \bigcirc 14.29). Calcification in the form of psammoma bodies is common and frequently is extensive (\bigcirc *Figs.* 14.25–14.26). This type of implant often resembles a mucosal lesion of the fallopian tube that has been termed "salpingolith," which is characterized by psammomatous calcification surrounded by a single layer of tubal-type epithelium. Salpingoliths are found in 51% of advanced-stage APST/MPSC as compared to 24% of stage I cases [309]. Their significance is unknown (see \bigcirc Chap. 11, Diseases of the Fallopian Tube).

The desmoplastic noninvasive implant is a plaque-like thickening overlying peritoneal surfaces and may extend into the septae that separate omental lobules creating a low-power appearance that suggests invasion (\triangleright *Figs.* 14.30 and \triangleright 14.31). These implants display an exuberant fibroblastic proliferation in which gland-like

Fig. 14.25

Noninvasive epithelial implant (implant). Papillary structures on the surface of the peritoneum and also within clefts of peritoneum

Fig. 14.26 Noninvasive epithelial implant (implant). Psammoma bodies and chronic inflammation are present; there is no invasion of underlying tissue

or papillary structures lined by epithelial cells are present. Psammoma bodies are usually present. The epithelium typically shows minimal and occasionally more marked cytologic atypia (\bigcirc *Figs.* 14.32–14.34). The fibroblastic proliferation often has a granulation tissue-like appearance characterized by edematous fascicles of plump fibroblasts, often with interspersed small vascular channels (\bigcirc *Figs.* 14.31 and \bigcirc 14.32). Typically, the cells forming the gland-like structures merge with the surrounding fibroblasts, which surround the glands, making

Noninvasive epithelial implant (implant). An adhesion on the uterine serosa is lined by mesothelial cells and displays surface papillae. Note psammoma bodies, chronic inflammation, and absence of invasion of underlying tissue

• Fig. 14.29 Noninvasive epithelial implant (implant). Mild cytologic atypia and small prominent nucleoli are present

Fig. 14.28 Noninvasive epithelial implant (implant). Papillae resembling primary ovarian atypical proliferative serous tumor

distinction between the two cell populations difficult at times, reminiscent of a reactive mesothelial proliferation (\bigcirc *Fig.* 14.32). The gland-like structures tend to be parallel to one another and can appear parallel or perpendicular to the peritoneal surface (\bigcirc *Figs.* 14.30 and \bigcirc 14.31). Notably, desmoplastic implants bear little resemblance to the associated ovarian tumor, suggesting that they arise in situ and reflect a reactive mesothelial process. Scattered cells with abundant eosinophilic cytoplasm may be seen in the stroma (\bigcirc *Fig.* 14.34). These resemble the eosinophilic

cells of the usual type of microinvasion (see above). Previously, some experts had considered this a reflection of early invasion, but these cells do not appear to alter prognosis and therefore are considered part of the desmoplastic noninvasive implant [25]. Mitotic figures are usually absent, and psammoma bodies are present in over 90% of cases.

Noninvasive desmoplastic implant (implant). Low power view showing a plaque-like lesion with granulation tissue and an acute inflammatory exudate. Note gland-like structures at the top of the field are oriented parallel to the surface

Fig. 14.33

Noninvasive desmoplastic implant (implant). The cells lining the gland-like spaces display abundant eosinophilic cytoplasm and mild cytologic atypia

Fig. 14.32

Noninvasive desmoplastic implant (implant). The gland-like structures are surrounded by a granulation tissue-like stroma

Inflammation is frequent in implants of all types. In noninvasive desmoplastic implants, chronic inflammation is nearly always present (\bigcirc *Figs.* 14.30 and \bigcirc 14.34), and in 20% of cases, an acute inflammatory exudate overlies the implant (\bigcirc *Fig.* 14.31). Salpingitis is associated with 60% of APST and noninvasive MPSC and is not stage-dependent. The presence and type of inflammation in the implants do not seem to correlate with the presence and type of salpingitis [309].

Noninvasive desmoplastic implant (implant). Single cells with abundant eosinophilic cytoplasm are in the stroma. This is not indicative of invasion. Note the inflamed and edematous stroma

Invasive Peritoneal Implants Among patients with APST or noninvasive MPSC, 9% (22% of those with implants) have invasive implants. In a population-based study from Canada, 12% of stage III patients had invasive implants [105]. About three fourths of patients with invasive implants have noninvasive MPSC; the finding of invasive implants with APST is very unusual and warrants

further sampling of the ovarian tumor to identify occult areas of MPSC or invasion (**>** *Table 14.12*).

The characteristic architectural feature of an invasive implant is a haphazard infiltrative growth pattern (\bigcirc *Figs.* 14.35–14.38). A confluent or cribriform glandular pattern may be present. An exophytic pattern is not uncommon (\bigcirc *Fig.* 14.39) and usually displays a

 $^{a}p < 0.0001$ (chi square). Modified from [311]. micropapillary pattern. Typically, micropapillae are haphazardly arranged and small solid nests of cells embedded in fibrous stroma and surrounded by a clear space or cleft are present (\bigcirc *Figs.* 14.35 and \bigcirc 14.40). Sometimes, micropapillae are present within glands, and may appear to fuse with one another to create a web-like appearance (\bigcirc *Fig.* 14.41). Invasive implants often display only mild cytologic atypia (\bigcirc *Fig.* 14.40), but occasionally atypia is moderate. If severe atypia is present, high-grade serous

carcinoma should be diagnosed. Mitotic figures are occasionally present.

The distinction of noninvasive desmoplastic implants from invasive low-grade serous carcinoma (invasive implants) may be very difficult at times, but is important since it is this feature that is the best predictor of outcome for tumors with extraovarian disease. Useful features that

Fig. 14.41
Metastatic low grade serous carcinoma (invasive implant).
Complex, confluent pattern creates a web-like appearance

distinguish invasive from noninvasive desmoplastic implants are summarized in \bigcirc *Table 14.13*. A helpful feature in distinguishing a desmoplastic noninvasive implant from an invasive implant is that the fibroblastic reaction associated with the noninvasive implant is generally much more extensive than the gland-like proliferation, which tends to be sparse (\bigcirc *Figs. 14.30* and \bigcirc *14.31*); this creates an appearance suggestive of sclerosing peritonitis with florid reactive mesothelial proliferation. In contrast, the

Table 14.13

Morphologic features distinguishing invasive from noninvasive peritoneal implants

		Noninvasive implants		
Feature	Invasive implants	Desmoplastic	Epithelial	
Growth pattern	Haphazard infiltration	Orderly arrangement	Exophytic or in submesothelial invaginations beneath the peritoneal surface	
	High ratio of epithelium to stroma	Low ratio of epithelium to stroma		
Epithelial component	Small rounded nests containing serous and mesothelial-type cells with high nuclear: cytoplasmic ratio, surrounded by a clear space	Irregular gland-like structures lined by one or two layers of nondescript epithelial and mesothelial-type cells, often with abundant eosinophilic cytoplasm	Papillary structures with thick papillae displaying a hierarchical pattern similar to primary ovarian APST	
	Endophytic micropapillae displaying a confluent pattern	The lining epithelial cells of the gland-like structures often appear to merge with the surrounding stromal cells		
	Exophytic micropapillae resembling MPSC of the ovary			
Stromal component	Loose or dense fibrous tissue	Frequent appearance of granulation tissue	No stromal reaction	
Psammoma bodies	Generally infrequent and sparse, but may at times be extensive	Frequent and can be extensive	Frequent	
Cytologic atypia	Generally mild to moderate	Mild to moderate	Mild to moderate	
Inflammation	Generally minimal	Frequent and occasionally marked; fibrinopurulent exudate may be present	Minimal	

MPSC, micropapillary serous carcinoma; APST, atypical proliferative serous tumor.

ratio of epithelium to stroma is much higher in the invasive implant (**)** *Fig. 14.35*). At times, the gland-like structures are more crowded, but the proliferation lacks the haphazard infiltrative pattern of carcinoma. It has been suggested that a small implant without underlying tissue be classified as noninvasive based on the assumption that it had been easily removed [24, 105]. There are no data to support this view.

At the 2006 annual meeting of the International Society of Gynecological Pathologists, five experts independently classified implants from photomicrographs. Despite prior concerns about the reproducibility of implant subclassification, the high level of interobserver agreement confirmed the accuracy of the diagnostic criteria. The critical issue for the general pathologist is recognition of the noninvasive desmoplastic implant. This type of implant has a very specific appearance as discussed and illustrated above, and once this is recognized, the noninvasive epithelial implants are easily recognized as noninvasive and the invasive implants as carcinoma. A study in which implants designated as invasive were associated with a 65% recurrence rate compared with a recurrence rate of 14% for implants designated as noninvasive confirmed that the presence of individual cells within the stroma was not helpful in separating invasive from noninvasive implants [25]. That study found that the vast majority of invasive implants could be identified in the absence of overt invasion of underlying normal tissue and yet still accurately predict poor outcome. Features found to be useful in diagnosing these lesions in the absence of invasion were the presence of solid nests surrounded by a clear space or cleft, or micropapillae sometimes displaying a confluent arrangement.

Pathogenesis of Peritoneal Implants The pathogenesis of the peritoneal lesions associated with APSTs and noninvasive MPSCs is unknown. As noninvasive epithelial implants to some degree resemble the ovarian tumors, these are the ones most likely to arise by the detachment–implantation mechanism, although

evidence for this is only circumstantial. In contrast, noninvasive desmoplastic implants more closelv resemble a reactive mesothelial process, and are likely to be independent of the primary ovarian tumor. Molecular data are conflicting in resolving whether noninvasive implants represent independent primary peritoneal lesions or arise from exfoliation or detachment from the ovarian tumor with subsequent attachment to the peritoneal surface. Molecular analysis of implants associated with APSTs or noninvasive MPSCs is particularly challenging because the lesions may be quite small, isolation of epithelial cells within highly desmoplastic stroma requires relatively sophisticated and laborious techniques such as laser capture microdissection, and proper histological classification of implant type (invasive versus noninvasive versus endosalpingiosis) is essential for reaching meaningful conclusions [319]. PCRbased assays for loss of heterozygosity and nonrandom X-chromosome inactivation patterns have been used to assess the clonal relationships of APSTs with associated invasive and noninvasive implants, but the studies were based on very few cases, particularly of invasive implants, and reached different conclusions about the clonal relationship of the implants to the ovarian APST [112, 192, 322]. Analysis of shared KRAS mutations in APSTs and associated implants concluded that most implants are probably derived from the ovarian tumor, but that some may reflect multifocal origin [74]. Details regarding the nature of the implants studied were not provided. Clearly, additional molecular analysis of greater numbers of carefully classified and microdissected implants will be necessary to definitively address this issue.

Invasive implants are rare, and bona fide invasive implants reflect peritoneal metastases of MPSCs (some with undetected occult invasion) or, less likely, independent primary peritoneal serous carcinomas. Since MPSCs are often exophytic, even in the absence of invasion malignant cells can be shed from the surface of the tumor and implant on peritoneal surfaces. The Borderline Ovarian Tumor Conference participants agreed that the terms invasive implants and invasive carcinoma are synonymous [310].

Lymph Nodes Forty five percent of patients with APST/ noninvasive MPSC, in whom lymph nodes are examined, have nodal endosalpingiosis, in comparison to about 10% of women who have nodes removed for other reasons. Up to 42% of these patients have nodes containing serous lesions with proliferative features beyond endosalpingiosis. The mean number of involved nodes is three, and nearly half of patients have at least one node with diffuse involvement. There is a strong association with invasive peritoneal implants [209] and micropapillary architecture [51]. In the Stanford series [209], 42% of patients with APST and lymph node resection had lymph node lesions, but this is likely an overestimate due to consultation bias and may also be related to the higher frequency of node sampling in patients with peritoneal implants. In a recent study from Korea, noninvasive MPSCs were significantly more likely to have lymph node lesions as compared to APSTs (p = 0.037, Fisher's exact test) [51].

Proliferative serous lesions have been reported in over 100 cases of APSTs [51, 209, 226, 305]. Although these lesions have been referred to as "metastases," it is preferable to refer to them as "associated serous lesions in lymph nodes" or "lymph node involvement," as they may or may not be related to the ovarian tumor.

Lymph node lesions apart from endosalpingiosis can be divided into two types. One is characterized by individual cells and clusters of cells with abundant eosinophilic cytoplasm in the sinuses, predominantly subcapsular sinuses (\bigcirc *Fig.* 14.42). The nature of these cells is unclear, but it has been suggested that some of them may be mesothelial in origin. When associated with simple papillae with serous features, they are not mesothelial and correspond to "individual cells, cell clusters and simple papillae" as described in the Stanford series [209]. Cells with abundant eosinophilic cytoplasm are nearly always present on the surface of primary APSTs, and are often present in the stroma of noninvasive desmoplastic implants. It is plausible that these cells exfoliate and are

Fig. 14.42 Lymph node lesion associated with atypical proliferative serous tumor. Single eosinophilic cells and cell clusters are seen in a subcapsular sinus

filtered from the peritoneal fluid by regional lymph nodes – so-called deportation.

The second type of lymph node lesion is characterized by glandular inclusions and papillary serous structures, usually within or just beneath the capsule of the lymph node, that resemble the ovarian APST (\bigcirc *Figs.* 14.43 and \bigcirc 14.44). The majority of these papillary serous lesions are also associated with endosalpingiosis in the same lymph node [226]. Cytologic atypia is mild or moderate and mitotic figures are rarely seen. The observation of papillary proliferations arising within endosalpingiosis, and the rare reports of APSTs and carcinomas arising within lymph nodes from endosalpingiosis suggest an independent origin of this second type of lymph node lesion. Bona fide metastatic low-grade serous carcinoma typically displays numerous papillae packing the sinuses or with a haphazard pattern (\bigcirc *Figs.* 14.45 and \bigcirc 14.46).

■ Fig. 14.43 Lymph node lesion associated with atypical proliferative serous tumor. Note detachment of cell clusters at the tips of papillae as occurs in the primary atypical proliferative serous tumor

Fig. 14.44 Lymph node lesion associated with atypical proliferative serous tumor. There is an admixture of endosalpingiosis and papillary structures resembling a noninvasive implant

Fig. 14.46
Lymph node with metastatic low-grade serous carcinoma.
Some of the papillae are thin and elongated, resembling the primary ovarian invasive micropapillary serous carcinoma

In the 2006 Stanford series, 8 of 31 patients (26%) with lymph node involvement had invasive peritoneal implants. Among 22 patients with follow-up, 4 were alive with disease and there were two deaths, one of a patient with indeterminate peritoneal implants. The presence of nodular aggregates of cells in the nodes was found to be an adverse prognostic factor.

Immunohistochemistry

Limited data on the immunohistochemistry of APSTs indicate that they are positive for CK7 and OC-125. About half the cases are positive for Leu M1. Focal positivity for CK20 is seen in a small minority of cases. WT1 is weakly positive [385]. Most cases express estrogen and progesterone receptors. They are also positive for other epithelial markers including EMA and cytokeratins. Patchy nuclear staining for p53 may occur, but such positivity does not correlate strongly with p53 mutation [328].

There are few studies examining the immunostaining of peritoneal implants. Lee and associates found that invasive implants and metastatic carcinoma show loss of calretinin-positive mesothelial cells and CD-34-positive fibroblasts, while they were preserved in noninvasive implants. Smooth muscle actin-positive myofibroblasts were present in both invasive and noninvasive implants [176].

Differential Diagnosis

Most papillary neoplasms in the ovary that are not serous cystadenomas or APSTs are obviously malignant, and are discussed below ("Malignant serous tumors, differential diagnosis"). Benign epithelial neoplasms that may display a papillary pattern resembling APST include atypical proliferative seromucinous tumor (APSMT; müllerian or endocervical-like type mucinous tumor) and atypical proliferative endometrioid tumor. These tumors are discussed in their respective sections below.

The distinction of a serous cystadenoma from an APST is not of major importance because both lesions are biologically benign. More importantly, the distinction of a noninvasive MPSC from an APST separates benign from a malignant neoplasm. Either a 5 mm confluent area or 10% of the tumor displaying micropapillary growth is required for a diagnosis of noninvasive MPSC (see "Malignant serous tumors" below).

Intraoperative Consultation Low-grade serous neoplasms are heterogeneous, and carcinomas nearly always have benign-appearing areas resembling a cystadenoma or an APST. It should therefore come as no surprise that

approximately 20–30% of ovarian tumors diagnosed as atypical proliferative ("borderline") at the time of frozen section examination prove to be carcinomas on further sampling. Accordingly, it is important that the surgeon perform a thorough exploration when the frozen section is diagnosed as an APST. Since only 15% of unilateral tumors are associated with extraovarian disease, formal staging is probably not necessary for a unilateral ovarian tumor unless suspicious peritoneal lesions are found. In contrast, 56% of bilateral tumors are associated with extraovarian disease and therefore staging in this setting is advisable.

Clinical Behavior and Treatment

In six prospective randomized trials including 373 patients with SBTs followed for a mean of 6.7 years, the survival was 100% [305], and large studies, some populationbased, in the United States, Korea, and Sweden show a 10-year survival of 96-100% [5, 65, 160, 252, 320]. The disease-specific survival rate of patients with SBTs (APSTs and noninvasive MPSCs) confined to the ovaries after a mean of approximately 6.7 years, based on over 2,000 reported cases, exceeds 99.5% [305]. Essentially all fatal cases have been shown to have not been comprehensively staged or sufficiently sampled. If patients with invasive implants (carcinoma) or indeterminate implants (histologically indeterminate or slides unavailable) are excluded, then the overall survival for patients with lymph node lesions other than endosalpingiosis is 98-99% [51, 76, 209, 305]. The survival for patients with microinvasion or microinvasive carcinoma unassociated with invasive implants is 100% [305].

The behavior of SBTs with extraovarian lesions is based on the type of implants that are present. In the older literature, survival for SBTs with peritoneal implants ranged from 70% to 90%. Now, after excluding noninvasive MPSCs, nontumor deaths, and invasive peritoneal implants, it is clear that the survival rate of patients with APSTs with noninvasive implants approaches 100% after a mean follow-up of 7.4 years [305]. Recurrences and deaths reported in the literature are poorly documented in the majority of cases. When carefully documented, most deaths are either treatment-related or are the result of complications from adhesions and bowel obstruction rather than carcinoma [169]. A literature review of over 18,000 borderline tumors, which included over 4,000 SBTs with clinical follow-up, failed to identify a single welldocumented case of an SBT with noninvasive peritoneal implants, whose primary ovarian tumor had been adequately sampled to exclude invasion (at that time, one section per centimeter of maximum tumor diameter)

that had progressed to documented invasive carcinoma. Among 27 published cases that reportedly progressed to invasive carcinoma, none were documented to have been adequately sampled for pathological examination [305]. Since that review, progression to invasive low-grade serous carcinoma has been reported in a few additional cases; however, these reports suffer from the same problems associated with older reports of fatalities including completeness of staging and extent of histological sampling [190, 326].

In general, the noninvasive serous tumors, SBTs, associated with invasive implants are noninvasive MPSCs, not APSTs. Based on a literature review of 467 noninvasive serous tumors, which included both invasive and noninvasive implants, the survival rate for patients with invasive implants was 66% after a mean follow-up of 7.4 years, compared to 95% for patients with noninvasive implants (p < 0.0001) [305]. The survival rate for patients with invasive implants is similar to that for patients with invasive low-grade (micropapillary) serous carcinoma [103].

Except for patients with invasive implants, conservative treatment, i.e., cystectomy or unilateral salpingooophorectomy, is sufficient therapy. Many women have had successful pregnancies after such treatment. Even though many women with APST have not had formal staging, if the primary tumor has been adequately sampled and there is no evidence of invasion or a micropapillary pattern (see "Micropapillary serous carcinoma" below), it is probably unnecessary to go back and do formal staging, although data addressing this question are scant. Limited data suggest that chemotherapy is of little, if any, value and may be detrimental [169]. For women with invasive peritoneal implants, i.e., low-grade serous carcinoma, there are insufficient data on upfront treatment for evaluation, but limited data suggest that surgery but not chemotherapy is of value after recurrence [34].

Low-Grade Serous Carcinoma; Micropapillary Serous Carcinoma, Invasive and Noninvasive Types; Micropapillary Serous Borderline Tumor; Psammocarcinoma

In 1996, it was observed that a characteristic micropapillary pattern in SBTs was associated with invasive implants and a worse prognosis than typical SBTs [37, 304]. Despite the lack of demonstrable invasion, these tumors behaved like low-grade carcinomas in contrast to the other tumors in this group that had nearly 100% survival. It was therefore proposed that they be designated MPSC [304]. The term "micropapillary serous

carcinoma" has been accepted by the WHO since 2000 [90]. Others have preferred the term "micropapillary serous borderline tumor" [310].

Unfortunately, the term MPSC has been used for two morphologically distinct, albeit related, entities and this has caused some confusion among clinicians [311]. The noninvasive form of MPSC is a variant of serous borderline tumor. The invasive form of MPSC has been classified as well-differentiated serous carcinoma. Thus, invasive MPSC is synonymous with low-grade serous carcinoma [103].

There are several possible explanations for the low-grade malignant behavior of a noninvasive tumor. MPSCs that do not display destructive infiltrative growth are morphologically noninvasive, but it is conceivable that the complex exophytic micropapillary pattern may be a form of invasion. Occult invasion may be missed due to sampling factors. Alternatively, it is possible that the exophytic micropapillary pattern is a form of intraepithelial carcinoma, or "carcinoma in situ," which, when exposed to the peritoneum, may exfoliate malignant cells which implant on peritoneal surfaces and subsequently invade. Any one of these explanations would account for the strong association of this pattern with invasive implants (metastatic carcinoma). When areas of stromal invasion exceeding 5 mm (the size limit for microinvasion; see **>** Microinvasion above) are present, the neoplasm is interpreted as the invasive form of MPSC and is also referred to as low-grade serous carcinoma.

Noninvasive MPSCs comprise 14% of SBTs in consultation-based material; 10% in stage I and 19% in advanced stage. In a population-based study from Canada, Gilks et al. found that 26% of advanced-stage SBTs were noninvasive MPSCs [105]. Invasive MPSCs are quite uncommon and comprise only 4% of ovarian carcinomas and 6% of serous carcinomas (> Table 14.4); 6–9% of advanced stage serous carcinomas are invasive MPSCs [103, 106, 300].

Clinical Findings The mean age of patients with the noninvasive form of MPSC is 42 years, the invasive form 45, and the psammomatous variant (psammocarcinoma) 54. The most common presentation is an asymptomatic pelvic mass, but abdominal pain, fullness, or distention are common symptoms in advanced stage [331].

Operative Findings For noninvasive MPSC, two thirds are bilateral as compared to only one third with APST. Half of patients are stage I and the remainder are stages II and III. For invasive MPSC, 80–90% are bilateral and 94%

are advanced stage [103, 331]. Bilateral tumors and those with an exophytic component are more likely to be associated with advanced-stage disease; 74% of intracystic tumors are advanced stage as compared to nearly all of those with exophytic tumors [331]. The psammomatous variant of invasive MPSC is more likely to be primary in the peritoneum.

Gross Findings The mean tumor size for the noninvasive form is about 8 cm, and for the invasive form about 11 cm [303, 331]. Surface involvement is present in 54% of cases (**)** *Figs. 14.2* and **)** *14.3*). As these tumors are very well differentiated, they tend to have a more papillary and cystic gross appearance like APSTs, and little if any necrosis, in contrast to many typical high-grade serous carcinomas, which often have solid areas and extensive necrosis. Bilaterality, exophytic growth, and peritoneal implants are more common with noninvasive MPSCs as compared to APST [70, 262]. The psammomatous variant is more likely to adhere to and invade the myometrium via the uterine serosa.

Microscopic Findings Noninvasive MPSC is a proliferating serous neoplasm that displays a high degree of epithelial proliferation and complexity but is noninvasive. The tumor displays a characteristic pattern of papillary branching (**>** *Figs.* 14.47-14.52). The distal papillary branches are thin and delicate with minimal fibrovascular support, and emanate abruptly from thick, more centrally located papillae without intervening branches of successive intermediate sizes, unlike the hierarchical branching pattern of APSTs (\bigcirc *Figs.* 14.47 and \bigcirc 14.48). When the papillae fuse, a cribriform pattern or a roman bridge-like pattern results on the surfaces of the large papillae (\bigcirc *Figs.* 14.49 and \bigcirc 14.50). Both micropapillary and cribriform patterns may be present (\bigcirc *Fig.* 14.51). A 5 mm diameter area of a confluent micropapillary pattern [310], or 10% of the tumor occupied by the micropapillary pattern [190, 276] is required for the

Fig. 14.48

diagnosis. The majority of noninvasive MPSCs have areas of typical APST [304, 330, 331] in contrast to only 2% of high-grade serous carcinoma [103]. In cases associated with metastases (invasive implants), invasion has been found in the primary tumor after exhaustive histologic sampling [303].

Noninvasive MPSC displays no invasion of the stromal cores of the papillae. Invasion in MPSC is recognized by haphazard infiltrative growth composed of solid nests or

complex gland-like structures displaying micropapillae (**)** *Figs. 14.53–14.59*). The nests and gland-like structures are often surrounded by a clear space or cleft. Psammoma bodies are common. The psammomatous variant of invasive MPSC, so-called psammocarcinoma, is characterized by a myriad of psammoma bodies occupying >75% of the papillae (**)** *Fig. 14.60*). An uncommon pattern of invasion designated "macropapillary" is characterized by large papillae invading the stroma, also surrounded by clear

Invasive micropapillary serous carcinoma. This tumor displays a spectrum of proliferation from areas resembling serous cystadenoma and atypical proliferative serous tumor with focal micropapillary features on the *left*, and invasive low-grade serous carcinoma on the *right*

spaces [390] (\diamond *Figs. 14.22* and \diamond *14.23*). The nature of these clefts is unknown, but as noted earlier, some probably reflect lymphatic spaces. Intratumoral lymphatic invasion is seen in about one third of cases [289]. It has also been suggested that the spaces are generated by the contraction of stromal myofibroblasts, particularly in peritoneal implants [176].

Fig. 14.57 Metastatic micropapillary serous carcinoma (invasive implant). Haphazard infiltrative pattern of glands and nests within the omentum. Fibrosis and psammoma bodies are present

MPSCs with or without invasion display similar cytologic features. Cells tend to be rounded with scant cytoplasm, and there is mild or moderate nuclear atypia, often with prominent small nucleoli (\bigcirc *Figs.* 14.50 and \bigcirc 14.52). These cytologic features differ somewhat from APST; however the mean nuclear area appears to be similar in both groups [132]. The cells in APSTs tend to be

Fig. 14.59 Metastatic micropapillary serous carcinoma. Complex micropapillary pattern involves the peritoneal surfaces

columnar, are often ciliated, and have less nuclear atypia. Mitotic activity tends to be low. Severe nuclear atypia warrants a designation of high-grade serous carcinoma even in the absence of overt invasion.

The peritoneal implants associated with MPSC are frequently invasive (i.e., carcinoma). Among 157 reported cases of advanced-stage noninvasive MPSC, 45% of the implants were invasive, in comparison to 7% of the implants associated with APSTs (p < 0.0001; **Table 14.12**). Noninvasive MPSCs also are more likely to be associated with serous lesions in lymph nodes that

replace the node parenchyma, supporting the view that these are invasive carcinomas with metastatic potential [51] (see ● Low Grade Serous Tumors Atypical Proliferative Serous Tumor (APST); Serous Borderline Tumor (SBT); ● Lymph Nodes).

Immunohistochemistry There are few published data on the immunohistochemistry of MPSC. p53 is usually negative but can be focally positive in up to 43% [237, 381]. However, only strong diffuse nuclear p53 positivity correlates with missense *TP53* mutation [328]. WT1 is usually positive (nuclear staining) [237]. ER and PR show nuclear positivity in about 50%, significantly more often than in high-grade serous carcinomas [381]. EMA, cytokeratin 7, and CA125 are also positive, with EMA showing membranous staining and the other two a cytoplasmic pattern of staining.

Differential Diagnosis A 5 mm diameter area of confluent micropapillary architecture distinguishes noninvasive MPSCs from APSTs, which often have scattered small foci of a micropapillary pattern. Ten percent of the tumor displaying the micropapillary pattern is also a valid cutoff [190, 276]. Either criterion can be used, as it is rare for less than 5 mm of confluent micropapillary growth to be more than 10% of the tumor [190]. Anything less than this, in the absence of other features of invasion, should be classified as an APST. The distinguishing morphologic features of serous neoplasms, including the invasive and noninvasive variants of MPSC, are shown in **>** *Table 14.14*.

Table 14.14

Distinguishing morphologic features of serous ovarian neoplasms

Diagnosis	Atypia	Stratification and detachment	Micropapillary pattern	Stromal invasion
Serous cystadenoma	Absent, or present in <10%	Absent, or present in <10%	Absent	Absent
APST	Present in $\geq 10\%$	Present in $\geq 10\%$	May be present, <5 mm of confluence	Absent
MPSC, noninvasive	Present	Usually present	Present, \geq 5 mm of confluence	Absent
MPSC, invasive	Present	Usually present	Present	Present

Development of low grade (micropapillary) serous carcinoma

Fig. 14.61 Schematic of the pathogenesis of low-grade serous carcinoma. Modified from reference [328]

Molecular Biology Activating mutations in KRAS and one of its downstream effectors, BRAF, have been identified in a variety of human cancers and mutations of either KRAS or BRAF lead to constitutive activation of MAPK signaling [371]. Molecular genetic studies have highlighted the importance of the Ras/Raf/MEK/MAPK signaling pathway in the pathogenesis of low-grade ovarian serous carcinomas. Frequent KRAS mutations in APST/serous borderline tumors were first reported by Mok and colleagues [225]. Several subsequent studies verified the original finding and further demonstrated that mutations in KRAS and BRAF characterize both APSTs and low-grade serous carcinomas [203, 323, 327]. Specifically, activating mutations in codon 12 and less commonly in codon 13 of KRAS or in codon 600 of BRAF occur in approximately two thirds of APSTs and low-grade serous carcinomas. Mutations in KRAS and

BRAF are mutually exclusive insofar as tumors with mutant KRAS do not have mutant BRAF and vice versa. Furthermore, a 12 bp insertion mutation of ERBB2 (HER2/neu), which activates an upstream regulator of K-Ras, has been found in 9% of APSTs and these mutations are only observed in tumors lacking mutant KRAS and BRAF [231]. These studies illustrate how different mutational defects can serve to deregulate the same signaling pathway in cancer cells. In contrast to APSTs and lowgrade serous carcinomas, KRAS and BRAF mutations are very uncommon in high-grade serous carcinomas [327]. Collectively these data indicate that KRAS and BRAF mutations are largely confined to low-grade serous carcinomas and APSTs and suggest that APSTs are likely precursors of low-grade serous carcinomas, but not the more common high-grade serous carcinomas (> Fig. 14.61). KRAS and BRAF mutations are lacking in isolated serous

cystadenomas, putative precursors of APSTs [54]. However, identical *KRAS* or *BRAF* mutations have been detected the APSTs and adjacent cystadenoma epithelium in serous cystadenomas associated with small APSTs [125]. These findings suggest that mutations of *KRAS* and *BRAF* are early events associated with serous tumor initiation and that a small subset of serous cystadenomas that acquire *KRAS* or *BRAF* mutations may progress to APST. Perhaps, not surprisingly, *TP53* mutations are uncommon in low-grade serous carcinomas and APSTs [328].

Overall, 70-80% of low-grade serous carcinomas and APSTs express active MAPK [131]. Activated MAPK signaling has been observed in a substantial fraction (41%) of high-grade serous carcinomas as well [131], presumably through mechanisms other than activating mutations of KRAS and BRAF, such as mutation of NF1, which is mutated in over 20% of these tumors [288]. Nf1 acts as a Ras-GTPase activating protein (Ras-GAP), which catalyzes hydrolysis of Ras-GTP to Ras-GDP, with resultant downregulation of downstream signaling through Raf, Ral/Cdc42, PLC, and PI3K. These findings are likely to have therapeutic relevance in the near term. Although published studies on the response of low-grade serous carcinomas to traditional chemotherapy are few, some investigators have noted poor response of low-grade (micropapillary) serous carcinomas to platinum-based therapeutic regimens [34, 331]. A number of anticancer agents targeting the Ras/Raf/MEK/ERK pathway are being developed and a few have been tested in clinical trials [379]. Molecularly targeted agents may provide an effective alternative or adjunct to platinum/taxane-based chemotherapy for low-grade serous carcinomas or for treatment of platinum-resistant high-grade serous carcinomas with activated MAPK signaling.

In contrast to high-grade serous carcinoma, discrete regions of chromosomal gains have not been reproducibly detected in low-grade serous carcinoma or its putative precursor lesion, APST. However, based on studies using a limited number of polymorphic markers, a few subchromosomal regions (e.g., 1p and 9q) show frequent deletion in low-grade serous neoplasms [161]. In a recent study using high-density SNP arrays to assess DNA copy number changes in tumor cells isolated from affinity purified borderline, low-grade, and high-grade serous ovarian neoplasms, Kuo and colleagues identified frequent allelic deletions of 1p36 and 9p21 in low-grade serous carcinomas, but not in serous borderline tumors. The 1p36 region contains several candidate tumor suppressors, including miR-34a, which encodes a p53regulated microRNA that mimics p53's effects on growth arrest and apoptosis. 9p21 harbors the *CDKN2A* locus, which encodes p16, p15, and p14 (Arf) [27, 164].

Clinical Behavior and Treatment Despite the absence of destructive infiltrative growth in the noninvasive variant of MPSC, the data indicate that it behaves as a low-grade serous carcinoma [51, 70, 80, 108, 190, 262, 304, 330, 331]. Stage I noninvasive MPSC appears to be cured by adnexectomy alone. Since the disease-specific survival for >2,000 stage I SBTs was 99.5% prior to the separation of APST from noninvasive MPSC [305], and 10% of these are expected to be MPSCs, it is reasonable to conclude that stage I noninvasive MPSC has virtually 100% survival as well [311, 331]. In contrast to noninvasive MPSCs, invasive MPSCs are rarely stage I. The 5- and 10-year survival rates for patients with advanced-stage noninvasive MPSC are approximately 75-85% and 40-60%, respectively. After recurrence as invasive carcinoma, the outcome of noninvasive MPSC is similar to that of invasive MPSC, with a progression-free survival of about 2 years and a median survival of 6-7 years [103, 321, 331].

Invasive MPSC is synonymous with invasive lowgrade serous carcinoma. Although the patterns of spread are similar to ordinary high-grade serous carcinoma, lowgrade serous carcinoma has a better prognosis. Stage III low-grade serous carcinoma is more likely to be stage IIIA (small volume peritoneal disease) as compared to highgrade serous carcinoma, which is nearly always stage IIIC (bulky peritoneal disease) [300]. The natural history of low-grade serous carcinoma is characterized by indolent growth that is resistant to chemotherapy, and recurrences that maintain the well-differentiated histological appearance of the primary tumor, even decades later. Rare exceptions show transformation to high-grade serous carcinoma [104].

A comparison of survival of 75 women with invasive and noninvasive MPSC found no significant survival difference between the two groups [331]. The strong association of noninvasive MPSC with invasive implants is a highly significant difference from APSTs (**)** *Table 14.12*). These findings indicate that noninvasive MPSCs are in fact carcinomas. Further sampling of apparent noninvasive MPSCs may reveal invasion in some, and perhaps most cases.

Low-grade serous carcinoma does not respond appreciably to platinum-taxane therapy in the firstline or neoadjuvant setting [103, 295]. Primary cytoreduction, and with recurrence, secondary cytoreduction, appear to be more effective approaches, but data are limited [34].

High-Grade Serous Carcinoma

Clinical Findings

High-grade serous carcinoma is the most common type of ovarian cancer and accounts for approximately 50% of ovarian carcinomas; however, if the clinically and pathologically identical peritoneal serous carcinomas are included (see below), the frequency is about 63% (Table 14.4). Serous carcinoma most often occurs in the sixth and seventh decades, and the reported mean age varies from 57 to 63 years. Nearly all comprehensively staged patients present in advanced stage with tumor usually disseminated throughout the abdominal and pelvic cavities. The most common presenting symptoms are abdominal pain and distention due to ascites or bulky abdominal tumor. A slightly older age, larger volume of ascites, and a lower frequency of a palpable pelvic mass occurs with peritoneal serous carcinomas as compared to ovarian serous carcinoma [19, 22, 26]. Gastrointestinal symptoms are also common. Other symptoms include urinary frequency, dysuria, and vaginal bleeding. Stage I tumors may present as an asymptomatic mass on a routine pelvic examination, but as noted above, stage I serous carcinoma is very rare. Importantly, three fourths of women with a history of breast cancer who subsequently develop peritoneal carcinomatosis are found to have new primary ovarian or peritoneal serous carcinomas [99]. Therefore, a woman with a history of breast carcinoma who develops peritoneal carcinomatosis should not be assumed to have a breast carcinoma recurrence.

Operative Findings

Two thirds of advanced-stage cases involve both ovaries. Nearly all advanced-stage ovarian carcinomas involve peritoneal surfaces, including the pelvic peritoneum (stage II) and the surfaces of the bowel and other abdominal organs (stage III). Both pelvic and abdominal spread can be by direct extension or metastasis. For example, direct extension to the rectosigmoid, broad ligament, or uterus can occur by contiguous growth, or by exfoliation of malignant cells resulting in seeding of the peritoneal surfaces of the bowel or pelvic peritoneum. Operative findings are described in more detail earlier in this chapter (see **P** Prognostic Factors, Stage above).

In 10–20% of women with advanced stage serous carcinoma, the ovaries are small and display predominantly surface involvement. These findings warrant a diagnosis of primary peritoneal serous carcinoma (see Differential Diagnosis below, and O Chap. 13, Diseases of the Peritoneum). It has been suggested recently that some of these may be tubal carcinomas of fimbrial origin.

On rare occasions, typical primary serous carcinomas arise in extraperitoneal locations including pelvic or retroperitoneal lymph nodes, broad ligament, retroperitoneum, or endocervix. More commonly, serous carcinomas arise in the endometrium (see **>** Chap. 9, Endometrial Carcinoma).

Gross Findings

Serous carcinomas range from microscopic to about 20 cm in greatest dimension. They are typically multilocular, cystic and solid, with soft, friable papillae filling the cyst cavities, and occasionally may be completely solid. The cysts also contain serous, turbid, or bloody fluid. The external surfaces may be smooth or bosselated and often display papillae. Solid areas on cut surface are pink to gray, and may be soft or firm depending on the character of the tumor stroma. Hemorrhage and necrosis are often present. Omental metastases are characterized by firm nodules of variable size with white or gray cut surfaces, which may coalesce to form an omental cake. A grossly normal omentum contains microscopic tumor in 22% of cases.

Microscopic Findings

High-grade serous carcinomas display complex papillary and solid patterns and marked cytologic atypia (\bigcirc *Figs.* 14.62–14.71). Frequently they display a lace-like or labyrinthine pattern (\bigcirc *Figs.* 14.64 and \bigcirc 14.65) characterized by extensive bridging and coalescence of papillae resulting in slit-like spaces. Areas of solid growth, and

Fig. 14.62

High-grade serous carcinoma. Low power view displaying absence of stromal invasion. Despite absence of invasion, the tumor should not be classified as borderline since the tumor cells are high grade (see **>** *Fig.* 14.63)

Fig. 14.63
High-grade serous carcinoma (same tumor as in
Fig. 14.62). Markedly atypical nuclei, high mitotic index, and abnormal mitotic figures

■ Fig. 14.65 High-grade serous carcinoma. Slit-like spaces are very characteristic of this neoplasm

Fig. 14.64 High-grade serous carcinoma. Slit-like spaces create a labyrinthine pattern. Nuclei are markedly atypical

glandular and cribriform patterns are common (**)** *Figs.* 14.66 and **)** 14.69). A villoglandular-type papillary pattern can be seen; the high-grade nuclear atypia, often with bizarre nuclei, identifies it as serous rather than endometrioid, and this pattern typically merges with other characteristic serous features. Cytoplasmic clear cell change may occur, but characteristic architectural patterns of clear cell carcinoma are not present (see **)** Differential Diagnosis, and **)** Clear Cell Carcinoma below; **)** *Fig.* 14.70). The cells may be small and uniform focally, but nearly all cases display areas of large,

Fig. 14.66 High-grade serous carcinoma. Solid growth, marked cytologic atypia and high mitotic activity

pleomorphic nuclei with obvious malignant features. Multinucleated tumor giant cells may be present (\bigcirc *Figs.* 14.67 and \bigcirc 14.68). Bizarre nuclei greater than 50 µm in diameter are characteristic, and occur in 86% of advanced stage tumors [300] (\bigcirc *Fig.* 14.67).

Serous carcinomas that are predominantly solid are composed of sheets of cells with high-grade nuclei and usually contain isolated bizarre mononuclear giant cells or syncytial-like aggregates. Mitoses, including abnormal mitoses, are numerous and necrosis is often pronounced (**)** *Fig. 14.67*). There are focal areas with papillary or

Surface Epithelial Tumors of the Ovary

High-grade serous carcinoma. Marked cytologic atypia, tufting, and detached cell clusters

glandular architecture that permit the diagnosis of a serous carcinoma rather than undifferentiated carcinoma. Psammoma bodies are present in 25% of cases. Rarely, a completely solid carcinoma without any evidence of glands, papillae, or other recognizable patterns occurs; this is probably a variant of high-grade serous carcinoma but is designated undifferentiated carcinoma (see **)** Undifferentiated Carcinoma below). Intratumoral lymphatic vascular invasion is seen in about one third of cases, and hilar lymphatic invasion in two thirds [289].

■ Fig. 14.70 High-grade serous carcinoma with focal cytoplasmic clearing and signet ring-like cells. This tumor should not be described as having clear cell carcinoma features as the architectural features of clear cell carcinoma are not present

Grade Morphometric measurement of nuclear area and direct measurement of nuclear size show a bimodal distribution for serous carcinoma that separates serous carcinomas into a small group of low-grade carcinomas and a much larger group of high-grade serous carcinomas [132, 300]. These findings along with the distinctly different molecular genetic profile that distinguish low- from high-grade serous carcinoma support the use of a two-tier

High-grade serous carcinoma. This small focus of highgrade serous carcinoma partially involves an ovarian surface epithelial inclusion. This could be an intraepithelial precursor of serous carcinoma or more likely extension of an established invasive serous carcinoma to an adjacent inclusion

grading system instead of the traditional three tier systems of well, moderate, and poorly differentiated serous carcinomas. Unlike the two-tier system proposed by Malpica and colleagues from MD Anderson (MDACC), the threetier system as advocated by Shimizu and associates [196, 197, 308] does not have a histological or molecular basis to separate grades II and III [104, 367]. It has been shown that in the unusual cases where the nuclear grade, which is the basis of the binary system, does not clearly appear to be low or high grade, i.e., grade II, these tumors lack KRAS and BRAF mutations (the hallmark of low-grade serous carcinoma) and display p53 mutations (the hallmark of high-grade serous carcinomas) in over 90% of cases [18]. Accordingly, these tumors that appear to be midway between low and high grade should be considered high grade. Such tumors of intermediate nuclear grade qualify as high grade in the MDACC system. Besides the morphometric and molecular underpinning that support the binary grading system, it more consistently separates prognostic groups [196, 197, 300]. The two-tier system has been validated to be reproducible among generalists and specialists [197]. The system does not require mitotic counting which is time-consuming and has poor reproducibility.

The MDACC system distinguishes low grade from high grade as follows. Low-grade serous carcinoma is characterized by uniform cells with mild to moderate nuclear atypia, whereas high-grade tumors have pleomorphic cells with marked nuclear atypia (>3:1 variation in nuclear size and shape). Low-grade tumors have a mitotic index <12 per 10 HPF, and usually much lower (<5 per 10 HPF), while high-grade tumors usually display >12 per 10 HPF.

This binary grading system effectively separates typical high-grade serous carcinoma from low-grade (micropapillary) serous carcinoma (see below) with 5-year survival rates of about 35% and 75%, respectively, for FIGO stage III. However, it is possible that patient's age and comorbidity have as much to do with this survival difference as grade. Women with high-grade serous carcinoma are nearly 2 decades older and consequently have more comorbid conditions and a shorter life expectancy as compared to those with low-grade serous carcinoma. In a population-based study of ovarian cancer in Denmark [350], ovarian cancer patients with severe comorbidity were about a decade older, and within each stage grouping, patients with more comorbidity had increased mortality. In one study of stage III ovarian serous carcinoma [300], the postoperative mortality (<2 months) in patients with high-grade tumors was 11% as compared to 0% for low grade. Thus, the high mortality rates in high-grade ovarian cancer may be disproportionately related to comorbid conditions as compared to low-grade ovarian cancer. In addition, low-grade serous carcinoma (invasive MPSC) is more likely to be stage IIIA or IIIB as compared to highgrade, which is nearly always IIIC, further confounding grade-stratified prognostication [103, 300]. It can therefore be argued that grade is at best a covariate, and at worst, not meaningful. A recent large population-based study on maximally debulked patients from Vancouver, Canada, found that stage and cell type are independent prognostic factors and grade is not [106].

Histologic Effects Induced by Chemotherapy Limited data are available on the histologic appearance of serous carcinoma shortly after chemotherapy [221]. Interval debulking specimens (after neoadjuvant chemotherapy) frequently show masses of psammoma bodies with scanty epithelium. Large omental cakes are often reduced to a normal size omentum with extensive fat necrosis and fibrosis, and with scattered foci of carcinoma throughout. Lymphocytes, foamy histiocytes, hemosiderin, and cholesterol clefts are often present. Scattered tumor cells show typical high-grade serous features, often with even more bizarre nuclear forms. In addition, they may show abundant clear, vacuolated, or eosinophilic cytoplasm and huge nucleoli. Sassen and associates found that the presence of scattered solitary tumor cells, fibrosis, foamy macrophages, and foreign body-type giant cells were highly specific (80–100%) but not sensitive indicators of neoadjuvant chemotherapy. Inflammation, hemosiderin, and isolated psammoma bodies were also associated with chemotherapy but were less specific [291].

Immunohistochemistry

Cytoplasmic immunopositivity is seen with CAM 5.2 and cytokeratin 7 in 100% of cases; BER-EP4, 95% [63], cytokeratin 20, 34%; vimentin, 45%; B72.3, 73% (usually weak)[63]; carcinoembryonic antigen, 19%; OC-125, 91%; gross cystic disease fluid protein-15 (GCDFP-15), 2%; and S-100, 30%. Membranous positivity is seen with epithelial membrane antigen (EMA) in 100% of cases. Nuclear positivity is seen for WT1 in 90% and for ER in 88-95% [63, 247] but some studies show that only a minority are ER-positive [381]. Nuclear staining for PR is usually absent or only weakly positive [63, 221] but can be strongly positive in up to 25% [178, 381]. The CK7/20 panel shows CK7+/CK20- in the majority of serous, endometrioid, and clear cell ovarian carcinomas, while the remainder are CK7+/CK20+. CK7 cytoplasmic positivity is nearly always strong and diffuse. When CK20 is positive, it is generally cytoplasmic and focal or patchy. p53, BRCA1, and WT1 nuclear stains and p16 (cytoplasmic, usually with concomitant nuclear staining) are positive in most high-grade serous carcinomas [12, 36, 47, 55, 229, 237, 352, 364, 385]. To be considered significant, p16 and p53 staining should be strong and diffuse. WT1positive tumors are more often high-stage, high-grade, bcl-2 positive and have a higher proliferation index based on increased nuclear staining for Ki-67, as compared to WT1 negative tumors [385].

Calretinin displays weak cytoplasmic positivity in up to one quarter of serous carcinomas [47, 227] and moderate to strong positivity in 5-10% [63, 194]. CK5/6 is weakly positive in about one fourth of cases [63]. bcl-2 is positive in one third [385]. TTF-1, a marker for lung and thyroid carcinomas, is focally or weakly positive (nuclear reactivity) in 24-37% of serous carcinomas, but occasionally can be diffusely positive [20, 162]. CD99 is often positive. Inhibin, a marker of sex cord-stromal tumors, is usually negative but can be focally positive [47, 206]. p63 is usually negative [260]. Other markers that are reliably negative include h-caldesmon and thrombomodulin. CA19-9, CD 15, and D2-40 are negative or only weakly positive [63]. One study comparing preand post-neoadjuvant chemotherapy tumor specimens showed that the immunophenotype of high-grade serous carcinoma does not change significantly after carboplatinpaclitaxel treatment [221].

Differential Diagnosis Although metastatic carcinomas to the ovary, particularly colorectal tumors, most often mimic mucinous or endometrioid ovarian carcinomas, metastases may display a wide variety of patterns, and metastatic colorectal carcinomas can rarely resemble serous carcinoma [185]. In addition to CK7 and CK20, a few investigators have found monoclonal CEA useful in this differential [206] (see ♥ Mucinous Tumors below, and ♥ Chap. 18, Metastatic Tumors of the Ovary).

The distinction of serous from endometrioid carcinoma is generally not important in practice because the stage-stratified prognosis and treatment are similar. Although there is morphologic overlap, many experts believe that high-grade nonpapillary adenocarcinomas with glandular and cribriform patterns (non-clear cell, non-mucinous) most often represent serous carcinomas and should not be diagnosed as mixed or as endometrioid carcinoma unless the classic patterns of endometrioid adenocarcinoma of the uterine corpus are clearly recognizable [154, 207, 333]. Diffuse strong ER and PR reactivity and negative staining for WT1, p53, and p16 favor an endometrioid carcinoma, while the opposite findings are more common in serous carcinoma [206]. Molecular studies have not vet resolved whether the nonspecific high-grade adenocarcinomas have genetic features of endometrioid or serous carcinoma. The contrasting features of high-grade serous and endometrioid carcinomas are shown in **>** Table 14.15.

Serous carcinomas often invade the fallopian tubes, and, on occasion, the distinction of an ovarian from a primary tubal carcinoma may be difficult (See **O** Chap. 11, Diseases of the Fallopian Tube and Paratubal Region, and Ochap. 18, Metastatic Tumors of the Ovary). Meticulous sectioning of the fallopian tube, which is typically dilated and filled with tumor when primary, can be helpful in making the distinction, but carcinomas involving the fimbriae are more difficult to clearly assign. Microscopically, the presence of carcinoma in situ in uninvolved tubal epithelium (serous tubal intraepithelial carcinoma -STIC) is helpful. It can be difficult to distinguish carcinoma in situ of the tube from hyperplasia and reactive changes [191]. Not infrequently, a primary tubal carcinoma is associated with metastases larger than 5 mm in the ovary. Since the 5 mm criterion is intended to separate ovarian from peritoneal tumors (see below), classification as primary tubal carcinoma is warranted if the tube shows the features of a primary tubal carcinoma.

Population-based studies have shown that approximately 10% of patients with apparent advanced-stage serous carcinoma have normal sized or slightly enlarged ovaries with only surface involvement [22], although

Table 14.15

Distinction between poorly differentiated serous adenocarcinoma and poorly differentiated endometrioid adenocarcinoma

Morphology	Serous	Endometrioid
Glandular spaces	Slit-like	Round, punched out
Psammoma bodies	Common	Rare
Tumor giant cells	Common	Rare
Papillae	Small, complex with budding	Longer and broader
Adenofibromatous growth pattern	Rare	Common
Squamous elements	Rare	Common
Endometriosis	Rare	Common
Immunohistochemistry		
WT1	Diffuse positive	Negative or focally positive
P53	Diffuse positive	Negative, focally or diffuse positive
P16	Diffuse positive	Negative or focally positive
Vimentin	Negative	Sometimes positive
Beta-catenin	Membranous	Membranous and, in some cases, nuclear positivity

Modified from [207]

recent series have shown a higher proportion ranging from 18% to 29% [115, 134, 301]. These are classified as primary peritoneal serous carcinomas. The following criteria for this distinction have been proposed by the GOG [26]: (1) both ovaries must be either physiologically normal in size or enlarged by a benign process; (2) the involvement in the extraovarian sites must be greater than the involvement on the surface of either ovary; (3) microscopically, the tumor in the ovary must be one of the following: (a) nonexistent, (b) confined to the ovarian surface epithelium with no evidence of cortical invasion, (c) involving ovarian surface epithelium and/or underlying cortical stroma but with no tumor nodule measuring greater than 5×5 mm; (4) the histological and cytological characteristics of the tumor must be predominantly of the serous type that is similar or identical to ovarian serous carcinoma, any grade.

From a practical standpoint, the distinction of ovarian from peritoneal carcinoma is not critical since the behavior and treatment are similar, but the distinction is important in epidemiologic, histopathologic, and molecular studies. Although widely used, the above criteria are arbitrary and too restrictive, and as such very likely underestimate the frequency of tubal as well as peritoneal carcinoma. In some cases, the ovaries display multiple small nodules of tumor, a feature characteristic of primary peritoneal carcinoma, but if only one nodule exceeds 5 mm, it must be classified as ovarian. Thus, primary peritoneal and tubal carcinomas are more common than previously realized.

The uterus is removed as part of the staging procedure for ovarian and peritoneal serous carcinomas. When the tumor appears to be primary peritoneal, the pathologist should meticulously examine the endometrium. Serous carcinoma of the endometrium and its putative precursor, endometrial intraepithelial carcinoma, can disseminate throughout the peritoneum even when microscopic and lacking myometrial invasion (see O Chap. 9, Endometrial Carcinoma). It is possible that a small proportion of apparent primary peritoneal serous carcinomas reflect disseminated endometrial serous carcinomas with an occult primary endometrial tumor.

When a large endometrial serous carcinoma lacking myometrial invasion is associated with carcinomatosis, it can be difficult to assign a primary site to the ovarian and peritoneal lesions using morphology alone. If the ovarian involvement is multinodular and bilateral, metastatic disease to the ovaries and peritoneum is likely. WT1 can be of value, as peritoneal serous carcinomas are positive like their ovarian counterparts, whereas endometrial serous carcinomas are usually negative or weakly positive [1, 86, 118, 205, 206]. p53 is not as useful as it is positive in ovarian, peritoneal, and endometrial serous carcinomas. Independent serous carcinomas of the ovary and endometrium are possible but rare, and diagnostic criteria for this situation have not been well defined.

Primary ovarian epithelial tumors of non-serous types may occasionally mimic serous carcinoma: typically clear cell and endometrioid carcinomas. Clearing of the cytoplasm is not uncommon focally in serous carcinoma and is not indicative of clear cell carcinoma unless the typical architectural patterns of clear cell carcinoma are present (**>** *Fig.* 14.70) [116, 207]. Similarly, glandular and cribriform patterns are common in serous carcinoma and should not be interpreted as endometrioid unless other characteristic features of eutopic endometrial carcinoma are present (**>** *Table* 14.15). More importantly, malignant germ cell tumors, particularly embryonal carcinoma and volk sac tumor, often have solid and papillary patterns, respectively, which may mimic serous carcinoma. The age of the patient is an important clue, as malignant germ cell tumors almost always occur in much younger patients. Immunohistochemistry utilizing antibodies against alpha fetoprotein, which reliably stains yolk sac tumors, can be useful in this distinction (see) Chap. 16, Germ Cell Tumors of the Ovary). Clinical correlation with serum levels of AFP may also be of value. On occasion, distinction of serous carcinoma from the retiform variant of Sertoli-Leydig cell tumor (SLCT) is difficult. Positive inhibin and negative EMA staining in the latter tumors, as well as the younger age of these patients, are useful distinguishing features (see O Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations).

Diffuse malignant mesothelioma, particularly those with a papillary pattern, may on rare occasion be difficult to distinguish from serous carcinoma. At the Washington Hospital Center from 1999 to 2009, one diffuse malignant mesothelioma was diagnosed in the same population as over 300 ovarian and peritoneal carcinomas. The best markers for distinguishing mesothelioma from serous carcinoma include calretinin, CK5/6, and thrombomodulin, which are positive in mesotheliomas, and ER and BER-EP4 which are negative. ER appears to be more sensitive and specific than other stains that are typically negative in mesotheliomas in women [247]. The panel of ER, calretinin, and BER-EP4 (or MOC 31) has been recommended for a clear distinction in most cases [206, 248] with some recommending the addition of hcaldesmon, which stains mesotheliomas [63]. Of note, OC-125 is often positive in mesothelioma [20].

Ovarian carcinoma is often considered in the differential diagnosis of a metastatic adenocarcinoma of unknown primary site. Of particular value in this differential diagnosis is the panel of CK7 and CK20, as the CK7/CK20 profiles of carcinomas of a variety of sites have been extensively studied. Endometrioid and serous ovarian carcinomas are typically CK7+/CK20-. This panel is most useful in distinguishing gastrointestinal primary carcinomas from ovarian mucinous carcinomas (see) Mucinous Tumors, **Differential** Diagnosis later in this chapter). Breast carcinoma, which is usually CK7+/CK20-, is typically GCDFP-15 positive and WT1 negative, while ovarian carcinomas are GCDFP-15 negative and WT1 positive. However 30-40% of breast carcinomas are negative for GCDFP-15 [20, 355]. TTF1 is not of great value in distinguishing ovarian from lung and thyroid carcinoma because it is positive in a significant number of ovarian carcinomas.

Molecular Biology Because serous carcinomas comprise the majority of ovarian carcinomas, most published studies of generic "ovarian cancer" or "ovarian carcinoma" in the older literature, unless otherwise indicated, likely included mainly serous carcinomas. Although recent clinical and molecular studies of ovarian cancer are more likely to take histological type into account, they are also usually weighted toward serous carcinomas since these tumors comprise the majority of malignant epithelial tumors. As a consequence, molecular alterations in typical (high-grade) serous carcinomas as well as a spectrum of benign, borderline, and low-grade malignant ovarian serous neoplasms have been studied quite extensively. In keeping with the now well-recognized adenomacarcinoma sequence in colorectal cancer pathogenesis, for many years it was widely assumed that ovarian serous tumors likely progress from benign serous cystadenoma to atypical proliferative (borderline) serous tumor (APST), to low-grade serous carcinoma, and ultimately to high-grade serous carcinoma. However, the correlation of clinicopathological observations with molecular genetic data has led to a paradigm shift, and we now recognize distinct pathways leading to the development of low-grade (Type I) versus high-grade (Type II) serous carcinomas.

Mutational Analyses Our understanding of gene mutations in serous carcinomas will undoubtedly become more refined in the near future by new technologies allowing large-scale sequencing of the genome in primary tumors. Unbiased genome sequencing of large numbers of primary serous carcinomas will almost certainly uncover as yet unsuspected gene mutations that occur frequently in these tumors. Indeed, ovarian serous carcinoma is one of three cancer types initially selected for analysis by The Cancer Genome Atlas, a comprehensive and coordinated effort jointly sponsored by the National Cancer Institute and National Human Genome Research Institute to accelerate our understanding of the molecular basis of cancer through the application of comprehensive genome analysis technologies [232]. These data are in the process of being collected and will be publicly released. Until then, investigators continue to evaluate primary tumors for mutations largely on a gene-by-gene basis. To date, relatively few genes have been found to be mutated in the majority of ovarian serous tumors. TP53 is mutated in 50% or more of advanced stage, high-grade serous carcinomas [327, 328]. TP53 mutation frequency was found to be even higher (\sim 80%) in high-grade serous carcinoma when purified tumor samples were used for sequence analysis [286]. In their study of early (stage I) serous

carcinomas Leitao and colleagues identified overexpression of p53 and mutation of *TP53* in well over half of the cases, suggesting that *TP53* mutation is an early event in the development of high-grade serous carcinomas [183]. On a related note, a small series of intraepithelial serous carcinomas in the fallopian tube and coexisting ovarian serous carcinomas were recently found to share identical *TP53* mutations, suggesting a common origin of tumors in the two sites and providing further evidence of a role for *TP53* mutations early in serous carcinoma pathogenesis [149]. Mutations in several other tumor suppressor genes and oncogenes such as *BRCA1/2*, *PTEN*, and *PIK3CA* have also been reported in ovarian serous carcinomas, but their mutation frequency is generally low (<10%) [220, 231, 376].

DNA Copy Number Changes Several studies have analyzed global DNA copy number alterations specifically in high-grade and low-grade serous carcinomas [164, 204, 215, 230] A general conclusion that can be drawn from these studies is that high-grade serous carcinomas are characterized by more diffuse and higher levels of subchromosomal gains and losses than low-grade serous carcinomas and APSTs, suggesting that chromosomal instability is more pronounced in high-grade serous carcinomas than in low-grade serous carcinomas and APSTs. Based on single nucleotide polymorphism (SNP) array analysis of DNA copy number alterations in purified ovarian serous carcinoma samples, Nakayama and colleagues found the most frequently amplified subchromosomal regions harbor the CCNE1 (cyclin E1), AKT2, NOTCH3, RSF1, and PIK3CA loci [230]. Dualcolor fluorescence in situ hybridization (FISH) was performed to validate the findings in a sizeable independent set of serous carcinomas. The results showed highlevel DNA copy number gains/amplification of CCNE1, NOTCH3, RSF1, AKT2, and PIK3CA loci in 36%, 32%, 16%, 14%, and 11% of high-grade serous carcinomas, respectively. In contrast, low-grade serous tumors did not show high-level amplification at any of the above loci. These gene amplifications have both biological and clinical significance. For example, deregulation of the PI3K/Pten signaling pathway through amplification of PIK3CA, which encodes the catalytic subunit of PI3K, has been shown to play a causal role in invasion, metastasis, and chemoresistance in ovarian cancer [11, 218]. CCNE1 gene amplification and overexpression contributes to oncogenesis and genetic instability, particularly in the presence of mutant p53, which is present in most high-grade serous carcinomas [23, 334]. Moreover,

expression of low-molecular-weight cyclin E is associated with worse clinical outcome in ovarian cancer patients [69]. The functional consequences of other gene amplifications in ovarian serous carcinomas are just beginning to be elucidated. Notably, although early studies identified rather frequent *HER2/neu* (*ERBB2*) amplification/copy number gains in ovarian serous carcinomas, a recent analysis using comprehensive genome-wide digital karyotyping technologies failed to identify high levels of *ERBB2* gene amplification in 33 high-grade or 10 low-grade serous carcinomas [230].

Gene Expression Transcriptome-wide gene expression profiling using serial analysis of gene expression (SAGE) and oligonucleotide microarrays has been applied to ovarian serous tumors including high-grade carcinomas, lowgrade carcinomas, and APSTs [28, 106, 128, 129, 215]. Several of these studies found that low-grade and highgrade serous carcinomas are distinguishable based on their gene expression profiles. In those studies that included APSTs, the APSTs always clustered with low-grade rather than high-grade serous carcinomas. This finding provides further evidence that APSTs and low-grade serous carcinomas are closely related and both tumors are distinct from high-grade serous carcinomas.

Although somatic mutations of BRCA1 and BRCA2 are known to be rather uncommon in sporadic ovarian carcinomas, accumulated studies suggest these genes may be inactivated, particularly in serous carcinomas, through mechanisms other than mutation [41]. Horiuchi and colleagues found reduced expression of BRCA1 transcripts in serous carcinomas, often associated with loss of heterozygosity at the BRCA1 locus [372]. Hypermethylation of the BRCA1 promoter accompanied by loss of Brca1 protein expression has been observed in 15-31% of sporadic ovarian carcinomas [21]. Moreover, high-grade serous carcinomas with genetic versus epigenetic inactivation of BRCA1 have recently been shown to have distinct molecular abnormalities involving the PI3K/Pten signaling pathway [265]. Specifically, tumors with BRCA1 mutations typically had decreased PTEN mRNA levels, while those with epigenetic loss of BRCA1 had copy number gains of PIK3CA. Finally, WT1 (Wilms' tumor 1) encodes a protein that plays important roles in genitourinary tract development. Several studies have noted preferential expression of WT1 in serous carcinomas (both lowgrade and high-grade) compared to the other histologic types of ovarian carcinoma [1, 237]. Because TP53 mutations in high-grade serous carcinomas are most often missense mutations that result in protein stabilization,

Clinical Behavior and Treatment

The survival rates for ovarian carcinoma, of which the majority are serous, are shown in **2** Table 14.9. As discussed above, stage I patients who have been carefully staged have a 5-year survival rate that exceeds 90%; however, comprehensively staged high-grade serous carcinomas are rarely stage I [182, 301] (1.1% of ovarian carcinomas in our series (> Table 14.4) and 0.5% of ovarian carcinomas in a population-based study from British Columbia (stages IA and IB only in the latter study [287])). In fact, serous histology may be a poor prognostic factor in stage I especially in patients who have not been comprehensively staged [313]. The vast majority of stage III and IV ovarian carcinomas are highgrade serous and overall survival is poor. However, these tumors are often very sensitive to PBC and the 5-year survival rate approaches 50% for optimally debulked patients; there are occasional 10-year survivors of advanced-stage high-grade serous carcinoma. Most studies show that survival for peritoneal serous carcinoma is the same as that for ovarian carcinoma when stratified by stage [19, 26, 134, 144]. Stage II tumors are uncommon (3% of serous carcinomas (> Table 14.4)) and represent an intermediate group, which, depending on other factors including completeness of surgical removal and substage, can have widely varying survival and cure rates [299]. Microscopic serous carcinoma, so-called early de novo carcinoma, despite its small size (less than 7 mm) is associated with recurrence and death in about a third of cases, usually with widespread peritoneal disease (> Fig. 14.71).

A recent study examining the histology of ovarian carcinoma after neoadjuvant chemotherapy (NAC) followed by interval debulking found that those patients with no residual tumor or only scattered solitary tumor cells had a significantly better survival than those with larger residual tumor, with median survival of 45 and 26 months, respectively [291]. A similar study showed that a moderate or marked degree of tumor necrosis, found in 49% of 73 patients treated with NAC, significantly correlated with a longer time to first recurrence independent of other established risk factors, but did not correlate with survival [173].

Serum levels of CA125 correlate with volume of disease but are not independent prognostic factors. Although high preoperative CA125 levels may predict unresectability and poor survival, postoperative CA125 levels appear to be more prognostic. CA125 levels are commonly used to monitor for recurrence.

Mucinous Tumors

At the outset, it must be noted that diagnosis of the mucinous cell type in ovarian epithelial tumors is based solely on hematoxylin and eosin-stained sections. Mucin stains do not play a role in classification as they can be positive in other cell types. Primary ovarian mucinous tumors include cystadenomas, atypical proliferative mucinous tumors (APMT; also referred to as borderline or low malignant potential tumors), and carcinomas (intraepithelial and invasive). The cystadenomas, followed by APMT, are the most commonly encountered, whereas primary ovarian mucinous carcinomas are much less common. Cystadenomas and APMT are noninvasive, and are distinguished from each another primarily by their degree of complexity and epithelial proliferation. The invasive carcinomas are distinguished from these two types by the presence of stromal invasion. There is a morphologic spectrum of epithelial proliferation in mucinous tumors which includes cystadenomas with focal epithelial proliferation and APMT with intraepithelial carcinoma and/or microinvasion, providing evidence that these tumors comprise a biologic spectrum with individual types representing steps in the sequence of ovarian mucinous carcinogenesis. Molecular studies support this view (see Nolecular Biology below).

The other types of mucinous tumors encountered in the ovary include metastatic mucinous carcinomas, most commonly from the gastrointestinal tract, and low-grade mucinous tumors of appendiceal origin secondarily involving the ovary in association with the clinical syndrome of pseudomyxoma peritonei (PMP). Both metastatic mucinous carcinomas and low-grade mucinous tumors of appendiceal origin can simulate primary ovarian mucinous tumors, including both APMT and primary ovarian mucinous carcinoma. Refined criteria for diagnosis of ovarian mucinous tumors in recent years, with distinction of these non-ovarian tumors from true primary ovarian mucinous tumors, have been instrumental in clarifying the behavior of ovarian mucinous tumors and in providing more appropriate therapy.

Studies using refined diagnostic criteria for ovarian mucinous tumors, particularly those focused on recognition of metastatic mucinous carcinomas that simulate primary ovarian mucinous tumors, have established that primary ovarian mucinous carcinomas are much less common than previously believed [306]. However, despite improved recognition of metastases, the problem of distinguishing primary and metastatic mucinous carcinomas persists (see Ochap. 18, Metastatic Tumors of the Ovary). The difficulty in recognizing metastases that morphologically simulate

primary ovarian mucinous tumors is compounded by the fact that some metastases present first in the ovary without a clinically evident extraovarian primary. In addition, ancillary techniques such as immunohistochemistry, while useful in certain situations (see) Differential Diagnosis below), are limited in their ability to distinguish some metastases from primary ovarian mucinous tumors. It is important to recognize this difficulty when evaluating the literature on behavior and therapeutic responses of ostensibly primary ovarian mucinous carcinomas, as older reports, particularly those prior to and even including the 1990s, likely include a subset of misclassified metastases. Even in expert hands, distinction of primary from metastatic mucinous carcinoma may be very difficult at times, and we estimate that the frequency of misclassification or genuine diagnostic uncertainty is at least 5%.

Benign Mucinous Tumors, Intestinal and Müllerian (Seromucinous, Endocervical-like) Types

Mucinous cystadenomas (including the müllerian type; see below) comprise 13% of benign ovarian epithelial neoplasms (> Table 14.5). Over 80% are of the intestinal type. The mean patient age is about 50 years. Intestinaltype mucinous cystadenomas are unilocular or multilocular tumors of variable size, ranging from a few centimeters to over 30 cm, with a mean of about 10 cm. They are typically unilateral (95%). The capsule is typically thick and white with a smooth outer surface. The cysts contain thick gelatinous material. The vast majority are composed of glands and cysts lined by simple non-stratified mucinous epithelium resembling gastric foveolar-type epithelium or intestinal epithelium containing goblet cells (> Fig. 14.72). The peripheral aspects of the cysts can form crypt-like structures where nuclei may appear reactive and exhibit mitotic activity, but the epithelium of the cysts generally lacks atypia or displays focal mild atypia. The epithelium can appear undulating but epithelial stratification and tufting are generally absent; when epithelial proliferation is present resembling APMT, this feature must be limited to <10% for the tumor to qualify as a cystadenoma (> Fig. 14.73). Tumors composed predominantly of cystadenoma with <10% of APMT are diagnosed as mucinous cystadenoma with focal proliferation [277] or focal atypia [310]. The majority of tumors contain calcification which is usually spiculated rather than psammomatous. Muciphages, pseudoxanthoma cells, and luteinized stromal cells are each present in 40-50%. Dissection of acellular mucin in the tumor stroma,

Fig. 14.72

Mucinous cystadenoma. The nuclei are small, bland, and uniform. The cytoplasm contains abundant lightly basophilic mucin

referred to as "pseudomyxoma ovarii," is seen in 10%, and 10% also display multinucleated giant cells [302]. Rarely, benign mucinous neoplasms are solid and adenofibromatous; these are referred to as mucinous adenofibroma. Up to 18% of mucinous cystadenomas contain transitional cell nests, also referred to as a Brenner tumor component, often in a discrete nodule which is usually interpreted as a concurrent Brenner tumor [302]. When the Brenner component is prominent or intimately admixed with the mucinous component, the tumor can be classified as metaplastic Brenner tumor or mixed mucinous–Brenner tumor (see **9** Brenner Tumors,

and **O** Mixed Epithelial Tumors, later in this chapter). In light of these findings and other observations, it has been suggested that the majority of intestinal type mucinous tumors arise from Brenner tumors or transitional cell nests.

Occasionally, cystadenomas have endocervicaltype mucinous epithelium. These are referred to as müllerian-type mucinous, endocervical-like mucinous, or seromucinous cystadenoma. They are unilocular or multilocular cystic tumors, often with papillary architecture in contrast to the pure glandular pattern of the intestinal type. The epithelium closely resembles endocervical mucinous epithelium with columnar cells having apical mucin and basally situated bland nuclei. When stringent criteria are applied to avoid misclassification as gastrointestinaltype tumors, which can occasionally have very few goblet cells when lined by foveolar-type epithelium, this subtype is uncommon. Mucinous cystadenomas and adenofibromas are benign but can recur if incompletely excised. Tumor rupture has not been associated with recurrence.

Atypical Proliferative Mucinous Tumor (Mucinous Borderline Tumors), Intestinal Type

Although the borderline category was intended mainly for serous tumors (see > Serous Tumors earlier in this chapter), the concept was also extended to mucinous tumors since they also appeared to have intermediate forms. These alleged intermediate forms were most often characterized by PMP and were felt to be analogous to serous borderline tumors with peritoneal implants, with the characteristic peritoneal mucin deposits of PMP representing the peritoneal implants of ovarian mucinous tumors. In the late 1970s, the term "atypical proliferative" or "atypically proliferating tumor" was introduced. Currently, three terms are used to refer to these tumors: "atypical proliferative mucinous tumor," "mucinous borderline tumor," and "mucinous tumor of low malignant potential." The 2003 Borderline Ovarian Tumor Conference established that the three terms are synonymous; "tumor of low malignant potential," was the least favored of the three [277, 310].

There are two types of APMT corresponding to the two types of mucinous cystadenomas: the gastrointestinal type and the endocervical-like (müllerian, or seromucinous) type. The gastrointestinal type of APMT is typically a large, multicystic tumor with a smooth capsule, and is usually unilateral (>95%) with mean and median sizes of about 20–22 cm [272, 391]. The locules of the tumor are usually filled with mucinous material and the lining appears smooth, without grossly evident papillations. Microscopically, the cysts are lined by stratified, proliferative gastrointestinal-type mucinous epithelium exhibiting tufted and villoglandular or papillary intraglandular growth and displaying variable (usually mild to moderate) nuclear atypia; by definition, stromal invasion is absent (> *Figs.* 14.74–14.79).

The clinical behavior of mucinous tumors is summarized in **2** *Table 14.16*. Review of the literature on tumors meeting the diagnostic criteria for APMT, gastrointestinal type, reveals an overwhelmingly benign behavior [148, 179, 235, 236, 272, 274]. More than 600 stage I tumors have been reported, and less than 1% of patients have died of disease. Parenthetically, most fatal tumors had inadequate or unknown degree of sampling and are reported in the older literature; most recent studies report 100% survival.

Fig. 14.75
Atypical proliferative (borderline) mucinous tumor.
Extensive epithelial proliferation with stratification and focal detachment of cell clusters

Atypical proliferative (borderline) mucinous tumor. Fusion of papillae focally creates small cribriform foci

Approximately 100 of so-called advanced-stage borderline mucinous tumors have been reported, with nearly 50% mortality. Of these, about 85% have been associated with PMP. Recent studies have established that virtually all cases of PMP are of gastrointestinal (usually appendiceal), not ovarian, origin (see Mucinous Tumors Associated with Pseudomyxoma Peritonei (PMP) below) [278, 280, 362, 363, 365]. The remaining 15% of advanced-stage mucinous borderline tumors reported are, in all likelihood, metastatic mucinous carcinomas typically from the biliary

Fig. 14.78 Atypical proliferative (borderline) mucinous tumor. Mild cytologic atypia and fusion of papillae

Fig. 14.79

Epithelial stratification with mild cytologic atypia. A few mitotic figures are present

tract, pancreas, and cervix that masquerade as mucinous borderline tumors. Therefore, true primary advancedstage ovarian APMT (i.e., with peritoneal implants) does not exist. When these latter tumors are removed from the APMT category, the remainder consist of stage I tumors with benign behavior. Rarely, a mucinous cystadenoma or APMT is associated with a localized collection of mucin involving the pelvic peritoneum, and may even contain a few strips of benign mucinous epithelium. This is probably due to tumor rupture and should not be classified as PMP or APMT with peritoneal implants.

Table 14.16

Behavior of ovarian mucinous tumors

Tumor type	Survival rate ^c
Atypical proliferative mucinous tumors (APMTs), stage I	>99%
Atypical proliferative mucinous tumors, advanced stage ^a	(see PMP category)
Atypical proliferative mucinous tumors with intraepithelial carcinoma ^a	~95%
Atypical proliferative mucinous tumors with microinvasion	>99%
Primary ovarian mucinous carcinomas, confluent glandular type ^a	~90%
Primary ovarian mucinous carcinomas, infiltrative type ^a	<<50%
Ovarian mucinous tumors associated with pseudomyxoma peritonei (PMP) ^b	~50%
Metastatic mucinous carcinomas	<<50%

^aMay include some misclassified metastatic mucinous carcinomas. ^bVirtually all tumors are derived from the gastrointestinal tract (usually appendix) and are thus not ovarian in origin.

^cData derived from review in [277].

Atypical Proliferative Mucinous Tumor, Seromucinous (Endocervical-like or Müllerian) Type

The seromucinous-type APMT (APSMT) is grossly, microscopically, and immunophenotypically distinct from the gastrointestinal-type tumor [361]. The seromucinous tumors are much less common, smaller, more frequently bilateral, architecturally resemble APST, and are much more often associated with endometriosis. In addition, they frequently display acute inflammation of the stroma, and a combination of endocervical mucinous and serous (ciliated)-type epithelium, often admixed with minor components (<10%) of other cell types (endometrioid, squamous, and eosinophilic "indifferent" cells)[228] (Figs. 14.80-14.83). The term "seromucinous" is more accurate than endocervical-type mucinous tumor for this group of tumors as it reflects the morphologic and behavioral features that are shared with the serous tumors, and that differ from the typical mucinous tumors of gastrointestinal type. Based on a small number of studies, these tumors, including very few with implants and intraepithelial and microinvasive carcinomas, have demonstrated a benign behavior [77, 273, 316].

Atypical Proliferative Mucinous Tumors with Intraepithelial (Noninvasive) Carcinoma

Based on the FIGO and WHO classifications of the early 1970s, the absence of stromal invasion distinguishes

Fig. 14.80

Atypical proliferative (borderline) seromucinous tumor (APSMT). Complex papillary proliferation at low magnification architecturally resembles atypical proliferative serous tumor

Fig. 14.81

Atypical proliferative (borderline) seromucinous tumor. Areas of epithelial stratification and detachment of cell clusters. Many cells contain abundant eosinophilic cytoplasm. An acute inflammatory reaction and microabscesses in the epithelium are characteristic of this tumor

APMT from mucinous carcinoma. Shortly thereafter, the criteria for mucinous carcinoma were expanded to include marked overgrowth of atypical epithelial cells manifested as stratification in excess of three layers, cribriform intraglandular proliferations, or fingerlike projections of solid cellular masses without connective tissue support; these patterns were often accompanied by marked nuclear

Atypical proliferative (borderline) seromucinous tumor. The epithelium displays minimal cytologic atypia and lightly basophilic cytoplasm resembling endocervical (müllerian) mucinous epithelium

G Fig. 14.84

Fig. 14.83

atypia. In addition, the presence of marked nuclear atypia alone was added as a diagnostic feature of mucinous carcinoma. Since then, mucinous tumors lacking stromal invasion but displaying epithelial overgrowth and atypia have been referred to as "noninvasive," "intraglandular," or "intraepithelial" carcinomas. Proposed diagnostic criteria for intraepithelial carcinoma vary slightly among different studies [179, 236, 272, 273, 277]. All studies consider noninvasive tumors with marked nuclear atypia as intraepithelial carcinomas, and this is the preferred

criterion (**)** *Figs.* 14.84–14.86). Excessive epithelial stratification and other complex intraglandular growth patterns can be seen in typical APMT and should not be used to diagnose intraepithelial carcinoma in the absence of severe atypia [277].

Intraepithelial carcinomas confined to the ovaries have an excellent prognosis (about 95% survival, with most recent studies reporting 100% survival) [148, 179, 236, 272, 273, 277]. A small number of so-called advanced stage intraepithelial mucinous carcinomas have been reported,

Fig. 14.86 Atypical proliferative (borderline) mucinous tumor with intraepithelial carcinoma. Marked cytologic atypia and mitotic figures are present

with a few tumor deaths. In view of the ability of metastatic mucinous carcinomas to simulate APMT with intraepithelial carcinoma (see below), it is likely that some of these apparent advanced-stage intraepithelial carcinomas with adverse outcome represent metastases from occult extraovarian primary tumors. It is also possible that some of these represent true primary ovarian mucinous carcinomas with foci of destructive invasion in unsampled tissue. Finally, these tumors may display patterns of invasion that are not recognizable as such using current criteria.

APMT with Microinvasion

Microinvasion in APMT has been defined as either small foci of stromal invasion characterized by single cells, glands, or small clusters or nests of mucinous epithelial cells within the stroma, or as small foci of confluent glandular or cribriform growth within the stroma (> Figs. 14.87-14.91). The size criterion for each focus has varied from 2 to 5 mm, with no requirement regarding the number of foci allowed [277]. Some tumors with microinvasion also have intraepithelial carcinoma. Based on the relatively small number of microinvasive tumors with follow-up that have been reported, no welldocumented recurrences or deaths due to disease have been reported [148, 179, 235, 236, 272, 273, 277]. Although microinvasion in mucinous tumors often resembles the lesion designated "microinvasive carcinoma" in serous tumors, the metastatic potential of small foci of invasion in mucinous tumors is probably low but there are no published studies specifically addressing this issue. Accordingly, the behavior of tumors with these minute

invasive foci is uncertain; the consensus among experts in the field is to use the term microinvasion [277].

Mucinous Tumors Associated with Pseudomyxoma Peritonei (PMP)

PMP has historically referred to the presence of mucinous ascites or mucoid nodules adherent to peritoneal surfaces and has not had a consistently applied histopathological

Atypical proliferative (borderline) mucinous tumor with microinvasion. Haphazard infiltrative growth of small nests adjacent to noninvasive neoplastic glands

Fig. 14.90

description. Recent studies have defined PMP as a clinicopathologic syndrome in which mucinous ascites is accompanied by low-grade neoplastic mucinous epithelium associated with pools of extracellular mucin and fibrosis [280]. Morphologic, immunohistochemical, and molecular genetic studies have provided compelling evidence that virtually all cases of PMP are derived from low-grade (adenomatous) mucinous tumors of the appendix, and that the ovarian involvement is secondary [278, 280, 281]. This concept is further supported by other studies showing that ruptured primary ovarian mucinous tumors have

not been associated with the subsequent development of PMP [179]. Because the ovarian mucinous tumors associated with PMP are almost invariably derived from the gastrointestinal tract, usually the appendix, they are now reported as secondary involvement of the ovary by lowgrade (adenomatous) mucinous tumor [277]. The term "metastatic mucinous carcinoma" should be avoided for the ovarian lesions (see) Metastatic Mucinous Carcinoma). When intraoperative consultation with frozen section leads to a diagnosis of a mucinous ovarian tumor in the setting of PMP, the need for appendectomy as well as thorough examination of the gastrointestinal and pancreaticobiliary tracts should be conveyed to the surgeon. The pathologist should examine the entire appendix microscopically. The rare exception to the gastrointestinal origin of PMP is the occurrence of mucinous tumors arising in ovarian mature cystic teratomas associated with mucinous ascites [211, 279]. Accordingly these are classified as germ cell tumors (see O Chap. 16, Germ Cell Tumors of the Ovary).

The terms "disseminated peritoneal adenomucinosis" (DPAM) and "involvement by low-grade appendiceal mucinous neoplasm" are now recommended as specific pathologic diagnostic terms for these low-grade peritoneal and ovarian mucinous tumors, respectively [278, 280, 281]. The term PMP is restricted to use as a clinical descriptor for the syndrome and is maintained as a general term for historical continuity. This recommendation is based on studies demonstrating that peritoneal mucinous tumors with the histologic features of the low-grade tumors are pathologically and prognostically

distinct from mucinous carcinomas, with the latter having significantly worse survival [280, 388]. Some investigators have proposed the terms, "mucinous carcinoma peritonei, low grade" for DPAM, and "mucinous carcinoma peritonei, high grade" for the carcinomatous tumors [30]. The DPAM terminology is already in widespread use and has the added advantage of not changing the term for the high-grade variant, which has always been referred to as invasive mucinous carcinoma or mucinous carcinomatosis. The distinguishing

Table 14.17

Distinguishing features of disseminated peritoneal adenomucinosis (DPAM) and peritoneal mucinous carcinomatosis (PMCA)

Feature	DPAM	РМСА		
Primary site	Appendix	Appendix, colon, small intestine		
Primary diagnosis	Mucinous adenoma; low grade mucinous neoplasm	Mucinous adenocarcinoma		
Surgical appearance	Mucinous ascites with characteristic distribution ^a	Carcinomatosis with invasive implants		
Peritoneal tumor				
Cellularity	Scant	Moderate to abundant		
Morphology	Abundant extracellular mucin containing simple to focally proliferative mucinous epithelium	Moderate to abundant extracellular mucin containing extensively proliferative mucinous epithelium or mucinous glands, clusters of cells, or individual cells consistent with carcinoma		
Cytologic atypia	Minimal	Moderate to marked		
Mitotic activity	Rare	Infrequent to abundant		
Lymph node involvement	Rare	Frequent		
Parenchymal organ involvement	Rare (except ovary)	Frequent		

^aThe distribution is characterized by superficial noninvasive involvement of the omentum, undersurface of the diaphragm, pelvis, right retrohepatic space, left abdominal gutter, and ligament of Treitz, with sparing of the peritoneal surfaces of the bowel.

Table 14.18

Distinction of ovarian mucinous tumors associated with pseudomyxoma peritonei (PMP) from primary ovarian mucinous tumors

Feature	Ovarian mucinous tumors in pseudomyxoma peritonei	Primary ovarian atypical proliferative mucinous tumors
Size	Variable (mean/ median = 14 cm) ^a	Large (mean/ median = 22 cm) ^b
Laterality	Bilateral (80%) ^a	Unilateral (100%) ^b
Location of tumor	Surface, superficial cortex, stroma	Within stroma (rarely on surface when ruptured)
Pseudomyxoma ovarii	Often prominent	Usually absent or limited
Amount and pattern of epithelium	Usually scant; haphazard when more abundant	Abundant; organized cysts with peripheral crypts
Associated appendiceal mucinous tumor	Virtually all cases	None

^aData derived from combination of data in [278, 391]. ^bData derived from [391].

Ovarian involvement by disseminated peritoneal adenomucinosis. The neoplastic mucinous epithelium closely resembles that in a primary ovarian mucinous neoplasm

Mucinous Tumors with Mural Nodules

Ovarian mucinous cystic neoplasms of all types can occasionally contain mural nodules. Three varieties of mural nodules have been described, including true sarcomas, sarcoma-like mural nodules, and foci of anaplastic carcinoma. In general, the sarcomatous nodules and foci of anaplastic carcinoma tend to occur in older patients and are characterized by larger size, poor circumscription, a monotonous spindle cell population in the former, evidence of carcinomatous differentiation in the latter, and aggressive behavior. In contrast, sarcoma-like mural nodules tend to occur in younger women and are characterized by smaller size, sharp demarcation, a heterogeneous cell population, and no demonstrable impact on the prognosis. The sarcoma-like mural nodules can have various histologic appearances, including a pleomorphic and epulis-like type with multinucleated giant cells, a pleomorphic and spindle cell type, and a giant cell-histiocytic type () Figs. 14.94 and () 14.95). The nodules can be solitary or multiple and mixtures of these histologic types can be encountered, with the pleomorphic and epulis-like type being the most common. Hemorrhage, necrosis, and a mixed inflammatory cell component are commonly seen. It is not clear whether sarcoma-like mural nodules are neoplastic or represent a reaction to hemorrhage within or rupture of a mucinous cyst. Sarcoma-like mural nodules usually coexpress vimentin (strong/diffuse) and cytokeratin (focal/weak), similar to true sarcomas yet

Fig. 14.94

Atypical proliferative mucinous tumor with sarcoma-like mural nodule. Neoplastic mucinous epithelium on the *left* is adjacent to a solid proliferation of markedly atypical cells including multinucleated giant cells

distinct from anaplastic carcinomas that usually have strong/diffuse cytokeratin expression.

Mucinous tumors with malignant mural nodules are probably best classified as variants of mucinous carcinoma or carcinosarcoma. Malignant mural nodules are fatal in 50% of cases. Sarcoma-like mural nodules, though believed to be benign, should be regarded with caution as their histologic appearance is worrisome and clinical follow-up data are very limited.

Invasive Mucinous Carcinomas

Mucinous carcinomas of the intestinal type are rare, and comprise 2–3% of ovarian carcinomas (**)** *Tables 14.4* and **)** *14.5* [301, 342].

Clinical and Operative Findings

Primary ovarian mucinous carcinomas most often present as large unilateral ovarian masses, usually without evidence of ovarian surface involvement or extraovarian disease, similar to APMT.

Gross Findings

The gross findings are similar to APMT in that they are typically large, unilateral, multicystic mucus-containing tumors with smooth white capsules and have mean and median sizes of 18–22 cm. They may contain solid areas and foci of necrosis and hemorrhage.

Microscopic Findings

Mucinous carcinomas of intestinal type typically are architecturally well differentiated and display a variety of glandular patterns, with many tumors having areas of APMT adjacent to areas of carcinoma (\bigcirc *Figs.* 14.96–14.101). The traditional definition of mucinous carcinoma required the presence of destructive stromal infiltration by malignant mucinous epithelium as the primary microscopic feature to establish a diagnosis of invasive

carcinoma. Tumors exhibiting typical APMT-type growth patterns with excessive epithelial stratification and lacking significant nuclear atypia or stromal invasion have not been associated with adverse outcome and are accepted as APMT.

Recent studies have drawn attention to a second pattern of invasion, termed the "confluent glandular" or "expansile" pattern [52, 179, 272]. In this pattern, the glandular epithelium is markedly crowded, with little intervening stroma, and interconnected in a confluent or labyrinthine pattern (\bigcirc *Figs.* 14.96–14.98). Primary ovarian mucinous carcinomas commonly exhibit this pattern

Fig. 14.97

Fig. 14.98 Mucinous carcinoma. A confluent glandular pattern with complex interconnecting neoplastic glands

Mucinous carcinoma. Glands of varying shape and size with complex interconnections and marked cytologic atypia

 Fig. 14.100
Mucinous carcinoma. Cribriform pattern. Necrotic debris is present in gland lumens

of invasion, and the presence of an infiltrative pattern of stromal invasion should raise concern for metastatic mucinous carcinoma (see **Differential Diagnosis** below). The confluent glandular pattern reflects invasive mucinous carcinoma. High nuclear grade is significantly more common with the infiltrative pattern [342]. For tumors composed predominantly of APMT, the foci of confluent growth should measure more than the upper size limit allowed for microinvasion (5 mm) to qualify for the diagnosis of invasive carcinoma.

The grading of mucinous carcinoma has not been wellstudied. Primary ovarian mucinous carcinomas are nearly

G Fig. 14.101

Mucinous carcinoma. Haphazard infiltrative pattern of small glands with marked cytologic atypia. Muciphages are present in the stroma

always predominantly glandular and papillary and therefore architecturally low grade. The nuclear grade is therefore the best discriminator and we prefer the binary system described earlier (see ≥ High-Grade Serous Carcinoma; > Microscopic Findings; > Grade, earlier in this chapter).

Mucinous carcinomas of the seromucinous (müllerian or endocervical-like) type are quite uncommon. They are clinically and grossly similar to the atypical proliferative tumors of this type. Microscopically, they also resemble APSMT but exhibit destructive stromal invasion or sufficient complex papillary or confluent glandular growth to be classified as carcinoma [177, 316].

Immunohistochemistry

Ovarian mucinous tumors, including APMTs of gastrointestinal type and mucinous carcinomas, are characterized by generally diffuse expression of cytokeratin 7 (CK7) and variable expression of CK20, with the majority being positive for CK20 but virtually always with less-diffuse staining compared with CK7 expression [362]. They can express CDX2 (nuclear staining); exhibit generally patchy expression of p16; and are negative for ER, PR, and CA125 [363-365]. Mucinous tumors arising in association with mature cystic teratomas, some of which have architectural features of APMTs, are more heterogeneous in their CK7 and CK20 coordinate expression profiles [211, 366]. A subset with morphologic features of lower intestinal tract tumors, often accompanied by pseudomyxoma ovarii, is strongly associated with the CK7-/CK20+ immunoprofile [211]. The morphology and this profile can suggest a metastatic mucinous tumor of lower

Differential Diagnosis

It is critical when evaluating a mucinous carcinoma involving the ovary to consider the possibility of an extraovarian primary. Metastatic mucinous carcinomas are usually readily recognized as such when the ovarian tumors exhibit at least two of the following features: bilaterality, small size (typically less than 10–12 cm), ovarian surface involvement, a nodular pattern of ovarian involvement, and a haphazard infiltrative pattern of stromal invasion (**>** *Table 14.19*) [272, 306, 391]. Immunohistochemistry can be of great value in this distinction. (see **>** Immunohistochemistry above, and **>** Metastatic Mucinous Carcinoma" below.)

An algorithm has been proposed to assist in the distinction of primary versus metastatic mucinous carcinoma, particularly at the time of intraoperative evaluation when only limited histologic material can be examined. As originally proposed, bilateral mucinous carcinomas and unilateral ones smaller than 10 cm are metastatic, and unilateral ones larger than 10 cm are primary [306]. This algorithm correctly classified 90% of mucinous carcinomas. Subsequent studies have confirmed and refined the algorithm, also with close to 90% accuracy, and suggest that 13 cm is a better cutoff than 10 cm [391].

Molecular Biology

The molecular changes in ovarian mucinous tumors have not been as extensively studied as in serous and endometrioid tumors. This is probably due to the relative rarity of primary mucinous carcinomas, now that metastatic mucinous adenocarcinomas to the ovary are being more rigorously excluded. As a consequence, most studies in the published literature have analyzed only limited numbers of mucinous carcinomas, and therefore the true prevalence of many specific molecular alterations in these tumor types is unknown.

In primary ovarian mucinous carcinomas, *KRAS* mutation is a very common molecular alteration – occurring in upward of 75% of ovarian mucinous carcinomas [85, 102, 133]. Mucinous adenocarcinomas often contain areas indistinguishable from mucinous cystadenoma and mucinous borderline tumor and progression from benign to borderline and from borderline to malignant neoplasia has been proposed. Interestingly, identical *KRAS* mutations have been detected in mucinous carcinomas and adjacent mucinous cystadenoma and borderline tumor

Table 14.19

Distinction of primary and metastatic mucinous carcinomas in the ovary

Feature	Primary ovarian mucinous tumors ^a	Metastatic mucinous tumors
Laterality	Unilateral (>>95%) ^a	Commonly bilateral (~65% overall; varies by site of origin)
Size	Large (mean/ median = 22/21 cm) ^a	Typically smaller (mean/median = 13/ 12 cm; values vary by site of origin, from 2–18 cm)
Gross features	Multicystic (+/– solid foci), smooth capsule	Often nodular with surface involvement but can be multicystic with smooth capsule
Location of tumor	Within stroma	Surface, superficial cortex, stroma
Microscopic features	Well-differentiated mucinous epithelium forming organized cysts with peripheral crypts in atypical proliferative (borderline) tumors; well-differentiated mucinous epithelium most commonly with confluent glandular/ cribriform pattern but occasionally infiltrative pattern in carcinomas	Typically infiltrative pattern of mucinous glands, often with nodules throughout or in superficial cortex; can have confluent glandular and borderline-like patterns without desmoplasia; nuclear atypia is often greater than expected relative to the low grade architecture
Extraovarian disease	Usually absent (stage I)	Often present (peritoneum, omentum)

^aAtypical proliferative tumors and carcinomas.

^bData derived from [391].

[67], a molecular finding supporting this morphological continuum of tumor progression in ovarian mucinous neoplasia, and in turn, their classification as Type I tumors in the dualistic model of ovarian cancer pathogenesis (see **2** Morphologic and Molecular Pathogenesis earlier in this chapter).

Genome-wide analyses of DNA copy number changes in primary ovarian mucinous carcinomas have not yet been reported. Not unexpectedly, the pattern of gene expression of mucinous carcinomas is largely distinguishable from serous, endometrioid, and clear cell carcinomas based on comprehensive gene expression profiling [120, 296]. Using high-density oligonucleotide microarrays, Heinzelmann-Schwarz and colleagues identified a characteristic gene expression profile associated with mucinous ovarian tumors [120]. Ovarian mucinous tumors express several mucin genes (MUC2, MUC3, and MUC17) that are characteristic of mucinous carcinomas irrespective of their tissue origins. Because primary ovarian mucinous tumors often display intestinal-type differentiation, it is not surprising that additional genes with preferential expression in ovarian mucinous tumors encode markers of intestinal differentiation such as the caudal-type homeobox transcription factors CDX1 and CDX2, and LGALS4 (galectin 40), which encodes an intestinal cell surface adhesion molecule that is overexpressed in intestinal carcinomas. Immunohistochemical analysis of LGALS4 expression in a spectrum of ovarian mucinous neoplasms showed that LGALS4 is not detectable in normal ovarian surface epithelium, but is expressed at high levels in mucinous cystadenomas, borderline tumors, and carcinomas, indicating that increased LGALS4 expression occurs early during mucinous ovarian tumor progression [120].

Behavior and Treatment

Patients with stage I mucinous carcinomas displaying a confluent or expansile type of invasion have a survival of about 90%; despite a few exceptions, adverse prognosis is more commonly associated with the infiltrative rather than the confluent glandular pattern of invasion [52, 179, 272, 274]. For patients with APMT with microinvasion and/or intraepithelial carcinoma, a staging procedure is unlikely to yield positive findings, but no data are available to address the value of staging.

As with the other cell types of ovarian carcinomas, platinum–paclitaxel is standard treatment for mucinous carcinoma. However, because of classification problems discussed earlier, published data on the value of this regimen for those with true primary ovarian mucinous carcinoma are of uncertain validity.

Metastatic Mucinous Carcinomas

Metastatic mucinous carcinomas are typically bilateral, small (typically less than 10–12 cm), display ovarian surface and superficial cortical involvement, a nodular pattern of ovarian involvement, and a haphazard infiltrative

pattern of stromal invasion (> Table 14.19) [272, 306, 391]. However, some metastatic mucinous carcinomas, especially those derived from the colorectum, pancreaticobiliary tract, appendix, and endocervix, can exhibit gross and microscopic features simulating a primary ovarian mucinous tumor. In particular, metastases can be large, unilateral (thus misclassified by the algorithm discussed earlier), and multicystic, and can display deceptive patterns of ovarian involvement. If these patterns are not recognized, these metastatic mucinous carcinomas can be misinterpreted as primary ovarian APMT with intraepithelial carcinoma or well-differentiated mucinous carcinoma [84, 391]. Not infrequently, some of these metastases display highly differentiated areas adjacent to carcinomatous areas, simulating benign and APMT precursor lesions. Recognizing such tumors as metastases is especially problematic when the ovarian tumor is the initial manifestation of disease and an extraovarian primary mucinous carcinoma is occult. When mucinous carcinomas in the ovaries are rigorously classified based on refined criteria and awareness of the deceptive patterns, metastatic mucinous carcinomas are much more commonly encountered than primary ovarian mucinous carcinomas, even if the obviously metastatic signet ring cell carcinomas are excluded [306, 391]. In general, the presence of a mucinous carcinoma in the ovary, particularly if extraovarian disease is present, should always prompt the pathologist to consider the possibility of metastatic mucinous carcinoma. Immunohistochemical analysis can be useful for identifying some metastatic mucinous carcinomas, especially those lacking characteristic features of metastases, which simulate primary ovarian mucinous tumors; however the utility of currently available markers is limited due to overlapping immunoprofiles of primary tumors and certain subsets of metastases (see Immunohistochemistry above) [139, 362–365]. Clinical evaluation is usually required to exclude metastatic mucinous carcinoma in the ovary derived from a clinically occult extraovarian source.

Endometrioid Tumors

The vast majority of endometrioid ovarian neoplasms are carcinomas. Endometrioid adenofibromas and atypical proliferative endometrioid tumors are uncommon (\bigcirc *Table 14.5*). Molecular biological studies have shown that endometrioid ovarian carcinomas have similarities with, and differences from, their uterine counterparts. For example, mutations of *PTEN*, *PIK3CA*, and *CTNNB1* (β -catenin) are observed in subsets of both

uterine and ovarian endometrioid adenocarcinomas, although the relative frequency of these alterations in carcinomas from the two sites are not identical. Comprehensive gene expression studies have shown differences in gene expression profile when comparing uterine and ovarian endometrioid adenocarcinomas [318, 398].

Ovarian endometriosis (including endometriomas and endometriotic cysts) is far more common than benign endometrioid neoplasms. Since the majority of ovarian endometriotic cysts are monoclonal and have a variety of molecular alterations, they are neoplastic [159, 374]. If endometriotic cysts were classified as benign endometrioid neoplasms, the relative proportions of ovarian epithelial tumors seen in O *Table 14.5* would be significantly altered. As noted earlier, endometriosis would qualify as the most common ovarian neoplasm, and endometrioid carcinomas would be much less common than benign endometrioid neoplasms.

Endometrioid Adenofibromas

Endometrioid adenofibromas are uncommon, comprise 1% of ovarian epithelial neoplasms, and 83% are unilateral. The median age is 57 years. The mean diameter is about 10 cm. The external surface is smooth and the cut surface is densely fibrous, often with intermixed cystic areas creating a honeycomb appearance. The cysts contain clear or yellowish fluid. Microscopically, the dominant pattern is that of an adenofibroma or cystadenofibroma. The epithelial elements are arranged in branching tubular glands and cysts, and usually resemble those of proliferative or mildly hyperplastic endometrium (> Figs. 14.102 and (> 14.103). The epithelium lining the glands is tall and columnar with oval nuclei containing coarse chromatin and small nucleoli; the cytoplasm is basophilic to amphophilic. The epithelium is often ciliated and resembles tubal epithelium. Sometimes the nuclei resemble those of atrophic or inactive endometrium, with uniform, elongated dark nuclei and scanty cytoplasm. Mitoses are variable but usually rare. Secretory changes and focal squamous differentiation may be present. The stroma is usually densely fibrotic; focal areas often resemble ovarian cortical stroma. Endometrioid adenofibromas are frequently associated with endometriosis. The distinction of endometrioid adenofibroma from serous adenofibroma may be arbitrary at times, as both may have ciliated epithelium. Tubular glands and lack of the multiple cysts and fibrous papillae of serous adenofibroma favor endometrioid differentiation. These tumors are benign, although rarely they may recur.

Atypical Proliferative Endometrioid Tumors (APET)

There is a spectrum of epithelial proliferation, glandular crowding, and cytologic atypia in benign endometrioid neoplasms ranging from mild atypia, mild glandular crowding, and epithelial stratification slightly beyond what is seen in endometrioid adenofibromas to confluent epithelial proliferation lacking stromal support in areas up to 5 mm in diameter resembling atypical hyperplasia and well-differentiated adenocarcinoma of the endometrium. A variety of terms have been employed for these tumors, including proliferating or proliferative endometrioid tumor, atypical endometrioid adenofibroma, endometrioid tumor of low malignant potential, endometrioid borderline tumor, and atypical proliferative endometrioid tumor. APET with microinvasion (<5 mm), which is very rare, constitutes the upper end of this spectrum after which a diagnosis of low-grade endometrioid carcinoma is used. The criteria for these diagnoses have differed among several series. Since the behavior of all of the tumors up to and including those with microinvasion has been benign, we prefer to combine these groups and refer to them as "APET." The lower end of the spectrum characterized by slightly crowded glands lacking cytologic atypia is best classified as endometrioid adenofibroma.

APET comprise only 0.2% of ovarian epithelial neoplasms. Among five series [182, 282, 308], there were 134 patients with a mean age of about 51 years. Six patients (4%) had bilateral tumors, and all but two were confined to the ovaries; one had a colonic "implant" and one was stage IIC [282]. The mean tumor size was about 9 cm. The characteristic gross appearance is cystic in two thirds and solid and cystic in the rest; the cyst fluid is usually hemorrhagic, and brown or green. Many patients have had endometriosis and some have also had endometrial hyperplasia. In a recent series of 30 cases, 63% had endometriosis and 39% of those whose endometrium was examined had endometrial hyperplasia or carcinoma [282].

The two characteristic microscopic architectural appearances of APET are adenofibromatous and glandular/papillary. The glandular/papillary proliferation can show varying degrees of glandular complexity and crowding () Figs. 14.104-14.107). An underlying adenofibroma is present in about half the cases [282]. When the glandular proliferation becomes confluent, this is considered evidence of invasion and is classified as microinvasion if the confluent area is less than 5 mm. Some investigators prefer to classify these as APET with intraepithelial carcinoma. A confluent epithelial proliferation or unequivocal invasion that exceeds 5 mm in diameter warrants a diagnosis of carcinoma. The glands show crowding, mild or moderate cytologic atypia, and epithelial stratification (> Fig. 14.104-14.107); tufting and bridging may be present. Severe cytologic atypia warrants a diagnosis of intraepithelial carcinoma, but this is rare. One third display a cribriform pattern [282]. Squamous metaplasia is present in nearly half of cases (> Figs. 14.104-14.106). The stroma may be cellular or fibrotic, and occasionally displays periglandular cuffing

G Fig. 14.104

Atypical proliferative (borderline) endometrioid tumor (APET). Squamous differentiation is present. A stromal reaction is noted. The glands in the center contain necrotic debris

Fig. 14.105
Atypical proliferative (borderline) endometrioid tumor.
Clusters of endometrioid glands with squamous (morular) metaplasia

characterized by increased stromal cellularity around the glandular elements; however these areas lack the stromal mitoses and atypia of adenosarcoma. Necrosis is common and is often confined to gland lumens or cysts (**)** *Fig. 14.104*). The two reported cases with apparent extraovarian disease may represent independent lesions arising in endometriosis [282]. Among 134 reported APETs, all of those with clinical follow-up have had a benign behavior after a mean follow-up period of

Atypical proliferative (borderline) endometrioid tumor. Mild cytologic atypia is present in both the endometrioid glands and the squamous morules

Fig. 14.107

Atypical proliferative (borderline) endometrioid tumor. Moderate cytologic atypia in markedly crowded glands is seen

approximately 5 years. Rarely, an endometriotic cyst is lined by markedly atypical epithelial cells that have cytologic features of malignancy (see **O** Chap. 13, Diseases of the Peritoneum). If the lesion is well sampled and invasion is not found, a designation of APET with intraepithelial carcinoma should be used.

Criteria for microinvasion in APETs differ among investigators. In two series, microinvasion was characterized by a haphazard infiltrative pattern of single cells, glands, and nests with cytologically malignant features. Among the five APETs with microinvasion reported in these series, all patients were alive and well after a mean of 5.3 years. Different criteria employed by another group required one or more foci of confluent (expansile) glandular growth, each measuring less than 5 mm, for a designation of APET with microinvasion. The five cases in that series had limited follow-up; all were alive but only two were known to be free of disease at 2 years of followup. Others have used a combination of these criteria [282]. In summary, microinvasion (12 cases), intraepithelial carcinoma (7 cases), and confluence of glandular growth when limited in extent, are atypical morphologic features and appear to be biologically benign, but only a few cases have been reported and clinical follow-up data are limited.

The immunohistochemical features of this tumor are similar to those of endometrioid carcinoma (see below). EMA and many cytokeratins are positive. P16 can be positive in up to half of cases, but staining is usually focal [364].

Endometrioid Adenocarcinoma

In the older literature, about 15–20% of reported ovarian carcinomas are endometrioid, up to 25% in some reports [338], but when strict criteria are applied, the figure is lower and probably in the range of 10–15%. When very strict criteria are used, requiring a readily recognized resemblance to uterine endometrioid carcinoma and relegating nonspecific high-grade adenocarcinomas to the serous group, the figure is about 7.5% (**)** *Table 14.4*; see **)** Differential Diagnosis below).

Clinical Findings

These tumors are most common in the fifth and sixth decades, and the mean patient age is 55–58 years, slightly but significantly lower than that for serous carcinoma [338]. The most common symptoms are abdominal distention and pelvic or abdominal pain. Abnormal vaginal bleeding is also frequent. This is, in part, related to the association of endometrioid ovarian carcinoma with endometrial hyperplasia and carcinoma (see below). Most patients have an adnexal mass on pelvic examination.

Operative Findings

Tumor size ranges from 12 to 20 cm, with a mean of about 15 cm. The stage distribution differs significantly from serous carcinoma. A high proportion of endometrioid carcinomas are diagnosed in stage I: 43% in a review of 874 cases from 19 series, and 50% at the Washington Hospital Center (**>** *Table 14.4*). In the FIGO database, 52% of patients are diagnosed in stage I or II. About 13% of early stage (FIGO I–II) cases are bilateral. Endometriosis, which may be extraovarian, in the ipsilateral or contralateral ovary or within the tumor itself, is found in at least 15–20% of patients.

Gross Findings

Endometrioid carcinomas have a smooth outer surface. On cut section, they are solid and cystic, with the cysts containing friable soft masses and bloody fluid. Cysts occasionally contain mucus or greenish fluid. Less commonly, the tumor is solid with extensive hemorrhage and necrosis. Tumors arising in endometriosis may display gross findings of an endometriotic cyst containing chocolate-colored fluid, with one or more solid nodules or papillary excrescences protruding from the wall and containing carcinoma.

Microscopic Findings

Destructive infiltrative growth characterizes one pattern of endometrioid carcinoma. This pattern is characterized by angulated glands with an infiltrative pattern, jagged irregularly spaced and unevenly shaped nests, often with an edematous or inflammatory stromal reaction, solid sheets with jagged edges, and single cell infiltration [52]. More commonly, a confluent glandular epithelial proliferation exceeding 5 mm (the limit for microinvasion) is present; this has also been termed "expansile invasion." This pattern typically excludes intervening stroma and is characterized by extensive glandular branching, budding, true cribriform architecture, and highly complex papillary proliferations (\bigcirc *Figs.* 14.108 and \bigcirc 14.109). Confluent or expansile invasion is the predominant pattern in most endometrioid carcinomas [52] (\bigcirc *Figs.* 14.109–14.111).

Architecturally well-differentiated endometrioid adenocarcinoma accounts for the majority of cases and is characterized by a confluent or cribriform proliferation of glands lined by tall, stratified columnar epithelium with sharp luminal margins () Figs. 14.109-14.111). A villoglandular growth pattern also occurs. Despite the low-grade architecture, high-grade nuclear features, at least focally, can be observed [313]. Mitotic figures are commonly seen. Squamous differentiation is present in up to 50% of cases. Degeneration of squamous cells may induce a foreign body-type giant cell reaction in the stroma. Focal secretory changes are seen in up to a third of cases. In the majority of cases, a component of endometriosis, endometrioid adenofibroma, or APET can be identified and often occupies a significant proportion of the tumor volume [52, 389]. This corresponds to the Type I pathway of tumorigenesis in which a noninvasive precursor is identified (see **S** Morphologic and Molecular Pathogenesis earlier in this chapter).

Luteinized stromal cells are seen in 12% of cases. Moderately and poorly differentiated endometrioid carcinomas show solid growth, complex glandular and microglandular patterns with marked nuclear

Fig. 14.108

Well-differentiated endometrioid carcinoma arising in an atypical proliferative endometrioid tumor. The confluent glandular/papillary proliferation reflects invasion in the absence of destructive infiltrative growth

Fig. 14.109

Well-differentiated endometrioid carcinoma. Most of the glands are back-to-back, but confluent foci are present. The proliferation resembles endometrioid carcinoma of the uterine corpus

pleomorphism, and mitotic activity (**>** *Figs. 14.110* and **>** *14.111*); however the majority of high-grade carcinomas with these features are usually classified as serous (see **>** Differential Diagnosis below). It has been suggested that solid areas in some endometrioid adenocarcinomas may reflect an undifferentiated component [325].

At present, clinicopathologic and molecular data indicate that it is important to be strict about classifying

an adenocarcinoma as endometrioid type. Most predominantly glandular, non-clear cell, non-mucinous highgrade ovarian carcinomas should be classified as serous carcinoma [154]. Glandular, cribriform, and solid patterns are common in serous carcinoma (see **>** Serous Tumors above). A bona fide endometrioid adenocarcinoma should resemble eutopic endometrial carcinomas (**>** *Table 14.15*) [207]. When strict criteria are applied, only 7.5% of ovarian carcinomas are of endometrioid type (**>** *Table 14.4*) and virtually all of these are well differentiated. Most tumors classified as poorly differentiated are more likely variants of high-grade serous carcinoma showing foci of gland formation. A diagnosis of mixed serous–endometrioid carcinoma can be made on occasion; we classified only 1.5% of ovarian carcinomas as mixed serous–endometrioid type.

There is no standard grading system for endometrioid carcinoma, although the WHO system for grading endometrial adenocarcinoma is often used (see **2** Chap. 9, Endometrial Carcinoma). When strict criteria are used to separate high grade endometrioid carcinoma from high grade serous carcinoma (see above), most endometrioid carcinomas are architecturally well-differentiated as they are predominantly glandular or glandular and papillary. The nuclear grade is therefore the best discriminator and we prefer the binary system described earlier (see **2** High-Grade Serous Carcinoma; **2** Microscopic Findings; **2** Grade earlier in this chapter). It is important to note that neither the WHO 3-grade system nor the binary system has been adequately tested for endometrioid carcinomas.

In addition to pure endometrioid carcinoma, which is the most common, several of the variants of endometrioid carcinoma of the uterine corpus also occur in the ovary. These include endometrioid carcinoma with squamous differentiation, and secretory and ciliated variants. Other variant microscopic patterns of endometrioid ovarian carcinoma have been described. One variant has been designated "sertoliform endometrioid carcinoma," or "endometrioid carcinoma resembling sex cord-stromal tumor." These tumors are characterized by a predominant pattern resembling a sex cord-stromal tumor, usually Sertoli-Leydig cell tumor (SLCT), characterized by small tubular glands lined by cuboidal or low columnar epithelium with a paired cell arrangement resembling welldifferentiated Sertoli cell tumor. Anastomosing solid tubules are often present (**>** Figs. 14.112 and **>** 14.113). Moderately cellular fibrous stroma resembling the spindle cell component of stromal tumors may also be present. In a few cases, large islands of cells with round nuclei and scanty cytoplasm may mimic a granulosa cell tumor, but nuclear grooves are generally absent. In nearly all of these cases, foci of typical endometrioid carcinoma can be identified. Among 30 patients in three series, 87% were FIGO stage I.

Endometrioid carcinomas occasionally contain a prominent spindle cell component that usually reflects a spindled squamous component. These should not be classified as carcinosarcomas unless the stroma displays unequivocally sarcomatous features (see Sarcomas; Carcinosarcoma later in this chapter). Other very rare variants include those with an undifferentiated neuroendocrine component [368], adenoid cystic-like and basaloid types, oxyphilic endometrioid carcinoma, and a ciliated cell variant.

Sertoliform endometrioid carcinoma. Cords and tubules with a paired cell arrangement resemble a Sertoli cell tumor or a well-differentiated Sertoli–Leydig cell tumor (SLCT)

Fig. 14.113 Sertoliform endometrioid carcinoma. The degree of cytologic atypia is high

Peritoneal keratin granulomas may be found in women with endometrioid ovarian carcinomas, presumably as a result of rupture of the neoplasm or exfoliation of squamous cells. The keratin within the metaplastic squamous component of these tumors incites a foreign-body-type granulomatous reaction. Follow-up of a limited number of these patients reveals that these lesions have no prognostic significance and therefore should not be considered evidence of advanced-stage disease. Endometrioid carcinoma after chemotherapy can show extensive keratin granulomas due to necrosis of the squamous component, and therefore peritoneal keratin granulomas after chemotherapy probably reflect devitalized tumor.

Immunohistochemistry

Endometrioid carcinomas stain strongly with epithelial markers including cytoplasmic staining for keratins (CK7, 97%; CK20, 13% positive) and membranous staining for EMA. The frequency of positivity for other markers is as follows: vimentin, 31%; B72.3, 86%; CEA, 30%; and OC-125, 76%. The immunohistochemical profiles of typical endometrioid carcinoma and sertoliform endometrioid carcinoma appear to be identical. ER and PR are positive in the majority of cases [178]. WT1 and p16 are usually negative [1, 124, 205, 206, 237] but WT1 can be positive in 17-29% [47, 395, 396] and p16 can be positive in up to half but is usually focal [364]. Brca1 protein is usually positive (nuclear staining) [352]. Inhibin is rarely positive. Calretinin is strongly positive in 10%, and weakly positive in an additional 10-25% [47, 194]. TTF1 is usually negative [162]. CD99 is often positive. PTEN expression is negative in well-differentiated carcinomas; however PTEN immunostaining is not that reliable [109]. Loss of staining for hMLH1and hMSH2 proteins occurs in the majority of tumors with the microsatellite instability-high phenotype, which represent approximately 20% of ovarian endometrioid adenocarcinomas [186].

Differential Diagnosis

The sertoliform or sex cord-like variant of endometrioid carcinoma creates the most problems in the differential diagnosis. The age of the patient is helpful since the mean age of patients with SLCTs is 25 years, while women with endometrioid carcinoma are usually peri- or postmenopausal. In addition, hormonal manifestations such as virilization can be associated with sex cord-stromal tumors and generally not with endometrioid carcinomas. The retiform variant of SLCT, which occurs in adolescents, can rarely simulate endometrioid or serous carcinoma, but this pattern is usually only focal. In most cases of sertoliform endometrioid carcinoma, extensive sampling of the tumor will disclose areas of typical endometrioid carcinoma. Other helpful features include squamous metaplasia, which does not occur in sex cord-stromal tumors, an adenofibromatous component that is typical of endometrioid carcinoma, endometriosis, and prominent luminal mucin, which occur in endometrioid carcinomas.

Although sex cord-stromal tumors often stain with keratins, they are almost always negative for EMA. In addition, inhibin is a very useful marker that is positive in the vast majority of granulosa and SLCTs, and nearly

always negative in ovarian epithelial tumors, although inhibin is nearly always positive in the non-neoplastic stromal cells within the tumor. Similarly, calretinin is nearly always positive in stromal tumors, but can stain endometrioid carcinomas, focally in 18-33% and strongly in up to 10% [364, 396]. Other epithelial markers including neuron-specific enolase, OM-1, and B72.3 are negative in granulosa and most SLCTs, and positive in the majority of endometrioid carcinomas. Positivity for CK7 and EMA together can help exclude yolk sac tumor (YST), which is negative for both; this may be a consideration when there is a clear cell component or to rule out the rare endometrioid variant of YST [267]. Occasionally, a prominent spindle cell component in an endometrioid carcinoma will create an appearance resembling a sex cord-stromal tumor, an adnexal tumor of wolffian origin, or a carcinosarcoma. The spindle cells are generally uniform and have nuclear features resembling the glandular component. In most cases, the spindle cells merge imperceptibly with the glands. The spindle cells in the spindle cell variant of endometrioid carcinoma are strongly positive for keratins and EMA.

Another common problem in the differential diagnosis of endometrioid carcinoma is metastatic adenocarcinoma, particularly from colonic carcinoma. Colonic metastases to the ovaries are often cystic and grossly mimic primary ovarian neoplasms. Useful features in the distinction are a characteristic "garland" pattern characterized by cysts lined by cytologically malignant tall columnar cells in which the epithelium displaying a cribriform pattern surrounds large areas of dirty necrosis. In addition, metastatic tumors are typically bilateral and display surface involvement. Although garlands and dirty necrosis are characteristic features of metastatic colonic carcinoma, they can also be seen in primary ovarian carcinomas, though usually only focally. The CK7/CK20 panel is of value in the distinction of primary ovarian versus metastatic colonic carcinoma, as ovarian endometrioid carcinoma is typically diffusely and strongly CK7 positive and CK20 negative, while most colon carcinomas are CK7 negative and are nearly always strongly and diffusely CK20 positive (see) Metastatic Mucinous Carcinoma earlier in this chapter, and S Chap. 18, Metastatic Tumors of the Ovary).

Molecular Biology

The association of ovarian endometrioid carcinoma with endometriosis is well established. The identification of genetic alterations in endometriotic lesions and the observation of a morphological transition from endometriosis to carcinoma in over one third of cases have led many to consider endometriosis a likely precursor of endometrioid carcinoma [285, 351]. Progression from endometriosis to benign endometrioid neoplasm to well-differentiated endometrioid carcinoma is analogous to that proposed for progression of low-grade serous carcinoma from serous borderline tumor. Hence, low-grade (well-differentiated) endometrioid carcinomas are classified as Type I tumors in the dualistic model of ovarian cancer pathogenesis. Classification of high-grade endometrioid carcinomas is less clear. Overlap of both morphological and molecular features between high-grade endometrioid and high-grade serous carcinomas has led some pathologists to default the vast majority of gland forming or near-solid cytologically highgrade ovarian carcinomas to the serous category, to the degree that "true" high-grade endometrioid carcinomas are considered by some to be very uncommon [207]. The molecular and morphological criteria for reliably distinguishing high-grade endometrioid from high-grade serous carcinomas have not yet been established, and for now, high-grade endometrioid carcinomas are classified as Type II tumors.

Mutational Analyses Well-differentiated ovarian endometrioid carcinomas share many molecular genetic features with their uterine counterparts. Indeed, mutations in several of the same tumor suppressor genes, oncogenes, and genes involved in DNA repair have been observed in both endometrial and ovarian endometrioid carcinomas. The molecular genetics of endometrial carcinomas have been recently reviewed by Di Cristofano and Ellenson [73].

The canonical Wnt (i.e., Wnt/β-catenin/Tcf, hereafter Wnt/ β -cat) signaling pathway is involved in the regulation of several important cellular processes, including cell fate determination, proliferation, motility, and survival. In this pathway, β -catenin is a key effector that is stabilized as a consequence of selected Wnt ligands binding to their cell surface receptors. β-catenin-mediated signaling is deregulated in 16-38% of human ovarian endometrioid carcinomas, usually on the basis of activating mutations of CTNNB1, the gene that encodes β -catenin, and rarely because of inactivating mutations in genes encoding negative regulators of β -catenin such as APC, AXIN1, or AXIN2 [383]. Notably, CTNNB1 mutations are very uncommon in the other major types of ovarian carcinoma [98, 382]. Several studies have noted the association of CTNNB1 mutation with squamous differentiation, low tumor grade, and favorable outcome [98, 383]. Inactivating mutations of the tumor suppressor gene PTEN have been reported in 14-21% of ovarian endometrioid carcinomas, and like CTNNB1, PTEN mutations are uncommon in the other major types of ovarian carcinomas [45, 238]. Inactivation of Pten, the

lipid phosphatase that converts PIP3 to PIP2, is one mechanism by which activation of phosphotidylinositol 3-kinase (PI3K) signaling occurs in human tumors.

An alternative mechanism by which PI3K signaling is activated in endometrioid adenocarcinomas is through activating mutations of PIK3CA, which encodes the p110 catalytic subunit of PI3K. Most reported PIK3CA mutations are clustered in exons 9 and 20, and PIK3CA mutations in these exons have been identified in 20% of ovarian endometrioid and clear cell carcinomas but in only 2% of ovarian serous carcinomas [12, 40]. Oda and colleagues reported a high frequency of concomitant PIK3CA and PTEN mutations in uterine endometrioid adenocarcinomas, and functional studies suggested that mutation of both genes may have an additive effect on PI3K pathway activation [240]. PIK3CA and PTEN mutations also cooccur in a subset of ovarian endometrioid carcinomas. In both the ovary and the endometrium, PIK3CA mutations are associated with adverse prognostic indicators [46, 376]. In a recent mutational analysis of 72 primary ovarian endometrioid carcinomas, Wu and colleagues found that mutational defects in canonical Wnt signaling were significantly associated with mutations predicted to deregulate PI3K/Pten signaling [383]. Tumors with these mutations were typically low grade and low stage. Hence, defects in these two signaling pathways appear to be particularly characteristic of low-grade endometrioid adenocarcinoma, a finding with implications for future therapeutic strategies that include molecularly targeted agents. Activating mutations in KRAS and BRAF have been reported in ovarian endometrioid carcinomas, but the frequency of mutations in these genes is rather low at less than 7% [85, 203, 383]. TP53 mutations are common in both uterine and ovarian endometrioid carcinomas. TP53 mutations have been reported in upward of 60% of endometrioid carcinomas arising in the ovary overall, and in a greater percentage of high-grade tumors [157]. Wu and colleagues documented TP53 mutations in approximately half of the aforementioned series of 72 endometrioid carcinomas, and mutations were significantly associated with high tumor grade, and were uncommon in tumors with documented Wnt/β-cat and/or PI3K/Pten signaling defects.

Akin to the serous carcinomas, the molecular findings support the division of ovarian endometrioid carcinomas into two subgroups. Low-grade tumors are characterized by mutations that deregulate the canonical Wnt/ β -cat and PI3K/Pten signaling pathways and typically lack *TP53* mutations. High-grade tumors often harbor mutations of *TP53* and lack Wnt/ β -cat or PI3K/ Pten signaling pathway defects. Whether some of the highgrade tumors in this series would have been more appropriately considered high-grade serous carcinomas remains unresolved.

DNA Copy Number Changes Given their reduced abundance compared to the serous carcinomas, comprehensive studies of DNA copy number changes specifically in ovarian endometrioid carcinomas are rather few. Using conventional comparative genomic hybridization (CGH) methods, Tapper and colleagues identified gains of chromosome 1q in five of eight cases, but the genes presumably targeted by these gains were not identified [349]. These investigators also evaluated several serous and mucinous carcinomas and found divergence of DNA copy number changes between the three tumor types, providing additional molecular evidence for each type as a distinct disease entity. More recently, Mayr and associates used both conventional and array CGH to identify frequent gains at the JUNB, KRAS2, MYCN, ESR, and CCND2 loci in six endometrioid carcinomas [204]. Clearly, comprehensive analysis of a larger number of cases is needed to help identify additional oncogenes and tumor suppressor genes that participate in the molecular pathogenesis of this group of ovarian cancers.

Gene Expression A number of investigators have used comprehensive high-throughput technologies to profile expression in ovarian cancers, including gene endometrioid carcinomas [200, 293, 296, 383, 398]. One of the more informative studies is that of Wu and colleagues. who used high-density oligonucleotide microarrays to analyze global gene expression in 41 serous, 37 endometrioid, 13 mucinous, and 8 clear cell ovarian carcinomas [383]. Notably, all of the endometrioid tumors were annotated with data on the mutational status of the TP53, CTNNB1, PTEN, PIK3CA, and KRAS genes. Although the gene expression profiles of both clear cell and mucinous carcinomas were found to be largely distinct from each other and from serous carcinomas, substantial overlap between the expression profiles of endometrioid and serous carcinomas was identified. When the mutational status of the above genes was taken into account, it was noted that endometrioid tumors with gene expression profiles similar to serous carcinomas were usually high grade and harbored TP53 mutations, while the endometrioid tumors with expression patterns distinct from the serous carcinomas tended to be low grade and harbor mutations of CTNNB1, PTEN, and/or PIK3CA. Once again, the molecular data support the division of endometrioid carcinomas into two major groups based at least in part, on tumor grade. Shared genetic alterations such as TP53 mutation may be responsible for similarities in global gene expression pattern between high-grade endometrioid carcinomas and high-grade serous carcinomas. Some of the overlap in gene expression between serous carcinomas and highgrade endometrioid carcinomas may be due to pathologists' inability to reliably distinguish between the two based solely on morphological criteria. Further studies are needed to address this issue and to determine whether moderately differentiated endometrioid carcinomas have molecular features more in keeping with high-grade versus low-grade tumors. Moreover, it is worth noting that the study of Wu and colleagues identified at least a few tumors with molecular features typical of both low-grade (i.e., Wnt/β-cat and/or PI3K/Pten pathway mutations) and high-grade (TP53 mutations) tumors suggesting that "progression" from Type I to Type II endometrioid carcinoma may occur in a subset of cases.

Microsatellites are segments of DNA in which a short sequence motif, usually one to five nucleotides in length, is repeated several times. Microsatellite instability (MSI) refers to alterations in the DNA of tumor cells in which the number of sequence repeats within these microsatellites is different from the number of repeats at the same locus in DNA from the patient's non-neoplastic cells. MSI in tumor cells is associated with mutational or epigenetic inactivation of genes that encode proteins involved in DNA mismatch repair, such as MSH2, MSH6, and MLH1. A recent metaanalysis of ovarian carcinomas estimates the frequency of the microsatellite instability phenotype in unselected ovarian cancers at approximately 12%, with overrepresentation of non-serous histologic subtypes [251]. MSI has been observed in 13-20% of ovarian endometrioid carcinomas, and is usually associated with loss of expression of proteins involved in mismatch repair, particularly hMLH1 and less frequently, hMSH2 [45, 186]. Loss of expression is most often attributable to promoter hypermethylation rather than inactivating mutations in sporadic ovarian carcinomas with MSI [101].

Clinical Behavior and Treatment

Overall, endometrioid carcinomas of the ovary have a better prognosis than typical serous carcinomas due to the high proportion of stage I cases. The favorable prognosis may also be due, in part, to endometrioid carcinoma being low grade significantly more often than serous carcinoma, although data on the influence of grade on prognosis are less clear because grade and stage are mutually confounding factors (see **Prognostic Factors**, Grade above). One recent large prospective series found that in stages II and III, the prognosis was significantly better for endometrioid as compared to serous carcinoma. In that series, however, endometrioid carcinomas were significantly more likely to be optimally debulked as compared to serous carcinomas, and occurred in younger women. In addition, neither substage nor grade was considered in that analysis [338]. Treatment for endometrioid carcinoma is generally the same as that for other ovarian carcinomas. However, progestational agents, antiestrogens, tamoxifen, and other hormonal therapies have been used with limited success in previously treated endometrioid carcinomas; 10–15% response rates have been reported. There may be a correlation between the presence of steroid hormone receptors in tumor tissue and response rates, but data are limited. Hormonal therapy may be an option for the treatment of recurrence in patients who have failed or cannot tolerate chemotherapy or surgery.

Endometrioid Carcinoma Associated with Uterine Endometrial Carcinoma

Approximately 14% of women with endometrioid ovarian carcinoma also have endometrial cancer of the uterine corpus. Endometrial hyperplasia is also commonly present. As both tumors are often well-differentiated endometrioid adenocarcinomas, they resemble each other, and excluding the possibility that the ovarian tumor is metastatic can be a problem. Usually this can be determined based on a careful evaluation of the clinicopathologic features [201]. If the uterine endometrial tumor is low grade with no or only inner half myometrial invasion, its metastatic potential is very low, and the ovarian tumor can confidently be regarded as independent. If the endometrial tumor is high grade and/or deeply myoinvasive, the features of the ovarian tumors come into play. Bilaterality and a multinodular pattern, as well as other patterns characteristic of metastatic disease (See) Chap. 18, Metastatic Tumors of the Ovary) indicate metastatic tumor. Close association of the ovarian tumors with either an underlying adenofibroma or endometriosis can also provide evidence that the ovarian tumor is independent.

The median age is about 50 years, significantly lower than high-grade serous carcinomas (about 60 years), but closer to that for women with endometrioid carcinomas (55–58 years). The median ovarian tumor size is about 9 cm. The majority of tumors in both sites are well differentiated. The 5-year survival is 70–92%, and the median survival is 10 years or longer [332, 338, 394]. Therefore, follow-up supports two independent tumors because most of these patients survive without recurrence, a finding more suggestive of stage I endometrial and ovarian carcinomas as compared to stage III endometrial cancer. It is conceivable, however, that an endometrioid carcinoma with an isolated ovarian metastasis may have a good prognosis. In one large series, 14% of patients had a relative with a gastrointestinal cancer and 18% had either a personal history of, or relative with, breast cancer [332]. In young women (<45 years) with endometrial cancer, 10–29% have synchronous ovarian cancer.

Over the last few years, investigators have employed several different molecular strategies to assess the likelihood that simultaneously detected endometrioid adenocarcinomas in the ovary and endometrium represent a single versus two independent primaries. Most of these have relied upon the presence or absence of shared genetic alterations in the ovarian and endometrial adenocarcinomas to identify single or dual primaries, respectively. Unfortunately, these approaches are rather labor-intensive and time-consuming, in part because investigators do not know, a priori, the specific genetic alterations present in a given tumor. Moreover, the certainty with which one can claim single versus dual primaries increases with the number of specific genetic alterations that can be compared in the ovarian and endometrial tumors. The difficulty of correctly classifying some of these cases is highlighted by the fact that virtually every published series of synchronous ovarian and uterine endometrioid adenocarcinomas includes cases that, after diagnosed using standard histologic criteria, would be reclassified based on molecular analysis [31, 91, 93, 270].

Endometrioid Carcinoma Arising in Endometriosis

On average, 15-20% of endometrioid carcinomas of the ovary are associated with endometriosis that may occur within the tumor, the ipsilateral or contralateral ovary, or elsewhere [392]. The frequency can be as high as 42%. It is likely that when strict criteria are applied to diagnose endometrioid carcinoma (see > Differential Diagnosis above), some cases would be reclassified as high-grade serous carcinomas and therefore the percentage of endometrioid carcinomas associated with endometriosis would be higher. Accordingly, the majority of bona fide endometrioid carcinomas can be shown to be associated with endometriosis when extensive histologic sampling and meticulous searching for the histologic features of endometriosis are performed, and strict diagnostic criteria are used. In only a minority of cases, however, can direct continuity from endometriosis to atypical hyperplasia to carcinoma be demonstrated. This is most commonly seen in the lining of an endometriotic cyst that may display a thickening of the cyst wall, papillary excrescences, or a nodule protruding into the cyst. The mean age of women with endometrioid carcinoma associated with endometriosis is about 5-10 years younger than when unassociated with endometriosis. Tumors associated

with endometriosis, and particularly those arising in an endometriotic cyst, are usually architecturally well differentiated and stage I, and therefore the prognosis is excellent. On rare occasions, a limited atypical epithelial proliferation in an endometriotic cyst will raise the differential diagnosis of atypical hyperplasia similar to the type seen in the uterine corpus, versus well-differentiated endometrioid adenocarcinoma. In such cases, criteria for this distinction used in the uterine corpus have been applied with minor modifications [298].

One study suggests that ovarian endometriosis has more chromosomal aberrations and may be more likely to undergo neoplastic transformation as compared to extraovarian endometriosis [159]. Another study suggests that expression of estrogen receptor alpha increases with transformation of endometriosis to endometrioid adenocarcinoma, the reverse of what is observed with transformation of endometriosis to clear cell carcinoma [3].

Clear Cell Tumors

The müllerian nature of clear cell tumors of the ovary, previously thought to be of mesonephric origin and referred to as "mesonephroma," is supported by the close association with endometriosis, their frequent admixture with endometrioid carcinoma, the occurrence of identical tumors in the endometrium, and their origin in vaginal adenosis in DES-exposed women. The vast majority of clear cell neoplasms of the ovaries are carcinomas, and comprise 8.5% of ovarian carcinomas (**)** *Table 14.4*). Clear cell adenofibromas and atypical proliferative clear cell neoplasms are vanishingly rare (**)** *Table 14.5*).

Clear Cell Adenofibromas

These are among the rarest of the ovarian epithelial tumors; we did not find a single example among 1,000 consecutive epithelial tumors (Table 14.5). Among 12 reported cases of benign clear cell tumors, the mean age was 45 years. One tumor was bilateral. The median diameter was 12 cm. The tumors display a smooth lobulated external surface and the cut surfaces have a fine honeycomb appearance with minute cysts embedded in firm rubbery stroma ("parvilocular"). The cyst fluid is clear. Microscopically, the tumor is characterized by tubular glands lined by one or two layers of peg-like or hobnail cells that may bulge into the lumen or are flattened. The cytoplasm is either scanty, often in the hobnail cells, or abundant clear, granular, or eosinophilic in the large

polyhedral cells. Nuclear atypia and mitotic activity are minimal. The stroma is compact and fibrocollagenous. The apical cell borders and lumens often contain mucin. The cytoplasm usually contains glycogen. The clinical behavior appears benign, although data are very limited.

Atypical Proliferative Clear Cell Tumors (APCCT)

APCCT comprise 0.2% of ovarian epithelial tumors (Table 14.5). Among approximately 30 cases of APCCT (clear cell adenofibroma of borderline malignancy or low malignant potential) in the literature, the mean age is 60-70 years. The mean tumor diameter is about 15 cm. The gross appearance is similar to that of the clear cell adenofibroma, but in addition there are softer and fleshier areas. Microscopically, the architecture is similar to the clear cell adenofibroma, but glands are more crowded. The tumor has greater epithelial proliferation and atypia than the adenofibroma and lacks stromal invasion. The cell types lining the glands and cystic spaces are similar to those in benign tumors but display significant nuclear atypia with coarse chromatin clumping, prominent nucleoli, and mitotic activity up to 3 per 10 HPF. The epithelium may display stratification and budding; true papillary structures are uncommon. Small solid nests of clear cells, significant gland crowding, or papillary growth should raise the suspicion of stromal invasion. Distinction of an APCCT from clear cell carcinoma is one of the most difficult distinctions in gynecologic pathology. Some clear cell carcinomas lack an obviously infiltrative pattern and are characterized solely by crowded glands. The point at which gland crowding in a clear cell neoplasm reflects invasion is not well defined. The vast majority of tumors in which this differential is considered are usually classified as clear cell carcinoma. This practice helps ensure comprehensive staging where metastases might be found and thereby confirm a diagnosis of carcinoma. Furthermore, it gives the patient the potential benefit of chemotherapy if there is doubt about the diagnosis.

Occasionally, an endometriotic cyst is lined by atypical epithelial cells with clear cytoplasm. This has been designated "atypical endometriosis" (see **>** Chap. 13, Diseases of the Peritoneum) [298]. Rarely, cytologic features of malignancy are present in this setting. If the lesion is well sampled and invasion is not found, the lesion is classified as APCCT with intraepithelial carcinoma. Microinvasion should be diagnosed if invasive areas measure less than 5 mm, but this finding should prompt additional sampling to look for diagnostic features of carcinoma. There are virtually no published data on clear cell tumors with microinvasion or intraepithelial carcinoma, both of which are exceedingly rare.

The rarity of clear cell adenofibroma and APCCT could reflect the fact that precursors of clear cell carcinoma most often have the morphology of endometriosis with atypia rather than a clear cell neoplasm. Peritoneal "implants" have not been described with APCCTs. Among the limited reported APCCTs, there is one alleged recurrence and no tumor deaths.

Clear Cell Carcinomas

Clinical Findings

The mean age of patients with clear cell carcinoma is 50–53 years. Symptoms usually relate to a pelvic or abdominal mass. Clear cell carcinoma is the most common epithelial ovarian neoplasm to be associated with vascular thrombotic events (18–46% of patients) and paraneoplastic hypercalcemia (2–10%)[254, 345] (see Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). In a large series from Australia, 27% of patients with clear cell carcinoma had a thromboembolic event as compared to 7% of those with other cell types of ovarian carcinoma [202].

Operative Findings

The relationship with endometriosis is strongest for clear cell carcinoma among all cell types of ovarian carcinoma. Accordingly, endometriotic implants are commonly present in close proximity to the tumor or elsewhere in the pelvis or abdomen. About 35–60% of clear cell carcinomas present in FIGO stage I, and 9–22% in stage II [255, 369]. Eight percent are bilateral; 4% of stage I cases are bilateral [353]. As noted earlier, several recent studies have shown that stage I clear cell carcinoma is more likely to be stage IC (55–74%) as compared to the other cell types [57, 224, 313, 341, 343, 353, 369]. The reason for this is not clear but it seems to be correlated with a higher risk of tumor rupture [224].

Gross Findings

Tumors range up to 30 cm in diameter with a mean of about 13–15 cm. Although they may be solid and fibrous with a honeycomb cut surface resembling benign and atypical proliferative clear cell tumors, more commonly the cut surfaces reveal a thick-walled unilocular cyst with multiple yellow-beige fleshy nodules protruding into the lumen, or a multiloculated cystic mass with cysts containing watery or mucinous fluid. Most tumors arise in endometriosis and display features of an endometriotic cyst, which typically contains chocolate-brown fluid, and a thickened, polypoid or nodular area in the wall, or a larger solid area reflecting the focus of malignant transformation. Less commonly, there is a prominent adenofibromatous component which is solid; this pattern is not as strongly associated with endometriosis [369].

Microscopic Findings

Clear cell carcinomas display several different patterns, which often occur together (> Figs. 14.114-14.122). These include papillary, tubulocystic, and solid. In minority of cases, there is a prominent а adenofibromatous component [369] (> Figs. 14.121 and ≥ 14.122). Recently, some investigators have subdivided clear cell carcinomas into those arising in a cyst and those that have an adenofibromatous background [369]. The cystic tumors are more frequently papillary, whereas the tubulocystic pattern tends to dominate in the adenofibromatous tumors. The cystic variant is more frequently associated with endometriosis. In addition, the behavior of the two types of tumors may be different although the data have been conflicting [369]. These findings suggest that the two variants arise along different pathways.

The solid pattern of clear cell carcinoma is characterized by sheets of polyhedral cells with abundant, clear cytoplasm separated by delicate fibrovascular septae or dense fibrotic stroma. The papillary pattern is characterized by papillae that are either fibrotic but more often are hyalinized (\bigcirc *Figs.* 14.116, \bigcirc 14.117, and \bigcirc 14.120). In fact, the hyalinized papillary cores are a very characteristic feature of this tumor. The tubulocystic pattern is characterized by varying size tubules and cysts (\bigcirc *Fig.* 14.114). The majority of tumors display combinations of all of these patterns [369]. Despite being designated clear cell carcinoma, many of the cells comprising clear cell carcinoma contain slightly granular eosinophilic cytoplasm.

Fig. 14.115

Clear cell carcinoma. The tumor is composed of tubules lined by a single layer of epithelium containing a large number of hobnail cells

G Fig. 14.114

Clear cell carcinoma. Tubulocystic pattern. The glands are cystically dilated and the epithelium is flattened. As a consequence nuclear atypia can appear beguilingly innocuous

 Fig. 14.116
Clear cell carcinoma. Tubulopapillary architecture with hobnail and clear cells

Clear cell carcinoma. Clear cells and cells with abundant eosinophilic cytoplasm (oxyphilic cells). Marked variation in nuclear atypia ranging from minimal to marked. This is not an unusual feature of clear cell carcinoma

 Fig. 14.119
Clear cell carcinoma. Hobnail cells with marked nuclear atypia and clear cytoplasm

Fig. 14.118 Clear cell carcinoma. Solid and glandular pattern composed exclusively of cells with clear cytoplasm. Note homogeneous eosinophilic stromal hyalinization

When the majority of the cells have this appearance the term "oxyphilic clear cell carcinoma" has been used (**>** *Fig. 14.117*). So-called hepatoid carcinoma may be a variant of oxyphilic clear cell carcinoma and can be mixed with serous and mucinous components [354]. The cells with clear cytoplasm contain glycogen and at times intracytoplasmic mucinous inclusions. The majority of clear cell carcinomas contain hyaline globules that

are PAS positive. The nuclei vary from small and rounded and angular to large and pleomorphic with prominent nucleoli (\bigcirc *Figs.* 14.117–14.119 and \bigcirc 14.122). Often, the nuclear grade within a tumor varies from mild to markedly atypical. However, even when the majority of cells display only mild nuclear atypia, cells with marked atypia will be present. Accordingly, the nuclear grade is nearly always high regardless of the grading system used

Clear cell carcinoma. Adenofibromatous pattern of clear cell carcinoma with small angulated glands

■ Fig. 14.122 Clear cell carcinoma. Moderate cytologic atypia is present (same case as) *Fig. 14.121*)

and for that reason all clear cell carcinomas are considered high grade. Mitotic activity tends to be low, exceeding 10 per 10 HPF in only one fourth of cases [369]. In the tubulocystic and papillary patterns, the cells often have a hobnail appearance with the nucleus protruding from the papillae, tubule, or cyst into the lumen (\bigcirc *Figs.* 14.115, \bigcirc 14.116, \bigcirc 14.119, and \bigcirc 14.120). Occasionally, the epithelium lining the tubules and cysts is flattened (\bigcirc *Fig.* 14.114), and the nuclear grade is low in these areas but careful scrutiny will reveal cells with high-grade nuclei elsewhere [387]. Necrosis, hemorrhage, and stromal lymphocytic infiltrates are variable. Luteinized stromal cells and psammomatous calcifications are occasionally present.

Clear cell carcinomas arising in endometriosis are usually cystic and may display atypia of the lining of an endometriotic cyst with either a gradual or abrupt transition to cytologic features of malignancy and invasive clear cell carcinoma. This can be seen in one third of clear cell carcinomas [369]. If cytologic atypia is marked and invasion is absent, a diagnosis of APCCT with intraepithelial carcinoma is warranted. Cystic clear cell carcinomas are significantly more likely to be associated with endometriosis and atypical endometriosis as compared to the adenofibromatous type [369].

About 30-35% of reported ovarian clear cell carcinomas are associated with endometriosis either in the involved ovary or elsewhere in the pelvis or abdomen. These figures vary widely and many recent studies have observed 50% or greater associated with endometriosis [369, 389]; one clinical study found that 88% of clear cell carcinomas were preceded by a sonographically detected endometriotic cyst [387]. One recent large study found endometriosis to be present in about 90% of cystic clear cell carcinomas, while the association of endometriosis with adenofibromatous clear cell carcinomas was only 44% [369]. When carefully sought, nearly all ovarian clear cell carcinomas are associated with endometriosis and at least one third of cases can be demonstrated to have arisen within endometriosis, usually an endometriotic cyst [336, 369].

Immunohistochemistry

Like other ovarian carcinomas, clear cell carcinomas stain strongly and diffusely for epithelial markers including keratins, particularly CK7, CAM5.2, EMA, Leu M1, and B72.3. Alpha fetoprotein, CK20, p53, and CD 10 are generally negative [20, 39, 116, 206], although CD10 can be positive in up to 20%, usually at the apical border [242]. CEA is negative in most cases [130], and vimentin is positive in about 50%. OC125 is usually positive [130, 206]. BRCA1 is usually positive [352]. WT1 is positive in 10-22% [1, 116, 124, 130]. TTF1 is positive in less than 20% [20, 130, 162]. Estrogen receptor [116, 290] and progesterone receptor are usually negative [92, 130, 178], and evidence suggests that expression of these receptors is lost during malignant transformation of endometriosis which is usually receptor positive [3]. 34ß E12 (highmolecular-weight cytokeratin) is always positive [242]. The hyalinized stroma is immunoreactive for type IV collagen and laminin.

Several reports indicate that clear cell carcinoma expresses a variety of investigational markers significantly

more frequently than the other cell types. These include hepatocyte nuclear factor 1 β [384], ABCF2 [234], early mitotic inhibitor-1 protein [113], and GPX3 [128, 296].

Differential Diagnosis

Germ cell tumors including yolk sac (endodermal sinus) tumor, dysgerminoma, and rarely struma ovarii are important to consider in the differential diagnosis of a clear cell neoplasm in the ovary. Clinical information including young age for yolk sac tumors and dysgerminomas, and elevated serum AFP levels in women with yolk sac tumors, is helpful. Morphologically, the papillary structures of clear cell carcinomas are more complex and have hyalinized cores, thus differing from the festoon pattern of yolk sac tumors. In addition, yolk sac tumors display a variety of features not seen in clear cell carcinoma including the characteristic Schiller-Duvall bodies as well as other patterns (see) Chap. 16, Germ Cell Tumors of the Ovary). Lack of staining for alpha fetoprotein (AFP) is an important feature in excluding volk sac tumor, although rare clear cell carcinomas have been reported to secrete AFP. The combination of positive LeuM1 and negative AFP may help discriminate clear cell carcinoma from yolk sac tumor, but the sensitivity and specificity of AFP are not high. A more useful panel is CK7 and EMA, which, when both are positive, excludes YST, which is negative for these antibodies [267]. Glypican-3 can also be of value in this distinction [290]. Positivity for EMA and strong diffuse positivity for cytokeratins help exclude dysgerminoma. The solid pattern of clear cell carcinoma resemble dysgerminoma, can but dysgerminoma lacks the tubulocystic and papillary patterns of clear cell carcinoma and displays primitiveappearing nuclei. In addition, clear cell carcinoma lacks stromal chronic inflammation and granulomas frequently present in dysgerminomas. Extensive sampling may reveal other germ cell components or endometriosis that can assist in diagnosis.

A papillary pattern with low to moderate nuclear grade can mimic APST, particularly on frozen section when sampling is limited. "Pink cell" tufting in APST may cause confusion with the hobnail pattern. The characteristic detached cell clusters of APST can be seen in cyst lumens in clear cell carcinoma. Psammomatous calcification and low mitotic index are frequent in both tumors. Clear cell carcinomas are more frequently unilateral and occur in an older age group as compared to APST, but these features are not very helpful in an individual case. A useful panel is WT1 and ER. APST is positive for both, while clear cell carcinoma is usually negative [290].

The clear cytoplasm of these tumors has been overemphasized in differential diagnosis. The histologic patterns particularly the tubulocystic and papillary patterns are quite characteristic and warrant a diagnosis of clear cell carcinoma even in the absence of cells with clear cytoplasm. The papillae of clear cell carcinoma are thinner and delicate and the stroma is more frequently hyalinized as compared to serous carcinoma. Conversely, serous carcinomas not infrequently contain focal areas with clear cytoplasm (> Fig. 14.70); these should not be diagnosed as clear cell carcinoma in the absence of the typical papillary and tubulocystic architecture of clear cell carcinoma [207, 333]. A useful panel for this distinction is ER, HNF-1β, and WT1. The most common profiles are WT1+, ER+, and HNF-1β- in high-grade serous carcinoma and WT1-, ER-, HNF-1 β + in clear cell carcinoma [155].

Although hyaline globules are commonly found in clear cell carcinomas, these are nonspecific. They are a characteristic feature of yolk sac tumor, but also occur in the majority of carcinosarcomas, and in a small minority of endometrioid, serous, and mucinous ovarian neoplasms.

Endometrioid carcinomas with secretory changes can mimic clear cell carcinoma. When the cells are tall columnar with sub- or supranuclear vacuoles resembling early secretory endometrium, the tumor is classified as the secretory variant of endometrioid carcinoma. When the clear cell changes are more extensive and the cells become more cuboidal, the distinction is more difficult. Rarely, a metaplastic squamous component of an endometrioid carcinoma, in which the squamous cells contain abundant glycogen, can be confused with clear cell carcinoma. Steroid cell tumors of the ovary can have prominent areas of clear cytoplasm. Benign or low-grade nuclear features, a delicate fibrovascular stroma, small size, wellcircumscribed border, and confinement within the ovarian stroma are features of a steroid cell tumor that help to distinguish it from clear cell carcinoma.

Rarely, struma ovarii will mimic a clear cell tumor if the thyroid follicles become so cystic that the pattern resembles the tubulocystic pattern of clear cell carcinoma, and classic features of thyroid are not recognizable. Extensive sampling to identify other teratomatous elements can be of value, and staining for thyroglobulin is also useful. Metastatic clear cell neoplasms such as renal cell carcinoma are very rare (see **O** Chap. 18, Metastatic Tumors of the Ovary). A useful panel for this distinction is CD10 and CK7; renal cell carcinomas are typically CK7 negative and CD10 positive [39, 242], the reverse of the pattern for ovarian clear cell carcinoma, but CK7 can be focally positive in up to 37.5% [242]. 34β E12 can also be helpful and is always negative in renal cell carcinoma [242].

Molecular Biology

The molecular changes in ovarian clear cell tumors have not been as extensively studied as in serous and endometrioid tumors. This is probably due to the relative rarity of clear cell tumors. As a consequence, most studies in the published literature have analyzed only limited numbers of clear cell carcinomas and therefore the true prevalence of many specific molecular alterations is unknown. In addition, the extent to which serous carcinomas containing clear cells have been misclassified as clear cell carcinomas and consequently affected these studies is unknown. Nevertheless, some important conclusions can be drawn regarding the role of a few molecular alterations in the pathogenesis of these tumors.

Mutation Analyses Mutations in KRAS, BRAF, and TP53 are present in some clear cell carcinomas but their frequency is generally low [203, 376]. For example, TP53 mutation and BRAF mutation were found in 8.3% and 6.3% of clear cell carcinomas, respectively. Mutations predicted to deregulate PI3K/Pten signaling are more common in clear cell carcinomas, with PIK3CA mutations reported in 20-25% and PTEN mutations in 8% of tumors in a few small series [40, 292, 376]. Kuo and colleagues recently analyzed 97 affinity-purified primary ovarian clear cell carcinomas for mutations in PIK3CA, TP53, KRAS, PTEN, CTNNB1, and BRAF. Mutations were identified in 33%, 15%, 7%, 5%, 3%, and 1% of cases, respectively [165]. Interestingly, Sato et al. demonstrated somatic mutations of PTEN in 21% of ovarian endometriotic cysts, indicative of shared molecular alterations between clear cell and endometrioid carcinomas of the ovary and their putative precursor lesion [292]. Among seven clear cell carcinomas with synchronous endometriosis, allelic deletions/loss of heterozygosity (LOH) at the PTEN locus in both the carcinoma and associated endometriosis was detected in three cases, and one case displayed LOH only in the carcinoma. In no cases were there LOH events involving PTEN in the endometriosis only. The findings suggest that inactivation of the PTEN tumor suppressor gene, when it occurs, is a relatively early event in the development of ovarian clear cell carcinoma. Although studies to date are rather limited, the clear cell carcinomas do not appear to share many other changes with endometrioid carcinomas, as canonical Wnt signaling pathway defects and microsatellite instability have not been observed with significant frequency in the clear cell tumors overall [94, 150, 376]. However, a recent study of microsatellite instability and mismatch repair protein defects in ovarian cancers affecting patients <50 years of age found evidence of mismatch

repair defects in a significant proportion (17%) of ovarian clear cell carcinomas [138].

DNA Copy Number Changes At least two independent reports describe the use of classical CGH to study DNA copy number changes in clear cell carcinomas [72, 339]. In their analysis of 18 tumors, Dent and colleagues found that chromosome 9p21 deletion was the most common copy number alteration, followed by losses on chromosomes 1p, 11q, and 10q (including the PTEN locus at 10q23.3). DNA copy number gains were generally not detected [72]. In contrast, in their analysis of 12 ovarian clear cell carcinomas, Suehiro and colleagues identified increased DNA copy number at several chromosomal regions as well as frequent losses of chromosome 19p [339]. The discordant findings between the two studies suggest that clear cell carcinomas may be quite heterogeneous and analysis of large numbers of tumor samples using more advanced technologies with higher resolution may be needed to reliably identify common alterations of DNA copy number in clear cell carcinomas. Toward this end, Tsuda and colleagues employed a cDNA microarray platform to perform simultaneous genomic and expression array analyses on 30 ovarian clear cell carcinomas [357]. Using this approach, 12 and 5 genes showed significant increase and decrease, respectively, in both DNA copy number and mRNA levels compared to serous carcinomas. Although the clinical and biological significance of these molecular alterations remains unclear, overexpression of one gene, ABCF2, was associated with poor response to chemotherapy. In order to test the notion that some clear cell carcinomas might arise from clear cell adenofibromas and borderline tumors, Yamamoto and colleagues evaluated DNA isolated from clear cell adenofibromas/borderline tumors and adjacent clear cell carcinomas for LOH at 17 different polymorphic loci on 11 chromosomal arms [386]. The overall frequency of LOH was significantly higher in the clear cell carcinomas (49%) than in adjacent areas of borderline tumor (30%) or adenofibroma (22%). Furthermore, an identical LOH pattern involving the same alleles at one or more loci was found in 13 of 14 cases, a finding highly unlikely to have occurred at random. Allelic losses on chromosomes 5q, 10q, and 22q were frequent in clear cell carcinomas and their putative precursors, while LOH on 1p and 13q were frequent in the carcinomas but not in the adenofibromas. The data suggest that clear cell adenofibromas and borderline tumors can serve as clonal precursors for a subset of clear cell carcinomas [386].

Gene Expression Several comprehensive gene expression analyses of ovarian carcinomas have noted that clear cell

carcinomas are readily distinguishable from the other histological types of ovarian carcinomas based on their global gene expression profiles [293, 296, 398]. A number of genes have been reported to be preferentially expressed in ovarian clear cell carcinomas and in some cases, in associated endometriosis. Among these overexpressed genes, HNF-1 β appears to be a relatively specific marker of ovarian clear cell carcinoma [356]. HNF-1 β is a nuclear homeodomain protein that participates in regulating gene expression in liver and several other tissues including secretory endometrium. Given that HNF-1B is essential in controlling multiple genes involved in glucose/glycogen metabolism, HNF-1ß upregulation may be in part responsible for the characteristic cytological feature (i.e., the glycogen-rich, clear-appearing cytoplasm) of clear cell carcinoma. Furthermore, many genes relatively specific to clear cell carcinoma are also regulated by HNF-1ß [315, 346]. Although not specific for clear cell differentiation, a recent study found that IGF2BP3 expression is a marker of unfavorable prognosis in ovarian clear cell carcinomas [156].

Clinical Behavior and Treatment

There are conflicting data on the behavior of clear cell carcinoma. In some studies, the prognosis appears similar to that for other ovarian carcinomas, but in others, the prognosis is said to be worse. Comprehensively staged ovarian carcinoma (of all histologic types) in FIGO stage I has a 90% or better 5-year survival, and several recent studies have shown comparable survival rates for clear cell carcinoma (see **Prognostic Factors**, earlier in this chapter). Evidence that clear cell histology is an adverse prognostic factor in advanced stage is somewhat more convincing [49, 50, 256]. The treatment is similar to that of other epithelial cell types of ovarian carcinoma.

Brenner (Transitional Cell) Tumors

Transitional cell tumors comprise 10% of ovarian epithelial tumors. Nearly all of these are benign Brenner tumors; atypical proliferative and malignant forms are very uncommon. The transitional epithelial cell type, characterized by a relatively uniform population of stratified cells with ovoid nuclei displaying nuclear grooves, is named because of its resemblance to urothelium. Evidence suggests that benign Brenner tumors have some true urothelial differentiation, while transitional cell carcinoma (unassociated with a benign Brenner component) is a variant of high-grade serous carcinoma [246, 271].

Brenner (Benign Transitional Cell) Tumors

The mean patient age is 56 years. These are common incidental findings and are often microscopic in size. Therefore, the presenting symptoms are often unrelated to the ovarian tumor. Most tumors are 2 cm or smaller, and although a 1 cm minimum size is used for the other cell types of ovarian epithelial tumors, this has not been applied to Brenner tumors that frequently measure only a few millimeters. Multiple microscopic tumors are seen in 17% of patients. Occasionally they are large and may exceed 10 cm. Most tumors are well circumscribed, firm, and rubbery, with a smooth or slightly bosselated serosal surface. The cut surfaces are typically solid and fibrous; usually gray, white, or yellow; and may be whorled or lobulated; occasionally a cystic component is present. Small tumors can usually be seen to be arising in the ovarian cortex or hilus.

Microscopically, the characteristic feature is sharply demarcated epithelial nests in a dense fibrous stroma (\triangleright *Figs.* 14.123 and \triangleright 14.124). The epithelial cells are relatively uniform in size with prominent cell borders and pale to eosinophilic cytoplasm. The nuclei are oval, often with small nucleoli, and longitudinal grooves are usually present (\triangleright *Fig.* 14.125). Atypia and mitotic activity

Fig. 14.123

Brenner tumor. Rounded and ovoid nests of transitional cells are dispersed in a densely fibrotic stroma. Some nests are cystic and contain eosinophilic material. Spiculated calcification is seen at the *top right*

Fig. 14.124 Brenner tumor. Transitional cell nests have smooth contours

are generally not present. The nests often become cystic and contain eosinophilic debris or mucin. In 30%, metaplastic mucinous epithelium lines the cystic nests (**>** *Fig.* 14.125); when extensive, some investigators have termed these tumors, "metaplastic Brenner tumor." The metaplastic mucinous component may occasionally form the dominant part of the tumor and accounts for the association of mucinous Brenner tumors with cystadenomas (> Fig. 14.126). It has been suggested that the majority of nonteratomatous mucinous tumors arise in Brenner tumors as an overgrowth of the mucinous component [302] (see Nixed Brenner-Mucinous Tumors below). The stroma varies from closely resembling ovarian cortical stroma to densely fibrous. Hyalinized areas are common, and dystrophic, spiculated calcification is present in about half of cases (> Fig. 14.123). Calcification is seen in 20% of tumors smaller than 1 cm and in over 80% of larger tumors [302]. Rare examples of "epidermoid cyst" of the ovary may represent cystic variants of Brenner tumor with squamous metaplasia (see **S**quamous Tumors later in this chapter) [146]. Walthard nests are seen in 50% of patients with Brenner tumors, significantly more often than those with serous, clear cell, or endometrioid tumors, but similar to those with mucinous tumors [302]. The clinical behavior is benign.

Histochemical stains indicate that the neoplastic cells contain glycogen, and mucin is present at the luminal borders and in the luminal contents. Immunoperoxidase stains reveal that the epithelial nests stain strongly for epithelial markers including keratins and EMA. CK7 is typically positive, and CK20 negative. Calretinin [194],

Fig. 14.125

Brenner tumor. Cells with ovoid nuclei and longitudinal grooves create a resemblance to urothelial tumors. Metaplastic mucinous epithelium is present within a nest

inhibin, and WT1 are negative [47]. Uroplakin III, a urothelium-specific marker, is focally positive in a luminal pattern in a majority of cases. Thrombomodulin, a sensitive but less specific marker of urothelium, shows strong membranous staining in 82% [20, 187, 271]. CEA and CA 19-9 are positive in the majority of cases. The tumors are weakly reactive or negative for p16, cyclin D1, EGFR and Ras protein, and negative for p53 and Rb [66]. Stains for steroidogenic enzymes are usually negative. Tumors containing both Brenner and mucinous components are more common than previously appreciated (> Fig. 14.126). These are believed to be variants of Brenner tumor and can be classified as metaplastic Brenner tumor (see above) or mixed Brenner-mucinous tumor (see Nixed Epithelial Tumors later in this chapter). One fourth of benign ovarian epithelial tumors that have a mucinous component also contain a Brenner component. Conversely, 16% of tumors with a Brenner component contain a mucinous component. These patients are significantly older than those with pure mucinous or pure Brenner tumor, with a mean age of 68 years. They are unilateral and most often have discrete Brenner and mucinous components, but in 30% the components are admixed. The other clinical and pathologic features are similar to their pure counterparts [302].

Atypical Proliferative Brenner (Transitional Cell) Tumors

These rare neoplasms, also termed "proliferating" or "borderline" transitional cell or Brenner tumor, or transitional cell or Brenner tumor "of low malignant potential," present in patients whose mean age is 59 years. They are always unilateral and confined to the ovary. They are larger than their benign counterparts, are usually cystic, and measure 10-28 cm with a mean diameter of 18 cm. Friable papillary or polypoid masses project into the cyst lumens, and there is usually a benign Brenner component present with a more solid and fibrous cut surface. Microscopically, the intracystic papillary component is composed of transitional-type epithelium resembling low-grade noninvasive papillary transitional cell neoplasms of the urinary tract (> Figs. 14.127-14.130). Mucinous metaplasia may be present in the epithelium lining the papillae (> Fig. 14.130). Underneath the papillae and within the wall there may be solid areas of transitional epithelium with little intervening stroma. Nearly all cases display areas of benign transitional cell neoplasm, and occasionally, the proliferating component can be seen to be arising directly from the benign component. The cytologic features are similar to those in benign transitional cell tumors, but occasionally significant atypia and mitotic activity are present. Some authors have separately classified "proliferative" and "low malignant potential" transitional cell tumors. The former are characterized by a resemblance to grade I-II urothelial papillary transitional cell carcinoma, whereas the latter display high-grade nuclear atypia resembling grade III urothelial papillary transitional cell

Fig. 14.127

Atypical proliferative (borderline) Brenner tumor. Large nest of proliferating transitional-type epithelium in center of field with extensive stratification and cystic change

Fig. 14.128 Atypical proliferative (borderline) Brenner tumor. Transitional cell nests are larger and more densely packed than in a benign Brenner tumor

carcinoma or in situ squamous cell carcinoma. In all cases, stromal invasion is absent; microinvasion has not been reported. EGFR, Ras, and CEA are usually positive. Rb, cyclin D1, p16, and p53 are usually weak or negative [66]. Among over 50 reported cases of atypical proliferative transitional cell tumors, there has been one local recurrence and no convincing evidence of malignant behavior. Accordingly, we prefer the term, "atypical proliferative transitional cell (Brenner) tumor."

Atypical proliferative (borderline) Brenner tumor.

Proliferating transitional-type epithelium fills and expands the epithelial nests without invading the stroma

Transitional epithelium is highly stratified and has a surface layer of mucinous epithelium

Malignant Transitional Cell Tumors (Malignant Brenner Tumors and Transitional Cell Carcinomas)

Malignant transitional cell tumors are difficult to define clinicopathologically for several reasons. First, published data are very limited. Second, large databases including the FIGO annual report and the SEER database do not separately classify ovarian transitional cell carcinomas (TCC); in addition, malignant Brenner tumor is erroneously classified by SEER in a miscellaneous category for non-carcinomas. Third, serous carcinomas not infrequently have focal areas that display features resembling TCC. Nearly all tumors classified as ovarian transitional cell carcinomas are now regarded as high-grade serous carcinomas with transitional-like features.

Some investigators have found that approximately 10–15% of advanced-stage ovarian carcinomas contain a transitional cell component; others have found that a transitional cell pattern predominates in 22% of advanced-stage ovarian carcinomas. In contrast, we found only 3% of advanced-stage serous carcinoma were classifiable as TCC (**)** *Table 14.4*), although we tend not to diagnose TCC unless the features are absolutely classic [301]. Some investigators have defined two clinicopathologic types of malignant transitional cell tumor: malignant Brenner tumor, in which a benign or atypical proliferative Brenner component is identified, and TCC, in which no benign or atypical proliferative Brenner component is identified.

Clinical Findings

The clinical presentation is nonspecific and is similar to those of the more common cell types of ovarian cancer; thus pelvic or abdominal pain and a mass are common. Malignant Brenner tumors occur at a mean age of 63 years, while TCCs present at a mean age of 56 years [81].

Operative Findings

The size of malignant Brenner tumors ranges up to 25 cm with a mean diameter of 14 cm. Among stage I tumors, 16% are bilateral. The stage distribution is as follows: stage I, 64%; stage II, 12%; stage III 18%; and stage IV, 6%. In contrast, 53% of transitional cell carcinomas present in advanced stage. The mean size is 10 cm [81].

Gross Findings

The gross appearance of TCC is similar to high-grade serous carcinoma, typically solid and cystic. The cysts may exhibit polypoid, friable mural nodules, and the cyst fluid is watery or mucinous. Hemorrhage and necrosis may be prominent, and half have foci of gritty calcification. In the malignant Brenner tumor, the benign Brenner component may be identifiable as a solid fibrous nodule within a cyst wall. Sometimes malignant Brenner tumor is completely solid. Serous carcinomas that have a transitional cell component have the gross features of serous carcinoma (see "Malignant serous tumors" above).

Microscopic Findings

The histologic patterns of TCC are often mixed with other types of carcinoma, most often serous. Approximately 10% of ovarian carcinomas containing the TCC pattern are said to be pure. More than 50% of the tumor should display the patterns of TCC for a diagnosis of TCC. A diagnosis of malignant Brenner tumor is warranted when a benign or atypical proliferative Brenner component is identified within or contiguous with the tumor.

The characteristic microscopic feature is thick, blunt, and often elongated papillary folds with fibrovascular cores, lined by transitional-type epithelium resembling urothelium (**)** Fig. 14.131). The papillae often appear to arise from a cyst wall with a similar lining of stratified and atypical transitional cells. A solid pattern is present in about half the cases. Microspaces, large cysts, and necrosis are seen in the majority of cases [81]. Foci of squamous or glandular differentiation are seen in less than 20%. Stromal invasion is present and characterized by haphazard infiltrative growth of epithelium at the base of the papillae into the cyst wall, or extensive areas of solid epithelial proliferation with scant or no fibrovascular support. Another architectural pattern of malignant Brenner tumor is characterized by a solid tumor resembling benign Brenner tumor, but the epithelial nests are more angulated and have a disorderly growth pattern that appears invasive. Stromal desmoplasia is occasionally present. Slit-like fenestrations are found in half of TCCs [81], highlighting

Fig. 14.131

Transitional cell carcinoma (TCC). Thick papillae are lined by malignant epithelium resembling urothelium and mimicking papillary transitional cell carcinoma of the urinary tract the resemblance to serous carcinoma. Cytologic atypia is usually prominent and corresponds to grade II or III papillary transitional cell carcinoma of the urinary tract. High-grade pleomorphic nuclear features and bizarre giant cells occur in about one third, further supporting that these tumors are transitional-like variants of serous carcinoma. In the solid type of malignant Brenner tumor with angulated and disorderly nests, mild or moderate atypia may be present (\bigcirc *Fig. 14.132*). Mitotic activity may be prominent. In addition, malignant Brenner tumors, like their benign counterparts, often have prominent stromal calcification that is usually spiculated, in contrast to TCCs in which calcification is less common and more often psammomatous.

Immunohistochemistry

Ovarian TCCs are positive for CK7 as well as WT1, p16, and p53 [66, 206]. They are negative for CK 20 in contrast to TCCs of the urinary tract, which are usually CK20 positive. EGFR, Ras, and cyclin D1 are usually weakly reactive or negative [66]. A minority of TCCs are positive for CEA and CA 19-9. Urothelial markers uroplakin III and thrombomodulin are positive in only a small minority [187, 246, 271]. Published data on the immunohistochemistry of malignant Brenner tumors are very limited.

Differential Diagnosis

On occasion, a predominantly solid serous carcinoma resembles TCC due to dropout of large areas of necrosis, which gives rise to an undulating or apparent

Fig. 14.132 Malignant Brenner tumor. Infiltrating high-grade carcinoma on the *left*, and Brenner nest with only mild atypia on *right*

macropapillary pattern [81]. TCCs must be distinguished from metastatic TCC from the urinary tract. This is rarely a clinical problem as urothelial carcinomas that metastasize to the ovaries do so late in their evolution and are clinically evident.

Malignant Brenner tumor is diagnosed only in the presence of a benign or atypical proliferative Brenner component. Otherwise, a designation of TCC has been used. The appearance of thick, blunt papillae of transitional cell differentiation contrasts with the papillae of typical highgrade serous carcinoma, which are generally thinner.

Clinical Behavior and Treatment

Limited data suggesting that TCC is more chemosensitive than serous carcinoma have not shown a prognostic difference independent of stage and volume of residual disease [158]. Ovarian TCC is clinically different from malignant Brenner tumor. TCC presents in advanced stage, while most malignant Brenner tumors present in stage I. TCC is a variant of high-grade serous carcinoma and thus is a Type II tumor. This is supported by similar clinical and pathologic features between these two types of ovarian carcinoma, and an immunophenotype that more closely resembles serous carcinoma rather than TCC of the urinary tract. In contrast, malignant Brenner tumor has features of a Type I tumor (see Morphologic and Molecular Pathogenesis earlier in this chapter).

Squamous Tumors

Benign Squamous Tumors (Epidermoid Cyst)

Epidermoid cysts comprise 1.4% of ovarian epithelial tumors. They are lined by squamous epithelium and lack teratomatous elements. About half of these have either contralateral mature cystic teratomas suggesting that they are insufficiently sampled or monodermal teratomas, foci of Brenner tumor suggesting that they are Brenner tumors with squamous metaplasia, or features indicating a metaplastic change in endometriosis. Occasionally, other teratomatous elements are identified after extensive sampling of an apparent epidermoid cyst. Accordingly, pure epidermoid cyst is quite rare and comprises less than 1% of surface epithelial tumors [146].

Squamous Cell Carcinoma

Pure invasive squamous cell carcinoma is very rare, comprising 0.5% of ovarian carcinomas. In a series of 18 cases, endometriosis was found in 7 cases, and no underlying lesion was found in 11 cases. Invasive squamous cell carcinoma in the ovary is most commonly due to malignant transformation of a mature cystic teratoma; in such cases, the tumor is classified as a germ cell tumor with malignant transformation (see) Chap. 16, Germ Cell Tumors of the Ovary). Rarely, metastatic disease from the uterine cervix is the source of squamous cell carcinoma in the ovary, and very rarely, in situ squamous cell carcinoma of the cervix spreads intraepithelially into the endometrium, fallopian tubes, and may involve the ovaries. Rare reports of nonteratomatous in situ squamous cell carcinoma of the ovary not extending from the cervix probably reflect atypical proliferative transitional cell tumors (see **>** Atypical Proliferative Brenner (Transitional Cell) Tumors above). Rarely, an endometrioid carcinoma with a prominent metaplastic squamous component will mimic a pure squamous cell carcinoma.

The majority of patients with primary ovarian squamous cell carcinoma are in advanced stage and die within 1 year. Although data are limited, there appears to be a significantly worse prognosis compared to high-grade serous carcinoma as well as squamous cell carcinoma arising in a mature cystic teratoma.

Mixed Epithelial Tumors

The presence of two epithelial cell types in an ovarian epithelial neoplasm, each comprising at least 10% of the tumor, warrants a designation of a mixed epithelial tumor. Nonetheless, as mixed epithelial tumors are by necessity a heterogeneous group, it is more convenient and of no significant clinical import to ignore the minor components and classify tumors based solely on the predominant component, unless the minor component is malignant in an otherwise benign tumor, or is of a higher grade than the remainder of the tumor. As the prognosis for all cell types is essentially the same when stratified by stage, it is preferable to designate tumors based on the predominant component. We prefer to minimize the use of the mixed category, particularly for carcinomas, and accordingly require at least 25% of the minor component.

Serous and endometrioid differentiation may occur together. In particular, poorly differentiated serous and endometrioid carcinomas often display overlapping features, and at times, assignment to one or the other group is arbitrary and varies among observers. As discussed earlier, it has been suggested that there is no clinical or molecular basis for separating high-grade serous and endometrioid

carcinomas. Many experts believe that most of these tumors are preferably classified as serous, reserving endometrioid for those tumors that display easily recognizable and characteristic features of eutopic endometrioid adenocarcinomas. Similarly, endometrioid and clear cell differentiation are not infrequently mixed. A mucinous component is often observed in benign transitional cell neoplasms (see "Mixed transitional cellmucinous tumors"). Among atypical proliferative tumors, the most common mixed type is seromucinous, also called müllerian mucinous, or endocervical-like atypical proliferative ("borderline") mucinous tumor. Serous (papillary) architectural features and mucinous cytologic features in these tumors are often mixed with other cell types. However, APSMT is a unique variant of APST rather than simply a mixture of different cell types (see > Atypical Proliferative Mucinous Tumor, Seromucinous (Endocervical-like or Müllerian) Type above).

Undifferentiated Carcinomas

Undifferentiated carcinomas show no readily identifiable features of any of the cell types of ovarian surface epithelial neoplasms. Therefore, any element of glands, papillae, or psammoma bodies removes a tumor from this category. Solid carcinomas with rare foci of glands or papillae are preferably classified as serous, although a few experts include such tumors in the undifferentiated category. There are four types of primary ovarian undifferentiated carcinoma, referred to as follows: undifferentiated carcinoma NOS, non-small-cell neuroendocrine carcinoma, the hypercalcemic type of small cell carcinoma, and the pulmonary type of small cell carcinoma. When strict pathologic criteria are employed for these diagnoses, all types are very uncommon, together comprising less than 1% of invasive carcinomas. In the Washington Hospital Center series of 435 carcinomas (\bigcirc Table 14.4), there was a solitary case (0.23%) of undifferentiated small cell carcinoma (hypercalcemic type). In all cases when a diagnosis of undifferentiated carcinoma is considered, it is very important to exclude metastatic tumor, particularly from the lungs.

Although data are limited, undifferentiated carcinoma NOS appears to be more common than the other three types that are very rare. The small cell type of undifferentiated carcinoma associated with hypercalcemia is the most common type of undifferentiated carcinoma in women <40 years. The usual type of undifferentiated carcinoma shares many clinical and pathologic features with high-grade serous carcinoma. The mean age at presentation is 60 years. Seventy-eight percent present in stages III and IV. Tumors are composed of solid sheets of large pleomorphic cells with high-grade nuclear features, and usually with abundant cytoplasm that is often eosinophilic. Immunoperoxidase stains for epithelial markers (EMA, CAM 5.2, and B72.3) are positive. In nearly all cases, CK7 is positive and CK20 is negative; 21% stain for CEA, and 79% for OC-125. Overall, 22% survive 5 years, but only 14% of stage III and IV patients survive 5 years. Although overall survival appears worse than that for serous carcinoma, when stratified by stage, they do not have a significantly worse prognosis.

Non-small cell neuroendocrine carcinoma is usually associated with another cell type of surface epithelial carcinoma, most often mucinous carcinoma [241, 368], and therefore is best classified according to the betterdifferentiated component. Undifferentiated small cell carcinoma associated with hypercalcemia is a distinctive neoplasm, and is described in detail in **O** Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, Paraneoplastic Manifestations. Undifferentiated small cell carcinoma, pulmonary type, is extremely rare and is described in **O** Chap. 17, Nonspecific Tumors of the Ovary Including Mesenchymal Tumors.

Malignant Mixed Mesodermal Tumor (Carcinosarcoma)

Previously thought to be rare, MMMTs comprise about 7.5% of ovarian carcinomas in the United States (Table 14.4) and 2.5% in Thailand [147]. The mean age, 64-66 years, is higher than that for serous carcinoma [198]. These tumors are typically large, ranging from 15-20 cm in diameter. The stage distribution is identical to that of serous carcinoma [35]. The morphology is similar to its uterine counterpart (see S Chap. 9, Endometrial Carcinoma). The characteristic microscopic feature is an intimate admixture of malignant epithelial and stromal elements. The malignant epithelial element is most commonly a high-grade serous or endometrioid carcinoma, but can be of any of the surface epithelial cell types of ovarian tumors. The stromal component usually contains sheets of hyperchromatic rounded to spindled cells with marked nuclear atypia and a high mitotic index. Heterologous elements, most commonly cartilage, osteoid, and rhabdomyoblasts, are commonly found and, as in the uterine counterpart, their frequency depends on the diligence with which they are sought. Occasionally, a tumor that is otherwise a typical carcinoma has a small

focus of malignant stroma. Although there are few published data on such tumors, they are classified as MMMTs. Immunohistochemical stains for epithelial markers are often positive in the sarcomatous component, and their behavior and patterns of spread are similar to high-grade serous carcinomas. Like endometrial carcinosarcomas, the majority have been demonstrated to be monoclonal [140]. These observations suggest that these tumors should be classified as metaplastic carcinomas like their uterine counterparts [201], and accordingly represent a Type II tumor (see) Morphologic and Molecular Pathogenesis earlier in this chapter). Immunohistochemistry for skeletal muscle markers such as desmin, MyoD1, and myogenin can be used to help identify heterologous rhabdomyoblasts. In the older literature, MMMTs were considered aggressive, rapidly fatal tumors with a median survival of \sim 1 year, but more recent data suggest that with cisplatin and either a taxane or ifosfamide therapy, survival rates approaching those for serous carcinoma can be achieved [181, 324]. When stratified by stage, however, limited data suggest that the prognosis is worse than that for serous carcinoma [35, 198]. Most but not all studies have shown that like their uterine counterpart the presence of heterologous elements does not influence prognosis [13].

Sarcomas

Though nonepithelial, these tumors are included in this chapter for convenience. Although primary pure or mixed sarcomas of the ovary are very uncommon, they constitute a heterogeneous group with four different types of neoplasms: endometrioid stromal sarcoma, adenosarcoma, sarcoma arising in a mature teratoma, and miscellaneous soft tissue sarcomas. Most carcinosarcomas are no longer considered sarcomas and are discussed above (see) Malignant Mixed Mesodermal Tumor (Carcinosarcoma) above). All of these tumors are extremely rare. Sarcomas arising in teratomas are classified as germ cell tumors with secondary malignant transformation (see O Chap. 16, Germ Cell Tumors of the Ovary). Miscellaneous soft tissue sarcomas rarely arise in the ovary. Their pathologic features do not appear to be significantly different from their soft tissue counterparts (see) Chap. 22, Soft Tissue Lesions Involving Female Reproductive Organs).

Endometrioid Stromal Sarcoma (ESS)

ESS is an extremely rare primary ovarian neoplasm that is morphologically identical to its uterine counterpart (see Ochap. 10, Mesenchymal Tumors of the Uterus). Among approximately 27 reported cases, 63% have been closely associated with endometriosis from which the tumor probably arises. The mean patient age is 52 years. The mean tumor size is 10 cm. Over 70% present in advanced stage (FIGO II-III). Since primary uterine ESS is often slow growing and prone to late recurrence, it is important to consider the possibility of metastatic tumor from uterine primary, even if the patient has had а a hysterectomy in the remote past. Ovarian sex cordstromal tumors with a predominant spindle cell component, including cellular fibroma, thecoma, and poorly differentiated SLCT, are also important differential diagnostic considerations, and rarely an ovarian stromal tumor will have spindle cell patterns that are virtually identical to ESS. The behavior appears to parallel that of advanced-stage uterine ESS, although data are limited.

Müllerian Adenosarcoma and "Aggressive Endometriosis"

Müllerian adenosarcoma of the ovary is very rare. It is morphologically similar to its uterine counterpart (see • Chap. 10, Mesenchymal Tumors of the Uterus). Nearly 60 cases have been reported [82]. The mean age is 54 and the mean tumor size is 14 cm; 65% present in FIGO stage I. Nearly all cases are unilateral. Grossly, the majority are predominantly solid with some cystic areas, and 10% are predominantly cystic. The characteristic microscopic feature is periglandular stromal condensation with atypia and mitotic activity in these hypercellular areas of stroma. Leaflike processes of stroma covered by a single layer of benign epithelium are another characteristic pattern. The mitotic index averages about 4 per 10 HPF. About 15% have sex cord-like elements and 30% have sarcomatous overgrowth. In the largest series [82], among 40 cases, 9 tumors were considered high grade (moderate or severe atypia and/or 10 or more mitoses per 10 HPF in the most active areas) and 31 were low grade; 63% of stage I tumors recurred. The 5-year recurrence-free survival was 45% for low grade and 25% for high grade. The overall 5-year survival is about 65%. Interestingly, among 40 patients, 2 had small synchronous adenosarcomas that appeared to be independent: one in the endometrium and one arising in appendiceal endometriosis.

Rarely, histologically benign endometriosis appears infiltrative to the surgeon and/or displays perineural and vascular invasion. The stroma can be cellular but there is no atypia and mitotic activity is very low. It can prove difficult to resect and consequently may display low-grade malignant behavior. This may be a form of low-grade adenosarcoma and has been referred to as "aggressive endometriosis." It has also been suggested that these are low-grade endometrial stromal sarcomas with endometrioid glandular differentiation [208]. There are no large series of this entity and it is therefore poorly understood (see **>** Chap. 13, Diseases of the Peritoneum).

Acknowledgment

The authors thank Jonathan A. Cosin, M.D., for reviewing the clinical portions of the chapter, and Peter Russell, M.D., for his contributions in previous editions.

Sex Cord-Stromal Tumors

This category includes all ovarian neoplasms that contain granulosa cells, fibroblasts, theca cells (and their luteinized derivatives), Sertoli cells, Leydig cells, singly or in various combinations and in varying degrees of differentiation. Those who believe that all these cell types are derived from the "specialized stroma" of the genital ridge favor the term gonadal stromal tumors for these neoplasms [110]. Others, recognizing that many embryologists favor the participation of coelomic and mesonephric epithelium in the formation of sex cords, which are the proximal precursors of granulosa cells and Sertoli cells, favor the term sex cord-stromal tumors, and it is now the most widely accepted designation [144].

In the developing testis, the sex cords are clearly distinguishable by the fifth week of embryonic life as slender columns of primitive Sertoli cells, but similar cords, at least in the sense of thin columns, are not encountered in the developing ovary; instead, packets of small pregranulosa cells enveloping germ cells become evident later in embryonic life. For that reason, the term sex cords has been criticized as inaccurate to describe the progenitors of granulosa cells. Nevertheless, the long-established usage of this designation by embryologists and the lack of a better term justify its retention. The term sex cordstromal tumors has the advantage of acknowledging the presence of neoplasms in this general category of derivatives of either or both the sex cords and the stroma. The components derived from the sex cords (granulosa and Sertoli cells) typically are arranged in epithelial configurations, whereas those derived from the stroma have the appearance of cellular gonadal stroma or its specialized derivatives, the theca and Leydig cells.

Most sex cord-stromal tumors (granulosa-stromal cell tumors) are composed of ovarian cell types but some (Sertoli-stromal cell tumors) contain cells that differentiate toward patterns more typical of the testis. Occasional tumors have significant components which in isolation would be in the granulosa-stromal or Sertoli-stromal categories and the term gynandroblastoma has been historically used for such cases. Although this heading is used in a section here, in accordance with the current World Health Organization classification, in our own practice, we prefer to categorize such neoplasms as mixed sex cordstromal tumors and itemize the components present, and their quantity, roughly, in accord with the manner of dealing with mixed germ cell tumors of the gonads. This gives the clinician more cogent information than the gynandroblastoma terminology. When the neoplastic cells are immature and their appearance is intermediate

between those of testicular and ovarian cell types, or when the architectural patterns of the tumor are not specific for either the testis or ovary, it may be impossible to determine whether the tumor belongs in the granulosa-stromal or Sertoli-stromal cell category; in such cases the term sex cord-stromal tumor, unclassified is used.

The classification of sex cord-stromal tumors used in this chapter is presented in **?** *Table 15.1*. Sex cord-stromal tumors account for approximately 8% of all ovarian tumors, with fibromas accounting for approximately half the cases. The majority of clinically malignant tumors in the overall category are granulosa cell tumors and thus they are, practically, the most important neoplasm being considered here simply due to that and their frequency which exceeds significantly that of all other malignant tumors in the group. Accordingly, it and other neoplasms

Table 15.1

Classification of sex cord-stromal tumors

Granulosa–stromal cell tumors
Granulosa cell tumor
(i) Adult type
(ii) Juvenile type
Tumors in the thecoma-fibroma group
(i) Thecoma
(a) Typical
(b) Luteinized
(c) Of the type usually associated with sclerosing
peritonitis
(d) Unclassified
(ii) Fibroma–fibrosarcoma
(a) Fibroma
(b) Cellular fibroma
(c) Fibrosarcoma
(iii) Stromal tumors with minor sex cord elements
(iv) Sclerosing stromal tumor
(v) Microcystic stromal tumor
(vi) Signet-ring stromal tumor
(vii) Unclassified
Sertoli–stromal cell tumors
Sertoli cell tumor
Leydig cell tumor
Sertoli–Leydig cell tumors
(i) Well differentiated
(ii) Of intermediate differentiation
(iii) Poorly differentiated
(iv) With heterologous elements
(v) Retiform
Gynandroblastoma (specify components)
Sex cord tumor with annular tubules

Unclassified

in the granulosa-stromal cell category are considered first after some comments on the overall aproach to evaluating these tumors, including a few remarks on immunohistochemistry.

Within the overall category of tumors considered in this chapter, one finds some of the most mundane diagnoses in ovarian tumor pathology, such as a typical fibroma, and on the other hand, a great array of other cases in which diverse patterns can bring almost any other ovarian tumor into the differential diagnosis. Fundamental to the approach to evaluating the more difficult cases is a broad knowledge of the great diversity of cell types and patterns seen in ovarian tumors, and the overlap that exists between various categories [184]. As difficult as some of these cases can be, it should also be noted that in many cases, one of the most crucial aspects of ovarian tumor evaluation, thorough sampling, will uncover foci that point firmly to the correct diagnosis. Accordingly, in an age when there is often a rush to apply immunohistochemistry, the importance of exceedingly thorough sampling of challenging cases cannot be overemphasized. The sampling must be based not only on the size of the tumor but also its overall gross characteristics and differing features thereof, and, of course, the differential diagnosis engendered when the initial sections are evaluated. Although in certain cirumstances these should point to judicious application of immunohistochemistry, they should also often cause reflection as to whether even further sections might give clues to the diagnosis. Although immunohistochemistry can be exceedingly helpful, the extent to which it is done in the current era is not matched by the aid actually provided from the viewpoint of arriving at the correct diagnosis. In some cases, it is also confusing, such as when a negative inhibin stain is obtained in a case of granulosa cell tumor, not a rare event.

Apart from thorough sampling, other fundamentals of ovarian tumor evaluation such as knowledge of the clinical background and awareness of the age of the patient should never be overlooked, albeit they are by no means always significant. The diagnostic formulation is impacted if the patient is known to have had a deeply invasive melanoma a few years ago; such tumors metastatic in the ovary can simulate a malignant steroid cell tumor or both adult and juvenile granulosa cell tumors quite closely. From the viewpoint of the age, clearly one approaches an ovarian tumor with a pattern of slit-like spaces and papillae differently in the first 10 years of life compared to in the seventh decade; in the first situation, a retiform pattern of Sertoli–Leydig cell tumor is high on the list, whereas of course in the older patient, one is most likely looking at another routine serous neoplasm.

The above emphasis on thorough sampling, awareness of age, and clinical history notwithstanding, there certainly is a role for immunohistochemistry in this area, although the extent to which it will be called upon will inevitably vary depending upon the experience of the evaluating pathologist with the spectrum of morphology of these tumors in general. Since Dr. Robert E. Scully first wrote an essay on the application of immunohistochemistry in ovarian tumor pathology in 1985 [142], there has been a vast literature on this topic. No attempt is made here to be complete from the viewpoint of citation and many excellent papers are not cited. Periodic reviews of this topic appear and three of those are cited here [11, 87, 93] as are a selected group of peer-reviewed contributions [24, 26, 34, 36, 39, 50, 57, 74, 85, 87–91, 104, 116, 131, 132, 158, 159, 197-201]. Some of these deal with now wellknown applications such as that of inhibin and calretinin, but a few deal with more recently explored topics, whose benefit remains to be fully characterized with ongoing experience.

The most helpful triad that currently exists in evaluating sex cord-stromal tumors and their mimics is that of inhibin, calretinin, and epithelial membrane antigen (EMA). The first two are typically positive in sex cord tumors and the third, typically negative [2]. However, routine evaluation still dominates in arriving at the correct diagnosis and an appreciable minority of typical granulosa cell tumors in our experience are negative for inhibin and even occasionally for calretinin. Also, rare carcinomas are positive for inhibin [88]. If a tumor is negative for inhibin and calretinin and positive for EMA, that it is a granulosa, cell tumor is close to unheard of. If a tumor shows squamous differentiation, it rules out a sex cord-stromal tumor, irrespective of any immunohistochemical results. One of the most helpful findings in this area of differential diagnosis is the lack of squamous differentiation in sex cord-stromal tumors and its frequent presence, albeit often in abortive form, in one of the tumors that most often mimics a sex cord tumor, endometrioid carcinoma. Another area discussed here where immunohistochemistry may be important is in the realm of steroid cell tumors in which the broad differential of an oxyphilic neoplasm may pertain, particularly when the neoplasm is not one of the typical low-grade steroid cell tumors but one with atypical features. Staining for inhibin, calretinin, or melan-A may be very helpful positive results, as may certain negative results (such as those related to malignant melanoma), that would rule out other oxyphilic malignant tumors. It should be remembered that the luteinized

stromal cells of many ovarian tumors may be inhibincalretinin positive, and this occasionally causes confusion if the lack of staining of epithelial cells of the neoplasm is overlooked. Although immunohistochemistry has largely supplanted electromicroscopy as a diagnostic aid in ovarian tumor interpretation, there is still an occasional role for ultrastructural evaluation in showing, for example, dense core granules in tumors of neuroendocrine type and even Charcot–Bottcher filaments in some Sertoli cell tumors. From the converse viewpoint, ultrastructural evaluation may show, for example in malignant melanoma, distinctive features of that neoplasm ruling out a sex cord-stromal or steroid cell neoplasm.

Finally, the molecular pathogenesis of sex cordstromal tumors is unknown as there have been very few molecular genetic studies of these neoplasms. Recently, it has been reported that mutation of FOXL2, a gene encoding a transcription factor critical for granulosa cell development, was present in 86 of 89 adult granulosa cell tumors (97%). Interestingly, the mutation was detected in only one of the ten juvenile granulosa cell tumors (10%), leading the authors to speculate that the juvenile granulosa cell tumor is a distinct disease from the adult type. Mutant FOXL2 was found in 3 of 14 thecomas (21%) and was absent in 49 sex cord tumors of other types, including Sertoli-Leydig tumors, fibromas, and steroid cell tumors, and in 329 unrelated ovarian and breast tumors. The findings suggest that mutant FOXL2 is a potential driver in the pathogenesis of adult-type granulosa tumors [150].

Granulosa-Stromal Cell Tumors

This category includes all ovarian tumors composed of granulosa cells, theca cells, and fibroblasts, singly or in any combination and in varying degrees of differentiation. Granulosa cell tumors that occur typically in middle-aged and older women differ in several important respects from those that usually arise in children and young adults and these two subtypes, which are referred to as adult and juvenile granulosa cell tumors, are discussed separately. It should be noted that the designations "adult" and "juvenile" are terms of convenience to capture the fact that the morphology seen under those headings is typically seen in adults and juveniles as the case may be. However, there are exceptions, some adult tumors being seen in young patients, even children, and some juvenile tumors being seen in the middle to later years of life. The adult and juvenile designations, however, are appropriate terms of

convenience, as the many differences between adult and juvenile granulosa cell tumors would be difficult to encapsulate in other than extremely lengthy descriptive designations. Tumors in the thecoma-fibroma group are composed exclusively or almost exclusively of theca cells, fibroblasts of ovarian stromal origin, or both. The presence of occasional small nests of granulosa cells or occasional tubules lined by Sertoli cells does not exclude tumors from this category; such tumors have been referred to as fibromas or thecomas with minor sex cord elements [185]. A distinctive tumor in the thecoma-fibroma group is the sclerosing stromal tumor. It has its own unique constellation of features, described below, which set it apart from other neoplasms. It can be viewed as a variant of luteinized thecoma inasmuch as it is a stromal tumor with lutein cells, but its particular features, and their rather repetitive nature warrant its separate categorization. Another tumor that best belongs in the stromal category on the basis of current knowledge is the recently described microcystic stromal tumor.

Adult Granulosa Cell Tumor

Clinical Features

Adult granulosa cell tumors account for approximately 1% of all ovarian tumors and 95% of all granulosa cell tumors. They occur more often in postmenopausal than premenopausal women, with a peak incidence between 50 and 55 years of age [14, 16, 110, 152, 155]. They are the most common estrogenic ovarian tumors clinically, but the precise proportion of adult granulosa cell tumors that secrete hormones is difficult to establish because a specimen of endometrium to evaluate the effects of estrogenic stimulation often is unavailable. The typical endometrial alteration associated with functioning tumors in this category is simple hyperplasia, usually exhibiting some degree of precancerous atypicality. Carcinoma of the endometrium, which almost always is well differentiated, has been reported in from slightly less than 5% to slightly more than 25% of the cases; the wide variation in these figures is attributable, at least in part, to differing views of the dividing line between complex atypical hyperplasia and grade 1 adenocarcinoma. If strict criteria for the diagnosis of carcinoma are used, and if all patients with a granulosa cell tumor, not only those who have had an endometrial curettage or hysterectomy, are considered, the best estimate for the frequency of associated endometrial carcinoma is under 5%.

The endometrial changes associated with adult granulosa cell tumors are manifested clinically in women in the reproductive age group by irregular, excessive uterine bleeding, but amenorrhea, lasting from months to years, may precede the abnormal bleeding or may be the only hormonal manifestation. Postmenopausal bleeding is the most common endocrine symptom in older women, in whom carcinoma of the endometrium is encountered about twice as often as in younger patients. Occasionally, swelling and tenderness of the breasts are prominent symptoms. Elevated levels of estrogens have been reported in the blood and urine, and vaginal cytologic smears typically show increased maturation of squamous epithelial cells. Alterations resembling those seen in a secretory endometrium have been observed rarely in association with granulosa cell tumors, suggesting the possibility of a significant production of progesterone in these cases [180].

Rarely, androgenic changes are the sole endocrine manifestation of an adult granulosa cell tumor [105, 111]. Most of the patients have been frankly virilized, but some have been only hirsute. The tumors may be solid or solid and cystic. The cysts typically are thin walled and may be single or multiple, resembling serous cystadenomas. Because granulosa cell tumors in general are composed exclusively of thin-walled cysts in only about 3% of the cases, the almost 50% frequency of a cystic gross appearance of tumors associated with androgenic manifestations is of interest but remains an enigma [105].

Hemoperitoneum occurs in about 10% of cases of granulosa cell tumor, and an acute abdominal presentation is accordingly more typical of that tumor than other forms of ovarian cancer.

Gross Findings

Adult granulosa cell tumors (\bigcirc *Figs.* 15.1–15.3) vary in size from those that are too small to be felt on pelvic examination (10–15%) [46] to very large masses that distend the abdomen; the average diameter is approximately 12 cm. At operation, the tumor may appear predominantly solid or predominantly cystic and is unilateral in more than 95% of the cases.

The external surface may show a site of rupture with blood occasionally associated with it. In most cases, however, it is intact and mostly smooth. Sectioning a solid tumor reveals a gray-white or yellow color, depending on its lipid content, and a soft or firm consistency, depending

Fig. 15.1

Adult granulosa cell tumor. The sectioned surface of the neoplasm is mostly solid and yellow but is focally cystic with abundant hemorrhage

Fig. 15.2
Adult granulosa cell tumor. The tumor has a friable appearance

on its relative content of neoplastic cells and fibrothecomatous stroma. Hemorrhage, which may be massive, is common as at least a focal finding. A friable nature may heighten the resemblance of some tumors to surface epithelial carcinomas (\bigcirc *Fig.* 15.2). Most characteristically, the tumor is solid and cystic, with numerous discrete compartments that are typically filled with fluid or clotted blood, or has ill-defined zones of hemorrhage, separated by solid tissue (\bigcirc *Fig.* 15.1). The occasional tumor that is

790

• Fig. 15.3 Adult granulosa cell tumor. The neoplasm is a unilocular cyst with a smooth inner lining

a multilocular or unilocular cyst (**>** *Fig. 15.3*) typically has a smooth lining. These may be indistinguishable from various other cystic ovarian masses.

Microscopic Findings

Microscopic examination of an adult granulosa cell tumor reveals only granulosa cells or, more often, an additional component of theca cells, fibroblasts, or both; in some cases, the latter cell types predominate. The granulosa cells grow in a wide variety of patterns, which are commonly admixed (\bigcirc *Figs.* 15.4–15.21): diffuse, microfollicular, macrofollicular, insular, corded to trabecular, solid-tubular, rarely hollow-tubular, miscellaneous other epithelial formations (\bigcirc *Fig.* 15.16), and sarcomatoid (\bigcirc *Fig.* 15.17). Although the microfollicular pattern is the best known (\bigcirc *Fig.* 15.14), it is less common, particularly as striking initial morphology, than a more or less diffuse

Fig. 15.4 Adult granulosa cell tumor, diffuse pattern

■ Fig. 15.5 Adult granulosa cell tumor. Focal cords and clusters idicating an epithelial nature are seen in region close to that depicted in ③ *Fig. 15.4*

Fig. 15.6

Adult granulosa cell tumor. The tumor displays a diffuse pattern with focal subtle cords (*left*). A reticulum stain (*right*) shows a paucity of staining overall supporting the diagnosis

pattern. However, although regions of neoplasms that fall in the category of a "diffuse" granulosa cell tumor do have a mostly nonspecific sheet-like growth of cells, in the great majority of cases, sometimes most strikingly at the periphery, one sees various, admittedly often somewhat subtle, patterns of epithelial differentiation on mediumto high-power scrutiny (\bigcirc *Figs.* 15.4–15.6). Most typically, delicate cords are the initial clue to the diagnosis of a granulosa cell tumor and overall, cords are probably the commonest epithelial arrangement.

The trabecular (\bigcirc *Fig. 15.8*) and insular (\bigcirc *Fig. 15.11*) patterns are characterized by bands and islands of granulosa cells, separated by a fibromatous or thecomatous stroma. In the solid tubular pattern, the tubules may be uniformly cellular or contain peripheral nuclei and central masses of cytoplasm; occasionally, a few hollow tubules or gland-like structures are encountered. The various tubular patterns encountered in granulosa cell tumors are indistinguishable from those of well-differentiated Sertoli cell tumors; their presence is ignored as a diagnostic criterion unless they account for a significant portions of the tumor (10% or more); in such cases, a diagnosis of mixed granulosa cell and Sertoli cell tumor, or gynandroblastoma, is warranted. Other patterns

of granulosa cell tumor are watered silk (moiré silk), gyriform (**>** *Fig.* 15.13), and pseudopapillary [69]. The first two patterns are manifested by undulating or zigzag rows of granulosa cells, generally in single file. The third is likely a degenerative phenomenon.

The microfollicular pattern, which only rarely predominates, is characterized by the presence of numerous small cavities simulating the Call–Exner bodies of the developing graafian follicle (\bigcirc *Fig.* 15.14). These cavities may contain eosinophilic fluid and often one or a few degenerating nuclei, hyalinized basement membrane material, or rarely basophilic fluid. The microfollicles are separated typically by well-differentiated granulosa cells that contain scanty cytoplasm and pale, angular or oval, often grooved nuclei arranged haphazardly in relation to one another and to the follicles. The macrofollicular pattern of the granulosa cell tumor (\bigcirc *Fig.* 15.15) is uncommon and characterized by cysts lined by welldifferentiated granulosa cells, beneath which theca cells often are present.

The neoplastic granulosa cells typically have scant cytoplasm and pale nuclei, some of which have nuclear grooves (\bigcirc *Fig. 15.18*). The pallor and frequency of nuclear grooves is variable from region to region and

case to case and can be impacted amongst other things by vagaries of fixation and staining. The mitotic rate in the tumors is also variable. It is generally not brisk, but there are exceptions; however, in cases with a brisk mitotic rate, particular care should be made to make sure one is not misinterpreting a mimic of a granulosa cell tumor as that neoplasm. In some granulosa cell tumors, the neoplastic cells contain abundant dense or vacuolated cytoplasm, approaching, to varying degrees, the appearance of the granulosa cells of the corpus luteum; in such cases, the term luteinized granulosa cell tumor is appropriate. Rarely, the neoplastic granulosa cells have a signet-ring cell morphology, more typical of the signet-ring cell stromal tumor considered later. Exceptionally, a granulosa cell tumor undergoes sarcomatous transformation [160] or transforms into an anaplastic carcinoma [144]. A handful of granulosa cell tumors have been intimately associated with a mucinous cystic tumor [95, 128].

An exception to the characteristic nuclear features described above is seen in approximately 2% of granulosa

Fig. 15.8 Adult granulosa cell tumor. A trabecular pattern is present

cell tumors that contain bizarre, enlarged hyperchromatic nuclei, including multinucleated forms [186] (\triangleright *Figs. 15.19* and \triangleright *15.20*). Cells with these nuclear features typically are a focal finding but rarely are conspicuous and may overshadow more characteristic foci, which can be overlooked if not carefully sought.

The prominence and nature of the stromal component in granulosa cell tumors vary considerably. In some cases, usually those with a diffuse pattern, it is essentially absent. In tumors in which the granulosa cells form nests or trabeculae, the stroma is usually conspicuous and composed of fibroblasts and theca cells that contain appreciable to abundant eosinophilic or vacuolated lipid-rich cytoplasm. The stroma is often quite vascular (**)** *Fig. 15.9*), and this may be striking on low-power examination.

Rarely, crystals of Reinke are present in the lutein-type cells of a granulosa cell tumor, enabling them to be specifically identified as Leydig cells [4]. Another recently recognized rare component of the stromal compartment of granulosa cell tumors is hepatic-type cells [4, 109]

(**○** *Fig. 15.21*). These cells are typically larger and have denser eosinophilic cytoplasm than lutein or Leydig cells. Bile pigment has been detected in canaliculi between some of the hepatic-type cells in three cases. The hepatic-type cells have been immunoreactive for epithelial membrane antigen (EMA), carcinoembryonic antigen (CEA), which stained canaliculi between the cells, and CAM 5. In contrast to lutein or Leydig cells, the hepatic-type cells are negative for inhibin [4].

The presence of theca cells in varying quantities in most granulosa cell tumors has led to the occasional usage of the term granulosa-theca cell tumor. Although this designation accurately describes the cellular content of many of these neoplasms, the term granulosa cell tumor is more widely accepted for tumors containing both cell types. One reason for this preference is the probability that the presence of theca cells in some cases reflects a response of the ovarian stroma to the growth of granulosa cells rather than the coexistence of a second neoplastic cell component. Evidence favoring such an interpretation includes the nonspecific presence of thecalike cells in a variety of ovarian tumors, both benign and malignant and both primary and metastatic, and the observation that theca cells usually are absent in granulosa cell tumors that have extended beyond the ovary [47]. It is possible, however, that some tumors in which the theca cell element is prominent or even greatly preponderant are truly mixed neoplasms. The theca cells in granulosa cell tumors may resemble theca externa or theca interna cells and may be luteinized. In some tumors, particularly those with a diffuse pattern, differentiation of granulosa and theca cells with routine staining may be difficult or impossible. In such cases a reticulum stain may be helpful. Just as in a developing graafian follicle, so in a granulosa cell tumor, the fibrils typically invest theca cells individually. In contrast, the granulosa cell layer of a follicle contains no fibrils, and in a granulosa cell tumor, the reticulum usually is sparse, being typically confined to perivascular zones.

The presence of blood-filled cysts in many granulosa cell tumors results in the frequent presence in the tumors of related changes that are nonspecific, but in the context of other typical features of granulosa cell tumors are at the same time quite characteristic. For example, the cysts often are lined by fibrous tissue associated with evidence of old and recent hemorrhage that is sometimes conspicuous.

Several histochemical reactions that are characteristic of steroid hormone-producing cells, particularly those that demonstrate various types of lipid content or oxidative enzyme activity, usually are positive in the theca cells and negative or only weakly positive in the granulosa cells of a tumor containing both cell types [79-81, 146]. This finding, as well as ultrastructural observations, has led some observers to conclude that the theca cell component of granulosa cell tumors produces the hormones responsible for estrogenic manifestations. Additional evidence in favor of this conclusion is the observation that granulosa cell tumors that recur outside ovarian tissue and lack theca cells typically are not obviously estrogenic. In some cases, however, histochemical and other evidence has suggested a role for the granulosa cells in estrogen secretion [7, 42]. The above histochemical studies are rarely indicated other than for academic interest.

Differential Diagnosis

Misinterpretation of an undifferentiated carcinoma as an adult granulosa cell tumor (AGCT) with a diffuse pattern occasionally occurs. If the clinical course of the patient is

Fig. 15.10
Adult granulosa cell tumor. Long ribbons of cells (*left*). Positive staining for inhibin (*right*)

atypically malignant for an AGCT, the possibility of such a misdiagnosis must be considered. The single best criterion for distinguishing these two tumors is the appearance of the nuclei, which are typically uniform, pale, and often grooved in the AGCT (tumors with bizarre nuclei being a noteworthy exception) and are hyperchromatic, usually of unequal size and shape, and rarely grooved in undifferentiated carcinomas; atypical mitotic figures often are found in the latter as well. Other features helpful in the differential diagnosis are summarized in **2** Table 15.2. The highly malignant small cell carcinoma, which usually is associated with hypercalcemia, also may be misdiagnosed as an AGCT. The differential features of these tumors are presented in **2** Table 15.3. The most helpful features are the much higher mitotic rate of the small cell carcinoma and the lack in that tumor of the typical cytologic features of the AGCT. Immunohistochemical differences will also aid if this step is deemed indicated [3, 92]. A diffuse AGCT occasionally is confused with a primary endometrioid stromal sarcoma or metastatic endometrial stromal sarcoma of the ovary, but a variety of features, including the frequent high stage and bilaterality of the latter tumors, the characteristic pattern of growth in extraovarian sites of spread, their typical content of numerous arterioles, and their rich reticulum content aid in this differential

diagnosis. In this, as in other problems in the diagnosis of granulosa cell and other sex cord-stromal tumors, extensive sampling of the specimen often is helpful as is an appreciation of the rarity of bilaterality and extraovarian spread at presentation in cases of sex cordstromal tumors.

AGCTs may be difficult to distinguish from pure stromal tumors such as cellular thecomas, particularly those that are more cellular than is normal, fibromas, and fibrosarcomas. Reticulum stains may show abundant intercellular fibrils in these tumors, unlike the scant reticulum of AGCTs. In some cases, the pattern of fibrils is intermediate between an AGCT and a thecoma, and in such cases, the differential diagnosis may be difficult or impossible. The almost exclusive spindle cell nature of the cells in fibromas and fibrosarcomas is rarely seen in an AGCT.

Occasionally, the distinction of a unilocular or multilocular macrofollicular AGCT from one or more follicular cysts may be troublesome; this is particularly likely if the patient is pregnant, or in the puerperium, because a large solitary luteinized follicle cyst of pregnancy and the puerperium is indistinguishable grossly from a unilocular cystic AGCT. The large luteinized cells of the former, some of which contain large bizarre nuclei, differ

Fig. 15.11 Adult granulosa cell tumor, insular pattern

from those of a unilocular AGCT, which are rarely uniformly luteinized and rarely contain bizarre nuclei lining the cysts.

Endometrioid carcinomas occasionally are misdiagnosed as AGCT when the former have small acini imparting a microfollicular pattern. Also, some endometrioid carcinomas have an insular pattern that on low power may suggest the diagnosis of an insular AGCT. Another source of confusion is the presence in some endometrioid carcinomas of a focal diffuse pattern that is occasionally difficult to distinguish from the diffuse pattern of an AGCT. In thoroughly sampled tumors, there will almost invariably be various patterns of one or the other tumor which will, however, establish the correct diagnosis. In the case of endometrioid tumors with a diffuse pattern, the focal presence of abortive squamous differentiation is a very major clue to the diagnosis. In most of these cases, the cytologic features in an endometrioid carcinoma differ from those of an AGCT, although there are rare cases in which the former tumors have pale nuclei that on cytologic grounds are consistent with a diagnosis of AGCT. In our experience,

Fig. 15.12 Adult granulosa cell tumor, insular and trabecular patterns

a combination of at least focal cytologic differences, and the presence in endometrioid tumors that are well sampled of other foci incompatible with the diagnosis of an AGCT, such as squamous foci, establish the diagnosis. Immunohistochemistry will aid if necessary, as noted in the introductory section of the chapter.

The rare AGCT in which the cells are extensively luteinized [180] may superficially resemble a steroid cell tumor. The focal presence of areas with the architectural and cytologic features of an AGCT usually facilitates the diagnosis in these cases. AGCTs should be distinguished from the small proliferations of granulosa cells within atretic follicles that are typically an incidental finding within the ovaries of pregnant women. Another rare problem in differential diagnosis is the distinction between a granulosa cell tumor, usually a luteinized one, and an epithelioid smooth muscle tumor. The latter diagnosis does not tend to be considered as quickly, not unreasonably, when examining an ovarian tumor as it does when evaluating a uterine one. This is an area in which immunohistochemistry, specifically strong desmin staining and negative staining for inhibin and calretinin, may play a major role.

Fig. 15.13 Adult granulosa cell tumor, gyriform pattern

Fig. 15.14 Adult granulosa cell tumor, microfollicular pattern

It is important to distinguish the Call–Exner bodies of AGCTs from the acini of carcinoid (**>** *Table 15.4*) and from the hyaline bodies that are seen in gonadoblastomas and sex cord tumors with annular tubules. The acini of

Fig. 15.15 Adult granulosa cell tumor, macrofollicular pattern

carcinoids often contain dense eosinophilic secretion that is sometimes calcified; the latter is not a feature of the AGCT. The nuclei of carcinoids, which have coarse chromatin, contrast with the pale nuclei of the AGCT. The hyaline bodies of gonadoblastomas and sex cord tumors with annular tubules typically are larger than Call–Exner bodies. Sometimes, the hyaline bodies can be observed to be continuous with hyaline thickenings of the basement membrane along the periphery of the tumor cell nests; these bodies also undergo calcification.

The AGCT may be confused with two types of metastatic tumors, metastatic malignant melanoma and metastatic breast carcinoma. Metastatic melanomas may have cells with scant cytoplasm that grow diffusely, imparting a low-power appearance that may closely mimic that of an AGCT. Patterns of growth incompatible with a diagnosis of AGCT usually are found when a tumor is thoroughly sampled, and the finding of melanin pigment or immunohistochemical stains may be helpful in problematic cases. Metastatic breast carcinoma sometimes also has a diffuse growth of cells with scant cytoplasm, particularly in cases of lobular carcinoma. The history often is helpful

Fig. 15.16 Adult granulosa cell tumor. A peculiar pattern of regular small clusters of cells

in these cases because breast carcinoma rarely presents with an ovarian metastasis. In cases in which a breast cancer is not known in the patient, it is only the presence of focal patterns more suggestive of breast cancer than a granulosa cell tumor and a lack of the typical cytologic features of granulosa cell tumor that will alert the pathologist to the possible correct diagnosis. In both this situation and that of metastatic melanoma, the ovarian metastatic tumors are much more frequently bilateral than is the AGCT. Immunohistochemical staining for gross cystic disease fluid protein 15, S-100, and HMB45 can be helpful in the distinction of metastatic breast carcinoma and metastatic malignant melanoma from the adult granulosa cell tumor.

Clinical Behavior and Treatment

After the removal of a granulosa cell tumor, the manifestations of hyperestrinism typically regress. If the uterus has been conserved in a young woman, estrogen withdrawal bleeding usually occurs in 1 or 2 days, and regular menses

Fig. 15.17 Adult granulosa cell tumor, sarcomatoid pattern

ensue shortly thereafter. Granulosa cell tumors of all patterns have a malignant potential, with a capacity to extend beyond the ovary or recur after apparently successful removal. Spread is largely within the pelvis and lower abdomen; distant metastases are rare but have been reported in many sites. Although recurrences may appear within 5 years, they often are not evident until a much longer postoperative interval has elapsed, and numerous cases have been reported in which the tumor has reappeared two or even three or more decades after the initial therapy. The 10-year survival figures that have been recorded in the literature have varied widely from less than 60% to more than 90%, and progressive declines in survival have been documented after longer follow-up periods [14-16, 155]. Unfortunately, many old studies of granulosa cell tumor are suspect from the viewpoint of the impact of various features on prognosis, and survival figures overall, because of the almost certain inclusion in some of them of tumors that are not granulosa cell tumors, differential features between the granulosa cell tumor and its various mimics having been much more appreciated in the last several decades.

Fig. 15.18 Adult granulosa cell tumor. The nuclei are pale and some have grooves

The optimal treatment of a granulosa cell tumor in menopausal or postmenopausal women is total hysterectomy with bilateral salpingo-oophorectomy. In younger women in whom the preservation of fertility is an important consideration, however, removal of only the ovary and the adjacent fallopian tube is justifiable if spread beyond the ovary is not demonstrable and examination of the contralateral ovary shows no suggestion of involvement. Some recurrent tumors have been treated successfully by reoperation, radiation therapy, or a combination of these.

At least 90% of granulosa cell tumors are stage I, and these tumors have a considerably better prognosis than the higher-stage tumors, as shown by an 86% versus a 49% relative survival at 10 years, respectively, in one large series and a 96% versus a 26% survival in another [16]. Rupture also adversely affects the outlook, with an 86% relative 25-year survival of patients with intact stage I tumors compared with only 60% survival of those with ruptured tumors that are otherwise in the same stage [16]. The impact of the stage has been confirmed in a recent study [9].

■ Fig. 15.19 Adult granulosa cell tumor with bizarre nucleil. Typical foci are also present (*bottom*) and a clue to the diagnosis

The size of granulosa cell tumors also has been related to their prognosis. In one series, all the patients with tumors 5 cm or less in diameter survived 10 years, but only 57% of those with tumors 6-15 cm in diameter and 53% of those with even larger tumors survived for that period of time [51]. Another investigation reported a 73% crude overall survival of patients with tumors less than 5 cm in diameter, a 63% survival of those with tumors between 5 and 15 cm, and a 34% survival of those with a tumor greater than 15 cm in diameter [155]. In a final series, stage I tumors 5 cm or less in diameter were associated with a 100% relative 10-year survival in contrast to a 92% survival of patients with larger stage I tumors [16]. The last series is the only one in which the survival rate was corrected for stage, and on that basis, the improvement in prognosis for the smaller stage I tumors was not statistically significant. Therefore, a relationship between tumor size and prognosis independent of stage has not been clearly established. Attempts to correlate the histologic pattern and the degrees of nuclear atypia and mitotic activity with prognosis have met with varying

Fig. 15.20 Adult granulosa cell tumor with bizarre nuclei. In isolation the picture is alarming

success; most investigators have been unable to show a prognostic importance for pattern alone in granulosa cell tumors [110, 152].

The degree of nuclear atypicality within granulosa cell tumors has been correlated with their prognosis. In one study, the 5-year survival of patients whose tumors showed no atypia was 92% compared with 80% for those with slight atypicality and 30% for those with moderate atypicality [155]. In another study, there was an 80% relative 25-year survival in cases with grade 1 nuclear atypicality in contrast to only a 60% survival in those with grade 2 atypia [16]. In both of these studies, nuclear atypicality was the most reliable prognostic index in cases of stage I tumors; for higher-stage tumors, nuclear atypicality and mitotic rate were of similar significance. With regard to the relation of nuclear atypicality to prognosis, it should be noted that assessment of its degree is somewhat subjective. Also, as noted earlier, approximately 2% of granulosa cell tumors contain mononucleate and multinucleate cells with large, bizarre, and hyperchromatic nuclei (> Figs. 15.19 and > 15.20), the

Fig. 15.21 Adult granulosa cell tumor with hepatic-like cells

Table 15.2

Granulosa cell tumor versus undifferentiated carcinoma and poorly differentiated adenocarcinoma

Granulosa cell tumor	Carcinoma
Bilateral, less than 5%	Bilateral, more than 25%
Stage I in 90% of cases	Stage III or IV in most cases
Nuclei round to angular, pale and commonly grooved ^a	Nuclei hyperchromatic, often bizarre with atypical mitoses
Mucin occasionally in follicles (mainly in juvenile type)	Intracellular droplets or extracellular pools of mucin, psammoma bodies, or glands may be present
Good prognosis	Poor prognosis
Indolent course, when clinically malignant ^b	Rapid course

^aException: dark, ungrooved nuclei of juvenile granulosa cell tumor. ^bException: rare juvenile granulosa cell tumors.

Table 15.3

Granulosa cell tumors (GCTs) versus small cell carcinoma

Juvenile GCT	Adult GCT	Small cell carcinoma
Mostly before 30 years	All ages, but mostly postmenopausal	Always premenopausal
Rarely malignant	Occasionally malignant, often with protracted course	Highly malignant
No hypercalcemia	No hypercalcemia	Hypercalcemia common
Usually estrogenic	Usually estrogenic	Never estrogenic
Thecomatous component common	Fibrothecomatous component common	Stroma scanty and nonspecific
Mucinous epithelium absent	Mucinous epithelium rare	Mucinous epithelium 12% of cases
Cytoplasm usually abundant	Cytoplasm usually scanty	Cytoplasm usually scanty, but may be abundant
Nuclei dark, ungrooved, and pleomorphic 13% of cases	Nuclei pale and often grooved	Nuclei dark, uniform, and ungrooved
Mitoses usually numerous	Mitoses variable	Mitoses numerous

Table 15.4

Granulosa cell tumor versus carcinoid

Granulosa cell tumor	Insular carcinoid
Variety of patterns	Islands, round acini, solid tubules, and ribbons
Call–Exner bodies, ill-defined, with watery to dense eosniophilic content, occasionally pyknotic	Acini sharply outlined with dense content, nucleisometimes calcified
Nuclei round to angular, pale, often grooved, haphazardly oriented	Nuclei round with coarse chromatin and regular orientation
Thecomatous stroma common, at least focally	Fibromatous or hyalinized stroma, may be focally luteinized
Usually uninodular and almost always unilateral; no teratomatous elements	Often multinodular and almost always bilateral if metastatic; always unilateral and usually associated with other teratomatous elements if primary
Cells nonargentaffin; may contain fine argyrophilic granules	Cells usually argentaffin; almost always argyrophilic

presence of which has not been shown to worsen the prognosis. These nuclear changes, which resemble those seen in the uterine leiomyoma with bizarre nuclei, also are encountered in occasional Sertoli–Leydig cell tumors and thecomas and probably are degenerative. In a study of 8 granulosa cell tumors, 7 Sertoli–Leydig cell tumors and 2 thecomas with bizarre nuclei, follow-up was obtained on 11 patients, all of whom were alive without evidence of disease 3–21 years postoperatively [186].

The mitotic activity of granulosa cell tumors also has been correlated with their prognosis. In one study there was a 70% 10-year survival associated with tumors that had two or fewer mitotic figures (MF) per ten high-power fields (HPF) compared with only a 37% survival for those with three or more [155]. In another investigation [110], tumors with many mitotic figures were associated with a worse prognosis than those with few, but most of the tumors with high mitotic rates also were at a higher stage than those with low mitotic rates, and differences in mitotic rate did not have a statistically significant effect on the prognosis of stage I tumors.

Juvenile Granulosa Cell Tumor

Clinical Features

Somewhat less than 5% of granulosa cell tumors are diagnosed before the age of normal puberty [82]. The great majority of these tumors as well as many granulosa cell tumors in young adults differ histologically from adult granulosa cell tumors (**)** *Table 15.5*), and the designation juvenile has been selected for such tumors because 97% of them occur in the first 3 decades [178]. Approximately,

Table 15.5

Adult versus juvenile granulosa cell tumor (GCT)

Adult GCT	Juvenile GCT
Less than 1% prepubertal	50% prepubertal
Usual after 30 years	Rare after 30 years
Mature follicles and Call–Exner bodies occasional	Immature follicles with mucin content Call–Exner bodies rare
Nuclei pale, angular, commonly grooved	Nuclei darker, round, rarely grooved
Luteinization infrequent	Luteinization frequent

80% of juvenile granulosa cell tumors (JGCTs) occurring in children result in isosexual precocity, accounting for 10% of cases of that syndrome in the female. More common forms of isosexual precocity are those of central origin, with premature release of gondadotropins from the anterior pituitary gland and those resulting from apparently autonomous formation of one or more follicle cysts. The precocity caused by granulosa cell tumors is more specifically designated pseudoprecocity because there is no associated ovulation or progesterone production, precluding the possibility of pregnancy, which exists, in contrast, in cases of true sexual precocity. Typically, pseudoprecocity is heralded by the development of the breasts, followed by the appearance of pubic and axillary hair, stimulation and enlargement of the external and internal secondary sex organs, irregular uterine bleeding, and a whitish vaginal discharge, believed to originate in the stimulated endocervical glands. Somatic and skeletal development typically are accelerated as well. Androgenic manifestations such as clitoromegaly occasionally occur [178].

When it occurs after puberty, the JGCT usually presents with abdominal pain or swelling, sometimes associated with menstrual irregularities or amenorrhea. Approximately, 6% of all the patients present with acute abdominal symptoms because of rupture of the tumor and hemoperitoneum. An interesting clinical association of the JGCT has been its association with Ollier's disease (enchondromatosis) in some patients and with Maffucci's syndrome (enchondromatosis and hemangiomatosis) in a few others. The JGCT is bilateral in only about 2% of the cases. It appears ruptured at operation in approximately 10% of the cases, and ascites is present in a similar percentage. Spread beyond the ovary is unusual; in our series only 2% of the tumors were stage II; rare tumors are stage III [178]. The diameter of the tumor has ranged from 3 to 32 cm, with an average of 12.5 cm. Because of a usual moderate to large size of the tumor, an adnexal mass is almost always detectable clinically. Rarely, however, a mass has not been palpable preoperatively even on bimanual rectal examination.

Gross Findings

The range of gross appearances of the JGCT is similar to that of the adult form. Like the latter, the single most common presentation is as a solid and cystic neoplasm in which the cysts may contain hemorrhagic fluid (**>** *Fig. 15.22*). Uniformly solid and uniformly cystic neoplasms also are encountered; the latter may be multilocular or, rarely, unilocular. The solid component typically is yellow-tan or gray, and occasionally exhibits extensive necrosis, hemorrhage, or both.

Microscopic Findings

Microscopic examination (**)** Figs. 15.23–15.26) typically reveals a solid cellular neoplasm, with focal follicle formation (> Fig. 15.23), but the tumor also may be uniformly solid or uniformly follicular. In the solid areas, the neoplastic cells may be arranged diffusely or divided into nodules by fibrous septa; occasionally, small clusters of tumor cells are present in a fibrous stroma. In the solid foci the granulosa cells usually predominate, but often there is an admixture of theca cells, and in some areas the latter may predominate. Occasionally, the granulosa cells and theca cells are admixed in a haphazard fashion. Foci resembling typical thecoma with hyaline bands are encountered rarely but usually are minor in extent. Rarely, areas of sclerosis and calcification are seen. A pseudopapillary pattern () Fig. 15.26) analogous to that seen in the AGCT may be seen.

The follicles usually vary in size and shape but may be regular and round to oval. They generally do not reach the large size of the follicles in the rare macrofollicular form of AGCT. Their lumens contain eosinophilic or basophilic secretion, which stains with mucicarmine in approximately two thirds of the cases. Granulosa cells of varying layers of thickness line the follicles and occasionally are surrounded by mantles of theca cells. More often, however, the granulosa cells lining the follicles blend into the intervening diffusely cellular areas. Rarely, the lining cells resemble hobnail cells.

The two characteristic cytologic features of the neoplastic granulosa cells that distinguish them from those of

Fig. 15.22

Juvenile granulosa cell tumor. The sectioned surface of the neoplasm is solid and cystic. Clotted blood is present in most of the cysts

the AGCT are their generally rounded, hyperchromatic nuclei, which lack grooves in most cases, and their frequent abundant content of eosinophilic (luteinized) cytoplasm (**>** *Fig. 15.24*). The theca cell element of the tumors usually is also luteinized, and lipid stains typically disclose moderate to large amounts of fat within the cytoplasm of both cellular components. The theca cells are more often spindle shaped than the granulosa cells and, like the latter, usually contain hyperchromatic nuclei. In rare JGCTs, small foci more characteristic of the AGCT are encountered.

Nuclear atypicality in JGCTs varies from minimal to marked. In approximately 13% of the cases severe degrees are present (\triangleright *Fig.* 15.25) [178]. The mitotic rate also varies greatly but is generally higher than that seen in AGCTs.

There are very rare neoplasms that we designate anaplastic juvenile granulosa cell tumor. In contrast to conventional neoplasms with striking nuclear atypia but

Fig. 15.23 Juvenile granulosa cell tumor. Follicles of varying sizes and shapes are separated by cellular areas

• Fig. 15.24 Juvenile granulosa cell tumor. The cells have abundant cytoplasm; their nuclei lack grooves and exhibit mitotic activity

Fig. 15.25 Juvenile granulosa cell tumor. Focally marked nuclear atypicality is present

Fig. 15.26 Juvenile granulosa cell tumor, pseudopapillary pattern

which still have an orderly architecture, these neoplasms have zones with a sheet-like growth that when viewed in isolation are not recognizable as juvenile granulosa cell tumor and indeed, in some instances, resemble undifferentiated carcinoma. A diagnosis of anaplastic juvenile granulosa cell tumor can only be made when thorough sampling discloses characteristic features of that neoplasm in the form of the typical follicles.

Differential Diagnosis

The differential diagnosis of the JGCT includes the AGCT and a wide variety of other neoplasms. The follicles of the JGCT are more irregular in size and shape than those of an AGCT, and its cells are more extensively luteinized with nuclei that are typically round and more hyperchromatic and lack nuclear grooves (see **2** *Table 15.5*). The mucicarminophilic, often basophilic follicular content in the JGCT, also differs from the eosinophilic fluid often

accompanied by degenerating nuclei or basement membrane material that is usually present in the microfollicles of AGCTs.

The JGCT may be misdiagnosed as a malignant germ cell tumor. The latter may be associated with human chorionic gonadotropin (hCG)-induced isosexual pseudoprecocity. The nuclei of the JGCT are not as primitive appearing as those of either a yolk sac tumor or an embryonal carcinoma, and the follicular pattern of the JGCT is not a feature of either germ cell tumor, although the cysts of the polyvesicular variant of yolk sac tumor can superficially resemble the follicles of a JGCT in rare cases. Immunohistochemical demonstration of hCG in embryonal carcinomas and of alpha fetoprotein in yolk sac tumors may be helpful in difficult cases.

The JGCT is sometimes misinterpreted as a thecoma because of the occasional absence or rarity of follicles, the typically abundant cytoplasm of the neoplastic cells and the occasional predominance of theca cells. Thorough sampling to demonstrate follicles and the performance of reticulum stains to establish the granulosa cell nature of at least some of the tumor cells are important diagnostically. Also, thecomas rarely exhibit significant mitotic activity, uncommonly occur before 30 years of age and are exceptionally rare in children. A focally diffuse pattern in a luteinized JGCT may suggest the diagnosis of a steroid cell tumor, but the uniformity of the pattern and cytologic features of the latter tumor would be unusual for a JGCT, which almost always contains more diagnostic areas. The pregnancy luteoma rarely contains rounded follicle-like spaces and may suggest a luteinized JGCT but, like the steroid cell tumor, its cells are uniform in appearance, and it is multiple and bilateral in one half and one third of the cases, respectively.

The common epithelial tumors with which a JGCT may be confused are clear cell, undifferentiated, and transitional cell carcinomas. The tubulocystic variant of the clear cell carcinoma is rarely suggested when follicles in a JGCT are lined by cells resembling hobnail cells, and JGCTs with high-grade nuclear atypia may suggest an undifferentiated carcinoma. Transitional cell carcinoma is mimicked in rare cases in which a cystic JGCT contains pseudopapillae lined by uniform granulosa cells [69]. The young age of the patient and the presence of follicles and of other areas typical of a JGCT should help indicate the correct diagnosis in these cases.

The JGCT may be confused with a small cell carcinoma of hypercalcemic type (see > Table 15.3) because both neoplasms contain follicles, and both are characteristically found in young patients. In the typical case of small cell carcinoma, the presence of cells with scanty cytoplasm is in marked contrast to the JGCT, in which the tumors almost without exception have cells with appreciable to abundant cytoplasm. The follicles in the small cell carcinoma rarely contain the basophilic secretion that is seen in many JGCTs. Although the JGCT characteristically has easily found mitotic figures, mitoses are in general much more numerous in the small cell carcinoma. Particular difficulty may be caused by cases of small cell carcinoma in which the tumor cells have abundant eosinophilic cytoplasm. The tumors usually can be distinguished even in these cases because the small cell carcinomas have a much more disorderly growth than seen in the JGCT. Additionally, the large cells seen in the cases of small cell carcinoma often have a rather distinctive dense, globular cytoplasm, a feature only occasionally seen in the JGCT.

The only metastatic tumor that we have seen confused with a JGCT is metastatic malignant melanoma, because some malignant melanomas, like many metastatic tumors, contain follicle-like spaces and this metastatic tumor frequently has cells with abundant eosinophilic cytoplasm. The result may be a striking simulation of the solid and follicular pattern of a JGCT. It is helpful clinically that metastatic malignant melanoma is very rare in the first 2 decades, when approximately 80% of JGCTs are encountered. The clinical history, of course, is helpful in many cases but as the history of malignant melanoma may be remote, or the primary tumor may have regressed, the possibility of malignant melanoma should be considered when entertaining the diagnosis of JGCT in a patient over 20 years of age. The likelihood of this diagnosis will be heightened if the ovarian tumor is bilateral. Other features of metastatic melanoma also may be helpful as will immunohistochemistry.

Clinical Behavior and Treatment

Although the JGCT usually appears less well differentiated than the adult type, follow-up to date indicates a high cure rate [82, 178, 193]. In contrast to AGCTs, which often recur late, all the clinically malignant juvenile tumors have reappeared within 3 years and several have had a rapid course.

In our series, the feature of greatest prognostic significance was the stage of the tumor [178]. Only 2 of the 80 stage I tumors for which follow-up information was available were clinically malignant. Rupture did not have an adverse effect on prognosis. Two of the ten stage IC tumors were malignant; in one of them, malignant cells were present on cytologic examination of the ascitic fluid. All three stage II tumors were fatal. Although both the mitotic rate and the degree of nuclear atypicality correlated with the prognosis when tumors of all stages were considered, no such correlation was evident when only stage I tumors were evaluated. In conclusion, despite the frequent presence of disquieting features such as severe nuclear atypicality and very high mitotic rates, a JGCT that is confined to the ovary appears to have an excellent prognosis with rare exceptions.

In view of the rarity of bilateral ovarian involvement, and their excellent prognosis, a stage IA JGCT can be treated by a unilateral salpingo-oophorectomy. Little experience has accumulated on the role of radiation therapy and chemotherapy in the management of persistent or recurrent tumor, but isolated examples of the efficacy of these modes of therapy have been recorded.

The comments just made on behavior, prognosis, and therapy do not apply to the rare cases that we designate anaplastic juvenile granulosa cell tumor, which are highly malignant in our experience.

Thecoma

Although different criteria for the microscopic separation of thecoma and fibroma have resulted in varying estimates of the frequency of these tumors, thecomas are approximately one third as common as granulosa cell tumors. The thecoma occurs at an older average age than the granulosa cell tumor, being very rare before puberty and uncommon before the age of 30 years. In one large series, 84% of the patients were postmenopausal, with a mean age of 59 years; only 10% of the patients were under 30 years of age [17]. In the same series, 60% of the postmenopausal women presented because of uterine bleeding, and 21% of the patients had endometrial carcinoma. Thecomas can be divided into typical and luteinized forms [12, 17, 55, 67, 136, 196].

Thecomas range in size from small, impalpable tumors to large, solid masses; most are medium size, 5-10 cm in diameter. Sectioning typically discloses a solid yellow mass (> Fig. 15.27), but in some cases, the tumor is white with only focal tinges of yellow; cystic change and foci of hemorrhage and necrosis occur occasionally. Microscopic examination reveals masses of cells, often intersected by fibrous bands or hyaline plaques (> Fig. 15.28). The tumor cells are ill defined and oval or rounded; the cytoplasm usually is moderate to abundant. It most often has a pale, almost dull grey appearance (> Fig. 15.29) and its lipid-rich character has been overemphasized. However, in some cases, the cytoplasm is to a degree vacuolated, containing moderate to abundant amounts of lipid. Rarely it is strikingly vacuolated. In occasional cellular thecomas the cytoplasm is inconspicuous. The nuclei vary from round to spindle shaped, indicating the overlap between

• Fig. 15.27 Thecoma. The sectioned surface of the neoplasm is uniformly solid, yellow, and lobulated

fibromas and thecomas (\bigcirc *Fig. 15.28*). There is usually little or no atypia, but bizarre nuclei are rarely seen; mitoses are absent or infrequent. In thecomas, in contrast to granulosa cell tumors, reticulum fibrils typically surround individual tumor cells although sometimes they surround small clusters of cells. The stroma is sometimes myxoid (\bigcirc *Fig. 15.30*) and rare tumors, particularly in the young, are calcified [176] (\bigcirc *Fig. 15.30*).

Typical thecomas are unilateral in 97% of the cases and are almost never malignant. A number of tumors have been reported as "malignant thecomas," but some of these tumors are better interpreted as endocrinologically inactive fibrosarcomas or diffuse granulosa cell tumors [175]. In cases in which the preservation of fertility is important, a thecoma can be treated adequately by oophorectomy. Total hysterectomy with bilateral salpingooophorectomy is indicated, however, in most patients who are menopausal or postmenopausal.

Tumors that are predominantly fibromatous or thecomatous but also contain collections of steroid-type

Fig. 15.28

Thecoma. Hyaline plaques are conspicuous. This region of what was overall a thecoma had hybrid thecoma–fibroma features

Fig. 15.29 Thecoma. Typical appearance of cytoplasm in many cases

cells, resembling luteinized theca and luteinized stromal cells have been called luteinized thecomas. In our series of 46 cases of these tumors, half of them were estrogenic, 39% were nonfunctioning, and 11% were androgenic [196]. Two of the four patients with tumors of this type described by Roth and Sternberg [136] also were virilized. This relatively high frequency of masculinization contrasts with its great rarity in association with nonluteinized thecomas. Luteinized thecomas also occur in a younger age group than typical thecomas; although they are most frequent in postmenopausal women, 30% of them have occurred in patients under 30 years of age. When, on rare occasions, crystals of Reinke are identified in the steroidtype cells [120], the term stromal-Leydig cell tumor is appropriate [18, 119, 141, 157, 196]. Approximately half of these tumors have been virilizing.

A rare subtype of luteinized thecoma with distinctive features (**>** *Figs.* 15.31–15.33) is that usually associated with potentially fatal sclerosing peritonitis [31, 154]. In contrast to typical thecomas and luteinized thecomas of the usual type, this lesion is nearly always bilateral. In some cases, it enlarges the ovary irregularly, often resulting

in a striking expansion of the cortex and an exaggerated cerebriform appearance, suggesting a nonneoplastic process in some cases (**>** Fig. 15.31). In other cases it forms a discrete mass. Microscopic examination discloses a process with dense cellular areas and less cellular areas in which edema with microcystic change is often conspicuous (> Fig. 15.33). Lutein cells are present but are smaller and less easy to recognize (> Fig. 15.32) than those in the usual luteinized thecoma. The proliferation frequently incorporates preexisting ovarian structures such as follicles. Another unusual aspect of this neoplasm is the brisk mitotic activity present in many cases, despite the lack of evidence that the lesion has the potential to metastasize. While the luteinized cells stain with sex cord markers such as inhibin and calretinin, the spindle cell component typically does not. The associated sclerosing peritonitis (seen in nearly all cases although sometimes only histologically) may cause significant morbidity and has occasionally been fatal [154]. The pathogenesis of the sclerosing peritonitis in these cases remains a mystery.

Fibroma

This tumor, which is composed of spindle cells forming variable amounts of collagen, accounts for 4% of all ovarian tumors. Fibroma occurs at all ages, but is most frequent during middle age, with an average age of 48 years [41]; fewer than 10% of the cases are encountered under the age of 30 years. The fibroma is rarely associated with steroid hormone production but may be accompanied by two unusual clinical syndromes, Meigs' syndrome [98] and the basal cell nevus syndrome (Gorlin's syndrome) [56]. The former, which complicates about 1% of ovarian fibromas, is defined as ascites and pleural effusion accompanying a fibrous ovarian tumor, usually a fibroma, and disappearing after the removal of the tumor. Ascites alone is present in association with 10-15% of ovarian fibromas larger than 10 cm in diameter [139]. The most widely accepted explanation of Meigs' syndrome is seepage of fluid from the tumor through its serosal surface into the peritoneal cavity, with subsequent passage into one or both pleural cavities either via lymphatics or through a communication between the abdominal and pleural cavity such as the foramen of Bochdalek.

The hereditary basal cell nevus syndrome is characterized by one or more of the following findings: basal cell carcinomas appearing early in life, keratocysts of the jaw, calcification of the dura, mesenteric cysts, and other less common abnormalities [56] as well as ovarian fibromas, which typically are bilateral, multinodular, and calcified

Fig. 15.30 Thecoma. There is myxoid stroma and focal calcification (*left*). An inhibin stain is positive (*right*)

(Fig. 19.28). A case of fibrosarcoma of the ovary in a child with the basal cell nevus syndrome has been reported [77].

Fibromas range in size from microscopic to very large. Sectioning typically reveals hard, flat, chalky-white surfaces that have a whorled appearance. Areas of edema, occasionally with cyst formation, are relatively common (**>** *Fig.* 15.34). Focal or diffuse calcification and bilaterality are each observed in fewer than 10% of the cases but, as already mentioned, these features are characteristic of the fibromas associated with the basal cell nevus syndrome. Microscopic examination reveals intersecting bundles of spindle cells producing collagen; a storiform pattern may be encountered. The presence of bands of hyalinized fibrous tissue is not uncommon. Many tumors show varying degrees of intercellular edema. The cytoplasm of the neoplastic cells of fibromas may contain small quantities of lipid (> Fig. 15.35). In rare tumors, the cytoplasm contains small red granules reminiscent of hyaline bodies, probably representing a degenerative phenomenon. As previously mentioned, an occasional fibroma contains a minor component of sex cord elements.

The fibroma must be distinguished from several nonneoplastic ovarian processes, specifically massive edema, fibromatosis, and stromal hyperplasia. The first two disorders usually are unilateral but may be bilateral and are characterized by proliferation of ovarian stromal cells with marked intercellular edema and the production of abundant dense collagen, respectively. Unlike fibromas, which almost always displace follicles, corpora lutea, and corpora albicantia, massive edema and fibromatosis encompass these structures. Stromal hyperplasia, in contrast to the ovarian fibroma, is bilateral and is characterized by a multinodular or diffuse proliferation of closely packed, small stromal cells with minimal collagen formation.

Occasional fibromas have varied cellularity (**)** *Fig. 15.36*) and some vascularity, which may cause them to be misinterpreted as sclerosing stromal tumor. The distinct pseudolobulation, lutein cells, and ectatic vessels, in aggregate, set the sclerosing stromal tumor apart from fibromas that may mimic them to a limited degree. Some fibromas undergo prominent cystic degeneration and may be misconstrued as surface epithelial stromal tumors. However, the cysts (pseudocysts) do not have an epithelial lining.

A subset of ovarian fibromas are intensely cellular and merit the descriptive designation "cellular fibroma" [126]. Even when these have relatively brisk mitotic activity, over

Fig. 15.31 Luteinized thecoma of type associated with sclerosing peritonitis. The ovarian cortex is strikingly cerebriform

four per ten high-power fields, the course is generally clinically uneventful, provided there is no appreciable cytologic atypia [68]. However, rarely, particularly if associated with adhesions or rupture, these tumors can recur and exceptionally even more mundane-appearing fibromas have been reported to implant in the peritoneal surfaces. Most cellular fibromas have alternating cellular and less cellular regions although in some cellularity is diffuse. More or less uniform hypercellularity with significant cytologic atypia and conspicuous mitotic activity merit the diagnosis of fibrosarcoma [29], but the distinction between low-grade fibrosarcomas and cellular fibromas is subjective, and it is impossible to provide rigid criteria.

Sclerosing Stromal Tumor

This tumor differs from the fibroma and the thecoma both clinically and pathologically [28]. Although the latter tumors are uncommon in the first 3 decades, more than 80% of sclerosing stromal tumors have been encountered

■ Fig. 15.32 Luteinized thecoma of type associated with sclerosing peritonitis. III-defined aggregates of lutein cells are seen

during the second and third decades, with an average age at diagnosis of 27 years. In contrast to the thecoma, the sclerosing stromal tumor has been associated with evidence of estrogen or androgen secretion, or both in only a few cases. All sclerosing stromal tumors encountered to date have been benign.

Gross examination typically reveals a unilateral, discrete, sharply demarcated mass; the neoplasm is rarely bilateral [71]. Its sectioned surface is solid and white but often shows areas of edema and cyst formation and foci of yellow discoloration (**?** *Fig.* 15.37). A rare specimen presents as a unilocular cyst. Microscopic examination discloses a number of distinctive features: a pseudolobular pattern (**?** *Fig.* 15.38), in which cellular nodules are separated by less cellular areas of dense collagenous or edematous connective tissue, sclerosis within the nodules, prominent thin-walled vessels in some of the nodules (**?** *Fig.* 15.39), and a disorganized admixture of fibroblasts and rounded, vacuolated cells within the nodules (**?** *Fig.* 15.40). Occasionally, the vacuolated cells have a signet cell appearance, creating some confusion with

 Fig. 15.33
Luteinized thecoma of type associated with sclerosing peritonitis. Edema with microcystic change is conspicuous

• Fig. 15.35 Fibroma. When cells are cut transversely and have pale cytoplasm due to a minor lipid content, an erroneous diagnosis of thecoma may result

■ Fig. 15.34 Fibroma. The sectioned surface of the neoplasm is solid, white, and slightly edematous

the signet cells of a Krukenberg tumor, but the former cells contain lipid instead of mucin. The lipid-laden cells appear to be inactive or weakly active lutein cells; in the rare functioning tumors, the lutein cells resemble more closely those encountered in a luteinized thecoma. Rare sclerosing stromal tumors are prominently myxomatous, opening the possibility that there may be overlap in some cases with the rare ovarian myxoma [35]. Although overlap exists between fibromas, thecomas, sclerosing stromal tumors, and even steroid cell tumors, the presence of various distinctive features of these four tumors, which are presented in **3** *Table 15.6*, almost always allows a specific diagnosis.

Microcystic Stromal Tumor

These rare tumors have recently been described as a distinctive variant within the stromal category [70]. All

Fig. 15.36 Cellular fibroma

Fig. 15.38 Sclerosing stromal tumor. Cellular pseudolobules are separated by edematous hypocellular tumor

Fig. 15.37

Sclerosing stromal tumor. The sectioned surface of the neoplasm is mostly solid with focal cystic degeneration particularly in the central region which was softer than the peripheral yellow component

the 16 tumors encountered to date have been in adults, nonfunctioning, and stage I with a mean size of 10 cm. They may be cystic or solid and cystic. On microscopic examination, there are typically lobulated cellular regions separated by hyaline bands and fibrous plaques (> Fig. 15.41). Definitionally, however, these regions are punctuated, oftentimes strikingly so, by small cysts (> Fig. 15.42) that anastomose with each other, giving a distinctive appearance and resulting in the designation that has been given to this tumor. The neoplastic cells contain finely granular faintly eosinophilic cytoplasm and round to oval nuclei with small nucleoli. Mitotic figures are rare. Occasionally there is bizarre nuclear atypia of the degenerative type. The tumors are typically negative for inhibin but positive for CD10. About one third of the tumors examined to date have been cytokeratin positive but they have been EMA negative.

The differential diagnosis of this tumor is broad and has been recently presented in detail elsewhere [70] so will not be repeated here. As a great many other ovarian

Fig. 15.39 Sclerosing stromal tumor. Pseudolobule is richly vascularized

tumors may have microcysts, the designation of microcystic stromal tumor should only be made after neoplasms have been thoroughly sampled to disclose other foci that may merit separate categorization.

Signet-Ring Stromal Tumor

In 1976, Ramzy [129] described an unusual ovarian tumor from a 28-year-old woman, which he designated signet-ring stromal tumor. These tumors are rare and only a small number of cases have been reported subsequently, all of them being in adults, nonfunctioning and benign [172]. There are no unique gross features. On microscopic examination, spindle cells are diffusely distributed and merge imperceptibly with rounded cells containing eccentric nuclei and single large vacuoles, resembling signet-ring cells (\bigcirc *Fig. 15.43*). These cells may be diffusely scattered or focally distributed. Stains for lipid and mucin are negative. Electron microscopic examination

■ Fig. 15.40 Sclerosing stromal tumor. Spindle cells are mixed with more rounded weak lutein cells

has shown that in some cases the vacuoles result from generalized edema of the cytoplasmic matrix, in others from swelling of mitochondria, and in still others from cytoplasmic pseudoinclusions of edematous extracellular matrix [40]. Negative staining for mucin excludes a Krukenberg tumor, the most important lesion in the differential diagnosis. There are many other differences between the two tumors. The signet-ring stromal tumor lacks the pseudolobulation, lipid-rich cells, and prominent vascularity of the sclerosing stromal tumor. Rarely a signet-ring change similar to that seen in this neoplasm may be encountered in granulosa cell tumors.

Unclassified Tumors

Rare tumors in the intermediate zone between fibromas and thecomas are impossible to classify more specifically. Such tumors are made up of cells having some but not all the features of theca cells, containing small to
Table 15.6

Sclerosing stromal tumor versus fibroma, thecoma, and steroid cell tumors

	Sclerosing stromal tumor	Fibroma	Thecoma	Steroid cell tumor
Age	80% under 30 years	10% under 30 years	Average age 63 years	25% under 30 years

moderate amounts of lipid, and being associated with equivocal evidence of estrogen secretion. Such tumors should be diagnosed as "tumor in the fibroma-thecoma category, unclassified," and often a descriptive notation is warranted to remark on the particular features of a given case.

Fig. 15.42 Microcystic stromal tumor, high power showing microcysts

Sertoli-Stromal Cell Tumors

Sertoli-stromal cell tumors contain Sertoli cells, Leydig cells, fibroblasts, or all these cells, in varying proportions and varying degrees of differentiation. Most tumors in this family are Sertoli–Leydig cell tumors. Other tumors

Fig. 15.43 Signet-ring stromal tumor

within this group are pure Sertoli cell tumors, pure Leydig cell tumors, and stromal-Leydig cell tumors; the latter already have been mentioned in the discussion of luteinized thecomas, and pure Leydig cell tumors are considered in the section on steroid cell tumors.

Sertoli Cell Tumors

Sertoli cell tumors account for approximately 4% of Sertoli-stromal cell tumors [114, 164, 166, 188]. The tumors are usually nonfunctioning but seven Sertoli cell tumors, most or all of which appear to have been of the lipid-rich type, have resulted in isosexual pseudoprecocity. Two of these tumors were from patients with Peutz– Jeghers syndrome [153, 188]. One Sertoli cell tumor was associated with progesterone as well as estrogen production [168]. All the Sertoli cell tumors reported to date have been unilateral and most have been stage I.

They have averaged approximately 9 cm in diameter and typically have formed lobulated, solid, yellow or brown masses. Microscopic examination usually shows a uniform tubular pattern or at least focal tubules, but a rare neoplasm is uniformly diffuse. The tubules may be hollow or solid. The hollow tubules are lined by bland columnar to cuboidal cells with moderate amounts of pale or slightly eosinophilic cytoplasm. Their lumens are usually empty but may contain an eosinophilic secretion and rarely even mucin. The solid tubules are typically elongated but may be round or oval. An apparent solid pattern results when tubules are closely packed, and in some cases, there is a true solid pattern, particularly when the tumors are less well differentiated than usual. In some of these cases, there is focally an interruption of a generally solid pattern by a fibrous stroma, which rarely can impart an alveolar to nested pattern (> Figs. 15.44-15.46) akin to that occasionally seen with testicular Sertoli cell tumors. As in that situation, rarely a low-power picture vaguely reminiscent of the alveolar pattern of dysgerminoma may result but high-power scrutiny shows differing cytologic features (> Fig. 15.45) and if indicated of course, immunohistochemical differences will be stark (> Fig. 15.46). Other less common patterns of Sertoli-cell neoplasia include the presence of cords, and also trabecular pseudopapillary, retiform, and even spindled patterns. Tumors with the latter patterns can impart many problems in differential diagnosis as discussed in detail recently elsewhere [114]. When the Sertoli cells contain abundant cytoplasmic lipid, the term lipid-rich Sertoli cell tumor is appropriate. Occasional Sertoli cell tumors have cells with abundant eosinophilic cytoplasm [49]. There is usually little if any nuclear atypia or mitotic activity, and the prognosis is generally excellent. A few tumors exhibit moderate degrees of nuclear atypicality, and exceptionally there is a malignant appearance with metastases [114, 125].

The differential diagnosis of Sertoli cell tumors is broadly similar to that of Sertoli–Leydig cell tumors, considered below. Brief note should be made of the rare tumors with little or no tubules, one of which is illustrated (\bigcirc *Figs.* 15.44–15.46). Their distinction from granulosa cell tumor is aided by lack of typical patterns of that tumor and nuclei lacking the distinctive features of it also. Distinction of these rare tumors from other neoplasms reasonably in the differential is one of the best examples of aid of staining for inhibin (\bigcirc *Fig.* 15.46) but of course, it will only be obtained if the diagnosis is entertained.

Sertoli-Leydig Cell Tumors

Sertoli–Leydig cell tumors account for less than 0.5% of all ovarian tumors. They are divided into three main

subtypes: well differentiated, of intermediate differentiation, and poorly differentiated. The latter two categories may additionally contain heterologous elements, a retiform component, or both, complicating an already often complex appearance. Sertoli-Leydig cell tumors occur in all age groups but are encountered most often in young women. The average age is 25 years; 75% of the patients are 30 years of age or younger and only about 10% are over 50 years [133, 191, 194]. The well-differentiated tumors [190] occur on an average a decade later, and retiform tumors [187] a decade earlier, than other Sertoli-Leydig cell tumors. Tumors with a retiform pattern are more common in the first decade than any other subtype. Recent molecular evidence [45] has indicated a true neoplastic nature for the Leydig cell component of these tumors. It should be emphasized that in some Sertoli-Leydig cell tumors, usually those that are poorly differentiated, recognizable Leydig cells are few, and in even some cases objectively cannot be appreciated. The

Fig. 15.45 Sertoli cell tumor. High power showing typical cytology

tumor is still put in the Sertoli–Leydig category when the overall patterns fit best with that designation.

Clinical Features

Although the most striking mode of presentation of Sertoli–Leydig cell tumors is virilization, it develops in only about one third of the cases. In such cases, a patient who has been having normal menstrual periods typically begins to have oligomenorrhea, followed within a few months by amenorrhea. There is a concomitant loss of female secondary sex characteristics, with atrophy of the breasts and disappearance of normal bodily contours. Progressive masculinization is heralded by acne, with hirsutism, temporal balding, deepening of the voice, and enlargement of the clitoris following in its wake. Androgenic manifestations are lower in tumors containing heterologous elements and lower again in those having a prominent retiform component. The androgen secretion by the tumor also may result in erythrocytosis.

Fig. 15.46 Sertoli cell tumor. Positive inhibin stain of tumor seen in two prior figures

Plasma levels of testosterone, androstenedione, and other androgens, alone or in combination, may be elevated in patients with Sertoli-Leydig cell tumors. The urinary 17-ketosteroid values usually are normal or only slightly raised, although occasionally a high level has been recorded. These findings are in contrast to those associated with virilizing adrenal tumors, which often are accompanied by high urinary levels of 17ketosteroids. The values for plasma androgens and urinary 17-ketosteroids are not reliable, however, in the differentiation of ovarian and adrenal virilizing tumors because the latter often are associated with elevated testosterone and normal urinary 17-ketosteroid levels [5]; also, tests involving attempted stimulation by tropic hormones and suppression by gonadal and adrenocortical steroids have not proved decisive in differentiating these tumors. Occasional Sertoli-Leydig cell tumors are associated with elevated plasma levels of alpha-fetoprotein but values as high as those accompanying yolk sac tumors are rare [13, 53].

Approximately, 50% of patients with Sertoli–Leydig cell tumors have no endocrine manifestations and usually complain of abdominal swelling or pain. Occasional tumors have been associated with various estrogenic syndromes similar to those of the granulosa cell tumor.

At laparotomy, almost all Sertoli–Leydig cell tumors are unilateral. The tumors are stage Ia in about 80% of the cases; in 12% the tumor has either ruptured or involved the external surface of the ovary, and in 4% ascites is present. Only about 2.5% of the tumors have spread beyond the ovary, usually within the pelvis and rarely into the upper abdomen. Poorly differentiated tumors more often are ruptured and present at a higher stage than tumors of intermediate differentiation. Well-differentiated tumors are essentially invariably state Ia.

Gross Findings

Sertoli-Leydig cell tumors vary greatly in their gross appearance (> Figs. 15.47-15.49), like granulosa cell tumors, and these neoplasms usually cannot be distinguished on gross examination alone. There are, however, a few general differences. Sertoli-Leydig cell tumors contain blood-filled cysts less often than granulosa cell tumors and, unlike the latter, almost never have the appearance of a unilocular thin-walled cyst. Sertoli-Leydig cell tumors vary in size from microscopic to huge masses but most are between 5 and 15 (average, 13.5) cm in diameter. Poorly differentiated tumors including those with mesenchymal heterologous elements tend to be larger than those of better differentiation and contain areas of hemorrhage and necrosis more frequently. Tumors with heterologous or retiform components are cystic more often than tumors without these elements. The heterologous tumors occasionally simulate mucinous cystic tumors on gross examination, and retiform tumors may contain large, edematous papillae, resembling serous papillary tumors or be very soft (> Fig. 15.49). The latter aspects are rare or absent features of granulosa cell tumor.

Well-Differentiated Tumors

These tumors are characterized by a predominantly tubular pattern (\bigcirc *Fig. 15.50*) [190]. On low-power examination, a nodular architecture often is conspicuous, with fibrous bands separating lobules composed of hollow or less often solid tubules; in some tumors tubules of

Fig. 15.47

Sertoli–Leydig cell tumor. The sectioned surface of the neoplasm is solid yellow and lobulated

Fig. 15.49

Sertoli–Leydig cell tumor with retiform pattern. The tumor on the left was soft and "spongy," a feature of many such tumors. Edematous polypoid structures project into the lumen of another neoplasm that was more cystic (*right*)

Fig. 15.48 Sertoli–Leydig cell tumor with mucinous heterologous elements. The sectioned surface of the tumor is mostly mucoid with a minor solid yellow component

both types are present. The hollow tubules typically are round to oval and small, but may be cystically dilated, and some of them resemble the tubular glands of a well-differentiated endometrioid adenocarcinoma (\bigcirc *Fig.* 15.51) [94]. The lumens usually are devoid of conspicuous secretion but in some cases eosinophilic fluid, which is occasionally mucicarminophilic, is present. The solid tubules typically are elongated but may be round or oval and occasionally resemble prepubertal or atrophic testicular tubules. The tubules contain cuboidal to columnar epithelial cells with round or oblong nuclei without

Fig. 15.50 Sertoli-Leydig cell tumor, well differentiated. Hollow and

solid tubules are separated by Leydig cells in intervening stroma

Fig. 15.51
Sertoli–Leydig cell tumor, well differentiated.
Pseudoendometrioid tubules

prominent nucleoli. Nuclear atypicality usually is absent or minimal, and mitotic figures are rare. The cells lining the hollow tubules and filling the solid tubules typically contain moderate amounts of dense cytoplasm, but in some cases, varying numbers of them have abundant pale cytoplasm rich in lipid. The stromal component consists of bands of mature fibrous tissue containing variable but usually conspicuous numbers of Leydig cells (\bigcirc *Fig.* 15.40). These cells may contain abundant lipochrome pigment; crystals of Reinke are identified in some of the Leydig cells in approximately 20% of the cases. Ossification has been described in one case [101].

Tumors of Intermediate and Poor Differentiation

These tumors form a continuum characterized by a variety of patterns and combinations of cell types (\triangleright *Figs.* 15.52–15.57). Some tumors exhibit intermediate

Fig. 15.52
Sertoli–Leydig cell tumor of intermediate differentiation.
Cellular lobules are intersected by a slightly edematous stromal component containing Leydig cells

differentiation in some areas and poor differentiation in others and, less commonly, tumors of intermediate differentiation contain well-differentiated foci. Either the Sertoli cells or Leydig cells or both may exhibit varying degrees of immaturity. In the tumors of intermediate differentiation, immature Sertoli cells with small, round, oval, or angular nuclei are arranged typically in poorly defined masses, often creating a lobulated appearance on low power (> Fig. 15.52); solid and hollow tubules (> Fig. 15.55), nests, thin cords resembling the sex cords of the embryonic testis, and broad columns of Sertoli cells often are present. There is sometimes an alveolar pattern (**)** *Fig.* 15.54) and as with some well-differentiated tumors some tubules may be pseudoendometrioid. Cysts that range from small to large may be seen (> Fig. 15.57) and when they contain eosinophilic secretion, may create a thyroid-like appearance; follicle-like spaces are encountered rarely. The Sertoli cells, or the Leydig cells, may have bizarre nuclei similar to those seen in some granulosa cell

 Fig. 15.53
Sertoli–Leydig cell tumor of intermediate differentiation.
Nests and cords of immature Sertoli cells and clusters of Leydig cells with abundant cytoplasm

tumors [186]. The Sertoli cell aggregates are separated by a stromal component that ranges from fibromatous to densely cellular to edematous and typically contain clusters of well-differentiated Leydig cells. Occasionally, part or all of the stromal component is made up of immature, cellular mesenchymal tissue resembling a nonspecific sarcoma. The Sertoli and Leydig cell elements, singly or together, may contain varying and sometimes large amounts of lipid in the form of small or large droplets. Poorly differentiated Sertoli-Leydig cell tumors originally were classified as sarcomatoid because, aside from the presence of specifically diagnostic elements, they resemble fibrosarcomas; however, they often have a diffuse pattern that is not clearly recognizable as that of a fibrosarcoma. We reserve the designation "poorly differentiated" for Sertoli-Leydig cell tumors that lack in large areas, any recognizable patterns of the neoplasm, but definitionally there must be at least minor foci that enable categorization as Sertoli-Leydig cell tumor.

Fig. 15.54 Sertoli–Leydig cell tumor of intermediate differentiation, alveolar pattern

Retiform Sertoli–Leydig Cell Tumor

Fifteen percent of Sertoli-Leydig cell tumors are composed, usually partially but occasionally entirely, of tubular structures arranged in a pattern resembling that of the rete testis [99, 134, 161, 187]. So far a retiform pattern has been encountered only in tumors that are otherwise intermediate or poorly differentiated. Microscopic examination reveals a network of irregularly branching, elongated, narrow, often slit-like tubules and cysts into which papillae or polypoid structures may project (> Figs. 15.58 and ≥ 15.59). The tubules and cysts may contain eosinophilic secretion; they are lined by epithelial cells that exhibit varying degrees of stratification and nuclear atypicality. The papillae and polyps are of three types: most commonly they are small and rounded or blunt, often containing hyalinized cores; sometimes they are large and bulbous, containing edematous cores. Finally, in some cases, they are delicate and branch extensively and may be lined by stratified cells, simulating the papillae of

Fig. 15.55 Sertoli–Leydig cell tumor of differentiation. Solid tubules and rare hollow tubules

a serous tumor of borderline or invasive type. A common finding in the retiform Sertoli–Leydig cell tumor is the presence of columns or ribbons of immature Sertoli cells. The stroma within a retiform area may be hyalinized or edematous (\bigcirc *Fig.* 15.60), moderately cellular, or densely cellular and immature.

Heterologous Sertoli–Leydig Cell Tumor

Heterologous elements occur in approximately 20% of Sertoli–Leydig cell tumors, most of which are of intermediate differentiation but some are poorly differentiated [105, 156]. Glands and cysts lined by moderately to welldifferentiated gastric-type or intestinal-type epithelium (**)** *Fig. 15.61*) are most common. The intestinal-type epithelium at times may contain goblet cells, argentaffin cells, and rarely Paneth cells [183]. The argentaffin cells [1] rarely give rise to small foci of carcinoid [145], typically taking the form of tiny aggregates or cords of cells (**)** *Fig. 15.62*) that may have admixed goblet cells,

Fig. 15.56
Sertoli-Leydig cell tumor of intermediate differentiation.
Jumbled admixture of Sertoli and Leydig cells and focal tubules

imparting a goblet-cell carcinoid morphology. Exceptionally, there is a more classic closely packed appearance of insular carcinoid that sometimes can even form a grossly evident nodule. Stromal heterologous elements are seen in 5% of all Sertoli–Leydig cell tumors [127]. Islands of fetaltype cartilage arising on a sarcomatous background, areas of embryonal rhabdomyosarcoma, or both (**?** *Fig. 15.63*) are seen. Rarely, Sertoli–Leydig cell tumors of conventional or heterologous type contain cells resembling hepatocytes [100, 182], and one contained retinal tissue and another had neuroblastoma in recurrent tumor [127].

Differential Diagnosis

Because of their many patterns, Sertoli-stromal cell tumors often are difficult to differentiate from tumors outside the sex cord-stromal category as well as from granulosa cell tumors. The small hollow tubular structures, solid tubular aggregates, and cords that occasionally

Fig. 15.57 Sertoli–Leydig cell tumor, of intermediate differentiated, microcystic pattern

are seen in endometrioid carcinomas may closely mimic structures characteristically encountered in Sertoli and Sertoli-Leydig cell tumors. Endometrioid carcinomas also may contain luteinized stromal cells that resemble Leydig cells, creating an even greater problem in differentiation. Mucin secretion, areas of squamous differentiation that range from nests of uniform immature spindleshaped epithelial cells to morules to keratinizing foci, and an adenofibromatous component of common epithelial type are present in most endometrioid carcinomas, facilitating their diagnosis. Clinical features, such as the usual older age of the patient and the absence of androgenic manifestations, support the diagnosis of endometrioid carcinoma, but it must be emphasized that endometrioid carcinomas occasionally have a functioning stroma, which sometimes is manifested clinically by estrogenic changes and rarely by virilization. Immunohistochemical staining for EMA may be helpful in difficult cases because it is almost always positive in cases of endometrioid carcinoma and only rarely focally positive in a few cells within

Fig. 15.58 Sertoli–Leydig cell tumor with retiform pattern. Prominent papillae

a Sertoli–Leydig cell tumor. Sertoli–Leydig cell tumors may be simulated by primary or metastatic endometrioid stromal sarcomas. Criteria that are applicable in the differential diagnosis of these tumors with granulosa cell tumors also are helpful in this situation.

Rarely the alveolar pattern of a Sertoli–Leydig cell tumor, or Sertoli cell tumor, may suggest the diagnosis of dysgerminoma. There is not the typical scattering of lymphocytes of the germ cell tumor and on high-power scrutiny, there are marked differences in the cytologic features of the neoplastic cells. Should it be indicated, immunohistochemistry will have differing results.

The tubular Krukenberg tumor may mimic a Sertoli– Leydig cell tumor especially if luteinization of the stroma is present; further, confusion arises if the former tumor is associated with virilization. Tubular Krukenberg tumors are bilateral, however, in most cases and contain markedly atypical cells, including signet-ring cells that contain mucin, easily demonstrable by special stains. Other general features of metastatic tumors will aid in cases of Krukenberg tumor.

Fig. 15.59 Sertoli–Leydig cell tumor with retiform pattern. Slit-like spaces are conspicuous

Carcinoid tumors, especially those of the trabecular type, may be confused with Sertoli-Leydig cell tumors of intermediate differentiation. The ribbons of the former, however, are longer, thicker, and more uniformly distributed than the sex cord-like formations of the latter. Also, rare carcinoid tumors with a solid tubular pattern can be difficult to distinguish from well-differentiated Sertoli cell tumors. Examination of the stroma of carcinoid tumors may be helpful in the differential diagnosis. It is typically less cellular and more fibromatous than that of Sertoli-Leydig cell tumors and rarely contains Leydig cells, typically at the periphery. Primary carcinoid tumors are associated with teratomatous elements in 70% of the cases, and metastatic carcinoids are almost always bilateral and usually are associated with an obvious primary tumor of the intestine and metastases elsewhere in the abdomen. Immunohistochemistry should be definitive in the occasional case in which it is needed.

The tubules seen in ovarian wolffian tumors may be indistinguishable from those seen in Sertoli and

Fig. 15.60 Sertoli–Leydig cell tumor with retiform pattern. Prominent edematous stroma

Sertoli–Leydig cell tumors but are virtually always accompanied by other patterns that exclude the diagnosis of a sex cord-stromal tumor.

Although in the past, Sertoli–Leydig cell tumors with heterologous elements were sometimes considered "teratomatous" [130], there are marked differences in the overall constituents of Sertoli–Leydig cell tumors and teratomatous neoplasms such that distinction between the two should be straightforward in the great majority of cases. Rare heterologous neoplasms have a dominant mucinous cystic component and the diagnostic Sertoli– Leydig elements can be absent on certain slides, but judicious sampling will variably show them, by definition.

The retiform variant of Sertoli–Leydig cell tumor causes specific problems in differential diagnosis. A common misdiagnosis is yolk sac tumor, which is suggested clinically by the young age of the patient and pathologically by the presence of papillae within cystic spaces. The occurrence of androgenic manifestations with about 20% of cases of retiform Sertoli–Leydig cell

Fig. 15.61
Sertoli-Leydig cell tumor with heterologous elements.
Mucinous glands are separated by intermediate form of tumor

tumor, however, contrasts with the rare occurrence of such changes in cases of yolk sac tumor, attributable to a functioning stroma. On gross examination, the retiform tumors generally appear less malignant than yolk sac tumors, and microscopic examination reveals less primitive-appearing cells. The presence of other distinctive patterns of either tumor and positive immunohistochemical staining for alpha-fetoprotein in the yolk sac tumor almost always facilitate the diagnosis.

A greater problem in the differential diagnosis of retiform Sertoli–Leydig cell tumors arises because of their characteristic papillary patterns and the frequent presence of cellular stratification particularly if those features predominate. Under such circumstances, a misdiagnosis of a serous tumor of borderline malignancy or a serous or endometrioid carcinoma occasionally is made. A variety of clinical and pathologic features, including the young age of the patient, the association with virilization, and the presence of other more easily recognizable patterns of Sertoli–Leydig cell tumor, are helpful

Fig. 15.62
Sertoli–Leydig cell tumor with heterologous elements.
Clusters and cords of carcinoid cells

clues to the correct diagnosis. Finally, the juxtaposition of epithelial and immature mesenchymal elements in some retiform tumors, and in some cases additional mesenchymal heterologous elements, has caused confusion with a malignant mesodermal mixed tumor, but the features already outlined also serve to exclude the latter diagnosis.

Because occasional sex cord-stromal tumors have a morphologic appearance intermediate between granulosa cell tumors and Sertoli–Leydig cell tumors or exhibit features of both tumors, it is sometimes difficult to decide whether a given tumor should be placed in the granulosa, Sertoli–Leydig cell, or mixed category. Major criteria that help to differentiate granulosa cell tumors and Sertoli–Leydig cell tumors are listed in **>** *Table 15.7*.

Clinical Behavior and Treatment

After the removal of a virilizing Sertoli–Leydig cell tumor, normal menses characteristically resume in about 4 weeks.

■ Fig. 15.63 Sertoli–Leydig cell tumor with heterologous elements. Rare nests of darkly staining Sertoli cells with bands of skeletal muscle and focus of cartilage

The excessive hair usually diminishes to some extent. Clitoromegaly and deepening of the voice are less apt to regress. The prognosis in cases of Sertoli-Leydig cell tumor is closely related to their stage and degree of differentiation. The rare tumors that present in an advanced stage have a poor prognosis, with a mortality rate of 100% in our series [191]. The survival rates of patients with stage I tumors correlate with the degree of differentiation. In our series, none of the well-differentiated tumors, 11% of those of intermediate differentiation, 59% of the poorly differentiated tumors, and 19% of those with heterologous elements were clinically malignant. The homologous component of the tumor was poorly differentiated in all eight clinically malignant tumors in the heterologous category, and in seven of these the heterologous elements included skeletal muscle, cartilage, or both.

Earlier studies in the literature failed to establish a relation between the degree of differentiation of Sertoli–Leydig cell tumors and their prognosis, but later

Table 15.7

Adult granulosa cell tumor versus Sertoli-Leydig cell tumor

Granulosa cell tumor	Sertoli–Leydig cell tumor
All age groups, mostly postmenopausal	Mainly young women
Usually estrogenic, rarely androgenic	Usually androgenic, occasionally estrogenic
Microfollicular, macrofollicular, trabecular, insular and diffuse patterns	Hollow or solid tubules, cords, diffuse patterns
Granulosa cells usually mature with pale, often grooved nuclei	Sertoli cells often immature
Fibrothecomatous component common	Fibromatous component uncommon; mesenchyme often immature and cellular, or edematous
Steroid-type cells (lutein cells) usually not prominent and uncommonly clustered	Steroid-type cells (Leydig cells) tend to cluster; rarely contain crystals of Reinke
Heterologous elements rare	Heterologous elements in 20% of cases
Retiform elements absent	Retiform elements in 15% of cases

investigations have supported the findings in our series. In our study, there also was evidence that the presence of a retiform pattern had an adverse effect on the prognosis; 25% of stage I tumors of intermediate differentiation with a retiform component were malignant as opposed to 10% of those with no retiform component [191]. It is noteworthy that the only stage III tumor of intermediate differentiation in our series had an almost completely retiform pattern, and we have seen an additional Sertoli-Leydig cell tumor with a predominantly retiform pattern that was stage III. Rupture also adversely affected the outcome of stage I tumors. Thirty percent of the tumors of intermediate differentiation that had ruptured were clinically malignant, in contrast to only 7% of those that were intact; in the poorly differentiated category, 86% of the ruptured tumors were malignant compared with 45% of those that had not ruptured.

In contrast to granulosa cell tumors, which often recur many years after primary therapy, Sertoli–Leydig cell tumors typically reappear relatively early. Sixty-six percent of the malignant tumors in our series recurred within 1 year and only 6.6% recurred after 5 years. The recurrent tumor usually is confined to the pelvis and abdomen, but distant metastases to the lung, scalp, and supraclavicular lymph nodes have been reported. Three of the patients in our series had parenchymal liver metastases.

The treatment of a patient with Sertoli–Leydig cell tumor depends on her age, the stage of her tumor, the presence or absence of rupture, and the degree of differentiation. In young women, the low frequency of bilaterality justifies the performance of a unilateral salpingo-oophorectomy if the tumor is stage IA and preservation of fertility is desired. More aggressive surgical therapy and adjuvant therapy are indicated for advanced-stage tumors. Adjuvant therapy also may be advisable for stage I tumors that are poorly differentiated, contain mesenchymal heterologous elements, or are ruptured tumors of intermediate differentiation.

Other Types of Sex Cord-Stromal Tumors

Gynandroblastoma

Gynandroblastoma, an extremely rare tumor [5], has been greatly overdiagnosed. Because small foci of ovarian cell types often are encountered in well-sampled, otherwise typical Sertoli-Leydig cell tumors and conversely, testicular cell types are demonstrable focally in occasional granulosa-stromal cell tumors, the diagnosis of gynandroblastoma should be restricted to the very rare tumors that contain significant components of both forms of neoplasia. According to our criteria, the minor component should account for at least 10% of a tumor in the sex cord-stromal category to warrant a diagnosis of gynandroblastoma. As indicated in the introductory remarks, we prefer to avoid the designation gynandroblastoma for reasons noted there. The nature of the hormones secreted by a sex cord-stromal tumor should not determine its morphologic diagnosis in view of the proven capacity of tumors of testicular cell types to secrete estrogens and of those of ovarian cell types to produce androgens.

Sex Cord Tumor with Annular Tubules

This neoplasm is characterized basically by the presence of simple and complex annular tubules (**)** *Figs.* 15.64–15.66) [143, 192]. The simple tubules have the shape of a ring, with the nucleus oriented peripherally and around a central hyalinized body composed of basement membrane material; an intervening anuclear cytoplasmic zone forms the major component of the ring. The much more numerous complex tubules are rounded structures made up of intercommunicating rings revolving

around multiple hyaline bodies. Tumors containing annular tubules have been interpreted as Sertoli cell tumors by some observers [164] and granulosa cell tumors by others [59], but the pattern of growth has features intermediate between these two tumors, albeit focal differentiation into both typical Sertoli cell tumor with elongated tubules and typical granulosa cell tumor with Call–Exner bodies is seen in some of the cases. Sertoli-type cells have been identified ultrastructurally by the demonstration of Charcot–Bottcher filament bundles [164] which are considered specific cytoplasmic inclusions of Sertoli cells.

Sex cord tumors with annular tubules vary both clinically and pathologically, depending on whether the patient has Puetz–Jeghers syndrome or not (Table 15.8). Almost all female patients with this syndrome whose ovaries have been examined microscopically have had sex cord tumorlets with annular tubules, which have been multifocal and bilateral in at least two thirds of the cases; the largest reported lesion in a patient with this syndrome was 3 cm in diameter. Focal calcification has been seen in more than half the cases. In almost all the patients, the lesions have been incidental findings in ovaries removed for other reasons. All the tumorlets associated with Peutz–Jeghers syndrome have been benign, warranting conservative treatment.

patients without Peutz-Jeghers In syndrome (> Fig. 15.66), in contrast, the tumors are almost always unilateral and usually form palpable masses. Transitions to typical granulosa cell tumor are much more common than in tumorlets associated with Peutz-Jeghers syndrome. A focal solid proliferation of cells with eosinophilic cytoplasm may be seen (**>** Fig. 15.66). Forty percent of the patients have had manifestations of estrogen secretion; progesterone secretion, as evidenced by a decidual change of the endometrium, is relatively common. At least one fifth of the tumors have been clinically malignant, with a characteristic spread via the lymphatic system. Recurrences often are late. In one remarkable case, multiple recurrences occurred, mostly within regional and distal lymph nodes, over a period of 24 years, with each recurrent tumor removed surgically. In that case, the tumor produced large amounts of müllerian-inhibiting substance as well as progesterone, both of which were found useful as tumor markers in the serum in monitoring the course of the patient [58].

Four other ovarian tumors from girls with Peutz– Jeghers syndrome have caused sexual precocity. Two of them, occurring in sisters, had the features of Sertoli cell tumors with lipid storage [153], whereas the other two had microscopic findings that were unique in our experience, including diffuse areas, tubular differentiation, microcysts, and papillae, and the presence of two distinctive cell types,

one containing abundant eosinophilic cytoplasm and the other scanty cytoplasm [177]. All four tumors appeared to be clinically benign.

Sex Cord-Stromal Tumors, Unclassified

Sex cord-stromal tumors, unclassified, is a poorly defined group of tumors that accounts for less than 10% of those in the sex cord-stromal category [148, 151]. This group includes neoplasms in which a predominant pattern of testicular or ovarian differentiation is not clearly recognizable. The boundary lines between these tumors and those of both ovarian and testicular cell types are vague because interpretations of intermediate patterns of growth and closely similar cell types inevitably are subjective.

Talerman and his associates [162] have described a group of sex cord-stromal tumors, containing diffuse fibrothecomatous and/or granulosa cell-like proliferation

■ Fig. 15.65 Sex cord tumor with annular tubules. Simple and complex annular tubules encircle hyaline material

as well as areas of tubular differentiation in most of the cases. These authors have interpreted these tumors, which differ in appearance from usual forms of Sertoli–Leydig cell tumor, as diffuse nonlobular androblastomas, but in our opinion, it is more appropriate to place them in the unclassified sex cord-stromal category.

Sex Cord-Stromal Tumors During Pregnancy

Sex cord-stromal tumors may be particularly difficult to subclassify when they occur in pregnant patients because of alterations of their usual clinical and pathologic features. Their diagnosis is rarely suggested clinically because estrogenic manifestations are not recognizable during pregnancy, and androgenic manifestations are rare, possibly because of the ability of the placenta to aromatize androgens to estrogens. Indeed, virilization of a pregnant patient is much more likely to be caused by a nonneoplastic lesion such as the pregnancy luteoma or hyperreactio luteinalis or by a tumor with functioning stroma than a sex cord-stromal tumor. In one study, 17% of 36 sex cord-stromal tumors that were removed during pregnancy were placed in the unclassified group, and many of those which were classified in the granulosa cell or Sertoli-Leydig cell category had large areas with an indifferent appearance [179]. The features that led to difficulty in classification were the presence of prominent intercellular edema (**)** Fig. 15.67), increased luteinization in the granulosa cell tumors, and marked degrees of Leydig cell maturation in one third of the Sertoli-Leydig cell tumors. All these changes, which were most common in tumors removed during the third trimester, tended to obscure the underlying architecture. The behavior of sex cord-stromal tumors during pregnancy appeared to be similar to that of tumors of similar type unassociated with pregnancy on the basis of limited follow-up of 36 cases.

Steroid Cell Tumors

The terms lipid cell tumor and lipoid cell tumor were applied for many years to ovarian neoplasms composed

Table 15.8

Sex cord tumor with annular tubules with and without Peutz–Jeghers syndrome

	With	Without
Bilateral	62%	5%

■ Fig. 15.67 Sex cord-stromal tumor with unclassified features. The pateint was pregnant. There is prominent edema

entirely of cells resembling typical steroid hormonesecreting cells, that is, lutein cells, Leydig cells, and adrenal cortical cells [165]. However, as many as 25% of tumors in this category contain little or no lipid, and several years ago, the term steroid cell tumors was introduced for these neoplasms, because it reflects both the morphologic features of the neoplastic cells and their propensity to secrete steroid hormones [144]. These tumors, which account for approximately 0.1% of ovarian tumors, have been subdivided into two subtypes according to their cell of origin and a third subtype whose specific cell lineage is unknown (**)** *Table 15.9*). The features of the various subtypes of steroid cell tumors are contrasted in **)** *Table 15.10*.

Stromal Luteoma

The stromal luteoma accounts for approximately 25% of steroid cell tumors [61]. This designation is applied to small steroid cell tumors that lie within the ovarian stroma (Fig. 19.69) and therefore are presumed to arise from it. Such an origin is supported by the capacity of the ovarian stroma to differentiate into lutein cells in the nonneoplastic disorder designated stromal hyperthecosis [157]. Adrenal rest cells and Leydig cells, the other possible sources of tumors of this type, on the other hand, have been identified within the ovarian stroma on only extremely rare occasions. The diagnosis of stromal luteoma is supported in approximately 90% of the cases by the finding of stromal hyperthecosis elsewhere in the same or contralateral ovary. In some cases of the latter disorders, the nests of lutein cells may form nodules (nodular hyperthecosis). The dividing line between a large hyperthecotic nodule and a stromal luteoma is arbitrary; we reserve the former designation for large nodular foci of microscopic size and the latter for nodules that are grossly visible.

Stromal luteomas are almost always less than 3 cm in diameter and, with rare exceptions, are unilateral. They are well circumscribed, solid, and usually gray-white or yellow, but one third of them have red or brown areas or are uniformly so (\bigcirc *Fig.* 15.68).

Fig. 15.68
Stromal luteoma. The tumor is dark brown

small and round with a single prominent nucleolus. Mitoses generally are rare. The cells may be arranged diffusely or in small nests or cords and are more or less completely surrounded by ovarian stroma. One confusing feature, seen in about 20% of the cases, is focal degeneration, with the formation of irregular spaces that may simulate glands or vessels. These spaces may contain, or be surrounded by, lipid-laden cells and chronic inflammatory cells and may be associated with fibrosis. In some cases they contain red blood cells. Some steroid cell tumors in the "not otherwise specified" category may be overgrown stromal luteomas, but the specific diagnosis cannot be made with certainty when the tumor is no longer confined to the ovarian stroma.

Eighty percent of stromal luteomas occur in postmenopausal women. The initial symptom in 60% of patients is abnormal vaginal bleeding probably related to hyperestrinism, although whether the tumor secretes estrogen directly or secretes an androgen that is converted peripherally to an estrogen is unknown. Androgenic manifestations are present in only 12% of the cases. This profile of hormonal function is the opposite of that associated with other categories of steroid cell tumor, which usually are androgenic and only occasionally estrogenic. Underlying stromal hyperthecosis may contribute to the clinical picture in some cases, particularly those in which there is a long history of hormonal disturbance. Stromal luteomas are benign.

Leydig Cell Tumors

A Leydig cell nature of a steroid cell tumor can be proved only by the identification of the more or less specific crystals of Reinke in the cytoplasm of the neoplastic cells on either light microscopic or electron microscopic examination [156]. Because only 35–40% of Leydig cell tumors of the testis contain crystals of Reinke on light microscopic examination and Leydig cells cannot be differentiated from lutein cells or adrenal cortical cells in the absence of these inclusions, it is probable that a number of unclassified steroid cell tumors are Leydig cell tumors that cannot be identified specifically as such.

Ovarian Leydig cell tumors have been divided into two subtypes by Roth and Sternberg [135], the hilus cell tumor and the Leydig cell tumor, nonhilar type. The former, which is much more common, originates in the ovarian hilus from hilar Leydig cells, which have been identified in 80–85% of adult ovaries, usually lying in relation to nonmedullated nerve fibers [156]. Hilus cell tumors, which account for approximately 20% of steroid cell

tumors [120], occur at an average age of 58 years and cause hirsutism or virilization in three quarters of the cases; they are rarely associated with estrogenic manifestations. The androgenic changes typically have a less abrupt onset and are milder than those associated with Sertoli-Leydig cell tumors. They sometimes have been present for many years. The urinary 17-ketosteroid levels usually are normal or only slightly elevated because these tumors produce predominantly the potent androgen, testosterone, which is not a 17-ketosteroid, instead of the weaker androgens androstenedione and dehydroepiandrosterone, elevations of which are typically associated with high values of urinary 17-ketosteroids. Hilus cell tumors exceptionally are palpable preoperatively. They are rarely bilateral. There is no convincing example of malignant Leydig cell tumor in the literature.

Hilus cell tumors usually are reddish brown to yellow, are centered in the hilar region, and rarely are large (mean diameter, 2.4 cm). Microscopic examination typically reveals a circumscribed mass of steroid cells with abundant eosinophilic cytoplasm and little intracellular lipid; cytoplasmic lipochrome pigment may be abundant. The cells usually are distributed diffusely but occasionally their nuclei cluster and are separated by nucleus-free eosinophilic zones. This pattern (> Fig. 15.69) is highly suggestive of a hilus cell tumor even in the absence of crystals of Reinke. In some tumors, the presence of a prominent fibrous stroma imparts a nodular appearance. An unusual feature in one third of the cases is fibrinoid replacement of the walls of moderate-sized vessels (> Fig. 15.69), unaccompanied by inflammatory cell infiltration. Degenerative spaces similar to those seen in stromal luteomas may be present. The tumor cells typically contain abundant granular eosinophilic cytoplasm; occasional cells have spongy cytoplasm, indicating the presence of lipid. Cytoplasmic lipochrome pigment, which usually is sparse, is present in most cases. The typically round nuclei often are hyperchromatic and contain single small nucleoli; there may be slight to moderate variation in nuclear size and shape, and occasionally bizarre nuclei (> Fig. 15.69) and multinucleated cells are encountered. Rare mitotic figures occasionally are present. Pseudoinclusions of cytoplasm into the nucleus may be seen. Elongated eosinophilic Reinke crystals of varying sizes are present in varying numbers in the cytoplasm or sometimes in the nucleus, but often are found only after prolonged search.

The diagnosis of hilus cell tumor is favored if a crystalfree steroid cell tumor located in the hilus has a background of hilus cell hyperplasia, is associated with nonmedullated nerve fibers, has fibrinoid necrosis of blood vessel walls, or shows nuclear clustering with intervening nucleus-free

Fig. 15.69

Hilus cell tumor. Several noteworthy features, all clues to this variant of steroid cell tumor, are seen – clusters of tumor cells, fibrinoid necrosis of vessel walls, and focal bizarre nuclei

zones [120]. On electron microscopic examination, crystals of Reinke typically are needle shaped when cut longitudinally and hexagonal when cut in cross section. The interior of the crystal has a cross-hatched appearance. Intracytoplasmic eosinophilic spheres, which may be crystal precursors, also are typically present but are not specific for hilus cell tumors. Stromal hyperthecosis, hilus cell hyperplasia, or both are associated findings in occasional cases. The Leydig cell tumor of nonhilar type is thought to arise directly from ovarian stromal cells. Only four examples of this tumor have been reported [135] and, except for their location, their clinical and pathologic features have not differed from those of hilus cell tumors. An ovarian stromal cell derivation of these tumors is supported by the very rare finding of Leydig cells containing crystals in the steroid cell nests of ovaries that otherwise have the typical appearance of stromal hyperthecosis. In some cases in which a Leydig cell tumor is in equal contact with ovarian

stroma and hilar stroma, it may be impossible to determine whether it is of the hilar or nonhilar type.

Steroid Cell Tumor, Not Otherwise Specified

These tumors occur at any age but typically at a younger age (mean, 43 years) than other types of steroid cell tumor, and in contrast to the latter, occasionally occur before puberty [60]. Steroid cell tumors not otherwise specified (NOS) are associated with androgenic changes, which may be of many years duration, in approximately half the cases, estrogenic changes, including rare examples of isosexual pseudoprecocity in approximately 10% of the cases, and occasionally progestagenic changes. A few tumors have secreted cortisol and caused Cushing's syndrome [189] and others have been accompanied by elevated cortisol levels in the absence of clinical manifestations of the syndrome; one secreted aldosterone. Rare tumors have been associated with hypercalcemia, erythrocytosis, or ascites. The remaining cases have not been accompanied by endocrine or paraendocrine manifestations. Hormone studies performed in patients with androgenic changes, Cushing's syndrome, or both typically show elevated urinary levels of 17-ketosteroids and 17-hydroxycorticosteroids as well as increased serum levels of testosterone and androstenedione. The tumors that resulted in Cushing's syndrome were associated with elevated levels of free cortisol in the blood or urine.

Gross Findings

The tumors typically are solid and well circumscribed, occasionally are lobulated, and have a mean diameter of 8.4 cm; only about 5% of them are bilateral. The sectioned surfaces typically are yellow or orange if large amounts of intracytoplasmic lipid are present, red to brown if the cells are lipid poor, or dark brown to black if large quantities of intracytoplasmic lipochrome pigment are present. Necrosis, hemorrhage, and cystic degeneration occasionally are observed.

Microscopic Findings

On microscopic examination, the cells typically are usually arranged diffusely, but occasionally they grow in large aggregates, small nests, irregular clusters, thin cords, or columns. The stroma is inconspicuous in most cases, but in approximately 15% of them it is relatively prominent (**>** *Fig. 15.70*). A minor fibromatous component may be seen. Rarely the stroma is edematous or myxoid, with tumor cells loosely dispersed within it and, exceptionally, it exhibits calcification and even psammoma body formation. Necrosis and hemorrhage may be prominent, particularly in tumors that have significant cytologic atypia.

The polygonal to rounded tumor cells have distinct cell borders, central nuclei, and moderate to abundant amounts of cytoplasm that varies from eosinophilic and granular (lipid free or lipid poor) to vacuolated and spongy (lipid rich) (**)** *Figs. 15.70* and **)** *15.71*); lipid was present in 75% of the tumors in one series [60]. Steroid cell tumors NOS have lipid-rich cytoplasm more often than other subtypes of steroid cell tumor. Rarely, cells with large fat droplets have a signet-ring appearance. Intracytoplasmic lipochrome pigment has been found in 40% of the cases. In 60% of the cases in the largest published series, nuclear atypia was absent or slight, and mitotic activity was low (less than 2 MF/10 HPFs) [60]. In the remaining cases, grades 1–3 nuclear atypia, usually

associated with an increase in mitotic activity (up to 15 MFs/10 HPFs), was present.

Clinical Behavior and Treatment

Extraovarian spread of tumor is present at the time of operation in a small minority of cases; three of the patients with Cushing's disease had extensive intraabdominal spread of tumor [189]. In the two largest series in the literature, the proportion of tumors that were clinically malignant was 25% and 43% [60, 165]; rare tumors have recurred as many as 19 years postoperatively. Patients with clinically malignant tumors were on average 16 years older than patients with benign tumors in one series [60]; no malignant steroid cell tumors have been reported in patients in the first 2 decades.

The best pathologic correlates with malignant behavior in one series [60] were 2 or more MF/10 HPFs (92% malignant), necrosis (86% malignant), a diameter of 7 cm

Fig. 15.70 Steroid cell tumor, not otherwise specified. Cells with abundant pale cytoplasm focally separated by fibrous bands

Fig. 15.71 Steroid cell tumor, not otherwise specified. Typical oxyphil cells

(78% malignant), hemorrhage (77% malignant), and grade 2 or 3 nuclear atypia (64% malignant), occasional tumors that appear cytologically benign, however, may be malignant. The metastatic tumor appears similar to the primary tumor in some cases but more poorly differentiated in others.

Differential Diagnosis of Steroid Cell Tumors

Stromal luteomas and Leydig cell tumors usually do not pose great diagnostic difficulty for the pathologist because of their characteristic locations and obvious composition of steroid-type cells, which contain crystals of Reinke in the Leydig cell tumor. The extensive formation of spaces in occasional tumors in these categories, however, may cause confusion with an adenocarcinoma and more often with a vascular tumor. Awareness of this degenerative phenomenon and its association with cellular debris, inflammatory cell infiltration, and fibrosis, as well as the finding of typical areas elsewhere in the specimen, particularly at the periphery, should facilitate the diagnosis.

Steroid cell tumors in the NOS category vary more widely in appearance than the stromal luteoma and Leydig cell tumor, both architecturally and cytologically and are accordingly the cause of greater diagnostic difficulty. The tumors that may enter the differential diagnosis include extensively luteinized granulosa cell tumors and thecomas, lipid-rich Sertoli cell tumors, clear cell carcinomas, particularly those of the oxyphilic type, rare oxyphilic endometrioid carcinomas, hepatoid yolk sac tumors and hepatoid carcinomas, endocrine tumors such as oxyphilic struma ovarii, pituitary-type tumors and paragangliomas (pheochromocytoma), metastatic renal cell carcinomas, other metastatic tumors with oxyphilic appearance, and primary and metastatic melanomas.

The presence of characteristic nonluteinized cells in both luteinized granulosa cell tumors and thecomas, as well as the typical cytologic features and patterns of these neoplasms, and the finding of abundant reticulum in thecomas are of help in the identification of these tumors. The recognition of areas with a solid tubular pattern helps distinguish a usually estrogenic lipid-rich Sertoli cell tumor with a predominant diffuse pattern from a typically androgenic steroid cell tumor. In contrast to steroid cell tumors, the clear cells of clear cell carcinomas and metastatic renal cell carcinomas have glycogen-rich cytoplasm and eccentric nuclei. Also, the presence of tubular, glandular, and papillary patterns, which are inconsistent with a steroid cell tumor, generally facilitate the differential diagnosis. Radiologic studies to rule out a renal cell carcinoma may be additionally helpful.

Oxyphilic clear cell carcinomas and endometrioid carcinomas and hepatoid yolk sac tumors and hepatoid carcinomas are all characterized by neoplastic cells with abundant eosinophilic cytoplasm. The first two tumors generally exhibit epithelial patterns, may contain glandular lumens, and are almost always accompanied by more easily recognized patterns. The oxyphilic clear cell carcinoma is almost always accompanied by a variable component of clear and hobnail cells not seen in steroid cell tumors. The hepatoid tumors also have epithelial patterns and may contain glandular lumens; they are characterized by immunohistochemical staining for alpha-fetoprotein. Primary and metastatic melanomas can simulate steroid cell tumors if amelanotic, and if they are pigmented, the pigment granules may be confused with the lipochrome granules of a steroid cell tumor. Melanomas generally have more malignant nuclear features than steroid cell tumors. Special staining, including staining for S-100 protein and HMB-45, may be helpful in difficult cases. An association with other teratomatous elements and the presence of colloid and immunohistochemical staining for thyroglobulin should enable one to distinguish an oxyphil struma from a steroid cell tumor NOS.

A rare pituitary-type tumor containing cells with abundant eosinophilic cytoplasm that arose in a wall of a dermoid cyst secreted ACTH and caused Cushing's syndrome [10]. Such a tumor might be confused with a steroid cell tumor. In that case, immunohistochemical staining for ACTH and several other pituitary hormones was positive. In one case, we have seen of pheochromocytoma of the ovary, immunohistochemical staining of the tumor cells for chromogranin, was helpful in establishing that diagnosis over steroid cell tumor. Electron microscopic examination of most of the neoplasms that simulate steroid cell tumors should disclose strikingly different features. Finally, the presence or absence of endocrine manifestations and their nature may be important clinical clues to the diagnosis.

Pregnancy luteomas, which are hyperplastic nodules composed of lutein cells that develop during pregnancy, may form large masses that resemble steroid cell tumors grossly and microscopically. As with the latter, they also may be virilizing (in about one quarter of the cases). Unlike steroid cell tumors, however, approximately one third of pregnancy luteomas are bilateral and approximately one half are multiple. Microscopic examination reveals masses of cells with abundant eosinophilic cytoplasm containing little or no lipid; mitotic figures may be numerous, sometimes up to 2 or 3/10 HPF. In contrast, a steroid cell tumor with minimal cytologic atypia that resembles a pregnancy luteoma usually contains only rare mitotic figures. Although it may be impossible to distinguish a lipid-poor or lipid-free steroid cell tumor from a solitary pregnancy luteoma, a lesion encountered during the third trimester of pregnancy is presumed to be a solitary pregnancy luteoma unless clear-cut evidence indicates otherwise.

Other Ovarian Tumors with Endocrine Function

Ovarian Tumors with Functioning Stroma

A wide variety of ovarian tumors other than those in the sex cord-stromal and steroid cell categories may be hormonally active as a result of steroid hormone production by stromal cells [66] within or adjacent to the tumor (\diamond *Figs.* 15.72 and \diamond 15.73). These tumors, which have been designated ovarian tumors with functioning stroma, may be benign or malignant and, if in the latter category, primary or metastatic. Almost every ovarian tumor has been reported to be associated with steroid hormone production, but this phenomenon is seen much more often with some neoplasms than others.

Ovarian tumors with functioning stroma [86] are associated infrequently with overt endocrine manifestations but commonly accompanied by subclinical elevations of steroid hormone values. The stromal cells responsible for the hormone secretion in ovarian tumors with functioning stroma typically resemble lutein or Leydig cells and have been referred to as luteinized stromal cells. These cells almost always lie within the tumor singly, diffusely, or in clusters, but rarely they are mainly distributed just outside the tumor, sometimes forming a peripheral band (\bigcirc *Fig. 15.73*) [137]. Exceptionally, crystals of Reinke can be identified in the lutein-like

Fig. 15.72 Mucinous cystic tumor from virilized pregnant patient. The neoplastic glands are separated by luteinized stromal cells

Fig. 15.73
Strumal carcinoid. There is a peripheral band of steroid-type cells

cells, warranting their interpretation as Leydig cells [75]. It must be emphasized, however, that steroid-type cells may be prominent in the absence of clinical evidence of hormone overproduction and, conversely, evidence of function may exist in the absence of fully developed cells of steroid type. Ovarian tumors with functioning stroma can be divided into three major categories. In the first two categories, germ cell tumors that contain syncytiotrophoblast cells and tumors in pregnant patients, the luteinized stromal cells probably develop as a result of stimulation by hCG. The cause of the stromal alteration in the third (idiopathic) group, which accounts for most of the cases, is unclear, but ectopic production of hCG or some other stromal stimulant by the neoplastic cells may be responsible.

Germ Cell Tumors Containing Syncytiotrophoblast Cells

Two dysgerminomas with syncytiotrophoblast cells have been associated with luteinization of the stroma and endocrine manifestations; one was accompanied by isosexual precocity and the other by postpubertal virilization [171].

Germ cell tumors that produce hCG, including dysgerminomas with syncytiotrophoblast giant cells [195], choriocarcinomas, embryonal carcinomas, and polyembryomas and mixed primitive germ cell tumors, also may cause manifestations of steroid hormone secretion as a result of hCG stimulation of the ovary contralateral to the tumor to form luteinized follicles that secrete steroid hormones.

Tumors with Functioning Stroma Occurring During Pregnancy

Although it is logical to speculate that ovarian tumors with functioning stroma in pregnant patients may secrete estrogens, this possibility has not been investigated by hormone assay, and clinical manifestations of estrogen excess are not expected to be present during gestation. In contrast, more than 20 examples of virilization caused by ovarian tumors with functioning stroma during pregnancy have been reported. These tumors were mostly Krukenberg tumors or mucinous cystic tumors, but a few have been Brenner tumors or isolated other tumor types. The onset of the virilization in these patients has ranged from the third to the ninth month of gestation. Female offspring may be virilized.

Idiopathic Group

Although ovarian tumors with functioning stroma in the first two categories are encountered in young girls, patients with tumors in the idiopathic group usually are postmenopausal, reflecting the higher prevalence of ovarian tumors, both primary and metastatic, and possibly the higher levels of circulating luteinizing hormone in this age group. A wide variety of ovarian tumors has been associated with an idiopathic functioning stroma, but its frequency has varied from one type of neoplasm to another.

Mucinous tumors often contain functioning stroma, occasionally resulting in either estrogenic or androgenic manifestations (**>** *Fig.* 15.74). Brenner tumors have been accompanied by endometrial hyperplasia in 10–16% of

Fig. 15.74 Mucinous cystic tun

Mucinous cystic tumor of borderline malignancy that was associated with the Zollinger–Ellison syndrome. In the bottom panel some of the neoplastic cells are immunoreactive for gastrin

the cases and occasionally are virilizing. Rare cases of endometrioid carcinoma have been reported to be associated with endometrial hyperplasia in postmenopausal women, and in one case, virilization and breast secretion developed. We have seen a well-differentiated endometrioid carcinoma from a patient with an elevated serum testosterone level and the recent development of hirsutism. Serous and clear cell tumors have been accompanied only exceptionally by hormone manifestations. Germ cell tumors of various types lacking trophoblastic cells have been associated rarely with stromal luteinization and evidence of steroid hormone secretion in the absence of pregnancy. The germ cell tumors within the idiopathic category that have been accompanied by androgenic or estrogenic manifestations have included a variety of subtypes such as dermoid cyst, struma ovarii, carcinoid tumors, embryonal carcinoma, and yolk sac tumor. The steroid cells that are stimulated in cases of germ cell tumor are peripheral rather than within the tumor in many, if not most, of the cases. The lesions associated with peripheral steroid cell formation in the series of Rutgers and Scully [137] describing this phenomenon were struma ovarii (nine cases), strumal or trabecular carcinoids (four cases), rete cysts (four cases), mucinous cystadenomas (three cases), dermoid cysts (two cases), and single examples of dysgerminoma with syncytiotrophoblast giant cells and metastatic carcinoid. In three of the cases, all strumas, a yellow color was appreciated grossly at the periphery or on the surface of the tumor.

The steroid cells that develop adjacent to ovarian tumors rather than within them are of three types: lutein cells within adjacent ovarian stroma, Leydig cells within ovarian stroma, and hilus cells, which are present only along the hilar border of the tumor. The number of cases in each of these three categories in the series of Rutgers and Scully [137] were 14, 2, and 8, respectively. The tumors with hilus cell hyperplasia were typically large with an average greatest diameter of 18 cm. The lutein cells and stromal Leydig cells were located predominantly or exclusively in the cortex or medulla peripheral to the tumor and were arranged singly and in nests, forming a discontinuous band up to 2 mm in thickness. The hilus cells were arranged singly and in small nests forming discontinuous bands in the walls of the cysts in which they arose. Lutein cell formation is accompanied most often by estrogenic manifestations, whereas stromal Leydig cell formation and hilar Leydig cell hyperplasia are associated most often with androgenic changes.

Metastatic carcinomas that contain mucinous cells, such as primary mucinous tumors of the ovary, frequently are associated with luteinization of the stroma and in a significant proportion of cases with clinical evidence of elevated steroid hormone levels. Scully and Richardson [147] found clinical evidence of excess estrogens as manifested by irregular premenopausal bleeding or postmenopausal bleeding in one quarter of patients with metastatic adenocarcinoma from the large intestine and stomach. Occasional Krukenberg tumors from nonpregnant patients have been associated with virilization. Other metastatic tumors are associated much less often with stromal luteinization. One postmenopausal woman was virilized as a result of luteinization caused by bilateral metastatic lobular carcinoma of the breast [25]. One metastatic colonic carcinoid was associated with peripheral stromal luteinization [137].

Ovarian Tumors with Thyroid Hyperfunction

Although strumas and strumal carcinoids of the ovary have been demonstrated by immunohistochemical staining to contain thyroglobulin, triiodothyronine, and thyroxine and, therefore, probably produce thyroid hormones at subclinical levels in many cases, clinical evidence suggestive of hyperthyroidism is present in only 25% of the cases, and florid thyrotoxicosis in only about 5%. Factors that make it difficult to determine accurately the frequency of hyperthyroidism in patients with struma ovarii include variable criteria for the amount of thyroid tissue required for a diagnosis of struma, the observation that approximately one sixth of patients with struma ovarii have concomitant enlargement of the thyroid gland, and a lack of confirmation of the hyperthyroidism by modern laboratory tests in most of the reported cases.

In some patients with clinical or laboratory evidence of hyperthyroidism, the preoperative diagnosis of hyperfunctioning struma ovarii has been established by high iodine uptake in the pelvis with low radioiodine uptake in the neck [21]. Other cases of struma-associated hyperthyroidism have not been recognized until the symptoms regressed after removal of an ovarian tumor. In some of these cases, a prior thyroidectomy had had no effect on the hyperthyroidism. Occasionally, oophorectomy for struma may precipitate compensatory enlargement of the thyroid gland, increased uptake of radioactive iodine by the thyroid gland, or an episode of thyrotoxicosis. Similarly, torsion of an ovary containing a struma precipitated striking hyperthyroxinemia in a pregnant patient. Occasional strumal carcinoids have been accompanied by evidence of hypersecretion of thyroid hormone in the form of postoperative thyroid storm or hypothyroidism, and thyroglobulin has been demonstrated in the colloid within tumors of this type.

Ovarian Tumors Associated with the Carcinoid Syndrome

Of the four major categories of primary carcinoid tumor of the ovary, insular, trabecular, strumal, and mucinous, one third of the insular tumors and a single example of strumal carcinoid have been associated with the carcinoid syndrome. One patient with the syndrome also had elevated serum levels of calcitonin [149]. Metastatic carcinoids involving the ovary are associated with the carcinoid syndrome in almost half the cases. The volume of the carcinoid is an important factor determining the presence or absence of the syndrome in cases of primary carcinoids. The syndrome is present in about two thirds of the cases when the tumor is large. One 74-year-old woman had the carcinoid syndrome attributable to an ovarian tumor that resembled an atypical carcinoid with areas of neuroendocrine (oat cell) carcinoma [20]. That patient also was virilized and had Cushing's syndrome. Although no immunohistochemical staining was performed, the authors concluded that the tumor was elaborating both serotonin and ACTH. The carcinoid syndrome typically occurs in the absence of hepatic or other metastases in cases of ovarian carcinoid, because the hormonal effluent of the tumor enters the systemic circulation directly, bypassing the portal venous system and avoiding inactivation in the liver. The carcinoid syndrome caused by a primary ovarian carcinoid, therefore, is usually curable if the tumor is confined to the ovary and irreversible damage to cardiac valves has not occurred.

Ovarian Tumors Associated with Zollinger–Ellison Syndrome

Eleven mucinous tumors (two cystadenomas, five borderline tumors, and four cystadenocarcinomas) have caused the Zollinger–Ellison syndrome with disappearance of the syndrome after removal of the tumor [19, 54]. Most of the tumors were large, with a mean diameter of 21.5 cm. Gastrin-containing cells were identified immunohistochemically within the cyst lining in all cases in which staining was performed (\bigcirc *Fig. 15.74*), and gastrin was demonstrated within the cyst fluid in about half of them.

The association between ovarian mucinous tumors and Zollinger–Ellison syndrome is consistent with the frequent finding of neuroendocrine intestinal-type cells within mucinous tumors. A number of studies have shown that all categories of mucinous tumors (benign, borderline, and malignant) commonly contain argyrophil and hormone-immunoreactive cells, although in most of the studies, these cells have been found most frequently in mucinous borderline tumors. The argyrophilic cells often are immunoreactive for serotonin and a variety of polypeptide hormones. The most commonly identified of the latter have been corticotropin, gastrin, somatostatin, glucagon, secretion, and pancreatic polypeptide; in many cases, the tumors have been immunoreactive for multiple hormones.

Ovarian Tumors with Paraendocrine Disorders

A variety of paraendocrine disorders have been described in association with numerous types of ovarian tumor, some manifested by signs and symptoms of a wellknown endocrine disease and others by subclinical laboratory abnormalities, indicating ectopic production of hormones or hormone-like substances by the tumor cells. In some of these cases, the hormone being produced has been identified whereas in others, such as in cases of hypercalcemia, the mechanism of the disorder remains unclear. In all the cases included within this category of neoplasms, successful therapy of the tumor has led to disappearance of the paraendocrine state.

Hypercalcemia, Including Small Cell Carcinoma

About 60% of these tumors have been a distinctive type of small cell carcinoma [181]; almost half the remainder have been clear cell carcinomas with serous carcinomas, squamous cell carcinoma arising in a dermoid cyst, dysgerminoma, and miscellaneous other neoplasms, each accounting for about one quarter of the remainder.

The mechanism of the hypercalcemia associated with ovarian cancers is unknown [113]. Attempts to demonstrate parathormone (PTH) within the tumor cells have been unsuccessful with rare exceptions, and in several cases in which PTH has been measured in the serum, the level was normal. Recent evidence has implicated PTH-related peptide (PTHRP) which has been elevated in the serum [62, 169] or detected by radioimmunoassay in some cases [52]; three tumors (one, a small cell carcinoma) were immunoreactive for PTHRP [22, 169]. Because of the binding of PTHRP to a receptor common for PTH and PTHRP, the secretion of PTHRP by a neoplasm may produce the biochemical features of hyperparathyroidism. In one case, the patient also had abnormally high serum concentrations of 1,25-dihydroxyvitamin D (1,25-DHD)

and increased intestinal calcium absorption [62]. Tumor removal was followed by normalization of the serum calcium, PTHRP, and 1,25-DHD levels, suggesting an intestinal contribution to the maintenance of the hypercalcemia in this patient.

The small cell carcinoma of hypercalcemic type is the most common form of undifferentiated carcinoma of the ovary in females under 40 years of age and has been accompanied by elevated levels of calcium in 66% of the cases in which it has been measured [181]. The age of the patients has ranged from 14 months to 44 (average, 24) years. The presenting symptoms usually are abdominal pain and swelling.

At laparotomy almost all the tumors have been unilateral; spread beyond the ovary is usual. Gross examination reveals fleshy white to pale tan masses, often containing large areas of hemorrhage and necrosis (> Fig. 15.75). The most common microscopic appearance is a diffuse arrangement of closely packed epithelial cells interrupted focally in most cases by distinctive follicle-like structures containing eosinophilic fluid (> Fig. 15.76). The neoplastic cells typically have scanty cytoplasm and small nuclei (> Fig. 15.77) that typically contain single small nucleoli; mitotic figures are numerous. The tumor cells also grow in nests, cords, and irregular groups. In many tumors, large cells with abundant eosinophilic cytoplasm resembling lutein cells to varying extent have been present focally (> Figs. 15.78 and > 15.79); rarely, these cells predominate. In about 10% of the cases, occasional glands lined by mature mucinous epithelium, signet cells, or highly

Fig. 15.75

Small cell carcinoma, hypercalcemic type. The sectioned surface of the neoplasm is mostly creamy white with focal hemorrhage and necrosis

atypical cells containing mucin are present. The stroma is generally relatively scanty and consists of nonspecific fibrous tissue.

Special staining and immunohistochemical [3] and ultrastructural [96] examination have not revealed any features that identify the specific cell type of this epithelial tumor; dense-core granules have been absent in most cases. Flow cytometry on paraffin-embedded material typically shows that the cells are diploid [44]. The age distribution and the characteristic presence of uniform small cells and follicle formation suggest a sex cord derivation, but transitions to recognizable forms of sex cord tumors have not been observed.

The small cell carcinoma often is confused with a granulosa cell tumor of either adult or juvenile type. The features of these three types of tumor are contrasted in **7** *Table 15.3.* Diffuse small cell carcinomas also may resemble malignant lymphomas, particularly on low-power examination, but adequate sampling reveals patterns of

■ Fig. 15.76 Small cell carcinoma, hypercalcemic type. Follicles are present within an otherwise densely cellular neoplasm

Fig. 15.77
Small cell carcinoma, hypercalcemic type. Typical small cells

Fig. 15.78 Small cell carcinoma, hypercalcemic type. Typical large cells

growth that indicate the epithelial nature of the tumor; also, the cytologic features of the neoplastic cells are incompatible with any form of malignant lymphoma. Exceptionally, the differential diagnosis of a small cell carcinoma includes other small cell malignant tumors of the ovary, including several metastatic tumors such as metastatic melanoma and metastatic small cell sarcomas. The small cell carcinoma has a poor prognosis even when at stage I and no form of adjuvant therapy is of proven benefit.

Cushing's Syndrome

Five cases of clinically typical and biochemically documented Cushing's syndrome have been caused by cortisol production by a steroid cell tumor [189]. Most of the tumors occurred in adults and had metastasized within the abdomen at the time of presentation and had atypical cytologic features. Rarely, primary ovarian tumors other than those of steroid cell type have been associated with Cushing's syndrome, probably in most cases on the basis of ectopic production of corticotropin or corticotropin-releasing factor.

These cases have included bilateral endometrioid adenocarcinoma [38], a poorly differentiated adenocarcinoma [121], a malignant Sertoli cell tumor [108], a trabecular carcinoid (in which the tumor cells were immunoreactive for corticotropin) [144], and a tumor that resembled an atypical carcinoid and small cell carcinoma of the lung [20]. Finally, two cases have been described in which anterior pituitary tissue within a dermoid cyst caused Cushing's syndrome. In one of these cases, it was not clear whether the pituitary tissue was neoplastic or hyperplastic, but in the other case, there was a chromophobe adenoma in which the neoplastic cells were immunoreactive for corticotropin [32].

Human Chorionic Gonadotropin Secretion

Ectopic hCG production was reported by Civantos and Rywlin [30] in three women with serous papillary or

mucinous adenocarcinomas of the ovary. All the patients had elevated urinary hCG level. Each tumor contained poorly differentiated areas with cells resembling syncytiotrophoblast cells; these cells were positive for hCG on immunofluorescence. In one case, the contralateral ovary contained numerous lutein cells, and a decidual reaction was present in the endometrium; that patient had vaginal bleeding, but no endocrine effects were present in the others. Two poorly differentiated surface epithelial carcinomas with a choriocarcinomatous component had elevated serum hCG levels [115]. The choriocarcinoma appeared grossly as a necrotic, hemorrhagic, circumscribed, brown nodule. Matias-Guiu and Prat [86] conducted the most extensive immunohistochemical investigation of hCG in ovarian tumors, using single polyclonal antibodies to the whole hormone and its beta subunit and four monoclonal antibodies to the whole hormone, its beta subunit, and two regions of the carboxyl terminal of the beta subunit. Correlating positive staining results with the presence or absence of an "active" stroma of the tumor

(luteinization and/or "condensation"), these authors found that the epithelial cells of 41% of the tumors with active stroma reacted with the polyclonal antibodies and 62% with the monoclonal antibodies; the corresponding figures for the epithelial cells of the tumor with an inactive stroma were 14% and 37%, respectively.

Hypoglycemia

Six ovarian neoplasms have been associated with hypoglycemia: a serous cystadenocarcinoma, a dysgerminoma, a fibroma, a malignant schwannoma, a strumal carcinoid, and a carcinoid tumor with a mixed insular and trabecular pattern [8, 103, 144]. In the case of the malignant schwannoma, insulin and proinsulin were recovered from the tumor tissue and the cells of the carcinoid tumor were immunoreactive for insulin. The patient with the insulartrabecular carcinoid tumor also had a parathyroid adenoma and pituitary hyperplasia.

Renin and Aldosterone Secretion

Three cases of hypertension related to hormone secretion by an ovarian tumor have been reported; two of the patients also had Gorlin's syndrome. In eight cases, the hypertension was associated with a renin-secreting tumor, hyperreninism, and secondary hyperaldosteronism [6, 76]. In three cases, an aldosterone-secreting ovarian tumor resulted in primary hyperaldosteronism associated with low or normal plasma renin levels [72, 78, 167]. Elevated aldosterone levels were present in the 12th case (but plasma renin levels were not measured) [144] and in the 13th case (neither renin nor aldosterone levels were determined) [144], reported in 1966. In four cases, the tumor also elaborated steroid hormones as manifested by isosexual pseudoprecocity in two cases and elevated serum levels of estradiol and testosterone in two. Eight of the ovarian tumors were interpreted as sex cord-stromal tumors and two as steroid cell tumors. Three tumors in the first category were well-differentiated Sertoli cell tumors, whereas the other four had an appearance that was too nonspecific or poorly differentiated to subclassify. One of these last four tumors occurred in a woman with Peutz-Jeghers syndrome and was benign, whereas the other three were clinically malignant and two were fatal. One of the "steroid cell" tumors occurred in a 7-year-old girl and had a prominent follicular pattern, more in keeping with a diagnosis of JGCT. The final two tumors were a leiomyosarcoma and a mucinous adenocarcinoma.

Immunohistochemical staining in five of the sex cordstromal tumors and the leiomyosarcoma showed cells containing immunoreactive renin or prorenin.

Prolactin Secretion

Two ovarian dermoid cysts have been associated with the elaboration of prolactin [73, 118]. The patients were both in the reproductive age group. In one case, the dermoid cyst contained a 2.5-cm tumor composed of small rounded nests of epithelial cells, some of which surrounded lumens filled with colloid-like material (\bigcirc *Fig. 15.80*). The cells had

Fig. 15.80

Prolactinoma within ovarian dermoid cyst, partly seen at the top, with cellular proliferation of pituitary type cells beneath it. The tumor was composed of epithelial cells with scanty cytoplasm and small round uniform nuclei; there were a few lumens filled with colloid-like material (*bottom left*). Most of the tumor cells were strongly immunoreactive for prolactin (*bottom right*) scanty cytoplasm and small, round, uniform, mitotically inactive nuclei. Most of the tumor cells were strongly immunoreactive for prolactin (**>** *Fig. 15.80*). In the other case, pathologic examination of an otherwise typical dermoid cyst disclosed a 1-mm focus of pituitary tissue composed of large polygonal cells with abundant eosinophilic cytoplasm that was immunoreactive for prolactin. In one patient with gonadoblastoma [63], a prolactin gradiant was present between the vein draining the tumor and peripheral veins, although the patient did not have hyperperlactonemia. Cells within the gonadoblastoma that resembled Sertoli cells were immunoreactive for prolactin.

Ovarian Tumors Associated with Paraneoplastic Syndromes

Nervous System Disorders

Ovarian cancer of surface epithelial type is one of the malignant tumors most often associated with nervous system disorders. The tumor is occasionally occult [84]. A variety of lesions affecting both the gray matter and white matter of the cerebrum, cerebellum, spinal cord, the peripheral nerves, and the myoneural junction, accompanied by myasthenia gravis, may occur [170]. Paraneoplastic subacute cerebellar degeneration (SCD) is one of the most common lesions, with ovarian cancer accounting for from 16% to 47% of the cases [123]. The cerebellar manifestations usually antedate recognition of the cancer, and typically there is no improvement after the removal of the tumor. In one case, manifestations of the cerebellar degeneration partially regressed after plasmapheresis [32]. The pathogenesis of SCD in these cases appears to be related to the presence of circulating anti-Purkinje cell antibodies that have been shown to react with antigens in the tumor. The presence of such antibodies appears to be much more common in patients with SCD and gynecologic or breast cancer than in patients with SCD and other types of carcinoma. Inflammatory limbic encephalitis has been associated with dermoid cysts [138] and in these cases, N-Methyl-D asparate receptor antibodies have been found in the blood and cerebrospinal fluid.

Connective Tissue Disorders

The connective tissue disorder most commonly associated with ovarian cancer is dermatomyositis. In one study of ten patients with dermatomyositis or polymyositis and a malignant tumor of the female genital tract, five had ovarian cancer [173]. The tumors are most commonly high-grade, high-stage serous carcinomas [102], but there is one case of dysgerminoma and one of leiomyoma associated with dermatomyositis. The onset of the dermatomyositis generally precedes recognition of the tumor, which usually becomes evident within 2 years. Medsger and his associates [97] described six patients with ovarian carcinoma in whom polyarthritis and palmar fasciitis preceded the diagnosis of carcinoma by 5-25 months. The arthritic symptoms were similar to those of rheumatoid arthritis. Four of the ovarian tumors were endometrioid carcinomas, one a serous carcinoma, and one an undifferentiated carcinoma. Occasional patients have had hypertrophic pulmonary osteoarthropathy, rheumatoid arthritis, scleroderma, systemic lupus erythematosus, or the shoulder-hand syndrome.

Cutaneous Disorders

Acanthosis nigricans occurs in some, typically young, women in association with polycystic ovary disease (POD), stromal hyperthecosis, or combinations thereof [43], representing a component of the so-called HAIR-AN syndrome (hyperandrogenemia, insulin resistance, and acanthosis nigricans). Four cases of so-called malignant acanthosis nigricans have been cases of ovarian carcinoma. The sign of Leser-Trelat, the sudden onset and rapid increase in size of numerous seborrheic keratoses in association with an occult cancer, considered by some a variant of "malignant" acanthosis nigricans, has been associated with ovarian cancer in one case [64]. Rarely, ovarian carcinomas have occurred in patients with the Torre-Muir syndrome [33] or Sweet's syndrome [107]. Cutaneous melanosis has occurred with a strumal carcinoid [8]; the tumor cells were immunoreactive for alpha-melanocyte-stimulating hormone. Other uncommon associations of ovarian neoplasms and skin lesions are sporadically reported [48].

Nephrotic Syndrome

In cases of the nephrotic syndrome, 5–10% have a paraneoplastic background, although the causative tumors in such cases are located only rarely in the female genital tract. Hoyt and Hamilton [65] described a 65-year-old woman who was found to have the nephrotic syndrome 8 months before the detection of a stage IV poorly differentiated serous carcinoma of the ovary. A renal biopsy showed membranous glomerulopathy. The proteinuria markedly diminished after debulking of the tumor, and

after 10 months of combination chemotherapy, the proteinuria had disappeared and there was no evidence of tumor at a second-look laparotomy.

Hematologic Disorders

Approximately 30 ovarian tumors have been reported to be associated with autoimmune hemolytic anemia, which is usually Coombs positive. Most of these tumors have been dermoid cysts [122], but occasional examples of carcinoma and a single case of granulosa cell tumor also have been reported [122]. In the latter case, the patient also had splenic angiomas. In many cases, corticosteroid therapy, splenectomy, or both have resulted in little or no improvement, but removal of the ovarian tumor has produced a rapid remission of the hemolytic disorder. Payne and coworkers [122] have listed several mechanisms proposed to explain the relation of the dermoid cyst to the anemia: (1) liberation by the tumor of a substance that alters the surface of red cells, making them antigenic to the host, (2) stimulation of production of an antibody that crossreacts with the red cells by an antigen in the wall or lumen of the cyst, and (3) direct production of a red cell antibody by the tumor. Support for the last theory is provided by the finding of immunoglobulin in the cyst fluid in several cases.

Ovarian tumors are commonly associated with laboratory evidence of disseminated intravascular coagulation (DIC), but clinical manifestations of this disorder are uncommon. Ovarian tumors also have been associated with migratory thrombophlebitis (Trousseau's syndrome). Nonbacterial thrombotic endocarditis also has been recorded as a complication of ovarian cancer, as has microangiopathic hemolytic anemia. Excluding cases of mild erythrocytosis that may accompany androgenic ovarian tumors, paraneoplastic erythrocytosis, is associated only rarely with ovarian tumors [122]. Examples of erythropoetin-secreting ovarian tumors have included a dermoid cyst and a steroid cell tumor [122]. Other hematologic abnormalities that have been described rarely in association with ovarian tumors include nonthrombocytopenic purpura (mucinous cystadenoma), granulocytosis (clear cell carcinoma), thrombocytosis (serous carcinoma), thrombocytopenia (hemangioma and adenofibroma) [174], and pancytopenia (granulosa cell tumor).

Miscellaneous Rare Conditions

One ovarian example of inappropriate antidiuresis syndrome has been reported in association with a serous carcinoma that had a component of small cell carcinoma of pulmonary type [163]. Electron microscopic examination of the tumor disclosed neuroendocrine granules, and the neoplastic cells were also immunoreactive for antidiuretic hormone.

A small number of patients with ovarian tumors, usually with high-stage serous carcinomas but rarely with lowstage endometrioid carcinomas, have had hyperamylasemia [117]. Monitoring the serum amylase level may be a marker of tumor progression and response to therapy in such cases. Rarely, patients with ovarian cancer have had a clinical presentation that has mimicked that of acute pancreatitis [112]. In one unusual case, a patient with pseudo Meigs' syndrome had a pleural infusion rich in amylase that disappeared after removal of a serous tumor or borderline malignancy, which had ruptured preoperatively [37]. Six patients with poorly differentiated surface epithelial carcinomas [27] have had uveal melanocytic lesions as may be seen with other visceral cancers. Microscopic examination of the eves of these patients who undergo progressive blurring and loss of vision shows bilateral diffuse proliferation of melanocytes throughout the uvueal tracts with the involvement of the sclerae in some instances [83]. Rarely, pyrexia is a presenting manifestation of a patient with ovarian carcinoma [140]. One of the two cases in this category was classified as a clear cell carcinoma, and the other was not subclassified.

Acknowledgment

When the late Dr. Ancel Blaustein prepared the first edition of this book in the mid-1970s, he asked Dr. Robert E. Scully to contribute the chapter on ovarian sex cord-stromal tumors and it duly appeared in 1977. In the 1980s, I had the pleasure and privilege of reviewing numerous sex cordstromal tumors of the ovary in Dr. Scully's remarkable collection and a number of original publications with Dr. Scully and others came to pass. This resulted in Dr. Scully asking me if I would co-author the contribution on this topic for the third edition, expanded by the inclusion of consideration of steroid cell tumors and a variety of miscellaneous other neoplasms associated with various interesting clinical manifestations. This chapter appeared in the 1987 third edition. Dr. Scully, being retired, declined to participate in this most recent reedition of the chapter and although many of the words were initially written, or edited by him, given his customary awareness of the importance of ethics in medicine, he declined to have his name associated with a work which he did not actively participate in at this time. However, I would like to

acknowledge my debt to Dr. Scully for the initial chapter, which laid the groundwork for everything to follow, the opportunity to learn from his cases, and most important of all, to be educated by him on the remarkable and fascinating microscopic spectrum encountered within the family of tumors reviewed in this chapter. Similar remarks pertain to O Chap. 18, Metastatics Tumors of the Ovary.

Clinical and Pathologic Features of Tumors	
Composed of Germ Cells and Sex Cord–Stromal	
Derivatives	892
Gonadoblastoma	892
Mixed Germ Cell–Sex Cord–Stromal Tumor	897
Germ cell tumors are composed of a number of histologically different tumor types derived from the primitive germ cells of the embryonic gonad. The concept of germ cell tumors as a specific group of gonadal neoplasms has evolved over the last several decades. It is based on (1) the common histogenesis of these neoplasms, (2) the relatively frequent presence of histologically different neoplastic elements within the same tumor, (3) the presence of histologically similar neoplasms in extragonadal locations along the line of migration of the primitive germ cells from the wall of the yolk sac to the gonadal ridge [253], and (4) the remarkable homology between the various tumors in the male and the female. In no other group of gonadal neoplasms is this homology better illustrated. Although the strong morphologic resemblance between the testicular seminoma and its ovarian counterpart, the dysgerminoma was noted soon after these neoplasms were first described, for a long time there was no agreement as to their histogenesis. Nevertheless, these were the first neoplasms to become accepted as originating from germ cells. It was not until the studies by Teilum [231, 232] on the homology of ovarian and testicular neoplasms, the studies by Friedman and Moore [59] and Dixon and Moore [50] on testicular tumors, and those by Friedman [58] on related extragonadal neoplasms that the germ cell origin of other neoplasms belonging to this group was proposed. These views were supported by the embryologic studies of Witschi [253] and Gillman [66], and later by the experimental work of Stevens [200-202] and Pierce et al [149, 151] on germ cell tumors in rodents.

Although occasional unusual neoplasms composed of germ cells and sex cord derivatives had been noted previously, it was not until Scully's detailed description of gonadoblastoma [181] that these neoplasms were established as a distinct entity. More recently, another neoplasm composed of germ cells and sex cord derivatives, the mixed germ cell–sex cord–stromal tumor, has been described in detail [209, 210]. This chapter, therefore, is devoted not only to neoplasms of germ cell origin, but also to those composed of germ cells and sex cord derivatives.

Histogenesis

The histogenesis and interrelationships of the various types of germ cell neoplasms, as suggested by Teilum [235], are shown in \bigcirc *Fig. 16.1.* According to Teilum [235], dysgerminoma (seminoma) is a primitive germ cell neoplasm that has not acquired the potential for further differentiation. Embryonal carcinoma is regarded as a conceptual as well as a morphologic entity and

represents a germ cell neoplasm composed of multipotential cells that are capable of further differentiation. This process can take place in an embryonal or somatic direction, resulting in teratomatous neoplasms showing various degrees of maturity, or in an extraembryonal direction along either of two pathways: vitelline, differentiating toward yolk sac (endodermal sinus) tumor, or trophoblastic, differentiating toward a choriocarcinoma. The process of differentiation is dynamic and, therefore, neoplasms may be composed of different elements showing various stages of development. According to this view [235], dysgerminoma was considered incapable of further differentiation, but immunohistochemical evidence indicates that some seminoma or dysgerminoma cells can differentiate into embryonal carcinoma and further [137]. The intimate admixture of dysgerminoma cells with other neoplastic germ cell elements seen in some germ cell tumors also supports this concept [82].

Classification

The World Health Organization (WHO) classification [186] divides germ cell tumors into a number of groups and also includes neoplasms composed of germ cells and sex cord-stromal derivatives. In the most recent version (Table 16.1) [230], the yolk sac tumor category has been expanded to include the polyvesicular vitelline, hepatoid, and glandular subtypes, which unlike other patterns of differentiation in yolk sac tumors can occur in pure form and thus pose diagnostic problems. The new classification also expands the category of teratoma, dividing it into biphasic or triphasic teratoma and monodermal teratoma and somatic-type tumors associated with biphasic or triphasic teratoma [230]. The tumors composed of germ cells and the sex cord-stromal derivatives are divided into two categories: gonadoblastoma and mixed germ cell-sex cord-stromal tumor; each of these is subclassified to include those tumors associated with dysgerminoma or other germ cell tumors.

Clinical and Pathologic Features of Germ Cell Tumors

Germ cell tumors constitute the second largest group of ovarian neoplasms after the surface epithelial–stromal tumors and comprise approximately 20% of all ovarian neoplasms observed in Europe and North America. In countries in Asia and Africa, where the prevalence of surface epithelial–stromal tumors is much lower, germ

Fig. 16.1

Hypothetical model of histogenesis of germ cell tumors as proposed by Teilum (Modified from [232])

cell tumors constitute a much larger proportion of ovarian neoplasms. Germ cell tumors are encountered at all ages from infancy to old age but are seen most frequently from the first to the sixth decades. They also have been observed during fetal life. In children and adolescents, more than 60% of ovarian neoplasms are of germ cell origin, and one third are malignant [129]. In adults, the great majority of germ cell tumors (95%) are benign and consist of mature cystic teratomas (dermoid cysts). Malignant ovarian germ cell tumors occur in the first four decades and are rare thereafter.

Dysgerminoma

Histogenesis

Dysgerminoma is composed entirely of germ cells that show morphologic, ultrastructural [105], and histochemical [116] similarity to primordial germ cells. The cells of dysgerminoma are considered to be in an early and sexually indifferent stage of differentiation; they have been believed to be arrested at a developmental stage at which they have not yet gained the ability for further differentiation [232]. However, there is evidence that occasional cells may acquire this ability and differentiate to embryonal carcinoma and further [120, 137]. An origin from the primordial germ cells that migrate to the ovary during early embryogenesis from their site of origin in the wall of the yolk sac [253] is the most widely accepted view of the histogenesis of dysgerminoma. It is supported by the occurrence of homologous neoplasms in the testis (seminoma) and along the route of migration of the primordial germ cells from the wall of the yolk sac to the primitive gonad, in the mediastinum, retroperitoneum, posterior abdominal wall, and parapineal and sacrococcygeal regions.

Cytogenetic and Molecular Features

An increased amount of DNA, double the amount present in normal somatic cells, is present in the nuclei of dysgerminoma [9, 93]. The demonstration of a small isochromosome, i(12p), as a specific abnormality and therefore a possible chromosomal marker for testicular germ cell tumors, especially seminoma [11], has been noted in dysgerminomas [12, 43]. However, i(12p) has also been

identified in non-dysgerminatous components of ovarian germ cell tumors [153].

Comparative genomic hybridization has revealed multiple DNA copy number changes in dysgerminoma [94, 159]. Common alterations include gains on chromosome arms 12p, 12q, 21q, and 22q and losses from 13q. A subset of tumors exhibits mutation of the *KIT* oncogene [77].

Prevalence

Dysgerminoma is an uncommon tumor, accounting for 1–2% of primary ovarian neoplasms and 3–5% of ovarian malignancies [121, 173]. It is the most common malignant ovarian germ cell neoplasm occurring in pure form. The exact prevalence of dysgerminoma in different parts of the world is not known because most cancer registry reports do not differentiate between the various types of ovarian neoplasms. Although most reports emanate from Europe and North America, dysgerminoma has been encountered in all parts of the world and in all races. In some countries, there are considerable regional variations.

Clinical Features

Dysgerminoma has been reported in infants from 7 months to women aged 70 years [121], but most cases occur in the second and third decades; nearly half the patients are under 20 years of age, and 80% are under 30 years [9, 24, 69, 121]. Dysgerminoma occurs not infrequently before puberty but is very rare after menopause. Therefore, dysgerminoma is one of the most common malignant ovarian neoplasms of childhood, adolescence, and early adult life [9, 24, 69, 121, 129].

Pure dysgerminoma has been reported in siblings [223] as well as in a mother and daughter. The symptomatology of dysgerminoma is not distinctive and is similar to that observed in patients with other solid ovarian neoplasms [9, 24, 69, 121]. The duration of symptoms is usually short; despite this, the tumor is often large, indicating rapid growth [24]. The most common presentation is abdominal enlargement and presence of a mass in the lower abdomen, which sometimes is associated with abdominal pain due to torsion. Loss of weight may also occur. In a number of cases, the tumor has been found incidentally; in these, the tumor is usually small. In pregnancy, the tumor may be discovered as an incidental finding or may obstruct labor.

The common association of dysgerminoma with gonadoblastoma, a tumor that nearly always occurs in patients with dysgenetic gonads [174, 175, 182], indicates that there is a relationship between dysgerminoma and genetic and somatosexual abnormalities. Several reports

emphasize the occurrence of dysgerminoma in normal female patients [9, 24] and some have even cast doubt on the relationship with developmental and sexual abnormalities [9].

Dysgerminoma may also be discovered incidentally in patients investigated for primary amenorrhea; in these cases, it is usually associated with gonadoblastoma [174, 175, 182, 251]. Occasionally, menstrual and endocrine abnormalities may be the presenting symptoms, but this finding tends to be more common in patients with dysgerminoma containing syncytiotrophoblastic giant cells or when combined with other neoplastic germ cell elements, especially choriocarcinoma. The latter qualifies as a mixed germ cell tumor. In children, precocious sexual development may occur [171]. Dysgerminoma associated with evidence of virilization is found mostly in association with gonadoblastoma in patients with pure or mixed gonadal dysgenesis. A case of dysgerminoma associated with hypercalcemia has been reported and was found to be due to increased circulating levels of active form of vitamin D, 1,25-dihydroxyvitamin D3, rather than increased synthesis of parathyroid hormone-related peptide, as seen in other ovarian tumors with hypercalcemia [56]. Dysgerminoma has also been encountered in a patient with triple-X syndrome [86].

Gross Features

Dysgerminoma affects the right ovary in approximately 50% of cases and the left in 35%, and it is bilateral in 15% [9, 69, 121]. A much higher frequency of bilateral tumors is observed in patients with dysgerminoma associated with gonadoblastoma, the dysgerminoma arising from and overgrowing the gonadoblastoma [174, 175, 182]. Thus, inclusion of such cases tends to increase the prevalence of bilaterality.

Pure dysgerminomas are solid tumors that are round, oval, or lobulated, with a smooth, gray-white, slightly glistening fibrous capsule. They vary in size from a few centimeters in diameter to large masses measuring 50 cm across [9], which fill the pelvic and abdominal cavities. Tumors weighing more than 5 kg have been described [121]. The capsule is usually intact but may be ruptured, especially in large tumors, which may lead to the formation of adhesions between the tumor and surrounding structures. The consistency of dysgerminoma varies from firm and rubbery in small and medium-sized tumors to soft in large ones. On cut surface (\bigcirc *Fig. 16.2*), the tumor is solid and varies from gray-pink to light tan. Red, brown,

Fig. 16.2 Dysgerminoma. The cut surface is solid. There is some lobulation. Focally, hemorrhage is present

or yellow discoloration caused by hemorrhage or necrosis is also seen, especially in large tumors; this may sometimes lead to the formation of small cysts, but generally dysgerminomas are solid. The presence of cystic areas suggests the possibility that other neoplastic elements may be present, most likely teratoma. In view of the important therapeutic and prognostic implications concerning the presence of other neoplastic germ cell elements, extensive and judicious sampling of different parts of the tumor, especially of the less typical areas, is recommended.

Microscopic Features

Dysgerminoma is identical to seminoma of the testis. It is composed of aggregates, islands, or strands of large uniform cells surrounded by varying amounts of connective tissue stroma containing lymphocytes (\bigcirc *Figs. 16.3–* 16.5). The cells are large and measure from 15 to 25 µm in diameter. They are oval or round and usually have distinguishable cytoplasmic borders. In well-fixed material, the cell boundaries are well defined. The cells contain an ample amount of pale, slightly granular eosinophilic or clear cytoplasm.

The centrally located vesicular nucleus is large, occupying nearly half the cell. The nucleus is oval or round, has a sharp nuclear membrane with unevenly dispersed finely granular chromatin, and contains usually one, but sometimes two, prominent eosinophilic nucleoli. Some variation in the size of the cells and nuclei and in the amount of nuclear chromatin is usually seen. Large or giant

Dysgerminoma. The tumor is composed of large aggregates of uniform cells

Fig. 16.4

Dysgerminoma. The tumor is composed of trabeculae of tumor cells surrounded by connective tissue stroma containing lymphocytes

mononucleate tumor cells, which in all other respects resemble typical dysgerminoma cells, may be seen. Mitotic activity is almost always detectable and may vary from slight to brisk. This difference in mitotic activity may be observed not only in different tumors but also in different parts of the same tumor.

The cytoplasm of the tumor cells contains glycogen, which can be demonstrated with the periodic acid–Schiff (PAS) reaction and is removed by diastase digestion. The amount of glycogen in tumor cells is variable, and glycogen is lost from the cytoplasm on prolonged fixation in formalin. In view of this, the PAS reaction may vary from

Fig. 16.5

Dysgerminoma. Nests of tumor cells are present within fibrous stroma, which contains abundant lymphocytic component

strong to very weak. Lipid can be demonstrated in the cytoplasm of the tumor cells in frozen tissue.

The stroma that surrounds the tumor cells almost always displays lymphocytic infiltration, which can vary from slight to marked (**>** *Fig.* 16.5). Occasionally, lymphoid follicles containing germinal centers may be seen. Plasma cells, eosinophils, and sometimes a granulomatous reaction are present in the connective tissue stroma. The lymphoreticular cell infiltrate has previously been studied immunohistochemically, and most of the cells are T cells and macrophages. There are relatively few B cells, natural killer cells, and other types of lymphoreticular cells [49].

The connective tissue stroma shows considerable variation ranging from a fine, delicate fibrovascular network that can be loose and edematous to densely hyalinized. Depending on the amount of stroma, the tumor cells form large aggregates, smaller nests, islands, cords, or strands. Occasionally, the amount of stroma may be very abundant leading to wide separation of the nests of tumor cells. In some cases hyalinization may be so marked that tumor cells are detected with difficulty. At the opposite end of the spectrum, there are tumors that are cellular and contain only an imperceptible amount of stroma. There may be considerable variation in the amount of stroma in various parts of the same tumor.

Foci of necrosis and hemorrhage are frequently found and may be extensive in large tumors or in tumors that have undergone torsion. Calcification is only occasionally seen in dysgerminoma. It occurs as small spots or flecks of calcified material that are found in association with necrosis, hemorrhage, fibrosis, or hyalinization. Occasionally,

Dysgerminoma arising from gonadoblastoma. A large calcified concretion is present. Nests of gonadoblastoma were found in other parts of the tumor

relatively large, round, or ovoid calcified bodies are found, which may indicate the presence of a burnt-out gonadoblastoma [182] (> *Fig. 16.6*).

In 6–8% of dysgerminomas, there are individual or collections of syncytiotrophoblastic giant cells that produce human chorionic gonadotropin (hCG). The presence of these cells is associated with elevation of serum hCG levels; hCG can also be demonstrated in tissue sections by immunohistochemistry. This evidence provides another possible explanation, apart from the presence of true choriocarcinomatous elements, for the occasional presence of endocrine activity in cases of dysgerminoma. However, there remains a small group of cases in which, despite a careful search, trophoblastic elements have not been found. In some of these cases, the dysgerminoma has been associated with an increase in luteinized stromal cells and it is likely that they may be responsible for the feminizing side effects and occasionally virilization [171].

The syncytiotrophoblastic giant cells may form large syncytial masses resembling the syncytiotrophoblast of a choriocarcinoma, but they differ from the latter because there is no cytotrophoblast (\bigcirc *Fig. 16.7*). The presence of choriocarcinoma in association with dysgerminoma is not frequent, but most of the reported series contain cases of this type [141, 173]. The syncytiotrophoblastic cells must also be differentiated from foreign body and Langhans' giant cells and from mononucleate and multinucleate tumor giant cells, which are seen in some dysgerminomas. There is no evidence that dysgerminomas containing syncytiotrophoblastic giant cells are associated with

Fig. 16.7 Dysgerminoma with a large syncytiotrophoblastic giant cell

a worse prognosis [259]. The serum hCG level can be monitored as a tumor marker in the same way as in patients with gestational trophoblastic disease (see Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions) or with mixed germ cell tumors containing choriocarcinoma. The serum hCG levels in these cases are much lower compared with dysgerminoma admixed with typical choriocarcinoma.

Pure dysgerminoma is not associated with elevated levels of serum alpha-fetoprotein (AFP) [227]. The presence of elevated levels of AFP is an indication of presence of other neoplastic germ cell elements, virtually always yolk sac tumor, either within the primary tumor or its metastases.

Immunohistochemical Features and Differential Diagnosis

SALL4 is highly sensitive and specific for primitive germ cell tumors, including dysgerminoma [32]. Immunohistochemical staining for placental alkaline phosphatase (PLAP) has been used less extensively in ovarian dysgerminoma as compared to testicular seminoma [82], but when applied PLAP stains dysgerminoma cells in the same way as testicular seminoma cells, showing membrane-bound staining in most cells [82]. As PLAP also stains the tumor cells in other malignant germ cell tumors, it cannot be used to differentiate dysgerminoma from other malignant germ cell neoplasms [82]. It may be useful in differentiating dysgerminoma from nongerm cell malignancies that occasionally may resemble it such as clear cell carcinoma, lymphoma, and granulosa cell tumor. Dysgerminoma shows expression of the c-kit

Fig. 16.8 Dysgerminoma. Diffuse expression of CD117

proto-oncogene product (CD117) (> Fig. 16.8) [188, 242]. It has been suggested that this finding may have potential therapeutic value as the c-kit receptor may serve as a target for site-specific immunotherapy [188]. Recently, OCT-4 nuclear staining has been shown to be specific for dysgerminoma, seminoma, and embryonal carcinoma and was found to be negative in other germ cell tumors, thus providing another useful immunohistochemical marker for dysgerminoma [36]. Although D2-40 (podoplanin) is not specific for germ cell origin, it is expressed in dysgerminoma and negative in other ovarian germ cell tumors [35]. Most dysgerminoma cells do not show immunohistochemical staining for low molecular weight cytokeratin although occasional cells may show expression [42, 119, 120]. Thus, low molecular weight cytokeratin is useful for distinguishing dysgerminoma from embryonal carcinoma and yolk sac tumor, in which the latter two show diffuse expression [82, 119, 120].

The main tumors in the differential diagnosis of dysgerminoma include embryonal carcinoma, yolk sac tumor, clear cell carcinoma, and steroid cell tumor. Solid patterns of embryonal carcinoma, yolk sac tumor, and clear cell carcinoma can overlap with the histologic appearance of dysgerminoma, but (a) the admixture of glandular and papillary growth patterns in embryonal carcinoma, yolk sac tumor, and clear cell carcinoma; (b) lobulated architecture with lymphocytes in the interlobular fibrous septae seen in some dysgerminomas; and (c) immunohistochemical differences mentioned above usually allow for distinction. In addition, embryonal carcinoma typically shows a greater degree of nuclear pleomorphism than dysgerminoma. Histologically, dysgerminoma and steroid cell tumor can occasionally resemble one another because of sheets of clear cells. The younger age of patients with dysgerminoma, lobulated architecture with lymphocytes in the interlobular fibrous septae seen in some dysgerminomas, finely vacuolated cytoplasm of steroid cell tumor, and immunohistochemical expression of inhibin and calretinin in steroid cell tumor and CD117 and OCT-4 in dysgerminoma should facilitate the correct diagnosis.

Clinical Behavior and Treatment

Dysgerminoma is a malignant neoplasm capable of metastatic and local spread. Despite its less aggressive behavior compared with other malignant germ cell neoplasms, the malignant potential of dysgerminoma should not be underestimated. Dysgerminoma is a rapidly growing neoplasm, but metastatic spread does not occur early in the course of the disease (although it is not possible to predict this in individual cases). When the tumor is small and freely mobile, its capsule is usually intact, but large tumors may be adherent to surrounding structures or may rupture. Rupture may occur either spontaneously or at operation; this leads to spillage of the tumor contents and peritoneal implantation, causing serious consequences. Penetration of the ovarian surface by the tumor and formation of adhesions to surrounding structures may lead to direct extension by the tumor.

Metastatic spread occurs via the lymphatic system; the lymph nodes in the vicinity of the common iliac arteries and the terminal part of the abdominal aorta are first affected. Occasionally, there may be marked enlargement of these lymph nodes, with formation of large masses. Usually the enlargement is slight to moderate and can be detected by computerized tomography (CT) scanning or magnetic resonance imaging (MRI). From the abdominal lymph nodes, the tumor spreads to the mediastinal and supraclavicular lymph nodes. Hematogenous spread to distant organs occurs later, and any organ may be affected, although involvement of the liver, lungs, and bones tends to be most common [9, 24, 121]. In cases of pure dysgerminoma, the metastases usually present a similar histologic appearance to the primary tumor, but occasionally tumors composed of pure dysgerminoma may be associated with metastases composed of other neoplastic germ cell elements. This metastatic pattern is observed much more commonly in combined tumors. It has been suggested that cellular tumors with marked atypia and high mitotic activity and small amounts of stroma with only slight lymphocytic infiltration tend to be more aggressive [10]. However, there is at present no good evidence that the behavior of an individual tumor can be assessed by its histologic appearance [24]. The presence of other malignant germ cell elements, however, has an adverse effect on prognosis [9, 24, 98, 141].

Dysgerminoma, similar to its testicular counterpart seminoma, is associated with elevated levels of serum lactic dehydrogenase (LDH) and its isoenzyme-1 (LDH-1). These substances can be used as tumor markers [60, 180]. There is a good correlation between the volume of tumor tissue present and the serum levels of the enzymes.

The prognosis of patients with pure dysgerminoma is very favorable with a 5-year survival ranging from 75% to >90% [24, 64, 69, 104, 140, 237]. The 5-year survival of patients with unilateral encapsulated dysgerminoma has been reported as >90% [9, 24, 64, 104, 140, 237], although patients treated by unilateral salpingo-oophorectomy have recurrence rates ranging from 18% to 52%. Unfavorable prognostic features include presence of metastases at the time of diagnosis, presence of adhesions, spread into adjacent structures, bilaterality, and large size of the tumor [69, 141]. It should be noted that even when these features are present many patients have been cured with chemotherapy. Age does not appear to be an important prognostic factor [9, 24, 64, 140].

Like other malignant germ cell tumors, dysgerminoma responds very well to combination chemotherapy of cisplatin, etoposide (VP16), and bleomycin (BEP). In the cases studied, 80% of recurrences occur in the first 2 years after diagnosis [141], and it has been reported that more than 75% occur in the first year. In rare cases, recurrences occurred many years after excision of the original tumor.

For young women with unilateral encapsulated pure dysgerminoma, two different therapeutic approaches have been advocated. One consists of unilateral oophorectomy, or salpingo-oophorectomy, and careful follow-up. The second approach advocates similar surgical therapy, but to decrease and prevent metastases and recurrences, adjuvant chemotherapy is administered. The advantages of the first approach are that fertility is preserved and there are no genetic hazards associated with administration of chemotherapy. Although the second approach tends to decrease the risk of metastases and recurrences [24, 223], this risk is not very serious especially because metastases or recurrences can be treated successfully by combination chemotherapy [9, 24, 64, 140]. The conservative approach to the therapy of unilateral encapsulated dysgerminoma is recommended, but each individual case should be considered on its merits. It should be noted that before this mode of treatment can be considered, the opposite ovary must be normal, there should be no evidence of spread of

the tumor in the abdominal cavity, and the abdominal and pelvic lymph nodes must be free from metastases on inspection, CT scanning, and MRI. In addition, the patient must have a normal female 46,XX karyotype.

In patients with widely disseminated metastases, administration of three to four cycles of combination chemotherapy composed of cisplatin, etoposide (VP16), and bleomycin combination (BEP) has been successful in eradicating the disease [64, 140]. The treatment of patients with dysgerminoma occurring in dysgenetic gonads must be hysterectomy and bilateral salpingogonadectomy in view of the high risk of development of bilateral neoplasms in these patients [61]. Furthermore, their gonads are hormonally and functionally inactive. Therefore, determination of the karyotype of all patients with dysgerminoma, especially those with evidence of virilization or developmental and menstrual abnormalities, is recommended. This is important in prepubertal patients, because these patients lack other signs of abnormal function, such as primary amenorrhea, virilization, and absence of normal sexual development. Following adnexectomy, patients are given hormone replacement therapy. Adequate treatment in these cases prevents development of a tumor in the opposite gonad [61]. Follow-up is advisable to prevent any deleterious effects of hormone replacement therapy.

Yolk Sac Tumor

Histogenesis

Yolk sac tumor is a malignant germ cell neoplasm that is thought to originate from the undifferentiated and multipotential embryonal carcinoma by selective differentiation toward yolk sac or vitelline structures, in the same way as nongestational choriocarcinoma differentiates trophoblastic structures. The recognition and classification of yolk sac (endodermal sinus) tumor as a specific entity stems from the studies of Teilum [232–234]. The concepts regarding the histogenesis of this neoplasm that Teilum proposed have been supported by the experimental studies of the neoplastic rodent yolk sac by Pierce et al [151]. The hyaline, PAS-positive material in yolk sac tumor has been found to be similar to the hyaline material produced by mouse teratocarcinoma during its conversion to the ascitic form, and this is considered to be a strong argument in favor of the yolk sac origin of the tumor [146, 147, 151]. When examined with the electron microscope, the cells of yolk sac tumor resemble those of the normal human yolk sac [68, 82, 124].

In 1939, Schiller [177] described an ovarian neoplasm composed of clear and hobnail cells with a pattern that he designated a mesonephroma because of the presence of structures resembling immature glomeruli. Other investigators [85] were unable to demonstrate the mesonephric origin of this tumor and considered it an endothelioma of the ovary [179]. In 1946, Teilum [232] demonstrated that the tumor described as mesonephroma [177] included two distinct neoplasms with different histogenesis, histologic pattern, age distribution, and clinical behavior. One of these tumors was highly malignant, occurred in young patients, was homologous with certain testicular neoplasms, and was of germ cell origin [232]. The other tumor was less aggressive, occurred in older women, and ultimately was shown by Scully to be of mülleriantype origin. He designated this neoplasm "clear cell carcinoma."

In addition to the terms mesonephroma and endothelioma, yolk sac tumors have been designated as embryonal carcinoma because of certain similarities to embryonal carcinoma of the testis [50]. Although embryonal carcinoma showing the histologic pattern resembling the typical embryonal carcinoma of the testis [50] is seen occasionally in ovarian tumors [97], most ovarian tumors of this type show a distinctive pattern with differentiation toward yolk sac or vitelline structures [234, 235] and should be termed yolk sac tumor.

The term yolk sac tumor is more inclusive than the original term endodermal sinus tumor. Ovarian yolk sac tumor differs from the undifferentiated embryonal carcinoma [50] and resembles closely the yolk sac tumor of both infantile and adult testes [212, 234, 235]. It is now generally accepted that the term embryonal carcinoma should be used only to designate ovarian neoplasms showing the typical histologic pattern of the embryonal carcinoma as described in testicular tumors [50, 97]. It is notable that most true ovarian embryonal carcinomas are combined with yolk sac tumor. The not infrequent combination of yolk sac tumor elements in ovarian tumors with other neoplastic germ cell elements [82, 98] is one of the arguments in favor of the germ cell origin of this neoplasm. Yolk sac tumor, either pure or combined with other neoplastic germ cell elements, has been encountered in extragonadal locations where germ cell tumors are known to occur, in the mediastinum, sacrococcygeal region, pineal gland, and vagina.

Alpha-fetoprotein (AFP) was first identified as a specific constituent of normal human fetal serum by Bergstrand and Czar [21] in 1956. In the human embryo, serum AFP peaks at approximately 3,000 mg/L at about 12–13 weeks of gestation. The level decreases slowly until birth, when it is approximately 55 mg/L. After birth, AFP disappears rapidly from the serum, and 3 weeks after fullterm delivery, it can be detected only in very small amounts (0-15 ng/mL) by radioimmunoassay or sensitive enzyme immunoassays. In fetal development, AFP is produced by the yolk sac, liver, and upper gastrointestinal tract. Certain histologic components of germ cell neoplasms correlate with elevated serum AFP. It has been demonstrated that germ cell tumors in patients with elevated serum AFP are either composed entirely of, or contain, yolk sac tumor elements [128, 227]. Elevation of serum AFP has not been observed in patients with pure dysgerminoma [227], mature cystic teratoma of the ovary [227], or pure gonadoblastoma [227]. Slight elevations of serum AFP have been noted in occasional cases of immature teratoma of the ovary; this is most likely related to the presence of neuroepithelium.

Apart from yolk sac tumor, elevated levels of serum AFP are seen in patients with hepatoid carcinoma of the ovary and occasional Sertoli–Leydig cell tumors, especially those showing a retiform pattern [215, 219, 257]. Slightly elevated levels of serum AFP up to 60 ng/mL (upper limit of normal serum AFP, 20 ng/mL) have been observed in some cases of embryonal carcinoma of the testis [227]. Using immunohistochemical techniques, AFP has been identified in the cells of yolk sac tumor and embryonal carcinoma of the ovary [82, 97], and in the eosinophilic, PAS-positive, diastase-resistant globules present both inside and outside the tumor cells. Large amounts of AFP have been extracted from tumor tissue in yolk sac tumors of the ovary and testis [226].

In view of the fact that normal yolk sac in the human and other mammalian species has been shown to be associated with AFP synthesis [67], it is reasonable to assume that the selective synthesis of AFP by yolk sac tumors provides further support to the view that yolk sac tumor develops as a result of differentiation of primitive malignant germ cell elements in the direction of yolk sac or vitelline structures [82, 96, 218, 227]. The immunohistochemical localization of AFP in embryonal carcinoma and in areas of yolk sac tumor showing no morphologic evidence of yolk sac differentiation suggests that the biochemical manifestations of yolk sac differentiation, such as AFP synthesis, precede morphologic differentiation [82, 97].

Clinical Features

Yolk sac tumor is the second most common malignant ovarian germ cell neoplasm after dysgerminoma. It is one of the most common malignant ovarian neoplasms of childhood, adolescence, and early adult life [82].

Yolk sac tumor has been encountered in all races [65, 82, 96]. The reported age distribution of patients with yolk sac tumor ranges from 16 months to 46 years, but most patients have been under 30 years of age [65, 82, 96]. Yolk sac tumor is encountered most frequently in the second and third decades, followed by first and fourth, and is rare in women in the fifth decade. It has been encountered in occasional postmenopausal patients. Yolk sac tumor associated with an ovarian surface epithelial tumor has been rarely reported in elderly patients [113, 125, 172]. Although the histogenesis of these tumors is uncertain, the likely explanation is that it originates from the surface epithelium by a process of neoplastic differentiation and therefore the histogenesis is totally different from that of germ cell neoplasms [113, 172]. In some cases studied by one of the authors (AT), the yolk sac tumor component overgrew the surface epithelial-stromal element, and only extensive sectioning demonstrated focal presence of the latter. The serum AFP level was highly elevated, reflecting the presence of the yolk sac tumor component. A small series of similar cases has been reported [125].

Most patients with yolk sac tumor present with abdominal enlargement, pain, and a lower abdominal or pelvic mass [65, 82, 96]. Occasionally, symptoms are acute and severe and may lead to the diagnosis of acute appendicitis or a ruptured ectopic pregnancy; this usually is caused by torsion of the tumor. A number of cases have been encountered during pregnancy [82, 96]. The presence of yolk sac tumor is not associated with endocrine manifestations. On clinical examination, a tumor mass is usually palpable and is frequently of considerable size [65, 82, 96]. Increased levels of AFP are found in the sera [65, 128, 226], and this is a useful diagnostic test for the presence of yolk sac tumor elements in the primary tumor, its metastases, and recurrences [226, 227].

Gross Features

Yolk sac tumors are almost always unilateral [65, 82, 96, 226]. Bilaterality typically is a manifestation of metastatic spread. Yolk sac tumor shows a certain predilection for the right ovary [82, 96]. The tumor is usually large, varying in size from 3 to 30 cm in diameter, with most tumors measuring more than 10 cm [82, 96, 226]. It frequently weighs more than 500 g; tumors weighing 5 kg have been recorded. The tumor is usually encapsulated, round, oval, or globular; firm, smooth, or somewhat lobulated; and gray-yellow, with areas of hemorrhage and cystic or

gelatinous changes. The tumor may form adhesions to the surrounding structures and invade them. On sectioning, yolk sac tumors are mainly solid, but cystic spaces containing gelatinous fluid frequently are present. Necrosis and hemorrhage and the presence of other neoplastic germ cell elements, especially teratoma, may alter the appearance of the tumor.

Microscopic Features

Yolk sac tumors exhibit a wide range of histologic patterns that differ considerably from each other and, although all the different patterns may be observed in the same tumor, one or two may predominate. The following histologic patterns may be observed in yolk sac tumor: (1) microcystic or reticular, (2) endodermal sinus, (3) solid, (4) alveolar–glandular, (5) polyvesicular vitelline, (6) myxomatous, (7) papillary, (8) macrocystic, (9) hepatoid, and (10) glandular or primitive endodermal (intestinal) (\bigcirc *Figs. 16.9*–16.20) [82].

The polyvesicular vitelline, the hepatoid, and the primitive endodermal (intestinal) patterns tend to occur in pure form, unassociated with other yolk sac tumor elements. Although such tumors are rare, they pose considerable diagnostic difficulties, and because of this they have been classified as specific subtypes of yolk sac tumor in the revised WHO classification of ovarian neoplasms [184, 186, 230] (see **)** *Table 16.1*).

Endodermal sinuses or perivascular formations (Schiller–Duval bodies) are the hallmark of the tumor

(\bigcirc *Fig.* 16.9). The microcystic or reticular pattern (\bigcirc *Fig.* 16.13) and myxomatous pattern (\bigcirc *Fig.* 16.10) are composed of a loose vacuolated network with small cystic spaces or microcysts forming a honeycomb pattern. The microcysts are lined by flat, pleomorphic, mesothe-lial-like cells with large hyperchromatic or vesicular nuclei that show brisk mitotic activity. There is usually some variation in the size of the cysts (\bigcirc *Fig.* 16.13). In the underlying capillary spaces, hematopoiesis may be seen. The vacuolated network may contain pale, PAS-positive, mucinous material forming small lakes or precipitates as well as small, round, brightly eosinophilic, PAS-positive, diastase-resistant globules or droplets. These globules are also found within the cytoplasm of the tumor cells (\bigcirc *Fig. 16.11*). Areas composed of fine, loose myxomatous tissue containing alveolar spaces, occasional gland-like structures lined by cuboidal epithelium, and small cellular aggregates, often merging with the microcystic or other patterns, are also present. The loose myxomatous pattern

Fig. 16.14 Yolk sac tumor. The tumor has a solid pattern

Fig. 16.15 Yolk sac tumor. The tumor displays a pronounced papillary pattern

was considered to be analogous to the *magma reticulare* or the extraembryonic mesoderm of the exocoelom, and the presence of this pattern led to the recognition of the mesoblastic nature of this tumor [233].

The endodermal sinus pattern (**>** *Fig.* 16.9) is composed of perivascular formations, consisting of a narrow band of connective tissue with a capillary blood vessel in the center and lined by a layer of cuboidal or low columnar embryonal epithelial-like cells. The cells have large, slightly vesicular nuclei, prominent nucleoli, and show mitotic activity. The surrounding capsular sinusoid space is lined by a single layer of flat cells with prominent hyperchromatic nuclei. These characteristic perivascular

■ Fig. 16.17 Yolk sac tumor, hepatoid pattern. The tumor is composed of solid aggregates or cords of polygonal cells with even or granular eosinophilic cytoplasm resembling hepatocytes

formations are said to recapitulate the so-called endodermal sinuses [234, 235] that, although not conspicuous in the human placenta, are well-defined embryologic structures in the rat placenta. These structures are also known as sinuses of Duval, Schiller–Duval bodies, or glomerulus-like structures and resemble superficially immature renal glomeruli. When sectioned longitudinally, the perivascular structures consist of a central connective tissue core containing a longitudinal vessel surrounded by epithelial-like cells that often form small papillary formations projecting into the surrounding capsular sinusoid space.

Yolk sac tumor. Basement membrane material is frequently observed in these tumors

Fig. 16.19 Yolk sac tumor, endodermal (intestinal) pattern. The cells show abundant goblet cells

The presence of these perivascular formations or Schiller–Duval bodies can be considered diagnostic of yolk sac tumor, but in some tumors they may be poorly represented, somewhat atypical, or absent. Although the tumor should always be examined carefully and searched to identify these structures, their absence does not preclude the diagnosis, if the appearances of the tumor are typical in all other respects. Apart from the presence of the perivascular structures, this pattern consists of a complicated labyrinth of communicating cavities and channels. In addition, there are papillary processes and blood vessels surrounded by narrow connective tissue cores and epithelial-like cells radiating into the

• Fig. 16.20 Yolk sac tumor, endodermal pattern. The so-called endometrioid variant resembles secretory endometrial adenocarcinoma

surrounding stroma, resembling the typical perivascular formations but differing from them by the absence of the sinusoid space.

The solid pattern () *Fig. 16.14*) is composed of aggregates of small epithelial-like polygonal cells with clear cytoplasm and large vesicular or pyknotic nuclei with prominent nucleoli and exhibits brisk mitotic activity. The tumor cells in the solid aggregates may resemble dysgerminoma cells, but they usually show greater pleomorphism and presence of at least occasional microcysts. The presence of the latter helps differentiate between these two entities. The presence of other patterns of yolk sac tumor is also helpful in this respect, as is diffuse or focal staining for AFP and uniformly positive staining for low molecular weight cytokeratin, which are observed in yolk sac tumor and not in dysgerminoma.

The alveolar–glandular pattern (**Figs.** 16.12) is composed of alveolar, gland-like, or larger cystic spaces and cavities lined by flat or cuboidal epithelial-like cells with large, prominent nuclei and surrounded by myxomatous stroma or cellular aggregates. Some of these spaces may be lined by more than one layer of cells, and sometimes the lining cells form small papillary projections protruding into the lumen. The layer of cells lining these spaces may be continuous with the lining of the perivascular sinusoid spaces [234]. Gland-like formations lined by columnar or cuboidal epithelial-like cells may be seen and in some tumors may be prominent and may form bizarre patterns. The macrocystic pattern is observed when yolk sac tumor exhibits larger cysts in contrast to microcysts or alveolar spaces. In some tumors, this pattern may predominate.

The papillary pattern (\bigcirc *Fig. 16.15*) is composed of papillary structures consisting of connective tissue cores lined by epithelial-like cells showing a considerable degree of cellular and nuclear pleomorphism and mitotic activity. The connective tissue may show variable hyalinization. This pattern may be the predominant pattern within a tumor.

The polyvesicular vitelline pattern [235] is composed of numerous cysts or vesicles surrounded by compact connective tissue stroma, which may vary from dense to loose (\bigcirc *Fig.* 16.16). The vesicles are lined partly by columnar or cuboidal epithelial cells, frequently showing basal or paraluminal vacuolation, and partly by flat mesotheliallike cells. The individual vesicles or cysts vary in size and shape. The wall of the cyst may show a constriction dividing the part lined by the mesothelial cells from that lined by the columnar or cuboidal epithelium. This division was considered to reflect the embryologic conversion of the primary yolk sac into the secondary yolk sac [235]. Occasionally, the whole tumor may exhibit the polyvesicular vitelline pattern; such tumors have been designated as polyvesicular vitelline tumors [235].

The eosinophilic, hyaline droplets may be present either within the tumor cells or outside them; they may be numerous and prominent in some tumors (> Fig. 16.11). The droplets may be observed in tumors exhibiting all the histologic patterns described, and their identification is a helpful diagnostic feature. However, their presence is not diagnostic of yolk sac tumor because they are observed in many malignant, often poorly differentiated neoplasms, particularly clear cell carcinoma. The droplets are considered to be secreted by the tumor cells and accumulate within the cytoplasm. As the amount of secretion increases, the cell becomes distended and ruptures, discharging its contents into the surrounding tissue. Previously, these globules in yolk sac tumors have been shown by immunohistochemical techniques to contain AFP [82, 96, 191]. Other globules may contain alpha₁antitrypsin and other plasma proteins such as transferrin [82, 191, 240].

The hepatoid pattern is composed of cells with eosinophilic, uniform, or granular cytoplasm, showing a solid pattern and considerable resemblance to hepatocytes. Such collections of hepatocyte-like cells are not infrequently observed in yolk sac tumors; however, if these cells are the dominant population, the neoplasm is designated "hepatoid yolk sac tumor" [154] (\bigcirc *Fig. 16.17*). These tumors are infrequently admixed with other histologic patterns of yolk sac tumor or other neoplastic germ cell elements, and this, together with the rarity of the tumor, may cause diagnostic problems. The presence of a solid ovarian tumor composed of hepatocyte-like cells surrounded by connective tissue and forming solid aggregates, cords, or clusters and associated with elevated serum AFP in a young patient would strongly favor a diagnosis of yolk sac tumor with a hepatoid pattern. It should be noted that this variant also shows immunohistochemical expression of hepatocyte paraffin 1, similar to primary ovarian hepatoid carcinoma and metastatic hepatocellular carcinoma involving the ovary [152].

The presence of hyaline, PAS-positive material forming bands or connective tissue cores surrounded by tumor cells is not an infrequent finding in yolk sac tumor; in some tumors, it may be a prominent feature, with the tumor cells resting on and surrounding the bands of hyaline material (\bigcirc *Fig. 16.18*). When this material is deposited in linear bands in stroma, other authors have designated this the "parietal pattern" of yolk sac tumor [185]. There may be an increased amount of the eosino-philic, PAS-positive globules described here in the vicinity of the hyaline bands, suggesting a relationship between them and a possibility of common origin [235].

Although scattered primitive endodermal glands are not uncommon in yolk sac tumors, the glandular or primitive endodermal (intestinal) pattern, in which the tumor is composed entirely of primitive endodermal glands, is encountered only occasionally [40] (> Fig. 16.19). This pattern has been designated as "glandular (intestinal) yolk sac tumor." The tumor in these cases is composed of nests or collections of primitive endodermal glands surrounded by connective tissue, which varies from loose and edematous to dense and hyalinized. The degree of differentiation varies from primitive to relatively well differentiated. The glands may contain inspissated secretion within the lumen, and the tumor may resemble a mucinsecreting adenocarcinoma. Ultrastructurally, the nuclei are large and show prominent nucleolonema, whereas the cytoplasm contains many ribosomes, rough endoplasmic reticulum, and mitochondria. Dense amorphous intracellular material is also present. Yolk sac tumors showing this pattern have been associated with very high serum levels of AFP [40]. It is of interest that the only tumor that was diploid in a series of 20 yolk sac tumors was a tumor of the pure glandular (primitive intestinal) type, whereas all the other tumors were aneuploid [93].

The presence of primitive endodermal glandular tissue, lobular or nest-like pattern, and high levels of serum AFP differentiate this type of yolk sac tumor from mucinous tumors of the ovary. A variant of this pattern composed of primitive glands of various sizes lined by tall columnar or cuboid cells with basophilic or clear cytoplasm containing subnuclear vacuoles resembling

Yolk sac tumor. The tumor shows uniform strongly positive staining for AFP

secretory endometrial carcinoma, so-called endometrioid variant (**>** *Fig. 16.20*), has been described [39]. This variant may be seen in pure form, showing a pronounced glandular or villoglandular pattern, or may be composed of glands surrounded by fibrous or densely cellular stroma [39]. Elevated serum levels of AFP and immunohistochemical demonstration of AFP within the tumor cells confirm the diagnosis of yolk sac tumor (**>** *Fig. 16.21*).

Occasionally, yolk sac tumor may exhibit a greater degree of cellular and nuclear pleomorphism with some giant cells, usually mononucleated, but sometimes multinucleated. This picture may be seen in association with the solid, papillary, and glandular–alveolar patterns. The pleomorphic cells show variable immunohistochemical staining for AFP, and the absence of hCG confirms that the giant cells are not trophoblastic in origin but are part of a yolk sac tumor.

Immunohistochemical Features and Differential Diagnosis

Yolk sac tumor may be confused with clear cell and endometrioid carcinomas, embryonal carcinoma, and dysgerminoma. Clear cell carcinoma shows more regular tubular patterns, lacks the honeycomb network composed of microcysts, and has papillary frond-like projections that are often lined by clear or hobnail cells. The typical perivascular formations, endodermal sinuses, or Schiller– Duval bodies present in yolk sac tumor are absent. The epithelial cells lining the tubules are cuboidal with clear cytoplasm or are hobnail with nuclei bulging into the lumen. Areas composed of large polygonal cells with clear cytoplasm and small, dark, uniform, centrally situated nuclei resembling those of renal carcinoma are present. When clear cell carcinoma is composed entirely of tubules or spaces, confusion may arise with the polyvesicular vitelline pattern of yolk sac tumor. However, the epithelial lining in clear cell carcinoma is usually composed of hobnail cells and not of the two types of epithelia in the vesicles comprising the polyvesicular vitelline pattern. The cystic spaces are more tubular and less vesicle-like. Clear cell carcinoma shows diffuse immunohistochemical expression of CK7 and EMA and is usually negative for AFP while yolk sac tumor typically shows the opposite immunoprofile [54, 157]. Glypican-3 is usually diffusely expressed in yolk sac tumor, whereas clear cell carcinoma is either negative or focally positive; [54] however, the extent of expression of this marker can overlap between both tumors [107]. SALL4 is highly sensitive and specific for primitive germ cell tumors, including yolk sac tumor [32].

The endometrioid-like glandular variant of yolk sac tumor can simulate endometrioid carcinomas with secretory differentiation. However, women with yolk sac tumor are typically younger and have an elevated serum AFP level while a subset of patients with endometrioid carcinoma has endometriosis in the ipsilateral ovary or elsewhere in the pelvic cavity. Other admixed classic patterns of yolk sac tumor and endometrioid carcinoma, as well as hyaline globules in the former and squamous differentiation in the latter, help support either diagnosis. Demonstrating immunohistochemical expression of AFP in volk sac tumor and CK7 and EMA in endometrioid carcinoma is also useful [157]. Estrogen and progesterone receptors are not detected in yolk sac tumors [92], but diffuse expression of these markers is common in endometrioid carcinomas [261]. It should be noted, however, that rare cases of mixed yolk sac tumor and endometrioid carcinoma have been reported [125].

The embryonal carcinoma, which is uncommon in the ovary [82, 97, 234], lacks the specific patterns observed in the yolk sac tumor. In its undifferentiated form, it is composed of aggregates of primitive embryonal cells. The tumor cells are frequently larger than those seen in the solid cellular aggregates in yolk sac tumor. The cytoplasm is more granular, there is more marked cellular and nuclear pleomorphism, and the nucleoli are more prominent. Even when the tumor is better differentiated, with the embryonal cells forming cords, tubules, or papillae and lining clefts or spaces, it still lacks the typical patterns associated with yolk sac tumor.

Yolk sac tumor with a solid pattern may be confused with dysgerminoma. The cells of dysgerminoma are usually more uniform, lack microcysts, and are usually associated with lymphocytic and granulomatous reactions. The cells of yolk sac tumor are uniformly low molecular weight cytokeratin positive [119, 120]. The presence of this feature as well as positive staining for AFP and lack of expression of CD117 and OCT-4 differentiate between yolk sac tumor and dysgerminoma, in which the latter shows only occasional cytokeratinpositive cells.

Yolk sac tumor, because of its cystic pattern and the presence of numerous small blood vessels, has been confused with vascular tumors, but careful examination reveals that the pattern is more cystic, and a vascular tumor can be excluded with the use of appropriate immunohistochemical stains. It should be pointed out that yolk sac tumor elements may show hematopoiesis and are sometimes intimately associated with immature vascular tissue in some mixed germ cell tumors; this may also contribute to diagnostic problems. Confusion may arise occasionally, with some Sertoli-Leydig cell tumors showing a retiform pattern, especially when the latter are associated with elevated serum levels of AFP [215, 257]. The presence of more marked cellular and nuclear pleomorphism, brisk mitotic activity, and other histologic patterns observed in yolk sac tumor (as well as their absence in Sertoli-Leydig cell tumors) aid in the differential diagnosis. Immunohistochemical expression of inhibin further confirms the diagnosis of Sertoli-Leydig cell tumor.

Occasionally, confusion may arise with juvenile granulosa cell tumor when it presents with small vesiclelike collections of cells surrounded by connective tissue stroma that simulate the vesicles seen in polyvesicular vitelline yolk sac tumor. Presence of solid nests typical of juvenile granulosa cell tumor, absence of the various patterns of yolk sac tumor, absence of immunohistochemical staining for AFP, immunohistochemical expression of inhibin, and a lack of elevated serum levels of AFP indicate that the tumor is a juvenile granulosa cell tumor.

Clinical Behavior and Treatment

Yolk sac tumor is highly malignant, metastasizing early and invading surrounding structures and organs. Local invasion and intra-coelomic spread frequently lead to extensive involvement of the abdominal cavity. Yolk sac tumor metastasizes first via the lymphatic system to the para-aortic and common iliac lymph nodes and then to the mediastinal and supraclavicular lymph nodes. Hematogenous spread occurs later, with metastases found in the lungs, liver, and other organs. The tumor is locally aggressive, and spread beyond the ovary is observed in a number of patients at diagnosis [65, 82, 96]. Recurrences in the pelvis are frequent, even when the tumor and the affected adnexa have been excised completely [82, 96]. Such recurrences usually appear within a few weeks or months after excision of the primary tumor.

Until the advent of efficacious combination chemotherapy, the treatment of patients with yolk sac tumor was very disappointing. The treatment was primarily surgical [96, 234]. Extensive surgery did not improve prognosis [96, 234]. The few long-term survivors in the past had tumors confined to the ovary, and most were treated by unilateral adnexectomy [96, 234]. Since then, there has been marked improvement in prognosis with conservative surgery (unilateral salpingo-oophorectomy) and adjuvant multiagent combination chemotherapy [64, 140]. The combination chemotherapy originally used was dactinomycin, vincristine, and cyclophosphamide or dactinomycin, 5fluorouracil, and cyclophosphamide. Although this therapy proved to be effective in many cases, recurrences were still frequent.

The introduction of a combination of cisplatin, bleomycin, and vinblastine, which has been superseded by less toxic cisplatin, etoposide (VP 16), and bleomycin (BEP) in combination, has been found to be much more effective and has produced remissions in patients with advanced-stage disease and in patients in whom other combinations of multiagent chemotherapy have failed [64, 140]. This combination chemotherapy has revolutionized the treatment of patients with yolk sac tumor. Complete cure for all stages is more than 80% [64, 140]. The occasional cases of pure hepatoid and glandular (primitive intestinal) yolk sac tumor show a less satisfactory response to combination chemotherapy and are therefore associated with poorer prognosis [39, 40, 154].

Serum AFP determination is useful diagnostically and in monitoring therapy. It should be noted, however, that a normal result may not always indicate the absence of active disease but only the absence of the tumor element associated with AFP synthesis. Preoperatively, if the tumor contains yolk sac tumor elements, considerable amounts of AFP can be detected in the serum. AFP levels fall postoperatively and, if there are no metastases, reach normal levels within 4–6 weeks, depending on the preoperative serum AFP level. Serum alpha₁-antitrypsin levels can also be used to monitor disease activity, but it is inferior to AFP [224].

Beta-hCG is normal in patients with yolk sac tumor. Carcinoembryonic antigen (CEA) has also been studied in patients with germ cell neoplasms and has been found to be of no value as a tumor marker in this group of patients [225].

Embryonal Carcinoma

The term embryonal carcinoma in this text includes only ovarian neoplasms showing histologic appearances resembling those observed in embryonal carcinomas occurring in the testis of adults. Dixon and Moore [50] consider embryonal carcinoma as both a morphologic and a conceptual entity, and this interpretation is being followed. Embryonal carcinoma is considered to be the least differentiated form of germ cell tumor, which may differentiate either to somatic (teratomatous tumors of various degrees of differentiation) or extraembryonal structures, forming yolk sac or vitelline (yolk sac tumor) or trophoblastic structures (choriocarcinoma) (**>** *Fig.* 16.1). Although ovarian embryonal carcinoma [82, 97] shows similar appearances and is considered to be homologous with its testicular counterpart, it is uncommon as a component of mixed germ cell tumors and rare as a pure entity. However, tumors showing this histologic pattern are relatively frequent in the testis. The reason for this difference is unknown. Ovarian embryonal carcinoma is usually combined with other neoplastic germ cell elements, most frequently yolk sac tumor, and forms a part of a mixed germ cell tumor [82, 98, 226]. Embryonal carcinoma occasionally has been observed in association with gonadoblastoma [182, 211, 216].

Clinical Features

The age, clinical presentation, and findings of embryonal carcinoma are similar to those observed in patients with other malignant germ cell neoplasms, with the tumor almost always occurring in children and young adults [82, 97, 226].

Embryonal carcinoma may produce AFP, even when it is not combined with yolk sac tumor, but the serum AFP levels in such cases are only slightly elevated. When embryonal carcinoma contains syncytiotrophoblastic giant cells, as is often the case, or is combined with choriocarcinoma, it produces hCG and is associated with endocrine manifestations, such as isosexual precocious puberty in children and abnormal vaginal bleeding in adults [97]. A positive pregnancy test is found in almost all such patients.

Gross Features

Because embryonal carcinoma usually is a component of mixed germ cell tumors, the appearances of the tumor vary according to the type and amount of the different components present. On sectioning, the embryonal carcinomatous component is solid, gray-white, and slightly granular, with foci of necrosis and hemorrhage in the larger tumors.

Microscopic Features

In its most primitive and undifferentiated form, embryonal carcinoma is composed of solid aggregates of epithelial-like, medium to large, polygonal or ovoid cells containing an ample amount of somewhat pale eosinophilic granular cytoplasm, with poorly defined cytoplasmic borders, frequently forming a syncytial arrangement (**)** *Figs. 16.22–16.24*). The cells have a large, prominent, centrally situated, and somewhat irregular vesicular or hyperchromatic nucleus with a fine nuclear membrane and frequently more than one nucleolus. Mitotic activity is usually brisk, and abnormal mitoses are frequently seen. Pleomorphism is usually marked. Giant cells and multinucleated cells may be seen.

In the better differentiated tumors, the cells, apart from forming solid areas, also tend to line clefts and spaces and form papillae. The cells appear more epithelial than those of the more undifferentiated type, being more cuboidal or columnar in shape. Although there is

 Fig. 16.22
Embryonal carcinoma. The tumor shows pseudoglandular and solid patterns

Embryonal carcinoma. The tumor cells display more nuclear pleomorphism and overlapping of nuclei compared with dysgerminoma

Fig. 16.24

Embryonal carcinoma. The tumor shows a solid pattern and a syncytiotrophoblastic giant cell. Note the characteristic nuclei of embryonal carcinoma

a suggestion of glandular differentiation, true gland formation is absent. The papillae are composed of solid collections of cells or may contain a cystic space or a small vessel surrounded by tumor cells. They must be differentiated from perivascular formations observed in yolk sac tumor. Very primitive mesenchymal tissue may be present in conjunction with the epithelial-like component. Syncytiotrophoblastic giant cells immediately adjacent to aggregates of embryonal carcinoma cells or lying isolated in the stroma are frequently found. Foci of necrosis and hemorrhage are also frequent.

Immunohistochemical Features and Differential Diagnosis

Embryonal carcinoma may be present in the form of small solid aggregates or pseudoglandular or cleft-like formations surrounded by better-differentiated malignant teratomatous elements showing somatic differentiation. It may coexist with other neoplastic germ cell elements, such as yolk sac tumor, immature or mature teratoma, choriocarcinoma, polyembryoma, or dysgerminoma. Differentiation from dysgerminoma is important because of a totally different prognosis and response to treatment. It is usually the solid primitive type of embryonal carcinoma that is more likely to be confused with dysgerminoma, but the presence of clefts, alveoli, or cell-lined spaces militates against the diagnosis of dysgerminoma.

The cells of embryonal carcinoma are usually larger and show much more pleomorphism. Mitotic activity is usually more prominent, and bizarre mitoses are more frequent. The nuclear membrane is less sharp and the nuclei are more irregular, larger, and usually contain more than one dark hyperchromatic nucleolus, in contrast with the rounded, prominent, usually single, and frequently eosinophilic nucleolus of dysgerminoma. The presence of connective tissue stroma infiltrated by lymphocytes and at times a granulomatous reaction is a prominent feature of dysgerminoma. These features usually are absent in embryonal carcinoma. Embryonal carcinoma shows immunohistochemical expression of cytokeratin, whereas most dysgerminomas are negative. In contrast, dysgerminoma expresses CD117, which is negative in embryonal carcinoma. In addition, some embryonal carcinomas stain for AFP, in contrast to dysgerminomas, which are invariably negative. Most embryonal carcinomas stain for CD30 (> Fig. 16.25), whereas only occasional dysgerminomas are CD30-positive. Recently, OCT-4 has been found to be consistently positive in embryonal carcinoma, but this marker is also expressed in dysgerminoma. SALL4 is highly sensitive and specific for primitive germ cell tumors, including embryonal carcinoma [32].

Clinical Behavior and Treatment

Embryonal carcinoma of the ovary is a highly malignant neoplasm. It is aggressive locally, spreads extensively in the abdominal cavity, and metastasizes early. The metastatic spread is similar to that of other malignant germ cell neoplasms, taking place first via the lymphatics and later by hematogenous spread. The primary treatment of embryonal carcinoma is unilateral salpingo-oophorectomy and

Fig. 16.25
Embryonal carcinoma. Diffuse expression of CD30

chemotherapy. The response to combination chemotherapy using bleomycin, vinblastine, and cisplatin or, preferably, cisplatin, etoposide (VP 16), and bleomycin [64, 140] is similar to that observed in patients with embryonal carcinoma of the testis.

Polyembryoma

General Features

Polyembryoma is a rare ovarian germ cell neoplasm composed of numerous embryoid bodies resembling morphologically normal presomite embryos [19, 89, 207]. Similar homologous neoplasms occur more frequently in the human testis [19, 55], although pure polyembryoma is very rare. In all ovarian cases, the polyembryoma was associated with other neoplastic germ cell elements, mainly immature or mature teratoma [19, 89, 192, 207]. All these tumors occurred in young patients or in patients in the reproductive age group [19, 89, 192, 207]; the oldest patient was 38 years old [192]. The clinical findings are similar to those observed in patients with other malignant germ cell neoplasms of the ovary. It should be noted that polyembryoma is not the same entity as "diffuse embryoma," which is a form of mixed germ cell tumor composed of yolk sac tumor and embryonal carcinoma with a unique admixture of both components [185].

Histogenesis

There are conflicting views of the origin of embryoid bodies. It has been suggested that they arise by parthenogenic development from primitive germ cells present in an immature (malignant) teratoma [111, 145, 192]. Other investigators question this view as well as the entire concept that embryoid bodies bear a close similarity to early human embryos because embryoid bodies never appear to develop beyond the 18-day stage [19]. They consider that embryoid bodies probably develop transiently by bizarre differentiation, possibly in response to local release of factors in malignant teratomas of the gonads.

Another view that has been advanced accepts the morphologic similarities between the early embryo and the embryoid bodies but disputes their parthenogenic origin [55, 147, 201]. It maintains that embryoid bodies are formed after initiation of teratogenesis, most likely from multipotential malignant embryonal cells present in a tumor and not directly from germ cells [202]. This concept is supported by the observations of the development of embryoid bodies from undifferentiated embryonal cells in strain 129 mice. The tumor, a teratoma that had been serially transplanted for many years, was considered to be devoid of germ cells [147, 201]. These findings are in accordance with the view that embryoid bodies probably persist only transiently within the tumor, and while new embryoid bodies are being formed others lose their identity and their multipotential cells undergo further differentiation [55]. Although the origin and development of embryoid bodies are still a matter of dispute, the view that they originate from multipotential malignant embryonal cells, which is supported by experimental observations [147, 201], is most favored at present.

Gross Features

Polyembryoma is usually unilateral. Macroscopically, the tumor resembles other malignant germ cell tumors, varying in size from 9.5 cm [19] to tumors filling almost the whole abdominal cavity and invading the surrounding structures [192]. The tumor is usually solid and contains hemorrhagic and necrotic areas.

Microscopic and Immunohistochemical Features

Polyembryoma is composed of numerous embryoid bodies, and the better-differentiated ones are composed of structures resembling an embryonic disk, amniotic cavity, and yolk sac surrounded by primitive extraembryonic mesenchyme (\triangleright *Fig. 16.26*). Sometimes trophoblastic

Fig. 16.26 Polyembryoma. The embryoid body shows amniotic cavity (right), embryonic disk (center), and atypical yolk sac (left)

differentiation may be seen in the vicinity of the embryoid body. When the embryoid bodies are less well formed, they are composed of a medullary plate and amnion associated with a blastocystic space or with extraembryonic mesenchyme. They may have two or more amniotic cavities and share a single yolk sac cavity or vice versa. There may be a considerable disproportion between the two cavities, and the cavities may be malformed. There also may be considerable variation in size between the different embryoid bodies; some may be more primitive and others appear to be better developed.

Some embryoid bodies may be malformed and show bizarre appearances. None of the embryoid bodies appear to have developed beyond the 18-day stage. The embryonic disk of a typical embryoid body is lined on one side by cuboidal epithelial cells of uniform size, resembling endoderm, and on the other by tall columnar epithelium, resembling ectoderm. The latter merges with low cuboidal epithelium lining the rest of the cavity, which resembles the amnion. The cavity resembling the yolk sac is on the opposite side of the embryonic disk from the amnion (\triangleright *Fig. 16.26*). The embryoid bodies are surrounded by extraembryonic mesenchyme, which is composed of either closely or more loosely packed spindle-shaped cells of regular appearance and showing occasional mitotic figures. Loose myxomatous areas may be present.

Occasionally, embryoid bodies resemble earlier developmental stages, mainly the blastocyst and morula stage and form numerous round or oval structures. In some tumors this pattern may predominate, although occasional fully developed embryoid bodies may be seen [89]. Teratomatous structures in various stages of differentiation are frequently seen interspersed with the embryoid bodies. In one reported case [19], hCG and human placental lactogen were demonstrated within syncytiotrophoblastic cells that were present in the vicinity of the embryoid bodies. Cytotrophoblastic cells were not identified in this tumor. In another reported case, there was elevation of serum AFP and hCG. AFP was demonstrated by immunohistochemistry within the cells lining the yolk sac cavities and hCG within the syncytiotrophoblastic giant cells that were present in the vicinity of the embryoid bodies [207].

Clinical Behavior and Treatment

Polyembryoma is a highly malignant germ cell neoplasm. In most cases, it has been associated with invasion of adjacent structures and extensive metastases, which were mainly confined to the abdominal cavity [192].

The primary treatment of polyembryoma is surgical, and because the tumor is usually unilateral unless there is spread beyond the ovary, excision of the tumor and the adjoining adnexa is the treatment of choice. Polyembryoma responds to the combination chemotherapy used in treatment of malignant germ cell tumors [64, 207].

One patient with a relatively small mobile tumor, absence of capsular penetration, and no evidence of metastases survived more than 5 years [19]. Another patient was alive and free of disease for more than 12 years after excision of the affected adnexa and excision of intra-abdominal metastases composed of grade 1 immature teratoma [89]. A third patient was well and disease-free 6 months after diagnosis [207]. Before the introduction of effective combination chemotherapy, most patients with polyembryoma died of their disease.

Choriocarcinoma

General Features

Pure ovarian choriocarcinoma of germ cell origin is a rare neoplasm [81, 82, 185, 247], and even the presence of choriocarcinomatous elements admixed with other neoplastic germ cell elements is uncommon. In most cases, the tumor is admixed with other neoplastic germ cell elements, and their presence is diagnostic of non-gestational choriocarcinoma, except for the remote possibility of the tumor being a gestational choriocarcinoma metastatic to an ovarian germ cell tumor. The presence of other neoplastic germ cell elements is a particularly helpful diagnostic feature in postmenarchal patients in whom exclusion of gestational origin of the tumor may be difficult. In view of this, non-gestational choriocarcinoma may be diagnosed with confidence in postmenarchal patients and not only in young children, as had been considered earlier. A small number of ovarian germ cell tumors containing choriocarcinoma have been reported [81, 112, 247]. The tumor occurs in children and young adults. In some series, 50% of cases occurred in children who had not reached puberty [112]. This high frequency in children may stem from the reluctance of making the diagnosis in adults. Detection of paternal DNA has been successful in differentiating gestational and nongestational choriocarcinoma. In two cases, DNA polymorphism analysis confirmed the non-gestational origin of the tumor [190, 241].

Histogenesis

Choriocarcinoma of the ovary may originate in three different ways: (1) as a primary gestational choriocarcinoma associated with ovarian pregnancy, (2) as metastatic choriocarcinoma from a primary gestational choriocarcinoma arising in other parts of the genital tract, mainly the uterus, and (3) as a germ cell tumor differentiating in the direction of trophoblastic structures, usually admixed with other neoplastic germ cell elements. In each case, it is important to ascertain the mode of origin of the tumor because this has important therapeutic and prognostic implications. Alternatively, choriocarcinoma of the ovary may be divided into two broad groups: (1) gestational choriocarcinoma encompassing the first two groups mentioned and (2) non-gestational choriocarcinoma, a germ cell tumor differentiation toward trophoblastic structures. As this chapter is concerned solely with germ cell tumors, only the non-gestational choriocarcinoma is discussed here.

Clinical Features

The clinical findings in patients with ovarian nongestational choriocarcinoma are similar to those observed in patients with other malignant ovarian germ cell neoplasms, except that they may be modified by the endocrine activity of the tumor, which secretes hCG. This effect is particularly noticeable in prepubertal children who show evidence of isosexual precocious puberty, with mammary development, growth of pubic and axillary hair, and uterine bleeding. Adult patients may have signs of ectopic pregnancy. Very occasionally, the tumor may cause symptoms of thyrotoxicosis, including a severe acute form. Because the non-gestational choriocarcinoma, resembling its gestational counterpart, is associated with increased production of hCG, determination of urinary or plasma hCG is a useful diagnostic test. Serum hCG levels are useful in monitoring response to therapy. It should be noted that normal levels of hCG do not exclude the presence of metastases or recurrences composed of other neoplastic germ cell elements.

Gross Features

The tumor typically is large, unilateral, solid, gray-white, and hemorrhagic. Necrosis may be evident. Because most of these tumors are composed of a combination of neoplastic germ cell elements, the appearances tend to vary according to the elements present in the tumor.

Microscopic and Immunohistochemical Features

Choriocarcinoma is composed of two cell populations, mononucleate and multinucleate trophoblast (● *Fig. 16.27*). The former is composed of cytotrophoblast and intermediate trophoblast and contains medium-sized polygonal, round, or oval cells with clear cytoplasm and sharp borders. Some cells have centrally situated, small, round, and hyperchromatic nuclei, whereas others have larger vesicular nuclei containing nucleoli and showing

Fig. 16.27

Choriocarcinoma. Cytotrophoblast composed of mediumsized cells are situated centrally; syncytiotrophoblast composed of very large multinucleated cells are situated peripherally brisk mitotic activity. The multinucleate population corresponds to syncytiotrophoblast, which is composed of large basophilic, vacuolated cells with irregular outlines, and although frequently elongated they may vary in shape. These cells contain multiple hyperchromatic nuclei, varying in shape and size. The cytotrophoblastic cells are usually disposed centrally within a tumor mass and are partly or completely surrounded by irregular collections or layers of the syncytiotrophoblastic cells.

There is a considerable variation in the pattern and in the ratio of the two components in different parts of the same tumor and in different tumors. The tumor cells form solid aggregates, nearly always associated with hemorrhage and necrosis. At times the tumor is limited to the periphery of the hemorrhagic mass. When the tumor is combined with other germ cell elements, the choriocarcinoma may form small nodules associated with hemorrhage and surrounded by other germ cell elements. The presence of other germ cell elements within the tumor is a frequent finding. As choriocarcinoma is often hemorrhagic, a careful search may be necessary to demonstrate the presence of choriocarcinomatous elements.

The cytotrophoblast is the more primitive element, and the syncytiotrophoblast is formed from it either directly or indirectly. The syncytiotrophoblast is the differentiated, nondividing, hormone-secreting component. These findings are supported by electron microscopic and immunohistochemical studies [148, 150]. Immunohistochemical staining for beta-hCG provides a useful confirmatory diagnostic method. Although intermediate trophoblastic cells may be seen occasionally in non-gestational choriocarcinomas, ovarian placental site trophoblastic tumors have been reported only rarely [8, 14, 41].

Clinical Behavior and Treatment

Non-gestational choriocarcinoma of the ovary is a highly malignant germ cell neoplasm. It invades adjacent structures, spreads widely throughout the abdominal cavity, and metastasizes via the lymphatics and the blood vessels. Although gestational choriocarcinoma tends to spread primarily via the bloodstream, non-gestational choriocarcinoma shows lymphatic and intra-abdominal spread as well as hematogenous spread. Sometimes the hematogenous spread may be less marked.

Until the introduction of effective combination chemotherapy, the prognosis of patients with choriocarcinoma was distinctly unfavorable but was somewhat better than of patients with yolk sac tumor. Treatment has been revolutionized by the introduction of combination chemotherapy containing cisplatin with marked improvement in prognosis and survival. Cisplatin, etoposide (VP 16), and bleomycin currently is the most favored combination [64, 140].

Teratoma

The origin of teratomas has been a matter of interest, speculation, and dispute for centuries. The parthenogenic theory, which suggests an origin from the primordial germ cell, is now the most widely accepted. Two other theories, one suggesting an origin from blastomeres segregated at an early stage of embryonic development and the second suggesting an origin from embryonal rests have few adherents currently. Support for the germ cell theory has come from the anatomic distribution of the tumors, which occur along the line of migration of the primordial germ cells from the yolk sac to the primitive gonad, and from the fact that the tumors occur most commonly during the years of reproductive activity. Support also comes from animal experiments in which cystic teratomas can be produced only during the period of reproductive activity of the gonad, as in roosters injected with zinc and copper salts [15, 33], and from the karyotyping of teratomas. The karyotype of mature ovarian teratomas is 46,XX [103, 158].

The histogenesis of mature cystic teratoma of the ovary has been studied using both cytogenetic techniques and the electrophoretic patterns of four enzymes in normal as well as in tumor cells. These studies demonstrated that teratomas are of germ cell origin and arise from a single germ cell after the first meiotic division [102, 103]. Subsequent studies using more advanced cytogenetic techniques further confirmed these observations. Although most mature cystic teratomas arise in this manner, some arise before the first meiotic division [126, 138]. This indicates that both modes of origin occur. The classification of ovarian teratomas is shown in > Table 16.1. Briefly, they are divided into three main groups: (1) immature teratomas, (2) mature teratomas, and (3) monodermal and highly specialized teratomas. Most cases (99%) are mature cystic teratomas also known as dermoids or dermoid cysts.

Immature Teratoma

Immature teratomas are composed of tissues derived from the three germ layers – ectoderm, mesoderm, and endoderm – and, in contrast to the much more common mature teratoma, they contain immature or embryonal structures. Mature tissues are frequently present and sometimes may predominate. In these cases, the tumor should be differentiated from a mature teratoma with malignant transformation. The presence of immature or embryonal elements as opposed to the neoplastic transformation of mature tissues differentiates between these two types of neoplasm.

Clinical Features

The immature teratoma of the ovary is an uncommon tumor, comprising less than 1% of teratomas of the ovary [27, 34, 109, 168, 185, 255]. In contrast with the mature cystic teratoma, which is encountered most frequently during the reproductive years but occurs at all ages, the immature teratoma has a specific age incidence, occurring most commonly in the first 2 decades of life and being almost unknown after the menopause [27, 31, 109, 185, 255]. In view of this, teratomas occurring in childhood, adolescence, and early adult life should always be examined carefully and thoroughly sampled.

The tumor is usually asymptomatic until it reaches a considerable size. It tends to grow rapidly and may manifest itself as a pelvic or lower abdominal mass. It may cause pressure symptoms, abdominal heaviness, dull pain, or it may undergo torsion, causing acute abdominal pain.

Gross Features

The tumor is usually unilateral [27, 31, 34, 74, 255], but may coexist with a mature cystic teratoma in the opposite ovary [252], as is seen in at least 10–15% of cases. Immature teratomas are usually larger than their mature counterparts, with the reported range from 9 to 28 cm in the largest dimension [31]. They may form a round, oval, or lobulated, soft or firm solid mass, which frequently contains cystic structures with solid areas present in the cyst wall [27, 31, 34, 74, 109, 252]. The tumor is often prone to perforate its capsule, which is not always well defined [31, 252]. The cut surface is usually variegated, trabeculated, and lobulated, varying in color from gray to dark brown. Occasionally, foci of cartilage or bone may be recognizable and hair may be present. The cystic areas are usually filled with serous or mucinous fluid, colloid, or fatty material.

Microscopic Features

Immature teratomas are composed of a variety of immature and mature tissues derived from the three germ layers although usually derivatives of all the three germ layers are present. Occasionally, the tumor may be composed of a small number of tissues. Ectoderm is usually represented by neural tissue. Glia, ganglion cells, neuroblastic tissue, neuroepithelium, nerve trunks, and ocular structures are often represented (\bigcirc *Figs. 16.28* and \bigcirc *16.29*). Skin elements, including pilosebaceous units, sweat eccrine glands, and hair, are frequently present. Mesodermal elements include fibrous connective tissue; cartilage; bone; muscle, usually smooth but sometimes striated (\bigcirc *Fig. 16.30*); lymphoid tissue; and undifferentiated embryonic mesenchyme. Endodermal elements are usually represented by tubules lined by columnar, sometimes

Fig. 16.28

Immature teratoma. The immature neuroepithelium is composed of solid patterns punctuated by rosettes

Fig. 16.29 Immature teratoma. The tumor shows both immature neuroepithelial and mesenchymal elements

Fig. 16.30 Immature teratoma. The tumor shows immature cartilage and rhabdomyoblastic components

ciliated, epithelium. Occasionally, gastrointestinal or renal epithelium may be present. Endocrine elements may be present but, apart from thyroid tissue, are uncommon.

All these tissues, which may be in stages of maturity varying from embryonic to mature, are scattered haphazardly throughout the tumor and so differ from the orderly organoid arrangement seen in a mature teratoma. In cases in which the tumor is composed mainly of mature tissues, differentiation from mature teratoma may be difficult, and patients have been diagnosed as having a benign lesion only to return within a short time with recurrence. In a number of such cases, review of the material taken from the original tumor has revealed immature elements. Therefore, careful examination and thorough sampling of the tumor are strongly recommended. Immature teratoma may be combined with other neoplastic germ cell elements, such as yolk sac tumor, dysgerminoma, embryonal carcinoma, choriocarcinoma, and polyembryoma. It can therefore form a part of a malignant germ cell tumor composed of two or more neoplastic germ cell elements (mixed germ cell tumor). Immature teratoma has been reported to develop from the germ cell element of gonadoblastoma and mixed germ cell-sex cord-stromal tumor.

Differential Diagnosis

Immature teratoma must be differentiated from malignant mesodermal mixed tumor (MMMT), which although occurring most frequently in the uterus, also occurs in the ovary. MMMT is composed of tissue resembling derivatives of müllerian mesoderm, a primitive structure that gives rise to both the stroma and the epithelium of the endometrium. The characteristic histologic appearance of MMMT combined with the absence of other germ layer derivatives distinguish MMMT from teratoma; neuroectodermal derivatives, prominent in solid immature teratoma, are seen only exceptionally in MMMT. MMMT occurs most frequently in postmenopausal women between the ages of 50 and 70 years and, unlike immature teratoma, occurs only occasionally in younger patients. MMMTs are composed of sarcomatoid and carcinomatous tissue. The carcinoma is invariably an adenocarcinoma, squamous cell carcinoma, or adenosquamous carcinoma, and the sarcomatoid elements may be composed of a wide variety of tissues, including leiomyosarcoma, chondrosarcoma, rhabdomyosarcoma, fibrosarcoma, undifferentiated sarcomatous tissue, and myxomatous tissue. MMMT does not exhibit the great variety of tissues present in teratoma, and the tissues present in MMMT generally form more typical sarcomatous or carcinomatous patterns (see O Chap. 10, Mesenchymal Tumors of the Uterus).

Clinical Behavior and Treatment

Immature teratoma is a malignant neoplasm that usually grows rapidly, penetrates its capsule, and forms adhesions to the surrounding structures. It spreads throughout the peritoneal cavity by implantation and metastasizes first to the retroperitoneal, para-aortic, and more distant lymph nodes and later to the lungs, liver, and other organs. Peritoneal implants and metastases are not infrequently present at operation for the removal of the primary tumor [31, 252]. Excision of the tumor is often followed by a local recurrence within a few weeks or months. Recurrences usually occur within the first year after the primary treatment [31]. Rupture of the tumor with spillage of the contents during operation is not infrequent, but because of the satisfactory response of the tumor to combination chemotherapy the favorable prognosis is not affected. The metastases and peritoneal implants may be composed of different tissues, and thus their teratomatous nature is readily apparent, but they may also be composed of a single tissue. The histologic appearances of the metastases and of the peritoneal implants may or may not reflect the appearances of the primary tumor. In two related conditions, the growing teratoma syndrome and chemotherapeutic retroconversion [51], the metastases of immature teratoma may consist of pure mature teratoma after chemotherapy.

It has been noted that there is a good correlation between the histologic appearances of the tumor and prognosis [27, 74, 130, 131]. Very immature and poorly differentiated tumors have been found to be associated with worse prognosis, whereas a more favorable outcome has been observed in patients with more mature and better differentiated tumors [74, 130, 252]. One study of immature teratoma in children showed that less mature tumors were more likely to be associated with yolk sac tumor [74].

Grading

O'Connor and Norris [131] proposed that immature teratomas should be divided into two grades, those with a slight degree of immaturity (grade 1; low grade), which are not treated with combination chemotherapy, and those with a more marked degree of immaturity (grades 2 and 3; high grade), which are treated. It was demonstrated that although there was considerable interand intraobserver disagreement when a large series of immature teratomas were being graded into three grades, this was markedly decreased when a two-grade system was used. The study further confirmed the good correlation between the grade of the tumor and behavior. Furthermore, it should be noted that rare and small microscopic foci of immature tissue within a mature cystic teratoma have been associated with an excellent outcome [256].

Ovarian immature teratomas and their metastases should be graded because the grade correlates with outcome and determines which patients receive chemotherapy. In order to ensure that the primary ovarian tumor has been adequately sampled, one block of tissue per centimeter of the greatest tumor dimension should be submitted. The currently used grading system is the Armed Forces Institute of Pathology (AFIP) system, which is endorsed by the WHO. In this system, it is the immature neuroepithelium that is graded. The grade is based on the *aggregate amount* of immature neuroepithelium on *any single slide* [130, 131] \bigcirc *Table 16.2*:

Metastases/implants are considered Grade 0 when no immature tissue is present, regardless of the grade of the ovarian tumor. In particular, a specific type of Grade 0 implant composed entirely of mature glial tissue

Table 16.2

Grading of immature teratomas

Grade 1	Amount of immature neuroectoderm occupies \leq 1 low-power (4x objective) magnification field
Grade 2	Amount of immature neuroectoderm occupies >1 but \leq 3 low-power (4x objective) magnification fields
Grade 3	Amount of immature neuroectoderm occupies >3 low-power (4x objective) magnification fields

("gliomatosis peritonei") is associated with an excellent outcome.

In the opinion of some authorities on the topic, when tissues other than neuroepithelium are present, their degree of immaturity must also be taken into consideration when grading; however, this is not the method specified by the WHO.

The recommended treatment for patients with grade 1 (low-grade) immature teratoma confined to one ovary is unilateral salpingo-oophorectomy and careful follow-up. This treatment is curative in nearly all cases [27, 140]. For grade 2 and 3 (high-grade) tumors, adjuvant chemotherapy is administered following unilateral salpingooophorectomy, resulting in complete cure in the majority of patients [27]. More extensive surgery is necessary if the tumor extends beyond the ovary. Current combination therapy is vincristine, dactinomycin, and cyclophosphamide (VAC); vinblastine, bleomycin, and cisplatin (VBP); or cisplatin, etoposide (VP 16), and bleomycin (BEP) regimens. Therapy with VAC had been the treatment of choice [130] because the results obtained were considered to be similar to those with VBP or BEP regimens and the latter are more toxic. There is evidence that the recurrence rate with BEP is less than with VAC regimen, and for patients with metastatic disease, the cisplatin-containing regimens are the treatment of choice, especially as the BEP regimen is less toxic than the VBP [27, 64, 140].

In a collaborative study of immature teratoma (ovarian, testicular, and extra-gondal) in children [74], it was demonstrated that pure immature teratomas in this population have a very good prognosis. The authors concluded that the presence of microscopic foci of yolk sac tumor rather than the grade of immature teratoma was the only valid predictor of recurrence; however, it should be noted that ovarian cases were not separately analyzed for correlation between grade and outcome.

Mature Solid Teratoma

General Features

Mature solid teratoma is an uncommon ovarian teratoma. The age at presentation is similar to that of immature solid teratoma, the tumor occurring mainly in children and young adults [142, 255]. Most solid ovarian teratomas are composed at least partly of immature tissues and therefore are considered to be malignant. The occasional cases of solid ovarian teratoma composed entirely of mature tissues have usually been included in this group and thus misinterpreted as malignant. As the presence of immature neural elements immediately excludes the

tumor from this group, it is very important to recognize the mature tissue as such, as by definition only tumors composed entirely of mature tissues may be diagnosed as mature solid teratoma.

Gross Features

The tumors are usually large, do not exhibit any specific features, and show similar appearance to most solid teratomas, which are composed of immature tissues. They grow slowly in comparison with immature solid teratoma, but because they are usually discovered after they have reached a considerable size, this feature is of little help in diagnosis. In all reported cases of mature solid teratoma, the tumor has been unilateral [142, 252, 255].

Microscopic Features

Mature solid teratoma is composed entirely of mature tissues derived from the three germ layers. Rigid diagnostic criteria must be used, and the examination and sampling of the tumor must be thorough, because inclusion of cases with immature elements completely changes the prognosis of this neoplasm [142, 252, 255]. The tissues derived from the three germ layers are arranged in an orderly manner resembling the much more common mature cystic teratoma, except that the neoplasm is solid or at least predominantly solid. Neurogenic elements, which are among the most common tissues present in this tumor, often pose diagnostic problems because they may not be recognized as mature. Occasionally, mature solid teratoma may be associated with peritoneal implants composed entirely of mature glial tissue (gliomatosis) (> Fig. 16.31). Despite extensive peritoneal disease and irrespective of the mode of therapy employed, the

 Fig. 16.31
Mature glial implant. Mature glial implants on omentum ("gliomatosis peritonei")

prognosis is excellent [160, 168, 185]. Presence of peritoneal implants composed entirely of mature glial tissue occasionally may be observed in patients with immature solid teratoma and with mature cystic teratoma. The presence of these implants does not affect the prognosis [74, 123, 160, 168, 185].

Clinical Behavior and Treatment

Because the tumor is unilateral, oophorectomy or unilateral adnexectomy is the treatment of choice, resulting in a complete cure [142, 252, 255].

Mature Cystic Teratoma

General Features

Mature cystic teratoma of the ovary, or dermoid cyst, has been known since antiquity. The tumor is composed of well-differentiated derivatives of the three germ layers – ectoderm, mesoderm, and endoderm – with ectodermal elements predominating. In its pure form, mature cystic teratoma is always benign, but occasionally it may undergo malignant change in one of its elements. It may also form a part of a germ cell neoplasm composed of a number of different neoplastic germ cell elements (mixed germ cell tumor).

Clinical Features

Mature cystic teratoma is the most common type of ovarian teratoma and the most common type of ovarian germ cell neoplasm. It occurs relatively frequently and comprises approximately 20% of all ovarian neoplasms [144, 168, 185]. Mature cystic teratoma occurs most commonly during the reproductive years, but, unlike other germ cell tumors of the ovary, it has a wider age distribution and may be encountered at any age from infancy to old age [13, 34, 144]. In some series, more than 25% of cases have been observed in postmenopausal women [110]. It has also been encountered in newborns. Mature cystic teratoma is often discovered as an incidental finding on physical examination, radiologic examination, or during abdominal surgery performed for other indications.

Patients present with abdominal pain (47.6%), abdominal mass or swelling (15.4%), and abnormal uterine bleeding (15.1%) [144]. The abdominal pain is usually constant, slight, or moderate but, in a number of cases, may be severe and acute because of torsion or rupture of the tumor. In children and young adults, the tumors tend to be more easily mobile and therefore are more frequently affected by torsion. Abnormal uterine bleeding and its cessation after excision of the tumor suggest hormone synthesis by the tumor, but histologic examination has failed to reveal any explanation for the endocrine function [110]. Slightly decreased fertility has been observed in patients with mature cystic teratoma, but in most cases there is no satisfactory explanation. In 10% of cases, the tumor is diagnosed during pregnancy [13, 34]. Mature cystic teratoma has been diagnosed radiologically because of the presence of teeth, bone, and cartilage [110, 144].

Cytogenetic Features

Mature cystic teratomas are diploid, have a normal 46,XX karyotype, and have been considered to originate from germ cells after the first meiotic division; thus, they are in contrast to mature teratomas of the postpubertal testis, which are malignant, are aneuploid, have complex cytogenetic abnormalities including 12p amplification, and are considered to originate from other forms of germ cell tumor [10, 102, 244]. Of note, ovarian mature cystic teratomas and prepubertal testicular mature teratomas are similar in that both are diploid, have normal karyotypes, and are benign [244]. Previous studies [126, 138] using banding techniques demonstrated diverse modes of origin of mature cystic teratoma. Although most ovarian mature cystic teratomas originate from germ cells after the first meiotic division, some originate before this event [126, 138]. This distinction also applies to immature ovarian teratomas, which tend to be aneuploid, resembling their testicular counterparts.

Gross Features

Mature cystic teratoma does not have a predilection for either ovary; 8–15% of cases are bilateral [144, 168, 185]. The tumor varies in size from very small (0.5 cm) to large (measuring more than 40 cm) and can weigh up to several kilograms. Approximately 60% of mature cystic teratomas measure from 5 to 10 cm, and more than 90% measure less than 15 cm [144]. The tumor is round, oval, or globular, with a smooth, gray-white, and glistening surface (> Fig. 16.32). It is usually freely mobile but occasionally may form adhesions to surrounding structures, especially if there has been leakage. On palpation, the tumor is soft and fluctuant, with firm or hard areas; this is usually observed immediately after its removal, because at room temperature the tumor tends to solidify. The contents of the tumor are liquid at temperatures above 34°C and become solid at temperatures below 25°C [25]. The cut surface of the tumor reveals a cavity filled with fatty material and hair surrounded by a firm capsule of varying thickness. The fatty material is similar to normal sebum. The tumor is usually unilocular but may be multilocular. Several tumors may be present in the same ovary.

Fig. 16.32 Mature cystic teratoma. Well-encapsulated tumor containing hair

Arising from the cyst wall and projecting into the cavity is a protuberance that may vary in size from a small nodule to a rounded elevated mass. It is usually single but may be multiple and is frequently solid but may be partly cystic. This protuberance has been variously termed dermoid mamilla, dermoid protuberance, Rokitansky protuberance, embryonic node, or dermoid nipple. The hair present in the tumor arises from this protuberance, and when bone or teeth are present (\triangleright Fig. 16.33), they tend to be located within this area, which is composed of a variety of different tissues and is one of the sites that should always be carefully sampled. Mature cystic teratomas contain macroscopically recognizable and well-formed teeth in 31% of cases [25]. Phalanges, long and other bones, parts of the rib cage, loops of intestine, and even fetus-like structures are occasionally encountered [1, 250]. They have been classified as fetiform teratomas or homunculi [1, 250].

Microscopic Features

The outer side of the cyst wall is composed of ovarian stroma that may often be hyalinized, making its recognition difficult. The cavity of the cyst is lined mainly by skin, and in small tumors cutaneous structures may form the entire lining. The skin is composed of keratinized squamous epithelium and usually contains abundant sebaceous and eccrine glands associated with fat (\triangleright *Fig.* 16.34). In some tumors, a lipogranulomatous, fat necrosis-like, sieve-like, or pneumatosis cystoides-like pattern may be prominent. Hair and other dermal appendages are usually present. Occasionally, the cyst

Fig. 16.34 Mature cystic teratoma. The lining of the cyst is composed of skin with its appendages

wall may be lined by bronchial or gastrointestinal epithelium or epithelium of columnar or cuboidal type (\triangleright *Fig. 16.35*). The squamous epithelium may be present only in the region of the dermoid protuberance. Sometimes there may be loss of the lining epithelium caused by desquamation, and this may be associated with a foreign body giant cell reaction. The latter may be seen in other parts of the tumor as a reaction to the contents of the tumor. Foreign body giant cell reactions may also be seen when the contents of the tumor are spilled, leading to the formation of adhesions.

The area around the dermoid protuberance may contain a large variety of tissues derived from the three germ layers. Ectodermal tissue, represented by squamous

• Fig. 16.35 Mature cystic teratoma. Mature cystic teratoma lined by well-differentiated mature respiratory epithelium. Mature adnexal structures are seen beneath the lining

epithelium and other skin derivatives, is usually most abundant. Brain tissue, glia, neural tissue, retina, choroid plexus, and ganglia may also be encountered. In occasional cases, the glial tissue may be highly cellular, making the distinction between gliosis and a low-grade glial tumor, such as astrocytoma or oligodendroglioma, arising in a teratoma very difficult. Criteria have not been established for this distinction in the ovary. Furthermore, in view of the rarity of this problem in teratomas, the precise behavior of such lesions is not known, but in our experience (unpublished data), we are not aware of an adverse outcome.

Mesodermal tissue is represented by bone, cartilage, smooth muscle, and fibrous and fatty tissue. Endodermal

tissue is represented by gastrointestinal and bronchial epithelium and glands, thyroid, and salivary gland tissue. In a careful study of 100 cases, ectodermal structures were found in 100%, mesodermal in 93%, and endodermal in 71% of cases [25]. Rare tissues, such as prostate, have been reported [71]. The various tissues present in mature cystic teratoma show an orderly organoid arrangement forming cutaneous, bronchial, and gastrointestinal tissues, as well as bone and other structures. Although these tissues may be scattered diffusely, they do not exhibit the disorderly haphazard arrangement that is observed in immature teratoma.

With the exception of thyroid tissue, the presence of endocrine tissue of other types is distinctly uncommon in mature cystic teratoma, but pituitary, adrenal, and parathyroid tissues have been documented. Occasionally functioning endocrine tissue, forming an adenoma, may be found in a mature cystic teratoma [168, 185]. Mature cystic teratoma must be differentiated from the rare cases of fetus in fetu, considered most likely to be caused by an inclusion of a monozygotic diamniotic twin [29]. Fetus in fetu can be distinguished from a teratoma by its location in the retroperitoneal space, presence of vertebral organization with formation of limb buds, and a well-developed organ system. Fetus in fetu shows better organization than the most differentiated teratomas. Like mature cystic teratoma, fetus in fetu is a benign lesion [29].

Clinical Behavior and Treatment

Mature cystic teratoma of the ovary may be associated with various complications. In view of the fact that in many of these cases the condition is amenable to cure, their recognition is of considerable importance. These complications include (1) torsion, (2) rupture, (3) infection, (4) hemolytic anemia, and (5) development of malignancy.

Torsion is the most frequent complication [13, 34, 133, 144], occurring in 16.1% of cases in one large series [144]. This complication tends to be more common during pregnancy and puerperium [110, 144]. Mature cystic teratoma is said to comprise from 22% to 40% of ovarian tumors in pregnancy, and from 0.8% to 12.8% of reported cases of mature cystic teratoma have occurred during pregnancy [34, 144]. The fact that these tumors, when they occur during pregnancy, are more liable to be associated with torsion is of considerable importance. Torsion is also more common in children and younger patients [133, 144]. The patients usually have severe acute abdominal pain, and the condition is an acute abdominal emergency. Excision of the affected ovary or salpingo-oophorectomy is the treatment of choice.

Torsion tends to predispose to rupture of the tumor. Rupture of mature cystic teratoma is an uncommon complication, occurring in approximately 1% of cases [110, 144]. The immediate result of the rupture may be shock or hemorrhage, especially during pregnancy or labor, but the prognosis even in these cases is usually favorable. Rupture of the tumor into the peritoneal cavity may be followed by chemical peritonitis caused by the spillage of the contents of the tumor. It produces a marked granulomatous reaction and leads to the formation of dense adhesions throughout the peritoneal cavity. Rupture of the tumor occasionally may be followed by the development of glial implants on the peritoneum. This condition occurs when the tumor contains mature neuroglial elements, and spillage leads to deposition of numerous small nodules composed of mature glia in the peritoneal cavity. Despite the wide dissemination of these deposits throughout the peritoneal cavity, the prognosis is favorable, and simple surgical excision of the primary tumor is considered to be adequate therapy [160]. Mature cystic teratoma may rupture not only into the peritoneal cavity but also into adjacent organs, usually the bladder or the rectum. Several such cases have been reported [44]. Infection is an uncommon complication and occurs in approximately 1% of cases [110]. The infecting organism is usually a coliform, but Salmonella infection causing typhoid fever has also been reported [75].

Autoimmune hemolytic anemia has been noted occasionally in patients with teratoma of the ovary, mainly mature cystic teratoma. Excision of the tumor in these cases resulted in the disappearance of the anemia and a complete cure [22, 46, 139]. A small number of mature cystic teratomas and other cystic ovarian tumors associated with this complication have been reported [22, 139]. The patients have symptoms and signs of progressive anemia, which may be moderate or severe; it is accompanied by reticulocytosis, spherocytosis, and increased osmotic fragility. Normoblasts may be present in the peripheral blood. The indirect serum bilirubin is elevated, and the direct antiglobulin test (Coombs' test) is positive, indicating the presence of autoantibodies that react with the patient's red blood cells. The platelets are normal in number. The spleen may be palpable but is only slightly enlarged. Steroids are only transiently effective in treating the disease, and splenectomy has no effect on the progress of the disease [22, 139]. Excision of the ovarian tumor leads to the permanent disappearance of the anemia [22, 46, 139]. The following possible pathogenetic mechanisms have been suggested [22]:

(1) Presence in the tumor of substances that are antigenically different from the host and that stimulate the production of antibodies by the host, which cross-react with the patient's own red blood cells; (2) Antibody production by the tumor directed specifically against the host's red blood cells resembling the graft-versus-host reaction; and (3) Coating of red blood cells with products secreted by the tumor, resulting in changed red blood cell antigenicity.

In view of this, pelvic and radiologic examination is indicated in a young woman with autoimmune hemolytic anemia that does not respond to steroid treatment, as it may help detect an ovarian teratoma and prevent an unnecessary splenectomy [139].

The treatment of choice for an uncomplicated mature cystic teratoma in young patients is excision of the cyst with conservation of part of the ovary if possible. This treatment usually results in a complete cure. Local recurrences after conservative treatment for mature cystic teratoma are uncommon and occur in less than 1% of cases.

Mature Cystic Teratoma (Dermoid Cyst) with Malignant Transformation

General Features

Malignant transformation is an uncommon complication of mature cystic teratoma. It occurs in approximately 2% of cases [13, 95, 110, 136, 143, 168, 185, 199], although in one report the frequency was almost 4% [134]. The age of patients with this complication as reported in the literature ranges from 19 to 88 years [143], but this tumor usually is observed in postmenopausal patients [95, 110, 134, 143, 199].

Clinically, this tumor cannot be readily differentiated from an uncomplicated mature cystic teratoma or other ovarian tumor although evidence of its rapid growth, pain, loss of weight, and other systemic signs and symptoms suggest the presence of a malignant tumor. Sometimes, the tumor may be an incidental finding.

Gross Features

The tumor is frequently larger than the average mature cystic teratoma [34, 95, 185, 199]; it may exhibit a more solid appearance (\bigcirc *Fig. 16.36*), but differentiation usually cannot be made on gross examination. Malignant transformation in mature cystic teratoma tends to occur in patients with unilateral tumors [143, 144].

Microscopic Features

The most common tumor component to undergo malignant transformation is squamous epithelium, with formation of a typical squamous cell carcinoma (**)** *Figs. 16.37*

Fig. 16.36 Squamous cell carcinoma (*left*) arising in and overgrowing mature cystic teratoma

Fig. 16.37

Squamous cell carcinoma arising in mature cystic teratoma. The tumor has an infiltrating pattern showing numerous keratin pearls

and \bigcirc 16.38) [34, 76, 95, 134, 143, 199]. Any of the tissues present in a mature cystic teratoma may undergo malignant transformation, and a variety of malignant tumors have been reported, including mucinous carcinoma, carcinoid tumor, thyroid carcinoma, basal cell carcinoma, malignant melanoma, leiomyosarcoma, chondrosarcoma, and angiosarcoma (\bigcirc *Figs.* 16.39 and \bigcirc 16.40) [70, 114, 117, 143, 243, 248]. The malignant element invades other parts of the tumor and its wall, which may perforate. The malignant component may overgrow the remaining part of the mature cystic teratoma and pose diagnostic problems.

G Fig. 16.39

Melanoma arising in mature cystic teratoma. Note nested pattern within squamous epithelium

Clinical Behavior and Treatment

The mode of spread of the malignant tumor differs from that observed in other tumors of germ cell origin. The tumor spreads by direct invasion and peritoneal implantation and generally does not metastasize to the lymph nodes [95, 143]. Extensive local invasion and absence of lymph node involvement usually is observed at laparotomy [134, 199]. Hematogenous dissemination is uncommon.

The prognosis of patients with mature cystic teratoma with malignant transformation is unfavorable [95, 134, 143, 199]; only 15–30.8% of patients survive 5 years [95,

Fig. 16.40

Invasive mucinous carcinoma arising within mature cystic teratoma. Note extensive glandular component, slightly haphazard glandular arrangements, and prominent pseudomyxoma ovarii. The diagnosis of invasion in examples such as this can be very difficult, particularly with regard to distinction from non-carcinomatous tumors that have pseudomyxoma ovarii coupled with a slightly less extensive glandular proliferation and density of glands

143]. Better prognosis has been reported when the malignant element is a squamous cell carcinoma confined to the ovary and is excised without spillage of the contents. In such cases, the reported 5-year survival is 63% [143].

Treatment is hysterectomy and bilateral adnexectomy [95, 199]. Because the tumors are usually unilateral, in cases where there is no penetration of the capsule and no involvement of the adjacent structures, a more conservative surgical procedure may be just as effective. However, because malignant transformation of a mature cystic teratoma usually occurs in postmenopausal women, total abdominal hysterectomy and bilateral salpingo-oophorectomy is performed. If the tumor has spread beyond the confines of the ovary and there is involvement of the adjacent structures, a more radical procedure with resection of the tumor and the involved structures or viscera is advocated [134]. Response to chemotherapy is unsatisfactory [95, 134].

Mucinous Tumors Arising in Mature Cystic Teratoma

General Features

In general, the vast majority of primary ovarian mucinous tumors are of surface epithelial origin, but a subset is of germ cell origin. In the cases studied, 2–11% of ovarian mature cystic teratomas are associated with a mucinous tumor, and many of the latter in this setting are likely of germ cell origin.

Microscopic Features

Primary ovarian mucinous tumors associated with a mature cystic teratoma show a spectrum of histologic appearances [117, 248]. At the lower end of the spectrum, tumors display a cystadenomatous pattern. Proliferative tumors with architectural complexity and epithelial stratification resemble atypical proliferative (borderline) mucinous tumor of ovarian surface epithelial origin or low-grade adenomatous mucinous neoplasm of the appendix. Pseudomyxoma ovarii can be seen with some cystadenomatous and proliferative neoplasms. Compared to tumors without pseudomyxoma ovarii, neoplasms with pseudomyxoma ovarii more closely resemble lower gastrointestinal tract adenomatous tumors and tend to have hypermucinous columnar epithelium and abundant goblet cells. Other tumors may show goblet cell carcinoid-like morphology. At the upper end of the spectrum, the carcinomatous neoplasms may be of glandular (> Fig. 16.40) or signet-ring cell type. Pseudomyxoma ovarii can also be associated with goblet cell carcinoid-like tumors or carcinoma.

Immunohistochemical Features and Differential Diagnosis

Immunohistochemical stains for CK7 and CK20 show variable coordinate expression profiles [248]. Tumors without pseudomyxoma ovarii and having cystadenomatous or proliferative patterns show a variety of CK7/CK20 profiles, including a CK7 diffuse/CK20 variable pattern (a pattern frequently seen in ovarian surface epithelial tumors). Those with pseudomyxoma ovarii and having cystadenomatous, proliferative, or goblet cell carcinoidlike patterns characteristically display a CK7(-)/CK20 diffuse or CK7 focal/CK20 diffuse profile (patterns typical of lower gastrointestinal tract tumors). A minority of these tumors histologically and immunohistochemically resembling lower gastrointestinal tract adenomatous tumors can have the clinical syndrome of pseudomyxoma peritonei without a tumor in the appendix. Parenthetically, it should be emphasized that although nearly all cases of pseudomyxoma peritonei are of appendiceal origin, rare cases are of primary ovarian origin due to an appendiceal-type mucinous tumor arising within a mature cystic teratoma. The carcinomas can have variable CK7/CK20 profiles, but some will show a CK7(-)/CK20 diffuse or CK7 focal/CK20 diffuse pattern.

Ovarian mucinous tumors of germ cell origin with histologic and immunohistochemical features typical of primary lower gastrointestinal tract tumors can be misclassified as metastatic or secondary tumors involving the ovary. Thus, it is important to search for focal teratomatous components in such ovarian mucinous tumors in order to suggest a possible primary ovarian origin. Nonetheless, when problematic mucinous neoplasms in ovarian mature cystic teratomas histologically and immunohistochemically resemble lower gastrointestinal tract tumors, extensive sampling of the gross specimen and further clinical evaluation to exclude the rare possibility of a similar primary mucinous tumor in the appendix or colorectal region as part of a tumor-to-tumor metastasis (e.g., a primary lower gastrointestinal tract tumor with a metastasis to a coexisting ovarian teratoma) are recommended.

Primary ovarian mucinous tumors arising in a teratoma, which histologically and immunohistochemically resemble lower gastrointestinal tumors, are considered to be of germ cell origin. Tumors that are histologically and immunohistochemically analogous to ovarian surface epithelial mucinous cystadenoma or atypical proliferative (borderline) mucinous tumor may have developed in the same ovary containing a teratoma as an independent tumor; however, it should also be considered that some of those mucinous tumors could be of germ cell origin as it is possible that they arose from upper gastrointestinal/pancreaticobiliary or sinonasal tissue in a teratoma, which would have histologic and immunohistochemical features similar to mucinous tumors of ovarian surface epithelial origin.

Nomenclature

For primary ovarian mucinous tumors histologically and immunohistochemically resembling lower gastrointestinal tract tumors, descriptive terminology that parallels the nomenclature for tumors in lower gastrointestinal sites (e.g., low-grade adenomatous mucinous neoplasm for ovarian tumors histologically and immunohistochemically analogous to those of the appendix) is preferred, considering that (a) terms such as borderline tumor or atypical proliferative tumor are used for surface epithelial tumors of the ovary, (b) these mucinous tumors are of germ cell rather than surface epithelial origin, and (c) they resemble their counterparts in the lower gastrointestinal tract.

Clinical Behavior and Treatment

Data on the behavior of mucinous ovarian tumors of germ cell origin are limited, but in the series of McKenney et al.

and Vang et al., patients with cystadenomatous and proliferative/low malignant potential tumors on follow-up remained well and disease-free [117, 248]. In the same series, mucinous carcinomas showed variable outcome but exhibited the potential for aggressive behavior. However, Ueda et al [243] reported a case of a patient with an adenocarcinoma arising in a mature cystic teratoma who has survived for more than 15 years. Furthermore, the present authors have seen a case of a patient with an intestinal-type adenocarcinoma arising in a mature cystic teratoma who has survived for more than 5 years.

Struma Ovarii

General Features

Thyroid tissue is a relatively frequent constituent of mature cystic teratoma and has been demonstrated in 5–20% of cases. Struma ovarii is considered a one-sided development of a teratoma in which the thyroid tissue has overgrown all other tissues, or one in which only the thyroid tissue has developed. The term struma ovarii should be reserved for tumors composed either entirely or predominantly of thyroid tissue [168, 169, 185].

Clinical Features

Struma ovarii is uncommon; it comprises nearly 3% of ovarian teratomas. The age distribution of patients with struma ovarii is generally the same as that of patients with mature cystic teratoma and ranges from 6 to 74 years. Most patients are in the reproductive years [168, 169, 254]. There are usually no specific symptoms; the clinical findings are similar to those observed in patients with mature cystic teratoma. The only differences are that in some cases struma ovarii is associated with enlargement of the thyroid gland, and in other cases there is clinical evidence that the struma ovarii is responsible for the development of thyrotoxicosis although this has not been confirmed preoperatively by laboratory tests [193, 254]. The ectopic thyroid tissue present within struma ovarii, therefore, may be the subject of the same physiologic and pathologic changes as the thyroid gland [193].

Gross Features

Struma ovarii is usually unilateral but is often associated with mature cystic teratoma and rarely with a cystadenoma in the contralateral ovary [168, 169, 185, 254]. In some cases, the teratoma present in the contralateral ovary contained thyroid tissue.

Struma ovarii varies in size, but usually measures less than 10 cm. The surface is usually smooth and, before sectioning, the tumor resembles a mature cystic teratoma. Occasionally, adhesions may be present. The cut surface of the tumor may be composed entirely of light tan, glistening thyroid tissue. Hemorrhage, necrosis, and foci of fibrosis may be present. Solid tumors with small amounts of colloid appear less glistening and more fleshy. Some tumors may be cystic [205].

Microscopic and Immunohistochemical Features

The tumor is composed of mature thyroid tissue consisting of acini of various sizes, lined by a single layer of columnar or flattened epithelium (> Fig. 16.41). The acini contain eosinophilic, PAS-positive colloid. The intensity of the staining may vary. There may be a considerable variation in the size of the acini, which may be large, containing a large amount of colloid, or may be small. Thyroglobulin and TTF-1 can be identified in the epithelial cells by immunohistochemistry (> Fig. 16.42). Occasionally, the lining of the acini may be columnar, containing small papillary projections not unlike those seen in hyperactive thyroid gland. Sometimes the appearances may resemble a nodular adenomatous goiter. Adenoma-like lesions may also be observed. When the tumor exhibits markedly crowded follicles without features of malignancy, the designation "proliferative struma ovarii" has been suggested (> Fig. 16.43) [48]. Struma ovarii showing appearances suggestive of Hashimoto's thyroiditis has also been reported [52]. Rarely, the tumor may show clear cell or cystic patterns [205, 206].

Fig. 16.42 Struma ovarii showing diffuse expression of TTF-1

Fig. 16.43

Proliferative struma ovarii. The follicles are markedly crowded, but features diagnostic of follicular thyroid carcinoma are not seen

Clinical Behavior and Treatment

Most cases of struma ovarii are benign and can be treated by excision of the ovary or by unilateral salpingooophorectomy. In a small number of cases, there are complications, the most important being the development of malignancy [48, 62, 165, 168, 170]. In one series [48], proliferative struma ovarii was benign; however, in another series 26% of cases were clinically malignant, but the entire cohort of proliferative struma ovarii had good overall survival (98% survival at 10 years, 92% at 25 years) [165]. Another complication is the presence of ascites or ascites associated with pleural effusion producing a pseudo-Meigs' syndrome [84]. Ascites may be found in 17% of cases of struma ovarii, and its presence does not indicate that the tumor is malignant [193]. The cause of the ascites and pleural effusion has not been fully elucidated. In most reported cases, excision of the tumor led to complete remission.

Occasionally, struma ovarii may be associated with extra-ovarian extension caused either by rupture of the tumor or by local spread. In such cases, the peritoneal cavity contains tumor deposits, which may be numerous and are composed of mature thyroid tissue. The condition is thought by some to be benign and is termed benign strumosis [87], although some authorities believe that it represents a very well-differentiated follicular carcinoma [165, 167]. This condition is only rarely associated with untoward side effects, which are mainly caused by the formation of adhesions. As most patients with this rare condition have been treated by excision of the tumor deposits and by administration of radioactive iodine (¹³¹I) with successful outcome, or have been lost to follow-up after varying periods of time with no ill effects, it is not possible to resolve this controversy. However, rare patients with strumosis have died of disease [165].

Malignancy Arising in Struma Ovarii

Clinical Features

Malignant change in struma ovarii, in which the tumor shows histologic/cytologic features of thyroid carcinoma ("malignant struma ovarii"), is uncommon (3% of all cases of struma ovarii in one study [165]). A number of reported cases of malignant struma ovarii were actually examples of strumal carcinoid. Patients with malignant struma ovarii are relatively young. The mean ages of women with the different types of thyroid carcinoma arising in struma ovarii range from 38 to 46 years [170]. Most patients with papillary thyroid carcinoma and typical follicular carcinoma present with stage I disease.

Microscopic Features

More than a hundred well-documented cases have been reported [62, 165, 170]. Microscopically, most of the tumors were of the papillary type (**>** *Fig.* 16.44), including its follicular variant, followed by follicular carcinoma. A few tumors showed features of poorly differentiated carcinoma. *BRAF* mutations and *RET/PTC* rearrangements, as seen in papillary thyroid carcinoma of the eutopic thyroid gland, have been identified in papillary thyroid carcinoma arising in struma ovarii [28, 178].

Papillary thyroid carcinoma arising in struma ovarii. (a) Low power. Struma ovarii is present at the bottom, and carcinoma is present at the *top*. (b) Prominent papillary architecture. (c) Nuclear features characteristic of papillary thyroid carcinoma

In a number of reported cases, the diagnosis was based on the histology of the tumor, and there were no metastases or other features of malignancy [48, 169, 170]. Whether malignant struma ovarii should be diagnosed based on the same criteria used for tumors in the eutopic thyroid gland is unclear. Application of the eutopic thyroid diagnostic criteria for the follicular variant of papillary thyroid carcinoma (FVPTC) in struma ovarii (optically clear nuclei, overlapping nuclei, nuclear pseudoinclusions, nuclear grooves [165]) may be difficult given the recognized interobserver variability in diagnosis for tumors in eutopic thyroid locations. It should be noted that even ovarian tumors with subtle atypical nuclear features, which are suggestive of but not fully diagnostic for the FVPTC still have the ability to metastasize [62]. Therefore, it has been recommended that whenever an ovarian follicular thyroid-type tumor with cytologic features borderline for the FVPTC is encountered, it should be reviewed by at least two surgical pathologists with experience in thyroid pathology in order to prevent under- or overdiagnosis [62]. Application of eutopic thyroid criteria for the diagnosis of follicular carcinoma in struma ovarii (tumor invasion of cortex with growth on ovarian serosa and vascular invasion [165]) is also problematic, particularly because the ovary lacks a true capsule. Furthermore, ovarian tumors that histologically qualify as struma ovarii but which have an extra-ovarian metastasis or recurrence that histologically resembles non-neoplastic thyroid tissue have been designated "highly differentiated follicular carcinoma." [167] Thus, this form of follicular carcinoma can only be diagnosed when an extra-ovarian lesion is identified. It should be noted, however, that this entity is controversial and considered "peritoneal strumosis" by others. However, tumor deposits of obviously malignant papillary thyroid carcinoma and typical follicular carcinoma should be diagnosed as such.

For any ovarian tumor featuring a problematic proliferation of thyroid tissue, extensive sampling is strongly suggested. In rare and unusual cases (especially those with bilateral tumors), it may be necessary to recommend further clinical evaluation in order to exclude the possibility of a metastasis from the thyroid gland with secondary involvement of the ovary.

Clinical Behavior and Treatment

See above section on **O** Malignancy Arising in Struma Ovarii for behavior of proliferative struma ovarii. In addition to peritoneal involvement by malignant struma ovarii, other routes of spread are via the lymphatics to the para-aortic and other lymph nodes and via the bloodstream to the lungs and bones [170]. Metastases are uncommon [62, 170]. The disease is treatable with good outcome in most cases, including those with metastatic disease. Only 7%, 14%, and 0% of patients with papillary thyroid carcinoma, typical follicular carcinoma, and "highly differentiated follicular carcinoma," respectively, in struma ovarii died of disease [170]. In a recent study by Robboy et al of all histologically malignant thyroid-type tumors in struma ovarii, 81% and 60% of patients were alive at 10 years and 25 years, respectively [165]. In that study, malignant struma ovarii was assessed for pathologic features that might predict aggressive behavior, and the size of the strumal component correlated with malignant outcome. It was also demonstrated that abundant peritoneal fluid, numerous adhesions, or ovarian serosal defects were more common in clinically malignant tumors. In general, however, it is not possible to reliably determine which cases will develop progressive disease.

Treatment of malignant struma ovarii should consist of at least oophorectomy but may also include thyroidectomy, radioactive iodine (¹³¹I), and follow-up with serum thyroglobulin measurement. Long-term follow-up is important as metastases can occur decades later.

Carcinoid

Carcinoid tumors of the ovary may be primary or metastatic. Primary carcinoids are subdivided into four categories: (1) insular, (2) trabecular, (3) strumal, and (4) mucinous. Mixed types also occur (composed of any combination of the pure types). The latter are uncommon and often associated with a mature cystic teratoma. Of the metastatic carcinoids, the insular carcinoid tumor is the most common, followed by the trabecular and mucinous types. Metastatic carcinoid tumors of the ovary are discussed in O Chap. 18, Metastatic Tumors of the Ovary.

Insular Carcinoid

General Features Insular carcinoid tumor, considered to be of midgut derivation, is the most common type of primary ovarian carcinoid tumor. It usually arises in association with gastrointestinal or respiratory epithelium present in a mature cystic teratoma. It may also be observed within a solid teratoma, a mucinous tumor, in association with a Sertoli–Leydig cell tumor [258], or may occur in a pure form [163, 195, 214]. The latter is considered to arise either as a one-sided development of a teratoma or from enterochromaffin cells present within the ovary. The former is much more likely. Approximately 40% of ovarian insular carcinoids occur in pure form; the remaining 60% are combined [185, 195, 214].

Clinical Features More than 200 cases of primary ovarian insular carcinoid tumors have been reported [45, 163, 185, 214]. The age of patients ranges from 31 to 83 years, but most patients are either postmenopausal or perimenopausal [45, 163, 195]. One third of the reported cases have been associated with the typical carcinoid syndrome, despite the absence of metastases [45, 163, 195]. This is in contrast to intestinal carcinoids, which are associated with the syndrome only when there is metastatic spread to the liver. The reason for this difference is that the blood flow from the ovary goes directly into the systemic circulation and does not pass through the liver, which inactivates the serotonin produced by the tumor. The presence or absence of symptoms of carcinoid syndrome is also dependent on the number of secreting tumor cells.

Functioning ovarian carcinoid tumors, with only one exception, have all measured approximately 10 cm in greatest dimension, whereas intestinal carcinoids are usually smaller. Thus, there is a good correlation between the size of the tumor and the presence of carcinoid syndrome. The excision of the tumor is associated with rapid remission of the symptoms, disappearance of 5-hydroxyindole acetic acid (5-HIAA) from the urine [163], and marked decrease of serum serotonin. Determination of serum serotonin and urinary 5-HIAA may be used to monitor disease activity and response to therapy. If the tumor is nonfunctioning, there is no specific presentation.

Gross Features The tumor shows similar appearances to those of mature cystic teratoma within which it is usually found. The same applies if the tumor is associated with a solid teratoma or a mucinous tumor. If the carcinoid is not associated with other tissue elements, the tumor is solid. The carcinoid may vary in size from microscopic to 20 cm in greatest dimension and is solid and homogeneous. Its color may vary from light brown to yellow or pale gray. Primary ovarian carcinoids practically always are unilateral, although they may be associated with a mature cystic teratoma in the contralateral ovary.

Microscopic Features Primary ovarian insular carcinoid usually shows the typical appearance associated with midgut carcinoids [163]. The tumor is composed of collections of small acini and solid nests of uniform polygonal cells with ample amounts of cytoplasm and round or oval, centrally located hyperchromatic nuclei (\bigcirc *Fig.* 16.45). Mitotic activity is low. The cytoplasm is basophilic or amphophilic and may contain red, brown, or orange argentaffin or argyrophil granules, which are demonstrated in the majority of cases of primary ovarian carcinoids [163]. Ultrastructurally, the cells of the ovarian

insular carcinoid show similar appearances to those of insular carcinoid tumors from other locations [214] and show abundant neurosecretory granules, which exhibit marked variation in size and shape, being round, oval, or elongated.

Immunohistochemical Features and Differential Diagnosis Demonstration of immunohistochemical expression of chromogranin and synaptophysin (> Fig. 16.46) further supports the diagnosis and has become the method of choice to confirm the diagnosis. These two markers frequently show diffuse and strong staining [261]. Serotonin may be demonstrated within the cytoplasm of the tumor cells by immunohistochemical techniques [197]. Occasionally, other neurohormonal polypeptides may also be demonstrated within the cytoplasm of the tumor cells, but their finding is much less frequent than in trabecular or strumal carcinoids [197]. The connective tissue surrounding the tumor nests is frequently dense and hyalinized as a result of the fibrogenic effect of the serotonin produced by the tumor. If immunohistochemistry is needed because a carcinoma is in the differential diagnosis, one should be aware that carcinoid frequently expresses pan-cytokeratin and low molecular weight cytokeratin (CK8/18), which occasionally may be diffuse. CK7 and EMA are more specific in that they are frequently expressed in carcinoma and expressed uncommonly in carcinoid [261]. In carcinoids positive for CK7 and EMA, expression tends to be of limited extent. Also, ER and PR are usually negative in carcinoid and positive in

Primary insular carcinoid tumor of the ovary. The tumor shows diffuse expression of chromogranin. Note that the compartments of the cells showing chromogranin expression are the same compartments containing bright pink cytoplasmic granules in \bigcirc Fig. 16.45

endometrioid carcinomas and can be added to an immunohistochemical panel [261].

Primary insular carcinoid of the ovary must be differentiated from metastatic insular carcinoid of the ovary, which is usually of gastrointestinal origin. Metastatic carcinoid nearly always affects both ovaries [162], unlike primary ovarian carcinoid, which is unilateral [163]. Macroscopically, the metastatic carcinoid is composed of tumor nodules, whereas primary ovarian carcinoid forms a single homogeneous mass. Presence of other teratomatous elements associated with an ovarian carcinoid confirms that it is primary [163, 214].

Primary ovarian carcinoid sometimes may be confused with Brenner tumor, but the appearances of the cell nests and the grooved coffee-bean nuclei of the cells of Brenner tumor are against the diagnosis of a carcinoid, whereas the typical small acinar pattern and expression of chromogranin A are in favor of a carcinoid. Confusion with granulosa cell tumor may also arise because Call– Exner bodies may be mistaken for carcinoid acini, but the cells of the carcinoid tumor usually show an acinar pattern and contain more cytoplasm and argentaffin granules [163]. Cystic areas that may be present in a granulosa cell tumor are nearly always absent in a carcinoid. Presence of nuclear grooves typical of adult granulosa cell tumor further supports this diagnosis. Inhibin and calretinin are typically negative in carcinoid [261]. Occasionally, ovarian carcinoid may be confused with a Krukenberg tumor, but the latter is usually bilateral and larger. The cells of Krukenberg tumor tend to merge with the stroma, are larger, and show greater pleomorphism, at least focal signet-ring appearance, and more brisk mitotic activity. An acinar pattern is less evident. Demonstration of chromogranin and synaptophysin expression supports a diagnosis of carcinoid.

Clinical Behavior and Treatment Although insular carcinoid tumors of the ovary are considered to be malignant, they are slow growing and only occasionally are associated with metastases. Metastases have been observed in 11 patients, 7 of whom died with metastatic disease [45, 163]; this includes 6 patients with metastatic disease from a series of 9 cases of insular carcinoid tumors of the ovary collected over 40 years by Davis et al [45]. This series suggested that metastatic disease may be more frequent than generally reported. Although the malignant potential of insular carcinoid should not be minimized, it is considered that the series of Davis et al [45]. was somewhat selective as regards its content of metastasizing tumors and lethal outcome.

In occasional patients, features of carcinoid syndrome, such as tricuspid incompetence resulting in right-sided heart failure, may progress after the excision of the tumor and lead to the death of the patient, as has been observed in two cases [163]. In most patients with the carcinoid syndrome, the symptoms and signs of the syndrome observed preoperatively disappear or regress during the postoperative period [163]. Because nearly all patients with this tumor are postmenopausal or perimenopausal, bilateral salpingo-oophorectomy and hysterectomy is the treatment of choice. Surgical excision of foci of extra-ovarian spread or of metastases if present is indicated. There is little experience with chemotherapy. Estimation of serum serotonin and 5-HIAA in the urine may be used to monitor the progress of the disease.

Trabecular Carcinoid

General Features Trabecular carcinoid includes carcinoid tumors of hindgut or foregut derivation. Primary trabecular or ribbon carcinoid usually arises in association with teratomatous elements [164, 195], but in a later study of four cases of trabecular carcinoid, two tumors were pure and not associated with teratomatous elements [217].

Clinical Features Trabecular carcinoid is rare. Patient age varies from 24 to 74 years, with most patients being postmenopausal [45, 164, 195, 217]. Trabecular carcinoid is a slowly growing neoplasm that can reach a large size.

Fig. 16.47 Primary trabecular carcinoid tumor of the ovary. The tumor is composed of long ramifying cords of tumor cells surrounded by dense fibrous stroma

None of the known cases have been associated with the carcinoid syndrome. In three patients whose urine was examined immediately after the operation, 5-HIAA was normal [164].

Gross Features The appearance of trabecular carcinoid depends on whether the tumor is associated with teratomatous elements. When associated with teratoma, the appearance is similar to that of a mature cystic teratoma. When the tumor is pure, it is a solid, firm to hard, round or oval mass with a smooth outline and tan to yellow on cross section. The tumors have always been unilateral [164, 195, 217], but occasionally have been associated with mature cystic teratoma in the opposite ovary [164, 195]. In the reported cases, the tumors measured from 4 to 25 cm in greatest dimension [164, 195, 217].

Microscopic Features The tumor is composed of long, usually wavy ribbons, cords, or parallel trabeculae surrounded by fibromatous connective tissue stroma that is usually dense (**)** *Fig.* 16.47). The ribbons, cords, or trabeculae are composed of cells that form usually one but sometimes two cell layers. The nuclei are elongated or ovoid and contain finely dispersed chromatin. The cytoplasm is abundant and often contains orange to red-brown granules, which usually stain with argyrophil and argentaffin stains. Ultrastructurally, the neurosecretory granules are round or oval and show slight variation in size [187, 220], thus differing from those seen in insular carcinoids.

Immunohistochemical Features and Differential Diagnosis See section on **Insular** Carcinoid for details of immunohistochemistry. Immunohistochemical staining demonstrates a much wider range of neurohormonal polypeptides than insular carcinoids; these include serotonin, pancreatic polypeptide, glucagon, enkephalin, gastrin, vasoactive intestinal polypeptide, and calcitonin [197].

Primary trabecular carcinoid must be distinguished from metastatic trabecular carcinoid, which is usually bilateral and frequently associated with metastases elsewhere. The presence of teratomatous elements, which are found frequently in the primary lesion, helps distinguish the primary from a metastatic lesion. Trabecular carcinoid sometimes may exhibit an insular pattern in foci, but unless this is a major component the tumor need not be classified as a mixed carcinoid.

The presence of thyroid follicles indicates that the tumor is a struma ovarii and carcinoid (strumal carcinoid), and their presence must be excluded before a diagnosis of trabecular carcinoid is made. Occasionally, trabecular carcinoid must be distinguished from a Sertoli–Leydig cell tumor showing a cord-like pattern. In contrast to a Sertoli–Leydig tumor, trabecular carcinoid lacks tubules. Immunohistochemical expression of chromogranin and synaptophysin and lack of staining for inhibin and calretinin confirm the diagnosis of carcinoid.

Clinical Behavior and Treatment The prognosis of patients with trabecular carcinoid of the ovary is favorable because these tumors are not associated with metastases [45, 164, 217]. In one case, a peritoneal implant was found 2 years after bilateral salpingo-oophorectomy and hysterectomy [164]. The optimal treatment is the excision of the affected adnexa, which results in a complete cure, but follow-up of the patient is advisable.

Mucinous Carcinoid (Goblet Cell Carcinoid)

General Features Mucinous carcinoid is a variant of carcinoid tumor that has been encountered mainly in the vermiform appendix [90, 203, 249] and occasionally has been observed in the ovary [2, 16, 214]. However, it should be noted that at least some of the tumors described as primary Krukenberg tumors of the ovary may have been examples of this entity. Also, it should be emphasized that before establishing a diagnosis of primary ovarian mucinous carcinoid, a metastatic appendiceal carcinoma with goblet cell carcinoid-like features must be excluded. A number of the latter have been reported [78], and several more are known to the authors. It is likely that a proportion of "primary ovarian" mucinous carcinoids reported in the literature really represent metastases from an occult appendiceal primary.

Clinical Features The age of patients ranges from 14 to 74 years. Mucinous carcinoid is usually observed in pure

form but may be seen in association with mature cystic teratoma. The tumor is unilateral but may be associated with metastases in the contralateral ovary [2, 16, 214].

Gross Features Macroscopically, the tumor is usually of considerable size, ranging from 4 to 30 cm, and most of the tumors have been more than 8 cm in greatest dimension. The tumor is gray-yellow, firm, and usually solid but may contain cystic areas [2, 16, 214]. Similar appearances are encountered when the tumor forms part of a mature cystic teratoma.

Microscopic Features Microscopically, mucinous carcinoid is composed of numerous small glands or acini with very small lumens lined by uniform columnar or cuboid epithelium. The cells contain small round or oval nuclei or appear as goblet cells distended with mucin (> Fig. 16.48). Some cells may be disrupted by excessive distension with mucin, which may result in the formation of small pools of mucin within the glands or even in the obliteration of the gland with pools of mucinous material within the connective tissue. The glands are surrounded by connective tissue, which may vary from loose and edematous to dense fibrous or hyalinized. Some of the glands or acini may be larger and occasionally may be cystic; this represents the typical or classical pattern of mucinous carcinoid. In some areas, the tumor cells tend to invade the surrounding connective tissue, often assuming signet-ring appearance. The tumor cells may form large solid aggregates and show a less uniform appearance

Fig. 16.48

Primary mucinous carcinoid tumor. The tumor is composed of numerous small glands and acini with imperceptible or very small lumens. Numerous goblet cells distended with mucin are present and more atypical features, with large hyperchromatic nuclei and brisk mitotic activity.

In some tumors, such appearances may predominate. This second pattern resembles Krukenberg tumor and is described as atypical or Krukenberg tumor-like pattern. Sometimes mucinous carcinoid showing either the typical or atypical pattern or both merges with intestinal-like adenocarcinoma showing numerous neuroendocrine cells; this is regarded as a third pattern present in this tumor. Some mucinous carcinoids may be admixed with other types of carcinoid tumor, such as insular or trabecular, forming a mixed carcinoid tumor. Thus, primary ovarian mucinous carcinoid tumors can be divided into these four histologic types. In a study of 17 mucinous carcinoid tumors, 6 were of the typical type, 4 of the atypical or Krukenberg tumor-like type, 5 were admixed with intestinal-like adenocarcinoma, and 2 were of the mixed type [16]. The cytoplasm of the tumor cells may exhibit orange-red granules and may even be bright red. Argyrophil and argentaffin granules are always present and, in some tumors, may be abundant [2, 16, 214].

Ultrastructurally, neurosecretory granules are present in some cells and absent in others. The tumor cells may contain both neurosecretory granules and mucinous material. The neuroendocrine nature of the tumor cells is further confirmed using immunohistochemical stains.

Immunohistochemical Features and Differential Diagnosis

The tumor cells react positively with chromogranin A. Using immunohistochemical techniques, some of the tumor cells have been shown to contain serotonin and gastrin, and these substances may be present within the same tumor cell. Other neurohormonal polypeptides such as pancreatic polypeptide and prolactin also have been detected in the tumor cells, but the range is narrower than that observed in trabecular carcinoids. CEA and low molecular weight cytokeratin also can be demonstrated within the cytoplasm of the tumor cells. These tumors are expected to show a CK7(-)/CK20 diffuse profile [248] (\triangleright Fig. 16.49).

Primary mucinous carcinoid tumor of the ovary must be differentiated from its metastatic counterpart although a number of the latter probably are appendiceal carcinomas with goblet cell carcinoid-like features [78, 214]. The latter, in common with other types of carcinoid metastatic to the ovary, is nearly always bilateral and instead of forming a single tumor mass shows scattered tumor deposits involving ovarian tissue. Depending on their size, these deposits may form tumor nodules observed macroscopically or may be detectable only microscopically.

Fig. 16.49Primary mucinous carcinoid tumor

Histologically, they may have appearances indistinguishable from the primary tumor. The presence of teratomatous elements supports primary ovarian origin.

Mucinous carcinoid must be distinguished from mucinous tumors of the ovary, particularly, a mucinous carcinoma with goblet cell carcinoid-like features arising in a teratoma. That is especially so when the carcinoid tumor is composed of large acini, shows increased mucin production, and exhibits a pleomorphic pattern. Occasionally, confusion may arise with well-differentiated endometrioid tumors of the ovary, which may resemble mucinous tumors.

Mucinous carcinoid must be distinguished from a Krukenberg tumor. The differentiation between these two entities may be difficult, especially if the mucinous carcinoid assumes a predominantly Krukenberg-like pattern or if the Krukenberg tumor contains numerous argentaffin and argyrophil granules. The presence of these granules as well as of the neurosecretory granules observed ultrastructurally cannot be used for differentiation between these two entities. Involvement of both ovaries and the presence of primary extra-ovarian signet-ring or mucinous adenocarcinoma are indicative of Krukenberg tumor.

Clinical Behavior and Treatment Primary mucinous carcinoid of the ovary behaves in a somewhat more aggressive manner than other types of primary ovarian carcinoid tumors [2, 16, 214], similar to the behavior of mucinous carcinoid tumors of the vermiform appendix [90, 203, 249]. The tumor tends to spread mainly via the

lymphatics, and metastases may be present at the time of initial laparotomy. Patients who do not exhibit metastatic disease at the time of diagnosis have a much better prognosis compared to those who have metastases, however small, at the time of diagnosis [2, 16, 214]. A series of 17 patients has been reported [16]. Six patients with mucinous carcinoid of the typical or classical type had tumors confined to the ovary, and all five with available follow-up (27-147 months) were well and disease-free after excision of the tumor. Three patients with mucinous carcinoid of the atypical type had tumors confined to the ovary and were well and disease-free after excision of the tumor (follow-up, 36-168 months). Of the eight women with carcinoma arising in mucinous carcinoid, six were stage I, one was stage II, and one was stage III. Seven had available follow-up. Two patients died of disease at 9 and 12 months, respectively. Four were alive and well with 48-120 months of follow-up, and a fifth patient died of other causes at 36 months.

The treatment is surgical, depending on the extent of the disease, but in postmenopausal women, patients with involvement of the contralateral ovary, and patients who do not want children, hysterectomy, bilateral salpingooophorectomy, and omentectomy, as well as excision of all the tumor deposits, are indicated. Para-aortic lymph node dissection may be necessary because metastatic tumor deposits may be present. Surgery may be followed by combination chemotherapy, including 5-fluorouracil, although the efficacy of this mode of therapy is not proven. Premenopausal patients with tumors localized to the ovary may be treated by unilateral salpingooophorectomy with careful follow-up.

Strumal Carcinoid

General Features Strumal carcinoid is an uncommon ovarian tumor composed of thyroid tissue intimately admixed with carcinoid tumor, showing a ribbon-like or cordlike pattern. Other teratomatous elements are also present in most of the tumors [161]. Tumors showing the histologic pattern of struma ovarii, merging imperceptibly with carcinoid tumor exhibiting the ribbon-like pattern observed in hindgut carcinoids, were usually interpreted as a carcinoma developing in a struma ovarii, although the resemblance to a carcinoid tumor has been noted in some cases.

Clinical Features More than 60 cases have been reported [161, 194, 195], and there are probably as many unreported cases. The age distribution is similar to struma ovarii, ranging from 21 to 77 years. The tumor is usually not associated with any specific clinical findings. In one

reported case, it was associated with virilization. Like hindgut carcinoids and unlike the primary ovarian insular carcinoid, strumal carcinoid is not, as a rule, associated with the carcinoid syndrome [161, 194, 195] although this association has been described in a single case [244].

Gross Features Macroscopically, this tumor, if pure, may be similar to struma ovarii or carcinoid. If the tumor is a part of a teratoma, it manifests as a yellow nodule within the teratoma [161, 194].

Microscopic and Immunohistochemical Features Microscopically, strumal carcinoid is composed of thyroid follicles containing colloid that merge with ribbons of neoplastic cells usually set in dense fibrous tissue stroma similar to trabecular carcinoid (\bigcirc *Fig.* 16.50). The thyroid follicles are often small in size at the junction between the two types of tissue. The carcinoid is usually composed of long, winding or straight ribbons of columnar cells with elongated hyperchromatic nuclei. It may also be composed of small islands of tumor cells surrounded by dense fibrous tissue stroma. Slight mitotic activity is present in the carcinoid part of the lesion.

Argyrophil and argentaffin granules are identified in the carcinoid cells [161, 194, 198], as well as in some cells lining the thyroid follicles both histochemically and immunohistochemically. Chromogranin and synaptophysin are expressed in the carcinoid component. TTF-1 and CK7 are usually expressed in the strumal component with no expression in the carcinoid component [156]; however,

we have seen cases with focal TTF-1 expression in the carcinoid component. Ultrastructural examination demonstrates neurosecretory granules in the carcinoid component and in some of the thyroid follicular cells [194, 198]. In two tumors, amyloid deposits were identified and were verified both immunohistochemically and ultrastructurally [6, 47].

Some investigators consider that strumal carcinoid is a carcinoid tumor and that the thyroid tissue only resembles thyroid [73]. Other investigators have conclusively demonstrated thyroglobulin and TTF-1 within the thyroid component of the tumor, thus indicating its thyroid nature [156, 161, 194]. It is, therefore, considered that in verified cases of strumal carcinoid, the tumor consists of thyroid tissue intimately admixed with a carcinoid. Strumal carcinoid should be distinguished from carcinoma of the thyroid arising in struma ovarii, with which it has often been confused. The carcinoma has the typical appearances observed in the eutopic thyroid and usually exhibits the follicular or papillary pattern.

Clinical Behavior and Treatment Strumal carcinoid only once has been associated with metastases, and even in this case the patient was apparently cured by a combination of surgery and radiation therapy [161]. All other cases have followed a benign course [161, 194].

Monodermal Teratomas with Neuroectodermal Differentiation

Cysts lined entirely by mature glial [246] or ependymal tissue [238] have been described in the ovary. More importantly, however, neuroectodermal tumors may also develop in the ovary and are considered monodermal teratomas with neuroectodermal differentiation. Kleinman et al. have reported a series of 25 cases of primary neuroectodermal tumors of the ovary [91]. The average age was 23 years (range 6-69 years). The tumors were cystic and/or solid with an average size of 14 cm (range 4-20 cm). They consisted of three histologic types: differentiated (ependymoma () Fig. 16.51)), primitive (medulloepithelioma, ependymoblastoma, neuroblastoma, and medulloblastoma), and anaplastic (glioblastoma). Some were associated with a mature cystic teratoma. Occasional patients may present with advanced stage disease. It is noteworthy that ependymomas may contain papillary areas mimicking serous tumors or gland-like structures resembling endometrioid tumors. In the small number of neoplasms tested, immunohistochemical expression of glial fibrillary acidic protein

Fig. 16.51 Monodermal teratoma with ependymona. Perivascular pseudorosettes are present

(GFAP) was seen in the differentiated and anaplastic tumors but not the primitive tumors. Survival was dependent on stage; however, the differentiated group showed superior outcome compared with the other two categories of tumors, and deaths with stage I tumors were seen in the anaplastic group.

Monodermal Teratoma Composed of Vascular Tissue

Another type of monodermal teratoma is represented by neoplasms composed entirely or predominantly of immature vascular tissue. These occur in children and young adults, and the patients present with symptoms and signs suggestive of an ovarian tumor. The tumors may vary in size and are smooth, soft, solid, and gray-pink but may be hemorrhagic. Microscopically, they consist of collections of small vascular spaces lined by immature endothelial cells and surrounded by connective tissue, which varies from loose and edematous to dense and fibrous. The lining of the vascular spaces may be multilayered and the endothelial cells may form small projections bulging into the lumen. Small collections of endothelial cells, some forming abortive lumina and some devoid of a lumen, are also seen within the connective tissue and may predominate.

The endothelial cells show a considerable degree of cellular and nuclear pleomorphism, and mitotic activity is usually evident. Occasionally, hematopoietic activity may be seen within some of the vascular spaces. When these

tumors contain small teratomatous foci, their nature is more readily apparent, but when they occur in pure form, especially when the endothelial cells form a more solid pattern with fewer obvious vascular spaces, the nature of the lesion is more difficult to recognize. Occasionally, these tumors may be composed of immature pericytes and resemble a hemangiopericytoma. Further sectioning of the tumor, which may reveal a more typical vascular pattern, and immunohistochemical stains for CD31 and CD34 as well as for factor VIII may be helpful in reaching the correct diagnosis. This distinction is important because monodermal teratomas composed of immature vascular tissue or with a predominant vascular component behave on the whole in a less aggressive manner compared with high-grade immature teratomas and angiosarcomas of the ovary, with which they tend to be confused. As in most immature teratomas, the grade of the tumor is an important prognostic feature.

Baker et al. have reported a series of teratomas containing prominent benign vascular proliferations associated with neural tissue [17]. The underlying tumors were either mature cystic teratoma, immature teratoma, or a mixed germ cell tumor. The vascular proliferations consisted of long, thin-walled, and curved vessels or rounded cellular aggregates with glomeruloid patterns. Small vessels could be seen arranged in whorls, and focally, a trabecular pattern was present.

Monodermal Teratoma with Sebaceous Differentiation

Sebaceous tumors showing one-sided development of a teratoma or arising in mature cystic teratomas are rare [38]. The reported cases showed an age range from 31 to 79 years at presentation, but the majority of patients were older than 49 years. All presented with lower abdominal enlargement. The ovarian tumors found at laparotomy were large, ranging from 10 to 35 cm. Some of the patients were found to have a mature cystic teratoma in the contralateral ovary. The tumors were mainly cystic. Partly solid yellow and tan masses protruded into the cysts. The latter contained necrotic or cheesy material [38]. Similar findings were also noted in a case of sebaceous carcinoma recently seen by the authors.

Microscopically, the tumors consisted of sebaceous adenoma, basal cell carcinoma with sebaceous differentiation, and sebaceous carcinoma [38]. The adenomas were all composed of nodules or lobules of proliferating normal sebaceous cells showing various degrees of maturity, with mature cells predominating. The basal cell carcinomas with sebaceous differentiation were composed of masses or nests of malignant basal cells containing collections of mature sebaceous cells. The sebaceous carcinoma was composed of sebaceous cells showing marked cellular and nuclear pleomorphism growing in an infiltrative pattern. The tumor cells had the typical appearance of sebaceous cells. Lipid stains were strongly positive in all the tumors, confirming the diagnosis [38].

The patients were treated either by excision of the affected adnexa or by hysterectomy and bilateral salpingo-oophorectomy [38]. The outcome was favorable; only one tumor was known to have recurred. The tumor, a basal cell carcinoma with sebaceous differentiation, recurred in the pelvis; further follow-up was not available. All the other patients were well and disease-free for periods ranging from 1.5 to 6 years postoperatively. One patient had, in addition to the sebaceous adenoma, a squamous cell carcinoma arising in the same ovary and died as a result of disseminated disease 1 year after the diagnosis. The patient with sebaceous carcinoma was well and disease-free 6 years after diagnosis [38]. In the case of sebaceous carcinoma recently seen by the authors, the patient was well after complete excision of the tumor. There were no adhesions or metastases. Chemotherapy was also administered. Whether this additional treatment was necessary is debatable.

Other Types of Monodermal Teratoma

Some mucinous tumors of germ cell origin arising in mature cystic teratomas may overgrow the background teratomatous component and appear to be entirely composed of a mucinous tumor (see section on • Mucinous Tumors Arising in Mature Cystic Teratoma) [248]. This phenomenon is similar to the situation in which thyroid tissue in a pure struma ovarii or carcinoid has developed in a pure form or has overgrown all the other tissues. The presence of occasional teratomatous tumors composed mainly of mucinous (intestinal-type) epithelium of endodermal derivation and only a small amount of other teratomatous elements, as well as a 5% association of mature cystic teratoma with mucinous cystadenoma, lends strong support to this mode of origin for at least some mucinous tumors.

Mucinous epithelium resembling intestinal epithelium has been observed in association with struma ovarii and with strumal carcinoid. In these cases, it was the only other tissue element present. The mucinous epithelium frequently contains goblet cells resembling intestinal rather than endocervical epithelium. In 21% of cases, the epithelium lining mucinous tumors of the ovary contains argyrophil and argentaffin granules. In a considerable number of cases, Paneth cells are also present. These findings are considered to be a strong argument in favor of the derivation of at least some mucinous ovarian tumors from intestinal-type epithelium and their teratomatous (germ cell) origin. Molecular studies will help clarify the origin of pure mucinous tumors of the ovary and confirm that some of these are of germ cell origin [108].

Other rare examples of monodermal teratomatous neoplasms observed in the ovary include the epidermoid cyst, which is lined by epidermis without appendages, the melanotic tumor, resembling the retinal anlage tumor [88], and the possible benign cystic counterpart of the latter [5]. Monodermal teratomatous origin of some malignant connective tissue tumors is difficult to prove because of the occurrence of connective tissue neoplasms derived from normal ovarian tissue. Monodermal teratomatous origin of tumors derived from ectodermal or endodermal tissues is more easily acceptable, and there may be as yet undescribed tumors of this type.

Mixed Germ Cell Tumors

Mixed germ cell tumors are tumors composed of more than one neoplastic germ cell element, such as dysgerminoma combined with teratoma, yolk sac tumor, choriocarcinoma, embryonal carcinoma, or polyembryoma, as well as any other possible combination of these tumor types () Fig. 16.52). Some tumors may contain all these neoplastic germ cell elements. Histologically, the different neoplastic germ cell elements may be intimately admixed or found separated from one another. Some studies indicate a greater frequency of mixed germ cell tumors [98, 141] as compared with earlier reports [121]. This finding is a result of a more detailed examination of the tumors and a better recognition of the fact that germ cell tumors may be composed of histologically different neoplastic elements occurring in combination. This group includes only neoplasms composed entirely of neoplastic germ cell elements and does not include gonadoblastoma and mixed germ cell-sex cord-stromal tumor, which in addition to germ cells contain sex cord-stromal derivatives as an integral component. The relatively frequent finding of different neoplastic germ cell elements in gonadal tumors of germ cell origin is considered to be a strong argument in favor of the common histogenesis of

this group of neoplasms. The various tumor elements present in these tumors may be intimately admixed or may form separate areas adjacent to each other and separated by fibrous septa.

Although many ovarian tumors belonging to this group are classified according to the predominant element present, it is emphasized that when these tumors are examined, all areas of varying appearance should be sampled carefully. All the neoplastic germ cell elements observed within the tumor, however small, should be reported and described and, if possible, their relative size estimated. This is important because the behavior and treatment of these neoplasms vary considerably, and the presence of a small area composed of a more malignant element may alter the therapeutic approach and prognosis. This is especially true in children [74] where most immature teratomas behave in a nonaggressive manner; however, the presence of small foci of yolk sac tumor (YST) in an immature teratoma is associated with aggressive behavior.

Even though the presence of very small foci of YST or high-grade immature teratoma may not alter the behavior of a mixed germ cell tumor largely composed of lessaggressive components, the presence of larger amounts of more malignant elements within a tumor is usually associated with a more aggressive behavior. Before the introduction of effective combination chemotherapy, the presence of YST or other more aggressive elements was associated with an unsatisfactory response to therapy and poor prognosis [9, 98, 223]. However, it should be noted that the clinical course in most patients with tumors composed of yolk sac tumor associated with dysgerminoma or other germ cell elements usually does not differ materially from that observed in patients with pure yolk sac tumor [64, 140]. The different response to treatment and the different behavior of some cases of dysgerminoma described in the past may have been a result of the presence of other germ cell elements that were not identified. Although in the past mixed germ cell tumors were considered to be uncommon, they tend to figure quite frequently in subsequent reports, probably because of more careful and extensive examination of the tumors.

Clinical and Pathologic Features of Tumors Composed of Germ Cells and Sex Cord–Stromal Derivatives

Gonadoblastoma

General Features

In 1953, Scully [181] described two patients with a distinctive gonadal tumor, which he designated gonadoblastoma. The tumor was composed of germ cells and sex cord-stromal derivatives, resembling immature granulosa and Sertoli cells. One of the tumors also contained stromal elements indistinguishable from lutein or Leydig cells. Both tumors occurred in phenotypic females who showed abnormal sexual development. The older patient, who was postpubertal, showed virilization, and it was considered that the tumor was capable of steroid hormone secretion. The tumors were located at the site of normal ovaries, but normal ovarian tissue was not discernible and the exact nature of the gonads in which the tumors had originated could not be determined. Both patients had bilateral tumors that were partly overgrown by dysgerminoma. The tumor was designated gonadoblastoma because it appeared to recapitulate the development of the gonads and because it occurred in individuals with abnormal sexual development and in gonads, the nature of which could not be determined [182]. It was subsequently demonstrated that both patients were sex chromatin negative.

The neoplastic nature of gonadoblastoma has been questioned because some lesions are very small and may undergo complete regression by hyalinization and calcification. Furthermore, when malignancy supervenes, it manifests itself as germ cell neoplasia despite the fact that gonadoblastoma is composed of two or three different cell types. When the tumor has metastasized, gonadoblastoma as such has never been observed in the metastases. Nevertheless, gonadoblastoma shows exactly the same pattern in the very small lesions as in the large ones, including mitotic activity in the germ cell element and early overgrowth by dysgerminoma. The association with dysgerminoma is seen in 50% of cases and with other more malignant germ cell neoplasms in an additional 10% [182]. In view of this, the concept that gonadoblastoma represents an in situ germ cell malignancy is considered to be fully justified.

Genetic and Molecular Features

Gonadoblastoma occurs almost entirely in patients with pure or mixed gonadal dysgenesis or in male pseudohermaphrodites. Occasional patients are of short stature and may have other stigmata of Turner syndrome [30, 174, 189]. Nearly all patients with gonadoblastoma whose karvotype was recorded (96%) were found to have a Y chromosome [174]. Eight patients had 46,XX karyotype [20, 53, 122, 132, 228, 260], and four of these were fertile [20, 53, 122, 228, 260]. One patient had a 45,X/46,XX mosaicism [181]. The most frequently encountered karvotype was 46,XY, which was seen in half the cases; this was followed by 45,X/46,XY mosaicism, which was seen in a quarter of the cases. The remainder showed many different forms of mosaicism [174]. Six patients had morphologic abnormalities of the Y chromosome. Of 25 patients with gonadal dysgenesis and dysgerminoma, 24 had a Y chromosome. The karyotype was 46,XY in 60%, followed by 45,X/46,XY in 24%. The remainder showed various forms of mosaicism [174]. One patient had 45,X monosomy and Turner syndrome. All other patients with features of Turner syndrome had various forms of mosaicism containing a Y chromosome.

The similarity between the distribution of the karyotypes in the gonadoblastoma group and the patients with dysgerminoma and gonadal dysgenesis is striking, and 62% of the former group and 45% of the latter had clitoral hypertrophy [174]. Gonadal dysgenesis and dysgerminoma has been reported in a female with a 46,XX karyotype who had no evidence of Y chromosomal DNA [101]. Gonadoblastoma was not detected in the affected gonad, but the authors [101] suggested that it was probably overgrown by the dysgerminoma. This finding indicates that gonadoblastoma and gonadal dysgenesis may occur in patients who do not have Y chromosomal DNA. Family history of gonadal dysgenesis has been noted in at least 10 reports of patients with gonadoblastoma [3, 4, 26, 208]. Evidence of gonadal dysgenesis affecting three generations of the family of a patient with gonadoblastoma was obtained in two instances [3, 18]. Gonadoblastoma has been reported in one pair of twins [56] and in four pairs of siblings [3, 4, 26, 208]. All these patients had 46,XY karyotype. It has been postulated that the mode of inheritance is either an X-linked recessive gene or an autosomal sex-linked mutant gene [18, 174, 175]. The *TSPY* gene has been suggested as playing a role in the pathogenesis of gonadoblastoma [100].

Endocrine Features

The association of gonadoblastoma with certain endocrine abnormalities was noted in one of the two cases first reported [181]. In view of the fact that gonadoblastoma occurs almost entirely in patients with gonadal dysgenesis, the defective gonadal development present in these patients should not be confused with the presence of endocrine effects that are associated with the tumor and are not a result of the abnormal gonadal development. Although the virilization produced by the tumor may regress after the excision of the tumor, there is no further gonadal development and the gonadal abnormalities remain. Although the exact source of the steroid hormone production was not originally known, the interstitial cells resembling Leydig or lutein cells were considered to be the most likely source of the androgens [181]. Further observations have shown that the presence of Leydig or lutein-like cells is not always associated with the presence of virilization, although they are encountered more frequently in tumors from virilized phenotypic female patients than in those from non-virilized patients. The possibility that the tumor may secrete estrogens, as evidenced by complaints of hot flushes and other menopausal symptoms after the excision of the tumor, has also been noted [182]. Originally the evidence of hormone secretion was mainly clinical, usually evidenced by virilization occurring after puberty and manifesting itself as masculine body contour, hirsutism, and clitoromegaly. Slight elevation of the urinary 17-ketosteroid excretion was noted in some cases. The gonadotropins, when estimated, were usually elevated.

Subsequently, it has been shown that gonadoblastoma is capable of producing testosterone and estrogens from progesterone in vitro [4, 166]. Evidence of testosterone secretion in vivo in patients with gonadal dysgenesis has been presented [83]. Androgen and estrogen formation from progesterone in vitro has been demonstrated in a streak gonad that did not contain any Leydig and lutein cells microscopically, but from the description, it may have contained a small burned-out gonadoblastoma [106]. Although in vitro testosterone formation has been ascribed to the Leydig or lutein-like cells present in gonadoblastoma [166], the demonstration of steroid production by a streak gonad that did not contain Leydig or lutein cells indicates that the nondescript stromal tissue also has the capability of steroid synthesis [106].

Germ Cell Tumors of the Ovary

Despite the advances in the understanding of the hormonal aspects of gonadoblastoma and dysgenetic gonads, a number of questions remain, the most important being why some patients become virilized and others do not. Although there is an approximate relationship between virilization and the presence of Leydig or lutein-like cells in the tumor, this relationship is not constant. It may be that the amount of steroid secretion is inadequate to produce virilization because of a small cell mass. Another possible explanation is that the steroid metabolic pathways may be different and that some gonadoblastomas may produce hormones that are metabolically nonfunctioning whereas other gonadoblastomas produce metabolically active steroids.

Clinical Features

The exact prevalence of gonadoblastoma is not known, but it is certainly uncommon. Gonadoblastoma is usually seen in young patients, occurring most frequently in the second decade and somewhat less frequently in the third and first decades, in that order. With a few exceptions, all the reported cases occurred in patients under 30 years of age. Patients with gonadoblastoma usually have primary amenorrhea, virilization, or developmental abnormalities of the genitalia. The discovery of gonadoblastoma is made in the course of investigations of these conditions. Another mode of presentation is the presence of a gonadal tumor. The gonadoblastoma forms part of the tumor in these cases and is discovered on histologic examination. Most patients with gonadoblastoma (80%) are phenotypic females, and the remainder are phenotypic males with cryptorchidism, hypospadias, and female internal secondary sex organs. Among the phenotypic females, 60% are virilized and the remainder are normal in appearance [182].

Most of the phenotypic female patients exhibit abnormal genital development, and breast development is often diminished even among the non-virilized females. Although primary amenorrhea is a common presenting symptom among phenotypic females with gonadoblastoma, a few patients have episodes of spontaneous cyclical bleeding, but in most of these patients the episodes are sporadic and the bleeding scanty; occasional patients menstruate normally [182]. The virilization present in phenotypic female patients with gonadoblastoma usually does not regress after excision of the tumor, although this has been seen in occasional cases, and in a few additional cases there was partial regression.

Although most patients have gonadal dysgenesis, gonadoblastoma has been described in patients who have had normal pregnancies. These include patients with a 46,XX karyotype [20, 53, 122, 260] and true hermaphrodites [228].

In seven true hermaphrodites with gonadoblastoma, four had a 46,XX karyotype [115, 228] and the other three had 46,XY [135, 204]. Gonadoblastoma has also been diagnosed in five males with normally descended testes [79, 216], some of whom fathered children subsequent to the excision of the testis bearing the lesion.

Gross Features

Gonadoblastoma has been found more often in the right gonad than in the left and has been bilateral in 40% of cases or higher [182, 221]. Although some tumors are recognized on gross examination, in a number of cases the lesion is detected only on histologic examination; this may be the case with bilateral tumors, only one of which may be recognized macroscopically. In most cases, the gonad of origin is indeterminate because it is overgrown by the tumor. When the nature of the gonad can be identified, it is usually a streak or a testis. The contralateral gonad in these cases may be a streak or a testis, and the former is more likely to harbor a gonadoblastoma [182, 221]. Occasionally gonadoblastoma has been found in otherwise normal ovaries [122, 127, 155].

Pure gonadoblastoma varies in size from a microscopic lesion to 8 cm, with most tumors measuring a few centimeters. When gonadoblastoma becomes overgrown by dysgerminoma or other malignant germ cell elements, much larger tumors may be observed [182, 211, 221]. The macroscopic appearance of the tumor varies to some extent according to the presence of hyalinization and calcification, as well as overgrowth by dysgerminoma.

Gonadoblastoma is a solid tumor and presents a smooth or slightly lobulated surface. It varies from soft and fleshy to firm and hard. It is speckled with calcific granules and may be almost completely calcified.

Fig. 16.53

Bilateral gonadoblastomas with dysgerminoma. The outer surface is smooth, and the cut surface is solid, granular, and yellow-brown. The white nodule in the lower pole of the tumor on the *right* is a dysgerminoma (Published with kind permission of Dr. Robert E. Scully, Boston, MA)

Calcification has been recognized on gross examination in 45% of cases, and in more than 20% it has been detected radiologically [182]. The tumor varies in color from gray or yellow to brown, and on cross section it appears to be somewhat granular (\triangleright *Fig. 16.53*).

Although the external sex organs in patients with gonadoblastoma present a wide variety of appearances ranging from normal to completely ambiguous, the secondary internal sex organs consist almost always of a uterus, which is hypoplastic in most cases, and two or occasionally one normal fallopian tube; this is also seen in the phenotypic males. Male secondary internal sex organs, such as the epididymis, vas deferens, and prostate, are found occasionally in the virilized phenotypic females and are always found in the phenotypic male pseudohermaphrodites [182].

Microscopic and Immunohistochemical Features

Gonadoblastoma is composed of collections of cellular nests surrounded by connective tissue stroma (\triangleright *Figs. 16.54–16.56*). The nests are solid, usually small, and oval or round but occasionally may be larger and elongated. The cellular nests contain a mixture of germ cells and sex cord derivatives resembling immature Sertoli and granulosa cells (\triangleright *Fig. 16.55*). The germ cells are large

Fig. 16.54

Gonadoblastoma. Cellular nests surrounded by connective tissue stroma. Note foci of calcification

Fig. 16.55

Gonadoblastoma. A nest composed of large germ cells is intimately admixed with smaller sex cord derivatives. Hyaline Call–Exner-like bodies also are seen

and round, with pale or slightly granular cytoplasm and large round vesicular nuclei, often with prominent nucleoli showing histologic and ultrastructural appearances and histochemical and immunohistochemical (CD117[+], OCT-4[+], and SALL4[+] [32]) staining patterns similar to the germ cells of dysgerminoma or seminoma. The sex cord cells will show immunohistochemical expression of inhibin. The germ cells show mitotic activity, which may be marked in some cases. They are intimately admixed with immature Sertoli and granulosa cells, which are smaller and epithelial-like. The latter are round or oval and have dark, oval or slightly elongated carrot-shaped nuclei. Mitotic activity is not seen in these cells. The immature Sertoli and granulosa cells are arranged within the cell nests in three typical patterns: (1) along the periphery of the nests in a coronal pattern, (2) surrounding individual or collections of germ cells in the same way as the follicular epithelium surrounds the ovum of the primary follicle, or (3) surrounding small round spaces containing amorphous hyaline, eosinophilic, and PAS-positive material that resemble Call–Exner bodies.

The connective tissue stroma surrounding the cellular nests frequently contains collections of cells indistinguishable from Leydig cells or luteinized stromal cells. There is considerable variation in the number of these cells from case to case; in some cases they are numerous, in others they are identified with difficulty, or they may be absent.

Although in many cases the cells are indistinguishable from Leydig cells and may contain lipochrome granules, Reinke crystals, which are specifically diagnostic of Leydig cells, have never been identified in their cytoplasm. The Leydig or lutein-like cells are identified in 66% of cases, and they are present nearly twice as frequently in older patients as in those 15 years of age or younger [182]. The presence of Leydig or lutein-like cells is not necessary for the diagnosis of gonadoblastoma. The connective tissue stroma surrounding the cellular nests may be scanty or abundant, and may vary from dense and hyalinized to cellular, resembling ovarian stroma. These latter appearances are more common in tumors that either have arisen in, or are suspected to originate in, a gonadal streak [182]. Occasionally, the stroma may be loose and edematous.

The basic composition of gonadoblastoma, consisting of the two cell types present within the cellular nests and with the Leydig or lutein-like cells present in the stroma, has been confirmed by electron microscopy [63, 80, 106]. Although there is agreement concerning the nature of the germ cells, the nature of the sex cord-stromal cells is in dispute. They are considered by some to be Sertoli cells or granulosa cells or their precursors [106], whereas others consider them to be primitive sex cord-stromal cells and are unable to differentiate them further [182, 213]. The latter view is more widely accepted. The nature of the amorphous, hyaline, and eosinophilic material forming Call-Exner-like bodies also was a matter of dispute. It was considered to be either of basement membrane origin [80, 106] or composed of fibrillar material formed by the stromal cells before they undergo fragmentation and cell death. The former view is supported by most investigators.

The basic histologic appearance of gonadoblastoma may be altered by three processes: hyalinization, calcification, and overgrowth by dysgerminoma [182, 213, 221]. Hyalinization takes place by coalescence of the hyaline Call-Exner-like bodies within the nests and of the basement membrane-like band of similar material present around the nests. The hyaline material replaces the tumor cells, and the whole nest may be replaced. Calcification is a common feature (> Fig. 16.54) and is seen microscopically in 81% of cases; it usually begins in the Call-Exner-like bodies with formation of small calcific spherules that are frequently laminated, resembling psammoma bodies. The process continues with enlargement and fusion of the calcified bodies and calcification of the hyalinized material, resulting in formation of a calcified mass embracing the whole nest. The process may extend to the stroma, which may also undergo hyalinization and calcification. In such cases, tumor cells become very scarce or absent, and the presence of smooth, rounded, and calcified masses may be the only evidence that gonadoblastoma was present (**>** Fig. 16.6). Although this finding is not considered to be diagnostic of gonadoblastoma, and has been called a burned-out gonadoblastoma [182, 213, 221], it is a strong argument in favor of the diagnosis and indicates that a careful search should be made for more viable areas of the tumor.

Gonadoblastoma is frequently overgrown bv dysgerminoma, as is seen in 50% of cases [182, 213, 221]. The overgrowth may vary from the presence of a small collection of malignant germ cells in the stroma outside the gonadoblastoma nests to massive overgrowth of the whole tumor, in which occasional nests of gonadoblastoma may be seen. The dysgerminoma in these cases shows the typical appearances of pure dysgerminoma or seminoma - histologically, histochemically, immunohistochemically, and ultrastructurally. It should be noted that when gonadoblastoma becomes overgrown by dysgerminoma, the germ cell component present within the gonadoblastoma nests shows marked proliferative activity and overgrows the sex cord elements. When gonadoblastoma undergoes regressive changes, they manifest first as a decrease in germ cells. Gonadoblastoma may also be associated with, and overgrown by, other more malignant germ cell neoplasms, such as immature teratoma, yolk sac tumor, embryonal carcinoma, and choriocarcinoma, as occurs in 10% of cases [182, 213, 221]. A gonadoblastoma overgrown by dysgerminoma and containing a proliferation of sex cord element resembling a Sertoli cell tumor and occurring in a dysgenetic gonad of a 19-year-old phenotypic female with 46,XY karvotype has been reported [127]. Although it has been postulated that gonadoblastoma may coexist with mixed germ cell-sex cord-stromal tumor, the two cases describing such an association [23, 37] were in reality typical gonadoblastomas and not combined tumors.

Differential Diagnosis

Gonadoblastoma, because of its distinctive histologic appearance and its cellular composition, cannot be easily confused with any of the well-recognized gonadal neoplasms. Gonadoblastoma may be confused with the mixed germ cell-sex cord-stromal tumor [208, 209], which shares with gonadoblastoma the unique distinction of being composed of germ cells and sex cord-stromal derivatives. The mixed germ cell-sex cord-stromal tumor shows less uniform appearance, absence of nestlike pattern, absence of calcification and hyalinization, a more pronounced proliferative activity involving also the sex cord-stromal derivatives, the tendency to occur in normal gonads, and other genetic, endocrine, and somatic differences. The other lesion resembling gonadoblastoma is the ovarian sex cord tumor with annular tubules [183], which is frequently found in patients with Peutz-Jeghers syndrome. This lesion, which is also frequently bilateral, is composed of tubules lined by Sertoli and granulosa-like cells, contains similar round, eosinophilic, and hyaline Call–Exner-like bodies, and tends to calcify in the same manner as gonadoblastoma. The basic difference from gonadoblastoma is the absence of germ cells (see Ochap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations).

Clinical Behavior and Treatment

The prognosis of patients with pure gonadoblastoma is excellent, provided the tumor and the contralateral gonad, which may be harboring an undetectable gonadoblastoma, are excised. When gonadoblastoma is associated with dysgerminoma, the prognosis is still very good. Metastases tend to occur later and more infrequently than in dysgerminoma that is not associated with a gonadoblastoma. All patients with gonadoblastoma and dysgerminoma with known follow-up, including the occasional cases with metastases [72, 176, 182], are alive and well after treatment, with the exception of two patients who died of disseminated dysgerminoma [72, 236]. The prognosis is different when gonadoblastoma is associated with more malignant germ cell neoplasms, such as embryonal carcinoma, volk sac tumor, choriocarcinoma, and immature teratoma. In the past, none of these patients survived longer than 18 months [211]. Subsequently, the administration of combination chemotherapy used successfully in the treatment of malignant germ cell tumors has markedly improved the prognosis, which with adequate treatment is now favorable.

Because gonadoblastoma occurs almost entirely in patients with dysgenetic gonads, which are not capable of normal function, and that the gonadoblastoma may act as a source from which malignant germ cell neoplasms may originate [174], there is general agreement that excision of the gonads is the treatment of choice [175, 182, 213, 221]. This consensus applies not only to a contralateral gonad that appears to be abnormal but also, in most cases, to a normal-appearing gonad. There is no complete agreement regarding whether the uterus should be excised together with the gonads. It has been considered that for psychological reasons it should not be removed so that periodic bleeding simulating menstruation can take place on estrogen-progesterone substitution therapy. However, because estrogen administration is associated with a risk of development of endometrial carcinoma, excision of the uterus together with the gonads has been advocated by some [175].

Mixed Germ Cell-Sex Cord-Stromal Tumor

General Features

The descriptive term mixed germ cell–sex cord–stromal tumor originally was intended to embrace all the tumors composed of these cell types, including the gonadoblastoma. In view of the fact that the latter term is now so well established, the term mixed germ cell–sex cord–stromal tumor should be reserved for tumors composed of these cell types that exhibit distinctive histologic appearances differing from those of gonadoblastoma [209, 210]. This is the term used in the WHO classification.

Genetic and Molecular Features

Nearly all female patients with this neoplasm have had genotype and karyotype determinations and have been found to have the normal female chromosome complement of 46,XX. All the patients with this tumor showed normal somatosexual development. There is no evidence that patients with this tumor have chromosomal abnormalities or gonadal dysgenesis, except for a single patient reported to have monosomy 22 [196]. In a small number of tumors studied, a subset of neoplasms showed amplification of chromosome 12p, and no mutations of the *c-kit* or *PDGFRA* genes were identified [118].

Endocrine Features

Most patients with mixed germ cell–sex cord–stromal tumor do not exhibit any endocrine abnormalities as observed clinically. In most cases, tests of hormonal function have not been performed preoperatively. In cases in which tests have been performed postoperatively, function has been found to be normal. In one case, the patient, an 8-year-old girl, exhibited signs of precocious pseudopuberty manifesting as mammary development and menstrual bleeding for 3 years before the discovery of a large ovarian tumor [222]. There was an increased urinary estrogen excretion. After excision of the ovarian tumor, the uterine bleeding ceased and the urinary estrogens became normal [222].

Isosexual precocious pseudopuberty has been seen in nine other patients in the first decade, including four infants less than 1 year of age, who exhibited mammary development and vaginal bleeding. The urinary estrogens were elevated, and vaginal smears showed estrogen effect. After the excision of the tumor, there was a complete return to normality. There was no evidence of virilization in any of the patients. These findings indicate that female patients with this neoplasm either do not have any associated endocrine abnormalities or, if these are present, that they are manifested as feminization. One of the patients, who had a mixed germ cell–sex cord–stromal tumor excised at the age of 10 years [209], has developed normally and commenced menstruating at the age of 15 years. She was well and disease-free 12 years after excision of the tumor.

Clinical Features

These neoplasms are rare. A number of adequately documented cases have been reported [7, 99, 118], but it is likely that some cases may not have been recognized and have been included with tumors of germ cell origin or with sex cord-stromal tumors. This concept is supported by the fact that because this neoplasm has been recognized as a specific entity, additional well-documented and so far unreported cases have been encountered. Tumors of this type have been observed more frequently in normal phenotypic female patients but have also been encountered in normal adult males. Most of the known cases in females were encountered in children in the first decade. More than a dozen cases occurred in infants less than 1 year of age [210, 213]. In three cases, the tumor occurred in women aged 26, 31, and 43 years, respectively, who had normal pregnancies. In the ovary, the tumor is most common in the first decade, followed by the second and third, and is uncommon thereafter. Therefore, the age distribution of patients with this neoplasm differs from that of patients with gonadoblastoma [213].

Gross Features

The tumors encountered have been relatively large, varying from 7.5 to 18 cm and weighing from 100 to 1,050 g. The tumor was found to be unilateral in all except two patients, and the contralateral gonad has always been described as a normal ovary. In some cases in which excision or biopsy was performed, this was confirmed on microscopic examination.

The tumor is usually round or oval, firm in consistency, and surrounded by a smooth, slightly glistening gray or gray-yellow capsule. In most cases the tumor is solid [118, 209, 210, 221], but in some cases it is partly cystic [222]. The cut surface of the tumor is uniformly gray, pink, or yellow to pale brown. Neither calcified areas nor foci of necrosis have been observed on gross examination. The fallopian tubes and the uterus have always been found to be normal. There have been no abnormalities affecting the external genitalia.

Microscopic and Immunohistochemical Features

The tumor is composed of germ cells and sex cord derivatives, intimately admixed with each other. The tumor cells form four different histologic patterns [7, 118, 209, 210, 213, 222]. One is composed of long, narrow ramifying cords or trabeculae (\bigcirc *Figs.* 16.57 and \bigcirc 16.58), which in places expand to form wider columns and larger round

Fig. 16.57

Mixed germ cell-sex cord-stromal tumor. The neoplasm is composed of large cellular aggregates and more slender cords

Fig. 16.58 Mixed germ cell-sex cord-stromal tumor. Note large germ cells surrounded by sex cord-stromal cells

or oval cellular aggregates surrounded by connective tissue stroma. The second consists of tubular structures devoid of a lumen and surrounded by a fine connective tissue network. In some places, the tubular pattern is less obvious, and the tumor forms small clusters or larger round or oval cellular masses surrounded by connective tissue stroma. The latter varies in amount and appearance and tends to be more abundant in tumors showing mainly the cord-like or trabecular pattern, whereas the tubular variety tends to be more cellular and contains less connective tissue. The stroma may vary from loose and edematous to dense fibrous and hyalinized. The former is seen more often where the cordlike pattern is most prominent, whereas the latter surrounds the larger cellular aggregates.

The third pattern consists of scattered collections of germ cells surrounded by sex cord elements that may be very abundant. The germ cells admixed with sex cord derivatives may also be scattered individually and in small groups within connective tissue stroma. Sometimes there may be a suggestion of an insular pattern with islands of various sizes surrounded by fine fibrovascular stroma coalescing and forming aggregates, or occasionally being separated by large amounts of connective tissue and forming a more pronounced insular pattern. Admixture with all these patterns is often seen. The typical nest-like pattern present in gonadoblastoma is not observed. In only one case were a few small collections of Leydig or lutein-like cells observed [209], but in all the remaining cases these cells were not identified.

The fourth more recently encountered pattern [7, 118] shows similar appearances to the sex cord tumor with annular tubules (SCTAT) [183, 185], but differs from the latter by the presence of germ cells as an additional cellular element within the tumor (\bigcirc *Figs.* 16.59 and \oslash 16.60). The germ cells show similar appearances seen in the tumors showing the other three patterns, including mitotic activity. The sex cord elements are similar to those observed in typical sex cord tumors with annular tubules.

The two cellular elements present in the tumor, the germ cells and the sex cord derivatives, are intimately admixed. The sex cord derivatives are arranged peripherally in a single file, forming long rows at the periphery of the cords, or peripherally lining the tubular structures as well as surrounding individual or groups of germ cells within the small clusters or larger aggregates. The germ cells resemble those observed in dysgerminoma and gonadoblastoma in all respects, including ultrastructural, histochemical, and immunohistochemical (CD117[+] and OCT-4[+]) reactions. In some cases, a number of the germ cells present in this tumor appear more mature

Fig. 16.59

Mixed germ cell-sex cord-stromal tumor with SCTAT-like pattern. Note the marked similarity to the sex cord tumor with annular tubules (SCTAT) but differing from it by the presence of germ cells

Fig. 16.60
Mixed germ cell-sex cord-stromal tumor with SCTAT-like pattern. Typical cytologic features. Compare with
Figs. 16.55 and 16.58

than the germ cells observed in gonadoblastoma or dysgerminoma and tend to resemble primordial germ cells. In view of this, it is possible that they may represent a later stage in the maturation of the germ cell than that seen in gonadoblastoma or dysgerminoma. The germ cells show brisk mitotic activity. The sex cord derivatives generally tend to resemble Sertoli cells more than granulosa cells. They show variable degrees of mitotic activity.

The tumor does not show hyalinization, calcification, or the regressive changes observed in gonadoblastoma and appears to be actively proliferative. There is some variation in the cellular content in some parts of the tumor; in some areas there is a preponderance of germ cells, whereas in others the sex cord derivatives predominate. However, the intimate admixture of these two cell types is seen everywhere. Most tumors show a solid pattern, although occasional small clefts lined by sex cord elements may be present. In some tumors, cystic spaces of varying size either lined by sex cord derivatives or flattened epithelial-like cells or devoid of lining may be observed [222, 229, 239]; they closely resemble the cystic spaces observed in some retiform Sertoli-Leydig cell tumors [215, 219, 257] or cystic sex cord-stromal tumors. In occasional tumors, this pattern may be pronounced and may suggest that the tumor contains epithelial cells in addition to germ cells and sex cord derivatives [229]. It is considered that these cells are in fact sex cord derivatives and that the tumor in common with some sex cord tumors exhibits a retiform or cystic pattern or both.

Normal ovarian tissue as evidenced by the presence of normal ovarian stroma and at least some primordial follicles has been identified in all cases, including a case in which it could not be identified in the original sections available [209]. In a number of cases, graafian follicles also are present [210, 222]. In other cases, tumor deposits are found very close to the surface of the ovary, obliterating primordial and graafian follicles.

Differential Diagnosis

Histologically, this tumor is most likely to be confused with gonadoblastoma. In contrast to gonadoblastoma, this tumor lacks the typical nest-like pattern, has greater proliferative activity of both the germ cell and sex cord component, and lacks calcification, hyalinization, and in most cases Leydig or lutein-like cells. Macroscopically, the tumors are larger. The gonad of origin is a normal ovary, and there is no evidence of gonadal dysgenesis or any somatosexual abnormalities. The patients have a normal female 46,XX karyotype. There is no evidence of virilization, and if there are signs of abnormal endocrine activity, they manifest themselves as feminization.

Occasionally, if the germ cells are relatively scanty, the tumor may be confused with the sex cord–stromal tumors of the ovary, but the presence of germ cells should alert the observer to the true identity of the tumor. If the sex cord derivatives are few in number, are missed, or are disregarded, the tumor may be misclassified as a germ cell tumor, but the presence of sex cord elements intimately admixed with the germ cells should indicate its true identity. The presence of prominent clefts and cystic spaces, especially when the latter contain papillary projections, may cause confusion with Sertoli–Leydig cell tumors showing the retiform pattern or even with serous papillary tumors. The presence of germ cells admixed with sex cord derivatives indicates that the tumor is a mixed germ cell–sex cord–stromal tumor, irrespective of its pattern.

Clinical Behavior and Treatment

The prognosis of patients with mixed germ cell-sex cordstromal tumor of the ovary occurring in pure form is favorable. In the great majority of known cases when the tumor was confined to the ovary and not associated with other malignant neoplastic germ cell elements, there has been no recurrence or metastases after excision of the affected adnexa. The patients are well and disease-free for periods varying from 1 to 15 years [118, 213, 221]. Accordingly, after a unilateral salpingo-oophorectomy, careful examination of the abdominal cavity is recommended. If the contralateral ovary shows signs of abnormality, biopsy is advisable. After this procedure, the patient should have chromosome studies. If the karyotype is 46,XX and if no other abnormalities are detected, further therapy is not necessary, although careful long-term follow-up is essential.

One well-documented case of metastasizing mixed germ cell-sex cord-stromal tumor occurring in an 8year-old girl has been reported [99]. The metastases were found in the para-aortic lymph nodes and in the peritoneal cavity. The patient was well and disease-free 2 years after excision of the affected adnexa, para-aortic lymphadenectomy, excision of peritoneal metastases, and a course of cisplatin-based combination chemotherapy [99]. Another case of metastasizing mixed germ cell-sex cord-stromal tumor showing an unusual pattern resembling the SCTAT occurring in a 30-year-old woman has been reported [7]. Three years after excision of a rightsided ovarian tumor, a large tumor mass was noted in the region of the uterine fundus. The mass and a number of peritoneal implants were excised together with the uterus and the left ovary. The primary and the metastatic tumors showed identical appearances. The left ovary was normal. The patient was well and disease-free 1 year after excision of the metastases and administration of combination chemotherapy.

In three patients in their 20s, one in her early 30s, and one in her early 40s, the mixed germ cell-sex cord-stromal tumor was associated with dysgerminoma. There was no evidence of metastases. The patients are well and diseasefree from 2 to 7 years after unilateral adnexectomy and radiation therapy.

In four children, aged 5–16 years, the tumor was overgrown by other malignant germ cell elements, including choriocarcinoma and yolk sac tumor. In three of these cases, the tumor metastasized and resulted in the death of the patient. The metastases were composed of the malignant germ cell elements. One patient treated with cisplatin-based chemotherapy was alive and well 5 years later. When the tumor is associated with malignant germ cell elements, the patient should be treated with the appropriate combination chemotherapy used in treatment of non-dysgerminomatous malignant germ cell tumors.

When the tumor is encountered in postmenarchal women, there is an increased possibility that the tumor may not present in pure form but be associated with other neoplastic germ cell elements. In such cases, in addition to excision of the affected adnexa appropriate therapy to treat the neoplastic germ cell elements present is recommended. This can be exemplified by a case of a 26year-old woman with mixed germ cell sex cord stromal tumor associated with yolk sac tumor and immature teratoma. The patient was well and disease-free 3 years following excision of the tumor and a course of cisplatinbased combination chemotherapy.

The tumors discussed in this chapter comprise a heterogeneous group of neoplasms that are not specific to the ovary. They are uncommon in this location, occurring much more frequently in other parts of the body. Consequently, whenever they are encountered in the ovary, these tumors pose difficult problems in diagnosis, histogenesis, behavior, and therapy for the pathologist and clinician. These neoplasms must be differentiated from primary ovarian neoplasms containing mesenchymal tissue, as well as from metastatic and disseminated neoplasms affecting the ovary. Thus, mesenchymal neoplasms nonspecific to the ovary must be differentiated primarily from teratomatous neoplasms containing large amounts of mature or immature mesenchymal elements and from the malignant mesodermal mixed müllerian (mesodermal) tumors (MMMT), which are composed of different malignant connective tissue elements in addition to their malignant epithelial components. Tumors of teratomatous origin containing mesenchymal tissue are described in Ochap. 16, Germ Cell Tumors of the Ovary, and MMMTs/carcinosarcomas, endometrioid stromal sarcomas, and adenosarcoma are discussed in **S** Chap. 14, Surface Epithelial Tumors of the Ovary.

In addition to the connective tissue neoplasms nonspecific to the ovary, the adenomatoid tumor, which is of mesothelial origin, the ovarian tumor of probable wolffian origin, ovarian neoplasms of neural origin, hepatoid carcinoma of the ovary, small cell carcinoma of the ovary with pulmonary differentiation, and tumors of salivary gland type are included.

Mesenchymal Tumors Nonspecific to the Ovary

Mesenchymal neoplasms nonspecific to the ovary include all primary ovarian neoplasms of connective tissue origin found in the ovary that are nonspecific to it but are considered to originate from ovarian tissue, and are not of teratomatous or surface epithelial–stromal (müllerian) origin. However, this mode of origin cannot be excluded in a number of cases. The neoplasms discussed here are composed of a single neoplastic mesenchymal element, either benign or malignant, in contrast to teratomatous tumors or MMMTs, which usually are composed of a number of tissue elements.

Some issues of classification and histogenesis may not be reconcilable in view of the possibility of one-sided differentiation of a teratoma or of a malignant mixed müllerian tumor of the ovary. Thus, although some of these neoplasms can be shown to originate directly from ovarian tissue, a considerable number of cases are of indeterminate histogenesis and origin. Mesenchymal neoplasms nonspecific to the ovary can be benign or malignant, and are classified on the basis of the tissue of origin.

Myxoma

Primary myxoma of the ovary is a very rare neoplasm: only a very small number of cases have been reported in the literature [3, 13, 61]. The patients were aged 14–45 years, and in each case had an adnexal mass while the other adnexa was normal [3, 13, 61]. Macroscopically, the tumors measured from 5 to 22 cm in the greatest dimension [13, 61]. They were encapsulated, gray-white, and soft; on cut section, they were found to be partly cystic. Solid areas were slimy and mucinous, whereas the cystic spaces contained a viscous, glassy, gelatinous material.

Microscopically, the tumors showed typical appearances of myxoma as seen in other locations. They were composed of loose myxomatous stroma within which there were scattered stellate or spindle-shaped cells, some of which contained hyperchromatic nuclei. There was no nuclear pleomorphism, and mitotic activity was absent. The tumors varied from poorly vascularized, containing only a few capillary blood vessels and showing absence of plexiform vessels, to tumors with prominent capillary vessels within the tumor, and larger vessels with muscular walls at its periphery. The myxomatous stroma stained positively with alcian-blue stain and contained a network of fine reticulum fibers. Stains for fat were negative. In some areas, fibrosis was present. There were no other connective tissue elements, and the tumors had a homogeneous appearance.

Myxoma is immunoreactive for vimentin and focally for actin, but negative for desmin, cytokeratins, vascular markers, S-100, and neurofilaments [8, 13]. Most myxomas originate within connective tissue, and the origin of the tumor is still a matter of dispute. The histogenesis of ovarian myxomas is unknown; however, a gonadal stromal origin has been proposed [8].

Although myxoma is a benign neoplasm, because of its viscous nature it is difficult to excise it completely, and recurrences are not uncommon unless the entire adnexa bearing the tumor are excised. All the patients treated by unilateral adnexectomy and for whom there is follow-up information are free of disease after 1–13 years [13].

Myxoma must be differentiated from fibroma with myxoid degeneration, which contains normal fibrous tissue in some areas. Ovarian myxoma must be distinguished from massive edema of the ovary (see **O** Chap. 12, Nonneoplastic Lesions of the Ovary) [29, 78]. The patients with massive edema usually are younger, and the lesion shows entrapment of follicular derivatives, which is not observed in ovarian myxoma. More importantly, myxoma must be differentiated from myxomatous liposarcoma, which contains fat, is more vascularized, and shows lipoblasts at least in some areas. It also must be differentiated from mucinous cystadenomas and carcinomas, either primary or metastatic, which contain epithelial cells, show absence of stellate and spindle-shaped cells, and may show glandular differentiation. The epithelial tumor cells are cytokeratin-positive.

Myxoma also should be distinguished from embryonal rhabdomyosarcoma. The latter tumor shows less of a uniform appearance, displays greater cellular and nuclear pleomorphism, and contains rhabdomyoblasts. In addition, embryonal rhabdomyosarcoma shows immunohistochemical staining for muscle-specific actin, desmin, and myogenin. Ultrastructurally, Z-band formation, glycogen granules, and thick filament ribosomal complexes are observed.

Giant Cell Tumor of the Ovary

Giant cell tumor of the ovary, histologically indistinguishable from a giant cell tumor of bone, is very rare, and only a few cases have been reported [17, 36]. Most of the tumors were either associated with an epithelial component of surface epithelial stromal origin or were seen as part of mural nodules, but in two cases the tumor was composed entirely of multinucleated giant cells and small ovoid or spindle-shaped stromal cells [17, 36]. In the latter cases, the tumors were larger, showed hemorrhage, necrosis, and brisk mitotic activity in the smaller mononuclear component of the tumor. There was no evidence of metastases. One patient, a 31-year-old woman, was well and disease-free 4.5 years following surgery, while the other, a 76-year-old woman, died a few months following surgery and chemotherapy. Due to limited data it is not possible to draw any conclusions regarding the behavior of this tumor.

Undifferentiated Sarcoma

Some ovarian tumors are poorly differentiated, and although a diagnosis of sarcoma can be made, the tumor does not exhibit further differentiation beyond showing its mesenchymal origin. Careful and extensive gross sampling and histologic examination in such cases are helpful and may result in finding better-differentiated areas, which will yield a more accurate diagnosis. Immunohistochemical investigations may be very helpful in detecting accurately the tissue of origin and should be undertaken in all such cases. In some cases, a more precise diagnosis cannot be made despite very extensive investigations.

Tumors of Muscle Differentiation

Leiomyoma

Primary leiomyoma of the ovary is uncommon [10, 30, 34, 53, 61]. A small number of cases are on record, but it is likely that many cases are not reported, especially when the tumor is small and is discovered incidentally. More than a dozen unreported cases are known to the authors.

Primary ovarian leiomyoma probably originates from smooth muscle present in the walls of blood vessels in the cortical stroma, in the corpus luteum, and in the ovarian ligaments at their point of attachment to the ovary; its precise histogenesis is uncertain, however. This tumor usually is found in menopausal and postmenopausal women, but sometimes occurs in young women. The age of patients ranged from 3 to 65 years. Clinically, many patients are asymptomatic, and the tumor is discovered incidentally. When symptoms are present, they are related to the presence of an adnexal mass, often accompanied by abdominal swelling and pain. The latter may be acute because of torsion. Ascites is rare, and hydrothorax has not been reported. The uterus usually contains leiomyomas.

Ovarian leiomyoma is unilateral, although a single case of large bilateral ovarian leiomyomas occurring in a 21-year-old woman has been reported [30]. Macroscopically the tumors are solid, firm, and round or oval masses having a smooth surface. On cut section they have a white or gray-white solid whorled surface. Hemorrhage and necrosis may be evident, altering the appearance. Cyst formation caused by necrosis may occur, and calcification also may be present.

Microscopically, the tumor shows typical appearances of a leiomyoma, as observed in the uterus, the tumor being composed of smooth muscle cells that are uniformly spindle-shaped or elongated and contain elongated bluntended or cigar-shaped nuclei (**?** *Fig. 17.1*). Palisading of the nuclei may be present and may be prominent. Mitotic activity is absent or very low, and cellular and nuclear pleomorphism is not a feature. Most leiomyomas are of the typical type, but cellular, mitotically active, atypical, myxoid, and epithelioid types can be seen. The tumor cells form bundles intersected by fibrous septa that may be wide and show marked hyalinization. Other degenerative

■ Fig. 17.1 Primary leiomyoma of the ovary. The tumor shows an appearance similar to the much more common uterine leiomyoma

changes seen in uterine leiomyomas also may be present. Occasionally a leiomyoma may show an epithelioid pattern, which may cause some diagnostic problems. Immunohistochemical expression of smooth muscle actin, muscle-specific actin, desmin, ER, and PR can be seen. In four tumors that we have studied, this was further confirmed ultrastructurally.

A well-documented case of a large ovarian lipoleiomyoma occurring in a 63-year-old woman has been reported [41]. The tumor replaced nearly the entire ovary. The adipose tissue was found replacing and dissecting the smooth muscle within the tumor. There was no associated uterine leiomyomatosis.

Primary ovarian leiomyoma must be differentiated from pedunculated subserosal (parasitic) uterine leiomyoma, which has lost its attachment and instead has become attached to the ovary, from which it draws its blood supply. Leiomyoma also must be differentiated from ovarian fibroma as the latter is much more common. There is a tendency to diagnose leiomyoma as a fibroma, but use of immunohistochemical stains for this distinction should be used with caution since fibromas can also show expression of muscle markers [8, 70]. The treatment is excision of the affected adnexa.

Leiomyosarcoma

Primary leiomyosarcoma of the ovary is very rare. These tumors usually are found in postmenopausal women, but

Fig. 17.2

Primary leiomyosarcoma of the ovary. Low magnification. Note the similarity to the leiomyoma seen in **9** *Fig.* 17.1

sometimes may be seen in younger women [1, 34]. The tumors usually are large and solid, and patients have symptoms and signs related to the presence of an abdominal or pelvic mass. The tumors are gray-yellow, soft, fleshy, and frequently associated with hemorrhage and necrosis.

Microscopically, they differ from a leiomyoma by the presence of a variable combination of mitotic activity, cellular and nuclear pleomorphism, and necrosis (\bigcirc *Figs. 17.2* and \bigcirc *17.3*). It has been proposed that leiomyosarcoma

should be diagnosed when ≥ 2 of the following histologic features are present: significant nuclear atypia, mitotic index ≥ 10 mitotic figures/10 high-power fields, and tumor cell necrosis; it has also been suggested that a smooth muscle tumor with nuclear atypia can qualify as a leiomyosarcoma if the mitotic index is ≥ 5 mitotic figures/10 high-power fields, even if tumor cell necrosis is not present [34]. The diagnosis of "smooth muscle tumor of uncertain malignant potential" can be used for tumors with histologic features intermediate between leiomyoma and leiomyosarcoma.

Most leiomyosarcomas are of the conventional type, but occasional ovarian leiomyosarcomas may be of the myxoid or epithelioid type. It is important to recognize these unusual variants, which are similar to their counterparts in the uterus. Primary leiomyosarcoma of the ovary metastasizes via the bloodstream; the prognosis is generally unfavorable. Primary leiomyosarcoma of the ovary must be distinguished from MMMTs containing a prominent leiomyosarcomatous component. Primary leiomyosarcoma also should be distinguished from immature teratoma with a prominent leiomymatous tissue component. It also must be distinguished from metastatic leiomyosarcoma of uterine or other origin, as well as from poorly differentiated sarcomas and carcinosarcomas, both primary and metastatic to the ovary.

Rhabdomyoma

No well-documented case of pure ovarian rhabdomyoma has been recorded. A case of mural nodules of rhabdomyoma within a serous cystadenoma in a 48 year old has been reported [25].

Rhabdomyosarcoma

Primary rhabdomyosarcoma of the ovary is uncommon. A small number of cases have been reported in the literature, and nine unreported cases are known to the authors. A careful review of the literature shows that some cases, such as the frequently quoted case reported by Sandison [58], were not pure rhabdomyosarcomas but rather examples of MMMT or teratomas with a marked rhabdomyoblastic component. Therefore, before a diagnosis of primary ovarian rhabdomyosarcoma can be made, the tumor must be sampled carefully and extensively to exclude the presence of other neoplastic elements, the presence of which would preclude a diagnosis of a pure rhabdomyosarcoma of the ovary. The histogenesis of primary rhabdomyosarcoma of the ovary is uncertain. These tumors may originate from the connective tissue of the ovary, as a one-sided development of a teratoma, as a result of malignant transformation of a mature cystic teratoma with the malignant element overgrowing the tumor, or as a one-sided development of a MMMT.

The age of patients with ovarian rhabdomyosarcoma ranged from 2.5 to 84 years. The small number of cases makes it impossible to state whether there is a predilection for any particular age group, but, as with rhabdomyosarcomas occurring in other locations, the pleomorphic type occurs in older patients, whereas the embryonal and alveolar types occur in young women and children [5]. Patients with ovarian rhabdomyosarcoma usually have symptoms associated with the presence of a large, usually rapidly growing, abdominal mass, often associated with hemorrhagic ascites. Metastases frequently are seen at presentation.

Macroscopically, the tumors are unilateral, but metastatic involvement of the contralateral ovary may be present and should be differentiated from bilateral involvement. The tumors usually are large, exceeding 10 cm in diameter. They are solid, soft, fleshy, and gray-pink to yellow-tan, with areas of hemorrhage and necrosis that may be prominent.

Microscopically, the tumors may be of the embryonal (including the botryoid type), alveolar, or pleomorphic type and contain variable numbers of rhabdomyoblasts (**?** *Figs. 17.4–17.6*). Tumors composed of the former types occur in children and young adults, whereas those of the

Fig. 17.5 Primary rhabdomyosarcoma of the ovary. Distinctive crossstriations are seen (*arrow*)

pleomorphic type are observed in older women. The diagnosis of pleomorphic rhabdomyosarcoma should not present undue difficulty, because of the presence of at least some typical rhabdomyoblasts showing cross-striations. In cases of embryonal rhabdomyosarcoma, the diagnosis is much more difficult because the tumor cells are poorly differentiated, making rhabdomyoblastic differentiation discernible only with difficulty. Furthermore, it is necessary to recognize the distinctive alveolar or botryoid patterns, which also may not be easy.

The embryonal rhabdomyosarcoma is composed of small round primitive cells having a narrow rim of cytoplasm. They are poorly differentiated rhabdomyoblasts in various stages of differentiation. Therefore, the lesion is difficult to distinguish from poorly differentiated small cell carcinoma, lymphoma/leukemia, or even neuroblastoma [44, 48, 61]. Among the small round cells are scattered occasional rhabdomyoblasts, which are betterdifferentiated large cells with bright eosinophilic cytoplasm and eccentric nuclei (> Fig. 17.6). Presence of these cells and their recognition may provide a diagnostic clue. Occasionally, large, more typical rhabdomyoblasts may be seen. The presence of cross-striations is not necessary for diagnosis, but the cells comprising the tumor may be well-enough differentiated to exhibit crossstriations (> Fig. 17.5). Demonstration of Z bands or their precursors by electron microscopy is helpful in making the diagnosis. Immunohistochemical demonstration of myoglobin, desmin, muscle-specific actin, and myogenin are helpful in this respect (> Fig. 17.7). The tumor is frequently affected by edema, hemorrhage, and necrosis, making the diagnosis even more difficult. Therefore,

Fig. 17.6

Primary rhabdomyosarcoma of the ovary. The tumor contains abundant rhabdomyoblasts, each of which have an ample amount of bright eosinophilic cytoplasm and eccentric nuclei

Fig. 17.7 Primary rhabdomyosarcoma of the ovary showing diffuse expression of myogenin.

thorough examination and sampling of the tumor are essential to make the correct diagnosis. The tumor may be more common than has been hitherto believed, but because of its poor differentiation, it may have been either assigned to the group of undifferentiated ovarian tumors or misdiagnosed. In some cases, the tumor infiltrated the bone marrow and was originally diagnosed as leukemia [48]. It is therefore emphasized that embryonal rhabdomyosarcoma must be considered in the differential diagnosis of undifferentiated small round cell tumor of the ovary in a young patient. The presence of other neoplastic elements always must be excluded when making this diagnosis.

The importance of making the correct diagnosis is not only academic but practical, in view of the advances that have been made in the therapy of embryonal rhabdomyosarcoma during the past few decades. In the past, the prognosis was poor, and in most reported cases, the patients died of extensive metastatic disease within 1 year of diagnosis. Recently, patients with embryonal rhabdomyosarcoma, some of whom had metastases, are well and disease-free after surgery, chemotherapy, and radiotherapy. The combination chemotherapy advocated for such patients consists of dactinomycin, vincristine, and cyclophosphamide. The addition of methotrexate with folinic acid rescue and doxorubicin to this combination also may be of value.

Myofibroblastoma

A well-documented case of an ovarian myofibroblastoma has been reported recently [54]. A 22-year-old woman who was involved in an automobile accident was found to have an enlarged right ovary but refused laparotomy. Over the next 3 years the mass gradually increased in size, and laparotomy was performed. A $9 \times 8.5 \times 6$ cm, rightsided ovarian tumor weighing 215 g and adherent to the right fallopian tube and omentum was found and excised. The tumor was solid, white-tan, and on sectioning revealed whorled areas and focal calcification. Microscopically, it was composed of uniform bland-looking spindle cells arranged haphazardly in fascicles separated by bands of hyalinized collagen. In some areas there was increased vascularity. There was no atypia or mitotic activity. The tumor cells showed vimentin, smooth muscle actin, and muscle-specific actin positivity. There was no immunoreactivity with desmin and cytokeratin. The patient was well and disease-free 21 months after treatment. Myofibroblastoma is a benign lesion, and complete excision results in cure.

Tumors of Vascular and Lymphatic Differentiation

Hemangioma

Hemangioma is found only occasionally in the ovary. Only a small number of well-documented cases have been reported. Although some cases may not have been recognized or recorded, all investigators consider ovarian hemangioma uncommon [33, 67]. This is somewhat surprising as the ovary has a very rich and complex vasculature.

The origin of ovarian hemangioma in common with hemangioma in general is a matter of controversy; it is considered either a hamartomatous malformation or a true neoplasm. It is likely that both modes of origin are responsible for their formation. The reported age of patients with ovarian hemangioma ranges from 4 months to 63 years [20, 33, 67], and does not show a predominance in any decade. In most patients, ovarian hemangioma has been noted as an incidental finding at operation or autopsy [67]. In a few cases, the lesion was large and the patient had abdominal enlargement because of the presence of an ovarian mass [19, 37, 38] or had acute abdominal pain associated with torsion of the tumor [37, 63]. In some cases, there was ascites [19, 38, 59]. The lesions usually are unilateral, although in four patients they were bilateral [67]. Ovarian hemangiomas have been noted in patients with generalized hemangiomatosis [33] and in patients with hemangiomas in other parts of the genital tract [33, 67]. One patient with bilateral ovarian hemangiomas and diffuse abdominopelvic hemangiomatosis had thrombocytopenia. The platelet count returned to normal after excision of the affected ovaries [33].

Macroscopically, the lesions are small, red or purple, round or oval nodules, measuring from a few millimeters to 1.5 cm in diameter. Larger lesions also have been encountered measuring up to 11.5 cm in the longest diameter [19, 37]. On cut section, they usually are spongy and show a honeycomb appearance. Although they have been found in different parts of the ovary, the medulla and the hilar region appear to be the most common sites [67].

Microscopically, ovarian hemangioma is of the cavernous or mixed capillary-cavernous type. It consists of collections of vascular spaces, which may vary in size but usually are small, lined by a single layer of endothelial cells, and usually contain red blood cells in their lumens (\bigcirc *Fig.17.8*). Occasionally, thrombosis may be seen. A small amount of connective tissue may be present within the lesion. In a few reported cases, the hemangioma was associated with the presence of luteinized cells in the stroma of the lesion. In one such case, there was evidence of hormonal function [59]. In a recent case, a patient with capillary hemangioma presenting as an adnexal mass had elevated serum CA-125 and massive ascites [19]. Excision of the affected adnexa resulted in a complete cure.

Hemangioma must be differentiated from proliferations of dilated blood vessels, frequently seen in the hilar region of the ovary. Although a very small hemangioma may not be easily distinguished from such vascular proliferations, the hemangioma usually forms a nodule or a small mass. The presence of a circumscribed nodule composed of vascular spaces tends to distinguish hemangioma from vascular proliferations, which usually are smaller and more diffuse. The presence of numerous blood cells within the vascular spaces and the absence of pale eosinophilic homogeneous material usually distinguish hemangioma from the less common lymphangioma. Hemangioma also must be distinguished from teratoma with a prominent vascular component. In such cases, careful sampling will detect other teratomatous elements, the presence of which distinguishes the lesion from a hemangioma.

The treatment of choice is oophorectomy, which results in a complete cure.

Angiosarcoma (Previously Referred to as Hemangiosarcoma, Hemangioendothelial Sarcoma, Hemangioendothelioma, and Lymphangiosarcoma in the Ovary)

Angiosarcoma is a very rare ovarian neoplasm [43, 47, 61]. Six unreported cases have been seen by the authors. In some reported cases, the angiosarcoma had arisen within a mature cystic teratoma or may have been associated with an immature teratoma. Such cases are considered as germ cell tumors and are excluded from consideration here. The age of the patients with angiosarcoma varied from 19 to 77 years. The tumor usually is unilateral, but bilateral tumors have been recorded. Bilaterality must be differentiated from metastatic spread to the contralateral ovary. The histogenesis of primary ovarian angiosarcoma is uncertain. It may originate from the vascular tissue present in the ovary, as a one-sided development of a teratoma, or from a teratoma in which the vascular component has overgrown the other parts of the tumor. Patients usually have symptoms related to the presence of a lower abdominal mass, which may be associated with torsion and rupture of the tumor and hemorrhage.

Macroscopically, the tumors usually are large, bluebrown, hemorrhagic, soft, and friable. They may be confined to the ovary, but often are associated with invasion of the surrounding structures.

Microscopically, they are composed of vascular spaces of varying size and appearance, lined by endothelial cells that usually are large, showing atypical appearance, bizarre nuclei, and mitotic activity (**>** *Figs.* 17.9 and **>** 17.10). In some areas, the tumor may contain a considerable amount of connective tissue interspersed between the vascular spaces. Fine papillary projections lined by atypical endothelial cells may be seen and are prominent. Some tumors are composed of small closely packed spaces lined by atypical cells with a suggestion of a solid pattern [47].

Angiosarcoma of the ovary must be distinguished from immature teratomatous neoplasms with a prominent

• Fig. 17.8 Hemangioma of the ovary. The tumor is composed of numerous small blood vessels, some of which contain red blood cells in their lumens

Primary angiosarcoma of ovary. The tumor is composed of dilated vascular spaces lined by enlarged hyperchromatic cells

vascular component. The presence of other neoplastic germ cell elements distinguishes teratoma from primary angiosarcoma. Immunohistochemical stains for CD31 and CD34 are useful in confirming the diagnosis of angiosarcoma when the tumor is poorly differentiated, especially when showing a solid pattern.

The tumor invades locally and metastasizes via the bloodstream. Prognosis is poor, especially in patients who have metastases at the time of presentation. When the tumor is confined to the ovary, the prognosis is better and a few survivors have been reported. The tumor has not responded to combination chemotherapy regimens.

Lymphangioma

Lymphangioma of the ovary is very rare. We have seen two cases. In both cases, the tumor was small and was found incidentally. The tumor is usually unilateral but bilateral lesions have been reported. In the latter cases, it is possible that the lesions were malformations and neoplasms. Macroscopically, the tumor is small with a smooth, gray surface. On cut section, it is yellow, honeycombed, and composed of numerous small cystic spaces exuding clear yellow fluid.

Microscopically, lymphangioma of the ovary is composed of closely packed, thin-walled vascular spaces lined by flattened endothelial cells and containing pale, homogeneous eosinophilic fluid (**)** *Fig. 17.11*). Lymphocytes may be seen within the vascular spaces. The histogenesis

Primary ovarian lymphangioma. The tumor is composed of large and closely packed thin-walled lymphatic spaces lined by flattened endothelial cells and contains pale eosinophilic fluid

is a matter of controversy. Some investigators consider these lesions as malformations and some as neoplasms. Both modes of histogenesis are likely.

Lymphangioma is differentiated from a teratoma with a prominent vascular component by the absence of other germ cell elements. Lymphangioma also must be distinguished from hemangioma and an adenomatoid tumor that contains thin-walled, vessel-like spaces. In contrast to hemangioma, lymphangioma does not contain blood cells in the vascular spaces, and immunohistochemical expression of D2-40 is expected in the latter. The adenomatoid tumor has solid areas, and the cells lining the vessel-like spaces show immunohistochemical expression of cytokeratin and calretinin.

Tumors of Cartilage Differentiation

Chondroma

Only a few reports of ovarian chondroma are available, and documentation in most cases is unsatisfactory. One well-documented case considered to originate from the ovarian stroma has been reported [45]. The tumor, which measured $4 \times 3 \times 3$ cm and was composed entirely of mature cartilage, was found incidentally. Although chondroma may originate from the connective tissue of the ovary by a process of metaplasia, it is more likely that most ovarian tumors described as chondroma were either fibromas showing cartilaginous metaplasia or teratomas having a prominent cartilaginous component.

Chondrosarcoma

A single example of pure chondrosarcoma of the ovary (**>** *Figs.* 17.12 and **>** 17.13) has been reported [68]. A 61-year-old woman had an abdominal mass that on extensive microscopic examination proved to be a pure, well-differentiated chondrosarcoma. The patient was well and disease-free 6 years after one-sided oophorectomy. The histogenesis of this tumor is uncertain, but the age of the patient and the histologic appearances of the tumor point to an origin in a dermoid cyst with malignant transformation and overgrowth by the malignant cartilaginous component [68]. A well-documented case of mature cystic teratoma (dermoid cyst) with malignant transformation of the cartilaginous element has been reported; the patient died of extensive metastatic disease [7]. In malignant ovarian tumors with cartilaginous differentiation, additional sampling is recommended in order to exclude an MMMT.

Tumors of Bone Differentiation

Osteoma

Few documented examples of osteoma occurring in the ovary exist. Although an origin from ovarian stroma is possible, most such lesions probably were examples of osseous metaplasia occurring in fibromas or leiomyomas,

Fig. 17.12
Primary ovarian chondrosarcoma. Low magnification

or possibly examples of metaplasia or heterotopia and not neoplasia occurring in the connective tissue of the ovary. Teratomatous origin is also possible. The lesions usually are small, but may be large, and are histologically composed of dense cortical bone.

Osteosarcoma

Few cases of pure osteosarcoma of the ovary have been reported [16, 23, 24, 74]. Patients range in age from 24 to 76 years. The tumor is frequently associated with extensive metastatic disease. Survival is poor. In one case metastatic tumor deposits affecting the abdominal cavity were excised at operation, and the patient was treated with triple chemotherapy consisting of cyclophosphamide, mitomycin C, and bleomycin [24]. The tumor recurred, and cisplatin and doxorubicin were added to the chemotherapeutic regimen. In spite of this, the tumor progressed and the patient died 8 months after diagnosis.

Histologically, the tumors show typical appearances of osteosarcoma occurring in the skeleton. Although it was believed that the tumors originated directly from ovarian stroma, their histogenesis is uncertain. Occasional cases of osteosarcoma originating in ovarian teratoma have been recorded [66], but such cases should not be confused with pure ovarian osteosarcoma or with cases of MMMT with a prominent osteosarcomatous component.

Tumors of Neural Differentiation

Ovarian tumors originating from neural tissue are rare. The presenting symptoms usually are related to the

Fig. 17.13
Primary ovarian chondrosarcoma. Marked nuclear atypia

presence of an intraabdominal mass. The tumors are solid and usually are small. The histogenesis is uncertain and probably is similar to that of other mesenchymal tumors of the ovary.

Neurofibroma

Two cases of neurofibroma of the ovary have been reported in patients with generalized neurofibromatosis (von Recklinghausen's disease) [22, 64], one as an incidental finding [64]. Histologically, the tumors resembled neurofibroma occurring elsewhere.

Schwannoma (Neurilemmoma)

Three cases of ovarian schwannoma have been reported [40, 42]. In one case, the tumor was large [42]. The tumors were solid, and the patients were well and disease-free after the excision of the tumor. Histologically, the tumors resembled schwannoma occurring in other locations.

Malignant Peripheral Nerve Sheath Tumor

One case of "malignant neurilemmoma" (malignant schwannoma) of the ovary has been reported [65]. The affected patient, a 71-year-old nulliparous woman, was admitted for evaluation of lower abdominal enlargement and pain. There were no stigmata of generalized neurofibromatosis. At laparotomy, a 15 cm, firm, somewhat hemorrhagic tumor was found arising from the left ovary. There were numerous tumor deposits involving the peritoneal cavity. A debulking procedure was performed, and the ovarian tumor was excised together with the omentum. Histologic and ultrastructural examinations revealed that the tumor was a malignant neurilemmoma. After surgery, the patient was treated with combination chemotherapy consisting of doxorubicin and cyclophosphamide, but the disease progressed and she died 5 months after surgery of extensive intraabdominal metastatic disease [65]. One case of "neurofibrosarcoma" occurring in a 38-year-old woman with generalized neurofibromatosis (von Recklinghausen's disease) has been described [11]. The tumor was an incidental finding and had replaced the ovary. It was solid, and histologically showed the typical appearance of a neurofibrosarcoma with a moderate degree of nuclear pleomorphism and mitotic activity. There was no evidence

of metastases, and the patient was well and diseasefree 1 year after diagnosis [11]. A malignant epithelioid schwannoma of the ovary has been reported [32].

Paraganglioma/Pheochromocytoma

Paraganglioma of the ovary is rare. In a report of three cases, patients ranged in age from 22 to 68 years [39]. Two patients had hypertension. Some cases may have extraovarian spread of tumor. Tumors are characterized by the "zellballen" growth pattern seen in primary non-ovarian paragangliomas. With immunohistochemical stains, tumors are positive for neuroendocrine markers and negative for cytokeratin. Sustentacular cells can show expression of S-100. It should be noted that inhibin expression has been observed, which may create diagnostic confusion if a sex cord–stromal tumor is in the differential diagnosis.

A case of ovarian "pheochromocytoma" has been reported in a 15-year-old girl [18]. The patient had hypertension, convulsions, and a large, left-sided abdominal tumor mass. The tumor had undergone torsion and weighed 970 g. It was solid, and microscopic examination showed typical appearances of pheochromocytoma. Epinephrine and norepinephrine were extracted from tumor tissue. The symptoms disappeared after excision of the tumor, and the patient was well and disease-free 15 months after the operation [18]. Two additional cases were mentioned by Scully et al [61], but no further details were provided.

Ganglioneuroma

A single case of ovarian ganglioneuroma occurring in a 4-year-old girl has been reported [60]. The child had abdominal enlargement. The tumor was solid, weighing 200 g, and replaced nearly the whole ovary. Histologically, the tumor was composed of well-differentiated ganglion cells. There was a recurrence after the excision of the tumor. True ganglioneuroma must be differentiated from teratomas showing prominence of ganglion cells and from proliferations of ganglion cells occasionally seen in the hilar region of the ovary; the latter are nonneoplastic and probably hamartomatous in nature.

Tumors of Adipose Tissue Differentiation

Collections of adipose cells forming islands of fatty tissue that are not encapsulated are seen occasionally within
ovarian tissue and are attributed to metaplasia of connective tissue of the ovary. These collections have been described as adipose prosoplasia. Benign adipose tissue seen in the ovary may be part of a teratoma with a prominent adipose tissue component. Pure benign fatty tumors in the ovary are very rare. A single case of a pure lipoma has been reported [81]. Malignant adipose tissue may be part of a MMMT with a prominent liposarcomatous component, or it may represent metastases from a liposarcoma occurring at another location. Well-characterized cases of pure malignant fatty tumors of the ovary have not been reported.

Tumors of Mesothelial Differentiation

Adenomatoid Tumor

The adenomatoid tumor, which in females is found most frequently in the fallopian tubes and broad ligament and occasionally in the uterus near the serosal surface, is found only rarely in the ovary (see O Chap. 10, Mesenchymal Tumors of the Uterus and O Chap. 11, Diseases of the Fallopian Tube and Paratubal Region). Although its histogenesis was long disputed, it is now considered to be of mesothelial origin, as is supported by morphologic, histochemical, immunohistochemical, and ultrastructural observations. Adenomatoid tumor is benign and, therefore, is considered a benign mesothelioma.

Few cases of ovarian adenomatoid tumor have been recorded, most of which occurred in patients in the third and fourth decades [61, 80]. The lesions, which are small, round or oval, and 0.5–3 cm in diameter, usually are found in the hilus of the ovary as incidental findings. In two cases the tumors were larger, measuring 6 and 8 cm in the longest diameter, respectively, and were symptomatic.

Histologically, the tumors show similar appearances to adenomatoid tumors occurring in other locations and are composed of clefts and spaces lined by cuboidal, low columnar, or flattened epithelial-like cells (\bigcirc *Fig.* 17.14) and of solid aggregates of similar cells surrounded by connective tissue that varies from loose and edematous to dense and hyalinized. The epithelial-like cells may exhibit marked vacuolation. An oxyphilic variant has been described [51]. They exhibit positive staining with alcian blue, which is digestible with hyaluronidase, and similarly staining material is present in the clefts and spaces. Occasionally, the cells may show weak PAS staining. The tumor cells show strong positive immunohistochemical staining for low molecular weight cytokeratin, WT-1, calretinin, and D2-40. ER, PR, and Ber-EP4 are

negative. Ultrastructural observations support the mesothelial origin of this lesion and show an abundance of microvilli, bundles of cytoplasmic filaments, tight junctional complexes, and intercellular spaces. The lesion is benign, and its excision results in a complete cure.

Adenomatoid tumor may be confused with yolk sac tumor (YST) because the clefts and spaces may resemble the microcystic pattern of YST, but the nuclear appearances are totally different. The nuclei of adenomatoid tumor are bland and generally small and flattened, differing from the larger round and ovoid vesicular nuclei of YST, which exhibit brisk mitotic activity. The absence of other patterns associated with YST helps to distinguish adenomatoid tumor from YST. Confusion with lymphangioma may arise, and we have seen an adenomatoid tumor diagnosed as lymphangioma and vice versa. Immunohistochemical studies can be helpful in differentiating between these two entities. Lymphangioma is low molecular weight cytokeratin negative, whereas adenomatoid tumor is strongly positive. Vascular markers such as factor VIII, CD34, and CD31 show negative reactions with adenomatoid tumor and positive staining with lymphangioma. Calretinin and WT-1 are also expressed in adenomatoid tumor but negative in lymph-vascular tumors.

Peritoneal Malignant Mesothelioma

Occasionally, peritoneal mesothelioma may involve the surface of the ovary (see) Chap. 13, Diseases of the

Peritoneum). When the tumor affects the ovary, confusion with primary ovarian neoplasms or benign conditions may occur [69]. The involvement of the ovary may be very extensive, and the presentation is that of a primary ovarian neoplasm. In one series of nine malignant peritoneal mesotheliomas presenting as ovarian masses, two tumors were considered as primary ovarian malignant mesotheliomas because the tumors were confined to the ovary [6, 61]. The histologic pattern, immunohistochemical and ultrastructural observations, and behavior and distribution of the lesion are helpful in making the correct diagnosis [2, 6, 50, 61, 69, 72]. Most patients with malignant peritoneal mesothelioma are middle-aged or elderly adults, and the tumor shows a considerable male predominance, and association with asbestos exposure. Very rarely, it may occur in children [69].

Ovarian Tumor of Probable Wolffian Origin (FATWO)

In the original report describing tumors of this type [31], all the tumors were located within the leaves of the broad ligament or were attached to it or to the fallopian tube; this also applied to subsequent reports dealing with this entity. Subsequently, a small number of ovarian tumors of probable wolffian origin were reported [9, 26, 77], indicating that tumors of this type also occur in the ovary. The age of most patients ranged from 28 to 79 years. Some patients had abdominal enlargement, and in other patients, the tumor was found on physical examination [26, 77]. All the tumors were unilateral. In most cases, they were confined to the ovary, but in one case metastatic deposits in the abdominal cavity were reported. In the latter case, the tumor contained foci of undifferentiated carcinoma [77]. Most tumors ranged in size from 2 to 20 cm in the largest diameter. They are smooth and often lobulated and are either solid or solid and cystic. The cysts vary in size and may range up to 11 cm [77].

Microscopically, the tumor is composed of relatively uniform epithelial cells that line cysts and tubules, sometimes forming a sieve-like pattern. The tumor cells also may form closely packed tubules, grow in a diffuse pattern, or fill tubules or tubular spaces (**>** *Fig. 17.15*). They have uniform round or oval nuclei, and there is low mitotic activity. The tumor cells do not contain mucin but occasionally may contain glycogen. The amount of intervening connective tissue varies from imperceptible to considerable, forming fibrous bands separating the islands of tumor cells and producing a lobular pattern [77]. In two

Fig. 17.15 Ovarian tumor of probable wolffian origin. The tumor is composed of closely packed tubules and clefts with adjacent solid patterns containing spindle cells

Two patients have subsequently developed metastases [77]. Eight patients were known to be alive and disease-free from 1 to 15 years postoperatively, and one was lost to follow-up [77], indicating that in most cases the tumor is not associated with an aggressive course. It is also of note that there is a good correlation between the mitotic activity and the behavior of this neoplasm.

Ovarian tumor of probable wolffian origin may be confused with sex cord-stromal tumors, especially various types of Sertoli-Leydig cell tumors and surface epithelialstromal tumors (see O Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). The presence of the typical features of this tumor described here and the absence of the various patterns observed in Sertoli-Leydig cell tumors differentiate it from the latter. Female adnexal tumors of probable wolffian origin (FATWO) with a prominent spindle cell component may mimic cellular fibroma [35]. The tumor of probable wolffian origin is distinguished from the various surface epithelial-stromal tumors of the ovary by the absence of cellular and nuclear pleomorphism, papillary pattern, and intraluminal and intracellular mucin.

Lesions of the Rete Ovarii

Rete cysts/cystadenomas are uncommon, although probably more common than realized. The average age of patients with tumors of the rete ovarii is 59 years (range, 23–80 years). Patients can present with abdominal discomfort, pelvic pressure, virilization, postmenopausal bleeding, and/or hirsutism [56]. Most tumors are unilateral, and the average size is 9 cm. They may be uni- or multicystic, and the internal lining is usually smooth.

The rete lesions range in histologic type and include cyst, cystadenoma, adenoma, adenomatous hyperplasia, and adenocarcinoma [21, 46, 56]. Most are cysts/cystadenomas. Rete lesions are either found within the ovarian hilus or are anatomically related to the rete ovarii. The distinction between cyst and cystadenoma is arbitrary, but an upper limit of 1 cm for cysts has been proposed. The epithelial lining of the rete cyst/cystadenoma is simple, non-ciliated, and bland and characterized by irregular crevices. The periphery of rete adenoma is well circumscribed, and the tumor contains crowded tubules and papillae. The tubules and papillae have a simple layer of bland epithelial cells. Adenomatous hyperplasia is histologically similar to adenoma; however, the former is not well circumscribed.

Rete adenocarcinoma is rare. Only one well-documented case of adenocarcinoma of rete ovarii occurring in a 52-year-old woman with abdominal enlargement and ascites has been reported [56]. The patient had bilateral, partly solid and partly cystic tumors without specific macroscopic features. The tumor showed a predominant pattern of branching tubules and cysts containing simple papillae with fibrovascular or hyalinized cores. Some cysts contained eosinophilic material. Focally the tumor showed a solid tubular pattern. The cells lining the tubules and papillae were cuboidal, nonciliated, and atypical. Focally, they were multilayered and stratified. There was brisk mitotic activity. Adenocarcinoma of rete ovarii can only be diagnosed if the tumor has hilar location and is composed of collections of slit-like retiform tubules and cysts containing papillae lined by cells similar to those of normal rete ovarii [56, 61].

Rete cysts/cystadenomas are benign. The data on adenoma and adenocarcinoma is limited; thus, the behavior of these lesions is uncertain.

The most common lesion to histologically mimic rete cystadenoma is serous cystadenoma, but this is not a clinically important distinction. Rete cystadenoma is favored based on location in the hilus or anatomic connection with the rete ovarii, cyst lining with crevice-like contours, absence of ciliated cells, and smooth muscle and hilus cells within the cyst wall. Confusion may occur with retiform Sertoli–Leydig cell tumor, but the latter is likely to show other patterns of Sertoli–Leydig cell tumor and stain positively for inhibin. The role of immunohistochemistry in this setting is uncertain as immunohistochemical data on rete lesions is limited. Some serous carcinomas may also resemble adenocarcinoma of the rete ovarii, but they tend to be found in cortical location, generally do not show the fine slit-like papillae, and exhibit much greater nuclear pleomorphism.

Primary Ovarian Tumors of Uncertain Histogenesis

Hepatoid Carcinoma

In 1987, Ishikura and Scully [28] described five cases of ovarian carcinoma with hepatoid features, three of them primary and two probably primary. The age of the patients ranged from 42 to 78 years, and thus differed considerably from patients with YST with a hepatoid pattern, which is invariably seen in children, adolescents, and young women. The age range as well as the histologic appearances of the tumors showed considerable similarity to gastric carcinomas with hepatic features described some years earlier [27].

Unlike YST with a hepatoid pattern, which may be pure, mixed with other YST patterns, or combined with other germ cell tumors, hepatoid carcinoma of the ovary occurs in pure form, although occasionally it is associated with serous adenocarcinoma or other types of ovarian surface epithelial–stromal tumors [52, 61, 62, 71]. Hepatoid carcinoma of the ovary [28, 52, 71], like YST with hepatoid pattern and gastric adenocarcinoma with hepatoid features [27], is associated with alpha-fetoprotein (AFP) secretion, and AFP can be demonstrated within the tumor cells by immunohistochemical techniques. In three cases known to the authors, high levels of serum AFP were noted, and serum AFP was used to monitor the disease activity.

Clinically, patients present with symptoms and signs related to the presence of an adnexal mass. Abdominal enlargement, which may be associated with pain, malaise, and weight loss, is the main presenting sign [28].

Hepatoid carcinomas of the ovary are large and are associated with metastatic tumor deposits within the abdominal cavity (stage III) in most cases [28]. Histologically, the tumor shows a close resemblance to hepatocellular carcinoma (\bigcirc *Fig.* 17.16), and is composed of solid sheets or aggregates of uniform cells with moderate or

abundant eosinophilic cytoplasm, distinct cell borders, and centrally located nuclei with prominent nucleoli [28, 52, 71]. Mitotic activity generally is brisk, and abnormal forms are seen. In some parts of the tumor there may be a considerable degree of nuclear pleomorphism, and multinucleated giant cells may be seen [28]. PAS-positive diastase-resistant hyaline globules may be seen, and glycogen can be demonstrated within the cytoplasm of the tumor cells. Histologic patterns seen in germ cell tumors or surface epithelial–stromal tumors are not detectable when the tumor is seen in pure form [28, 61].

Immunohistochemical studies demonstrate the presence of AFP and hepatocyte paraffin 1 [52] in a considerable number of tumor cells (**>** *Fig. 17.17*). In addition, the tumor cells are immunoreactive for albumin, alpha₁antitrypsin, and alpha₁-antichymotrypsin. Focal positive immunostaining for carcinoembryonic antigen (CEA) also is seen [28].

Hepatoid carcinoma of the ovary is a highly malignant neoplasm [28, 61]. Most patients present with disseminated disease and die of the disease within a few years of diagnosis. One patient was well and disease free for 2 years after pelvic irradiation [28]. One patient was alive with evidence of disease 2 years after surgery and combination chemotherapy. She was treated with Taxol and for some time responded to treatment, as evidenced by some decrease in the highly elevated serum AFP level. She then relapsed and died of extensive disease.

The histogenesis of hepatoid carcinoma of the ovary has not been established. Unlike YST with hepatoid pattern, it is not of germ cell origin, as it occurs in older patients, is not associated with other neoplastic germ cell

 Fig. 17.17
Hepatoid carcinoma of the ovary showing expression of alpha-fetoprotein (AFP)

elements, and is not found in patients with gonadal dysgenesis. Because of the age distribution and the occasional association with ovarian surface epithelial–stromal tumors, it is likely that it is a metaplastic tumor and represents a variant of a surface epithelial–stromal tumor [28, 52, 61, 62, 71].

Hepatoid carcinoma of the ovary must be distinguished from YST with hepatoid pattern. It can be distinguished clinically by its occurrence in older, usually postmenopausal patients, and by its presentation in a more advanced clinical stage, usually in stage III. Histologically, hepatoid carcinoma shows a greater degree of cellular and nuclear pleomorphism, and tumor giant cells are much more frequently seen.

Demonstration of positive immunocytochemical staining for AFP in the tumor cells and elevated levels of serum AFP differentiate hepatoid carcinoma from other ovarian tumors such as undifferentiated adenocarcinomas, endometrioid adenocarcinomas with marked squamous differentiation, and steroid cell tumors [28]. Primary hepatoid carcinoma of the ovary also must be differentiated from hepatocellular carcinoma metastatic to the ovary [75]. Although the latter is uncommon, this possibility must be carefully excluded before the diagnosis of primary hepatoid carcinoma of the ovary is made.

Small Cell Carcinoma, Pulmonary Type

Eichhorn et al [15]. have reported 11 primary ovarian tumors that resembled small cell carcinoma of the lung and differed both clinically and histologically from primary small cell carcinoma of the ovary of hypercalcemic type [76]. The age of the patients ranged from 28 to 85 years [15]. Most patients presented with abdominal enlargement. Six of the tumors were unilateral, and five were bilateral. Spread beyond the ovary was noted in seven tumors. None of the patients had distant metastases at presentation [15]. The tumors measured from 4.5 to 26 cm in the greatest dimension; they were mostly solid with a variable minor cystic component [15].

Histologically, the tumor is composed of small to medium-sized round to spindle-shaped cells with scanty cytoplasm, hyperchromatic nuclei, and inconspicuous nucleoli forming sheets, large aggregates, and closely packed nests (> Fig. 17.18). Sometimes an insular or a trabecular pattern was seen [15]. In four tumors a component of endometrioid carcinoma was present, one tumor showed focal squamous differentiation, two tumors were associated with Brenner tumor, and one contained a cyst lined by atypical mucinous cells [15]. In two of six tumors, argyrophil granules were demonstrated. In nine cases, immunohistochemical studies were performed that demonstrated positive staining for cytokeratin in six cases, epithelial membrane antigen (EMA) in five, and chromogranin in two. All nine tumors were vimentin-negative. In a small number of cases evaluated, perinuclear dotlike staining for CK20 and variable TTF-1 expression have been observed [4, 55]. Flow cytometric studies performed on eight tumors showed that five tumors were aneuploid and three were diploid [15].

The tumors were aggressive, and of the nine patients with known follow-up, five died of the disease 1–13 months after diagnosis, one died after an unknown interval, and two had recurrent disease 6 and 8 months after surgery. Five of the patients with stage III tumors and two with stage I tumors were treated with combination chemotherapy, which included cisplatin in all cases and doxorubicin in most cases; one of these treated patients was alive at 7.5 years [15].

Aggressive treatment with agents effective in treating small cell pulmonary carcinoma appears to be the treatment of choice.

Primary ovarian small cell carcinoma with pulmonary differentiation must be distinguished from pulmonary small cell carcinoma metastatic to the ovary, which shows both clinical and pathologic differences [79]. It also must be differentiated from primary ovarian small cell carcinoma, usually associated with hypercalcemia [61, 76] (see O Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). The patients with primary ovarian small cell carcinoma with

Fig. 17.18

Small cell carcinoma, pulmonary type. (a) Solid growth pattern containing abundant geographic necrosis. (b) Small to medium-sized round cells with hyperchromatic nuclei, absence of nucleoli, scant cytoplasm, and numerous apoptotic bodies and mitotic figures (Case courtesy of Dr. Robert H. Young, Boston, MA)

pulmonary differentiation are older. The tumor is seen either in perimenopausal or postmenopausal women [15, 61]. Hypercalcemia is absent. The tumors are bilateral in 45% of cases, whereas in the hypercalcemic type, bilaterality is seen only rarely (1% of cases) [15].

Histologically, the cells of primary ovarian small cell carcinoma with pulmonary differentiation differ from those of the hypercalcemic type in having finely dispersed chromatin and inconspicuous nucleoli, whereas the latter is composed of cells with nuclei showing clumped chromatin and prominent nucleoli, as well as showing the presence of larger cells with abundant eosinophilic

925

cytoplasm in 40% of cases [15]. Follicle-like spaces are frequently seen in the hypercalcemic type and are virtually absent in the pulmonary type of small cell carcinoma [15]. Endometrioid and Brenner tumor components are present in more than half the small cell carcinomas with pulmonary differentiation and are absent in the hypercalcemic type. The former also tend to be more frequently aneuploid [15].

Although the histogenesis of the primary ovarian small cell carcinoma with pulmonary differentiation has not been established, the frequent association with endometrioid and Brenner tumors points toward a surface epithelial–stromal origin, as is supported further by the age range of the patients [15].

Neuroendocrine Carcinoma, Non-Small Cell Type

A small number of ovarian tumors composed of solid sheets, nests, cords, trabeculae, or solid islands of cells showing neuroendocrine differentiation have been reported [12, 61, 73]. These tumors were associated with either a surface epithelial-stromal or possibly germ cell component. The age of the patients ranged from 22 to 77 years. Some tumors were stage I, but in spite of this the prognosis was poor. Several cases presented with advanced stage disease, and the tumors demonstrated aggressive behavior, in common with neuroendocrine tumors occurring in other sites.

Histologically, the neuroendocrine component of the tumor consisted of solid islands or cords of medium to large epithelial cells with variable amount of cytoplasm and large nuclei, some of which had prominent nucleoli. Mitotic activity was variable but frequently high. The cellular islands and cords were surrounded only by a small amount of connective tissue. Immunohistochemical stains were frequently positive for pan-cytokeratin, CK7, CK20, chromogranin, and synaptophysin [73]. Other neurohormonal polypeptides were also detected in some of the tumors [12].

The neuroendocrine component of the tumor may resemble insular carcinoid tumor of the ovary, but the cells are usually larger and show much greater degree of cellular and nuclear pleomorphism. The presence of the surface epithelial–stromal component also helps to differentiate between these two entities. The distinction between them is very important because the prognosis of patients with neuroendocrine carcinoma is by far worse than that of patients with carcinoid tumors. The size of the tumor cells and the strong positive immunohistochemical reactions distinguish this tumor from the ovarian carcinoma of the small cell pulmonary type. The presence of the surface epithelial–stromal component confirming the ovarian origin differentiates this tumor from metastatic small cell tumors to the ovary [12].

Salivary Gland-like Carcinomas

Ovarian tumors resembling salivary gland carcinomas are rare, but a series of 12 tumors has been reported [14]. The tumors in six cases resembled adenoid cystic carcinoma. Most of the tumors also exhibited a minor component of surface epithelial-stromal neoplasia. The latter were of various histologic types and included serous, endometrioid, and clear cell carcinomas. The affected patients were elderly; nearly all were in the seventh or eighth decade. Most of the tumors were associated with extensive metastatic disease and the prognosis was poor, except for one case where the tumor was in pure form and another in which the associated surface epithelial-stromal component was of the serous borderline type. Histologically, the tumors showed architectural patterns seen in adenoid cystic carcinoma of the salivary glands (> Fig. 17.19). The tumor cells resemble myoepithelial cells, although this has not been confirmed immunohistochemically because in the majority of cases the cells did not stain positively for actin and S-100 protein [14, 61]. Histogenetically, these tumors are probably of surface epithelialstromal origin because they are usually associated with a surface epithelial-stromal component or recurred as an adenoid cystic carcinoma in a patient for whom the original tumor was an endometrioid carcinoma.

Fig. 17.19 Ovarian carcinoma resembling adenoid cystic carcinoma. (Case courtesy of Dr. Robert H. Young, Boston, MA)

The ovarian tumors in the remaining six cases from the study mentioned above showed basaloid or ameloblastomatous features [14, 61]. The age distribution was wide, ranging from 19 to 65 years. Most of the tumors were confined to the ovary (stage IA), and the prognosis was excellent after excision of the tumor although some of the follow-up periods were relatively short, varying from 16 to 71 months. Histologically, the tumors showed either a basaloid or ameloblastomatous pattern (\bigcirc *Fig.* 17.20). Several of them showed focal squamous and glandular differentiation, and one showed a minor component of endometrioid adenocarcinoma [14, 61]. The histogenesis of this neoplasm is uncertain, but surface epithelial– stromal origin, particularly endometrioid carcinoma, appears to be most likely.

Nephroblastoma (Wilms' Tumor)

One case of ovarian nephroblastoma occurring in a 56year-old woman has been reported [57]. The patient was treated by excision of the affected adnexa followed by radiotherapy and chemotherapy. She was well and disease-free 9 years after diagnosis. The tumor showed typical features of well-differentiated nephroblastoma with glomeruloid formations, small tubules, and prominent blastema. There were no other neoplastic elements [57]. A second case of a 3.5-year-old girl has also been

Fig. 17.20

Ovarian carcinoma with basaloid appearance. Note peripheral palisading at interface between neoplastic epithelium and fibrovascular cores (Case courtesy of Dr. Robert H. Young, Boston, MA) reported. A left salpingo-oophorectomy was performed, and there was no evidence of metastasis [49].

Although the tumors were described as primary ovarian nephroblastomas, their histogenetic origin is uncertain. It is considered that one-sided development of a teratoma, or a teratoma overgrown by its nephroblastomatous component, is the likely origin of this tumor. Nephroblastomatous differentiation is seen in a number of ovarian teratomas and has not been seen in association with other ovarian neoplasms, providing support for this contention. Occasionally, retiform Sertoli-Leydig cell tumors, because of the presence of tubules and papillary pattern resembling glomeruloid formations, have been misdiagnosed as ovarian nephroblastomas. Careful sectioning and examination of the tumor for the presence of other patterns associated with Sertoli-Leydig cell tumors and absence of renal blastema are helpful in differentiating between these two entities. Demonstration of positive inhibin staining using immunohistochemistry further supports the diagnosis of Sertoli-Leydig cell tumor.

Cervical Carcinoma	983
Other Uterine Tumors	987
Vulvar and Vaginal Tumors	990
Ovarian Involvement by Peritoneal Tumors	990

Tumors that spread to the ovary from elsewhere are an important group of ovarian neoplasms because the misinterpretation of cases encountered as surgical pathology specimens may have significant adverse consequences for the patient. The spread may be from adjacent sites by direct local extension or from distant extragenital sites [27, 44, 61, 66, 90, 94, 111, 145, 152, 155, 161, 162]. The latter tumors are truly metastatic, whereas the designation "metastatic" is sometimes not used for those that are secondary from local sites. However, for simplicity, this discussion includes spread to the ovary from all sites.

We first review general principles of clinical, gross, and microscopic evaluation that aid the pathologist in arriving at the correct diagnosis of a metastatic tumor, also highlighting some general pitfalls that are encountered. The subsequent discussion is site- or organ-specific, with the exception that a few tumors that may originate at more than one site (Krukenberg tumors, carcinoids, or gastrointestinal stromal tumors) are considered under those headings. We divide our consideration into three basic categories: (1) spread from extragenital sites (the most significant practical issue), (2) spread from other sites in the genital tract, and (3) involvement by peritoneal tumors. Hematopoietic tumors are covered in a separate chapter.

General Principles

Confident recognition of the metastatic nature of an ovarian tumor depends on several factors: (1) an awareness of the frequency with which metastases occur and simulate a variety of primary tumors; (2) a thorough clinical history, which in some cases may require the pathologist to prompt the clinician to explore it in greater detail than first done; (3) when indicated, a thorough clinical and operative search by the surgeon for a primary tumor outside the ovary; (4) a careful evaluation of the gross and routine microscopic features of the ovarian tumor by the pathologist, including in some cases reinspection of the gross specimen and submission of additional sections; and (5) judicious use of conventional special stains and immunohistochemistry.

The diagnosis of a metastatic tumor is often missed by the pathologist because the existence of a concurrent or prior tumor in another organ is either not known or disregarded. The surgical and pathologic findings from previous operations should be reviewed if there is any possibility that they could be related to the ovarian tumor being evaluated. In some cases a search for an extraovarian primary tumor must be conducted postoperatively, based on the pathologist's suspicion that the ovarian tumor is metastatic. Even if an extraovarian primary tumor is not detected, a diagnosis of a metastasis to the ovary must be strongly considered if the distribution of disease is atypical for primary ovarian cancer or if pathologic examination is highly suggestive of metastasis. For example, the presence of pulmonary or hepatic metastases in the absence of extensive peritoneal disease would be an unusual pattern of spread for an ovarian cancer, but not for certain other tumors that are prone to metastasize to the ovary. The mere presence of tumor outside the ovaries should lead to the serious consideration of a metastasis in certain situations. For example, if a well-differentiated ovarian mucinous tumor is associated with extensive mucinous adenocarcinoma in the omentum and on the peritoneal surfaces, the possibility of spread to the ovary, particularly from the pancreas or biliary tract, should be entertained. Additionally, certain tumors, such as Sertoli cell tumors or primary carcinoid tumors, which are most often benign, should be diagnosed with caution in cases in which there is also extraovarian tumor. In cases of these types, the putative Sertoli cell tumor may prove to be a metastatic tumor that is mimicking it, such as tubular Krukenberg tumor [14], and the carcinoid tumor probably is metastatic rather than primary in the ovary. It also must be emphasized that an association of an ovarian tumor with clinical or pathologic evidence of excess estrogens, androgens, or progesterone does not exclude the diagnosis of a metastatic tumor, which may have a functioning stroma [128] (see O Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations).

For a variety of reasons, it is difficult to establish accurately the frequency of metastatic tumors among all ovarian tumors from the available literature. Some studies have been based on autopsy findings, others on surgical specimens, and still others on both. In addition, some series have included clinically silent metastases such as breast carcinoma found in prophylactic or therapeutic oophorectomy specimens and small metastases detected incidentally during operations for gastric or intestinal carcinoma. In contrast, other series have been restricted to metastatic tumors that presented clinically as pelvic or abdominal masses. Finally, some investigations have included as metastases ovarian carcinomas associated with uterine cancers of similar histologic type, but in many cases the ovarian tumors likely represent independent primary tumors [143, 184].

The frequency of metastases to the ovary also varies from one country to another because of wide differences in the prevalence of the various cancers that are associated with high rates of ovarian spread. For example, metastatic carcinoma accounts for approximately 40% of ovarian cancers in Japan where gastric carcinoma is common, but is far less common in Africa where this form of cancer is relatively rare. The frequency of metastases also has varied greatly in series in which differences in the prevalence of the primary tumors do not adequately explain the discrepant results. Such variations may be related, in part, to the frequency and thoroughness of microscopic examination of the ovaries, because gross inspection may not reveal evidence of involvement in one third to one half the cases. The figure for the frequency of ovarian metastases that is most meaningful is one that expresses the probability that an ovarian neoplasm found on exploration of a pelvic or abdominal mass is metastatic; this figure is on the order of 5–10%.

The age distribution of patients with ovarian metastases depends to a great extent on that of the corresponding primary tumors, but for each of the most common types (intestinal, gastric, and breast) the average age of patients with ovarian involvement is significantly lower than that of those without ovarian spread, suggesting that the richly vascularized ovaries of young women are more receptive to metastases than those of older patients.

Tumors spread to the ovary by several routes. Spread from distant sites is mainly via blood vessels and lymphatics. The frequent association of ovarian metastases with other blood-borne metastases, the common finding of tumor within ovarian blood vessels on microscopic examination in cases of metastasis, and the higher frequency of ovarian metastases in young patients support the important role of hematogenous spread.

Transcoelomic dissemination with surface implantation is an important route by which intraabdominal cancers spread to the ovary, as is supported by the common association of ovarian involvement with generalized peritoneal spread. The pathologist often encounters foci of metastatic carcinoma on the surface of the ovary or superficially located within the cortex, supporting implantation as the mechanism. It is possible that ovulation, by creating a defect in the ovarian surface, provides a portal of entry for cancer cells floating in the peritoneal cavity in premenopausal patients.

Direct spread is an important pathway for carcinomas of the fallopian tube and uterus, for mesotheliomas, and for occasional colonic carcinomas and retroperitoneal sarcomas. Another mechanism of spread of genital tract carcinomas is through the lumen of the fallopian tube and onto the surface of the ovary; this route is taken most often by carcinomas of the uterine corpus [23], but may also account for some cases of spread from the uterine cervix [113, 124].

The gross features of tumors metastatic to the ovary vary greatly and may resemble those of a variety of primary ovarian tumors [119]. Because of the relatively high frequency with which metastases are bilateral (two-thirds to three-quarters of the cases), the possibility of metastasis should especially be considered when evaluating bilateral tumors (> Fig. 18.1) other than serous and undifferentiated carcinomas, which also are commonly bilateral. Endometrioid and mucinous carcinomas, in contrast, are bilateral in less than 15% of cases, and bilateral tumors with endometrioid-like or mucinous features merit more serious consideration for possibly being metastatic [181]. Still, many metastatic tumors are unilateral and, if the microscopic features of a tumor suggest metastasis, unilaterality should not be considered a significant argument against it. In general, almost 10% of bilateral ovarian cancers presenting as adnexal masses prove to be metastatic on careful evaluation. It has recently been suggested that a simple assessment of size and laterality can distinguish primary from metastatic mucinous neoplasms: bilateral tumors of any size or unilateral tumors under 10 cm have a strong likelihood of being metastatic, compared to unilateral tumors over 10 cm, which are usually primary [130]. This is an appropriate general guideline and may be helpful, particularly in the intraoperative setting; however, there are unfortunately many exceptions [67, 134], especially in cases of colorectal and endocervical primaries [157]. It is also of note that metastatic tumors involving

Fig. 18.1

Metastatic appendiceal adenocarcinoma. The tumor is bilateral, and the smaller ovary shows several discrete nodules, mainly in the lower half. In the other ovary, the nodules have become confluent, but ill-defined nodularity is still evident

Fig. 18.2 Metastatic cecal adenocarcinoma. Foci of mucoid tumor are seen on the ovarian surface

the ovary are often large and may dwarf their primary tumors.

Two other gross findings that are suggestive, but not pathognomonic, of metastasis are the presence of multiple tumor nodules (> Fig. 18.1) and tumor on the surface of the ovary (> Fig. 18.2), sometimes without significant involvement of the underlying parenchyma. As examples of the only suggestive nature of these findings, we note the well-known surface location of some serous carcinomas and in other cases, the multinodularity of some serous and undifferentiated carcinomas. The microscopic features of these carcinomas generally are not problematic, however. It should also be noted that some endometrioid carcinomas arise from foci of endometriosis in the superficial cortex or on the ovarian surface, and accordingly may project off the ovary. An association with endometriosis, which is easily overlooked, can be crucial in supporting an ovarian origin for such a tumor. A gross feature of some metastastic tumors that should not be regarded as establishing the primary nature of the tumor is the presence of cysts (> Fig. 18.3). These are often large and occasionally thin-walled, and they can occur even when there is an absence of cysts in the primary neoplasm.

The microscopic appearance of a metastatic tumor obviously varies with the appearance of the primary neoplasm. In addition to the specific features of various primary tumors, the microscopic correlates of the findings

■ Fig. 18.3 Metastatic cecal adenocarcinoma. Sectioned surface of tumor in prior figure showing a mainly cystic neoplasm grossly consistent with a primary neoplasm

Fig. 18.4

Metastatic pancreatic adenocarcinoma. Typical surface implant in the form of a nodular protrusion composed of infiltrating small glands and prominent stroma. Note maturation of the underlying cystic component (Reproduced with permission from Ref. [161])

noted in the prior paragraph, namely implants on the surface of the ovary (**2** *Fig. 18.4*) and multinodularity (**2** *Fig. 18.5*), suggest metastasis in many cases, but with the same caveats as above. These findings have particular weight in cases with mucinous or endometrioid-like

morphologies, as well as in those with any of a diverse number of unusual microscopic appearances. Surface implants typically are focal, often projecting above the surface of the adjacent cortex, and the tumor is frequently embedded in desmoplastic or sometimes hyalinized fibrous tissue (\bigcirc *Fig.* 18.4). A conspicuous stromal reaction of the type just noted is also often seen in more central regions of metastatic tumors (\bigcirc *Fig.* 18.6) and, particularly if multifocal, is on average much more common in metastatic tumors than in primary neoplasia. Metastatic tumors more often envelop preexisting normal ovarian structures than primary tumors (\bigcirc *Fig.* 18.7).

Another feature more typical of metastasis is what has been referred to as heterogeneous or nodular invasive growth (\bigcirc *Fig. 18.6*). This terminology is intended to reflect the varied appearance that results when scattered foci of obviously invasive growth, often in a desmoplastic stroma, are present within a background neoplasm that has a more leisurely growth and sometimes even deceptively benign features. Infiltrating moderate- to highgrade cancer with destructive invasion in a primary mucinous tumor may have a similar appearance, but it is generally not as multifocal nor as striking as in many cases of metastasis. Although certainly not diagnostic on its

Fig. 18.5

Metastatic malignant melanoma. Two discrete nodules of tumor are seen

Fig. 18.6

Heterogeneous nodular growth. Three separate distinct patterns of growth are evident in this case of metastatic colon cancer: a dilated gland at the *top*, conventional adenocarcinoma at the *right*, and small gland adenocarcinoma in a prominent desmoplastic stroma at the *bottom left* (Courtesy of Dr. Kenneth R. Lee; Reproduced with permission from Ref. [161])

Fig. 18.7 Metastatic colon carcinoma surrounding a corpus albicans

own, this pattern should cause metastasis to be entertained and should be evaluated in context. A similar comment pertains to all features overall more typical of metastasis. The mere nature of the neoplasia may be important. For example, primary mucinous carcinomas of the ovary only rarely have a colloid morphology, whereas this is a wellknown pattern of colonic carcinoma; when this morphology is seen in the ovary (\bigcirc *Fig. 18.8*), metastasis should enter consideration and certainly be excluded before the tumor is accepted as a primary neoplasm.

The epithelium of most metastatic carcinomas in the ovary is clearly malignant, but a treacherous aspect is the propensity of some tumors, particularly those that are mucinous, to differentiate and result in a borderline-like or even cystadenoma-like appearance. This so-called maturation phenomenon [182] may even result in flattened epithelium that appears benign, and if separated by bland stroma, an adenofibroma or cystadenofibroma may be mimicked (**)** *Fig. 18.9*). Another confusing microscopic feature of some metastatic tumors is the presence of cysts,

Fig. 18.8

Metastatic colloid adenocarcinoma. This pattern of mucinous carcinoma is uncommonly primary in the ovary and accordingly such a picture should cause concern for a metastasis (Reproduced with permission from Ref. [161])

some of which simulate follicles. These follicle-like spaces (\bigcirc *Fig. 18.10*) may be encountered in a variety of metastatic tumors including gastric and intestinal carcinomas, carcinoids, small cell carcinomas from various sites, and malignant melanomas. A wide variety of other patterns and cell types in metastatic tumors suggest diverse possible primary sites, as discussed in detail and presented in tabular form elsewhere [182]. Lymphatic or blood vessel invasion, sometimes particularly striking in the hilus, strongly suggests metastasis (\bigcirc *Fig. 18.11*).

Immunohistochemistry, selectively applied based on a differential diagnosis generated by routine microscopic features, may aid in certain cases [7, 21, 91, 93, 94], but is uncommonly diagnostic on its own. Even after the most thorough evaluation, it is sometimes impossible for the pathologist to be definitive whether a neoplasm is primary or metastatic, but on the basis of the morphology one may

Fig. 18.9

suggest the most likely possible extra-ovarian primary sites to direct clinical evaluation. **>** *Table 18.1* presents a comparison of various features of primary and meta-static mucinous tumors in the ovary, but is also broadly applicable, in great part, to the overall topic being considered here.

Extragenital Tumors

In this category, we begin with tumors of the gastrointestinal tract (except sarcomas, considered later) and associated structures, which cause in aggregate the majority of diagnostic problems. We first discuss the Krukenberg tumor, arguably one of the most well-known cancers involving the ovary [14, 28, 42, 49, 55, 71, 161].

Fig. 18.10 Metastatic malignant melanoma. Follicle-like spaces are clearly evident (Reproduced with permission from Ref. [161])

Carcinoma of the Stomach

Metastatic Tumors with Signet Ring Cells (Krukenberg Tumor)

The great majority of metastatic gastric carcinomas to the ovary are Krukenberg tumors, which are defined by us as metastatic tumors characterized by the presence of mucinfilled signet-ring cells accounting for at least 10% of the tumor. The source of Krukenberg tumors in the great majority of reported cases is a gastric carcinoma, usually arising in the pylorus. Carcinomas of the large intestine, appendix, and breast are the next most common primary sites; the gallbladder, biliary tract, pancreas, cervix, and urinary bladder are rare sources of these tumors. Saphir [126] demonstrated in an autopsy study that signet-ring cell carcinomas of various organs are associated more

 Fig. 18.11
Metastatic carcinoma. Prominent lymphatic involvement (Reproduced with permission from Ref. [161])

often with ovarian metastasis than carcinomas of other histologic types by a ratio of about 4:1. More recent studies have supported his observation: gastric signet-ring cell carcinomas metastasize to the ovary much more often than intestinal-type carcinomas of the stomach do [81], and signet-ring cell carcinomas of the colon also metastasize to the ovaries more frequently than conventional colonic adenocarcinomas [5].

The frequency of the Krukenberg tumor varies with that of gastric carcinoma in the population analyzed. In countries such as Japan, with a high prevalence of gastric carcinoma and a low prevalence of primary ovarian carcinoma, the Krukenberg tumor accounts for a large proportion of all ovarian cancers [156].

The average age of patients with Krukenberg tumors is about 45 years. One quarter to almost one half the patients are under 40 years, and only slightly more than 10% of

Table 18.1

Comparison of helpful clinicopathologic features in distinguishing metastatic from primary mucinous cystic tumors

Feature	Metastatic	Primary
History of, or clinical evidence of, extraovarian primary	Usual ^a	Rare ^b
Extraovarian disease	Common	Rare
Bilaterality	Common	Rare
Size >15 cm	Uncommon	Common
Gross tumor on surface of ovary	Occasional	Rare
Microscopic surface implants or surface mucin	Common	Rare
Heterogeneous nodular invasive growth	Common	Rare
Colloid pattern	Occasional	Rare
Mucin granulomas	Uncommon	Common
Vascular invasion	Occasional	Rare
Single cell growth	Occasional	Uncommon
Müllerian nature of epithelium	Rare	Occasional
Association with teratoma, endometriosis, adenofibroma, Brenner tumor ^c	Rare	Occasional
So-called mural nodules	Absent	Occasional

^a In some cases the primary tumor may initially be occult and require clinical evaluation to detect.

^b The possibility that a patient may have independent primary tumors always exists, particularly as primary mucinous tumors of the ovary and certain tumors that may mimic them when they spread to the ovary are common.

^c As the four listed lesions are common, by happenstance they might be present in an ovary involved by metastasis. Also, it should be noted that maturation in some metastatic tumors may impart a focal adenofibroma-like appearance.

Modified from Lee and Young [78].

them are over 60 years of age. This age distribution is related in part to the disproportionate frequency of gastric signet-ring cell carcinomas in young women as well as the greater vascularity of the ovary in young women. In one study, 10% of women 35 years or younger with this tumor had ovarian metastases at presentation [142].

Almost 90% of patients with Krukenberg tumors have symptoms related to ovarian involvement, the most common of which are abdominal pain and swelling; occasionally, there is abnormal uterine bleeding and rarely, particularly during pregnancy, overt signs of excess hormone production such as virilization. The remainder of the patients have gastrointestinal or miscellaneous

symptoms related to spread of the signet-ring cell cancer to other sites such as lungs or bone, or are asymptomatic. A history of prior carcinoma of the stomach or, less often, another organ can be obtained in 20-30% of the cases. The interval between the diagnosis of a gastric carcinoma and the subsequent discovery of ovarian involvement usually is 6 months or less, but periods as long as 12 years have been reported [42]. In most cases, the diagnosis of the gastric carcinoma is made preoperatively, during the operation for the ovarian metastasis, or within a few months thereafter. Not infrequently, the primary tumor is too small to be detected at operation, and radiographic examination of the upper gastrointestinal tract also may fail to reveal evidence of a tumor even after the diagnosis of Krukenberg tumor has been established. Rarely, the gastric carcinoma may not be detected until 5 or more years after discovery of the ovarian metastatic tumor. Primary carcinomas, particularly those arising in the breast and stomach, may be very small, requiring exhaustive sectioning to detect them, despite the presence of metastases in some cases. It is possible that tiny primary tumors were missed in these or other organs in the reported autopsied cases of "primary" Krukenberg tumors. Ulbright and Roth [144] cited a case observed by Kraus in which a primary tumor in the stomach was detected only after microscopic sections prepared from 200 blocks had been examined.

Almost all the patients die within a year of the diagnosis of ovarian metastasis, but a rare patient has survived, apparently free of tumor, for as long as 6 years after gastrectomy and bilateral oophorectomy [49]. Such a result, even though exceptional, justifies removal of both the stomach and the ovarian metastases for possible cure in cases in which the tumor appears limited to those organs. It also is prudent for the surgeon to remove the ovaries routinely in menopausal and postmenopausal women who have a gastric resection for carcinoma so as to prevent the later complication of ovarian metastasis and avoid another operation.

Gross Findings

Krukenberg tumors typically form rounded or reniform, firm, white masses that may be bosselated and may attain a large size. The surfaces are generally devoid of appreciable adhesions. The sectioned surfaces usually are tan or white (\bigcirc *Fig.* 18.12), but areas of purple, red, or brown discoloration and extensive hemorrhage also are encountered. The appearance may be relatively uniform or, in other cases, ill-defined nodularity or even discrete nodules may be seen. The consistency is characteristically firm, but fleshy, gelatinous, or spongy areas are common.

Fig. 18.12 Krukenberg tumor. The sectioned surface is more or less uniform and tan

• Fig. 18.13 Krukenberg tumor. The central region in this case differed in appearance from the periphery, a feature occasionally seen

Sometimes the periphery is distinctly different in appearance from the central region, the latter often being softer than the periphery (**>** *Fig. 18.13*). Occasionally, the gross presentation is atypical with large, thin-walled cysts containing mucinous or watery fluid, separated by relatively small amounts of solid tissue. Both ovaries are involved in 80% or more of the cases.

Microscopic Findings

The histologic appearance of these tumors is much more varied than the most emphasized morphology in the literature, namely that of signet-ring cells in a cellular stroma (**>** *Fig. 18.14*). This picture, which is of historical interest because it resulted in the initial confusion with fibrosarcoma, is present in only a minority of cases as a finding of any prominence. We first consider the low-power features of the Krukenberg tumor and then aspects related to signet-ring cells (and other cell types), other epithelial elements, and stroma in turn.

Like many metastatic tumors, growth as distinct nodules, or at least as vague nodules, is typically conspicuous on low-power examination (\bigcirc *Fig.* 18.15), but the nodules and intervening stroma may be quite variable in appearance, particularly when the other features noted below are present (**2** *Figs. 18.16–18.32*). The tumor nodules are often separated by edematous stroma, and a picture of densely cellular pseudolobules is often seen (**2** *Fig. 18.16*). The nodules themselves are generally composed of jumbled admixtures of signet-ring cells, indifferent cells, glands, cysts, and background stroma. Similar admixtures of epithelial and stromal elements are seen in tumors that have a more diffuse arrangement. Sometimes a striking low-power feature is a greater cellularity at the periphery, with aggregates of tumor cells, stroma, or both ramifying from the periphery into central, more edematous regions (**2** *Fig. 18.17*). Residual ovarian structures may be present in the midst of the tumor (**3** *Fig. 18.18*).

The signet-ring cells vary greatly in amount and, accordingly, prominence. Occasionally vast numbers are

Fig. 18.14 Krukenberg tumor. Numerous signet-ring cells are present within a cellular stroma

 Fig. 18.15
Krukenberg tumor. Typical alternating hypercellular and hypocellular regions

Fig. 18.16 Krukenberg tumor. Pseudolobular pattern

present, and a "sea" of signet-ring cells is immediately striking (**>** Fig. 18.19). Conversely, it is not rare for these cells to be relatively inconspicuous, at least on initial lowpower evaluation and even sometimes on high-power scrutiny. The arrangement of the signet-ring cells (> Fig. 18.20) to one another and to other epithelial elements is equally variable. They may grow diffusely, in somewhat orderly clusters (> Fig. 18.21), in pseudotubular formations, or in a totally random fashion within the stroma or between glands and cysts. The individual signet-ring cells are generally of relatively similar size and usually have pale to basophilic cytoplasm, which compresses the nucleus to the periphery in the well-known manner. This results in the nuclei often having rather deceptively bland cytologic characteristics. Occasionally the cytoplasm is eosinophilic, and sometimes densely so (> Fig. 18.22). The cytoplasm may have a bull's-eye appearance, containing a large vacuole with a central eosinophilic body. Other neoplastic cells may be present that are mucinous but not of

signet-ring cell morphology, and it is not rare for a component of the tumor to have nondescript mucin-free cells; such regions may be prominent (**>** *Fig. 18.23*). Rarely, cells with clear cytoplasm are present (**>** *Fig. 18.24*), and exceptionally, one can even see squamous or transitional-like cells.

It has recently been reemphasized that other epithelial elements, specifically glands and cysts, are present in most Krukenberg tumors [71, 161] (\bigcirc *Fig. 18.25*). In many cases, these can be as striking a finding as the signet-ring cells. The glands are usually small and often impart a microcystic appearance (\bigcirc *Fig. 18.26*), but a spectrum is encountered up through medium-sized glands to large cysts. The glands can appear indifferent or have a striking intestinal-type appearance, but the pseudoendometrioid morphology typical of non-signet-ring cell intestinal carcinoma (see below) is rarely present, and dirty necrosis is likewise uncommon. The glands and cysts may have

Fig. 18.18 Krukenberg tumor. An entrapped follicle is evident

attenuated lining cells or, uncommonly, columnar mucinous cells. Small round tubules, larger hollow tubules, and solid pseudotubular formations with or without signetring cells may all be seen (\bigcirc *Fig.* 18.27) and when prominent, account for the description "tubular Krukenberg tumor." Mucin stains may highlight signet-ring cells in these and other cases (\bigcirc *Fig.* 18.28). Many tumors have nondescript patterns of carcinoma, such as masses, nests, cords (\bigcirc *Fig.* 18.29), and individual cells, at least focally. Follicle-like spaces may be prominent (\bigcirc *Fig.* 18.30).

In our experience, the stroma is more often edematous than cellular, and a highly cellular "sarcoma-like" picture is distinctly uncommon. Indeed, densely cellular regions are more often due to a conspicuous content of small hyperchromatic epithelial cells with scant cytoplasm than to a cellular stromal proliferation. Mucin in the stroma is sometimes prominent and may contain signet-ring cells, form acellular mucin pools, or be separated by wispy collagen producing a pattern that has been referred to as

Fig. 18.19
Krukenberg tumor. Numerous signet-ring cells

feathery degeneration (**>** *Fig. 18.31*). When glands are set in a relatively regular fashion on the background stroma, there may be a deceptively orderly architecture, albeit usually only focally. If the stroma is cellular in such instances, a superficial resemblance to an adenofibroma may result; this can be particularly treacherous at the time of frozensection examination. If only a bland "fibroma-like" appearance of the stroma is captured for frozen section, a misdiagnosis of fibroma may result (> Fig. 18.32). Occasionally, these fibromatous regions have a storiform appearance. The Krukenberg tumor is one of the ovarian tumors most often associated with stromal lutein cells (> Fig. 18.20). They are often present in at least small numbers and may be prominent, particularly if the patient is pregnant as is sometimes the case given the relative youth of many patients. As with metastases in general, blood vessel and lymphatic invasion are common, generally identified at the periphery or in the hilar aspect of the neoplasm. In one unique case of a gastric primary,

the ovarian metastases showed yolk sac differentiation, none being identified in the primary tumor [186]. In two other unusual cases, metastatic signet-ring cell carcinoma in the ovaries originated in the cervix, a judgment based significantly on identification of human papilloma virus by in situ hybridization [151].

Differential Diagnosis

The Krukenberg tumor may resemble a fibroma or any other type of solid ovarian tumor on gross examination. Its appearance also occasionally may be deceptive on frozen section, as noted above, or low-power examination, but it should be readily diagnosable on high-power microscopic examination, especially with the aid of mucin stains. A frequent misdiagnosis is a Sertoli–Leydig cell tumor, particularly when a prominent tubular component and luteinization of the stroma are encountered [14]; signet-ring cells, however, are not a feature of Sertoli– Leydig cell tumors except for occasional tumors of heterologous type (see **2** Chap. 15, Sex Cord-Stromal, Steroid Cell, and Other Ovarian Tumors with Endocrine, Paraendocrine, and Paraneoplastic Manifestations). The

Fig. 18.21 Krukenberg tumor. Signet-ring cells aggregate together in a rather orderly manner within uniform spaces

sclerosing stromal tumor may contain cells resembling signet-ring cells as well as a proliferating fibroblastic component, but such cells contain lipid rather than mucin. The rare signet-ring stromal tumor also may enter the differential diagnosis, but the signet-ring cells in that tumor also fail to react with mucin stains.

Surface epithelial tumors generally cause fewer problems in differential diagnosis than sex cord-stromal tumors. Cells with clear cytoplasm may raise the issue of clear cell carcinoma, but the clear cells in the latter contain glycogen; mucin, when present, is typically luminal and extracellular. In rare cases, clear cell carcinomas may have focal signet-ring cells, but the presence of other characteristic features, such as a typical tubulocystic pattern or papillae, permit their identification. Primary mucinous tumors are rarely difficult to distinguish from Krukenberg tumors, as the latter have so many features pointing to a metastatic process. It should be noted that rare mucinous tumors can contain signetring cells, but as recently emphasized, their similarity to Krukenberg tumors is otherwise minimal [95]. Occasional serous and even some endometrioid and undifferentiated carcinomas can have signet-ring cells [19], but the many

Fig. 18.22 Krukenberg tumor. Many signet-ring cells in this illustration have dense eosinophilic cytoplasm

differences between these tumors and Krukenberg tumors are such that resolving any issue in differential diagnosis should be straightforward.

Mucinous carcinoid tumors that contain large numbers of signet-ring cells are distinguished from Krukenberg tumors by their additional component of carcinoid, the presence of which can be confirmed by special stains. Infrequently, a mesothelial neoplasm may be a diagnostic consideration. The vacuoles of the rare adenomatoid tumor that involves the ovary may be misconstrued as signet-ring cells, but many differences, including even the much less ominous gross appearance of the adenomatoid tumor, should help one avoid misdiagnosis [112]. Adenomatoidlike foci may be seen in some malignant mesotheliomas [6], such that one involving the ovary could cause a Krukenberg tumor to be entertained in the differential diagnosis; however, the tubulo-papillary patterns of mesothelioma are generally distinctive, and these tumors lack the many above-described features seen in most Krukenberg tumors.

Finally, the rare nonneoplastic lesion, mucicarminophilic histiocytosis [73], which is caused by injection

Fig. 18.23

Krukenberg tumor. Epithelial cells without conspicuous mucin grow as cords and clusters separated by luteinized stromal cells, imparting a superficial resemblance to Sertoli–Leydig cell tumor

of substances containing polyvinylpyrrolidine, is characterized by signet-ring-like cells and may involve numerous tissues and organs including the ovaries. Although these cells are stained by mucicarmine, they are periodic acid– Schiff negative.

Metastatic Intestinal-Type Adenocarcinoma of the Stomach

Only a small number of cases of this type are documented [81]. This precludes firm conclusions on differing clinical features from the Krukenberg tumor, but the limited information available suggests that these patients are somewhat older than the usual patient with a Krukenberg tumor. To date, the endocrine manifestations seen with some cases of the latter have not been a feature of the intestinal-type cancers.

Fig. 18.24

Krukenberg tumor. Cords and clusters of cells with appreciable clear cytoplasm are present in a moderately cellular fibrous stroma. The appearance in this field is non-specific

Gross Findings

The tumors are typically solid, cystic, and large, resembling metastatic colon cancer rather than the usual Krukenberg tumor. They may be bilateral or unilateral.

Microscopic Findings

The tumors are typically formed of medium-sized tubular glands, resulting in a pseudoendometrioid pattern (\triangleright *Fig.* 18.33) as seen with metastatic colon cancer. Other familiar features of the latter such as dirty necrosis may also be encountered. Findings common to many cases of metastatic disease in the ovary, such as prominent stromal edema (\triangleright *Fig.* 18.34) and notable morphologic variability within a small zone of tumor (\triangleright *Fig.* 18.35), are seen, as are nonspecific patterns of growth such as cords. Less often the picture is that of a mucinous neoplasm. A very minor component (definitionally <10%) of signet-ring cells is present in some metastatic intestinal-type tumors.

Fig. 18.25 Krukenberg tumor. Glandular differentiation

Differential Diagnosis

The differential diagnosis is with other metastatic tumors that may have pseudoendometrioid or mucinous features, such as metastatic colorectal carcinoma, and with primary endometrioid and mucinous neoplasia. Clinical evaluation is paramount in the distinction from other metastatic tumors, and features elaborated elsewhere in this chapter are applicable in the distinction from primary neoplasms. Immunohistochemistry is of limited value, as the immunoprofile of gastric carcinoma overlaps with both primary and metastatic tumors in the differential diagnosis. Many, but not all, gastric carcinomas express cytokeratin 7 (CK7), whereas cytokeratin 20 (CK20) expression is variable [7]; this is essentially identical to the immunoprofile of primary ovarian mucinous neoplasms. Immunohistochemistry may provide more helpful information if the tumor has an endometrioid-like morphology. A CK7+ tumor is most likely non-colorectal in origin, as those tumors are characteristically CK7-/CK20+. Reactivity for CK20 points away from a primary endometrioid neoplasm (typically CK7+/CK20-). CDX2 positivity may

Fig. 18.26 Krukenberg tumor. Small microcysts of the type seen in many cases

be seen in all the aforementioned tumors, but is usually strong and diffuse in colorectal carcinomas [7].

Intestinal Carcinoma

Most metastatic ovarian tumors of intestinal origin are from the large intestine, with occasional examples of small intestinal derivation. Ovarian metastases from intestinal carcinomas have been reported to be less common than those from gastric carcinomas at autopsy, 14% versus 38% respectively [126], but when malignant ovarian tumors encountered at the time of operation are evaluated, metastases from intestinal carcinomas are almost five times as frequent as those from gastric carcinomas [2, 11, 153]. Lash and Hart [75] have estimated that up to 45% of large intestinal metastases to the ovary are clinically thought to be primary ovarian tumors, and many are misinterpreted

■ Fig. 18.27 Krukenberg tumor. There is a prominent tubular pattern ("tubular Krukenberg tumor"). The cells have clear cytoplasm and could be misconstrued as the lipid-rich cells of a Sertoli cell tumor

as such on pathologic examination even when there is a known intestinal cancer.

Approximately 4% of women with intestinal cancer have ovarian metastases at some time during the course of their disease [11], but in one study this figure was as high as 10% when the ovaries were sectioned into 2 mm slices [38]. Four of the six metastatic ovarian tumors in that series of 58 cases were not recognized on gross examination. Metastasis from the large intestine to the ovary is seen relatively more frequently when this cancer occurs in women under 40 years of age (in 18–27% of the patients in this age group) [114]. In one large series, one quarter of the patients were less than 40 years old [82] and in another about 43% were under 50 years [58]. In the latter study, it was noted that patients initially presenting with an ovarian mass were significantly younger than those having ovarian

Fig. 18.28 Krukenberg tumor. A mucicarmine stain highlights signetring cells in a tumor with a tubular pattern

spread in the setting of a known colorectal primary (average 48 versus 61 years). We have seen ovarian spread in a 12-year-old girl. The serum CA-125 level may be elevated contributing to potential confusion with primary neoplasia.

From a clinical point of view, patients with this type of metastatic carcinoma fall into three categories: (1) patients with a known intestinal carcinoma (50–75% of the cases) that antedates diagnosis of the ovarian tumor by as much as 3 years in 90% of the cases, (2) patients in whom ovarian involvement is found unexpectedly during an operation for resection of an intestinal carcinoma, and (3) patients whose initial manifestations are those of an ovarian tumor (3–20% of the cases). Ovarian metastases have been found in up to 8% of patients who have bilateral prophylactic oophorectomy because of intestinal carcinoma [89]. In one study, 77% of the large intestinal primary tumors were in the rectum or sigmoid colon, 5% in the descending colon, 9%

Fig. 18.29 Krukenberg tumor. Indifferent tumor cells are growing as cords with only scattered signet-ring cells

in the ascending colon, and 9% in the cecum [75] Three of the small number of clear cell adenocarcinomas of the intestine that spread to the ovaries were primary in the small intestine [170]. Occasional patients have luteinized stromal cells in the ovarian tumor with resultant hormone production and endocrine symptoms.

Gross Findings

These neoplasms, which are bilateral in approximately 60% of the cases, may form solid masses with a nonspecific appearance but are more often at least focally cystic (\triangleright *Fig. 18.36*), and in many cysts predominate. Frequently the tumors are large, with a median largest dimension in one series of 11 cm [75], and they may closely simulate primary carcinomas of the ovary. Sectioning typically reveals friable or mushy yellow, red, or gray tissue with

Fig. 18.30
Krukenberg tumor. Prominent follicle-like spaces

cystic compartments that contain necrotic tumor, mucinous or clear fluid, or fresh or old blood. Approximately 10% of the tumors rupture spontaneously during pelvic examination or removal. An occasional example is composed of multiple, thin-walled cysts filled with mucinous or clear fluid.

Microscopic Findings

The neoplastic cells grow in patterns similar to those of primary intestinal carcinomas of usual type, typically forming small or large glands with a frequent cribriform pattern [25] (\bigcirc *Figs. 18.37* and \bigcirc *18.38*). Necrosis is common and often extensive, forming striking eosinophilic masses containing nuclear debris within the lumens; this feature, referred to as dirty necrosis (\bigcirc *Fig. 18.37*), was present in all the cases in one series [75]. Two other features of the tumor, the frequent disposition of glands in a ring at the edge of the necrotic material (likened to

• Fig. 18.31 Krukenberg tumor. Mucin is separated by wispy collagen, imparting an appearance that has been referred to as "feathery degeneration"

a garland) (> Fig. 18.37) and focal segmental necrosis of the glandular epithelium (**>** *Fig. 18.39*), were emphasized by Lash and Hart [75]. Cysts may be prominent and contain central necrotic debris, clusters of tumor cells (> Fig. 18.40), or appear empty. A papillary pattern is seen occasionally. Mucin-containing cells (> Fig. 18.41), including goblet cells, may be scattered among mucinfree cells, the latter usually predominating or being the exclusive cell type. The epithelial cells are usually strikingly atypical (**)** Fig. 18.42). Glands and cysts lined by welldifferentiated mucin-rich cells may be a prominent component of the tumor, and rarely the tumor has the pattern of colloid carcinoma. Signet-ring cells may be present in minor amounts, being present in 10% of cases in one series [82]. The stroma varies from negligible to abundant (> Fig. 18.43); it may be desmoplastic, edematous, or mucoid, and often contains luteinized stromal cells.

■ Fig. 18.32 Krukenberg tumor. Fibroma-like stromal proliferation with paucity of signet-ring cells

The tumors metastatic from intestinal clear cell adenocarcinomas have a glandular pattern architecturally similar to that of the usual intestinal adenocarcinoma metastatic in the ovary, including dirty necrosis. These tumors, however, differ in the conspicuous clear cytoplasm of the tumor cells (\bigcirc *Fig.* 18.44). In some instances the clarity is subnuclear (\bigcirc *Fig.* 18.45) imparting a resemblance to the secretory variant of endometrioid carcinoma, but in most the closest resemblance is to clear cell adenocarcinoma. In a few tumors, a colloid-like secretion has been conspicuous.

Signet-ring cell carcinomas of the colon may form typical Krukenberg tumors; 5.4% of the latter originated in the sigmoid colon in one large series [156]. Three cases of intestinal small cell carcinoma with ovarian metastases have been reported [30].

Differential Diagnosis

In one series, more than two thirds of the cases of metastatic intestinal carcinoma were initially misinterpreted as primary ovarian adenocarcinomas [145]. The most

Fig. 18.33
Metastatic intestinal-type carcinoma from the stomach.
Glands of varying sizes and shapes impart
a pseudoendometrioid appearance

difficult tumors to exclude on microscopic examination are primary endometrioid and mucinous adenocarcinomas. In the series of 22 metastatic intestinal cancers described by Lash and Hart [75], 19 mimicked endometrioid carcinoma, 2 mucinous carcinoma, and 1 a mixed endometrioid and mucinous carcinoma. Aside from clinical clues, gross features may be helpful in the differential diagnosis. The usual bilaterality of metastatic intestinal carcinomas contrasts with the less than 15% frequency of bilateral involvement in cases of primary endometrioid and mucinous carcinomas. Endometrioid adenocarcinomas often are cystic, like many metastatic colonic cancers, but the cysts are sometimes filled with chocolate material. The presence of the latter is generally related to a background of endometriosis. A more homogeneous, less often necrotic, solid component is usually present.

With regard to the microscopic differential diagnosis of metastatic intestinal adenocarcinoma and endometrioid adenocarcinoma, the glands of the former typically are

Fig. 18.34
Metastatic intestinal-type carcinoma from the stomach.
Small glands are separated by conspicuous edematous stroma

lined by more poorly differentiated cells with greater nuclear hyperchromatism and loss of polarity than those of endometrioid adenocarcinomas with a similar degree of glandular differentiation. In addition, extensive confluent necrosis is common in metastatic intestinal carcinomas, but uncommon in gland-forming endometrioid carcinomas. A similar comment pertains to so-called dirty necrosis within gland lumens, but it should be emphasized that this and the other features typical of metastatic intestinal carcinoma, such as focal segmental necrosis of glandular-lining epithelium, may be seen in some cases of endometrioid carcinoma [26]. Foci of squamous differentiation are frequent in endometrioid carcinomas but rare in intestinal carcinomas, and an adjacent or background adenofibromatous component or endometriosis strongly favors endometrioid carcinoma. The features just summarized, in conjunction with the general features of metastatic tumors to the ovaries and the clinical findings, also aid in the uncommon problem of differentiating a metastatic clear cell adenocarcinoma from the intestines

Fig. 18.35 Metastatic intestinal-type carcinoma from the stomach. Markedly varied morphology within a small zone of tumor is a feature of many tumors metastatic to the ovary

Fig. 18.36 Metastatic carcinoma from the colon. The tumor is solid and cystic

Fig. 18.37 Metastatic carcinoma from the colon. There is extensive so-called dirty necrosis

from a primary secretory endometrioid adenocarcinoma or clear cell adenocarcinoma.

In cases in which the differential is between a metastatic intestinal adenocarcinoma and primary mucinous adenocarcinoma, the frequent presence of glands and cysts lined by endocervical-type mucinous cells with basal nuclei favors a primary ovarian mucinous carcinoma over a metastasis, although differentiated glands and cysts are encountered in some metastatic intestinal carcinomas. Goblet cells are encountered more commonly in primary mucinous carcinomas, but they also may be seen in metastatic mucinous tumors. The other typical features of metastatic disease in the ovary already discussed are helpful in many cases, but occasionally it may be impossible to differentiate between a metastatic and primary mucinous adenocarcinoma on the basis of examination of the ovarian tumor alone. Metastatic mucinous carcinomas are more characteristically from the pancreas (discussed in more detail later), although they can derive from diverse sites. In one series eight metastatic mucinous adenocarcinomas were from the pancreas, six from the

Fig. 18.38 Metastatic carcinoma from the colon. Closely packed glands with focal cribriform pattern

colon and rectum, three from the endocervix, two from the stomach, one possibly from the appendix, and one from the esophagus [119]. Other primary sites of metastatic mucinous carcinomas include the gall bladder and intra- and extrahepatic bile ducts, and even, exceptionally, urachus and lung.

Immunohistochemistry can be helpful in differentiating a typical metastatic large intestinal carcinoma from a primary endometrioid adenocarcinoma. Colorectal carcinomas are characteristically CK7–/CK20+, CEA+, and CA125–, whereas most endometrioid adenocarcinomas have the opposite immunoprofile [9, 91]. It should be noted, however, that right-sided colon carcinomas appear to be more frequently CK20– [76]. Cytokeratin stains are less helpful for the distinction of metastatic mucinous colorectal carcinomas from primary ovarian mucinous carcinomas. The former may be focally CK7+ and are usually CK20+, and the latter are usually CK7+ and may be focally CK20+, resulting in significant immunohistochemical overlap [93]. Furthermore, those mucinous carcinomas arising in teratomas may show a similar

 Fig. 18.39
Metastatic carcinoma from the colon. Segmental necrosis of epithelium

Fig. 18.40 Metastatic carcinoma from the colon. Cysts contain clusters of tumor cells

CK7–/CK20+ immunoprofile to many large intestinal carcinomas, reflective of their likely origin from intestinal elements [96, 147]. Small intestinal carcinomas are often CK7+ and are not infrequently CK20– [20, 76], and therefore in many cases they have a similar cytokeratin profile to primary ovarian carcinomas.

As mentioned previously, CDX2 is often strongly and diffusely positive in colorectal carcinomas, but it can also be positive in ovarian mucinous and endometrioid tumors [86, 148]. Colon carcinomas and mucinous ovarian carcinomas tend to show an inverse staining pattern for MUC2 and MUC5AC, with the former tumors usually positive for MUC2 and uncommonly positive for MUC5AC, and the latter showing MUC5AC positivity and limited MUC2 staining of goblet cells [7]. Estrogen receptor may be helpful for differentiating endometrioid adenocarcinomas from metastatic intestinal carcinomas, as the former are usually positive and the latter are negative [91]. In general, these immunohistochemical markers are most informative when the differential diagnosis is between a pseudoendometrioid metastasis and a primary endometrioid adenocarcinoma. Because most mucinous carcinomas and mucinous borderline tumors of the ovary are of intestinal type, they not surprisingly show a similar immunoprofile to tumors arising from the intestinal tract. It is important to remember that there are exceptions to all of the above "typical" immunoprofiles, and careful consideration of the clinical, gross, and standard morphologic features is critical and oftentimes most informative.

Tumors of the Appendix

Ovarian involvement is most common in cases of lowgrade mucinous tumors of the appendix that often have the gross features of a so-called mucocele. Ovarian spread may also be seen in cases of frankly invasive adenocarcinomas of the usual intestinal and typical mucinous types

Fig. 18.41 Metastatic carcinoma from the colon. In this tumor, many neoplastic cells were mucinous

Fig. 18.42 Metastatic carcinoma from the colon. Typical moderate- to high-grade cytology of the epithelial cells

[97, 121], carcinomas with neuroendocrine differentiation and focal goblet cell carcinoid-like patterns, colloid and signet-ring cell carcinomas, and rarely, typical carcinoids. Although there is a modest literature on ovarian spread of goblet cell carcinoids, in our opinion [51] most of them should be classified as carcinomas albeit with neuroendocrine differentiation and often containing foci that could be classified as goblet cell carcinoid if viewed in isolation [139]. We shall not discuss colloid and signetring cell carcinomas here as their features are no different than when seen arising from other sites, the signet-ring cell tumors being one origin of the Krukenberg tumor. Carcinoid tumors are discussed below. We will restrict our detailed comments to low-grade appendiceal mucinous neoplasms, using the terminology of Misdraji et al. [100], and more briefly to mucinous carcinomas,

intestinal-type carcinomas, and those with neuroendocrine differentiation.

Spread from Low-Grade Appendiceal Mucinous Neoplasms

The patients are usually middle aged to elderly, and typically present with symptoms referable to an adnexal mass. In many cases, this is the first evidence of an appendiceal neoplasm, although in some cases the ovarian manifestations follow some time after the patient is known to have had a primary appendiceal neoplasm. The appendix, if not previously removed, is usually dilated and often covered with mucus. In some cases, however, the right iliac fossa is so obscured by mucoid material that identification of the appendix is difficult or impossible.

Fig. 18.43

Metastatic carcinoma from the colon. There is a prominent stromal reaction surrounding small aggregates of neoplastic cells

Gross Findings

Laparotomy typically discloses cystic ovarian tumors that are often bilateral (\bigcirc *Fig.* 18.46), average about 16 cm in diameter, and usually are multilocular. There is often generalized pseudomyoma peritonei [160], and the mucinous material may conspicuously coat the surfaces of one or both ovaries. Sectioning the ovaries typically reveals abundant jelly-like mucoid material (\bigcirc *Fig.* 18.47), although in some cases it has a firmer consistency. A multicystic appearance is most common, but organized mucin with fibrosis can impart a solid aspect in areas.

Microscopic Findings

Low-power examination shows glands and cysts growing in a leisurely fashion, often between residual recognizable ovarian elements. Mucin, with or without epithelial cells, may be prominent on the surface, or mucinous cells alone may line the surface (\bigcirc *Fig.* 18.48). Glands and cysts spread into the underlying stroma in a generally somewhat indolent-appearing manner (\bigcirc *Fig.* 18.49) The glands and

Fig. 18.44 Metastatic carcinoma from the intestine, clear cell type. The clear cell morphology may cause confusion with clear cell carcinoma

cysts are lined by columnar mucinous epithelial cells (**)** *Fig. 18.50*) that are typically taller than those seen in primary ovarian mucinous tumors and in other types of metastatic mucinous neoplasia. Mucin often appears to exude from the apical portion of the cytoplasm (**)** *Fig. 18.51*). Although mild to moderate nuclear atypia is often seen, overall there is a remarkably banal appearance to the mucinous cells throughout most of these neoplasms in the majority of cases. The epithelium often lifts off its basement membrane, a likely artifact, but nonetheless one that has struck us as being a somewhat distinctive feature of these particular metastatic neoplasms (**)** *Fig. 18.50*). In many cases, mucin dissects into the ovarian stroma (pseudomyxoma ovarii) (**)** *Fig. 18.48*).

Differential Diagnosis

The first issue to briefly address is whether these are indeed cases of metastatic neoplasia, a point of some controversy in the past but now largely settled in favor of metastatic disease [116, 122, 123, 129, 137, 167]. The typical synchronous

■ Fig. 18.45 Metastatic carcinoma from the intestine, clear cell type. There is a prominent secretory-like appearance

presentation of the ovarian and appendiceal tumors, their histologic similarity, the frequent bilaterality of the ovarian tumors, and the predominance of right-sided ovarian involvement in unilateral cases favors spread to the ovary. The lack of identification of appendiceal rupture has been used as an argument against the appendix being the primary site in these cases. Ongoing experience, however, has indicated that the site of rupture may be very small and require extensive sectioning to demonstrate it; such examinations have not been performed in most of the cases in which a site of rupture has not been identified. Additionally, in some cases a rupture site heals over, and is represented only by fibrosis in the appendiceal wall.

The association of the ovarian tumors with pseudomyxoma peritonei and, in most cases, known appendiceal pathology generally facilitate recognition of these tumors as metastatic. The rare primary mucinous tumors that are associated with pseudomyxoma peritonei usually have an additional teratomatous component; like primary appendiceal neoplasms, these are frequently CK7–/CK20+/CDX-2+, limiting the diagnostic utility of immunohistochemistry for determining site of origin in such cases [96, 149].

Mucinous Carcinoma and Intestinal-Type Carcinoma

These appendiceal tumors resemble those of similar type arising from elsewhere in the intestinal tract. Their features when they spread to the ovary have no unique characteristics, other than operative or other clinical findings drawing attention to the appendix as the likely primary site. A remarkable diversity of morphology is present in some cases.

Columnar cells line the ovarian surface and mucin dissects into the ovarian stroma ("pseudomyxoma ovarii")

Carcinomas with Neuroendocrine Differentiation

Hristov and colleagues [51] recently reported a series of ovarian metastases of carcinomas of this type and emphasized that the overall clinical features and morphologic findings support classification of the appendiceal tumors as carcinomas rather than goblet cell carcinoids. They may have foci of the latter nature, but the presence of clearly infiltrative and destructive growth merits designation as frank carcinoma (\bigcirc *Fig.* 18.52). Signet-ring cells are often a conspicuous feature, and metastases of such tumors constitute one form of the Krukenberg tumor. Although neuroendocrine stains may be done for academic interest, in our opinion they are not necessary for routine diagnostic purposes. The broad principles of evaluating metastatic tumors in the ovary assist in these cases. The prominent

• Fig. 18.49 Metastatic low-grade appendiceal mucinous neoplasm. Mucin is on the surface and cystic glands invaginate in a leisurely fashion into the cortical stroma

tubular component and neuroendocrine differentiation may place suspicion on the appendix if an appendiceal neoplasm is initially not evident.

Carcinoid Tumors and Neuroendocrine Carcinomas

Carcinoid tumors account for approximately 2% of metastases that form ovarian masses, and a similar percentage of small intestinal carcinoids greater than 1 cm in diameter spread to the ovary. Although most metastatic carcinoids are of small intestinal origin [120, 135], rarely the primary tumor originates in the appendix, colon, stomach, pancreas, or lung [13, 50, 145, 174]. In the largest series of carcinoids metastatic to the ovary, the age of the 35 patients ranged from 21 to 82 years, with a median of

Fig. 18.50

Metastatic low-grade appendiceal mucinous neoplasm. The mucinous cells are tall and exhibit minimal atypia. There is retraction of the epithelium off its supporting basement membrane

57 years; almost all were older than 40 years [120]. Ten of the tumors in that series were not diagnosed until autopsy. Forty percent of the women whose metastases were discovered at operation had preoperative manifestations of carcinoid syndrome. Some of them also had signs and symptoms referable to intestinal or ovarian involvement. Extraovarian metastases were found in at least 90% of the cases, a figure that contrasts with the rarity of similar spread of primary ovarian carcinoids. The primary site usually was in the ileum, but cecum, jejunum, appendix, and pancreas were sources in occasional cases. One third of the patients died within 1 year and three fourths of them within 5 years after unilateral or bilateral salpingooophorectomy, which was accompanied by a hysterectomy and an intestinal operation in some of the cases. Six of the 25 patients, however, were asymptomatic for a median period of 5 years postoperatively. The symptoms of carcinoid syndrome generally abate after removal of the ovarian tumors.

• Fig. 18.51 Metastatic low-grade appendiceal mucinous neoplasm. Mucin appears to exude from the apical portion of the columnar cells

In view of the occasional complication of ovarian metastasis, menopausal or postmenopausal patients with gastrointestinal carcinoids should have a bilateral oophorectomy even in the absence of obvious ovarian involvement to prevent the subsequent growth of occult metastases or the development of new metastases. Whenever bilateral ovarian carcinoids are detected, a careful search for an extraovarian primary tumor should be instituted. Both the metastases and the primary tumor, if found, should be excised whenever feasible. In a young woman with a unilateral neoplasm, careful examination of the intestine and its mesentery and other organs for a primary tumor, biopsy of the opposite ovary if enlarged, a thorough search for teratomatous elements in the tumor, postoperative radiologic studies, and measurement of 5-hydroxyindole acetic acid in the urine may be necessary before a determination of the primary or metastatic nature of the tumor can be made. Because the primary tumor in the intestine may be very small, it may not be detected by radiologic studies for a year or more after the diagnosis of the ovarian metastasis.

Fig. 18.52

Metastatic appendiceal carcinoma with neuroendocrine differentiation. On the *left*, there is overt infiltration of an aggressive type. On the *right*, small clusters have an appearance consistent with goblet cell carcinoid

 Fig. 18.53
Metastatic carcinoid. The larger tumor contains multiple cysts simulating a cystadenofibroma

Gross Findings

Most of these tumors are bilateral (**)** *Fig. 18.53*) in contrast to primary ovarian carcinoids, which are almost always unilateral. The tumors are most often only of modest size but may be large and typically are predominantly solid, with smooth or bosselated surfaces. Sectioning reveals single or confluent, firm, white to yellow nodules, which may resemble ovarian fibromas or thecomas. Cysts of varying size occasionally are present (\bigcirc *Fig.* 18.53) and are often filled with clear, watery fluid, resulting in a gross appearance similar to that of a cystadenofibroma. Focal necrosis and hemorrhage may occur (\bigcirc *Fig.* 18.54).

Microscopic Findings

The microscopic features of metastatic carcinoids are generally similar to those of primary ovarian carcinoids except that teratomatous elements are not encountered, multinodularity is often prominent, and vascular invasion is occasionally observed. An insular pattern is most common (**>** *Fig.* 18.55), but trabecular (**>** *Fig.* 18.56), mixed, and rarely solid tubular patterns are also encountered. Acini, which typically are uniformly small and round,

• Fig. 18.54 Metastatic carcinoid. The tumor is predominantly cystic with extensive hemorrhage

are common (\bigcirc *Fig. 18.57*); they often contain homogeneous eosinophilic secretions that may undergo calcification, sometimes in the form of psammoma bodies. The acini sometimes punctuate otherwise solid nests or, in some instances, are arrayed at the periphery in an orderly manner. Follicle-like spaces are frequently quite striking (\bigcirc *Fig. 18.58*). They may appear empty, but in other cases neoplastic cells slough into the spaces in a conspicuous manner. Metastatic carcinoid often has an extensive paucicellular fibrous stroma (\bigcirc *Fig. 18.59*); occasionally this stroma is extensively hyalinized. Indeed, this tumor is the metastatic neoplasm most often associated with a very quiescent yet prominent fibromatous stroma.

Differential Diagnosis

In addition to the absence of teratomatous elements and frequent bilaterality, which are the dominant findings that aid in distinction from a primary carcinoid in most cases, the metastatic tumors less often have a trabecular pattern and may show vascular invasion. Mucinous glands that are

Fig. 18.55 Metastatic carcinoid. Striking insular pattern

Fig. 18.56
Metastatic carcinoid. Trabecular pattern

Fig. 18.57 Metastatic carcinoid. Typical acini

common in the primary strumal carcinoid in particular are not a feature of metastatic carcinoid. The presence of foci of carcinoid outside the ovary strongly favors that the ovarian tumor is a metastasis. CDX-2 does not distinguish between tumors of intestinal origin and primary ovarian carcinoids [117].

Metastatic carcinoids may be confused with a number of tumors other than primary carcinoid tumors, including granulosa cell tumors, Sertoli or Sertoli-Leydig cell tumors, Brenner tumors, benign or borderline adenofibromas and cystadenofibromas, and adenocarcinomas of various types. The Call-Exner body of the granulosa cell tumor may resemble the acinus of the carcinoid when the latter is filled with dense eosinophilic basement membrane material, but the former differs by containing watery, eosinophilic fluid and shrunken nuclei in its lumen. The examination of the neoplastic cells is the most helpful clue to the correct diagnosis. The cells of a microfollicular granulosa cell tumor usually have scanty cytoplasm and ovoid, angular, or round nuclei that typically are pale and grooved. The cells are generally haphazardly oriented with respect to one another and the cavities of the Call-Exner bodies. In

Fig. 18.58
Metastatic carcinoid. Prominent follicle-like spaces

contrast, the cells of carcinoid tumors characteristically have round nuclei with coarse chromatin, and their cytoplasm often contains prominent red or red-brown argentaffin granules. The cells tend to have an orderly distribution and are polarized around the acinar spaces.

The sex cord-like formations of Sertoli–Leydig cell tumors may resemble the ribbons of the trabecular carcinoid, but the latter are usually longer and thicker and have a more orderly architecture. The tubules of Sertoli or Sertoli–Leydig cell tumors may simulate the acini of insular carcinoids. Further confusion may be caused by the presence of a carcinoid component, which typically is minor in extent, in a Sertoli–Leydig cell tumor with heterologous elements. The presence of other distinctive patterns of Sertoli–Leydig cell tumor and attention to the characteristic cytologic features of carcinoid cells, however, should enable one to differentiate the two.

The fibromatous stroma of a Brenner tumor is often indistinguishable from that of a carcinoid, but the epithelial nests of the former contain cells of urothelial type with oval, pale, and grooved nuclei rather than cells with the characteristic cytologic features of carcinoid tumors. Benign and malignant adenofibromatous tumors and

Fig. 18.59 Metastatic carcinoid. Abundant stroma

endometrioid adenocarcinomas containing small tubules and acini are generally readily distinguished from carcinoid tumors by recognition of the differing patterns and cytologic features of these tumors. Metastatic breast carcinoma with a prominent insular pattern may simulate a carcinoid tumor. Rarely, an acinar cell carcinoma of the pancreas metastasizes to the ovary and, in the absence of a known pancreatic primary tumor, may be misdiagnosed as a metastatic carcinoid (see below).

If the diagnosis of a carcinoid tumor is difficult in any of the above situations, more thorough sampling, immunohistochemical staining for neuroendocrine markers, and in rare situations in which those studies are not definitive, electron microscopy for dense-core granules should resolve the differential diagnosis.

It is our opinion, as stated earlier, that if strict criteria are used, mucinous carcinoids rarely spread to the ovary. However, we have already noted that carcinomas of the appendix with neuroendocrine differentiation may do so, and so may the spectrum of neoplasms ranging from neuroendocrine carcinoma (\bigcirc *Fig. 18.60–18.62*) to small cell carcinoma of neuroendocrine type.

Fig. 18.60 Metastatic neuroendocrine carcinoma from small bowel. There is an insular pattern, albeit less discrete than in the better-differentiated carcinoid tumor

Tumors of the Pancreas

Usual Ductal Adenocarcinoma and Mucinous Cystadenocarcinoma

Spread of pancreatic carcinoma to the ovary was considered uncommon until relatively recently [125, 168], but current experience indicates that it is more common than was previously thought and has almost certainly been responsible for the miscategorization of some metastatic tumors in the ovary as primary mucinous carcinomas and even mucinous borderline tumors. Pancreatic primaries accounted for 7 of 82 nongenital cancers that spread to the ovary in one large series [111], and in another recent series of metastatic mucinous carcinomas, the single greatest number of cases, 8, originated in the pancreas [119]. The patients are usually in the mid to late years of life. Ovarian spread is often part of disseminated pre-terminal disease (or an autopsy finding in some cases), but in a sizeable subset of cases the ovarian manifestations have been

a dominant clinical finding and in some instances have even accounted for the clinical presentation [125, 168].

Gross Findings

The ovarian disease is typically bilateral and often takes the form of solid nodules, characteristic of many examples of metastatic spread to the ovaries. However, the ovarian tumors can also be large, cystic, and multiloculated and sometimes unilateral, mimicking primary tumors (\bigcirc *Fig. 18.63*). Sectioning shows an appearance that may be indistinguishable from primary mucinous neoplasia, although in some cases surface nodules may be noted and raise suspicion for metastasis.

Microscopic Findings

In cases grossly represented by solid nodules, small glands randomly infiltrating in a desmoplastic stroma comprise the typical histologic appearance. In tumors that are grossly cystic, foci resembling mucinous cystadenoma, mucinous cystic tumor of borderline malignancy, and moderately or well-differentiated mucinous cystadenocarcinoma may be present (**>** *Fig. 18.64*). However, foci of more obvious carcinoma, typical of the grossly solid

 Fig. 18.62
Metastatic neuroendocrine carcinoma. Positive chromogranin stain of tumor depicted in prior two illustrations

tumors, are also often present (\bigcirc *Fig. 18.65*) but may be very minor in amount, and identification is very dependent on thorough sampling. In some cases, multifocal high-grade carcinoma randomly scattered among, and contrasting markedly with, much more indolent low-grade cystic neoplasia is a clue to the diagnosis. In both gross forms of disease, surface implants may be seen (\bigcirc *Fig. 18.66*). The maturation of epithelium in some of these cases is remarkable (\bigcirc *Fig. 18.67*), but high-power scrutiny of areas initially thought to represent benign neoplasia may show a degree of cytologic atypia disproportionate to the degree of architectural differentiation. Vascular invasion may be seen. The pancreatic tumors are usually typical ductal adenocarcinomas but are rarely mucinous cystadenocarcinomas.

Differential Diagnosis

A number of features are helpful in distinguishing between a primary and metastatic mucinous tumor in these cases and in other cases of metastatic mucinous carcinoma,

■ Fig. 18.63 Metastatic carcinoma from the pancreas. The cystic tumor mimics a primary mucinous tumor

irrespective of the primary site. Bilaterality of the ovarian tumors strongly favors metastasis. A helpful finding is the presence of desmoplastic implants of carcinoma on the ovarian surface and in the superficial ovarian cortex. The clinical findings often aid, and the frequent presence of intraabdominal spread is most consistent with secondary involvement of the ovary in cases of bilateral mucinous carcinomas. The heterogeneous picture noted in our microscopic description above may also be helpful. The reader is again referred to **?** *Table 18.1*. We have recently added to it so-called mucin granulomas [68], which we feel are considerably more common in primary, compared to metastatic, mucinous tumors.

Immunohistochemistry is of limited utility for distinguishing metastatic pancreatic adenocarcinoma from a primary ovarian mucinous neoplasm. Both are usually CK7+ and show variable reactivity for CK20 (**9** *Fig. 18.68*) [91]. A lack of reactivity for Dpc4 suggests a pancreatic primary, since almost half of pancreatic adenocarcinomas

Fig. 18.64 Metastatic carcinoma from the pancreas. The cystic nature and varied degree of differentiation are evident

■ Fig. 18.65 Metastatic carcinoma from the pancreas. Foci of high-grade carcinoma on background of more indolent morphology

Fig. 18.66 Metastatic carcinoma from the pancreas. Surface implant

show loss of this marker, whereas ovarian mucinous tumors express it [57]. However, a positive reaction for Dpc4 is obviously of no discriminatory value.

Acinar Cell Carcinoma

Four cases of ovarian spread of this carcinoma have been only recently reported, indicative of its rarity [146]. The patients were all adults, and in three of them the ovarian tumors were detected prior to the pancreatic neoplasm. In these three patients, however, the primary tumor became evident within a short period of time. Three patients also had involvement of sites other than the ovary or pancreas.

Gross Findings

The ovarian tumors, three of which were bilateral, had an average maximum dimension of about 7 cm, and were solid and firm for the most part, with only one showing "myxoid" degeneration.

Microscopic Findings

The neoplasms were characterized by solid nests and formations with lumina (**>** *Fig. 18.69*), the latter ranging

G Fig. 18.67

Metastatic carcinoma from the pancreas. Marked maturation of the neoplastic epithelium resulting in morphology indistinguishable from benign primary neoplasia

from small acini (\bigcirc *Fig. 18.70*) to larger tubules to even larger gland-like formations that were sometimes cystic (\bigcirc *Fig. 18.71*). There was little intervening stroma. Comedo-like necrosis was conspicuous in some cases. The tumor cells had abundant pale to eosinophilic, finely granular cytoplasm. Their nuclei were round with stippled chromatin and prominent nucleoli. The mitotic rate was typically brisk. Vascular invasion was seen in all cases. Immunostains showed positivity for chymotrypsin and trypsin in all cases (\bigcirc *Fig. 18.72*). Neuroendocrine stains were negative.

Differential Diagnosis

Because of the striking acinar differentiation, these tumors can be misdiagnosed as carcinoids or other forms of neuroendocrine neoplasia. Indeed, this initially happened in some of the reported cases. The at least focally brightly eosinophilic granular cytoplasm, reflecting the presence of zymogen granules, contrasts with the typical appearance of

Fig. 18.68

Metastatic carcinoma from the pancreas. Immunohistochemical stains show prominent CK7 staining (*left*) and more focal CK20 staining (*right*), as seen in many cases of this type

the cytoplasm of neuroendocrine neoplasms. Acinar carcinoma cells also lack the typical "salt and pepper" chromatin of the latter. The large prominent single nucleolus typifying most of the acinar carcinoma cells is also a noteworthy difference. These contrasting features notwithstanding, the immunohistochemical differences noted above may play an important role in diagnosis. Other rare issues in differential diagnosis, such as consideration of Sertoli cell tumor, may also be aided by immunohistochemistry, and this and other aspects have elaborated in detail recently by Vakiani et al. [146].

Other Pancreatic Neoplasms

Rare islet cell carcinomas have spread to the ovaries [105, 113]. In the most recent case reported, a 41-year-old woman presented with hirsutism, Cushing's syndrome, and a pelvic mass. Work-up disclosed a primary pancreatic neuroendocrine neoplasm with bilateral solid and cystic metastatic tumors in the ovary [105].

Tumors of the Gall Bladder and Extrahepatic Bile Ducts

Sporadic examples of this phenomenon have been reported over the years [178], usually as isolated case reports, but Khunamornpong and colleagues [63] have recently reported the largest series whose features reflect the overall experience.

Their 16 cases occurred in patients from 21 to 87 (mean 59) years. Almost half the patients presented with gynecologic manifestations. The remaining patients had the usual symptoms attributable to biliary neoplasia.

Gross Findings

All but one ovarian tumor was bilateral. Most ovaries showed grossly evident disease with a mean size of 9.4 cm. The cut surfaces were variable, most often solid and cystic but sometimes uniformly solid and in five instances, multicystic.

G Fig. 18.69

Metastatic acinar cell carcinoma of the pancreas. Islands of tumor cells contain numerous small acini. The tumor mimics a carcinoid tumor

Microscopic Findings

The multinodular growth that typifies many examples of metastasis was seen in about 60% of the cases, and surface implants were seen in two thirds (**>** *Fig. 18.73*). The overall features were similar to other cases of metastatic adenocarcinoma from various abdominal sites, including pancreas and colon. For example, a differentiated mucinous morphology as seen with pancreatic primaries was observed in some cases, whereas others showed a colloid (**>** *Fig. 18.74*) or pseudoendometrioid morphology more typical of colonic metastases. Signet-ring cells justified the diagnosis of Krukenberg tumor in four cases.

Differential Diagnosis

This is broadly similar to that of other metastases from abdominal sites, with no unique features being evident other than the clinical determination of the primary site.

Fig. 18.70
Metastatic acinar cell carcinoma of the pancreas.
High-power view of typical small acini

Three tumors in the above series were hilar cholangiocarcinomas, five common bile duct carcinomas, and eight gallbladder carcinomas. Like primary ovarian mucinous neoplasms and other adenocarcinomas of the pancreatobiliary tract, these tumors tend to be CK7+ and show variable expression for CK20+ [63], so the cytokeratin profile does not provide discriminatory information.

Tumors of the Liver

Hepatocellular Carcinoma

The spread of hepatocellular carcinoma to the ovary is even rarer than that of pancreatic and biliary tumors, but five clinically important cases have been reported [64, 165]. The patients have all been adults. In two patients, bilateral ovarian tumors were discovered at the same time as the liver primary. In another patient, the liver tumor was discovered by radiologic investigation after bilateral

Fig. 18.71 Metastatic acinar cell carcinoma of the pancreas. Cysts are conspicuous

ovarian tumors had been removed. In the other two cases, unilateral ovarian tumors were discovered 3 and 7 months, respectively, after the liver tumors had been detected.

Pathologic Findings

The ovarian neoplasms ranged from 4 to 11 cm in diameter and three of them were solid. A green color may be a clue to the diagnosis (\bigcirc *Fig. 18.75*). Microscopic examination revealed features typical of metastatic disease, such as striking surface involvement in some cases (\bigcirc *Fig. 18.76*), and overall findings characteristic of hepatocellular carcinoma, except in one case in which cysts were prominent. A trabecular pattern is sometimes conspicuous, and the neoplastic cells almost invariably have moderate to abundant eosinophilic cytoplasm (\bigcirc *Figs. 18.77* and \bigcirc *18.78*).

Differential Diagnosis

The major differential diagnosis in these cases involves both primary and metastatic hepatoid tumors of the ovary. In most cases of hepatoid yolk sac tumor, the finding of foci of more typical yolk sac neoplasia or

Fig. 18.72
Metastatic acinar cell carcinoma of the pancreas.
Immunoreactivity for chymotrypsin

other germ cell elements excludes the diagnosis of metastatic hepatocellular carcinoma, and the young age of the patient will argue against the latter diagnosis. In a postmenopausal patient, the differential diagnosis involves hepatoid carcinoma rather than hepatoid yolk sac tumor. Hepatoid carcinomas usually contain foci of more typical surface epithelial carcinoma, typically serous. Bilaterality and other characteristic patterns of metastatic spread to the ovary may be helpful in indicating the metastatic nature of a tumor. Hepatoid carcinomas may also arise outside the ovary, for example in the stomach and lung, and may potentially metastasize to the ovary, although we are not aware of documented examples. HepPAR1 is not useful in distinguishing among metastatic hepatocellular carcinoma, hepatoid yolk sac tumor, and hepatoid ovarian carcinoma as it is expressed in all [115].

Intrahepatic Cholangiocarcinoma

Particularly in the Far East, spread of intrahepatic cholangiocarcinoma to the ovary is seen with some

Fig. 18.73 Metastatic biliary tract carcinoma. Surface involvement by colloid carcinoma

frequency because of the high incidence of that form of cancer due to endemic infestation with the trematode *Opisthorchis viverrini*. Only rarely has this tumor been documented to spread to the ovary in other parts of the world. A series of 16 cases has significantly expanded information on this topic [65].

Pathologic Findings

About two-thirds of these cases have been bilateral in the ovaries, and they have had a mean size of about 12 cm. The majority of tumors have been solid and cystic, but almost half have been cystic and the remainder uniformly solid. Microscopic examination showed a quite varied morphology, but typical features of metastatic disease were generally present, including prominent nodules, or at least a vague multinodular pattern (\bigcirc *Fig.* 18.79). In some cases striking maturation with a cystic pattern was seen (\bigcirc *Fig.* 18.80). Occasionally small micropapillae were encountered (\bigcirc *Fig.* 18.81). In many cases there was a degree of cytologic atypia that was discordant with the degree of glandular differentiation, a finding that can be

 Fig. 18.74

Fig. 18.75 Metastatic hepatocellular carcinoma. Multiple nodules are visible on the sectioned surface of a yellow-green tumor

Fig. 18.76 Metastatic hepatocellular carcinoma. Prominent surface involvement

a subtle clue to the diagnosis of metastatic adenocarcinoma (**>** *Fig. 18.82*).

Other Rare Neoplasms

A hepatoblastoma that occurred in a 19-year-old woman and was associated with bilateral ovarian metastases at presentation has been reported [40].

Breast Carcinoma

Ovarian involvement is seen at autopsy in about 10% of cases of breast cancer. The metastases are bilateral in approximately 80% of those cases and in approximately two thirds of all cases, autopsy and surgical combined. Most surgical pathology experience with ovarian metastases of mammary carcinoma has resulted from

• Fig. 18.77 Metastatic hepatocellular carcinoma. Tumor cells with eosinophilic cytoplasm are arranged in trabeculae. Note the presence of bile (Reproduced with permission from Ref. [162])

examination of ovaries removed to decrease the estrogen level in patients with known spread of the tumor [88]. In such cases, ovarian involvement has been reported in up to half the cases but is often only a microscopic finding.

It is unusual for metastatic carcinoma of the breast to produce signs or symptoms of an ovarian tumor, and only rarely is the ovarian metastasis evident before the primary tumor is detected [35, 163]. In one large series, breast carcinoma accounted for almost 40% of all metastases to the ovary, being slightly more common than gastrointestinal tract metastases [35]. However, 22 of the 59 breast metastases were autopsy findings, and 28 were incidental findings in therapeutic oophorectomy specimens. In four of the remaining nine cases, the ovarian metastases were incidental findings during an operation for another indication; in the remaining five patients, however, the ovarian

■ Fig. 18.78 Metastatic hepatocellular carcinoma. The neoplastic cells have abundant eosinophilic cytoplasm. There are scattered hyaline droplets

metastases caused a mass of sufficient size to be the clinical indication for operation. The ovarian metastatic tumor was detected before the breast cancer in only one case. This patient presented with hepatic and ovarian tumors, and her primary breast cancer was not identified until 15 months later. The median interval between the diagnosis of breast cancer and the ovarian metastasis was 11.5 months and was related to the stage of the breast cancer. The median survival after the diagnosis of ovarian metastasis was 16 months. One patient with metastatic breast carcinoma in the ovaries presented 10 years after initial treatment of the breast cancer, as a result of virilization caused by stromal luteinization associated with the ovarian metastasis [18]. Although ovarian metastases of breast cancer are usually accompanied by other foci of abdominal spread, isolated ovarian metastases occasionally are encountered. Lobular carcinomas, including those of signet-ring cell type, spread to the ovary more frequently than those of ductal type; in an autopsy study 36% of the former metastasized to the ovaries in contrast to only 2.6% of the latter [43].

 Fig. 18.79
Metastatic intrahepatic cholangiocarcinoma. There is a vague multinodular pattern

Gross Findings

On gross examination, the visibly involved ovaries often have irregular, nodular surfaces and typically contain firm or gritty, white to yellow nodules of various sizes (**)** *Fig. 18.83*). When the organ is replaced by tumor, it is transformed into a smooth-surfaced or bosselated mass; exceptionally, it contains cysts and very rarely it is entirely cystic. When all cases are considered, tumors larger than 5 cm are uncommon, accounting for only 15% of the cases in one large study [35].

Microscopic Findings

Microscopic examination reveals the same variety of patterns and cell types that are observed in primary breast carcinomas. In early examples, small cords and clusters of cells may be found in the ovarian cortex. In premenopausal women, small deposits often are situated in the highly vascular theca interna of a graafian follicle or in the

granulosa or theca layer of a corpus luteum. Surface tumor may be seen (> Fig. 18.84) but is generally not as conspicuous as in metastatic tumors from the abdominal viscera. Multinodular growth may be striking (> Fig. 18.85). A pattern of tubular glands and nests similar to that of ductal carcinoma is common (> Figs. 18.86 and > 18.87), as is the single-file pattern of lobular carcinoma (**)** *Fig. 18.88*); such patterns were seen in 42 and 32% of the cases, respectively, in one series [35]. A pure cribriform pattern is infrequent but focal cribriform areas are relatively common. In approximately 10% of the cases, there is a diffuse pattern, and occasionally the tumor cells grow as single cells or in clusters. Rarely, papillae are seen and equally uncommonly there is a striking oxyphilic appearance. Admixtures of these various patterns may occur. Signetring cells usually are not a conspicuous feature of metastatic breast carcinoma unless the primary tumor is of the relatively uncommon signet-ring type but, rarely, the features of a metastatic breast cancer are those of a Krukenberg tumor (> Fig. 18.89). The stroma of the

 Fig. 18.81
Metastatic intrahepatic cholangiocarcinoma. Micropapillary pattern

tumor varies from sparse to abundant; it rarely shows luteinization in contrast to the stroma of metastatic carcinomas of intestinal origin. Lymphatic invasion was seen in 15% of the cases in one series [35].

Differential Diagnosis

The differential diagnosis of metastatic breast carcinoma may be difficult, particularly if the primary tumor is remote, not apparent, or its existence is not known by the pathologist. Rare, predominantly glandular tumors may resemble surface epithelial tumors, particularly those of endometrioid type, and the insular pattern may mimic a carcinoid tumor. Exceptionally, a tumor with a diffuse pattern or one with a single-file arrangement of the cells simulates a lymphoma or granulocytic sarcoma. Metastatic breast carcinomas also have been misinterpreted as granulosa cell tumors. The growth patterns and characteristics of the neoplastic cells and the clinical features, however, almost always permit their distinction from these and other tumors, but this is

 Fig. 18.82
Metastatic intrahepatic cholangiocarcinoma. Striking atypia of cells lining a gland

Fig. 18.83

Metastatic breast cancer. The sectioned surface shows a lobulated yellow-white neoplasm. This tumor spread to an ovary involved by a dermoid cyst, which is evident in the picture

Fig. 18.84 Metastatic breast cancer. Prominent surface involvement by a metastatic mucinous adenocarcinoma

occasionally difficult on the evaluation of routinely stained sections alone. It should be remembered that patients with breast cancer have an increased frequency of ovarian carcinoma [24], especially those patients harboring BRCA mutations, and rarely ovarian carcinoma metastasizes to the breast.

Staining of an ovarian neoplasm immunohistochemically for gross cystic disease fluid protein-15 (GCDFP-15) (> Fig. 18.90) may be helpful in distinguishing a metastasis from the breast from a primary ovarian carcinoma [101]. Between 40 and 70% of breast carcinomas metastatic to the ovary have been reported to be positive for GCDFP-15, whereas primary ovarian carcinomas are almost always negative [80, 141, 154]. GCDFP-15 expression in breast carcinoma is usually strong but focal. Mammoglobin is another marker of breast origin that is expressed in about 50% of breast carcinomas () Fig. 18.91) [10, 127]. It appears to show greater sensitivity but less specificity for breast origin than GCDFP-15. Mammoglobin expression has been demonstrated in rare ovarian serous carcinomas; its expression in other subtypes of ovarian carcinoma has not been

Fig. 18.85 Metastatic breast carcinoma. Multinodular pattern

extensively studied, but it is noteworthy that mammoglobin is frequently positive in endometrioid carcinomas of the uterine corpus [10, 109].

Other markers are commonly expressed in primary ovarian carcinomas but not breast carcinomas. WT-1 is positive in >80% of serous and transitional cell carcinomas of the ovary, but it is only very exceptionally positive in breast carcinomas [77, 80, 102, 104, 141]. Similarly, mesothelin is frequently expressed in ovarian carcinomas but not breast carcinomas; its expression in the former, however, may be focal [45, 60]. In a tissue microarray study, nonmucinous ovarian carcinomas were immunoreactive for PAX-8 in greater than 88% of cases; 243 breast carcinoma samples were negative [104]. CA-125 reactivity may occur in either ovarian or breast carcinomas, but the latter express this antigen much less frequently [80, 102, 141]. As in other settings, when necessary, a panel of immunohistochemical stains is recommended as no currently available individual marker is entirely specific for breast or ovarian origin.

Finally, in cases of ovarian involvement by the intraabdominal desmoplastic small round cell tumor [164], the diagnosis of metastatic breast cancer may be

Fig. 18.86 Metastatic breast carcinoma. Small glands typical of ductal carcinoma

suggested in areas. However, these patients usually are in their teens, when breast cancer is rare, and other more characteristic foci of the tumor and its typical immunohistochemical profile facilitate the interpretation. We have seen one case in which this tumor involved the breast, confusing the picture, but the breast involvement suggested metastasis and the tumor exhibited the characteristic immunohistochemical staining of the desmoplastic small round cell tumor.

Renal Tumors

Renal cell carcinoma rarely spreads to the ovary, with only 15 cases of clinically detectable ovarian metastatic tumors reported in detail [53, 133, 150, 169]. In seven of the cases, the ovarian tumor was discovered first, leading to the initial misdiagnosis of primary ovarian clear cell carcinoma in three cases. The renal tumors were usually detected within a short period of time in these patients, but in one the renal primary was not detected until 8 years

Fig. 18.87 Metastatic breast carcinoma. Insular pattern

later. In the other cases the ovarian tumor was usually detected within 2 years after the renal tumors had been removed, but in one case the interval was 14 years.

Gross Findings

The ovarian tumors, only a minority of which were bilateral, were often large (average 12.5 cm in greatest dimension), and were either solid or solid and cystic, with one cystic tumor being unilocular and containing a 2.5 cm solid nodule in one area. The solid components of the tumors were either uniformly or focally yellow to orange (**>** *Fig. 18.92*).

Microscopic Findings

With one possible exception the reported renal tumors were well-differentiated clear cell adenocarcinomas; microscopic examination showed a relatively uniform picture of diffuse sheets of clear cells or tubules lined by similar cells and containing eosinophilic material or blood; a prominent

 Fig. 18.88
Metastatic breast carcinoma. Growth in cords typical of metastatic lobular carcinoma

sinusoidal vascular pattern was almost always present (**>** *Fig. 18.93*).

Differential Diagnosis

It is helpful in differential diagnosis that primary clear cell carcinoma of the ovary has a tubulocystic and papillary component, hobnail cells, and intraluminal mucin in the great majority of cases. Hobnail cells and conspicuous mucin production, in contrast, are exceptional in renal cell carcinomas. In addition, the typical sinusoidal vascular framework of renal cell carcinoma is not a feature of ovarian clear cell carcinoma. In cases of pure clear cell carcinoma of the ovary without hobnail cells or mucin secretion, radiologic evaluation of the kidney may rarely be necessary to exclude a renal cell carcinoma. A panel of antibodies may aid in evaluation: ovarian clear cell carcinomas are usually positive for CK7 and mesothelin and negative for CD10 and renal cell carcinoma marker (RCCma), whereas renal clear cell carcinomas often demonstrate the opposite immunoprofile

Fig. 18.89

Metastatic breast carcinoma. This tumor had a signet-ring cell component qualifying it as a Krukenberg tumor

(CK7-/mesothelin-/CD10+/RCCma+) (**)** *Fig. 18.94*) [16, 79, 107]. Although PAX-2 may be a somewhat more sensitive marker than RCCma for metastatic renal cell carcinoma, it should be noted that about 40% of ovarian clear cell carcinomas also express this protein [36].

Renal transitional cell tumors rarely spread to the ovary, but exceptionally a patient with a renal pelvic tumor of this type has an ovarian metastasis at the time of presentation [52, 108]. Ovarian metastases from Wilms' tumor of the kidney are rare and no examples are present in several large series of this neoplasm. In one remarkable case, a patient with a rhabdoid tumor of the kidney presented with an ovarian metastasis, initially misinterpreted as a granulosa cell tumor, the primary renal tumor being undiscovered until autopsy [172].

Tumors of the Urinary Bladder, Ureter, and Urethra

Tumors from these sites uncommonly metastasize to the ovaries. Three signet-ring cell carcinomas metastatic from

the bladder have had the appearance of a Krukenberg tumor [176]. In one of them the ovarian tumor was an autopsy finding and in another the ovarian involvement was an incidental finding on microscopic examination. In the third case, the ovarian metastatic tumor, which was symptomatic, was not discovered until 7 years after the primary bladder tumor had been resected. A small number of urachal adenocarcinomas have formed metastatic mucinous cystic tumors in the ovary [106, 159]. Only isolated examples of ovarian metastasis of ureteral or urethral cancer have been reported in the literature.

In many cases of possible transitional cell carcinoma metastatic to the ovary, it is difficult to distinguish between a metastatic tumor and a borderline or malignant Brenner tumor or independent primary transitional cell carcinoma of the ovary [132, 176]. In almost all borderline or malignant Brenner tumors, however, foci of typical benign Brenner tumor also can be found and the presence of associated benign mucinous elements also favors the diagnosis of a Brenner tumor. The extent of invasion of the primary extraovarian tumor, and the general features of metastatic involvement of the ovary, all have to be considered in the evaluation of these cases. The metastatic transitional cell carcinoma in the series of Ulbright et al. [145] was cystic, exemplifying the great propensity of ovarian metastases from various sites to undergo cystic change.

Transitional cell carcinomas of the bladder are often positive for CK20, uroplakin III, and thrombomodulin; they are typically negative for WT-1 [85]. Primary ovarian transitional cell carcinomas, on the other hand, are usually negative for CK20, uncommonly express uroplakin III and thrombomodulin, and are frequently positive for WT-1. This difference in immunoprofile supports that the shared histologic features of the two tumors do not indicate a shared histogenesis, and that primary ovarian transitional cell carcinomas are variants of surface epithelial neoplasia. Interestingly, Brenner tumors show a high frequency of uroplakin III and thrombomodulin expression, suggesting true urothelial differentiation in these tumors [85].

Adrenal Gland Tumors

Neuroblastoma spreads to the ovary more frequently than other tumors of the adrenal gland. From 25 to 50% females with neuroblastoma have ovarian involvement at autopsy [98]. Clinically significant metastases during life are rare but documented [136, 172]. Rarely, neuroblastoma is primary in the ovary, and such tumors must be distinguished from metastatic neuroblastomas.

Fig. 18.90

Metastatic carcinoma to a serous neoplasm. Confirmation that the infiltrating carcinoma was metastatic carcinoma from the breast rather than a component of the primary serous neoplasm was aided by positive immunohistochemical staining of the breast cancer for gross cystic disease fluid protein-15 (*right*)

The unilaterality of the primary tumors, their occasional association with a teratoma, and the absence of a known primary tumor elsewhere are helpful in the differential diagnosis in individual cases. The prominent fibrillary background of neuroblastoma and the presence of pseudorosettes should aid in the distinction of metastatic neuroblastoma from other metastatic small cell tumors; immunohistochemical staining also may help in a case in which routine stains are not diagnostic.

Metastases of adrenal cortical carcinomas to the ovary are rarely found even at autopsy. One non-autopsy case resulted in the broad differential of a malignant oxyphilic ovarian tumor [74]. Pheochromocytomas spread to the ovary even less commonly; a review of the literature has failed to disclose a documented case.

Malignant Melanoma

Autopsies of patients who died of malignant melanoma have revealed ovarian involvement in about 20% of the cases. Most of the tumors have originated in the skin, but occasional examples have arisen in the choroid or elsewhere. Occasionally ovarian involvement is clinically symptomatic, as exemplified by many of the 52 cases in three relatively large series of melanomas metastatic to the ovary [34, 41, 180]. The patients in these reports had an average age of 38 years and two were teenagers. The usual presentation is abdominal swelling or pain, but a history of melanoma is usually existent, albeit not always immediately made known to the pathologist. Approximately 80% of the patients have metastatic tumor outside the ovary, usually within the pelvis and upper abdomen.

Gross Findings

The ovarian tumors average 10 cm in diameter; about 30% are noted to be black (**>** *Fig. 18.95*) or brown. About 80% have a minor cystic component. Rarely, a tumor is mostly cystic.

 Fig. 18.92
Metastatic renal cell carcinoma. The tumor is orange (Courtesy of Dr. Mahul B. Amin)

Microscopic Findings

On low-power examination, a feature suggesting the metastatic nature in a number of the cases is growth of the tumor in the form of multiple nodules. The most common microscopic appearance is that of large cells with abundant eosinophilic cytoplasm (> Fig. 18.96). Occasional tumors are characterized by small cells with scanty cytoplasm (> Fig. 18.97), and a minority by spindle cells; admixtures of these cells types may be encountered. Follicle-like spaces are seen in approximately 40% of the cases (> Fig. 18.10). A helpful diagnostic feature of many metastatic melanomas is the presence of discrete rounded aggregates with a nevoid appearance (> Fig. 18.98). Prominent nucleoli are seen in many cases, and cytoplasmic pseudoinclusions are present in many nuclei in about 25%. The presence of melanin pigment is an obvious clue to the nature of the tumor in these cases, but melanin

• Fig. 18.94 Metastatic renal cell carcinoma. This tumor, which had an unusual oxyphilic morphology, was immunoreactive for CD10

was inconspicuous or absent in approximately half the cases in the reported series. Miscellaneous potentially confusing findings have been clear cells, rhabdoid cells, growth as cords, and myxoid stroma.

Differential Diagnosis

Metastatic melanoma must be distinguished from the rare primary melanoma [92] that usually arises in the wall of a dermoid cyst, which is sometimes accompanied by junctional activity beneath the squamous lining of the cyst or is associated with another teratomatous component such as struma ovarii. Because recognition of teratomatous elements is important in establishing the primary nature of a melanoma, the pathologist should sample the specimen extensively. In cases of apparently pure ovarian melanoma without obvious evidence of a primary tumor elsewhere,

• Fig. 18.95 Metastatic malignant melanoma. The tumor has a bosselated external surface and is black

a meticulous search for an occult primary tumor should be conducted. If there is no evidence of a primary tumor elsewhere, it is possible that a primary cutaneous melanoma that has regressed was the source of the ovarian tumor. In these cases, bilaterality or growth of the ovarian tumor in the form of multiple nodules strongly suggests metastasis even in the absence of a known primary tumor. In some cases, removal of a primary melanoma may be remote and possibly not considered relevant by the patient or known by the clinician.

Metastatic melanoma, particularly if it is amelanotic, may resemble closely a lipid-poor steroid cell tumor or, if it is found during pregnancy, a pregnancy luteoma. Melanin can be misinterpreted as lipochrome pigment, the presence of which may be a feature of steroid cell tumors and impart a dark green-brown or almost black color to the neoplastic tissue. The presence of follicle-like spaces in metastatic melanomas has resulted in their confusion with small cell carcinomas of the hypercalcemic type (when the

cells are small) as well as juvenile granulosa cell tumors (when the cells have conspicuous eosinophilic cytoplasm). Rarely, surface epithelial neoplasms, particularly undifferentiated carcinoma and transitional cell carcinoma, may be reasonable considerations in the differential diagnosis, but surface epithelial neoplasms will often have at least minor obvious epithelial characteristics that rule out melanoma. In a young person, dysgerminoma is rarely entertained, but a variety of architectural and cytologic differences should resolve this issue. In all the aforementioned situations, the diagnosis of metastatic melanoma to the ovary may be confirmed by the immunohistochemical demonstration of S-100, HMB-45, and MART-1 positivity and negative staining for keratin and other antigens characteristic of other neoplasms that may be in the differential diagnosis.

Pulmonary and Mediastinal Tumors

Only approximately 5% of women with lung cancer have ovarian metastases at autopsy, and the surgical pathologist

Fig. 18.97 Metastatic malignant melanoma. The picture is that of a small cell malignant tumor

uncommonly encounters an ovarian tumor of this type. Exceptionally, an ovarian metastasis either precedes the discovery of a pulmonary tumor or is found simultaneously. Salient features of this phenomenon based on a relatively recent series, by far the largest on the topic, are summarized [56].

These tumors have occurred at an average age of 47 years. A history of lung cancer is known at presentation in slightly more than half the cases. In most of the remainder, the two tumors are discovered essentially synchronously, but in almost 20% the ovarian manifestations antedate recognition of the pulmonary primary, sometimes by as much as 2 years.

Gross Findings

The tumors have been bilateral in only about one third of the cases, and they average about 10 cm in maximum dimension. No unique gross characteristics have been evident in the cases encountered to date, but some have

 Fig. 18.98
Metastatic malignant melanoma. Nests of cells have a nevoid appearance

Fig. 18.99
Metastatic bronchioloalveolar carcinoma of the lung.
Note the multiple nodules (Courtesy of Dr. Jaime Prat)

features, such as striking multinodularity (**>** *Fig. 18.99*), in keeping with a metastatic neoplasm. Rarely a primary surface epithelial neoplasm is mimicked (**>** *Fig. 18.100*).

Microscopic Findings

The greatest number of cases, about 44%, are small cell carcinomas (\bigcirc *Figs. 18.101* and \bigcirc *18.102*), the remaining neoplasms being largely split between adenocarcinoma and large cell carcinoma with a ratio of about 2:1. Rare more differentiated neuroendocrine neoplasms falling in the atypical carcinoid–neuroendocrine carcinoma group have spread to the ovary (\bigcirc *Fig. 18.103*). Perhaps surprisingly, spread of squamous cell carcinoma, although documented, is exceptionally uncommon. The morphologic features of the tumors in the ovary are similar to those encountered in the lung except for features relevant to metastatic ovarian disease, specifically surface involvement, nodularity, and vessel space invasion.

Differential Diagnosis

When a patient has pulmonary and ovarian neoplasms, it can be difficult to decide which tumor is primary. When the histologic features are typical of a lung carcinoma, a pulmonary origin can be assumed with rare exceptions. Small cell carcinomas of pulmonary type may be primary in the ovary, but there is typically no pulmonary

Fig. 18.100

Metastatic small cell carcinoma from the lung. The solid and cystic sectioned surface mimics a surface epithelial neoplasm

Fig. 18.101 Metastatic small cell carcinoma from the lung. Trabecular pattern

involvement in such cases, facilitating the diagnosis of an ovarian primary. The focal presence of a surface epithelial tumor is also sometimes helpful in excluding a metastasis. In the absence of such a finding and in the presence of tumor in the lung, it may be impossible to decide whether an ovarian small cell carcinoma of pulmonary type is primary or metastatic. Gland differentiation may be seen in some cases of metastatic small cell carcinoma () Fig. 18.102). This should be borne in mind in the differential diagnosis with a primary ovarian small cell carcinoma of pulmonary type, which is sometimes associated with endometrioid carcinoma; the latter may be suggested by the glands of what in fact is a metastatic small cell carcinoma. This exemplifies the diagnostic problems that can be hard to resolve in rare cases.

The metastatic adenocarcinomas generally have nonspecific glandular features, which, should a pulmonary neoplasm be known to exist, will aid in distinction from independent primary ovarian adenocarcinoma. Unfortunately, given the spectrum of primary ovarian

Fig. 18.102 Metastatic small cell carcinoma from the lung. There is focal gland differentiation

neoplasia, particularly of endometrioid type, recognizing a tumor as metastatic in the absence of known pulmonary neoplasia may be difficult or impossible. The large cell carcinomas may have a broad differential diagnosis of oxyphilic tumors of the ovary.

The utility of TTF-1 in the recognition of metastatic lung carcinoma depends on the morphologic subtype under consideration. Approximately 75% of pulmonary adenocarcinomas are positive for TTF-1, whereas only 40% of large cell carcinomas are positive and the majority of squamous cell carcinomas are negative [29, 47, 62, 118]. TTF-1 may be also expressed in a subset of ovarian carcinomas [72, 187], including notably up to 37% of serous carcinomas in one study [72]. Its expression in primary ovarian tumors is usually focal but is occasionally diffuse. A negative reaction for TTF-1 does not exclude a lung primary, and although diffuse positivity may suggest a pulmonary origin, it is not independently diagnostic of such. Cytokeratin 7/20 profiles do not aid in the distinction of metastatic pulmonary from primary ovarian adenocarcinoma, as both are typically CK7+/CK20- [91].

Fig. 18.103 Metastatic neuroendocrine carcinoma from the lung (*left*) with immunoreactivity for chromogranin (*right*)

Metastatic small cell carcinomas in the ovary may originate in sites other than the lung. Three such tumors were primary in the mediastinum, apparently of thymic origin, and had ovarian metastases at the time of presentation [30]. Small cell carcinomas from various sites express TTF-1, and thus TTF-1 positivity is not specific for pulmonary origin among tumors of this type [4]. One of two ovarian small cell carcinomas of pulmonary type was found to be positive for TTF-1 in a recent study [17].

One neuroblastoma primary in the posterior mediastinum metastasized to the ovary [172]. Thymomas have involved the ovary rarely [158].

Extragenital Sarcomas

Extragenital sarcomas, whether from the viscera or the soft tissues, uncommonly metastasize to the ovary except in late stages of the disease. An exception to this is the recently characterized gastrointestinal stromal tumor, a small series of which metastatic to the ovary pointed out some appreciable diagnostic problems [54].

The five patients described were all adults. In three, the primary (two small bowel and one its mesentery) and metastatic tumors were discovered synchronously. In one, however, ovarian masses were discovered 18 months before the gastric primary, and in the fifth case, ovarian spread was found 27 years after a primary small bowel tumor had been resected.

The ovarian tumors had no specific gross features but were often sizeable. Microscopic examination, as expected given the known morphology of this tumor, typically showed a low-grade spindle cell neoplasm (\bigcirc *Fig.* 18.104), but a number of features such as the presence of signetring-like cells and palisading (\bigcirc *Fig.* 18.105) complicated the appearance. The differential diagnosis may be broad and include cellular and typical fibromas, smooth muscle tumors, and other primary soft-tissue-type tumors. In cases in which any of these is a consideration but there is an atypical feature, such as bilaterality or extraovarian disease, immunohistochemistry for c-kit (\bigcirc *Fig.* 18.106) is appropriate to rule out the possibility of a gastrointestinal stromal neoplasm.

Eleven rhabdomyosarcomas metastatic to the ovary have been reported in patients 6 to 27 years of age [177]. Six tumors were alveolar rhabdomyosarcomas, three embryonal, one mixed embryonal and alveolar rhabdomyosarcoma, and one of unstated subtype. In most of the

Fig. 18.104 Metastatic gastrointestinal stromal tumor. The picture may be confused with cellular fibroma

cases, the ovarian spread was a late manifestation of disease. The ovarian tumors were symptomatic in only two patients, in whom the ovarian involvement was detected within a few weeks of discovery of a soft tissue mass by the patient. The ovarian tumors were bilateral in two cases. In cases of embryonal rhabdomyosarcoma metastatic to the ovary, the diagnosis of rhabdomyosarcoma usually is evident because of the presence of strap cells, and the tumor must be distinguished from a primary embryonal rhabdomyosarcoma, which is the most common subtype of primary malignant striated muscle tumor of the ovary. Because a primary alveolar rhabdomyosarcoma of the ovary has not, to the best of our knowledge, been reported, metastatic alveolar rhabdomyosarcoma more commonly raises the question of other primary and metastatic small cell tumors of the ovary in young women. A combination of clinical findings, thorough sampling, and immunohistochemistry to varying degrees in individual cases will help resolve what can be a very challenging area. Two other cases in which the ovary was involved by rhabdomyosarcoma

Fig. 18.105 Metastatic gastrointestinal stromal tumor. Palisading is seen

have occurred in patients with a clinical picture that simulated acute leukemia [46].

In one study of 21 metastatic sarcomas to the ovary other than rhabdomyosarcoma, 10 were extragenital in origin and all were clinically significant [179]. These tumors have included a miscellaneous group of soft tissue sarcomas primary at a variety of sites. Rare cases of hemangiosarcoma that metastasized to the ovaries have been documented as have a few cases of Ewing's sarcoma. The latter are noteworthy as they may be part of the broad differential diagnosis of a small cell malignant tumor of the ovary.

Miscellaneous Rare Ovarian Metastases

Metastases to the ovary other than those already discussed are of great rarity and generally only of relevance to autopsy pathology. Carcinomas of the thyroid only exceptionally spread to the ovary even in autopsy series, but a few cases documented during life exist. In one case [171], a 29-year-old woman had a 17 cm right ovarian tumor

Fig. 18.106
Metastatic gastrointestinal stromal tumor.
Immunoreactivity for c-kit

12 years after undergoing a partial thyroidectomy for follicular carcinoma. The tumor also had spread to the brain and one adrenal gland by the time the ovarian tumor was discovered. Initial consideration was given to the diagnosis of a malignant struma ovarii in this case because of the interval since the thyroid tumor, and also because it was only the existence of the ovarian tumor that prompted review of the thyroid neoplasm and its reinterpretation as carcinoma, a diagnosis not made initially. In another case [12], a 38-year-old woman with papillary carcinoma and local lymph node spread returned 7 years later with bilateral cystic ovarian metastases. In another case of papillary carcinoma, ovarian metastasis was uncovered after 10 years [84].

A review of the literature on parathyroid carcinoma has not disclosed any examples of ovarian metastasis. Rare examples of head and neck carcinoma metastatic to the ovary are documented and we have seen one case in which the primary tumor was an undifferentiated carcinoma of the ethmoid sinus. Salivary gland tumors also spread to the ovary with extreme rarity. We have seen a case of a young woman who had an adenoid cystic carcinoma of the parotid gland excised at the age of 12 years followed by local recurrence, lung metastasis, and bilateral symptomatic ovarian metastases 11 years after presentation. Longacre and colleagues [87] described a case of a 30-year-old woman with an adenoid cystic carcinoma of the submandibular gland who had a 10 cm left ovarian metastasis, followed by a smaller tumor in the opposite ovary 10 years later. These cases emphasize that a history of neoplasia of any type, even relatively remote, may be relevant in the evaluation of an unusual ovarian tumor. Esophageal cancer rarely spreads to the ovary. A case of metastatic esophageal adenocarcinoma to the ovary is briefly mentioned in one series [119].

There are only two reports to our knowledge in which ovarian spread of tumors of the central nervous system and cranium is mentioned. One was a case of metastatic meningioma and the other was a metastatic medulloblastoma in a 4-year-old girl, in whose ovary "a cleft near the hilum was full of tumor cells" [172]. Tumors of the skin, other than malignant melanoma, rarely spread to the ovary; clinically significant spread of Merkel cell tumor is documented [30]. One chordoma has metastasized to the ovary [188]. There are sporadic reports of a metastatic tumor involving an ovary that contains a primary ovarian neoplasm [48, 131], and there seem to be no unique features of these happenstance events, a few examples of which we have seen (**>** *Fig. 18.90*).

Female Genital Tract Tumors

Tubal Carcinoma

The ovary is involved secondarily in 10-15% of tubal carcinomas, usually by direct extension, sometimes via tuboovarian inflammatory adhesions, and at other times by surface implantation on the ipsilateral or contralateral ovary. In some cases, there is clinical or pathologic evidence of salpingitis and salpingo-oophoritis, but often it is unclear whether the inflammatory process preceded or followed the development of the carcinoma. If the involvement of the tube and the ovary is extensive, the primary site of the tumor may not be established with certainty; the term tuboovarian carcinoma has been suggested for these cases. Green and Scully [39] encountered six such tumors in an investigation of 24 carcinomas initially considered to be of tubal origin. The tuboovarian carcinomas formed solid or cystic masses; at least one of the cystic tumors appeared to have developed in a postinflammatory tuboovarian cyst.

Because most tubal carcinomas closely resemble serous, endometrioid, or undifferentiated carcinomas of the ovary, microscopic examination often fails to establish whether a carcinoma involving both organs is primary in one or the other unless the tumor is grossly clearly centered in one of them. Because of the great rarity of primary mucinous and clear cell carcinomas of the fallopian tube, a tumor of either of these cell types involving both organs usually is considered primary in the ovary. It should be emphasized that surface growth within the tube may be seen as a result of implantation from an ovarian carcinoma and does not necessarily indicate a tubal primary.

Recent studies from one group have raised the possibility that a greater number of serous carcinomas of the ovary than hitherto thought may actually represent spread of fallopian tube cancers, especially those of the fimbria [70].

Endometrial Carcinoma

Ovarian involvement in cases in which a diagnosis of endometrial carcinoma has been made has been reported in 34-40% of autopsy cases [8, 15] and 5-15% of hysterectomy and bilateral salpingo-oophorectomy specimens. Conversely, in approximately one third of the cases in which a diagnosis of endometrioid carcinoma of the ovary has been made, an endometrial carcinoma also has been found. When the uterine corpus and the ovary are both involved by carcinomas, the question arises whether both cancers are primary or one is metastatic from the other [31, 143, 184]. If the endometrial carcinoma extends deeply into the myometrium with lymphatic or vascular invasion; if tumor is present in the lumen of the fallopian tube; or if tumor is on the ovarian surface, within its lymphatics, or in blood vessels, it is usually reasonable to conclude that the ovarian involvement is secondary. On the other hand, if lymphatic or hematogenous spread is absent, if the corpus carcinoma is small and limited to the endometrium or superficial myometrium, if it arises on a background of atypical hyperplasia, and if the ovarian tumor arises on a background of endometriosis, the tumors probably are independent primaries. Criteria that are helpful in the determination of primary versus metastatic concomitant ovarian and endometrial carcinomas are presented in > Table 18.2. Although synchronous ovarian and uterine tumors are of endometrioid type in most cases, occasionally they are of similar but other cell types, and rarely the histologic type of tumor is different in the two organs [31].

In some cases of combined involvement it is impossible to establish the site of origin even after consideration of the features just described. In our experience and that of most series, most synchronous ovarian and corpus carcinomas are independent primary tumors; in one study, however, the ovarian tumors were interpreted as metastatic from the corpus in most of the cases [143], and other valid cases of metastasis are reported in the literature. An independent primary explanation for most concomitant ovarian and corpus carcinomas is supported by the survival rates associated with this combination of tumors, which have generally been high. These results would be surprising if either the ovarian or corpus carcinoma was metastatic in most of the cases.

Rarely, spread to the ovary from an adenocarcinoma of the uterine corpus with squamous differentiation takes the form of deposits of keratin or degenerated mature squamous cells associated with a foreign body giant cell response on the serosal surface of one or both ovaries [69]. If no viable-appearing tumor cells can be identified in these deposits on careful sampling, this finding does not appear to worsen the prognosis even when the granulomas are also found elsewhere on the peritoneum.

Cervical Carcinoma

Ovarian spread of cervical carcinomas of all types generally has been considered rare. There has been considerable recent interest in this topic [33, 59, 83, 175], however, simulated in part by observations suggesting that it is more common in cases of adenocarcinoma than in cases of squamous cell carcinoma, and raising the question of whether ovarian conservation is justified in patients with cervical adenocarcinoma. In addition, occasional patients with cervical carcinomas of diverse types have had clinically significant ovarian metastases [166].

One of the most detailed studies of ovarian spread of cervical carcinoma is that of Tabata et al. [138] In their autopsy series, ovarian metastases were detected in 104 of 597 (17%) cases of squamous cell carcinoma and in 22 of 77 (28.6%) cases of adenocarcinoma. The frequency of ovarian metastases of squamous cell carcinoma at autopsy in their series is much higher than the 3% frequency in the prior literature. Ovarian metastases discovered during life are much rarer. In their series of 318 patients with stage IA cervical carcinoma treated by hysterectomy with ovarian preservation, Tabata et al. [138] found no examples of subsequent ovarian metastasis during follow-up periods that exceeded 5 years in more than half the cases. In cases of stage IB, II, and III carcinoma in their series, there were no ovarian metastases in 278 cases of squamous cell carcinoma in contrast to 6 ovarian metastases of 48 (12.5%) cases of adenocarcinoma. In another series there were

Table 18.2

Criteria for interpretation of nature of concomitant uterine corpus and ovarian carcinomas

Corpus primary Ovarian metastasis	Ovarian primary Corpus metastasis	Ovarian primary Corpus primary	Ovarian metastasis Corpus metastasis	Uncertain primary
Direct extension to ovary from large corpus tumor	Direct extension to corpus from large ovarian primary	No direct extension of either tumor	Usually no direct extension of tumors	Massive involvement of both organs or conflicting findings listed in first four columns
Deep myometrial invasion from endometrium	Myometrial invasion from serosal surface	Myometrial invasion usually absent or superficial	Tumor characteristically in endometrial stroma	Myometrial invasion may be present
Lymphatic or blood vessel invasion in corpus, ovary, or both	Lymphatic or blood vessel invasion in corpus, ovary, or both	No lymphatic or blood vessel invasion	Lymphatic or blood vessel invasion frequent in ovary and corpus	
Atypical hyperplasia of endometrium frequent	Atypical hyperplasia of endometrium usually absent	Atypical hyperplasia of endometrium frequent	Atypical hyperplasia of endometrium absent	
Tumor present in fallopian tube	Tumor present on peritoneal surfaces and sometimes in fallopian tube	Usually both tumors confined to primary sites or have spread minimally	Tumor usually evident outside female genital tract	
Tumor predominant on surface of ovary	Tumor predominant within ovary	Tumor predominant within ovary and endometrium	Ovarian tumor usually bilateral, ovarian surface involvement frequent	
Usually no endometriosis in ovary	Endometriosis sometimes present in ovary	Endometriosis sometimes present in ovary	Endometriosis absent	
Histological types uniform and consistent with corpus primary	Histological types uniform and consistent with ovarian primary	Histological types uniform or dissimilar	Type of tumor inconsistent with or unusual for either organ	

3 cases of microscopic ovarian metastasis in 185 cases of stage IIB cervical carcinoma [140]; in the same series, there were no metastases in 335 cases of stage IB disease, 71 cases of stage IIA disease, and 6 cases of stage IIIB disease. One of the ovarian metastases was from a squamous cell carcinoma (0.2% of all squamous cell carcinomas), whereas two were from adenocarcinomas (5.5% of these tumors). The cervical carcinomas in these three cases had invaded the uterine corpus and vascular spaces. Tabata et al. [138] also found that ovarian metastasis was much more common when a cervical carcinoma had invaded the uterine corpus.

Adenocarcinomas

The commonest cervical carcinoma to exhibit ovarian spread is what we refer to as endocervical adenocarcinoma

of the usual type. We have seen many unpublished examples and a series of 29 cases has recently been reported [124]. These experiences enable the following observations. We shall only comment in detail on the ovarian aspects, but it is pertinent to briefly note that the primary cervical tumors may only be microinvasive or even have features that objectively make recognition of definite invasion questionable. It has been suggested that contiguous spread to the corpus may contribute to the development of metastases by heightening the chance of transtubal spread to the ovarian surface [124].

The ovarian tumors are bilateral in only about one third of the cases and are often over 10 cm. Given that usual endocervical adenocarcinoma has a somewhat distinctive histologic appearance, it is not surprising that this morphology is also seen in the ovaries (\bigcirc *Figs. 18.107–18.109*).

Fig. 18.107 Metastatic endocervical adenocarcinoma of the usual type. There is a pseudoendometrioid picture

Approaching the topic from the ovarian perspective, the picture is more often pseudoendometrioid than truly mucinous in nature, and yet the morphology is not typical of classic endometrioid glandular neoplasia. As summarized elegantly by Ronnett et al. [124], the tumors often have a hybrid appearance with low-power endometrioidlike features but with apical mucin appreciable on higher power. The nuclei are typically hyperchromatic and elongated () Fig. 18.109), more atypical than seen in true endometrioid carcinomas with a similar degree of gland differentiation. Apically located mitotic figures are usually prominent, and apoptotic cells are often numerous. With increasing experience, it is possible to suspect a cervical origin when confronted with cases with this morphology, but it is a difficult area given the inherent subjectivity. As recently emphasized, help may be garnered by p16 immunohistochemical staining (**)** Fig. 18.108), which supports a secondary nature but is not specific. Should p16 be positive, more definitive evidence can be obtained by evaluating the ovarian tumor for human papilloma virus using in situ hybridization or polymerase chain reaction. Cases have been documented in which these results have

prompted evaluation of a clinically non-suspicious cervix and subsequent identification of the occult primary neoplasm [124].

Less often, the rarer primary mucinous adenocarcinoma of the cervix with ovarian spread is encountered (**>** *Fig. 18.110*). In a series from the Armed Forces Institute of Pathology, as many as 10% of mucinous adenocarcinomas of the cervix were reported to metastasize to the ovary [59], although the referral nature of that material may have introduced some bias in the frequency of the phenomenon; occasional other examples have been reported in detail [175] or included in series of metastatic mucinous adenocarcinoma and an ovarian mucinous adenocarcinoma coexist, the general features of metastatic spread to the ovary usually help in diagnosis.

Squamous Cell Carcinomas

There are only eight well-documented examples of clinically significant ovarian metastases from invasive squamous cell carcinomas of the cervix [103, 166]. The youngest patient was 30 years old and the oldest 59 years. The ovarian and cervical tumors were discovered at essentially the same time in three of the patients. In four others, the ovarian metastases occurred 18 months to 10 years after the cervical primary tumor had been treated. In the eighth case the cervical tumor was not discovered until autopsy 7 months after the patient had been treated for a squamous cell carcinoma involving the left ovary. The cervical tumor in that case was invasive only to 3.8 mm, whereas in the other cases there appears to have been deep infiltration of the cervical wall with frequent extrauterine extension of the neoplasm [166]. The ovarian tumors, two of which were bilateral, ranged from 5 to 17 cm in greatest dimension. Four of the 10 tumors in these patients were solid, 3 solid and cystic, and 3 cystic. Microscopic examination has shown the typical features of squamous cell carcinoma except that many of the tumors had striking cystification within the squamous nests. In one case, a cervical squamous cell carcinoma that was invasive to only 1.2 mm extended in an in situ manner to involve the endometrium and the surface and inclusion glands and cysts within one ovary, tumor cells presumably having spread there via the tubal lumen. In a final remarkable case, a cervical squamous cell carcinoma in situ was associated with contiguous spread to the endometrium, fallopian tubes, and ovaries, extensively replacing the endometrial and tubal epithelium and focally invading the wall of the tubes and parenchyma of both ovaries [113].

Metastatic endocervical adenocarcinoma of the usual type. Companion staining with hematoxylin and eosin (*left*) and for p16 (*right*)

The differentiation of metastatic squamous cell carcinoma from the cervix from primary squamous cell carcinoma of the ovary usually has been aided by the knowledge of the presence of a cervical tumor, but in the one case in which the cervical tumor was not detected until autopsy and some of the others, there were major problems in diagnosis [166]. Before the diagnosis of primary squamous cell carcinoma of the ovary is made, the possibility of spread from a cervical tumor, even one that is occult, should be considered unless overt features of primary neoplasia are immediately obvious. As most squamous cell carcinomas of the ovary arise on the background of a preexistent neoplasm such as a dermoid or endometriotic cyst, thorough sampling to identify such a component may be crucial in determining the primary nature of the neoplasm. Although the evidence strongly points to the ovarian tumors being metastatic when both organs have been involved by squamous cell carcinoma, the rare association of squamous cell carcinoma of the ovary with squamous cell carcinoma in situ of the cervix leaves open the possibility of independent primary neoplasms in some cases. Although the differential in these cases is generally between primary and metastatic

squamous cell carcinoma, in some cases metastatic squamous cell carcinoma undergoes cystic degeneration and as squamous and transitional cell types are closely related, a resemblance to primary transitional cell carcinoma may result () *Fig. 18.111*).

Other Carcinomas

Two adenosquamous carcinomas and two glassy cell carcinomas with ovarian metastases have been reported [166]. Both metastatic adenosquamous carcinomas were discovered at the same time as the cervical primary tumors. The ovarian tumors were bilateral in both cases, and the cervical tumors were deeply invasive with extracervical extension, findings facilitating the diagnosis in these cases. In one of the cases of glassy cell carcinoma the ovarian involvement was a microscopic finding; in the other the ovarian involvement was grossly evident but the ovary was not enlarged.

Four cases have been reported in detail in which cervical small cell carcinomas or mixed tumors with a component of adenocarcinoma and small cell carcinoma or poorly

Fig. 18.109
Metastatic endocervical adenocarcinoma of the usual type.
Typical cytologic features

differentiated carcinoid have been associated with ovarian metastases. In each of these four cases, the ovarian spread was manifest clinically [166]. In one, the patient had evidence of the carcinoid syndrome. The four patients were from 23 to 34 years of age. The cervical tumors and ovarian tumors were synchronous findings in two of them. In the other two, the ovarian tumors were discovered 10 months and 3 years after the cervical tumors. In one final case, a cervical transitional cell carcinoma metastasized to the ovary and was detected before the cervical tumor, which was not discovered until pathologic examination. The ovarian metastatic tumor in this case was a large cystic mass that was indistinguishable microscopically from a primary transitional cell carcinoma of the ovary but was associated with prominent vascular space invasion, suggesting its metastatic nature.

Other Uterine Tumors

The most important of these by far is metastatic endometrial stromal sarcoma because it has some proclivity for

Fig. 18.110
Metastatic endocervical adenocarcinoma, mucinous type.
Highly differentiated glands of the type seen in adenoma malignum

ovarian spread and can cause a wide array of problems in differential diagnosis. This sarcoma metastasizes to the ovary more frequently than leiomyosarcoma. In a series of 11 uterine sarcomas that metastasized to the ovary (none of which were autopsy findings), 8 were endometrial stromal sarcomas and 3 leiomyosarcomas [179]. The patients with endometrial stromal sarcomas ranged from 33 to 79 (average 50) years of age; 5 of them were less than 50 years old. The ovarian metastases accounted for the clinical presentation in three of the patients. In two patients, the primary uterine tumors were not discovered until 7 months and 10 months after bilateral ovarian tumors had been resected. In four of the other cases the ovarian and uterine tumors were found synchronously, and in the remaining two the ovarian metastases occurred 4 to 9 years after the uterine neoplasms had been discovered. The ovarian tumors were bilateral in six cases, and ranged up to 17 cm in greatest dimension. These tumors usually are solid () Fig. 18.112) or solid and cystic, but rarely are cystic.

Fig. 18.111

Metastatic squamous cell carcinoma from cervix. The lining of cysts by thick undulating bands of neoplastic cells without overt squamous differentiation imparts a resemblance to a primary transitional cell carcinoma of the ovary

Fig. 18.112
Metastatic endometrial stromal sarcoma. Peculiar nodular growth

■ Fig. 18.113 Metastatic endometrial stromal sarcoma. The tumor has a diffuse pattern

The major problem with the interpretation of these tumors on microscopic examination is that, in the ovary, the tongue-like pattern of infiltration characteristic of this neoplasm often is inconspicuous. A diffuse pattern is common (> Fig. 18.113). Other diagnostic problems result from the presence in some of the tumors of large fibromatous areas (> Fig. 18.114) and hyaline plaques (> Fig. 18.115). Yu et al. [183] described the case of a 24-year-old woman with a metastatic endometrial stromal sarcoma that was misinterpreted initially as a thecoma for this reason. In other cases with a diffuse pattern, the characteristic small arteries resembling the spiral arteries of the endometrium are inconspicuous, resulting in a resemblance to a diffuse granulosa cell tumor. Confusion with sex cord-stromal tumors may be heightened by the occasional presence of areas of sex-cord-like differentiation in metastatic endometrial stromal sarcomas. However, high-power examination does not show the typical nuclear features of granulosa cell tumors and careful examination usually demonstrates, at least focally, the typical vascular pattern of endometrial stromal tumors

• Fig. 18.114 Metastatic endometrial stromal sarcoma. Typical pattern at the *top* and unusual fibroma-like morphology at the *bottom*

(Fig. 18.116). Reticulum stains may be helpful in the differential diagnosis by showing individual cell investment by fibrils in endometrial stromal sarcoma and only small amounts, mainly perivascular, in granulosa cell tumor. Bilaterality also is far more common in the former than the latter, as is the presence of extraovarian tumor, examination of which often shows the distinctive growth pattern of endometrial stromal sarcoma.

Metastatic endometrial stromal sarcomas in the ovary must be distinguished from primary endometrioid stromal sarcomas [173]. An association of the tumor with endometriosis is evidence for an ovarian origin. Bilaterality favors metastasis, although it is possible that some bilateral tumors may represent independent primaries.

Leiomyosarcomas of the uterus with ovarian metastases are probably more common than the rare reports in the

Fig. 18.115 Metastatic endometrial stromal sarcoma. Hyaline plaques are conspicuous and may cause the diagnosis of thecoma to be entertained

literature suggest, particularly in patients with widespread disease. The three leiomyosarcomas with ovarian metastases in our series occurred in patients 35, 44, and 49 years of age [179] In the first patient, a large ovarian metastatic tumor became symptomatic 14 months after hysterectomy. In the second patient, the ovarian metastatic tumor occurred in the setting of widespread disease. In the third case, the ovarian involvement was only microscopic. Ovarian spread of malignant mixed müllerian tumors is common but not usually a diagnostic problem. Ovarian involvement in cases of müllerian adenosarcoma of the uterus is uncommon and in some cases may be an independent primary, particularly if it is associated with endometriosis.

Gestational choriocarcinoma of the uterus may spread to the ovary, but in the light of known uterine disease is not a diagnostic problem [3]. If such an ovarian tumor in

■ Fig. 18.116 Metastatic endometrial stromal sarcoma. Typical arterioles are present (same tumor as in ② Fig. 18.113)

a woman of childbearing age is not clearly metastatic from a uterine or tubal choriocarcinoma, thorough sampling may be needed to demonstrate the presence or absence of teratomatous elements. If such elements are not found, it may be difficult or impossible to differentiate between a primary choriocarcinoma of the ovary of either gestational or germ cell origin and a metastatic tumor from a choriocarcinoma of the uterus that has regressed. Invasive hydatidiform mole has also been documented to spread to the ovary, and in rare cases the placental site trophoblastic tumor has spread through the uterine wall to involve an ovary [1, 99].

Vulvar and Vaginal Tumors

Vulvar and vaginal carcinomas rarely exhibit ovarian spread. Occasional vaginal clear cell adenocarcinomas have metastasized to the ovary, in most cases associated with extensive pelvic spread.

Fig. 18.117 Ovarian involvement by malignant mesothelioma of peritoneum. Note typical tubulopapillary pattern

Ovarian Involvement by Peritoneal Tumors

Although ovarian involvement in cases of peritoneal serous carcinoma may be secondary in most of the cases, this subject is generally not included in discussions of secondary tumors of the ovary because the ovarian involvement is only one part of widespread peritoneal disease. More pertinent to our interest here are cases of significant ovarian involvement in cases of malignant mesothelioma that may engender a broader array of problems in differential diagnosis [6].

In one series of peritoneal mesotheliomas, ovarian involvement was common [37], and this phenomenon was the focus of another report that included seven cases of peritoneal malignant mesothelioma that presented clinically as "ovarian cancer" [22]. The differential diagnosis in these cases is primarily with an ovarian surface epithelial carcinoma, particularly serous carcinoma. Although there is some overlap, in typical cases the tubulopapillary (**)** *Fig. 18.117*) and diffuse patterns of mesothelioma, and

Fig. 18.118

Ovarian involvement by malignant mesothelioma of peritoneum. Note typical eosinophilic cytoplasm and relatively bland cytology

the characteristic cuboidal to rounded cells with abundant eosinophilic cytoplasm (**>** *Fig. 18.118*), produce a picture that is distinctly different from that of serous carcinoma. Psammoma bodies, although occasionally seen in mesotheliomas, are rarely numerous and if present in significant number, they favor a serous neoplasm. Histochemical and immunohistochemical stains may aid in this differential. Special stains in serous tumors frequently reveal apical or luminal neutral mucin and one or more antigens that are usually absent in mesothelioma including TAG-72, S-100, Leu-M1, PLAP, CEA, and Ber-EP4 [22].

The broad spectrum of morphology of peritoneal mesothelioma may result in other diverse but generally rare issues in differential diagnosis, should a case be dominated by ovarian involvement. This topic has been reviewed in detail by Baker et al. [6] and only two issues that have struck us as being perhaps more realistic than most are briefly noted here. A superficial resemblance to clear cell carcinoma may be imparted in some cases by the tubular and papillary patterns of mesothelioma, but the

Fig. 18.119 Ovarian involvement by intraabdominal desmoplastic small round cell tumor. Nested pattern

latter is generally less cytologically atypical and when the spectrum of morphology is evaluated, the two neoplasms should be distinguishable. A malignant mixed mesodermal tumor may be entertained when a mesothelioma has a spindle cell morphology or a prominent myxoid stroma, but the mesothelial cells are almost always less pleomorphic than the high-grade carcinomatous component of a malignant mixed mesodermal tumor.

Another peritoneal tumor that may have ovarian manifestations as a major component of the clinical presentation and present as "ovarian cancer" is the intraabdominal desmoplastic small round cell tumor with divergent differentiation. A small number (circa 10) of these tumors with ovarian involvement at presentation have been described in patients in the second and third decades, the oldest patient being 27 years old [32, 110, 164, 185]. In some cases the ovarian tumor initially was thought to be the primary neoplasm. In all the cases there was extensive extraovarian tumor at the time of presentation.

Fig. 18.120

Ovarian involvement by intraabdominal desmoplastic small round cell tumor. In this illustration, desmoplastic stroma is conspicuous and, in the setting of widespread abdominal disease, is a strong clue to the diagnosis, particularly in a young female

The ovarian involvement is usually bilateral. Microscopic examination of the ovarian tumors shows large nodules, smaller nests, and clusters composed predominantly of small cells with hyperchromatic nuclei and scanty cytoplasm surrounded by a prominent desmoplastic stroma (**?** *Figs. 18.119* and **?** *18.120*). The neoplasms exhibit the characteristic immunohistochemical staining profile, with many of the tumor cells staining for cytokeratin, epithelial membrane antigen, desmin, and vimentin.

The differential diagnosis in these cases is extensive and is primarily related to a number of small cell tumors that may involve the ovary, either primarily or secondarily in young females, as presented in detail elsewhere [177]. Rarely other problems in diagnosis may be encountered related to unusual findings such as focal tubular differentiation or cells with more appreciable eosinophilic cytoplasm than is typical. Generally these are only focal findings in neoplasms dominated by more distinctive morphology.

The placenta is crucial for fetal growth and survival, performing the most important functions of many somatic organs before birth. Thus, pathologic processes interfering with placental function may result in abnormalities of fetal growth or development, malformation, or stillbirth, and there is increasing recognition that some long-term (especially neurologic) disabilities can be traced to injury occurring before birth. The purpose of this chapter is to describe clinically important placental lesions and to emphasize the context in which these lesions are directly or indirectly important to the fetus, the mother, or both.

Normal Anatomy and Development

The monograph by Boyd and Hamilton [23] provides a detailed description and exquisite illustrations of the various stages of human implantation. The ovum is fertilized in the fallopian tube and develops rapidly, reaching the endometrial cavity as a blastocyst. At this stage, the outer cell layer of the blastocyst has differentiated into trophoblast, and there are only a few cells in the inner cell mass from which the embryo will develop. The trophoblast attaches to and penetrates the endometrium on the 6th to 7th postovulatory day, and by the 10th to 11th postovulatory day, the blastocyst is totally embedded in endometrial stroma that has reestablished continuity over the penetration defect. The trophoblast grows rapidly and circumferentially, invading maternal blood vessels. Blood-filled spaces (lacunae) separate the trophoblast into trabecular columns (> Fig. 19.1), with an outer syncytiotrophoblastic layer oriented radially around central solid cores of cytotrophoblast. As the extraembryonic mesenchyme penetrates the cytotrophoblastic cores, small blood vessels form within it, and these eventually connect with each other and with those forming independently in the allantois of the body stalk (chorioallantoic placentation), establishing the fetoplacental circulation by the 5th-6th week. A shell of solid trophoblast remains at the periphery of the stem villi, anchoring them to the basal plate and continuing to grow and expand the intervillous space (> Fig. 19.2).

Successful implantation requires a series of complex, coordinated interactions between maternal tissue and trophoblast. The trophoblast consists of several morphologically and functionally distinct cell types, each with characteristic anatomic distribution. The great majority of cytotrophoblastic and syncytiotrophoblastic cells are located on the villi (villous trophoblast). Cytotrophoblast (CT), the germinative, mitotically active component of trophoblast, is present as a layer of uniform cells with

Fig. 19.1

Implantation at 13 days. Trophoblast has differentiated into inner (cytotrophoblast) and outer (syncytiotrophoblast) layers. Focally, the cytotrophoblast has proliferated to form projections, the forerunners of the primary villi. The germ disk is located near the center (Reprinted courtesy of Department of Embryology, Davis Division, Carnegie Institute of Washington)

single, round–oval nuclei, clear cytoplasm, and distinct cell borders directly overlying the stromal core of the villus. The syncytiotrophoblast (ST) overlies the CT and is the terminally differentiated component of trophoblast responsible for transport functions, protection, and pregnancy-specific protein and hormone production. Its abundant, often vacuolated cytoplasm is amphophilic with multiple small dark nuclei and a distinct brush border. Intermediate trophoblast (IT) is a constituent of villous trophoblast, primarily in the anchoring cell columns, but is most prevalent in extravillous sites. IT developing from the trophoblastic shell invades the endometrium and myometrium at the implantation site. Subpopulations of IT in the villi (villous IT), implantation site, and membranes (chorionic IT) are morphologically and immunohistochemically distinct [172]. IT nuclei are irregular and hyperchromatic with coarsely granular chromatin. Most cells are mononucleate, although multinucleate forms occur. IT may be round, polyhedral, or spindle shaped depending on location with abundant eosinophilic, amphophilic, or clear cytoplasm. The cytologic features are generally sufficiently distinctive to identify IT, but their intermingling with decidua at the implantation site is so intimate that it may be difficult to characterize any particular cell as maternal or fetal by conventional light microscopy. When findings are equivocal (as in some abortion specimens), immunohistochemical stains for

Fig. 19.2

Secondary villi. Mesenchyme has penetrated the trophoblastic cores. The trophoblastic shell is peripheral

keratin help distinguish IT (keratin positive) from decidua (keratin negative).

The IT that infiltrates the decidua and myometrium at the implantation site is responsible for remarkable physiologic structural modifications in the spiral arteries. In the early weeks of pregnancy, IT invades the decidual segments of the spiral arteries, forming intraluminal plugs. Later, between the 12th and 20th weeks of pregnancy, endovascular IT extends from the decidual into the myometrial segments of the spiral arteries. Eventually, IT and fibrinoid completely replace the endothelium and the muscular and elastic tissue of the media (\bigcirc *Fig. 19.3*). Altered by this process, the spiral arteries undergo progressive distension, eventuating in large funnel-shaped channels that augment blood flow to the implantation site. Dissolution of the muscular media results in fixed vascular dilatation unresponsive to vasculospastic influences.

As it grows and enlarges, the chorion undergoes gross structural modifications. Initially, villi surround the entire chorionic cavity, but as the chorion prolapses into the endometrial cavity, the villi oriented toward the uterine cavity undergo progressive atrophy to form the smooth chorion (chorion laeve) or fetal membranes (> Fig. 19.4). These atrophic villi are still apparent in sections of membranes in the mature placenta (> Fig. 19.5). The villi on the embryonic aspect of the chorion continue to proliferate, forming the definitive placenta (chorion frondosum). Differential villous atrophy and proliferation reflect maternal blood flow. Departure from the usual pattern of villous growth and atrophy is thought to result in some of the aberrant placental shapes described below. Continued growth and enlargement of the chorion results in eventual obliteration of the uterine cavity through fusion

Fig. 19.3

Normal spiral artery remodeling. Intraluminal IT (*left*) later invades and replaces the vascular media along with fibrinoid matrix (*right*)

Formation of chorion laeve. As the chorion prolapses into the endometrial cavity, the villi on the intracavitary aspect atrophy to form the fetal membranes

Fig. 19.5 Chorion laeve. Atrophied villous remnants remain in the membranes at term

of the decidua capsularis and the decidua vera of the opposite uterine wall, usually around 20 weeks. In time, the chorionic cavity is obliterated by progressive expansion of the amnion. Irregular folds of the basal plate drawn into the intervillous space by the relatively slow growth of anchoring villi form septae, appearing at about 3 months. IT islands are prominent in the septae. The septae partition the maternal surface incompletely and irregularly into 15 to 20 divisions that have no physiologic significance.

Villous structure changes dramatically over the course of a normal gestation reflecting placental growth, development,

■ Fig. 19.6 Immature intermediate villi. These are characterized by reticular stroma and channels containing Hofbauer cells

and maturation. Five villous types have been detailed in the work of Kaufmann and others [17]. Mesenchymal villi are a primitive, transient stage in villous development. The loose stroma of mesenchymal villi is abundant with numerous Hofbauer cells, central small vessels, and an orderly surface bilayer of CT and ST. Mesenchymal villi predominate in early pregnancy but may be found in small numbers even at term. According to Kaufmann, mesenchymal villi begin to develop into immature intermediate villi around 7-8 weeks. Immature intermediate villi are defined by abundant loose reticular stroma with empty channels containing Hofbauer cells, features that may lead to erroneous interpretation as villous edema (> Fig. 19.6). Immature intermediate villi predominate through the second trimester, but small clusters persist in the center of lobules at term (normally 0-5% volumetrically). Immature intermediate villi are gradually transformed into stem villi as their vessels acquire a distinct muscular media and progressively prominent adventitia and fibrous stroma. The stem villi divide progressively, and some insert into the basal plate, anchoring the placenta to the uterus. Stem villi support the villous tree and transport blood but do not participate significantly in oxygen or nutrient exchange. Stem villi comprise 20-25% of villi in a normal term placenta, with highest concentration centrally beneath the chorionic plate.

Beginning in the last trimester, newly formed mesenchymal villi transform into mature intermediate villi. Mature intermediate villi are long and slender with roughly the same diameter as terminal villi and numerous small vessels and capillaries, comprising less than 50% of the villus. Roughly one fourth of the villous volume at term is made up of mature intermediate villi. Terminal villi are the final ramifications of the villous tree produced along the surfaces of mature intermediate villi during the third trimester. Terminal villi have sinusoidally dilated capillaries (occupying more than 50% of the villous stroma) that bulge beneath overlying attenuated syncytiotrophoblast. Fusion of endothelial and trophoblastic basement membranes results in the formation of vasculosyncytial membranes (\bigcirc *Fig. 19.7*). In these areas, where the maternal and fetal circulations are most closely approximated, gas and nutrient exchange occur. Normally, terminal villi make up more than 40% of the villous volume at term.

With villous maturation, the barrier between maternal and fetal circulations is reduced by thinning of syncytiotrophoblast, diminution in cytotrophoblast, decrease in mean villous diameter, and apposition of fetal capillaries to the villous surface. The factors that normally control villous maturation are not understood, but considerable evidence suggests that the maturational rate is altered in pathologic states. The villi in any placenta are not completely homogeneous. The peripheral villi and those beneath the chorionic plate tend to be smaller with more collagenous stroma and a thicker trophoblastic basement membrane than the less mature villi located centrally in the fetal lobule. These regional differences, probably related to maternal blood flow, should always be considered when judging placental maturity, which is best assessed in standardized sections from central placental zones.

The placenta has two circulations – maternal and fetal. Maternal blood is delivered to the intervillous space through spiral arterial inlets in the basal plate. Maternal blood flows toward the chorionic plate, disperses laterally, percolates around the villi, and exits through venous outlets concentrated peripherally in the placental floor. Deoxygenated fetal blood reaches the placenta through the two umbilical arteries that branch and divide in stem villi until they ultimately terminate in the complex capillary network of the terminal villi. Oxygenated and fortified fetal blood returns via venous tributaries to the umbilical vein. The placental circulation normally receives about 55% of the fetal cardiac output. Lacking autonomic innervation, it responds only to local factors such as pressure and flow.

Abnormal Placentation and Villous Development

Anomalous Shapes

The pattern of villous atrophy and proliferation that occurs during placental development resulting in ultimate placental shape and configuration is thought to be determined by maternal blood flow. The *accessory* or *succenturiate lobe* is a common shape variation (3–6% of placentas) in which usually one but occasionally multiple discrete masses of placental tissue are separated from the main placenta by fetal membranes (\bigcirc *Fig. 19.8*). The umbilical cord usually

■ Fig. 19.7 Third-trimester terminal villi, vasculosyncytial membranes. Fetal capillaries protrude beneath thinned syncytiotrophoblast cytoplasm between knots. The endothelial and syncytiotrophoblastic basement membranes fuse forming vasculosyncytial membranes

Fig. 19.8 Accessory (succenturiate) lobe. A discrete mass of placental tissue is separated from the main disk by fetal membranes containing unsupported fetal vessels

inserts into the main placental mass, and the fetal vessels supplying the accessory lobe traverse membranes unsupported by underlying villous parenchyma. If these membranous vessels are traumatized during delivery, severe fetal hemorrhage may result. Thrombosis of membranous vessels may be associated with fetal thrombo-embolic events. Occasionally, an accessory lobe presents as placenta previa or is retained in utero after delivery resulting in postpartum bleeding or infection. Succenturiate lobes have a tendency to atrophy or infarct but otherwise show no specific histologic changes. The *bilobate* or *bipartite placenta* is a variant in which two equally sized placental lobes are separated by fetal membranes or connected by a narrow isthmus of placental tissue. The umbilical cord often inserts centrally between the lobes.

Other anomalous shapes are uncommon. Multilobate placentas have multiple lobes defined by indentations measuring >50% of the disc diameter. Placenta membranacea is a large, thin placenta with functional chorionic villi covering the entire gestational sac. In this condition, differential atrophy of the chorion laeve and proliferation of the chorion frondosum do not occur. The placental parenchyma may vary in thickness, but only exceptionally is there a dominant area resembling a placental disk. Placenta membranacea occurs commonly in animal species but is extremely rare in humans. The few reported cases have been complicated by antepartum bleeding and abnormal placental adherence relating to the obligate placenta previa that accompanies this form of placentation. Nearly all cases are associated with preterm delivery and high fetal mortality. The annular or cylindrical ring-shaped placenta is very rare. In fenestrate placentas, focal absence of the villous parenchyma may result in a through-and-through hole or the chorionic plate may remain intact over the parenchymal defect.

Extrachorial Placenta

Extrachorial placentation is a common gross structural deviation in which the chorionic plate of the placenta is smaller than the basal plate. The chorionic plate does not extend to the placental margin as in a normal placenta, but undergoes transition to fetal membranes central to the disk edge, leaving a rim of bare placental tissue (extrachorial portion) extending beyond the limits of the chorionic plate (\bigcirc *Fig. 19.9*). Fetal vessels appear to terminate at the margin of the chorionic plate but actually continue their course peripherally in the deeper villous tissue.

Etiology and pathogenesis. There have been many theories attempting to explain the etiology and pathogenesis

of extrachorial placentation including abnormally deep implantation and premature fixation of the disc-membrane boundary. Recently, recurrent marginal hemorrhage resulting in circumvallation has been documented on serial ultrasound images, providing evidence that recurrent hemorrhage at the disk margin elevates and displaces the membrane insertion site centrally [151]. This may represent the pathologic correlate of recurrent and persistent maternal bleeding throughout pregnancy (chronic abruption). Amnionic fluid loss also contributes and is thought to be the primary mechanism in the circumvallation invariably associated with extramembranous pregnancy.

Pathology. Historically, extrachorial placentas have been subdivided into circummarginate and circumvallate types based on the nature of the transition from the chorionic plate to the fetal membranes. In circumvallate placentas, the marginal membrane ring is often reflected centrally, folded, and rolled back upon itself (> Fig. 19.10). Variable amounts of fibrin and recent and old blood clot are often found in the reflected membrane fold, with focal, or in severe cases, diffuse hemosiderin deposits in the chorionic plate. A flat transition from the chorionic plate to the membranes without reflection or prominent fibrin accumulation has been termed a circummarginate placenta (**)** *Fig.* 19.11). Either finding may be partial or complete, and they frequently merge imperceptably with one another. Multiple authors have suggested that the term circummarginate should be abandoned and that all extrachorial placentas should be considered part of the spectrum of circumvallation [84].

Clinical behavior. Estimates of the frequency of extrachorial placentation vary widely presumably because the terms are not used uniformly. It is more common in

Extrachorial placenta. The fetal membranes do not extend to the peripheral margin of the disk, leaving a ring of placental tissue extending beyond the chorionic plate. This membrane ring is rolled and reflected centrally

Fig. 19.11 Extrachorial placenta. The membrane transition in this extrachorial placenta is flat

multigravidas. The clinical sequellae seem to parallel the amount of associated hemorrhage. Mild or focal circumvallation without hemorrhage is clinically insignificant. More severe cases with chronic marginal abruption and oligohydramnios are associated with antepartum bleeding, preterm labor (PTL), intrauterine growth restriction (IUGR), and long-term neurologic impairment [145]. Circumvallate placentation may recur in successive pregnancies.

Placenta Accreta, Increta, and Percreta

Placenta accreta, increta, and percreta are defined as abnormal adherence of the placenta to the uterine wall so that placental separation does not occur after delivery of the newborn. The degree of abnormal adherence/invasion is variable; placental villi may adhere to (*placenta accreta*) or invade the myometrium (*placenta increta*), sometimes penetrating through the serosa (*placenta percreta*.) The condition may be total (involving the entire placenta), partial (involving one or more cotyledons), or focal (involving isolated foci).

Etiology. The pathologic basis of this condition is partial or complete absence of the decidua. Decidua normally regulates trophoblastic invasion during gestation and allows the placenta to separate from the myometrium after delivery. Lack of decidua explains the abnormal placental adherence that occurs in ectopic (cornual, tubal, or cervical) implantation or in scarred endometrium over leiomyomas or cesarean section scars.

Clinical features. The frequency of placenta accreta is difficult to determine. Reported figures have varied widely from 1 in 540 to 1 in 70,000 pregnancies. Fox emphasized the particular tendency of placenta accreta to occur in multigravid and obstetrically elderly women [45]. A number of predisposing factors have been linked to this condition, the two most significant being placenta previa (placental implantation in the lower uterine segment near or overlying the cervical os) and previous cesarean section. In some reports, as many as 64% of placentas accreta have been associated with placenta previa, many occurring in cesarean section scars. Often only the portion of the placenta implanted in the lower uterine segment or over a cesarean section scar is abnormally adherent. Other risk factors include prior uterine instrumentation or intrauterine infection, previous manual removal of the placenta, uterine structural defects (leiomyomas, septae), and nonfundic implantation. The common endpoint in all these conditions is a deficiency in, or absence of, the decidua. In less than 10% of cases, no risk factors are identified.

Pathology. The diagnosis is usually obvious in a hysterectomy performed at the time of delivery. The placenta is almost invariably implanted in the lower uterine segment or cervix, often anteriorly in the region of prior cesarean section (\bigcirc *Fig.* 19.12). The myometrium is variably but often markedly thinned. The uterus and placenta may be disrupted by attempts to remove the adherent placenta at the time of delivery. Microscopically, the cardinal feature is partial or complete absence of the decidua basalis. Placental villi adhere directly to, or invade

Placenta percreta. The placenta at left implanted over the cervical os (*upper left*) and penetrated the serosa. The placenta at right also penetrated the serosa in the anterior lower uterine segment at the site of three prior cesarean sections

Fig. 19.13

Placenta increta. The placenta has invaded the myometrium almost to the serosa. Villi invade the myometrium without intervening decidua

into, the myometrium (**)** *Fig. 19.13*), penetrating through the uterine serosa in some instances. The diagnosis can also be established on placental exam. Microscopic sections of grossly fragmented, low-lying, or manually removed placentas may show a thin layer of myometrial fibers adherent to the placenta without intervening decidua. Occasional smooth muscle cells in a basal plate containing decidua is not diagnostic of accreta. The diagnosis in a postpartum curettage calls attention to the placental tissue is not removed.

Clinical behavior and treatment. Placenta accreta is compatible with normal fetal growth and development. Although usually anticipated, it may not be suspected until the placenta fails to separate in the third stage of labor. Postpartum bleeding may be life threatening, requiring immediate hysterectomy, or bleeding may be delayed. Antepartum bleeding and premature labor are common due to the high frequency of associated placenta previa. Uterine rupture may occur at any stage of pregnancy or during labor. Maternal and fetal mortality are now uncommon. Placentas with mesenchymal dysplasia are usually very large, often over 1,000 g. The chorionic vessels are aneurysmally dilated and often thrombosed. Enlarged cystic stem villi are recognizable grossly (\bigcirc *Fig.* 19.14). Microscopically, the stem villi are large and edematous with cyst formation and prominent thick-walled muscular stem vessels (\bigcirc *Fig.* 19.15). Terminal villi are usually normal but may show distal villous immaturity and chorangiosis. Chorangiomas are common. There is no trophoblastic hyperplasia. This rare lesion is often identified as partial hydatidiform mole on ultrasound. Over one half of reported cases have been associated with Beckwith Wiedemann syndrome. Mesenchymal dysplasia is associated with IUGR, intrauterine fetal demise (IUFD), and neonatal death [71, 101, 116]. Females are disproportionally affected.

Multiple Pregnancy

Multiple gestations are common and becoming more so with assisted reproductive techniques (ART). In the United States in 2000, ART accounted for 14% of all twin births, and 45% of ART births were twins [153]. Multiples are associated with a disproportionate share of complications including higher rates of morbidity, mortality, low birth weight, anomalous development, and malformation than singletons. Careful pathologic examination of the placenta(s) can provide important insight into problems peculiar to multiples, and pathologists must be aware of the special considerations required in the examination of placentas from multiple births.

Twin Gestation

Zygosity

Definition. Twins may arise from the fertilization of two separate ova (dizygous or fraternal twins) or from the division of a single fertilized ovum (monozygous or identical twins). Monozygous twins are genetically and usually phenotypically identical, but dizygous twins are genetically dissimilar like singleton siblings. Rare variants of dizygous twinning result when ova are fertilized by sperm from different sources (superfecundation) or when ova are ovulated and fertilized at different times resulting in twins of disparate developmental ages (superfetation). A rare variant of monozygous twins, monozygous heterokaryotic twins, have different karyotypes and sometimes even different sex [14]. These twins are thought to result from chromosome non-disjunction, most commonly involving the sex chromosomes, but on occasion the autosomes as well. A third type of twinning, polar body or dispermic monovular twinning, presumably results from fertilization of an oocyte and a polar body. Bieber described a triploid acardiac/diploid twin gestation resulting from fertilization of an oocyte and its first polar body [20]. Theoretically, fertilization of the oocyte and second polar body could also occur. The frequency of this phenomenon is unknown. It has been hypothesized that dispermic monovular twins are monochorionic due to the proximity of the oocyte and the polar body and because cytoplasmic imbalance equips only the oocyte with its more abundant cytoplasm to implant.

Fig. 19.14

Mesenchymal dysplasia. The gross abnormalities in this placenta with mesenchymal dysplasia were identified on antenatal ultrasound. The infant was normal

Fig. 19.15

Mesenchymal dysplasia. The stem villi are greatly enlarged with abundant, focally degenerated cystic stroma and large thick muscular vessels

Frequency and etiology. Twins occur in about 1 in 80 Caucasian pregnancies in the United States, and approximately 30% of these are monozygous. The frequency of monozygous twinning is relatively constant worldwide (about 3.5 in 1,000 pregnancies), but there are marked geographic differences in total twinning rate reflecting excess dizygous twinning in certain populations and families who have a genetic predisposition for high FSH and polyovulation. Dizygous twinning is also age-related, increasing with maternal age until 35 years, again probably reflecting a role for increasing FSH levels with age. The cause of monozygous twinning is unknown. Monozygous twinning is increased in pregnancies following ART [98]. ART has changed the epidemiology of multiple pregnancy. It is as yet unclear if or how this technology may affect developmental events [26]. So far, pathologic placental lesions do not appear to be increased in ART multiples [163].

Placentation

The object of placental exam in multiple gestation is the same as in singleton gestation – to identify pathologic processes affecting placental function. The gross and

microscopic manifestations of these processes are identical in the placentas of singletons and multiples, although some lesions are particularly pertinent to the problems experienced by multiples. Comparison of the relative distribution of lesions in the placental territories and correlation with the size and condition of the fetuses is an important aspect of placental assessment in multiple gestation. Features unique to multiples include (1) the relationships of the disks and fetal membranes and (2) the pattern and degree of vascular anastomoses.

Chorionicity, Amnionicity, and Placental Mass

Placentas in twin gestation are either monochorionic or dichorionic. Virtually all dizygous twins have dichorionic placentas (diamnionic dichorionic – DiDi). In double ovulation, each blastocyst generates a placenta. If these implant in close proximity, varying degrees of fusion may result (DiDi fused); otherwise they are entirely separate. Monozygous twins may show any type of placentation depending on when division occurs (\bigcirc *Fig. 19.16*). If the single fertilized ovum divides very early, before differentiation of the chorion (first 5–6 days), the situation is analogous to dizygous twinning; two placentas develop that may be separate or fused (25% of monozygous

Fig. 19.16

Diagrammatic representation of twin placentation. (After [44] used with permission of the American Registry of Pathology/ Armed Forces Institute of Pathology)

twins). If splitting occurs after formation of the chorion but before formation of the amnion (8th day after fertilization), there will be a single placenta with two amnionic sacs (diamnionic monochorionic - DiMo), occurring in about 75% of monozygous twins. A split after formation of the amnion (between the 8th and 15th days), will result in one placenta with one amnionic cavity (monoamnionic monochorionic - MoMo), and still later splitting, in conjoined twins (> Fig. 19.17). Practically speaking, twins with monochorionic placentas are monozygous with very rare exceptions (monovular dispermic and one case of dizygous monochorionic twins) [178]. Twins with dichorionic placentas, whether separate or fused, may be either dizygous or monozygous. Obviously, different fetal sex establishes a dizygous relation, but further investigation (blood group analysis, HLA typing, and DNA analysis) is required to determine zygosity in like-sex dichorionic twins.

Establishment of placentation type is important, not only as an initial step in determining zygosity, but primarily because it has an important relationship to the increased morbidity and mortality that occur in multiple gestations. Many factors contribute, importantly the premature onset of labor and delivery, but placentation is also a very significant risk factor. Twins with monochorionic placentas have much higher mortality rates than those with dichorionic placentas, and monoamnionic placentation is associated with a fetal mortality rate as high as 50%.

Placentation type is usually reliably established on gross examination. Two entirely separate placentas are obviously dichorionic (DiDi separate), each requiring routine examination. Frequently the disks are separate but the membranes are fused. The membranes of one twin may overlap the disk of the co-twin (irregular chorionic fusion) when there is differential expansion of the membranous sacs. When the blastocysts implant close to one another, the two placental disks fuse to form an apparently single disk with a dividing septum (DiDi fused).

The principal task for the pathologist is to distinguish between monochorionic and dichorionic fused placentas. The nature of the membranous septum and the pattern of chorionic vascularization are critical in this distinction. The septum in dichorionic fused placentas is relatively thick and opaque due to the presence of chorionic tissue between the two amnionic layers (\bigcirc *Fig. 19.18*). Because each embryo is developing within its own chorion, any fusion between them will contain chorionic tissue. The chorionic tissue in the septum is continuous with the underlying placenta remaining firmly attached to the fetal surface. If the amnions are separated, chorionic tissue will remain as a ridge at the base of the septum. In contrast, the

Fig. 19.17

Conjoined twins. (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.18

DiDi fused placentas. The two placentas are fused but discrete. The septal membrane is thick and the fetal vessels do not cross the line of fusion (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) septum in a diamnionic monochorionic placenta is thin and translucent, composed of two directly apposed layers of amnion (**>** *Fig. 19.19*). This septum, devoid of chorion, is easily detached from the placental surface. Some pathologists peel the dividing membranes in order to identify monochorionic placentas that require injection studies. Histologic examination of the membranous septum confirms the gross impression. This is most easily accomplished in a section of rolled septal membranes

Fig. 19.19

DiMo twin placenta. The septal membranes are thin and filmy. Note velamentous insertion of the cord into the septal membranes (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) (\bigcirc *Figs. 19.20* and \bigcirc *19.21*), although identical information may be obtained from a section of the T zone where the septum meets the fetal surface. The latter method is particularly useful when the septal membrane has been torn or otherwise distorted and cannot be rolled.

The distribution of the fetal vessels on the chorionic plate is equally helpful in distinguishing DiDi fused from DiMo placentas. In dichorionic placentas, the septum represents the apposed borders of the two fused placentas and as such defines the vascular equator of the two placentas. In DiDi fused placentas, fetal chorionic vessels approach, but do not cross the area of fusion (\triangleright *Fig.* 19.18). In diamnionic monochorionic placentas, portions of the same placenta are shared by both fetuses, and the two vascular districts are intimately intermingled (\triangleright *Fig.* 19.22). The position of the membranous septum in the DiMo placenta is independent of, and does not necessarily conform to, the fetal vascular districts.

Rarely, a monochorionic placenta presents as two apparently distinct disks, superficially resembling dichorionic separate placentas. The nature of the septum and the intermingling of the vascular districts with anastomosis identify these as monochorionic. The appearance of two separate "disks" is due to involution or atrophy of intervening villous tissue related to factors at the implantation site affecting maternal blood supply.

Monoamnionic monochorionic placentas (MoMo) are very uncommon, accounting for less than 1% of twin gestations. In MoMo gestations, both twins develop within a single amnionic sac. Before considering a monochorionic placenta to be monoamnionic, the amnion between the cord insertions should be complete and continuous.

 Fig. 19.20
DiDi septum. A central layer of fused chorion intervenes between amnions

Fig. 19.21 DiMo Septum. The septum is composed of two directly apposed amnions

Because the amnion commonly separates from the underlying chorion and is often nearly completely detached at delivery, more apparently single sacs are artifactual than truly monoamnionic. Remnants of detached amnion and septum may be found encircling the cords or attached to the free membranes when carefully sought. Although membrane patterns are established early and persist throughout pregnancy, intragestational disruption of diamnionic septae has been reported. This suggests that at least some monoamnionic placentas may have been diamnionic originally. The umbilical cords in monoamnionic gestations are

Fig. 19.22

DiMo twin placenta. The fetal vessels are intimately intermingled, and some are anastomosed (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) typically closely inserted, usually within 6 cm of each other (**>** *Fig. 19.23*). Rarely there is partial cord fusion. Large vessel anastomoses are frequent but not invariable between the closely inserted cords. Cord entanglement is common and a significant cause of morbidity and mortality (**>** *Fig. 19.24*).

The pattern and adequacy of chorionic vascularization, the relative proportion of the chorionic surface populated by vessels from each twin, and the relative placental mass serving each twin are pertinent observations in multiple gestations. Dichorionic fused placentas can be divided and weighed. Estimates of the placental mass serving monochorionic twins are based on the chorionic vasculature. The pattern of venous return is a good indicator of placental supply. Not all discordantly grown twins have asymmetric placentas, and not all twins with asymmetric placentas are discordantly grown, but these associations are not uncommon. In twins with discordant placental mass, the smaller placenta is frequently associated with a lesser number of chorionic vessels. Whether the smaller placenta impairs the growth of the fetus, or both fetus and placenta are small secondary to other influences is not always clear.

Vascular Anastomoses

An important feature of monochorionic placentas is the presence of vascular communications between the two fetal circulations. The fetal circulation is established when small vessels developing independently within the villous mesenchyme connect with larger vessels in the chorionic plate and body stalk. When twins share the same placenta, the potential exists for the two developing circulations to merge in a number of different ways.

 Fig. 19.23
Cord insertion, MoMo. Close cord insertion is typical of MoMo placentation

■ Fig. 19.24 Cord entanglement in MoMo. This cord entanglement resulted in IUFD at 25 weeks

For example, the capillary bed supplied by an artery from one twin might establish continuity with a vein returning to its co-twin resulting in a parenchymal arteriovenous (A–V) anastomosis. In contrast, the two circulations in dichorionic twins are established independently explaining why vascular communications in DiDi-fused placentas are absent with rare exception.

It is generally agreed that vascular communication is invariable in monochorionic placentas although the number, size, and type of anastomoses are highly variable. Anastomoses between large chorionic plate vessels are very common. The majority of large vessel anastomoses are between arteries (A-A); vein to vein (V-V) anastomoses are less common. Of greater physiologic significance are the arteriovenous (A-V) anastomoses that occur between capillaries deep within shared villous parenchyma. Vascular anastomoses may be compound with surface (large vessel) and parenchymal (villous capillary) connections involving the same vessels (> Fig. 19.25). A-A anastomoses alone (20-28%) and A-A with A-V anastomoses (25-40%) are most common. A-V anastomoses alone, unmodified by concomitant large vessel anastomoses, are estimated to occur in 11-20% of cases.

Large vessel anastomoses are easily identified grossly (> Fig. 19.22) and can be confirmed by moving blood back and forth between the contributing vessels or highlighted by the injection of dye or air (> Fig. 19.26). The size, diameter, location (central or peripheral), type (arteries cross over veins), and number of anastomoses should be recorded. A-V anastomoses are more important physiologically but are more difficult to identify as they occur between capillaries deep in the villous parenchyma and cannot be directly visualized. Potential sites of A-V anastomosis can be suspected when an unpaired artery from one twin penetrates the chorionic plate in close proximity to an unpaired vein from the co-twin (> Fig. 19.27). This configuration is highly suggestive of an underlying anastomosis as arteries and veins are normally paired. A simple method to confirm the presence of arteriovenous anastomoses is to inject air into the arterial branch supplying a suspected anastomosis and document its return to the venous district of the co-twin. This has the advantage of displacing blood from the shared placental district. The resulting pallor allows estimation of the volume of shared parenchyma. Air injection can be repeated at multiple sites in an attempt to document the extent of anastomoses. All injection studies are qualitative. They do not necessarily reflect the physiologic significance of an anastomosis, or the overall balance of blood flow in vivo. Nevertheless, their documentation is essential if vascular anastomosis is to be invoked as a cause of, or contributor to, discordant fetal

Fig. 19.25

Types of vascular anastomoses in monochorionic placentas. Large vessel anastomoses (artery-artery and vein-vein) are easily identifiable on the chorionic plate. Arteriovenous anastomoses occur between capillaries in shared placental lobules. The presence of an unpaired artery penetrating the chorionic plate in the vicinity of an unpaired vein from its co-twin suggests this possibility. Superficial (large vessel) and capillary anastomoses may involve the same vessels (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.26

Vascular anastomosis. This large anastomosis has been highlighted by air injection (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) growth. Injection studies are precluded by fixation and may be compromised by villous disruption.

Umbilical Cord

Anomalies of the umbilical cord are much more common in multiple than in singleton gestations. The incidence of velamentous cord insertion in twins has been reported to be up to nine times higher than in singletons. The frequency of anomalous insertion (marginal and velamentous) increases with proximity of the twins (dichorionic separate < dichorionic fused < monochorionic). Anomalous cord insertion in multiples has the same significance as in singletons. In addition, there is some evidence that velamentous cord insertion is a factor that influences twin–twin transfusion and associated early delivery.

Single artery cords are also more frequent in multiple gestations, occurring in approximately 3% as compared to 0.53% of singletons. Most twins are discordant for single umbilical artery, although concordance is greater in monozygous than dizygous twins. The length of the umbilical cord is on average 7.6 cm shorter in twins than singletons, and the incidence of hypocoiled cords is also increased.

Twins that share an amnionic cavity (monoamnionic) are at increased risk for cord entanglements. Cord entanglements of all types occur in monochorionic twins with a reported frequency between 53 and 71%, and they may be remarkably complex (> Fig. 19.28). Such entanglements may result not only in cord compression but in mistaken cord transection when one twin's cord is looped around its co-twin at delivery. Cord entanglement as a factor in fetal mortality is most common prior to 24 weeks while there is still sufficient room for fetal movement. After 30-32 weeks and in higher multiples, cord entanglement is less common as opportunity for movement decreases. Cord entanglements may result in chronic vascular compromise or they may not become a problem until the forces of labor result in acute vascular obstruction.

Complications of Multiple Pregnancy

Twin–Twin Transfusion Syndrome (TTTS)

Vascular communications in monochorionic placentas create the potential for blood flow between the twins. When there is a net flow of blood from one twin to the other, the clinical manifestations depend on the size, number, and type of vascular communications. Capillary-sized arteriovenous (A–V) anastomoses involve the transfusion of small amounts of blood over long periods of time

Fig. 19.27

Arteriovenous anastomosis. An unpaired artery from the umbilical cord barely visible at bottom penetrates the chorionic plate adjacent to an unpaired dilated vein from the co-twin at right (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.28 Complex cord entanglements in MoMo twins (a and b)

Diseases of the Placenta

(chronic transfusion). A large volume of blood can be transferred rapidly through large caliber chorionic plate vessels often at the time of labor and delivery (acute transfusion). Not infrequently, both occur – an acute transfusion is superimposed on a chronic longterm process (acute on chronic transfusion). Large vessel anastomoses are likely to be bidirectional and A–V connections are likely to be unidirectional.

Chronic Transfusion

Definition and etiology. Chronic TTTS is the most common form of twin-twin transfusion, and is an important cause of perinatal mortality in monochorionic twins. Schatz proposed the view that the chronic TTTS results when there is unbalanced flow of blood from one twin (the donor) to its co-twin (the recipient) through A-V anastomoses deep within shared placental lobules (the "third circulation") [17]. Chronic unidirectional diversion of blood results in anemia, relative deprivation, and growth retardation of the donor as compared to the larger, polycythemic recipient. Hypervolemia and hypertension in the recipient result in increased urine output and polyhydramnios, while hypotension and hypovolemia in the donor lead to oliguria, oligohydramnios, and decreased movement (the "stuck" twin.) Either twin may be hydropic, reflecting cardiac dysfunction and congestive heart failure in the recipient and profound anemia in the donor.

Although vascular anastomoses are a necessary precondition for the development of the TTTS, additional factors beyond shifts of blood (differential protein, atriopeptin, growth factor concentration, or colloid osmotic pressure) may contribute. Velamentous cord insertion is significantly more common in monochorionic gestations with the TTTS. It has been proposed that velamentous cords are more easily compressed, resulting in decreased umbilical vein flow and enhanced flow through A–V anastomoses. Others have speculated that polyhydramnios may contribute to umbilical and chorionic vessel compression providing the therapeutic rationale for amniocentesis.

The clinical definition of the TTTS is complicated because twins commonly show asymmetric growth for reasons other than a chronic twin–twin transfusion (maternal, fetal, umbilical cord, or placental factors). A hemoglobin concentration difference >5 g/100 mL and twin weight difference of 15–20% are considered definitive criteria by some, although similar weight and hemoglobin discrepancies are just as common in dichorionic twins without an anatomic basis for transfusion [140]. Conversely, hemoglobin concentration in twins with the chronic twin-twin transfusion may be similar if the donor's compensatory hematopoiesis has been sufficient. A relatively selective criterion is a recipient heart weight that is two to four times that of the donor. This feature is generally not present in any other process resulting in twin weight-growth discordance. The disparity in heart size is due not only to a generalized growth differential but also to the increased cardiac work load associated with the hypervolemia, hypertension, and hyperviscosity experienced by the recipient twin. Heart size discrepancy may be the first manifestation of the chronic TTTS, evident on ultrasound as early as 10 weeks. Difference in overall fetal size is usually apparent only later in gestation. Discrepant amnionic fluid volumes, hydrops, and a "stuck twin" are other ultrasound findings very suggestive of the TTTS.

Frequency. Recent studies indicate close correspondence between the number of cases with well-documented twin-twin transfusion and the number of monochorionic twin placentas with A-V anastomoses without concomitant large-vessel anastomoses [18]. This occurs in 9-20% of monochorionic gestations. Superficial vascular anastomoses appear to mitigate against the effects of A-V transfusion probably by allowing transfer of blood back to the donor from the recipient. In the absence of superficial anastomoses, arteriovenous transfusions are uncompensated, resulting in marked growth discordance, hydramnios, early delivery, and high perinatal mortality. The TTTS is not a significant cause of fetal mortality in monoamnionic twins presumably because the majority of MoMo twins have large-vessel anastomoses that modify parenchymal connections. In addition, any intra-amnionic pressure differences that potentially could affect blood flow in diamnionic twins are equalized in monoamnionic twins. For unexplained reasons, the twin-twin transfusion syndrome is more common in females.

Gross and microscopic pathology. After delivery, there is a marked discrepancy in the size and appearance of the infants and their corresponding placental territories. The donor twin is smaller, pale, and anemic; the recipient is heavier, edematous, plethoric, and polycythemic (> Fig. 19.29). Either twin may be hydropic. The organs of the recipient are larger and heavier than those of the donor (> Fig. 19.30). The recipient's heart especially is comparatively enlarged, with myocardial hypertrophy involving all chambers. Smooth muscle mass is increased in the media of pulmonary and systemic arteries and arterioles. Pulmonary arterial calcification has been described in the recipient twin. The donor heart is usually small, and arterial muscle mass is decreased. Glomeruli are enlarged, up to twice normal size in the recipient twin, and they are either normal or small in the donor.

■ Fig. 19.29 Twin-twin transfusion syndrome (TTTS). The donor twin (*left*) is smaller and pale. The recipient twin (*right*) is larger and plethoric (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

The donor's placental territory may be large, bulky, and pale reflecting fetal anemia (\bigcirc *Fig 19.31*). The villi are large and edematous with numerous Hofbauer cells and capillaries containing nucleated red blood cells (\bigcirc *Fig. 19.32*). In other cases, the donor's placenta has been described as pale and atrophied. Amnion nodosum may be found when there is associated oligohydramnios. The recipient's placental territory is generally smaller, firm, and deep red. The villi are appropriately mature with dilated and intensely congested vessels (\bigcirc *Fig. 19.33*).

Clinical features. Typically, the chronic TTTS is clinically manifest in the second trimester with acute hydramnios and growth discrepancy between the twins, but it may be suspected earlier based on the ultrasound demonstration of different amnionic fluid volumes. The

Fig. 19.30

Twin-twin transfusion syndrome (TTTS). The organs of the recipient twin are larger and heavier. Congestion of the smaller (donor) organs and pallor of the larger (recipient) organs is a reversal of the expected pattern, suggesting that the recipient twin exsanguinated into the donor (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

consequences of the twin–twin transfusion syndrome are grave. Mortality rates are as high as 70–100% depending on the gestational age at diagnosis and delivery. The earlier the syndrome is manifest, the more likely the outcome will be fatal. When the condition develops in the second trimester, it is often associated with pre-term labor and death of one or both fetuses or significant morbidity if the neonates survive. Both twins are at great risk. The recipient twin is subject to cardiac failure, hemolytic jaundice, kernicterus, and thrombosis due to hemoconcentration. The donor twin may be severely anemic or hypoglycemic. Both twins are likely to suffer from

G Fig. 19.31

Twin-twin transfusion syndrome (TTTS). The donor's

placental territory (*left*) is larger and pale reflecting anemia. The recipient's territory is smaller and congested (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.32

complications of prematurity. Multiorgan necrotic lesions including white matter infarcts, leukoencephalopathy, hydranencephaly, porencephaly, intestinal atresia, renal cortical necrosis, and aplasia cutis (\bigcirc *Fig. 19.34*) may occur in either or both twins. These lesions are attributed to the altered hemodynamics, transitory cardiovascular compromise, and hypoperfusion associated with complex fluctuating placental vascular connections.

Although most chronic transfusions progress, some may fluctuate or even reverse. If one twin dies in utero

and the transfusion ceases, the situation may resolve itself. Alternatively, the surviving twin (usually the recipient) may exsanguinate into the suddenly relaxed circulatory system of the dead co-twin (usually the donor) (> Fig. 19.30). Acute hypotension and/or blood loss after co-twin death is considered a likely explanation for necrotic lesions in the surviving twin, a view supported by Doppler studies showing dramatic umbilical flow velocity changes in the surviving twin. It has been estimated that neurologic sequelae occur in as many as 27% of surviving twins. Cerebral lesions have been demonstrated sonographically in twins at birth and in utero, developing rapidly in some cases. These observations are important in attempting to explain the high incidence of cerebral palsy in twins, reportedly five times the incidence in singletons and affecting primarily monozygous twins. Recognition that lesions predictive of cerebral palsy are of prenatal onset is important not only in medicolegal considerations, but also when contemplating the possible consequences of intentional fetal reduction for the surviving twin.

Attempts to alter TTTS have included treatment with indomethacin to reduce fetal urine output and polyhydramnios, digoxin to treat congestive heart failure, decompressive amniocentesis to prolong pregnancy and affect fetal blood flow, division of intervening membranes, selective feticide, and laser ablation of anastomoses. The latter approach requires accurate prenatal mapping of physiologically significant arteriovenous anastomoses and their successful ablation in vivo. Increasingly sophisticated Doppler studies are used to tailor treatment strategies to individual vascular patterns and to assess the results of intervention. Pathologic evaluation of laser sites and mapping of residual anastomoses play an important part in this treatment strategy. The enthusiasm for intervention must be tempered by the knowledge that the two fetal circulations are connected and that any manipulation will potentially affect both fetuses. Given the complexity and uniqueness of the vascular anatomy, it is difficult to predict the consequences.

Acute Transfusion

Plethora of one twin and pallor of the other do not always signify a chronic transfusion, but may reflect acute shifts of blood through large superficial vascular anastomoses. A large blood volume may shift rapidly through largevessel connections. Simple acute transfusions are usually diagnosed at birth. The donor is pale and the recipient plethoric, but there is no growth differential and hemoglobin and hematocrit levels are equal in initial assessments. Acute transfusions may occur when one twin experiences circulatory collapse for whatever reason or

Twin-twin transfusion syndrome (TTTS). The recipient's villi are appropriately mature but congested (*left*). The contrast between the donor and recipient placental territories is dramatic (*right*)

Fig. 19.34

Twin-twin transfusion syndrome (TTTS). Both twins may have necrotic lesions including aplasia cutis as seen here in the donor twin (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

when a twin exsanguinates through the unclamped cord of its delivered co-twin. Although clinically documented simple acute transfusion is rare, silent cases occurring in utero may account for the dramatic increase in cerebral palsy in like-sex twins.

Acute on Chronic Transfusion

Superimposition of acute transfusion on established chronic transfusion is more common than simple acute transfusion, and when this occurs, there is reversal in the expected pattern with plethora of the smaller, original donor twin and pallor of the larger, recipient twin (\bigcirc *Fig. 19.30*). Whether this pattern develops after the donor dies and the recipient's blood drains into the

donor's flaccid vascular tree, or the acute transfusion occurs first, overwhelming the capacity of the donor's heart causing death is unknown. Both mechanisms may be operative. On occasion, an acute transfusion and/or fetomaternal hemorrhage may occur in twins with discordant growth for reasons unrelated to chronic transfusion. While this scenario may mimic an acute on chronic transfusion, lack of evidence for adaptation to chronic transfusion (no heart-size discrepancy, polyhydramnios, or oligohydramnios) may help exclude chronic transfusion as a relevant contributing factor.

Asymmetric Growth

Established growth standards indicate that the growth curves for dichorionic and monochorionic twins approximate those of singletons prior to 30–34 weeks [7, 84]. Twins weigh progressively less than singletons as pregnancy advances. When twin growth is discordant, the larger twin approximates the growth of an age-matched singleton, and the growth rate of the smaller twin slows and may gradually decline into the range of small for gestational age (SGA). In dichorionic twins, growth discordancy is usually manifest around 25 weeks, but in monochorionic twins, the onset is more variable, commencing in some cases as early as 18–20 weeks.

Twin birth weight discordance is strongly associated with pre-term birth, perinatal death, and postnatal morbidity [28]. The majority of twins with discordant growth are dichorionic, and even among monochorionic twins, TTTS is not the most common cause of growth discrepancy. Even when chronic transfusion occurs, other factors may contribute as much or more to discordant growth. Cord anomalies including velamentous insertion and single umbilical artery are associated with decreased fetal weight, and both are much more frequent in twin gestations. In one recent study, peripheral cord insertion (velamentous, marginal, and markedly eccentric) was the strongest predictor of discordant growth and SGA in dichorionic and monochorionic twins [140]. Velamentous and marginal cord insertion may be accompanied by differences in placental vascularization; higher Doppler S-D ratios, and lower numbers of small muscular arteries in tertiary villi have been demonstrated in the smaller of discordant twins with peripheral cord insertion. Discordant birth weight is also associated with placental mass; smaller babies have smaller placentas. Since the fetal-placental weight ratio in smaller twins is normal to decreased, maternal vascular insufficiency is unlikely to be a major cause of impaired growth. Rather, poor placentation with asymmetrical trophotropism and abnormal cord insertion, asymmetric placental volume, and decreased placental vascularization are major causative factors in IUGR and twin growth discordance. These factors may also explain the coexistence of oligohydramnic, growth-restricted, and polyhydramnic larger twins (twin oligohydramnios-polyhydramnios sequence - TOPS) in dichorionic gestations and in monochorionic gestations in which twin-twin transfusion has been carefully excluded by marker erythrocyte studies [24]. Whether placental and fetal growth asymmetries reflect a generalized problem in the conceptus or result from a primary placental problem is unclear.

While discordant parenchymal lesions present a possible explanation for growth asymmetry, most placental disease processes involve twin placentas to similar degree; concordance for most findings is higher than might be expected based on their prevalence in singleton placentas. In one recent study, the only lesion significantly associated with discordant SGA twins was the finding of fibrotic avascular villi (FAV) [140]. This lesion, indicative of fetal vascular occlusion (fetal thrombotic vasculopathy) and associated with neurologic impairment in term infants, might contribute to the increased morbidity and mortality in twins. The incidence of fetal vessel thrombosis is higher in monochorionic than dichorionic placentas, correlating with peripheral cord insertion, vascular cushions, and IUGR [163].

Intragestational Fetal Loss

Multiples have higher mortality rates at all stages of gestation and after birth. The causes of intrauterine twin death vary with gestational age but are essentially the same as in singletons with the important addition of the specific complications of monochorionic placentation. Monochorionic twins are greatly over-represented among twin deaths at all gestational ages. The pathologic findings in intragestational fetal loss also depend on the time of fetal death and duration of retention in utero. One or both twins may die, concordantly or discordantly, and they may be delivered at intervals or retained and delivered together.

Vanishing Twin

Twin gestations are commonly converted to singletons with the embryonic/early fetal death of one twin (*vanishing twin*). Of twins diagnosed before 10 weeks, about 70% are born as singletons. When a twin dies spontaneously early in the first trimester, it is often difficult or impossible to identify any residue. A flattened mass of sclerotic placenta may remain as a vaguely thickened area in the membranes of the surviving co-twin. Microscopic examination may identify the membranous septum and establish chorionicity. Rarely there is an embryonic remnant, invariably severely degenerated (\bigcirc *Fig. 19.35*). Electively reduced embryonic remnants are more easily identified (\bigcirc *Fig. 19.36*).

Fetus Papyraceus

A twin dying in the second trimester may be retained, progressively compressed, and flattened by the growth of

Fig. 19.35

Early twin demise. This growth disorganized tiny twin was delivered at term with its normal co-twin. The abnormal morphology suggests that this early twin death was the result of an abnormal karyotype

Multiple pregnancy with elective reduction. Reduced fetuses are usually about the same size and relatively easily identified in the membranes (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.37 Fetus papyraceus

the co-twin. Depending on the length of retention, this flattened dead twin, a *fetus papyraceus*, is variably altered (**>** *Fig. 19.37*). Some are still easily recognizable and others resemble amorphous necrotic material. Specimen radiographs may reveal skeletal remnants. It has been estimated that the creation of a fetus papyraceus takes about 10 weeks. The degree of maceration generally precludes establishment of the cause of death, although anomalous cord insertion and TTTS have been implicated in many cases. Fetus papyraceus may occur in both monochorionic and dichorionic gestations. The amnionic cavity of the fetus papyraceus is gradually compressed as the amnionic

fluid is resorbed. The corresponding placenta is generally pale, thinned, and sclerotic with avascular, fibrotic villi enmeshed in fibrin.

Survivors of Co-Twin Demise

Abnormalities including intestinal atresia, skin defects, amputations, gastroschisis, and especially brain damage have been reported in twins surviving the in utero death of a co-twin. The risk of serious cerebral damage in surviving twins is reportedly around 20% and may be even higher in certain subsets. Monochorionic twins appear to be at greatest risk [117]. At all gestational ages, the risk of cerebral palsy is higher in like-sex surviving co-twins. Lesions occurring in surviving co-twins are similar to those in monochorionic twins with complex vascular anastomoses, suggesting a similar pathogenesis. Survivors of co-twin death also have a higher postnatal mortality rate.

Duplication Abnormalities

Occasional monozygous twins show marked discrepancies in size and configuration or varying degrees of incomplete separation. These asymmetric and incomplete duplications include acardiac and parasitic twins and conjoined fetuses. A parasitic twin is a variably developed fetiform mass attached to its co-twin either internally or externally (**)** *Fig. 19.38*). Conjoined twins retain their overall symmetry but are either incompletely separated or possibly secondarily fused during development. Neither parasitic nor conjoined twins show specific placental abnormalities.

Acardiac Twin (Chorangiopagus Parasiticus)

Acardiac twinning is the commonest form of asymmetric duplication anomaly, occurring in 1% of monochorionic twins. The acardius is a grossly malformed, often bizarre fetus of variable size, appearance, and degree of organogenesis. No two are alike. Some are amorphous, shapeless masses resembling teratomas (> Fig. 19.39) and others are remarkably well developed. Commonly, acardiac fetuses have relatively well-developed legs and perineal structures, a trunk into which the umbilical cord inserts and a rounded, dome-like upper body (> Fig. 19.40). A single body cavity may contain abdominal viscera, but thoracic structures and the heart are typically absent. Cardiac remnants or a deformed heart may be identified on occasion. Organ development is highly variable; some acardiacs may demonstrate absence of most organs, while in others, the organs may be well developed. Acardiacs may be hydropic, and some are larger than the co-twin.

The essential feature common to all acardiac fetuses is their circulation, which is maintained entirely by the cotwin (the "pump" twin). Blood from the normal "pump" twin reaches the acardiac through an artery to artery anastomosis, flows through the acardiac in reverse course, then returns to the normal twin through a vein to vein anastomosis (twin reversed arterial perfusion – TRAP). The majority of acardiacs have a single umbilical artery. The specific vascular communications between the acardiac and pump twins are large, occurring at the level of the umbilical cord or chorionic plate. There are no placental parenchymal vascular connections, and therefore the acardiac is analogous to a conjoined twin and not to the TTTS. The histologic features of the placenta in acardiac twinning have not been described in detail. Villous immaturity and recent and remote thrombosis of umbilical

and chorionic plate veins have been reported [179]. Acardiacs may occur in diamnionic or monoamnionic monochorionic placentas, although monoamnionic placentation is especially prevalent. Acardiacs are greatly over-represented in triplet and higher multiple gestations.

The pump twin is at risk for cardiovascular overload. The extra work involved in circulating blood through the acardiac may result in cardiomegaly and high output failure associated with hydrops and hydramnios. Pump twins also tend to be growth impaired perhaps because the blood diverted away from the placenta to the acardiac returns deoxygenated. Many pump twins have congenital

Fig. 19.39

Acardiac fetus. This amorphous acardiac fetus had a single umbilical artery (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.38

Parasitic twin. This parasitic twin (a and b) was removed from the abdominal cavity of its co-twin (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.40 Acardiac fetus.

Acardiac fetus. A dome shaped upper body with lower extremities is a relatively common configuration in acardiac fetuses (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) anomalies. Classification of the acardiac anomaly based on prognostic factors including the cardiovascular condition of the pump twin and the size of the acardiac twin has been proposed [191]. Strategies similar to those employed in management of the twin–twin transfusion syndrome have been successful in ameliorating the effects of cardiac overload in the pump twin [180].

Higher Multiple Births

Examination of placentas from higher multiple births extend the observations applied to twins. Chorionicity, membrane relationships, cord insertion, chorionic vascularity, potential vascular anastomoses, and relative placental volumes are assessed as in twins. Patterns of placentation vary depending on zygosity. Triplets, for example, may be monochorionic, dichorionic, or trichorionic with variable amnionicity (\bigcirc *Figs. 19.41* and \bigcirc *19.42*). Multichorionic placentas are usually fused as space in the uterus is limited. Combinations of monozygous and polyzygous multiples are common. With increasing use of assisted reproductive techniques, triplets and even quadruplets or quintuplets are no longer unusual in many institutions (\bigcirc *Fig. 19.43*). Higher multiples experience the same complications as twins – prematurity, low birth weight, congenital anomalies, increased perinatal morbidity/mortality – all progressively problematic with increasing numbers. Acardiacs are much more frequent in higher multiples as compared to twins. Cord entanglement is less common in

Fig. 19.41

Triplet placentation (After [44])

Fig. 19.42

Triplet placentation. Tri-Tri triplets (*left*). DiMo triplets (*right*). Although the placental territory at left is discrete, the fetal vascular pattern confirms monochorionicity. The middle and right triplets are monoamnionic

Fig. 19.43 Quintuplet placentas

monoamnionic higher-order multiples presumably due to limited opportunity for movement in the increasingly crowded uterus. While the outlook in higher multiple births has improved, complications are common and the outcome is often poor. Consequently, selective fetal reduction has been advocated, and there is now a substantial body of accumulated experience. Remnants of reduced fetuses are regularly identified when carefully sought.

Placental Inflammation and Intrauterine Infection

Placental inflammation is a common and important histologic finding. The character of a given inflammatory infiltrate and its pattern of involvement reflect, in general, its etiology and determine its clinical significance [127]. Placental inflammatory infiltrates can be divided into two major categories: (1) acute chorioamnionitis (ACA), an acute inflammatory reaction in the fetal membranes and umbilical cord; and (2) villitis - inflammation, usually chronic, of the villous parenchyma. ACA is invariably infectious due to microorganisms, usually bacteria, that ascend from the vagina or cervix (ascending infection). Villitis is almost invariably idiopathic, although rarely, it may be infectious, caused by microorganisms (viruses, some bacteria, or protozoa) that reach the placenta through the maternal blood (hematogenous infection). Passage through an infected birth canal is an important mode of fetal infection, but the placenta is not involved in this circumstance.

The consequences of intrauterine infection and inflammation include abortion, stillbirth, preterm birth (PTB), fetal malformation, active postnatal infection, and long-term sequelae, frequently neurologic. At worst, affected children may be severely handicapped, retarded, blind, or deaf. The social, financial, and emotional burden posed by the support of these children is enormous.

Ascending Infection and Acute Chorioamnionitis

Frequency, etiology, and pathogenesis. ACA is the most common form of placental infection and inflammation in humans [134]. Histologic ACA is found in approximately 10–15% of term and in up to 50–70% of preterm placentas. This striking inverse relationship between ACA and gestational age emphasizes the strong association between ACA and PTB. The term "chorioamnionitis" when used by clinicians to describe a symptom complex suggestive of intrauterine infection (maternal fever, uterine tenderness, or elevated white blood cell count) correlates poorly with histologic chorioamnionitis.

While historically controversial, it is now clear that ACA is a maternal and fetal acute inflammatory response to infectious agents that have gained access to the gestational sac. Microorganisms, usually bacteria, have been cultured from fetal membranes, amnionic fluid, cord blood, and fetal tissues in a high percentage of cases [194], and have been demonstrated by PCR in culture negative cases [48]. ACA can be produced experimentally in animals by the intraamnionic injection of bacteria but not by sterile exogenous irritants. Most cases of ACA result from the ascent of vaginal or cervical bacteria into the uterus. Other potential sources of intrauterine infection include endometritis or contiguous spread of organisms from the fallopian tubes, bladder, appendix, or intestines. Recent epidemiologic and experimental data have linked periodontal disease due to Fusobacterium nucleatum to PTL and have suggested that these microorganisms may reach the decidua hematogenously in some cases [57, 65].

ACA may either preceed or follow membrane rupture. There is a consistent and well-documented relationship between chorioamnionitis and membrane rupture; the longer membranes have been ruptured, the greater the likelihood that ACA will occur. Ascending infection and ACA, however, frequently precede membrane rupture, initiating premature rupture of membranes (PROM) and/or PTL, rather than following it, explaining the strong association between ACA and PTB. Outcome studies would suggest that ACA with intact membranes is a distinct entity with a greater risk to the developing fetus than ACA following membrane rupture, although the histologic changes are identical [129]. The bacteria most commonly identified in women with spontaneous

PTL and intact membranes are low-virulence vaginal and enteric organisms – *Fusobacterium*, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Gardnerella vaginalis*, *Bacterioides* and *Peptostreptococcus* species. Whether susceptibility to ACA is more related to factors that facilitate access of microorganisms to the intrauterine environment or to the virulence of, and host response to, a given infectious agent is unclear. To some extent, the maternal response to intrauterine infection is blunted by adaptations in the immune system that prevent rejection of the fetus [129].

Pathology. Maternal response: In most cases of ACA, the fetal membranes are macroscopically normal. In cases of particularly severe, long-standing infection, they may be opaque, friable, or foul smelling. Histologically there is a maternal and often a fetal inflammatory response to amnionic infection that progress sequentially and predictably as originally described by Blanc [21]. The initial response is maternal, manifested by the migration of maternal neutrophils from the intervillous space and from vessels in the membranous decidua. Neutrophils accumulate first in the subchorionic fibrin (acute subchorionitis) and membranous chorionic trophoblast (early acute chorionitis) (> Fig. 19.44), migrating progressively through the connective tissue layer of the chorion (acute chorionitis) and amnion (acute chorioamnionitis) (> Fig. 19.45) and into the amnionic fluid in response to chemotactic factors released by the infecting agent and/or inflammatory reaction. With time, the neutrophils undergo apoptosis and karyorrhexis followed by amnionic epithelial necrosis (necrotizing chorioamnionitis) (> Fig. 19.46).

The sequential changes and disease progression (stage) in the maternal inflammatory response are constant. A clinically relevant scheme for staging and grading the

Fig. 19.45 ACA, maternal response (intermediate, stage 2). Maternal neutrophils migrate into the connective tissue of the chorion and amnion

maternal inflammatory response has been proposed by the Perinatal Section of the Society for Pediatric Pathology (**Table 19.1**) [141]. The time course of progression in the maternal inflammatory response has been estimated based on personal observation and clinical correlation as well as experimental data. According to Redline, the initial maternal inflammatory response (acute subchorionitis) occurs within 6–12 h of infection. Involvement of amnionic connective tissue (ACA) most probably develops over 12–36 h after which the initial wave of neutrophils undergoes apoptosis and karryorhexis (36–48 h) [131]. Whether and how the timing of the maternal response may be altered by maternal factors such as preexisting

ACA, maternal response (advanced stage 3, severe). Diffuse intense inflammation with karyorrhexis of neutrophils and amnionic epithelial necrosis (*left*) and chorionic microabscesses (*right*)

Table 19.1

Ascending infection

Maternal response		
Stage 1 early:	Acute subchorionitis/early chorionitis	
Stage 2 intermediate:	Chorionitis/chorioamnionitis	
Stage 3 late:	Necrotizing chorioamnionitis	
	Subacute chorioamnionitis	
Grade severe:	Subchorionic microabscesses	
Fetal response		
Stage 1 early:	Umbilical phlebitis/chorionic vasculitis	
Stage 2 intermediate:	Umbilical arteritis	
Stage 3 late:	Necrotizing funisitis	
Grade severe:	Intense chorionic vasculitis	

maternal antibodies or the characteristics of the specific causative organism is not understood. The intensity (grade) of the maternal inflammatory response is more difficult to quantify. Grading based on the number of neutrophils in the most inflamed area of the chorionic plate has been suggested. The formation of subchorionic microabscesses has long been recognized as an indicator of severity since associated with fetal sepsis by Keenan (**>** *Table 19.1*) [78, 141].

Fetal inflammatory response: Depending on the gestational age and status of the fetal immune system, the fetus may also respond to amnionic infection. A fetal leukocytic response is often absent in gestations less than 19–20 weeks and in fetuses less than 500 g. The first

manifestation of a fetal inflammatory reaction is the migration of fetal neutrophils into the umbilical vein (umbilical phlebitis) and/or chorionic plate vessels (chorionic vasculitis). The migration of inflammatory cells is crescent-shaped, oriented toward the source of infection in the amnionic cavity (\bigcirc *Fig.* 19.47). In later stages, fetal neutrophils migrate from the umbilical arteries (umbilical arteritis) and into Wharton's jelly. With increasing duration, the neutrophils undergo necrosis forming necrotic bands around the umbilical vessels (necrotizing/subacute necrotizing funisitis) that may undergo calcification or vascularization (\bigcirc *Fig.* 19.48). Umbilical cord inflammation is often segmental, sometimes identified in only one of multiple sections, often from the fetal end.

ACA, fetal response (late, stage 3). Necrotizing funisitis. Prominent crescentic band of necrotic leukocytes around umbilical vessels can be appreciated grossly

Fig. 19.49

ACA, fetal response (severe). Fetal neutrophilic infiltration of chorionic vessels with medial disarray and in this case thrombosis

Progression of the fetal inflammatory response has also been staged (O *Table 19.1*), although the rate of progression of the fetal inflammatory response is more variable than the maternal response, depending significantly on gestational age. The intensity (grade) of the fetal inflammatory response has important associations with adverse fetal outcome. Scattered neutrophils in the chorionic plate or umbilical vessels are considered to be mild to moderate (grade 1). Intense chorionic vasculitis (severe/ grade 2) is characterized by near confluent neutrophilic infiltration of vessels accompanied by attenuation or disarray of the vascular smooth muscle media (O *Fig. 19.49*). Inflamed vessels may be thrombosed.

Amnionic infection, then, is a unique situation in which two individuals, mother and fetus, respond to the

Fig. 19.50

Acute villitis. Bacterial colonies are prominent in villous capillaries and neutrophils have accumulated beneath the trophoblast in the peripheral villous stroma

same infectious insult. The acute inflammatory infiltrate in chorioamnionitis is characteristically confined to the fetal membranes and umbilical cord. The villous parenchyma is not involved unless fetal septicemia results secondarily in villitis. In this event, bacteria (usually *Escherichia coli*, group B streptococci) are present in villous capillaries, often with accumulation of neutrophils beneath the trophoblastic basement membrane (\bigcirc *Fig. 19.50*). Although the majority of leukocytes in the fetal membranes are maternal, fluorescence in situ hybridization studies have demonstrated that the majority of neutrophils in amnionic fluid and fetal lung are fetal, emphasizing the important contributions of both maternal and fetal immune systems. The character of the inflammatory infiltrate is usually not specific enough to

identify a particular offending agent. In fact, it is relatively unusual to find bacteria in histologic sections even when they have been demonstrated on smears of the amnion. Notable exceptions to this include infections with group B β-hemolytic streptococci in which colonies of the organism are frequently found without difficulty even in the absence of histologic evidence of chorioamnionitis. Fusobacterium species may also be visible on conventional H&E stains as long (at least 15 µm), faintly basophilic wavy organisms often associated with very severe inflammation and necrosis in the membranes. Fusobacteria may be demonstrated with silver stains but are only faintly gram-negative on Brown and Hopps stain. In rare instances of Candida infection, tiny white fungal colonies 2-3 mm in size may be seen grossly on the amnionic surface of the umbilical cord. Yeast and hyphal forms Candida may also be identified on conventional H&E stains, characteristically in small, superficial, crescentic microabscesses under the amnionic surface of the umbilical cord (peripheral funisitis) (**)** Fig. 19.51).

Clinical significance. Although there are maternal hazards associated with chorioamnionitis (maternal sepsis), the principal clinical impact of chorioamnionitis is its potential adverse affect on the fetus.

Preterm birth (PTB). It is estimated that approximately 70% of perinatal mortality and nearly half of long-term neurologic morbidity can be attributed to PTB [40]. Multiple factors contribute to PTB, but chorioamnionitis is implicated in a high percentage of cases. Intrauterine infection as a cause of PTB is usually asymptomatic until labor begins or the membranes rupture prematurely, and therefore, early diagnosis is difficult. Many recent strategies have been aimed at the identification of women at risk and the development of therapeutic interventions targeting infection and the inflammatory response to

reduce spontaneous PTB and its associated mortality and long-term morbidity.

Data accumulating from experimental and human studies are clarifying how bacterial infection and chorioamnionitis result in spontaneous PTB. The inflammatory response to bacterial invasion results in the production of cytokines that initiate prostaglandin synthesis, resulting in uterine contractions. Certain bacterial species commonly associated with chorioamnionitis are high in phospholipase A2, which releases the prostaglandin precursor arachidonic acid from membrane phospholipids. The inflammatory response also results in increased synthesis of metalloproteases that are thought to remodel and soften cervical collagen and to degrade the extracellular matrix of the fetal membranes, leading to membrane rupture [85].

Placental villous edema in the context of ACA, most often in preterms, has been correlated with increased morbidity, mortality, and neurologic impairment [105, 144, 150].

Approximately 30% of cases of ACA at less than 25 weeks are associated with retroplacental hematoma eventuating in death and delivery in many [129].

Fetal inflammatory response syndrome (FIRS). Traditional thinking has attributed many of the neonatal complications of chorioamnionitis-induced PTB to prematurity, not to infection per se. Evidence is accumulating that pathologic lesions predictive of long-term morbidity (periventricular leucomalacia, intraventricular hemorrhage) are initiated in utero by the fetal response to placental infection (*fetal inflammatory response* syndrome – FIRS). Most data would not implicate infectious organisms as a direct cause of tissue damage but rather mediators of the fetal inflammatory reaction, principally cytokines (IL1, IL6, IL8, TNF- α) in the genesis of fetal lesions, especially white matter damage predictive of

Fig. 19.51 Candida peripheral funisitis. Small yellow foci on the umbilical cord correspond to superficial microabscesses

cerebral palsy [54, 88]. Cytokines may cause white matter damage directly via a toxic effect or indirectly by activating endothelium and microglia resulting in thrombosis or increased vascular permeability. Whether endotoxins or exotoxins cross the placenta or blood–brain barrier to directly injure the central nervous system is unknown.

The only histologic finding directly correlated with CNS injury in ACA is the severity of the fetal inflammatory response. Umbilical arteritis is associated with higher levels of circulating fetal cytokines than inflammation of the umbilical vein alone [81, 157]. Intense chorionic vasculitis has been associated with increased risk of cerebral palsy in term and preterm infants [130, 150]. The concomitant presence of mural thrombi in inflamed chorionic plate vessels is an additional risk factor for neurologic impairment in very low birth weight (VLBW) infants [150].

Neonatal infection. ACA implies that the fetus has been exposed to infection but not necessarily that the fetus is infected. The exposed fetus may be infected through the fetal skin, eyes, nose, or ear canals or by inspiring or swallowing infected amnionic fluid. Infants whose placentas show ACA are at increased risk to develop sepsis and die in the neonatal period. Although neither mother nor neonate is overtly ill in most cases, neonatal infection is an important cause of perinatal death, and most serious neonatal infections are associated with ACA. Fetal outcome is determined by a number of factors including gestational age and causative organism. Group B β-hemolytic streptococcus, E. coli, and Haemophilus influenzae are the most common causes of significant neonatal infection. Placental features associated with increased risk of neonatal infection include severe maternal and fetal inflammatory responses [78, 194].

Subacute Chorioamnionitis

Subacute chorioamnionitis is characterized by a mixed inflammatory infiltrate of mononuclear cells and degenerating neutrophils, usually concentrated in the upper chorion. This pattern may result from ongoing low-grade or repetitive infection, and has been associated with chronic lung disease in a subgroup of VLBW infants with concomitant amnionic necrosis. The maternal history may include repetitive bouts of vaginal bleeding [111].

Villitis and Hematogenous Infection

Etiology. Villitis, inflammation of the villous parenchyma, is almost never due to documented infection. No causative organism has been identified despite intensive study, and no maternal symptoms, seasonal or geographic pattern of

occurrence, neonatal inflammatory response, or congenital infections have been associated. Such cases have been termed *villitis of unknown etiology* (*VUE*). Recent investigations have identified the villous inflammatory cells as CD8 positive maternal T lymphocytes, supporting the theory that VUE represents a maternal immune response in fetal tissue (host versus graft reaction) [103, 135, 147].

Very rarely, villitis may result from a hematogenous infection in which infectious agents, usually viruses but also some bacteria and protozoa, reach the placenta through the maternal blood (*hematogenous infection*). In contrast to chorioamnionitis, a local infection, placental involvement in hematogenous infection is just one manifestation of maternal systemic disease. Although catastrophic fetoplacental infections caused by hematogenously acquired agents have been well documented, they are very infrequent.

Pathology. Villitis is almost always discovered incidentally on microscopic examination. Typically, there is neither clinical suspicion of nor gross pathologic clue to the underlying inflammatory process. There may be nonspecific findings – the placenta may be small or large and edematous – but only rarely are inflammatory foci identified grossly. The essential feature common to all villitides is an inflammatory infiltrate in the villi, but its character and the nature of associated changes are variable from case to case. The inflammatory infiltrate is usually chronic, composed of lymphocytes, histiocytes, and plasma cells in variable proportion (\geq *Fig.* 19.52), but occasionally it may be granulomatous, and rarely neutrophils are prominent. Usually the inflammatory infiltrate is associated with appreciable alterations in villous landmarks, but rarely it may infiltrate

Fig. 19.52 Villitis of unknown etiology (VUE). Villi infiltrated by lymphocytes and histiocytes

passively. Necrosis, dystrophic calcification, and stromal hemosiderin deposition may be present in some cases. The inflammatory cells are generally concentrated within the villi, but may also extend into the surrounding intervillous space, a feature commonly associated with syncytiotrophoblastic necrosis, intervillous fibrin deposition, and agglutination of contiguous inflamed villi (\bigcirc Fig. 19.53). Occasionally an intervillous component (*intervillositis*) may predominate. Inflamed villi are usually randomly distributed, but in some cases may be concentrated in the basal regions of the placenta or juxtaposed to the septa. The degree of villous involvement varies greatly from case to case and may be graded semiquantitatively as outlined by Fox and Sebire (grades 1–4) [45] or Redline (focal, multifocal, patchy, and diffuse) [84] \bigcirc Table 19.2.

Villitis of Unknown Etiology (VUE)

More than 95% of villitides are of unknown etiology. Although the extent and severity of VUE vary, it is very mild/mild or focal/multifocal in the majority of cases (60–75%). The villous inflammatory infiltrate is typically composed of macrophages and lymphocytes, but giant cells are common and are not indicative of infection. An active component with perivillous neutrophils may be present and when fulminant may be accompanied by intervillositis and fibrin deposition with villous necrosis (*active chronic villitis*) (\bigcirc *Fig.* 19.54). Since this pattern may be seen in some infectious villitides (gram-negative bacteria, nonsyphilitic spirochetes), special stains (gram,

Fig. 19.54

Active chronic villitis with intervillositis and villous necrosis. The villous stroma and intervillous space are infiltrated by neutrophils and chronic inflammatory cells. Fetal stem villous vasculitis, villous necrosis, and diffuse perivillous fibrin deposition result in grossly visible necrotic foci. Obliteration of stem vessels results in distal villous changes, here FAV

Table 19.2

Villous inflammation graded by extent

Grade 1:	Only one or two foci of villous inflammation, and in each focus only a very few villi are involved		
Grade 2:	Up co	Up to six foci of villous inflammation, each focus containing up to twenty villi	
Grade 3:	Multiple inflammatory foci, each occupying up to half a low power microscopic field		
Grade 4:	La of	Large areas of villous inflammation in most or all of the four sections	
Focal:		Small clusters of five-ten villi in a single slide	
Multifocal:		Small clusters of five-ten villi in multiple slides	
Patchy:		Larger foci (more than ten villi)	
Diffuse:		Diffuse involvement of all sections by groups of more than ten inflamed villi	

silver stains) should be considered. The inflammatory infiltrate is often confined to terminal villi but may also involve stem villi. Inflammatory obliteration of stem villous vessels with downstream fibrotic avascular villi (*VUE with fetal obliterative vasculopathy*) has been associated with neurologic impairment (**)** *Fig.* 19.55) [84]. Chronic deciduitis and chronic chorioamnionitis may accompany VUE in some cases. Villitis involving basal/periseptal villi

■ Fig. 19.55 Villitis of unknown etiology (VUE) with obliterative fetal vasculopathy. Vasculitis and obliteration of stem vessels result in avascular villi

(basal villitis) is frequently mild, purely lymphocytic, and passive. This pattern represents a subgroup of VUE often associated with plasma cell deciduitis.

Clinical significance. VUE is a common lesion involving 5–15% of third-trimester placentas [135]. When mild, VUE is usually clinically silent and the infant unaffected. More severe, extensive VUE is associated with IUGR, IUFD, cerebral palsy, and other forms of neurologic impairment [145]. These complications correlate directly with the severity of the villitis. In VUE, maternal cells enter not only the villi but the fetus itself [135]. Whether this contributes to perinatal morbidity or mortality is unclear. When fatal, VUE is generally massive, suggesting that impaired placental function may be a mechanism of injury. VUE may recur (10–25% when diffuse), and is associated with total reproductive failure. IUGR, IUFD, and preterm delivery are especially likely in cases of recurrent VUE.

Specific Infectious Villitides

Rarely the morphologic features of a villitis suggest an infectious cause, although differences between the infectious villitides and VUE may be quite subtle. In general, infectious villitides tend to be more severe with more villous fibrosis, necrosis, calcification, and inflammation of fetal membranes and umbilical cord.

Cytomegalovirus (CMV)

Pathology. The placenta may be normal, small (in cases of IUGR) or large and edematous. Histologically the villi may exhibit any or all of a wide spectrum of changes

Fig. 19.56
CMV placentitis. Plasmacytic villous infiltrate

related in part to gestational age. A plasmacytic villous infiltrate and stromal hemosiderin, often deposited around the remnants of occluded vessels, are characteristic (\bigcirc *Fig.* 19.56). Foci of stromal necrosis, calcification, and fibrosis may be found. The diagnostic cytopathic viral changes, large eosinophilic intranuclear and smaller basophilic cytoplasmic inclusions, may be present in endothelial cells, Hofbauer cells, or trophoblast (\bigcirc *Fig.* 19.57). They are most numerous and easily found in early, severe infections; as gestation proceeds, viral inclusions are typically scarce. When inclusions are not visualized on conventional H&E stains, CMV infection may be confirmed by immunohistochemistry, polymerase chain reaction (PCR), or in situ hybridization.

Diseases of the Placenta

Clinical significance. CMV is the commonest identified infectious cause of villitis. The prevalence of congenital infection ranges from 0.2 to 2.2% of all live births. Transmission to the fetus may occur in utero, at birth, or postnatally. Intrauterine infection may result from either primary or recurrent maternal infection. Congenital infections resulting from reactivation of latent virus are less likely to produce fetal damage and late sequelae than those resulting from primary maternal infection. At the present time, CMV is the most commonly recognized infectious cause of developmental impairments. Late complications including mental retardation, chorioretinitis, seizures, and especially neurosensory hearing loss are most common among survivors of symptomatic congenital infection but may also occur later in children with no manifestations at birth.

Treponema pallidum

Pathology. Infected placentas tend to be large and bulky. Histologically, the villi are large and relatively immature but not markedly edematous. The villous stroma is cellular as a result of the prominence of Hofbaur cells, and a lymphoplasmacytic infiltrate with subtrophoblastic neutrophils and microabscesses may be seen focally. Rarely, the inflammatory reaction has granulomatous features. Subendothelial and perivascular fibrosis resulting in luminal narrowing, recanalization, or occlusion of villous vessels is particularly characteristic. Marked decidual plasmacytic vasculitis and a chronic inflammatory infiltrate in the fetal membranes and umbilical cord have been noted in some cases. Necrotizing funisitis is a frequent finding but is not universal in, or specific for, congenital syphilis. The histologic changes in the placenta and umbilical cord are characteristic but not diagnostic. Definitive diagnosis depends on identification of spirochetes, most easily demonstrated in the umbilical cord whether inflamed or not.

Listeria monocytogenes

Pathology. The placenta is usually grossly normal but may contain minute yellow-white necrotic foci or rarely larger abscesses or infarcts (\bigcirc Fig. 19.58). The amnionic fluid is frequently meconium-stained. Unlike most other villitides, neutrophils predominate in Listeria villitis. Villi are commonly enmeshed in intervillous acute inflammation and fibrin, which, when extensive, may result in villous necrosis and abscesses. Neutrophils in the villi are often localized to a rim, often between the trophoblast and villous stroma (\bigcirc Fig. 19.59). Listeria villitis is usually accompanied by chorioamnionitis and often funisitis. Listeria monocytogenes is a small gram-positive motile bacillus with rounded ends that may be demonstrated with

Fig. 19.58 Listeria placentitis. Yellow white necrotic areas may be grossly apparent in some cases

Fig. 19.59

Listeria placentitis. Neutrophils aggregate in the intervillous space. Entrapped villi undergo necrosis forming abscesses. Neutrophils accumulate peripherally in the villous stroma beneath the trophoblast

Brown–Hopps, Warthin–Starry, or Dieterle stains. Immunohistochemical stains have been utilized to establish the diagnosis and to exclude other infections (*Campylobacter* species, *E. coli*, *H. influenzae*, *Francisella tularensis*, *Streptococcus* species, *Brucella abortus*, *Chlamydia psittaci*, *Coccidioides immitis*) that have similar histologic findings.

Clinical significance. L. monocytogenes is a significant cause of intrauterine infection, spontaneous abortion, prematurity, and neonatal sepsis, morbidity, and death. Perinatal listeriosis takes one of two forms. In the "early type," congenital infection results in devastating neonatal sepsis (granulomatosis infantisepticum) in which microabscesses similar to those in the placenta are disseminated in fetal organs. The "late type" of perinatal listeriosis, presumably acquired during birth, presents as meningitis in the second or third week of life. *L. monocytogenes* usually does not cause serious disease in adults, although gravidas may experience a flu-like syndrome and fever. The most common mode of infection is the ingestion of contaminated food, often a milk product. A brief hematogenous phase is followed by fecal shedding until immunity is established. Placental infection can result from hematogenous dissemination or via the ascending route. The particular predisposition for significant listerial infection in pregnant women and the fetus appears to be related to local factors at the maternofetal interface that compromise an effective immune response [125, 126].

Toxoplasma gondii

Pathology. The placenta infected with Toxoplasma gondii may be grossly normal but is commonly large and edematous. Microscopically, the changes are highly variable, ranging from a subtle low-grade lymphocytic villous infiltrate to a destructive process associated with necrosis or fibrosis. True granulomas with central necrosis, palisaded histiocytes, and Langerhans giant cells may predominate. Nodular accumulations of histiocytes beneath the trophoblast or extending into the intervillous space, decidual plasmacytic infiltrates and vasculitis, and chronic inflammatory infiltrates in the fetal membranes and umbilical cord have been described. The encysted form of the organism may be found in the fetal membranes, chorionic plate, umbilical cord, or villi (**>** Fig. 19.60). Toxoplasma cysts

■ Fig. 19.60 Toxoplasma villitis. A toxoplasma cyst is present in this chronically inflamed villus

are typically unassociated with inflammation, but once ruptured, the tachyzoites incite an intense inflammatory reaction and necrosis. Identification of tachyzoites, very difficult on H&E stains, is aided by immunohistochemistry, immunofluorescence, or PCR.

Clinical significance. Congenital infection appears to result mainly from primary maternal infection acquired early in pregnancy, usually by the ingestion of oocytes in undercooked meat or by contact with cat feces. During the parasitemic stage of maternal infection, the organism is transmitted to the placenta and fetus. The risk of fetal infection in these circumstances is about 50%. The likelihood of fetal transmission increases with gestational age, although the severity of infection is greatest when the infection is acquired in the first trimester. The clinical spectrum of fetal involvement ranges from severe damage to the central nervous system and eyes to completely asymptomatic infection, recognized only by the development of chorioretinitis after months or years of follow-up. Prenatal diagnosis (via fetal blood sampling or culture) and antibiotic treatment seem to reduce the frequency of congenital infection. In the presence of maternal antibodies from past infections, fetal lesions, with rare exception, do not occur.

Parvovirus B19

Pathology. Pathologic changes in the placenta reflect fetal anemia. Parvovirus B19 preferentially infects actively replicating cells, especially erythroblasts, which are then destroyed. Grossly, the placentas are large, pale, and friable. Microscopically, there is a uniform pattern of relative villous immaturity and edema. Diagnostic intranuclear eosinophilic inclusions with peripheral chromatin condensation are present in erythroblasts in the villous vessels (\bigcirc *Fig. 19.61*). In situ hybridization and immunohistochemistry are somewhat more sensitive than conventional microscopy in identifying infected cells or PCR may be used to confirm the diagnosis. Unlike most other congenital hematogenous infections, there is no villous inflammation.

Clinical Significance. Human parvovirus B19 is the agent of "fifth disease," or erythema infectiosum, a mild, acute exanthematous disease of children. In adults, most infections are asymptomatic, although self-limited polyarthropathy is common especially in women, and aplastic crises occur in individuals with chronic hemolytic anemias. To date, the most commonly recognized consequences of fetal parvovirus infection are non-immune hydrops (which may resolve spontaneously) and abortion. Most abortions occur between the 10th and 28th weeks of pregnancy, but the risk of fetal loss is low, estimated to be

Fig. 19.61

Parvovirus infection. Erythrocytes in the villous capillaries show central nuclear eosinophilic inclusions with peripheral chromatin condensation

less than 10%. Neonatal anemia has been observed in a few infants infected in the third trimester, and malformations reminiscent of ocular rubella embryopathy have been reported very rarely.

Herpes Simplex Virus

Disseminated herpes simplex virus infection is an important cause of devastating disease and death in the newborn. Intrapartum infection of the fetus is the most common, although ascending and transplacental dissemination have been described. Villous necrosis and agglutination, lymphocytic villitis, and fibrinoid necrosis of villous vessels have been documented in cases of hematogenous infection. Acute necrotizing and chronic lymphoplasmacytic chorioamnionitis, amnionic viral inclusions, and funisitis have been described in cases of ascending infection. An increased frequency of spontaneous abortion and congenital malformations have been reported in patients with primary infection in the first 20 weeks of pregnancy.

Varicella Zoster

Varicella infection in pregnancy is uncommon in the United States because the majority of women of childbearing age (95%) are immune. In congenital infection, the placenta may show small, grossly visible necrotic foci and villous necrosis, vascular occlusion, lymphoplasmacytic infiltrates, and granulomas with giant cells. Viral inclusions have been reported in villi and decidua. The spectrum of fetal manifestations is wide, ranging from completely asymptomatic babies to those with perinatal varicella/zoster or full-blown embryopathy, the latter occurring in less than 5% of fetuses infected in the first trimester. Reactivation of maternal zoster during pregnancy does not appear to be associated with severe fetal sequelae.

Rubella

Congenital rubella infection is now rare due to the effectiveness of immunization programs. The placental findings have been well documented during previous rubella epidemics, mainly in first- and second-trimester abortions but in a few term placentas as well.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) may be transmitted to the fetus transplacentally, at the time of delivery, or after birth (through breastfeeding). In utero transmission can be confirmed by the detection of virus in infants by PCR or coculture within 48 h of birth. Several factors (maternal, fetal, obstetric, and virologic) affect maternal-infant viral transmission, and timing of transmission may determine the subsequent course of infection in the infant. Antiretroviral therapy given to the mother before and during delivery and to the infant after delivery has reduced vertical transmission substantially. No histopathologic lesions directly attributable to HIV have been described in the placenta. Specifically, there have been no reports of villitis. Placentas from seropositive mothers have demonstrated an increased incidence of ACA.

Other Organisms

Massive chronic histiocytic intervillositis may occur in malaria [112]. Recurrent villitis has been described in association with nonsyphilitic spirochetes [1]. The placental lesions associated with hematogenous spread of other organisms are detailed elsewhere [45].

Other Patterns of Placental Inflammation

Chronic Histiocytic Intervillositis

Chronic histiocytic intervillositis is the diffuse uniform infiltration of the intervillous space by monocytemacrophages accompanied by variable perivillous fibrin deposition (**?** *Fig.* 19.62). Excluded from this category are cases with concomitant villitis or polymorphous intervillous inflammation. Placentas are often small for gestational age. The histologic features are very similar to those in placental malaria, distinguished from it by the absence of malarial pigment. Chronic histiocytic intervillositis is idiopathic, encountered most often in

■ Fig. 19.62 Chronic histiocytic intervillositis. There is diffuse infiltration of the intervillous space by monocyte-macrophages

first-trimester spontaneous abortions. It is associated with recurrent spontaneous abortion, IUGR, IUFD, and a high overall perinatality mortality rate.

Chronic Deciduitis

Chronic deciduitis has been defined as either the presence of plasma cells or diffuse chronic inflammation (with or without plasma cells) in the decidua basalis. The chronic inflammatory response may be directed against maternal or fetal antigens or microorganisms. Chronic deciduitis is often associated with VUE at term and with ACA in preterm placentas, but it may also occur as an isolated finding.

Chronic Chorioamnionitis

Rarely, an inflammatory infiltrate occurring in the same distribution as ACA is composed of chronic inflammatory cells (**>** *Fig. 19.63*). Typically, small mature lymphocytes predominate, but plasma cells, histiocytes, and rarely large lymphoid cells and immunoblasts are admixed [69]. In some cases, the chronic inflammatory cells may be accompanied by a minor component of neutrophils, which may be either entirely distinct from, or intimately admixed with, the chronic inflammatory component. The inflammatory infiltrate in chronic chorioamnionitis is commonly focal and typically mild. It is generally confined to the membranes, although involvement of the chorionic

■ Fig. 19.63 Chronic chorioamnionitis. Small lymphocytes infiltrate the amnion and chorion

plate may occur. Rarely, the large fetal vessels of the chorionic plate and umbilical cord are also chronically inflamed. Chronic chorioamnionitis is often accompanied by villitis and occasionally by chronic or subacute necrotizing funisitis. A specific infectious etiology is not identified in the great majority of cases, although rarely chronic chorioamnionitis may occur in association with rubella, herpes simplex, *T. pallidum*, or *T. gondii* infection.

Eosinophilic/T Cell Vasculitis

Eosinophilic/T cell vasculitis is a chronic inflammatory infiltrate composed of fetal eosinophils and lymphocytes involving chorionic plate and large stem villous vessels (**>** *Fig. 19.64*). There are no specific clinical associations, although in most reported cases there have been maternal or fetal abnormalities [47].

Circulatory Disorders

The placenta is a vascular organ with separate fetal and maternal circulations. The integrity of both circulations is essential to placental function. Clots, hematomas, and other pathologic processes affecting the vessels and spaces in and around the placenta may cause both fetal and maternal injury depending on their size, location, and extent. Measurement of size and evaluation of extent is important in assessing the significance of individual lesions. There is, however, no absolute "cutoff" beyond which a bad

■ Fig. 19.64 Eosinophilic T-cell vasculitis. Eosinophils and small lymphocytes invade the muscular wall of this chorionic plate vessel

outcome is inevitable or below which a good outcome is assured. The normal placenta has considerable functional reserve. The potential for injury depends not only on the nature and extent of the pathology but also on the amount and functional status of the uninvolved parenchyma. Thus, even a relatively small lesion in a compromised or small placenta may have greater clinical significance than a larger lesion in an otherwise normal placenta.

A balance between factors that favor coagulation and fibrinolysis is necessary for homeostasis; pregnancy itself shifts that balance toward thrombosis. Within the maternal intervillous space, clotting inhibitors such as annexin V at the syncytiotrophoblastic surface normally inhibit clotting. Thrombogenic factors may overcome this, resulting in thrombi and infarcts [123, 124]. Within the fetal circulation, stasis, local injury from inflammation or compression, or thrombophilic factors may result in clotting. The existence of an intravascular clot, regardless of cause, confirms that the balance has been broken at least locally, and may also promote or be associated with clotting elsewhere in the circulation.

Maternal Circulation

In relation to placental pathophysiology, the maternal circulation includes the uterine arteries and their branches, the spiral arteries, the maternal intervillous space, and the venous drainage of the uterus. Many pathologic processes affecting the maternal circulation can be traced to abnormal implantation and vascular remodeling [136].

Fig. 19.65 Incomplete vascular remodeling. This basal plate artery retains its muscular wall

Decidual Vasculopathy, Incomplete Physiologic Change, Acute Atherosis, and Maternal Vascular Underperfusion

Etiology. When normal physiologic trophoblastic remodeling of the spiral arteries does not evolve properly, arterial smooth muscle persists, the lumina fail to expand, and uteroplacental blood flow is reduced. The maternal blood pressure rises, the maternal vascular endothelium is injured, and the maternal syndrome of preeclampsia develops.

Pathology. Non-remodeled spiral arteries with persistent musculoelastic media (absence of physiologic change) may be identified in the basal plate (> Fig. 19.65). Nonremodeled spiral arteries are predisposed to develop a distinctive lesion, acute atherosis, characterized by necrosis and dense eosinophilia of the vessel wall with large foamy macrophages and inflammation (> Fig. 19.66). The lumens may be partly or completely occluded by thrombus. Acute atherosis involves muscularized maternal arteries in the basal plate and membranous decidua. The latter is often the best place to find acute atherosis (> Fig. 19.67). Immature IT in the superficial basal plate and trophoblastic giant cells in the deep basal plate are increased [149]. These changes together with the characteristic vascular alterations have been referred to as superficial implantation [84].

Mural hypertrophy of membrane arterioles is a less common pattern of decidual vasculopathy that occurs especially in women whose preeclampsia is complicated by diabetes mellitus [15]. The muscular walls of the affected vessels in the decidua parietalis are thickened, and there is marked luminal narrowing (**>** *Fig.* 19.67). Mural hypertrophy is diagnosed when the mean wall diameter is greater than 30% of the overall vessel diameter [139].

The most direct adverse effect of decidual vasculopathy is the reduction of maternal blood flow into the intervillous space (*maternal vascular underperfusion*) leading to reduced placental growth and weight. Microscopic changes include increased and prominent syncytiotrophoblastic knots (**)** *Fig. 19.68*). The nuclei in the small knots of a normal placenta undergo apoptosis and break away

Fig. 19.66

Acute atherosis. The spiral arteries show fibrinoid necrosis and accumulation of foamy macrophages. The largest artery is thrombosed, and there is infarction of the overlying placenta into the maternal circulation as membrane bound packets. In preeclampsia, the nuclei of the pathologic knots undergo ischemic necrosis ("aponecrosis") [67], releasing membrane fragments, DNA, and proteins into the maternal circulation. This circulating cellular debris may contribute to maternal endothelial injury in preeclampsia [67]. Adhesions between syncytial knots undergoing aponecrosis may result in the agglutination of small villous clusters (>2 <20) that commonly show karvorrhexis and stromal fibrosis (villous agglutination) (**)** Fig. 19.69). With more severe underperfusion, intervillous fibrin is increased, first around stem villi, and then around distal villi, accumulating as small nodules at sites of trophoblastic necrosis. Ultimately, large aggregates of villi may be enmeshed in fibrin [139]. Fibrin accumulation in the intervillous space may be the result of decreased maternal perfusion and stasis or to abnormal coagulation or both.

When reduced maternal blood flow is severe and longstanding, the villi develop abnormally. The distal villi are decreased in number and slender with reduced branching, and terminal villi are very small with increased syncytial knots. This constellation of features is referred to as *distal villous hypoplasia* (synonyms: *accelerated maturation*, *peripheral villous hypoplasia*) (> *Fig.* 19.70). To be significant, these changes must be demonstrated centrally in the mid and basal zones of the placenta because similar changes occur normally in the less perfused peripheral and subchorionic regions [192]. Hypoxia-related gene expression in trophoblast occurs in these areas even in the normal placenta [192] Localized areas of severe ischemia result in infarcts that may be large and numerous in cases of severe preeclampsia (> *Fig.* 19.71). Long-standing

Fig. 19.69

Maternal underperfusion. Villous agglutination. Clusters of degenerating distal villi are adherent to one another

maternal vascular underperfusion may cause fetal volume depletion, decreased extracellular fluid, and an abnormally thin cord.

Clinical significance. Maternal vascular compromise with placental underperfusion is one of the major causes of IUGR. Severe maternal vascular underperfusion may result in IUFD and is associated with cerebral palsy (CP) in VLBW infants [144]. Identical pathologic changes occur in the placentas of patients with systemic lupus erythematosus [93], scleroderma [38], the antiphospholipid antibody syndrome [159], and occasionally in the absence of hypertension. Similar changes in the spiral arteries with constrictions, dilations, hyalinization, and

Maternal underperfusion. Distal villous hypoplasia. Chronic severe maternal underperfusion results in distal villi that are thin and non-branched when cut longitudinally and very small when cut in cross section. Syncytial knots are prominent

 Fig. 19.71
Maternal underperfusion. Infarcts of varying ages. Recent infarct is red

thrombi occur in the placenta when thrombotic thrombocytopenic purpura develops in pregnancy [70].

Infarct

Etiology. An infarct in the placenta, as in any other organ, is an area of ischemic necrosis resulting from obstruction of blood supply. The spiral arteries that supply the placenta may be narrowed by acute atherosis, occluded by thrombi, or disrupted by a retroplacental hematoma. Extensive placental infarcts have been reported in association with thrombophilic states [9, 37, 80].

Pathology. Infarcts are wedge-shaped areas of induration often located at the placental margin. Fresh infarcts are difficult to see; they differ little in color, but are firmer and drier than the surrounding placenta. Older infarcts grow progressively firmer and change from red to brown, then tan, yellow, or white (> Fig. 19.71). Microscopically, the earliest change is collapse of the intervillous space. The villi are crowded, separated by only a thin layer of fibrin, and trophoblastic nuclei cluster together forming knots. The syncytiotrophoblast, vascular endothelium, and villous stroma undergo progressive necrosis until eventually only crowded, ghostlike villous outlines remain (> Fig. 19.72). The mummified infarcted villi are not removed by macrophages or replaced by fibrous tissue as occurs in other organs. A mild acute inflammatory response may occur at the margin of an infarct.

Clinical behavior. Infarcts occur in about 25% of otherwise normal term placentas. The finding of a small peripheral infarct in an otherwise normal placenta is of no clinical significance. Multiple or large (>3 cm) infarcts, central infarcts, or infarcts in the first or second trimester are indicative of significant, underlying maternal vascular disease, most often preeclampsia. Extensive placental infarction is associated with fetal hypoxia, IUGR, and IUFD. These ill effects on the fetus are not simply the result of the destruction of villous tissue but reflect the superimposition of infarction on a placenta already compromised by low maternal blood flow.

Retroplacental Hematoma

Definition. A retroplacental hematoma is a clot located in the decidua between the placental floor and the

myometrium. It represents the pathologic lesion responsible for the clinical diagnosis of placental abruption that is made by the obstetrician based on the presenting signs and symptoms manifested by the mother. These two terms should not be used interchangeably, a practice which leads to confusion between a clinical diagnosis with grave implications and a pathologically demonstrated clot whose impact depends primarily on size.

Frequency. Retroplacental hematomas are found in approximately 4.5% of placentas examined pathologically [45]. Based on data from the National Hospital Discharge Summary, symptomatic abruption occurs in 1% of singleton deliveries. The incidence appears to be increasing [6].

Etiology. The pathogenesis of retroplacental hematoma is not known, but bleeding from a decidual artery followed by dissection of the enlarging clot is the presumed sequence in most cases. An occluded ischemic artery that undergoes reperfusion may rupture, leading to a retroplacental hematoma. Retroplacental hematomas are increased threefold in women with preeclampsia, presumably due to the related vascular pathology. Other associations include PTL, chorioamnionitis, anemia, smoking, cocaine abuse, trauma, diabetes mellitus, and short umbilical cord. Traumatic separation of the attached placenta followed by bleeding from a disrupted vessel probably occurs, for instance, following an automobile accident.

Pathology. When confined by peripherally attached placenta, a retroplacental hematoma distorts and indents the overlying placental parenchyma (\bigcirc Fig. 19.73). Separated from its blood supply, the overlying placenta infarcts. The characteristic depression and overlying infarct are easily recognized even when the clot itself has become detached during delivery. Larger clots may dissect

Fig. 19.72

Maternal underperfusion. Infarcts. The intervillous space is collapsed with necrotic villi undergoing progressive necrosis eventuating in ghost like villous remnants

into the basal region of the placenta. Older retroplacental hematomas may be much more subtle, forming only a thin, inconspicuous layer of red-brown clot beneath an infarct. When retroplacental hematomas extend to the placental margin, the blood may be evacuated without causing any indentation. Very recent extensive placental separation is typically associated with little, if any, gross or histologic change in the placenta. These large hematomas generally result in immediate fetal distress, necessitating emergent delivery. A large fresh clot behind a "floating" detached placenta observed at the time of cesarean section may be the only objective sign of an acute retroplacental hemorrhage. Obstetricians should document this observation and submit the clot along with the placenta. Microscopic examination of the clot may offer supportive

Fig. 19.73 Retroplacental hematoma. The placenta is compressed and infarcted over this large retroplacental hematoma

evidence when clumps of decidua associated with strands of fibrin are demonstrated.

Retroplacental hematomas consist of stratified red cells and fibrin, the proportion of fibrin increasing as the lesion ages and the red cells degenerate. The time course of these evolutionary changes is unknown. The adjacent decidua may be necrotic. Macrophages containing hemosiderin are often present around older clots and sometimes involve the membranes. Organization may occur where the clot interfaces with the uterus, but not where it interfaces with the placenta. The placenta overlying the hematoma is often infarcted. Villous edema and villous stromal hemorrhage are secondary placental abnormalities indicating that the retroplacental hematoma has adversely affected the fetus. Nucleated fetal erythrocytes are often increased (\bigcirc *Fig* 19.74).

Clinical significance. The clinical significance of a retroplacental hematoma is related primarily to its size. Retroplacental clots block the passage of blood from the spiral artery into the intervillous space. Small clots may have little effect, since adjacent spiral arteries may suffice to keep the overlying placental villi functional. The larger the clot and infarct, the more likely it will exceed the functional reserve capacity of the placenta, which may be already marginal in a background of chronic uteroplacental ischemia. Older chronic lesions associated with hemosiderosis in the membranes indicate the possibility of chronic reduction of placental function. Extensive accumulations of blood lead to the full clinical picture of abruption – pain, and shock in the mother and severe acute hypoxia in the fetus.

Fig. 19.74

Villous stromal hemorrhage. Villous stromal hemorrhage is associated with acute retroplacental hematoma (*left*). nRBC are often increased (*right*)

Definition. A marginal hematoma occurs where the lateral margin of the placental disk joins the fetal membranes.

Etiology. Acute marginal hematomas are thought to result from rupture of uteroplacental veins at the margin of a low-lying placenta. Chronic recurrent venous hemorrhage at the disk margin (*chronic marginal hematoma, chronic abruption*) elevates and centrally displaces the membrane insertion site, resulting in circumvallation.

Pathology. Grossly, an acute marginal hematoma forms a crescent-shaped clot at the lateral margin of the placenta. On cut section, the clot is triangular with the apex at the junction of the membranous and villous chorion. Microscopically, a recent marginal clot usually lies entirely outside the placental disk but may occasionally involve the intervillous space. With this exception, the presence of an acute marginal hematoma has no effect on the adjacent villi. Chronic marginal hematomas are tan-brown clots usually occurring in the region of circumvallate membrane insertion and associated with membrane hemosiderin deposition (\bigcirc Fig. 19.75).

Clinical significance. An acute marginal hematoma may be associated with antepartum bleeding, in some cases followed by onset of labor, but it does not have any untoward effect on the fetus. Chronic marginal hematomas and circumvallation are often associated with

• Fig. 19.75 Chronic marginal hematoma. Old brown clot is prominent at the margin of this circumvallate placenta

antenatal bleeding. In this context, retroplacental hematomas and abruption are also more frequent.

Intervillous (Intraplacental) Hematoma

Definition, frequency, and etiology. Intervillous hematomas are clots in the intervillous space. They are common, found in 36–48% of placentas. Intervillous hematomas are thought to be initiated by fetal bleeding into the intervillous space through ruptured vasculosyncytial membranes. Small amounts of fetal blood can be demonstrated, although most of the clot is composed of maternal blood [75]. Factors cited as potential causes of villous damage resulting in fetomaternal hemorrhage include trauma, amniocentesis, and external version. Basilar intervillous hematomas may have a different etiology.

Pathology. Intervillous hematomas are round or oval blood clots that may occur anywhere in the intervillous space but are most common midway between the chorionic and basal plates. They begin as red, fluid, or semifluid blood and become progressively laminated and depigmented with age. They may be single, although multiple lesions are common. Most are 1–3 cm in diameter. Microscopically, the thrombi consist of layered red cells and fibrin, the proportion of fibrin increasing as the lesion ages (\triangleright *Fig. 19.76*). Villi displaced to the margins of the clot may be infarcted or fibrotic and avascular.

Clinical significance. An intervillous hematoma is significant in that it marks a site of hemorrhage from the fetal into the maternal circulation. Intervillous hematomas occur at the bleeding site. These are common and usually

Fig. 19.76 Intervillous (intraplacental) hematoma. A typical lesion composed of laminated fibrin and red cells

do not indicate that a significant fetal blood loss has occurred. Occasionally, a larger fetomaternal hemorrhage results in fetal anemia and fetoplacental hydrops if it occurs slowly and chronically, or sudden unexpected death if severe and acute. Severe fetal morbidity and mortality result from hemorrhages of 150 mL or more, but lesser amounts can be significant if chronic bleeding has occurred episodically. It has been suggested that the risk is greater when the mother and fetus have compatible ABO blood types, perhaps because of deficient clot formation at the site of bleeding [195]. There is often no clinical evidence of fetal distress or injury, even in cases resulting in IUFD. The amount of fetomaternal hemorrhage can be quantitated using the Kleihauer-Betke test. Flow cytometry may be more sensitive [31, 41]. Correlation between the severity of fetomaternal hemorrhage and size and number of intervillous hematomas is variable. In some cases of severe fetomaternal hemorrhage, there may be no hematoma and a site of bleeding may not be identified.

Small amounts of fetal blood leak into the maternal circulation in virtually every pregnancy. Fetomaternal hemorrhage may lead to isoimmunization of Rh negative mothers resulting in hemolytic anemia and immune hydrops in the fetus.

Massive Subchorial Hematoma (Breus' Mole)

The massive subchorial hematoma has been defined as coagulated blood, at least 1 cm in thickness, separating the chorionic plate from the underlying placenta over much of its area (\bigcirc *Fig.* 19.77). These are generally relatively fresh, red hematomas that distort the chorionic plate and protrude as nodular masses into the amnionic cavity. They may dissect into the chorionic plate or extend into the intervillous space, sometimes as far as the basal plate. This is a rare lesion, the incidence estimated to be 0.53 per 1,000 deliveries in one large study [170]. The etiology and pathogenesis are unknown. Most authors agree that the hematomas are maternal.

Massive subchorial hematomas are usually acute because catastrophic reduction in placental function results in abortion or IUFD. Rarely babies are liveborn.

Maternal Floor Infarct (MFI) and Massive Perivillous Fibrin Deposition (MPF)

Definition. These two lesions have many similar features, differing mainly in the extent and distribution of

abnormal fibrin(oid) in the placenta. *Massive perivillous fibrin (MPF)* deposits occur extensively throughout the placenta. In *maternal floor infarct (MFI)*, the same type of fibrin-like material is concentrated in the basal plate.

Etiology. Currently two types of fibrinoid or fibrin-like material are identified in the placenta [46, 186]. Matrix-type fibrinoid is composed of oncofetal fibronectin, collagen IV, laminin, and tenascin and usually does not include fibrin. It is consistently associated with, and apparently produced by, extravillous trophoblast. This type of fibrinoid and associated trophoblast surrounds the villi in both MPF and MFI. Fibrin-type fibrinoid has immunohistochemical features of blood clot product and lacks the cellular trophoblast component. This form of fibrin accumulates in maternal vascular underperfusion associated with decidual vasculopathy and the syndrome of pre-eclampsia.

The fact that the intervillous space is involved would seem to implicate a maternal circulatory abnormality. Isolated reports have identified a group of associations including antiphospholipid antibody syndrome [166], polymyositis [3, 66], long-chain L-3-hydroxyacyl-coA dehydrogenase deficiency [96, 122], chronic intervillositis [189], and thrombophilias [9, 76]. Two separate reports, however, document involvement of only one of dichorionic twins, suggesting a role for the fetus [56, 143]. Whether the fibrinoid material that encases the terminal villi in these disorders reflects coagulation

Fig. 19.78

Maternal floor infarct (MFI). The maternal surface is diffusely discolored and firm (*left*). The basal villi are entrapped in fibrinoid (*right*)

secondary to stasis of maternal blood in the intervillous space or aberrant secretion of matrix by villous trophoblast is unknown.

Pathology. Wide strands and interlacing clumps of hard waxy pale tan or gray material accumulate as a thickened rind in the basal portion and ramify throughout the placenta. When most of the material is concentrated basally, the term MFI best applies, even though other parts of the placenta may also be involved (> Fig. 19.78). In MPF, the deposition of fibrinoid is diffuse without preferential basal concentration, although there may be patchy, sometimes extensive involvement of the maternal floor as part of the process (> *Fig* 19.79). Classification based on fibrin distribution is subjective. When classified by criteria proposed by Katzman and Genest, 44% of lesions did not conform to any of the categories [77]. Microscopically, the villi are widely separated by pink amorphous matrix-type fibrinoid containing numerous mononuclear trophoblast cells (> Fig. 19.80). The syncytiotrophoblast and capillary endothelium disappear from entrapped villi, but the villous stroma and villous outlines persist.

Clinical significance. The reported incidence ranges from 0.5 to 5 per 1,000 deliveries [143]. First-trimester spontaneous abortions, sometimes recurrent, and midand late-trimester IUFD are common when the process is massive. Survivors are often delivered preterm with IUGR or develop long-term neurologic impairment [2]. MFI may recur in successive pregnancies. Villi entrapped in fibrinoid are isolated and non-functional. MFI and MPF represent the most severe end of a continuum. Redline and Patterson observed that perivillous fibrin deposits that entrapped more than 20% of villi in the central basal portion of the placenta (thought to be the primary region

Fig. 19.79

Massive perivillous fibrin deposits. Hard waxy material is distributed throughout the placenta including the maternal surface

Fig. 19.80

Massive perivillous fibrin deposition (MFD). Villi are separated by and enmeshed in dense perivillous fibrinoid containing IT of gas and nutrient exchange) were significantly associated with an IUGR and low placental weight [148]. Milder cases of perivillous fibrin deposition enveloping 5–20% of terminal villi showed a lesser degree of similar complications. Fibrin deposits at the placental margin or beneath the chorionic plate do not appear to have any adverse affect on the fetus.

Fetal Circulation

The fetal circulation of the placenta begins with the paired umbilical arteries, branches of the fetal iliac arteries. The umbilical arteries pass through the umbilical cord to the placenta where they branch on the chorionic plate and progressively rebranch in smaller stem villi ultimately reaching the villous capillaries where oxygen and nutrient exchange occur across vasculosyncytial membranes. The fortified blood flows through progressively larger veins in the stem villi and chorionic plate, reaching the umbilical vein, which passes back through the umbilical cord to drain into the sinus venosus of the fetus.

Fetal Thrombotic Vasculopathy (FTV) and Fetal Stem Vessel Thrombi

Definition. Clots that form in the fetal circulation obstruct blood flow to the villi, rendering them nonfunctional for the transfer of oxygen and nutrients from the mother to the fetus. *Fetal thrombotic vasculopathy* (*FTV*) refers to the changes in stem vessels and villi that follow occlusion and cessation of blood flow. Related lesions or terms with similar connotations include fetal stem artery thrombosis [43], fibrinous vasculosis [165], intimal fibrin cushion [35], avascular terminal villi [158, 160], and hemorrhagic endovasculitis [161, 162].

Etiology. The rules of Virchow's triad apply to thromboses in the placenta. Stasis, vascular injury, and a hypercoagulable state, especially in combination, may result in clots in the fetal circulation. The most common cause of stasis is chronic partial or recurrent intermittent umbilical cord compression resulting from cord entanglements or anatomic factors (excessive length, hypercoiling, etc.). Stasis may also result from compression of velamentous vessels or in the meandering vascular spaces of chorangiomas or mesenchymal dysplasia. Vascular injury may be due to a fetal inflammatory response to infection, exposure to cytokines or meconium, or vascular inflammation in VUE (*VUE with obliterative vasculopathy*). Hypercoagulable states occur in inherited (factor V Leiden, protein S or C deficiency, etc.) and acquired thrombophilias (antiphospholipidemias, lupus erythematosus). The occurrence of a thrombophilic state in the mother or newborn does not by itself predict vascular lesions in the placenta or fetus, but it may represent a risk factor in association with other conditions [10].

Pathology. Thrombi in large vessels of the chorionic plate or umbilical cord are often visible on gross inspection (\bigcirc Fig. 19.81). Villi in the distribution of a large thrombosed vessel form a pale triangular area often with the same consistency as the surrounding parenchyma (\bigcirc Fig. 19.82). Older lesions may be firmer, gray-white, and better delimited. Both thrombi and villous lesions are subtle, sometimes better estimated after formalin fixation. In the majority of cases, the occluded vessels are small,

Fig. 19.81 Chorionic vessel thrombus. This large chorionic plate vessel is occluded by a hard white thrombus

Fig. 19.82

Fetal vascular obstruction. When a large fetal vessel is occluded, the downstream villous changes are visible as a pale wedge shaped area

Fig. 19.83 Fetal vascular obstruction. Red cell extravasation and septation in fetal stem vessels

associated with small clusters of distal fibrotic avascular villi that are identifiable only microscopically.

The evolution of large vessel thrombi is similar to that in other sites except organization does not occur. Recent thrombi expand the vessel, are attached, and may have a layered appearance. The endothelium disappears and spindle-shaped cells invade the thrombus producing a multilocular pattern (*septation*) (\bigcirc *Fig.* 19.83). The erythrocytes fragment and blend into adjacent connective tissue. Smooth muscle may disappear and the wall may calcify.

The villi distal to an occluded vessel show a sequence of distinctive alterations. Early changes include karyorrhexis of intravascular, endothelial, and villous stromal cells with destruction of capillaries and extravasation of red cells (> Fig. 19.84). The stroma is mineralized and may be hypercellular. This constellation of alterations, currently termed villous stromal vascular karyorrhexis, is identical to hemorrhagic endovasculitis as originally described by Sander [161]. Eventually, the villi become fibrotic with bland, densely collagenized, hyalinized stroma (fibrotic avascular villi – FAV) (> Fig. 19.85). The surrounding syncytiotrophoblast is preserved and often knotted. Larger stem vessels distal to the occlusion show fibromuscular sclerosis. The thrombosed vessel resulting in these distal villous alterations may or may not be apparent depending on the plane of sectioning. The same sequence of changes occurs diffusely throughout the entire placenta after IUFD. The diffuse versus focal nature helps distinguish involutional from pathologic vascular alterations.

Clinical significance. A committee of the Perinatal Section of the Society for Pediatric Pathology has

Fig. 19.84

Fetal vascular obstruction, villous stromal-vascular karyorrhexis. Fragmented red cells are extravasated and there is nuclear debris in and around terminal villous capillaries. These represent early changes in villi downstream from an occluded vessel

suggested terminology and criteria for the reproducible diagnosis of fetal vascular obstructive lesions. They emphasized that the prognostic importance of fetal vascular obstructive lesions is related to their severity, recommending that the diagnostic term *fetal thrombotic vasculopathy* (*FTV*) be reserved for cases with severe involvement defined as an average of >15 affected villi per slide [138]. FTV is associated with neonatal

encephalopathy [97], cerebral palsy [130], IUFD, and fetal and neonatal thromboocclusive disease [83, 146]. FTV represents a major placental pathologic finding in IUGR and discordant twin growth [140].

The negative effects of FTV occur in at least two ways. First, the presence of thrombi in fetal circulation of the placenta indicates the potential for thrombi to occur elsewhere either as a result of generalized activation of the fetal coagulation system or direct embolism. Thrombi or emboli and infarcts in the fetal brain, kidney, lung, and liver causing severe perinatal liver disease have been reported [25, 30, 83]. While there is definite connection when clots in the placenta and fetus occur together, the finding of FTV in the placenta alone is not predictive. The prevalence of systemic thrombi or infarcts among newborns with placental FTV is low [87]. A second form of injury results from reduction of placental reserve caused by loss of a significant fraction of the placental circulatory bed. The occurrence of multiple lesions in the same placenta compounds the prospects for injury [138, 145, 187].

Intimal Fibrin Cushions and Fibrinous Vasculosis

DeSa described *intimal fibrin cushions* composed of intramural fibrin deposits and proliferating fibroblasts forming non-occlusive intraluminal protrusions, some calcified, in chorionic veins (**>** *Fig. 19.86*) [35]. The finding was attributed to local injury from elevated venous pressure. Clinical associations included low birth weight, abruption, maternal

Fig. 19.86

Intimal fibrin cushion. Fibrin(oid) is deposited in the wall of large chorionic plate vessel. Mural calcification is consistent with a long-standing process hypertension, and intrapartem hypoxia. Emphasizing associated wall edema, Scott et al. described a similar lesion, *fibrinous vasculosis*, associated with stillbirth and other adverse outcomes [165]. Currently these large vessel lesions are classified as intimal fibrin cushions and are thought to be pressure-related changes affecting vessels between the actual site of fetal vascular obstruction and the terminal villi [138]. They are often associated with other evidence of fetal vascular occlusion in distal villi including fibrotic avascular villi and villous stromal vascular karyorrhexis.

Fetal Vascular Narrowing and Increased Umbilical Vascular Resistance

Doppler velocimetry studies have identified a group of growth-restricted fetuses with increased resistance to fetal blood flow. In general, these placentas are small with distal villous hypoplasia. Small fetal stem arteries in such cases have been described as narrowed with thickened walls [53], an observation supported by morphometric studies [42, 100]. When severe and in the setting of a strong supporting clinical history, these changes may be noted, but they overlap significantly with post-delivery arterial vasospasm.

Villous Edema and Villous Stromal Hemorrhage

Abnormal accumulations of fluid in the villous stroma occur in three different contexts, each with distinct pathologic features. The first and most obvious form is the gross villous swelling of hydatidiform mole and certain other abnormal karyotypes (triploidy, monosomy X). A second pattern occurs in intermediate and terminal villi that are expanded by fluid in small discrete stromal lacunar spaces. Normal immature intermediate villi have a similar appearance but lack the expanded outlines caused by edema. This pattern of edema is associated with more severe grades and stages of ACA, most often in premature and VLBW newborns. In this context, severe edema is predictive of neurologic impairment [105, 138, 145]. Occasionally villous edema may occur with ACA at or near term or with abruption. The third category of villous edema occurs in fetoplacental hydrops in which all villi, terminal and stem, are diffusely edematous and relatively immature.

Hemorrhage into the villous stroma (*villous stromal hemorrhage*) is thought to result from capillary rupture due to acute ischemia. It is most common in preterm placentas with clinically suspected abruption (\triangleright *Fig. 19.74*).

Chorangiosis

Villous chorangiosis is a form of villous hypervascularity in which villi have expanded outlines and contain numerous capillaries. Groups of more than 10 terminal villi with more than 10 capillaries (actually more than 15 are usually present) involving several areas per microscopic section is definitional [4] (Fig. 19.87). The capillaries are centrally located with a thin basement membrane, and pericytes are absent. This condition is distinguished from congestion in which capillaries are prominent but normally distributed and not numerically increased.

Chorangiosis occurs in approximately 7% of placentas, usually at or near term, and often large with delayed villous maturation. The changes are common in diabetics. The occurrence of chorangiosis in pregnancies at high altitude suggests that it is an adaptive response to hypoxia [177]. While frequent in cases with abnormal outcome, chorangiosis has not yet been shown to be an independent causative factor [110].

In *diffuse, multifocal chorangiomatosis*, villous capillaries are also numerically increased, but unlike chorangiosis, they are accompanied by pericytes, involve stem villi, and usually occur in immature placentas of less than 32 weeks. The clinical significance of this recently described and uncommon lesion has not been fully defined [110].

Subamnionic Hematoma

A subamnionic hematoma lies between the amnion and chorion on the fetal surface of the placenta. It most often

Fig. 19.87 Chorangiosis. Small, central villous capillaries are greatly increased

results from trauma to the chorionic vessels during delivery, especially after excessive traction on the umbilical cord. Occasionally, particularly if the umbilical cord is short or entangled, sufficient traction may develop during labor to cause vessel rupture and significant fetal blood loss. This is virtually impossible to distinguish from the common thirdstage hemorrhage. Laceration of chorionic plate vessels during amniocentesis may also lead to subamnionic hemorrhage, sometimes severe. Older subamnionic fibrin clots form dome-shaped blisters containing a mixture of browntinged fluid and fibrin. Lesions diagnosed by ultrasound between the 18th and 30th weeks of gestation have been associated with elevated maternal alpha-fetoprotein levels, vaginal bleeding, polyhydramnios, and IUGR [33].

Fetal Membranes

The fetal membranes and contiguous placenta form a sac containing amnionic fluid in which the fetus grows and develops. The fetal membranes provide a crucial barrier against infection, contain the amnionic fluid, and have metabolic functions including the modulation of events related to the onset of labor. The fetal membranes examined in their natural anatomic configuration after reconstructing the gestational sac as it exists in utero permits assessment of size, completeness, membrane insertion, and point of rupture. The distance from the point of membrane rupture to the edge of the placental disk reflects the site of uterine implantation; the lower the implantation, the closer the membrane rupture site is to the disk. A configuration indicative of low implantation should prompt consideration of associated conditions such as marginal hematoma or placenta accreta. Microscopic sections of the fetal membranes include fetal amnion and chorion and maternal decidua. The amnion is composed of amnionic epithelium and a connective tissue layer separated from the surrounding chorion by a loose spongy layer. The chorion is also composed of a connective tissue layer and a cellular layer containing chorionic type IT and atrophied villi. The most peripheral layer is maternal decidua (**)** *Fig.* 19.5).

Squamous Metaplasia

Foci of squamous metaplasia are slightly elevated, sometimes targetoid, pearly-white macules that tend to be most numerous at the site of cord insertion (\bigcirc *Fig. 19.88*). Although they are generally no more than a few millimeters, rarely they may form larger plaques. Histologically, foci of squamous epithelium, with or without keratinization, have a sharp transition with the surrounding amnionic epithelium. Squamous metaplasia has no clinical significance, but it is important to distinguish from amnion nodosum, which it superficially resembles grossly.

Amnion Nodosum

Definition and pathology. Amnion nodosum is a rare condition in which the amnionic surface is studded with small (1–5 mm), irregular, yellowish elevated nodules (\bigcirc *Fig. 19.89*). These nodules are generally concentrated on the chorionic plate, particularly around the insertion of the umbilical cord, although they may occur anywhere on the amnionic surface. The nodules are composed of amorphous, eosinophilic material containing cells and hair

Fig. 19.88

Squamous metaplasia. Squamous metaplasia is visible as elevated white macules

fragments (\bigcirc *Fig. 19.89*). The amnionic epithelium may be totally or partially preserved or absent beneath the nodules, and a layer of amnionic epithelium is commonly present over their surfaces.

Etiology and clinical features. Amnion nodosum is associated with oligohydramnios. The particulate debris and cellular elements from the fetal epidermis, oral cavity, urinary and gastrointestinal tracts, and the amnion itself are abnormally concentrated when amnionic fluid is scant and are deposited on the amnionic surface. The cause of the oligohydramnios varies. In many cases, a fetal urinary tract abnormality (renal agenesis or urinary tract obstruction) is responsible for diminished fetal urine resulting in decreased amnionic fluid. Oligohydramnios may occur in association with IUGR or in the donor twin in the twin-twin transfusion syndrome. Long-standing amniorrhea is less likely to result in amnion nodosum than decreased amnionic fluid production, presumably because in the former, the cellular and particulate debris are lost along with the amnionic fluid. Amnion nodosum is a reliable indicator of oligohydramnios that should prompt an investigation for fetal abnormalities known to accompany it, including urinary tract anomalies and pulmonary hypoplasia.

Amnionic Bands

Definition. Separation of the amnion and chorion results in amnionic fragmentation, shredding, and exposure of mesoblastic tissue, leading to the formation of thin fibrous strands. These encircle fetal limbs, digits, neck, and umbilical cord, causing characteristic constriction, amputation, and syndactyly (**)** *Fig. 19.90*). Some babies with characteristic amnionic band defects have additional structural

Fig. 19.89

Amnion nodosum. Irregular elevated amnionic nodules (*left*) correspond to nodular deposits composed of degenerating cell fragments and hair embedded in amorphous granular material (*right*)

Fig. 19.90 Amnionic bands. Amnionic bands entangle limbs (a), digits (b), and the umbilical cord (c)

anomalies, usually severe, including major limb deficiencies, body wall or open cranial defects, short umbilical cord, club feet, or internal abnormalities. The wide spectrum of anomalies in this condition has been variously referred to as the *amnionic band syndrome*, *amnionic band disruption complex*, *early amnion rupture sequence*, *limb–body wall complex*, and *amnion adhesion malformation syndrome*. *Pathology.* Gross identification of the bands and strings may be difficult, sometimes facilitated by submersion of the placenta in water. The surface of the placenta may be dull and slightly roughened, also subtle findings. Microscopically, the bands usually consist of fibrous tissue, but occasionally amnionic epithelium is recognizable. Amnion is absent from the placental surface and the chorion is fibrotic. In cases associated with body wall or open cranial defects, the amnion may be continuous with the fetal skin at the site of the defect. Broad adhesions may occur between the placenta and fetus.

Etiology. Multiple theories have been proposed to explain the abnormalities in this syndrome. Torpin strongly espoused the concept that amnionic bands cause the structural defects [182]. The widely variable nature of the defects has been attributed to the timing of amnionic rupture; early rupture is thought to result in fetal compression, tethering, or swallowing of bands, resulting in severe multisystem defects, whereas constriction and amputation defects in limbs and digits have been attributed to amnionic rupture later in pregnancy. Malformations are thought to result when a band interferes with the normal sequence of embryonic development. Kalousek maintains that the extent of amnionic bands is as important as the developmental stage at which they occur in determining of the pattern of fetal involvement [72]. The etiology of amnionic rupture is unknown. Amnionic bands have been noted rarely after trauma, amniocentesis, and in women with connective tissue disorders. Others have postulated that the amnionic bands are secondary and that the more severe fetal abnormalities are the result of vascular disruption or a primary embryologic defect.

Clinical significance. The recognition of amnion rupture and its consequences are important in counseling parents because the risk of recurrence is negligible. Unless accompanied by typical constriction/amputation lesions, major craniofacial or body wall defects may be difficult to diagnose. An important clue is the variety and asymmetry of the fetal defects, which are unlike the pattern of any heritable syndrome. No two cases are alike.

Meconium Stain

Definition and frequency. Meconium, the intestinal contents of the fetus, is commonly passed into the amnionic fluid. The reported prevalence ranges from 7 to 25%. Meconium passage is especially common in post-term placentas, present in up to 31%. It is unlikely to be present before 30 weeks.

Pathology. Meconium can often be identified on gross examination, its appearance correlating roughly with the chronicity of meconium passage. Meconium passed shortly before delivery may be recognizable as such. The membranes become progressively green-stained and slimy, with longer exposure, dark and edematous, and eventually dull, muddy brown (> *Fig. 19.91*).

Microscopically, free meconium consists of amorphous green-brown material and anucleate squames. The amnionic epithelium exposed to meconium shows degenerative changes including heaping, stratification, and eventually nuclear pyknosis and necrosis. There may be marked edema of the spongy layer. With time, meconium is engulfed by macrophages in the amnion, chorion, and decidua (\bigcirc *Fig.* 19.92). In vitro studies indicate that meconium appears in amnionic macrophages in 1 h and in deeper chorionic macrophages within 3 h [99]. How closely these observations approximate events in vivo is unknown. Meconium is usually scant in the umbilical cord due to the paucity of macrophages. As meconium

Fig. 19.91 Meconium stained placenta

Fig. 19.92

Meconium reaction. Amnionic epithelium is heaped and stratified with macrophages containing meconium in the subjacent stroma

passes through the membranes and cord, it eventually reaches the large fetal vessels where the toxic effect of its constituents can lead to apoptotic cell death of medial smooth muscle cells at the periphery of umbilical or chorionic plate vessels (\bigcirc *Fig. 19.93*).

Meconium must be distinguished from hemosiderin, generally a larger, more refractile, and yellowish crystalline granule. Iron stain is helpful when an ambiguous pigment is encountered. Lipochrome and nonhemosiderin, nonmeconium pigments of unknown composition, have been identified in a variety of diverse clinical situations. It has been hypothesized that these pigments may represent metabolites of remotely passed meconium.

Clinical significance. Meconium staining has long been perceived as an indicator of perinatal morbidity. Meconium passage has been significantly associated with parameters of fetal distress including low Apgar scores, umbilical artery pH of 7.0 or less, respiratory distress, seizures in the first 24 h, and need for delivery room resuscitation. Neonatal morbidity of all kinds has been significantly associated with meconium stained as compared to clear amnionic fluid [84]. Equally clear is that many infants, especially at term or post-term, pass meconium as a reflection of physiologic maturity, usually unassociated with significant problems. The role of meconium as the primary factor in perinatal injury is, therefore, controversial. The most important consideration is the circumstance under which meconium is passed. Meconium staining is often superimposed on other significant pathologies, especially chorioamnionitis, that

may represent the major injurious factors. Meconium may, however, potentiate the effects of these underlying pathologies. For example, the growth of group B streptococcus is enhanced by the presence of meconium, and meconium has been shown to inhibit neutrophil function in vitro.

Meconium may induce injury directly (in amnionic epithelium and umbilical and chorionic plate vessels) and has also been demonstrated to cause vasoconstriction, a potential cause of ischemia [5, 173]. There is some evidence that meconium may interfere with surfactant function and, in high enough concentrations, have a direct toxic effect on type II pneumocytes, possibly contributing to the meconium aspiration syndrome [27]. The role of meconium as the primary factor in the meconium aspiration syndrome is controversial. Autopsy studies indicate that in most cases, meconium aspiration to intrauterine infection and chronic hypoxia [52].

Gastroschisis

Gastroschisis is a defect in the paraumbilical abdominal wall through which bowel protrudes. This is distinguished from the more common omphalocele in which bowel protrudes into a saccular defect at the cord insertion but remains enclosed in peritoneum and amnion. Gastroschisis is characterized by extensive fine, uniform vacuolization of amnionic epithelial cells (\bigcirc *Fig. 19.94*).

Fig. 19.93

Meconium induced vascular changes. The outer smooth muscle in the wall of this umbilical artery has undergone apoptosis in response to prolonged meconium exposure. The nuclei are pyknotic and the cytoplasm is dense and eosinophilic

Fig. 19.94

Gastroschisis. The amnionic epithelium in gastroschisis shows fine vacuolation. The epithelial stratification in this case is the result of meconium passage Ultrastructural studies confirm that the vacuoles contain lipid, but the origin of the lipid is obscure. These amnionic changes are not present in omphalocele.

Extramembranous Pregnancy

Rarely the amnion and chorion rupture completely leaving the fetus to develop outside the membranes. The placenta is invariably circumvallate and the umbilical cord is short. Amnion nodosum and membrane hemosiderin deposits are common. Pulmonary hypoplasia is common and often fatal. Compression deformities may occur. There is often a maternal history of amniorrhea and vaginal bleeding.

Umbilical Cord

Normal Anatomy and Embryonic Development

Early in gestation, the blastocyst is filled with a loose meshwork of extraembryonic mesoderm that cavitates centrally to form the chorionic cavity. The embryonic structures are connected to the trophoblastic shell by a bridge of extraembryonic mesoderm, the connecting stalk, and forerunner of the umbilical cord. The yolk sac and the allantois protrude into the connecting stalk. As the amnion enlarges, the embryo prolapses into the amnionic cavity, progressively lengthening the connecting stalk. The allantoic vessels connect with vessels developing independently in the villi to establish the fetoplacental (chorio*allantoic*) circulation.

The normal umbilical cord contains two arteries and one vein suspended in Wharton's jelly, a loosely structured myxoid tissue covered by firmly attached amnion. Wharton's jelly is derived from the extraembryonic mesenchyme and consists of myofibroblasts and abundant ground substance. The combination of loose gel and contractile cells helps maintain turgor and protect the vessels against compression. The umbilical cord is supplied by oxygen and nutrients from the umbilical vessels. No other vessels or lymphatics are found in the normal umbilical cord. Most umbilical arteries are either fused or connected via an anastomosis (Hyrtl's anastomosis) generally within 1.5 cm of the placental insertion site. This connection is important to equalize flow and distribute blood uniformly to the placenta. The normal umbilical cord is spiraled, usually counterclockwise (counterclockwise/clockwise = 7:1), and the average number of coils is \sim 0.2 coil/cm. The spiral is established early in the first trimester as demonstrated sonographically.

Vestigial Remnants

Vestigial remnants dating back to formation of the connecting stalk and umbilical cord are common microscopic findings. The presence of vestigial remnants has not been correlated with congenital anomalies, maternal age, race, gravidity, or gestational age at delivery. Remnants of the allantoic duct are frequent (about 15%) in the proximal portion of the cord. They are lined by flat or cuboidal cells reminiscent of transitional epithelium, with or without a lumen (**>** *Fig. 19.95*). *Allantoic remnants* are located between the umbilical arteries. Rarely, they are large

Fig. 19.95 Allantoic (*left*) and omphalomesenteric remnants (*right*)

enough to expand the cord or they may remain patent predisposing to urinary leakage from the cord stump.

Traces of the omphalomesenteric duct, which connects the fetal ileum and the yolk sac in the early embryo, are infrequent, occurring in 1.5% of umbilical cords. These remnants are usually discontinuous, located peripherally, and lined by columnar cells resembling intestinal epithelium (> Fig. 19.95). Omphalomesenteric remnants sometimes have a muscular wall, occasionally containing ganglion cells, liver, pancreas, gastric, or small intestinal mucosa. Vitelline vessels may accompany omphalomesenteric remnants or they may occur in isolation. These are usually paired but sometimes clustered, lined by endothelium lacking a muscular coat. Omphalomesenteric remnants are of little clinical significance. They are rarely associated with Meckel's diverticulum, small intestinal atresia, or intestinal protrusion into the cord that may be inadvertently clamped or cut. Cystic omphalomesenteric remnants are rare, more common in males (M:F = 4:1). The yolk sac remnant is commonly visible as a small white nodule between the amnion and chorion composed of amorphous basophilic material histologically.

Stasis Problems and "Cord Accidents"

The umbilical cord is a crucial lifeline between the fetus and placenta. Cessation of or diminished umbilical blood flow can result in severe fetal compromise or death. Umbilical flow may be compromised by mechanical factors (compression), vessel damage (trauma, inflammation, or meconium), or thrombosis. Cord abnormalities with the potential for obstruction of blood flow - abnormal coiling, stricture, abnormal length, true knots, entanglements, prolapse, and velamentous insertion - have been associated with increased risk of IUFD, IUGR, and neurologic injury [12, 13]. Many of these conditions are related; true knots and excessive coiling commonly occur in long cords, and stricture almost always occurs in a hypercoiled cord. Chronic partial or intermittent flow obstruction may be evidenced by umbilical, chorionic, or stem vessel dilatation and thrombosis, intimal fibrin cushions, and/or villous alterations reflecting fetal vascular occlusion (FAV/ villous stromal-vascular karyorrhexis) [113]. Based on these findings, non-acute cord compression has been implicated in over half of unexplained fetal deaths. Acute flow obstruction may supervene when a knot or entanglement tightens during delivery or there is cord prolapse. Doppler studies have confirmed that cord obstruction and compression impede venous return. Increasingly sophisticated imaging techniques provide opportunities for

better assessment of the relationship between pathologic findings and significant alterations in blood flow.

Cord Length

Umbilical cord length is an important parameter most accurately documented in the delivery room before the cord shrinks or cord segments are removed for other studies. Cord length declines by as much as 7 cm during the first few hours after delivery. Standards for cord length relative to gestational age have been established [84]. The mean cord length at term is about 55–60 cm.

Cord length reflects factors that influence its growth – mainly tensile forces related to fetal activity and intrauterine conditions affecting fetal movement. Umbilical cord growth slows during the last trimester as room for fetal movement declines, although some cord growth occurs normally until term. Conditions restricting fetal mobility – amnionic bands, oligohydramnios, and crowding (multiple pregnancy) – are often associated with relatively short cords. Infants with Down's syndrome have short cords. Naeye has correlated short cord with subsequent motor and mental impairment [104]. Whether cord length as an indirect indicator of fetal movement can be correlated ultimately with antenatal neurologic development deserves further study.

Extremes of cord length are associated with potentially adverse outcomes. Some consideration of relative as well as absolute cord length is appropriate. For example, a long cord with extensive looping may function as a relatively short cord.

Short Cord

Definition and frequency: Gardiner's calculation that a normal vertex delivery requires a minimum cord length of 32 cm provides a common definition of an abnormally short cord [49]. Using this definition, between 0.4 and 0.9% of umbilical cords are abnormally short. Berg and Rayburn found that 2% of cords are less than 35 cm [19].

Clinical significance: Unduly short cords have been linked to fetal distress in some cases, although blood pH and base deficit values in short cords are reportedly the same as in cords of normal length [19]. In the absence of fetal anomalies, short cords have been associated with low Apgar scores, neonatal hypotonia, and need for resuscitation. Short cords may be associated with rupture or hemorrhage, delayed second stage of labor, abruption, subamnionic hemorrhage, and uterine inversion. At the extreme, there may be complete or near-complete cord absence (acordia) characteristically associated with fetal anterior abdominal wall defects that are directly attached to the placenta.

Long Cord/Entanglements/Prolapse

Definition and frequency. Excessively long cords have been variously defined as greater than 70 [13], 80 [19], or 100 cm [84]. Cord entanglements encircling the fetal neck, body, and extremities are common, occurring in about 23% of deliveries, but they are much more common in excessively long cords. Umbilical cord prolapse is an obstetric emergency defined as presentation of the cord in advance of the presenting part, occurring in 0.25–0.5% of deliveries.

Clinical significance. Long cords have been associated with IUGR, IUFD, brain imaging abnormalities, and poor neurologic outcomes [12, 13]. Histological evidence consistent with venous obstruction has been described in the placenta. Abnormally long cords are also associated with excess knotting, hypercoiling, entanglements, and prolapse. Most cord entanglements do not have adverse outcomes, but some may result in cord compression. Tight entanglements have been associated with low Apgar scores and stillbirths. Babies with sonographically documented nuchal cords have higher rates of cesarean section and NICU admission. Nuchal cords have been demonstrated as a cause of IUGR, indicating that the deleterious effect is long term in some cases [175]. Tight nuchal cords restricting venous return may result in neonatal anemia or even hypovolemic shock. Cerebral palsy has been linked to tight nuchal cords at delivery [109]. Cord prolapse has a perinatal mortality rate of 20% [91].

Pathologic changes. Constriction of the umbilical cord and the encircled fetal part may be dramatic in some cord entanglements. Cord compression may be associated with edema, venous congestion, hemorrhage, and thrombosis of umbilical or large chorionic plate vessels and/or villous abnormalities reflecting fetal vascular occlusion.

Knots

Frequency and etiology. Between 0.35% and 0.5% of umbilical cords contain true knots. True knots (**)** *Fig. 19.96*) should be distinguished from false knots, which are focal accentuations of the vascular spiral, a varicosity, or excess Wharton's jelly (**)** *Fig. 19.97*). True knots are thought to be related to fetal movement and are increased in long cords, male fetuses, monoamnionic twins, multigravidae,

Fig. 19.96

True knots. Long cord with two true knots (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.97 False knot

and in association with excess amniotic fluid. They occur with equal frequency in abortions and term deliveries indicating that they probably develop early in pregnancy when there is ample opportunity for movement.

Pathology. Umbilical cord knots should be assessed for evidence of chronicity, tightness, and circulatory compromise. In long-standing tight knots, there is grooving and loss of Wharton's jelly with constriction of blood vessels, changes that persist when the knot is untied. Thrombosis of umbilical or chorionic plate vessels, sometimes calcified, and villous alterations reflecting fetal vascular occlusion indicate chronic vascular obstruction. Acutely tightened knots may be associated with venous distention distal to the knot, edema, and villous vascular congestion. Clinical significance. True knots are associated with an overall perinatal mortality rate of 8–11%, attributable to their potential for fetal circulatory obstruction (\triangleright Fig. 19.98). Either an acutely tightened or longstanding knot may be responsible for intrauterine or intrapartum fetal death [64]. False knots are generally of no clinical significance with only rare instances of thrombosis.

Torsion

Definition and frequency. The normal umbilical cord averages about 0.2 coils/cm (coiling index = no. of coils per cord length). Hypercoiled cords are generally considered to be those in which the coiling index is >0.3 coils/cm, and hypocoiled cords are those in which the coiling index is <0.1 coils/cm [84]. In one study, 7.5% of 120 unselected placentas had hypocoiled cords and 20% had hypercoiled cords [92]. About 4-5% of cords are noncoiled. Umbilical cord coiling is thought to reflect fetal movement; it is decreased in association with uterine constriction or fetal abnormalities that affect movement. Hypocoiled cords have been reported to occur more commonly in twins and in babies with chromosomal abnormalities. Hypercoiling is more common in long cords, male fetuses, multigravidae (presumably due to more room for fetal movement), and in association with maternal cocaine use.

Pathology. Hypercoiling may be localized or affect the entire cord (\triangleright *Fig. 19.99*) or be associated with stricture

(*Fig. 19.100*). Thrombosis of umbilical and chorionic plate vessels, intimal fibrin cushions, and vascular calcification suggest a chronic process in some cases. Hypocoiled cords are often thin with decreased Wharton's jelly.

Clinical significance. Hypercoiled cords have the potential for blood flow obstruction. Hypercoiling has been associated with adverse fetal outcome, including fetal IUGR, intolerance of labor, and IUFD [32]. Absent or minimal coiling is associated with fetal anomalies, chromosomal errors, fetal distress, and increased fetal and neonatal morbidity and mortality.

Stricture

Definition and etiology. An umbilical cord stricture is a sharply defined, usually short narrowed segment with decreased Wharton's jelly and vascular constriction

Fig. 19.99 Hypercoiled cord

 Fig. 19.98
Tight knot resulting in intrauterine fetal demise (IUFD).
(Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

 Fig. 19.100
Hypercoiled cord with stricture and intrauterine fetal demise (IUFD). (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) (Fig. 19.100). The etiology is unknown, but it rarely occurs outside the setting of excess torsion. Alternatively, it has been hypothesized to be the result of a primary deficiency of Wharton's jelly, perhaps an exaggeration of the normal gradual loss of Wharton's jelly at the fetal end of the umbilical cord.

Pathology. Strictures are most common at the fetal end of the cord, although occasionally they may occur at the placental end or elsewhere. They are usually associated with excessively long and hypercoiled cords. Many are seen in association with macerated fetuses, although the abnormality is not confined to abortions. The strictured segment shows decreased Wharton's jelly and vascular, especially venous, compression. Placental surface vessels may be thrombosed.

Clinical significance. Umbilical cord strictures are often associated with abortion [115]. Strictures have recurred in successive pregnancies and have been proposed as a cause of non-immune hydrops.

Cord Diameter

Umbilical cord diameter is affected by the number of vessels and the amount and fluid content of Wharton's jelly. Nomograms generated from uncomplicated pregnancies indicate a progressive increase in sonographic cord diameter and cross-sectional area until 32 weeks gestation with a decline thereafter presumably due to a reduction in fluid content of Wharton's jelly. Patel and colleagues established the normal cord circumference to be 37.7 \pm 7.73 mm [114]. Silver and colleagues determined that cord diameter ranged from 1.25 to 2.00 cm and circumference from 2.4 to 4.4 cm [174]. The factors that determine the amount of Wharton's jelly and its water content are poorly understood. More cord jelly and vascular spiraling have been associated with better fetal outcome, while compression patterns on fetal heart tracings occur more often in cords with decreased fluid content [174]. A thin ("lean") cord with decreased or absent Wharton's jelly may be associated with IUGR. At present, a lean cord is defined as one with a cross-sectional area less than the tenth percentile as assessed sonographically or 8 mm or less along its entire length [121, 139]. Diminished size appears to be due to a reduction in Wharton's jelly. Lean cords tend to have a lower coiling index and reduced umbilical vein flow normalized for fetal weight [36].

Cord edema, focal or diffuse, occurs inconsistently in a variety of clinical situations, especially diabetes, but often the cause is unknown. Edema is more common in prematures.

Rupture

Complete cord rupture is very rare. Most cord ruptures complicate precipitous delivery, but rarely rupture may occur in the early stages of labor or before labor begins. Short and velamentously inserted cords, trauma, or inflammation are proposed etiologic factors.

Insertion

Velamentous Insertion and Membranous Vessels

Definition and frequency. In velamentous insertion, the cord inserts into the fetal membranes.

Velamentous insertion is a common anomaly, occurring in about 1% of placentas. It is greatly increased in multiple pregnancies, extrachorial placentas, and in single-artery cords. Velamentous insertion is also reportedly increased in association with cigarette smoking and advanced maternal age. An associated condition, *vasa previa*, occurs when membranous vessels in the fetal membranes present in advance of a fetal part.

Pathology. After insertion, the umbilical vessels usually branch in the fetal membranes (**)** Fig. 19.101). Having lost their protective covering of Wharton's jelly and unsupported by underlying villous tissue, membranous vessels are vulnerable to injury – traumatic rupture, hemorrhage (**)** Fig. 19.102), compression, and thrombosis, especially when they traverse the cervical os in advance of the fetus. The length of membranous vessels provides

Fig. 19.101 Velamentous insertion

Fig. 19.102

Velamentous insertion. A ruptured membranous vessel is associated with surrounding hemorrhage (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

one measure of the degree of their vulnerability. Membranous vessels are not limited to velamentously inserted cords but may arise aberrantly from marginally or even centrally inserted cords, and they regularly supply succenturiate lobes. As a site of significant pathologic alterations, all membranous vessels should be inspected carefully and included in sections for microscopic exam. Rarely a velamentously inserted cord retains its Wharton's jelly, running in the membranes before its vessels branch (*interposito velamentosa*).

Etiology. Velamentous cord insertion may be due to malpositioning of the blastocyst at implantation with consequent aberrant body stalk – placental disk orientation (polarity theory). Alternatively, velamentous insertion may result when the placenta "moves" from its initial implantation site, leaving the cord insertion behind (trophotropism theory). This placental remodeling, probably in response to uterine crowding and/or maternal vascular supply, involves simultaneous atrophy on one aspect and growth/expansion on the other. The increased frequency of velamentous cord insertion in multiples, in uteri with structural defects and foreign bodies and the sonographic documentation of eccentric placental expansion with conversion of placenta previa to a higher uterine position support the trophotropism theory.

Clinical features. Velamentous cord insertion has several important clinical associations. The best-documented complications are related to the vulnerability of membranous vessels. Vessel compression with severe fetal distress or laceration with blood loss, even exsanguination, may occur suddenly during labor. Although bleeding is most common from membranous vessels near the os at the time of labor, bleeding may also occur antepartum and from vessels located higher in the uterus. Thrombosis of membranous arteries and veins has been associated with major fetal thromboembolic events and fetal death.

Velamentous cord insertion also provides a marker for poor placentation with decreased placental vascularization. This may explain its reported association with low birth weight, low Apgar scores, and abnormal fetal heartrate patterns. Velamentous cord insertion has also been associated with congenital anomalies, occurring in 8.5% of infants and in as many as 25% of spontaneous abortions with velamentous cords. The structural anomalies associated with velamentous cord insertion are deformations not malformations or disruptions indicating that they and the velamentous insertion are both the result of competition for intrauterine space. Velamentous cord insertion is significantly more common in monochorionic gestations with the twin–twin transfusion syndrome than in those without it.

Marginal Insertion

Definition and frequency. Umbilical cord insertion at the edge of the placental disk is termed a marginal or *Battledore* insertion. Marginal insertion occurs in about 7% of placentas and is hypothesized to develop via the same mechanism as velamentous insertion (abnormal primary implantation versus trophotropism).

Clinical associations. The clinical significance of marginal insertion is debated. Marginal insertion has been reported to occur with increased frequency in abortions and malformed infants and in association with neonatal asphyxia and PTL, although these associations have not been confirmed by others. Peripheral cord insertion (velamentous, marginal, and markedly eccentric) has been associated with discordant growth and SGA in twins [140].

Furcate Insertion

In furcate insertion, the cord loses Wharton's jelly before insertion, leaving the umbilical vessels unsupported (**>** *Fig. 19.103*). Furcate cords may insert velamentously or into the placental disk.

The unsupported vessels are subject to the same complications as membranous vessels.

Tethered Insertion ("Amnionic Web")

Amnionic webs or chorda are amnionic folds that encase the cord at the insertion site (> Fig. 19.104).

Large tight amnionic webs may limit mobility of the cord, potentially compromising blood flow.

Umbilical Vessels

Numerical Variation

Single Umbilical Artery

Definition and frequency. The presence of a single umbilical artery (SUA) is a common and important cord

Fig. 19.103 Furcate insertion

abnormality. In prospective studies of consecutive deliveries, the frequency of single umbilical artery is consistently somewhat less than 1%, although the frequency is considerably higher in perinatal autopsy studies (2.7-12%) and in spontaneous abortions (1.5-2.7%). The frequency of single umbilical artery is higher in white women, diabetic mothers, multiples, and chromosome abnormalities especially trisomies.

The likelihood of diagnosing single umbilical artery is increased when fixed versus fresh cords are examined, and histologic exam provides the most accurate means of establishing the diagnosis. Cord vascularity should be assessed at least 3-5 cm from the placental insertion site because the umbilical arteries frequently fuse close to the placenta.

Etiology. Whether single umbilical artery is due to primary aplasia or secondary atrophy has long been debated. When specifically sought, histologic evidence of vascular remnants is demonstrable in some single artery cords. The higher incidence of single umbilical artery in fetuses as compared to early embryos provides circumstantial evidence that single umbilical artery may be an acquired defect.

Pathology. Muscular or elastic remnants of an atrophied vessel are identified in some cases. Single artery cords are commonly associated with velamentous insertion (as high as 12%), circumvallation, and a magistral pattern of chorionic blood vessels. On occasion, two umbilical arteries are present but are of markedly different size. A difference of at least 1 mm in umbilical artery diameter as established sonographically is considered discordance [120] (> Fig. 19.105). Marked umbilical

Fig. 19.104 Tethered insertion

Fig. 19.105 Discordant umbilical arteries

artery discordance may be associated with fetal anomalies similar to those encountered with single umbilical artery.

Clinical Significance Congenital malformations. There is a well-documented association between single umbilical artery and fetal malformations, but there is no particular organ or specific abnormality characterizing this association. Any organ system may be affected, and malformations are frequently multiple. Congenital malformations are most numerous and most severe in stillborn and aborted babies and those dying in the neonatal period. Infants with single artery cords but no detectable abnormalities at birth who survive the neonatal period are unlikely to have other significant abnormalities detected subsequently. Single umbilical artery is almost invariable in sirenomelia and acardiac fetuses. Whether single umbilical artery plays a role in the development of congenital malformations or is just another manifestation of them is unclear.

Perinatal mortality. The perinatal mortality rate of infants with single umbilical artery is greatly increased (11–41%). This is attributable to associated major malformations in most instances, although otherwise normal infants with single umbilical artery have an increased perinatal mortality rate as well. The sonographic demonstration of decreased Wharton's jelly in single artery cords may contribute to cord vulnerability.

Low birth weight. Single umbilical artery is associated with low birth weight even when infants with malformations are excluded from analysis.

Vascular Abnormalities

Segmental Thinning

Quereshi and Jacques reported segmental thinning of umbilical vessels with virtual absence of the media in 1.5% of consecutively examined placentas [119]. The umbilical vein was involved in the majority of cases, although on occasion, one or both arteries exhibited identical changes. Both superficial and medial aspects of the vessels exhibited wall deficiencies. Segmental vascular thinning was accompanied by fetal malformations in a significant number of cases, and there was a high incidence of fetal distress.

Meconium-Induced Necrosis

Long-standing meconium exposure may induce muscle necrosis in umbilical and chorionic plate vessels. Myonecrosis usually involves the superficial aspects of the arteries closest to the surface. The necrotic cells are rounded with dense eosinophilic-smudged cytoplasm and pyknotic nuclei (\bigcirc *Fig.* 19.93) [82]. Meconium-associated vascular necrosis has been linked to cerebral palsy [145]. In addition to vascular damage, meconium has been shown to cause vasoconstriction of umbilical vessels in vitro [5].

Ulceration

Linear ulceration of Wharton's jelly with vascular necrosis, aneurysmal dilatation, and rupture may result in intraamnionic hemorrhage, profound fetal anemia, and fetal death in utero (**>** *Fig. 19.106*). These cord anomalies

Fig. 19.106

Ulceration of Wharton's jelly. Necrosis of Wharton's jelly with thinning and rupture of umbilical vessels resulted in IUFD in this baby with duodenal atresia (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

have been described in association with fetal intestinal atresia.

Thrombosis

Definition and frequency. Thrombosis of umbilical vessels may be occlusive or non-occlusive, and is often associated with similar changes in chorionic plate or stem villous vessels. Thrombosis of umbilical cord vessels is uncommon, occurring in 1 in 1,300 deliveries, 1 in 938 perinatal autopsies, and 1 in 250 high-risk pregnancies [164].

Etiology. Thrombi may be associated with cord compression, abnormal coiling, knots, stricture, hematoma, inflammation, anomalous insertion, amnionic bands, or entanglements. Other factors such as thrombophilic states could act synergistically to precipitate thrombosis. In many instances, the etiology is obscure.

Pathology. Thrombi more commonly involve the umbilical vein alone (71%) with a lesser frequency of combined vein and artery thrombosis (18%) or arterial thrombosis alone (11%). Thrombi may be associated with vessel calcification and necrosis (\bigcirc *Fig. 19.107*). The chorionic plate and stem villous vessels may be similarly affected.

Clinical significance. Fetal morbidity and mortality is high, particularly with occlusion of both umbilical arteries. Thrombi may embolize to the fetus causing infarcts in fetal organs or they may result in the loss of a significant fraction of the fetoplacental circulatory bed. Thrombi have also been associated with cerebral palsy, massive fetomaternal hemorrhage, IUGR, and IUFD.

Hematoma

Definition and frequency. Umbilical cord hematomas are accumulations of blood in Wharton's jelly. They are uncommon.

Fig. 19.107

Thrombosed umbilical artery. This thrombosed umbilical artery, cause undetermined, is visible as a dark spiral and was completely necrotic (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology) *Etiology.* In the great majority of cases, an obvious etiology is not apparent. Rarely, hemorrhage has a demonstrable origin from an umbilical vein or artery, and origin from omphalomesenteric vessels has been proposed. Rupture of a varix, traumatic damage at the time of amniocentesis or percutaneous umbilical cord sampling, or inflammation or structural anomalies of a vessel wall have been suggested as possible mechanisms.

Pathology. Most umbilical cord hematomas present as red-purple fusiform swellings (**)** *Fig. 19.108*). They are usually single, but may be multiple or even involve the full length of the umbilical cord. They are generally confined to the cord, but on occasion, they may rupture into the amnionic cavity. Small collections of fresh blood usually reflect cord blood sampling or traction at the time of delivery.

Clinical significance. A perinatal mortality rate in the range of 40–50% has been reported in association with umbilical cord hematoma. Fetal death may be due to blood loss or umbilical vascular compression with circulatory compromise.

Hemangioma

Definition. Hemangiomas are benign lesions composed of proliferating vessels sometimes associated with marked myxoid degeneration of Wharton's jelly (angiomyxoma).

Fig. 19.108

Localized cord hematoma. (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Fig. 19.109

Umbilical cord hemangioma. (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

Pathology. Hemangiomas present as fusiform swelling of the umbilical cord usually at the placental end. They can attain substantial size (up to 900 g in one report) (\bigcirc Fig. 19.109). Microscopically, these benign tumors show features similar to benign hemangiomas at other body sites.

Clinical significance. Hemangiomas with myxoid degeneration (angiomyxoma) can be associated with hemorrhage, increased alpha fetoprotein levels, and rarely nonimmune fetal hydrops, presumably due to high output cardiac failure.

Aneurysm

Umbilical cord aneurysms are rare. They may be so large as to compress adjacent vessels resulting in fetal death. Umbilical artery aneurysm has been reported in trisomy 18 [168].

Clinical Syndromes and Their Pathologic Correlates in the Placenta

Placentas come to the pathologist with limited clinical data supplied by the obstetrician. The diagnoses or problems listed do not necessarily provide insight into the nature of the pathologic abnormalities that the pathologist should look for. Here follow definitions of common clinical conditions that lead to submission of a placenta for pathologic examination together with the relevant pathologic lesions.

Preeclampsia

Definition. A previously normotensive pregnant woman whose blood pressure reaches 140/90 mm Hg or greater after 20 weeks gestation on at least two occasions has pregnancy-induced hypertension. The addition of proteinuria (1+ or greater on urine dipstick confirmed by a 24 h collection containing \geq 300 mg of protein) means that preeclampsia has occurred. Severe preeclampsia indicates the addition of one or more of the following: blood pressure over 160 mm Hg systolic or 110 mm Hg diastolic; proteinuria greater than 5 g/24 h or 3+ or greater on two dipstick evaluations at least 4 h apart; headache; visual disturbances, epigastric, or right upper quadrant pain; oliguria; thrombocytopenia or liver enzyme elevation; fetal growth restriction; and/or pulmonary edema. The HELLP syndrome is a form of severe preeclampsia with a specific triad of findings including hemolysis, elevated liver enzymes, and low platelet count. Seizures signify the onset of eclampsia. Delivery of the placenta, often premature, is the only effective medical intervention.

Etiology. The spiral arteries that supply maternal blood to the placenta must expand to accommodate the growing placentofetal unit. This is normally accomplished by tro-phoblastic remodeling of spiral arteries. A failure of this process results in decidual vasculopathy, reduced maternal flow, placental ischemia, and the maternal syndrome of preeclampsia [90].

In preeclampsia, there is generalized maternal endothelial dysfunction thought to be caused by soluble factors produced by ischemic trophoblast. Endoglin and sFlt-1 are two factors that have been implicated. Both appear prior to disease onset and cause endothelial dysfunction and hypertension in the mother. These factors act by neutralizing the angiogenic and vasodilatory effects of vascular endothelial growth factor and placental growth factor produced by the placenta [102]. When endoglin and sFlt-1 are overexpressed in an experimental rat model, the result is severe proteinuria, hypertension, and growth restriction as well as thrombocytopenia and liver dysfunction [185].

Pathology. Correlation between placental lesions and severity of maternal symptoms is poor. Two types of abnormal placentas are associated with preeclampsia. The first and most common is the small placenta with decidual vasculopathy, especially acute atherosis, the pathologic changes characteristic of maternal vascular underperfusion, and thin umbilical cord. Less common is the large placenta associated with a heterogenous group of conditions including diabetes mellitus, placental hydrops, multiple gestation, and hydatidiform mole.

Essential Hypertension

Patients with preexisting hypertension not complicated by superimposed preeclampsia may have similar but less pronounced abnormalities in the villi. Arteriosclerotic changes in the uterine or intramyometrial arteries may be sufficient to produce some degree of placental ischemia.

Diabetes Mellitus

Placentas associated with uncomplicated maternal diabetes mellitus vary. In about half of cases they appear normal, grossly, and microscopically. Correlation between placental findings, metabolic control, and clinical severity are poor. When they are abnormal, diabetic placentas tend to be large and heavy, with large and edematous umbilical cords. Villi in the larger placentas often show chorangiosis and *distal villous immaturity*, large distal villi with increased central capillaries, macrophages, and interstitial fluid (\bigcirc *Fig. 19.110*). Placental, fetal, and neonatal thrombi are more frequent, a manifestation of the thrombophilia associated with diabetes. When complicated by hypertension or preeclampsia, the placenta may be small with evidence of low maternal flow.

Preterm Birth, Preterm Labor, and Preterm Rupture of Membranes

A term birth takes place between 37 and 42 weeks of gestation. The most severe sequelae for the newborn

Fig. 19.110

Distal villous immaturity. Increased numbers of large distal villi with increased capillaries and evenly distributed interstitial fluid

occur before the 34th week. The category of "VLBW" infants refers to live-born infants weighing between 500 and 1,500 g. These are at greatest risk of neonatal death, neurologic injury, and pulmonary immaturity. PTB occurs in 12–13% of all pregnancies in the United States. The result is a 40-fold increase in perinatal morbidity and mortality.

Most PTBs are due to ACA or preeclampsia. The two pathologic subgroups show very little overlap [8, 59]. ACA is most common, occurring in 61% of premature placentas delivered within 1 h of membrane rupture [58, 59]. ACA is more common in earlier PTB. Lesions resulting from impaired blood flow are more common in later PTB [61]. Premature labor and delivery also have a significant correlation with decidual hemorrhage, which may directly initiate prostaglandin release and labor.

Post-Term Pregnancy

A gestation longer than 42 completed weeks (294 days) is considered post-term. Perinatal mortality is increased. The postmature newborn has a characteristically slender, elongated body and limbs, dried, wrinkled, often meconium-stained skin, long fingernails, and an apprehensive expression. Meconium staining is more common in postterm placentas, but otherwise there are no distinctive or definitive pathologic changes in the placenta [17].

Fetal Growth Restriction, Intrauterine Growth Restriction (IUGR)

Prenatal evaluation of fetal growth is based on ultrasound measurements of abdominal circumference, head circumference, biparietal diameter, and femur length (among others), which may also be used to estimate fetal weight [152]. IUGR is a significant risk factor for poor outcome and stillbirth [184]. IUGR is symmetric when head and abdominal measurements are decreased proportionately, and asymmetric when there is a greater decrease in abdominal girth. When IUGR is identified, Doppler studies of blood flow through the umbilical cord, middle cerebral artery, or other sites may be obtained. Absent or reduced umbilical artery blood flow is a significant adverse finding, which may begin early and persist for weeks until delivery [154]. Infants whose birth weight lies below an expected percentile for gestational age (which may be arbitrarily set at the third, fifth, or tenth percentile) are classified as small for gestational age (SGA) and qualify as growth-restricted.

Maternal factors that contribute to IUGR include preeclampsia, hypertension, diabetes mellitus, thrombophilias, extreme malnutrition, chronic renal disease, tobacco and other drug abuse, and poor obstetric history in general. Fetal factors include chromosomal anomalies (including confined placental mosaicism), congenital malformations, and multiple gestation [190]. Placental lesions associated with IUGR include: (1) vascular lesions that reduce maternal blood flow (decidual vasculopathy or chronic abruption), (2) vascular lesions that reduce fetal blood flow, (FTV, large chorangiomas, or umbilical cord abnormalities), and (3) lesions that greatly reduce the amount of functional placenta (extensive chronic villitis, MPF, MFI, or multiple infarcts.) [167]

Neonatal Encephalopathy (NE), Cerebral Palsy (CP), and "Birth Asphyxia"

Historically, the occurrence of abnormal neurologic findings in the first week of life was assumed to have followed a period of asphyxia (severe hypoxia with metabolic acidosis) during labor and delivery. This concept led to such clinical terms as "birth asphyxia" and "hypoxic-ischemic encephalopathy." While episodes of pure hypoxia do occur (acute abruption is a good example), other factors – intrauterine infection and other acute and chronic placental lesions – are much more common. The transient clinical state, characterized by hypotonia, apnea, coma, and seizures, is now called *neonatal encephalopathy*. The incidence varies from 6 to 8 per 1,000 births.

Cerebral palsy, by contrast, is a chronic, nonprogressive neurologic disorder, most often a form of spastic diplegia, hemiplegia, or quadriplegia, with an incidence of 2 per 1,000 births. It is usually not diagnosed much before age 2 years, certainly not at the time of delivery. Approximately 50% of cases develop after fullterm birth following an apparently normal gestation. The remainder are divided between VLBW infants (<1.5 kg) and a heterogeneous group of low-birth-weight and nearterm infants, some with IUGR [133]. Extreme prematurity is a risk factor for both NE and CP [108]. In a large population-based study of term infants with neonatal encephalopathy, 13% subsequently developed cerebral palsy, while 24% of CP patients had a prior history of NE [11]. The overall incidence of CP has not changed much over the past 50 years despite advances in intrapartum monitoring and antenatal diagnosis.

Clearly, the placenta from every newborn with NE deserves careful attention from the pathologist [79]. Acute lesions associated with NE include large

retroplacental hematomas, meconium-associated vascular necrosis, and severe chorioamnionitis, especially with intense chorionic vessel inflammation [145, 150]. Chronic lesions include chorionic vessel thrombi, fetal thrombotic vasculopathy [97, 107], especially with cord abnormalities [128], placental or fetal hydrops, diffuse chronic villitis, especially with obliterative fetal vasculopathy, diffuse chorioamnionic hemosiderosis, and massive perivillous fibrin deposits [130].

Fetal and Placental Hydrops

Hydrops is a state of marked generalized edema, with accumulation of fluid in subcutaneous tissue, body cavities, placenta, and umbilical cord. Most cases are now detected by prenatal ultrasound. Prenatal investigation to assign a specific cause is urgent because many cases are potentially treatable. In fatal cases, determination of the cause is still important for parental counseling and for appropriate management of future pregnancies. Even in the absence of specific changes in the placenta, the pathologist has a primary role in coordinating other forms of laboratory testing, including cytogenetics, immunologic and microbiologic studies, immunohistochemistry, and fluorescence in situ hybridization.

Immune hydrops, caused by maternal isoimmunization to the Rh (mainly D) antigen expressed by the fetal red blood cells, still occurs, but is now rare due to anti-D gammaglobulin (Rhogam) prophyllaxis. Nonimmune hydrops is now more common, but still infrequent, with incidence figures from 1 in 1,400 to 1.34 per 1,000 live births [183]. There are numerous causes of non-immune placental or fetal hydrops. The main pathophysiologic categories are cardiac failure, anemia, and hypoproteinemia. Among the most important lesions are cardiac malformations, chromosomal anomalies (45XO, trisomies 21 and 18), thoracic lesions (congenital cystic adenomatoid malformation, pulmonary sequestration, or tumors), anemias (parvovirus infection or fetomaternal hemorrhage), fetal infections (TORCH group or syphilis), large tumors (sacrococcygeal teratoma or angiomas), and urinary tract anomalies [156]. Chromosomal anomalies are more common prior to 24 weeks; cardiac and pulmonary lesions are more common after 24 weeks [176]. Hydrops caused by parvovirus anemia, cardiac arrhythmias, and hydrothorax respond more favorably to prenatal treatment [176].

A hydropic placenta is often massively enlarged (exceeding 1,000 g), soft, friable, and pale (**>** *Fig. 19.31*). Histologically, the villi appear enlarged, cytotrophoblast

G Fig. 19.111

Fetoplacental hydrops. The villi are immature and edematous (*left*). When due to fetal anemia, nucleated red blood cells and erythroblasts expand the villous capillaries as in this case of Rh incompatibility

cells are increased with occasional mitoses, villous capillaries are reduced or inconspicuous, and the stroma is edematous (**>** *Fig. 19.111*). In cases of anemia, nucleated red blood cells (nRBC – erythroblasts and normoblasts) are very prominent, often in clusters that expand the capillary outlines.

Nucleated Red Blood Cells in the Fetal Circulation

nRBC are rare in sections of a normal term placenta or in the blood of normal newborns. Absolute counts in the range of 500-1,000 nRBC/mm3 or 1-10 nRBC/100 white blood cells in fetal or neonatal blood are normal; counts in excess of these figures are abnormal [63]. An increased number of nRBC in the circulation of newborns is a wellrecognized parameter of potential neonatal injury [63]. nRBC elevation is believed to be caused by acute or chronic fetal hypoxia resulting in erythropoetin release. The most dramatic nRBC elevations occur in the severe anemias associated with immune or non-immune hydrops and congenital infections (especially parvovirus). Anemia caused by fetomaternal hemorrhage, either acute or chronic, may elicit a marked nRBC elevation. nRBC elevation occurs in a number of other clinical settings including maternal diabetes, acidosis [89], IUGR, maternal smoking [193], and other infections [63].

Erythropoetin can be measured in amniotic fluid as well as in fetal blood. Elevations occur in maternal diabetes, fetal growth restriction, maternal smoking, fetal anemia, acidosis, prolonged heart rate deceleration (demonstrable prior to deceleration), and after acute or repeated fetal hemorrhages [181]. Amniotic fluid levels are lower but persist longer. Episodic periods of hypoxia in cord entanglement may be reflected in this way even when blood levels have returned to normal [60].

The time interval between an acute event and nRBC elevation is not established. Elevated lymphocyte and platelet counts (as well as increased nRBC) may correlate with the timing of prenatal neurologic injury; counts tend to be higher and last longer in newborns with long-standing hypoxic injury [106, 118].

Clinically significant nRBC elevations are usually evident on microscopic examination of the placenta (**)** Fig. 19.74) [29, 137]. Redline found a highly significant correlation between cord blood counts and the number of nRBC observed in ten high-power fields (40× objective) in the placenta; 10 nRBC/10 HPF corresponded to an absolute count of 2,500 nRBC/mm³ with 90% sensitivity and 82% specificity [137]. In this study of placentas from babies with cerebral palsy, an elevated nRBC count was significantly associated with placental lesions - multifocal avascular villi (FTV) or chronic villitis. Meconium-associated necrosis in vessels of the chorionic plate or umbilical cord showed a borderline association. Increased nRBC, with or without placental lesions, were unassociated with acidosis or birth asphyxia indicating that the underlying causes of nRBC elevation in this context antedated immediate peripartum events [137]. Persistent nRBC elevation in the first week of life of a preterm growth-restricted newborn has serious implications for additional complications, including bronchopulmonary dysplasia, necrotizing enterocolitis, and intraventricular hemorrhage [16].

Thrombophilias

Inherited and acquired coagulation disorders are risk factors for adverse pregnancy outcomes (early spontaneous abortion, IUFD, abruption, IUGR, and preeclampsia) [37, 55, 94, 95, 132, 155].

The most widely studied thrombophilias include the *G1691A* mutation in the factor V gene (factor V Leiden), the *G20210A* mutation in the prothrombin gene, the *C677T* mutation in the methylene tetrahydrofolate reductase gene, deficiencies in protein S, protein C, antithrombin III, hyperhomocysteinemia, and acquired thrombophilic states such as antiphospholipid antibody syndrome. Coagulopathies also occur in patients with diabetes mellitus. The mere identification of an inherited thrombophilia is not predictive for pregnancy complications. Estimates of the risk for different outcomes in mothers with specific thrombophilic conditions have been summarized recently [132].

There is no specific placental lesion unique to or specific for maternal thrombophilia. The placental pathology linking thrombophilia to adverse pregnancy outcome is essentially identical to other disorders associated with chronic maternal vascular underperfusion (increased syncytial knots, increased intervillous fibrin, infarcts, retroplacental hematoma, distal villous hypoplasia, decreased placental weight, and thin cord) [9, 83, 95]. Maternal thrombophilia has been associated with MPF/ MFI and subchorionic hematomas in some reports [62, 132]. Whether coagulation abnormalities are underlying causes of abnormal placentation or exacerbate preexisting placental compromise is unknown. Acquired thrombophilic states such as the antiphospholipid antibody syndrome may promote intraplacental clotting, possibly by blocking the normal antithrombotic annexin V phospholipidbinding protein and by activating complement [123, 169]. A similar predisposition to placental clotting occurs in patients with lupus erythematosus [93] and scleroderma [38]. IgG antiphospholipid antibodies may cross the interhemal membrane to enter the fetal circulation.

Fetal thrombophilic mutations studied to date are by themselves not associated with fetal vascular thrombosis. The frequency of fetal thromboocclusive placental lesions in babies with fetal thrombophilias is not increased, and there is no increase in the prevalence of thrombophilic mutations in infants whose placentas have fetal thromboocclusive lesions. At most, fetal coagulation abnormalities may act in concert with other factors affecting fetal blood flow. FTV does have a clear and strong relationship with umbilical cord entanglement and cord abnormalities. Placental pathology has poor predictive value in identifying patients with thrombophilia. Coagulation studies are probably best focused on patients with specific clinical scenarios such as severe early onset or recurrent pregnancy loss in association with typical placental lesions [132].

Acute Fatty Liver of Pregnancy and HELLP Syndrome

Both the HELLP syndrome (hemolysis, elevated liver enzyme levels, low platelet count) and acute fatty liver of pregnancy (AFLP) present as preeclampsia complicated by liver malfunction. The HELLP syndrome is more common and usually has a reasonably good prognosis under appropriate management. AFLP, although rare, has a significant mortality rate. Liver biopsy in AFLP shows characteristic changes including microvesicular steatosis.

Although recognized by maternal diseases, one very important cause is an inherited gene mutation in the fetus that causes a deficiency of long-chain 3-hydroxyl-CoA dehydrogenase, resulting in abnormal fatty acid metabolism [68]. The mother's acute problem is usually relieved by delivery. The infant has severe liver dysfunction, hypoglycemia, cardiomyopathy, and neuromuscular abnormalities. Appropriate early dietary management may reduce morbidity and mortality.

Fatty acids are an important source of energy for the fetus. More than 20 different genetically determined disorders of fatty acid metabolism have been recognized [171]. Although rare, together they represent the most common metabolic disorder with severe consequences for the mother and fetus. Retrospective studies have identified these disorders in a significant number of unexplained stillbirths and sudden infant deaths.

Placental lesions in the context of the HELLP syndrome include all of the features of decidual vasculopathy found in severe preeclampsia. There is little information on the placenta associated with AFLP. In one instance, a maternal floor infarct was found [96].

Sickle-Cell Trait/Disease and Other Hemoglobinopathies

Sickled maternal cells in the intervillous space may identify sickle cell disease, although low oxygen tension in the placenta may result in sickling of maternal erythrocytes in sickle trait as well [22]. Clinical problems and placental lesions are unlikely in uncomplicated sickle trait. Sickle
cell disease has been associated with spontaneous abortion, stillbirth, premature delivery, and IUGR, although regular obstetric care and close hematologic surveillance have significantly reduced maternal and fetal morbidity. Placentas in sickle disease may be normal (with the exception of sickled maternal erythrocytes) or small and infarcted. We have seen an occasional instance of extensive placental infarction and postnatal morbidity in instances of sickle cell trait complicated by other hemoglobinopathies or maternal coagulopathies. Ultrastructural abnormalities in the umbilical vein have been attributed to hypoxia [34].

Storage Disorders

Metabolic storage disorders are rare and placental findings are incompletely documented. Placental abnormalities in some inherited metabolic storage diseases include vacuolar changes in trophoblastic, stromal, and Hofbauer cells. Placentas from two infants with Gaucher's disease causing nonimmune fetal hydrops and stillbirth were found to have circulating Gaucher cells. Genetic analysis and/or enzymatic and biochemical studies may aid in the identification of specific enzymatic defects.

Abortion, Stillbirth, and Intrauterine Fetal Death

Products of conception are commonly submitted for pathologic examination to confirm the presence of an intrauterine gestation, to exclude trophoblastic disease and, if possible, to explain why the pregnancy failed. The identification of embryonic or placental tissue – chorionic villi, implantation site infiltrated by IT, or isolated clumps of trophoblast – essentially confirms intrauterine pregnancy. Immunostaining for keratin highlights IT when findings are equivocal. When embryonic or placental tissue is not found, the possibility of an ectopic gestation cannot be excluded. It should be recognized that no combination of findings, including chorionic villi, can completely exclude an ectopic pregnancy because rarely intrauterine and tubal pregnancies occur simultaneously.

Approximately one half of all human gestations abort, of which about half are recognized by the mother or her physician. Of clinically recognized pregnancies, those that abort can be divided into two significantly different groups, early (up to 12 weeks) and late (>12 weeks). In general, embryonic/fetal factors, primarily chromosomal abnormalities, are responsible for most early abortions. Late spontaneous abortion/stillbirth is more likely to be associated with placental and maternal factors.

Early Abortion

The embryonic stage of development extends to the 8th gestational week. Early abortion includes losses up to the 12th week. More than half of early spontaneous abortions have demonstrable chromosomal anomalies, and most of these are eliminated in the embryonic period. Trisomies, triploidy, and monosomy X are most common [86].

In spontaneously passed tissue, the chorionic cavity, intact or disrupted, may be identified. The chorionic cavity is frequently empty but may contain remnants of cord or embryo. The amnionic sac, when present, is often abnormally large and prematurely fused to the chorion. Embryos frequently exhibit generalized abnormal development (growth disorganization), pointing to a high probability of a chromosomal anomaly (**)** Fig. 19.112). Localized developmental defects (facial fusion defects, ocular anomalies, limb bud deformities, neural tube defects, and cervical edema) are also commonly genetically determined, although specific morphologic defects are often difficult to identify in the early embryo. These are more easily evaluated in the larger previable fetus. The finding of a well-developed, normal embryo suggests the possibility of a maternal causative factor (infection, inflammation, immune rejection, or coagulopathy), although 20-25% of morphologically normal embryos are also karyotypically abnormal, usually triploid. Accurate assessment of embryo morphology requires

Fig. 19.112

Spontaneous abortion. The abnormal embryo in this early abortion is closely correlated with an abnormal karyotype

familiarity with normal developmental stages, which are well illustrated in the comprehensive work of Kalousek et al [74]. Gross assessment of the embryo and/or placenta is, at best, suboptimal in the dissociated tissues of curetted specimens.

The placenta is commonly retained in the uterus for a variable period after fetal death, and villi in abortion specimens often show alterations reflecting fetal death. Regardless of cause, fetal death leads to progressive involution of fetal vessels diffusely throughout the placenta. Involution begins with intravascular karyorrhexis (6 h), followed by septation of stem vessels (48 h) and ends with fibrous obliteration of vessels and villous stromal fibrosis (when extensive >2 weeks) [39, 50, 51]. This sequence of changes is identical to that which occurs locally in villi distal to an occluded fetal vessel.

The villi of abortions with abnormal karyotypes often appear abnormal, but the patterns are variable and nonspecific. Dysmorphic features suggestive of a chromosomal abnormality - villous enlargement with myxoid stroma, irregular villous outlines, multiple trophoblastic invaginations, and individual trophoblastic cells in the villous stroma - are common and may be more marked in karyotypically abnormal abortions, but are found in abortions with normal karyotypes as well. Complete and partial moles are the only morphologic entities with defined karyotypic abnormalities that can be diagnosed with any degree of confidence, although their distinction is becoming more difficult with earlier evacuation. Rarely, significant trophoblastic hyperplasia without molar change may occur in association with chromosomal abnormalities, (especially trisomies 7, 15, 21, and 22.) [142] These cases are best managed with a follow-up serum HCG titer to assure return to baseline.

Karyotyping may be clinically very useful in the evaluation of couples distressed by repeated spontaneous abortion. Trisomies can be identified by FISH in formalin fixed tissue. Occasionally, karyotypic abnormalities are confined to the placenta. In *confined placental mosaicism*, mosaicism is expressed in the placenta but not the fetus [73]. These placentas show no histologic abnormalities; their identification requires genetic evaluation of villous stroma and trophoblast and the fetus.

Late Abortion, Stillbirth, and Intrauterine Fetal Death

Chromosomal abnormalities still occur but are uncommon after 20 weeks. Important considerations in explaining late abortion, stillbirth, and IUFD include intrauterine infections and inflammatory processes, maternal and/or fetal circulatory compromise, destructive placental lesions, cord accidents, and fetal malformations. The gross and microscopic features of these conditions have been described throughout this chapter. Involutional changes that invariably occur following fetal death will be superimposed to greater or lesser extent. Fetomaternal hemorrhage is often overlooked as a cause of unexpected stillbirth. A Kleihauer–Betke test should be performed in all such cases. When the fetus is normally formed and the placental findings seem trivial, confined placental mosaicism is a consideration.

Recurrent pregnancy loss may be associated with thrombophilias, maternal vascular obstructive lesions, and VUE when these conditions are severe and of early onset. Massive perivillous fibrin deposition and chronic histiocytic intervillositis are rare lesions, but they almost always lead to recurrent reproductive loss in affected individuals [135, 188].

Nontrophoblastic and Metastatic Tumors

Hemangioma (Chorangioma)

Placental hemangiomas (chorangiomas) occur in about 0.5-1% of carefully examined placentas. They are usually small, entirely intraplacental, and may be difficult to appreciate, especially in the unfixed specimen. Large tumors distorting either the chorionic or basal plate are rare. Exceptionally a chorangioma is attached to the placenta by a thin pedicle. Chorangiomas are usually solitary (\triangleright *Fig. 19.113*), but they may be multiple or, rarely,

Fig. 19.113Placental hemangioma

involve the placenta diffusely (Fig. 19.114). They may be brown, yellow, tan, red, or white and are usually firm and well demarcated from the surrounding parenchyma. Most chorangiomas are composed of capillary-sized blood vessels supported by inconspicuous, loose stroma. Occasionally, they may be more cellular or show prominent myxoid change, hyalinization, necrosis, or calcification. Mitotic figures and nuclear atypicality have been reported in some chorangiomas, but these have not behaved aggressively. Trophoblastic hyperplasia may be prominent [110]. Localized groups of large stem villi with similar alterations

Fig. 19.114 Diffuse placental hemangioma

but without nodular expansion have been termed localized chorangiomatosis [110].

The tendency for chorangiomas to be found beneath the chorionic plate and at the placental margin in addition to their association with preeclampsia and high-altitude pregnancy suggest that decreased oxygen tension may play a role in their development. Although the majority of chorangiomas are of no clinical significance, various complications have been reported, usually in association with large lesions. Hydramnios and premature delivery are the most significant. Fetal cardiomegaly, congestive heart failure, and hydrops have been attributed the increased workload in shunting blood through a large chorangioma. When significant amounts of blood are directed through the chorangioma away from functional villi, chronic hypoxia may lead to intrauterine growth retardation. Complications including fetal anemia and thrombocytopenia reflect sequestration or destruction of cellular elements as they traverse the chorangioma. Skin angiomas have been reported in a few babies with placental hemangiomas.

Hepatocellular Adenoma and Adrenocortical Nodules

Rarely small nodules of hepatocytes occur in the placenta. Termed *hepatocellular adenoma*, these nodules may contain hematopoetic foci but lack bile ducts and central veins (**>** *Fig.* 19.115). Their immunoprofile is typical of hepatocytes. Tiny nodules of adrenal cortical cells have been considered heterotopias. The pathogenesis of these unusual findings is not understood.

Fig. 19.115 Hepatic adenoma. This discrete collection of hepatocytes showed extramedullary hematopoiesis

Other Placental "Tumors"

Despite intraplacental location and infiltrative border, careful molecular analysis of one intraplacental leiomyoma documented its maternal origin. Teratomas have been reported to occur rarely between the amnion and chorion on the chorionic plate and in the umbilical cord. Although teratomas have been distinguished from acardiac fetuses by lack of an umbilical cord and disorganization of the component tissues, this distinction is a matter of dispute.

Placental Metastases

Either maternal or fetal neoplasms may metastasize to the placenta but they are very rare. Malignant melanoma is the most common maternal tumor to metastasize to the placenta despite the fact that other tumors are more common in this age group. Other maternal neoplasms metastasizing to the placenta have included leukemia, lymphoma, breast carcinoma, and lung carcinoma. Malignant melanoma, leukemia, and lymphoma have been reported to metastasize to the fetus transplacentally [84].

Placentas harboring maternal metastases are often normal on gross inspection, although metastatic tumor deposits may be apparent grossly (**>** *Fig.* 19.116). Tumor cells are usually confined to the intervillous space (**>** *Fig.* 19.117). Villous or fetal vascular invasion is very uncommon, and even when present, does not correlate well with fetal spread.

Dissemination of a congenital fetal tumor to the placenta is also very rare. Neuroblastoma is most common, but rare cases of fetal leukemia, lymphoma, hepatoblastoma, sarcoma, and sacrococcygeal teratoma have metastasized to the placenta (**>** *Fig.* 19.118). Disseminated histiocytosis involving the vessels of the umbilical

Fig. 19.116 Metastatic breast cancer. The metastatic tumor is visible as small nodules (Used with permission of the American Registry of Pathology/Armed Forces Institute of Pathology)

cord has been documented. The placenta involved by a metastatic fetal tumor is consistently hydropic, pale, and bulky with tumor cells distending fetal vessels. Pigmented nevus cells may involve the villi in association with giant nevi, but these are not considered to be malignant or metastatic.

Examination of the Placenta

A gross examination of all placentas should be performed and recorded at the time of delivery by the clinician. Some

Fig. 19.117 Metastatic breast carcinoma. Metastatic tumor cells are confined to the intervillous space

Fig. 19.118 Metastatic fetal melanoma. This congenital scalp melanoma metastasized to the placenta

information - length of umbilical cord, location of placenta in utero, retroplacental hematoma, ruptured membranous vessels, completeness of membranes or maternal surface - may be of immediate relevance and is best documented by the practitioner. Cultures for microorganisms and tissue for cytogenetics are best obtained at this time. Placentas are most commonly submitted to the pathologist when either the mother or infant is abnormal, the course of pregnancy, labor or delivery is complicated, a gross placental abnormality is noted, or for the evaluation of multiple pregnancy. Guidelines for submission of placentas for pathologic exam have been established [84]. A request for pathologic examination of the placenta should include the reason for submission with specific questions as well as a summary of the clinical history pertinent to that evaluation - the mother's gravidity, parity, details concerning previous pregnancies, underlying maternal disease, antepartum course, labor and deliver, and the infant's gestational age, weight, and Apgar scores. Placentas not submitted to pathology can be retained in the event that a complete placental exam should become necessary.

A good placental exam can be performed on a fresh or fixed placenta. In our institutions, the placenta is examined fresh to establish weight and pertinent measurements, perform vascular injection when indicated, and roll the membranes. After overnight fixation, the cut surfaces are examined and sections are submitted. Important abnormalities are unlikely to be overlooked when the placenta is approached systematically as follows.

Fetal membranes

Point of rupture: Measure the distance between the point of rupture and the closest placental margin. This provides information relating to the site of implantation (low-lying or placenta previa.)

Completeness: By attempting to reconstruct the amnionic sac, an estimation may be made as to whether membranes have been retained in utero.

Insertion: The membranes may insert at the margin of the placenta or central to the placental margin (circumvallate). Note extent (complete, partial) and associated changes.

Color and opacity: Opaque or cloudy membranes suggest infection. Green/brown staining suggests meconium or hemosiderin deposition.

Roll the membranes to include the point of rupture and the placental margin. Remove the membranes.

Umbilical cord

Length: Measure all pieces. The most accurate assessment of cord length is obtained in the delivery room. Umbilical cord length decreases by as much as 7 cm within a few hours of delivery.

Diameter: Measure greatest and least.

Insertion: Measure the distance between the insertion of the umbilical cord and closest placental margin. Note the mode and site of insertion and the condition of all membranous vessels.

Vessels: Normally 3.

Torsion: Degree of twist can be expressed as number of coils per 10 cm.

Other: Strictures, edema, thrombosis, hematomas, ulceration, knots.

Remove the cord flush with the placental surface.

Placenta

Measure: Measure the diameter and thickness.

Weigh: Weigh after fetal membranes, umbilical cord and large clots have been removed. Formalin fixation adds about 10% to placental weight.

Shape: Note anomalous shapes.

Fetal surface: Evaluate color (blue, green, brown) and chorionic vessels. Arteries cross over veins.

Maternal surface: The maternal surface should be complete. Missing fragments suggest retained placental tissue. Evaluate all clots for site, size, and related placental alterations. Breadloaf the placenta at 1 cm intervals.

Cut surface: Placental color reflects fetal blood content. Describe, measure, and locate focal abnormalities. Assess percentage when large lesions or significant proportions of the placenta are altered.

Sections

Two sections of umbilical cord and two sections of the membrane roll can be included in one block. Do not section the cord within 2 cm of the insertion site – this may give a false impression of SUA. We routinely submit at least three sections of placenta including two sections from grossly normal central placental parenchyma. Additional sections to demonstrate pathologic alterations are submitted as appropriate. Selection of microscopic sections should be tailored to the specific clinical scenario. For example, additional sections of the membrane roll or basal plate optimizes evaluation of maternal vessels when there is a history of preeclampsia.

Special aspects of Multiple Pregnancy

The delivering physician should identify the umbilical cords, but if not, they can be arbitrarily identified or by distinguishing characteristics (cord length, insertion site, etc.). Maintain the separate identity of each placenta grossly and microscopically.

Placentation type: Two entirely separate placentas are obviously dichorionic, requiring routine examination. To distinguish between DiMo and DiDi fused placentas, assess the dividing membranes and fetal vascular pattern. In DiDi fused placentas, the septum is opaque and the fetal vessels do not cross the line of fusion. In DiMo placentas, the septum is thin and the two vascular districts are intermingled.

Placental mass: Quantify the placental mass belonging to each infant. DiDi fused placentas can be separated along the line of fusion and weighed separately. The placental territories of monochorionic infants correspond best with their chorionic venous distribution.

Vascular anastomoses: Assess monochorionic placentas for vascular anastomoses. Large chorionic vessel anastomoses are easily identified grossly. Deep arteriovenous anastomoses cannot be seen but can be screened for with air injection. After clamping the arteries proximally, inject them with air using a plastic syringe. Anastomoses will allow air to pass from an artery into a vein of the co-twin. Repeat to establish the extent of anastomoses. Placental injection studies require fresh placentas and may be compromised by villous disruption.

Special Techniques

Cytogenetics: Placental tissue may be easier to grow and karyotype than other fetal tissue. Chorionic villous sampling early in pregnancy is being used for prenatal diagnosis. Flow cytometry may be useful in the evaluation of molar pregnancies. Genetic questions regarding specific chromosomes may be addressed by FISH.

Culture: This is usually done by the obstetrician. Cultures may be accomplished by swabs of the amnionic surface or subchorionic fibrin after searing the amnion.

Immunoperoxidase stains: This technique may be useful in the identification of infectious agents and the delineation of cell types (i.e., CD68 in chronic histiocytic intervillositis.)

Introduction

Gestational trophoblastic disease (GTD) encompasses a heterogeneous group of lesions with specific clinical features, morphological characteristics, and pathogenesis. The World Health Organization classification of GTD includes complete and partial hydatidiform mole, invasive mole, choriocarcinoma, placental site trophoblastic tumor (PSTT), epithelioid trophoblastic tumor, exaggerated placental site, and placental site nodule (> Table 20.1) [145]. Some of these lesions are true neoplasms, whereas others represent abnormally formed placentas with a predisposition for neoplastic transformation of the trophoblast. Two benign entities, the exaggerated placental site and the placental site nodule, are included because they are trophoblastic lesions that must be distinguished from other entities with malignant potential. The literature on GTD is extensive and at times confusing because of inconsistencies in classification and terminology. In fact, the necessity of a morphologic classification has been questioned, because current management is largely medical and in the case of trophoblastic disease following a mole, treatment is often conducted in the absence of a histological diagnosis. Thus, all trophoblastic lesions are frequently combined under the rubric of GTD without applying specific pathological terms. However, recent studies demonstrate profound differences in the etiology, morphology, and clinical behavior of various forms of the disease. These studies underscore the importance of a uniform histological classification to facilitate standardized reporting of data and to ensure appropriate clinical management. Nonetheless, the term GTD has clinical

utility, as the principles of human chorionic gonadotropin (hCG) monitoring in follow-up and the chemotherapy of metastatic or persistent disease are similar for all these entities.

This chapter discusses the clinical and pathological features of each specific form of GTD as well as their clinical behavior, management, and treatment. In addition, the morphologic and immunohistochemical features of the distinct subtypes of trophoblastic cells are reviewed since these have important implications for diagnosis. Recent studies have shed light on the molecular mechanisms of trophoblastic function, especially as it relates to trophoblastic disease and this material is reviewed since it enhances our understanding of the biology of these entities.

Overview of Morphology, Development, and Biology of Trophoblast

The abnormal trophoblastic tissue in GTD recapitulates the trophoblast present in the early developing placenta and the implantation site. In normal placentation, the trophoblast growing in association with chorionic villi is referred to as villous trophoblast, whereas the trophoblast in all other locations is termed extravillous trophoblast. Three distinct types of trophoblastic cells have been recognized: cytotrophoblast (CT), syncytiotrophoblast (ST), and intermediate trophoblast (IT). Villous trophoblast is composed, for the most part, of CT and ST with small amounts of IT. In contrast, extravillous trophoblast that infiltrates the decidua, myometrium, and spiral arteries of the placental site is composed of IT.

CT (Langhans cells) is the germinative component of trophoblast, whereas ST is the differentiated component that interfaces with the maternal circulation and produces most of the placental hormones. IT is a distinct form of trophoblast that shares some of the morphologic and functional features of CT and ST. IT has been referred to X-cells, interstitial (cyto)trophoblast, extravillous (cyto) trophoblast, and "cytotrophoblast." The term "intermediate trophoblast" is preferred by pathologists since it more clearly reflects the morphological and functional features including hormone secretion of this unique cell population which is "intermediate" between cytotrophoblast and syncytiotrophoblast. Recent morphological and immunohistochemical studies have shown that intermediate trophoblast is a heterogeneous cell population that can be further categorized according to its anatomic location (> Fig. 20.1). Accordingly, we have proposed that intermediate trophoblast extending from the trophoblastic column at the anchoring villi be designated "villous

Schematic representation of trophoblastic subpopulations in the placenta and fetal membranes (Reprinted by permission from reference [158])

intermediate trophoblast," in the placental site (or basal plate) "implantation site intermediate trophoblast," and in the chorion laeve of the fetal membranes "chorionic-type intermediate trophoblast" (**>** *Fig. 20.1*). The intermediate trophoblastic cells in the trophoblastic islands and placental septae appear to be equivalent to the implantation site intermediate trophoblastic cells.

Human trophoblast is derived from the trophoectoderm, the outermost layer of the blastocyst. Shortly after implantation (day 7–8), the trophoectoderm differentiates into a syncytiotrophoblastic mass at the implantation pole. Small intrasyncytial vacuoles then appear in the syncytiotrophoblastic mass and expand, becoming confluent and forming a system of lacunae that are separated by syncytiotrophoblastic trabeculae. On approximately day 12, the previllous mononucleate trophoblast from the primary chorionic plate invades the syncytiotrophoblastic trabeculae wherein the peripheral ends of the trabeculae join together and form the outermost layer of the trophoblast, the trophoblastic shell. After 2 weeks of gestation, the extraembryonic mesenchyme grows into the trabeculae, transforming them into the primary chorionic villi. The lacunae coalesce to form the intervillous space.

After the development of the chorionic villi, distinctive trophoblastic subpopulations can be recognized (\bigcirc *Fig. 20.1*). The chorionic villus surface is lined by a continuous inner layer of cytotrophoblast and an outer layer of syncytiotrophoblast. Cytotrophoblast is the trophoblastic stem cell on the villous surface, demonstrating proliferative activity with a Ki-67 nuclear labeling index of approximately 30% in the first trimester. Cytotrophoblast, in early gestation, differentiates along two main pathways – villous and extravillous [145, 154]. On the villous surface, cytotrophoblast fuses directly to form syncytiotrophoblast. The differentiation of cytotrophoblast into syncytiotrophoblast is accompanied by complete loss of proliferation activity [151]. As gestation progresses, the proliferative activity of cytotrophoblast decreases with an increase in the relative number of syncytiotrophoblast to cytotrophoblast. The nuclei of syncytiotrophoblast gradually become apoptotic, forming so-called syncytial knots, clusters of pyknotic nuclei with a small amount of cytoplasm, which are eventually extruded into the intervillous space. The second pathway of differentiation of cytotrophoblast occurs at the pole of the villi that make contact with the placental bed. These villi, the so-called anchoring villi, display a morphologic spectrum of differentiation where cytotrophoblast merges imperceptibly into intermediate trophoblast within these trophoblastic columns (> Fig. 20.1). These intermediate trophoblastic cells in the trophoblastic columns are termed "villous intermediate trophoblast." The proliferative activity of villous intermediate trophoblast gradually decreases as the cells move away from the villi [151]. At the base of trophoblastic column at the junction with the endometrium, intermediate trophoblast infiltrates the decidua and myometrium and invades and replaces the spiral arteries of the implantation site (basal plate) to establish the maternal/fetal circulation. This subpopulation of intermediate trophoblast in the implantation site is designated "implantation site intermediate trophoblast." Although these trophoblastic cells extensively infiltrate the placental bed, they do not demonstrate proliferative activity. Some mononucleate implantation site intermediate trophoblastic cells fuse into multinucleated cells that are terminally differentiated. In contrast to anchoring villi, floating villi are not in contact with the placental bed. The trophoblast at the tips of these villi appears to be analogous to implantation site intermediate trophoblast. This cell population of trophoblast is associated with extensive deposition of extracellular matrix protein and fibrin forming "balloon-like" structures that have been designated "trophoblastic islands." Like implantation site intermediate trophoblast, the trophoblastic cells in the trophoblastic islands are not proliferative. In contrast, the intermediate trophoblast away from implantation site (i.e., the chorion frondosum) differentiates into "chorionic-type intermediate trophoblast." At around 20 weeks of gestation, the expanding gestational sac obliterates the endometrial cavity and the chorion frondosum fuses with the decidua parietalis to form the chorion laeve (\triangleright Fig. 20.2). As the surface area of the chorionic laeve increases towards term, the chorionic-type intermediate trophoblast continues to proliferate throughout gestation, albeit at a low level.

Morphology of Trophoblast

Previllous trophoblast. By light microscopy, the previllous trophoblast is composed of mononucleate trophoblast and primitive syncytiotrophoblast that invade the endometrium. The dimorphic pattern of previllous trophoblast is reminiscent of the dimorphic pattern of trophoblast in choriocarcinoma and it has been hypothesized that the morphologic appearance of choriocarcinoma is a recapitulation of the appearance of previllous trophoblast (*) Fig. 20.3*). Unlike choriocarcinoma, previllous trophoblast cellu- lar necrosis.

Cytotrophoblast. Following the development of villi, cytotrophoblastic cells appear as small primitive epithelial cells, uniform, and polygonal to oval in shape (**)** *Fig. 20.4a*). Cytotrophoblastic cells have a single nucleus, clear to granular cytoplasm, and well-defined cell borders. Mitotic activity is evident.

Syncytiotrophoblast. Syncytiotrophoblast is composed of a large, multinucleate cellular mass with dense amphophilic cytoplasm often containing multiple vacuoles that vary in size (\bigcirc *Fig. 20.4a*). A distinct brush border often lines the cell membrane. The syncytiotrophoblastic nuclei are dark and often appear pyknotic. They do not show mitotic activity.

Villous intermediate trophoblast. Villous intermediate trophoblastic cells are mononucleate and larger than cytotrophoblast with pale to clear cytoplasm and uniform round nuclei.

Implantation site intermediate trophoblast. Implantation site intermediate trophoblastic cells have a variable appearance, which to some extent is dependent on their anatomic location (> Figs. 20.4b and c). For example, implantation site intermediate trophoblastic cells in the endometrium are polygonal or round and contain abundant amphophilic cytoplasm closely resembling the decidualized stromal cells with which they are admixed. In contrast, implantation site intermediate trophoblastic cells in the myometrium are frequently spindle-shaped and resemble the smooth muscle cells of the myometrium. Generally, the cytoplasm of implantation site intermediate trophoblastic cells is abundant and is eosinophilic to amphophilic. Scattered small vacuoles may be present in the cytoplasm of implantation site intermediate trophoblastic cells. The nuclei of implantation site intermediate trophoblastic cells have highly irregular outlines and hyperchromatic, coarsely granular chromatin. Often the nuclei are lobulated or show multiple deep nuclear clefts. Nucleoli are smaller and less prominent than those

Schematic representation of the formation of the chorion laeve (yellow). At 3 weeks of gestation, the entire blastocyst is embedded in the endometrium at the implantation site and is surrounded by the trophoblastic shell. At 10 weeks, the definitive placenta is established at the implantation site and the chorionic villi at the opposite pole begin to degenerate. At approximately 12 weeks, the amnion (yellow)/chorion (blue) at the opposite end of the placental site fuses with the decidua capsularis. The intervillous space is obliterated and the chorionic villi (the small, round pale-gray structures) degenerate. This process continues and at approximately 17 weeks of gestation the uterine cavity is largely obliterated as the amnion and chorion laeve become apposed to the endometrium on the opposite side of the uterine cavity. The chorion laeve, amnion, and underlying decidua constitute the fetal membranes (Reprinted by permission from [158])

in cytotrophoblast. Cytoplasmic nuclear invaginations may be seen. Mononucleate implantation site intermediate trophoblastic cells occasionally fuse into multinucleated cells.

Implantation site intermediate trophoblastic cells infiltrate the decidua, surround glands, and invade the myometrium, dissecting between smooth muscle fibers without destroying them. These cells characteristically invade spiral arteries replacing the smooth muscle of the vessel wall but leaving the overall structure intact. Eosinophilic fibrinoid material is often deposited around implantation site intermediate trophoblast. The material contains a variety of extracellular matrix proteins including adult-type and oncofetal fibronectin, type IV collagen, laminin, and a small amount of fibrin. Implantation site intermediate trophoblastic cells are the predominant cellular population of the exaggerated placental site and the PSTT.

The intermediate trophoblastic cells in the trophoblastic islands are mononucleate, round, and uniform in size and contain rounded nuclei. They are embedded in an abundant, homogeneous, and eosinophilic fibrinoid matrix. In vitro studies suggest that the cell islands are derived from the floating cell columns, which are not anchored to the endometrium. As a result, abundant extracellular matrix accumulates among the cells replacing those in the center of the islands.

Chorionic-type intermediate trophoblast. Chorionictype intermediate trophoblast is composed for the most part of relatively uniform cells with either eosinophilic or clear (glycogen-rich) cytoplasm arranged in a cohesive layer in the chorion laeve (\bigcirc Figs. 20.1 and \bigcirc 20.5). Most of the cells are smaller than implantation site intermediate trophoblast but larger than cytotrophoblast. Occasionally, the cells form nests or cords that extend into the underlying decidua. As with implantation site intermediate trophoblastic cells, some chorionic-type intermediate trophoblastic cells are multinucleated. Chorionic-type intermediate trophoblast is the cellular population found in placental site nodules and epithelioid trophoblastic tumors [158].

Primitive trophoblast. The previllous trophoblast surrounding the blastocyst demonstrates a dimorphic pattern composed of mononucleate trophoblastic cells and syncytiotrophoblastic cells that resemble choriocarcinoma. The mononucleate trophoblastic cells, in contrast to those in choriocarcinoma, are smaller, more uniform, and not atypical (*inset*). Unlike choriocarcinoma, the trophoblast does not invade and destroy adjacent tissue

Gene Expression and Immunohistochemical Features of Trophoblastic Subpopulations

Trophoblast-associated gene expression as detected by immunohistochemistry has great value in the diagnosis of GTD as well as in the study of the biology of trophoblast (**)** *Table 20.2*) [145, 155]. The beta-subunit of hCG, human placental lactogen (hPL), placental alkaline phosphatase (PLAP), inhibin, and low-molecular-weight cytokeratin are well-recognized markers of trophoblast. Recently, several other genes have been identified in human trophoblast. Antibodies against these markers, especially those that are commercially available and recognize the epitopes in formalin-fixed, paraffin-embedded tissue sections, have considerable value in the study and differential diagnosis of different types of GTD. For example, HSD3B1 is a newly characterized trophoblastic marker that is expressed almost exclusively in a few normal tissues including trophoblast and sebaceous glands. The commercially available antibody that reacts to HSD3B1 protein has been shown to be very useful to distinguish a trophoblastic from a non-trophoblastic lesion [93].

All forms of trophoblastic subpopulations and gestational trophoblastic lesions react strongly for cytokeratin when broad-spectrum antibodies (e.g., the AE1/AE3 antibody cocktail) are used. More specifically, trophoblast is positive for low-molecular-weight epithelium-type cytokeratins, including cytokeratins 7, 8, 18, and 19. In contrast, trophoblast is variably positive for cytokeratin 20 and is rarely positive for high-molecular-weight cytokeratin that is normally expressed by stratified squamous epithelium. Cytokeratin immunostaining is especially useful for demonstrating the presence of implantation site intermediate trophoblastic cells at the placental site since these cells are always admixed with the other cell types. The intermediate trophoblastic cells that are positive for low-molecular-weight cytokeratin are easily identified amid nonreactive decidual cells and smooth muscle cells. Myometrial smooth muscle cells can display punctate cytoplasmic cytokeratin immunoreactivity that is easily distinguished from the diffuse membrane staining of IT.

Cytotrophoblast is immunoreactive for a variety of antigens, including p63, cyclin E, leukemia inhibitory factor receptor, epidermal growth factor receptor, P2Y6 purinergic receptor, and a number of cell adhesion molecules including integrin and E-cadherin (**>** *Table 20.2*). Unlike syncytiotrophoblast, cytotrophoblast fails to react with antibodies against a wide variety of steroid and pregnancy-associated hormones. Ki-67 proliferation-related antigen is highly expressed by cytotrophoblast (labeling index: 25–50%) especially in the region forming the trophoblastic columns (**>** *Table 20.2*). These findings confirm that cytotrophoblast is a stem cell with a high level of proliferative activity and a limited functional role.

The differentiation of cytotrophoblast into syncytiotrophoblast is accompanied by dramatic changes in gene expression. For example, syncytiotrophoblast expresses several pregnancy-associated hormones, including betahCG, hPL, estradiol, progesterone, placental growth hormone, pregnancy-specific glycoprotein, relaxins, and inhibin. The immunodistribution of some of these hormones in syncytiotrophoblast is variable, depending on gestational age. For example, syncytiotrophoblast contains abundant beta-hCG from at least 12 days of gestation until approximately 8–10 weeks, after which

Chorionic villus and implantation site. (a) An anchoring villus attaches to the implantation site. The villus is outlined by two trophoblastic layers – the inner cytotrophoblast (CT) and outer syncytiotrophoblast (ST). The intermediate trophoblast (IT) differentiates from the trophoblastic column and emanates from the distal column to the implantation site. (b) Intermediate trophoblastic cells infiltrate into endomyometrium and assume a distinctive pattern when they invade the myometrium. (c) Intermediate trophoblastic cells target the spiral arteries and transform them from small caliber and high resistant vascular channels (*inset*) into large caliber and low resistant arteries that direct blood into the intervillous space. Intermediate trophoblastic cells can be found in the lumen of the arteries and sometimes appear to occlude the entire lumen

Fig. 20.5

Anatomy of chorion laeve (fetal membrane). The chorion epithelium is no longer present in chorion laeve because of fusion between the amnion and chorion. However, a cleft that represents the location where the chorionic epithelium resides before the fusion is always present due to tissue processing artifacts. The trophoblastic cells in the chorion laeve are termed "chorionic-type intermediate trophoblastic cells" and are characterized by distinct morphological and immunohistochemical features as compared to other trophoblastic subpopulations. GV: ghost villi

it diminishes. By 40 weeks it is present only focally. hPL is also localized in syncytiotrophoblast at 12 days but increases steadily thereafter. From late in the second trimester to term, hPL is diffusely distributed in

the syncytiotrophoblast overlying the chorionic villi. Inhibin- α exhibits the highest expression in the first trimester and gradually decreases in immunointensity through the third trimester (\bigcirc *Table 20.2*) [152].

Table 20.2

Trophoblastic types	HSD3B1 HLA-G	hPL β-hCG	cyclin E p63	CD146*	HNK1	Muc4	β–cat
Cytotrophoblast							nuc

M : positive in multinucleated intermediate trophoblast (IT)							
: increased expression toward the implantation site in a trophoblastic column							
IT: intermediate trophoblastic cells; nuc: nuclear staining; memb: membrane staining; varied: variable staining pattern *CD146 is a synonym of Mel-CAM							

Expression of trophoblastic markers in different trophoblastic subpopulations

Syncytiotrophoblast also expresses placental alkaline phosphatase, leukemia inhibitory factor receptor, placental growth hormone, epidermal growth factor receptor, HSD3B1 (an enzyme involved in the synthesis of progesterone), p27^{kip1} (a negative regulator in cell cycle progression), c-fms oncoprotein CD10, and syncytin. Expression of syncytin has been shown to be involved in the fusion process of syncytiotrophoblast [102]. In contrast, several genes are down-regulated in syncytiotrophoblast as compared with cytotrophoblast. For example, syncytiotrophoblast fails to express E-cadherin and Ki-67 nuclear antigen. These findings are concordant with the view that syncytiotrophoblast is terminally differentiated and that its major functions are hormone production and molecular transport across the villous surface.

Among the various populations of trophoblast, the pattern of gene expression is most complex in intermediate trophoblast and depends on the differentiation status and anatomic location of the intermediate trophoblastic cells, i.e., the subpopulation of intermediate trophoblast (**)** *Table 20.2*). The villous intermediate trophoblast in the trophoblastic columns uniquely expresses the HNK-1 carbohydrate epitope on glycosphingolipids, which is not present in other subpopulations of trophoblastic cells [157]. The genes that are upregulated as villous intermediate trophoblast differentiate into implantation site intermediate trophoblast including melanoma cell adhesion molecule (Mel-CAM or CD146; [149] inhibin- α [152], hPL [81], and cyclin E [94] (**>** Table 20.2). The genes that are downregulated during differentiation of villous to implantation site intermediate trophoblast are Ki-67 nuclear antigen, epidermal growth factor (EGF) receptor, and E-cadherin. In terms of hormone production, implantation site intermediate trophoblast resembles syncytiotrophoblast. It contains abundant hPL, which appears as early as 12 days and reaches a peak at 11-15 weeks of gestation. Inhibin- α is also immunolocalized in the implantation site intermediate trophoblast after 10 weeks of gestation. In contrast, hCG is present only focally in implantation site intermediate trophoblast, appearing as early as 12 days and remaining until 6 weeks, after which it disappears. The socalled multinucleated trophoblastic giant cells exhibit an identical immunostaining pattern to the mononucleate counterparts except the former are negative for pregnancy-associated major basic protein [79]. Accordingly, these giant cells should be designated "multinucleated intermediate trophoblastic cells" rather than syncytiotrophoblastic giant cells [149].

The implantation site intermediate trophoblastic cells that invade the spiral arteries show the same staining

pattern as those within the decidua and myometrium except that expression of neural cell adhesion molecule (NCAM; [15], E-cadherin, and beta-catenin are upregulated [147]. Implantation site intermediate trophoblast in both the endometrium and myometrium expresses leukemia inhibitory factor receptor [142], which interacts with leukemia inhibitory factor expressed by maternal decidual leukocytes. Although leukemia inhibitory factor plays an important role in implantation and placentation in several species, the paracrine role of leukemia inhibitory factor in the biology of human implantation site intermediate trophoblastic cells is not known. Those intermediate trophoblastic cells also express CD10, a neutral endopeptidase [64, 122].

In contrast to implantation site intermediate trophoblast, chorionic-type intermediate trophoblast is diffusely positive for p63 but is only focally positive for several trophoblast-associated antigens including hPL, Mel-CAM (CD146), mucin-4, and cyclin E (\bigcirc *Table 20.2*). Chorionic-type intermediate trophoblastic cells exhibit mild proliferative activity as indicated by an increased Ki-67 labeling index (3–10%) in contrast to the absence of Ki-67 labeling in implantation site intermediate trophoblast.

The immunophenotype of trophoblastic cells in gestational trophoblastic lesions is similar to their normal counterparts. In routine pathology practice, HSD3B1, cytokeratin 18, hPL, p63, Ki-67, and cyclin E are particularly useful markers in the diagnosis of trophoblastic lesions. The practical application of immunohistochemistry in the differential diagnosis of gestational trophoblastic lesions is discussed under the section of immunohistochemistry application for differential diagnosis.

Functional Aspects of Trophoblast

Trophoblast plays a crucial role in implantation and embryonic development. The major functions of trophoblast are as follows. First, the villous trophoblast (syncytiotrophoblast and cytotrophoblast) provides a structural interface for molecular transport between the maternal and fetal compartments. Second, implantation site intermediate trophoblast establishes the fetomaternal circulation in the placental site (\bigcirc *Fig. 20.4*). Third, syncytiotrophoblast secretes several pregnancyassociated hormones that are necessary for successful maintenance of the placenta and fetus. Finally, syncytiotrophoblast as well as chorionic-type intermediate trophoblast in the fetal membranes serve as an immunological barrier that prevents allograft rejection of the fetus by the maternal immune system. Functional abnormalities of trophoblast may account for several common gestational disorders including failure of implantation, which leads to spontaneous abortion, preeclampsia, and intrauterine growth retardation. The functions of specific trophoblastic subpopulations are discussed below.

Previllous Trophoblast

The previllous syncytiotrophoblast is responsible for the initial erosion of maternal tissues during the early stages of implantation. Subsequently, it appears that the previllous mononucleate trophoblastic cells are responsible for further invasion and expansion of the implantation site (\bigcirc *Fig. 20.3*). At approximately 13 days of gestation, mesenchyme penetrates the trophoblastic mass and chorionic villi develop thus forming the rudimentary structure of the definitive placenta.

Cytotrophoblast

Cytotrophoblast is the trophoblastic stem cell and is located on the villous surface. Cytotrophoblast expresses epidermal growth factor receptor (EGF-R), which binds to EGF secreted by the decidua. It has been postulated that by a paracrine mechanism EGF-R and its ligand may provide persistent growth stimulation for cytotrophoblast. Cytotrophoblast differentiates along two main pathways. Along one pathway, cytotrophoblast continues to proliferate and fuses to form the overlying syncytiotrophoblast. This process results in expansion of the surface area of chorionic villi in the developing placenta. In the second pathway, cytotrophoblast differentiates into villous intermediate trophoblast in the trophoblastic columns and then into implantation site intermediate trophoblast in the placental site or chorionic-type intermediate trophoblast in the chorion laeve.

Syncytiotrophoblast

Syncytiotrophoblast is composed of terminally differentiated cells that synthesize and secrete a variety of pregnancyassociated hormones that are thought to be critical in the establishment and maintenance of pregnancy. Some of these secretory proteins may also have a paracrine function by regulating the local microenvironment of decidua cells, inflammatory cells, and smooth muscle cells at the placental site. In addition to its role as an endocrine organ, the syncytiotrophoblast is bathed in maternal blood and is responsible for the exchange of oxygen, nutrients, and a variety of metabolic products between the mother and fetus.

Villous Intermediate Trophoblast

Villous intermediate trophoblastic cells proliferate in the proximal portion of trophoblastic columns and serve as the source from which implantation site and chorionictype intermediate trophoblast are derived. In addition, villous intermediate trophoblastic cells may play an important role in maintaining the structural integrity of the villi that anchor the placenta to the basal plate. HNK-1 carbohydrate moiety expressed on the surface of the villous intermediate trophoblast may contribute to the intercellular cohesion in the trophoblastic columns that counteract the mechanical sheering forces resulting from fetal movements and the turbulence created by the pulsatile blood flow in the placental bed [157].

Implantation Site Intermediate Trophoblast

The major function of implantation site intermediate trophoblast is to establish the maternal-fetal circulation by invading the spiral arteries in the basal plate during early pregnancy. The mechanisms underlying trophoblastic invasion are similar to those involved in tumor cell invasion. For example, proteases are responsible for matrix degradation and tissue remodeling, a prerequisite for trophoblastic migration and invasion. Loss of E-cadherin expression is closely associated with the infiltrative phenotype of implantation site intermediate trophoblast [147]. Expression of growth factors and their receptors constitutes a unique molecular mechanism regulating trophoblastic behavior and cell-to-cell communication (autocrine or paracrine) including cellular migration, proliferation, and differentiation. Expression of cell adhesion molecules is important for trophoblastic migration in different extracellular substrates and for cross-talk between trophoblastic cells and their microenvironment. It has been shown that implantation site intermediate trophoblastic cells produce hyperglycosylated hCG, a variant of hCG. This variant appears to be an autocrine factor, participating in the initiation and regulation of trophoblastic invasion [23].

Unlike malignant tumors, the invasion of implantation site intermediate trophoblast is tightly regulated,

confined spatially to the implantation site and limited temporally to early pregnancy. While extensively infiltrating the endometrium of the basal plate, the implantation site intermediate trophoblast invade only the inner third of the myometrium in the first trimester, decreasing to less than 10% of the myometrium by term. Although the molecular mechanism underlying the control of trophoblastic invasion is currently unclear, the invasive process can be modulated by both the trophoblast and the local microenvironment. Fusion of mononucleate implantation site intermediate trophoblastic cells into multinucleated cells leads to the loss of their invasive and migratory phenotype. Although multinucleated implantation site intermediate trophoblastic cells can be seen in trophoblastic neoplasms such as PSTT, they are more frequently encountered in the normal or exaggerated placental site, a helpful morphological feature in distinguishing exaggerated placental site from PSTT.

Another feature that distinguishes non-neoplastic trophoblastic cells from tumor cells is their pattern of cellular proliferation. The differentiation of implantation site intermediate trophoblast is accompanied by a decrease in cellular proliferation in contrast to the uncontrolled proliferation in malignant neoplasms. Indeed, implantation site intermediate trophoblastic cells are negative for Ki-67, a proliferation marker, and are positive for several proteins which are involved in the arrest of cell cycle progression including p21^{WAF1/CIP1} [19] and p57^{kip-2} [21]. Accordingly, any proliferative activity (mitotic figures or Ki-67-positive trophoblastic cells) in the implantation site intermediate trophoblast should be considered abnormal and a neoplastic process must be considered.

Spiral arteries at the implantation site are the targets for invasion by implantation site intermediate trophoblast. The mechanisms that are responsible for the tropism of implantation site intermediate trophoblast to the spiral arteries, and not to other structures, are unclear; one postulate is that the oxygen gradient may be a guiding cue. The trophoblastic invasion into the vascular wall is associated with abundant deposition of extracellular matrix, which eventually replaces the entire smooth muscle layer of spiral arteries, resulting in the transformation of the arteries to large-caliber and low-resistant vascular channels. This unique feature of vascular invasion is not only observed in the normal placental site but also in the PSTT. Implantation site intermediate trophoblast replaces the lining endothelial cells and undergoes an epithelialendothelial transdifferentiation characterized by the acquisition of several endothelial markers including VCAM-1, VE-cadherin, and beta-4 integrin, [186] and Mel-CAM (CD146) [143, 149], all of which are expressed

by endothelial cells. Accordingly, the term "trophoblast pseudo-vasculogenesis" has been proposed to describe this unique differentiation pathway of implantation site intermediate trophoblast. Some of the implantation site intermediate trophoblastic cells that invade the spiral arteries migrate along the vascular wall in a retrograde fashion to reach the spiral arteries beyond the implantation site in the myometrium. The intravascular implantation site intermediate trophoblastic cells tend to form trophoblastic aggregates that act like valves or a sieve to control the blood flow in the trophoblast-modified spiral arteries. The process of aggregation is associated with the expression of NCAM and E-cadherin. These cell adhesion molecules may be responsible for the enhanced intercellular cohesion among cells in trophoblastic aggregates in the spiral arteries as NCAM and E-cadherin function as homotypic cell-cell adhesion molecules. This hypothesis has been supported by a recent study in which the E-cadherin gene was introduced into an E-cadherin negative implantation site intermediate trophoblastic cell line, IST-1, resulting in a stationary and cohesive phenotype of IST-1 cells in culture [147].

Chorionic-Type Intermediate Trophoblast

The functional role of chorionic-type intermediate trophoblastic cells is unknown. Unlike the implantation site intermediate trophoblast, the chorionic-type intermediate trophoblast proliferates throughout gestation as the total surface area of fetal membrane increases. Chorionictype intermediate trophoblast may contribute to the synthesis of extracelluar matrix, which is required to maintain the tensile strength of the fetal membrane. It is also possible that chorionic-type intermediate trophoblast acts as a biological and mechanical barrier to the maternal immune system and is important for fetal allograft survival (see below).

Classification of Gestational Trophoblastic Disease

According to current WHO classification, GTD can be broadly divided into molar lesions and non-molar lesions. The molar lesions include partial and complete hydatidiform moles and invasive moles. The non-molar lesions include choriocarcinoma and lesions derived from implantation site intermediate trophoblast (exaggerated placental site and PSTT) and those from the chorionictype intermediate trophoblast (placental site nodule and epithelioid trophoblastic tumor). In the past, exaggerated placental site and placental site nodule were classified as "unclassified GTD." Both lesions are benign and have distinct histogenesis and morphological features that justify their separate designation. The current classification also includes epithelioid trophoblastic tumor, which is a trophoblastic neoplasm distinct from choriocarcinoma, and PSTT.

General Features of Gestational Trophoblastic Disease

Epidemiology

The reported incidence of hydatidiform mole and choriocarcinoma varies widely throughout the world, being greatest in Asia, Africa, and Latin America and substantially lower in North America, Europe, and Australia. The incidence rates are difficult to compare, however, because of the limitations in the methodology of these studies. Furthermore, some studies of incidence rates have used hospitalbased rather than population-based figures, which probably result in overreporting. There are no epidemiologic data on incidence or geographic distribution reported for the more recently described PSTT and epithelioid trophoblastic tumor. Despite the various incidence rates documented, the overall incidence of GTD has been decreasing in last few decades, especially in those geographic areas that have previously reported a high incidence [51, 76].

In North America and Europe, the frequency of hydatidiform moles is approximately 100 per 100,000 pregnancies. A higher frequency was reported in some areas of Asia and the Middle East, with an incidence rate from 100 to 1,000 per 100,000 pregnancies [3]. Choriocarcinoma occurs with a frequency of 1 in 20,000 to 1 in 40,000 pregnancies in the United States and Europe [123]. Estimates for the incidence in Asia, Africa, and Latin America generally are higher with incidence rates as high as 1 in 500 to 1,000 pregnancies reported [123]. As with molar disease, there are marked regional variations in incidence rates. In Nigeria, choriocarcinoma is the third most common malignant tumor in women at one institution, ranking behind breast and cervical carcinoma. Thus, despite methodological problems it appears that choriocarcinoma occurs at a substantially higher rate in developing countries than it does in North America and Europe. Similar to hydatidiform moles, the overall incidence of choriocarcinoma in recent years has dramatically decreased as socioeconomic conditions improve. These observations suggest that low socioeconomic conditions or dietary

factors may contribute to the development of GTD. Recently, asbestos exposure has been reported to be associated with the development of GTD [135].

Gestational trophoblastic lesions are nearly always disorders of the reproductive years. Women who are sexually active are at risk for developing GTD, but the incidence is substantially higher in women before 20 and after 40 years. In rare cases, GTD can develop in a postmenopausal woman with a long interval between the diagnosis of GTD and the antecedent pregnancy. The absolute number of cases of mole or choriocarcinoma in women over 40 years is smaller because of their lower fertility. In contrast, maternal age has no effect on the risk of partial mole. Neither paternal age nor race seems to affect the risk of developing a hydatidiform mole. Malignant sequelae for hydatidiform mole occur more frequently in older patients. While hydatidiform mole, choriocarcinoma, exaggerated placental site, and placental site nodule are nearly always confined to reproductive age women, PSTT and epithelioid trophoblastic tumors occur infrequently in postmenopausal women.

Several studies reveal that a history of prior spontaneous abortions is more common in patients with hydatidiform mole and choriocarcinoma than with a normal pregnancy. Furthermore, women who have had one hydatidiform mole are at increased risk of having another [123]. Conversely, term pregnancy and live births have a protective effect, with GTD less common in patients who are parous [123]. The protective effect appears to increase with an increased number of live births.

Cytogenetics

Cytogenetic studies of complete and partial hydatidiform mole show that chromosomal abnormalities play an important role in their development [3, 175]. The karyotypic patterns of the two types of moles are considerably different. Complete hydatidiform moles have a normal DNA content and most complete moles have a karyotype of 46,XX and develop from the fertilization of an anuclear "empty" ovum by a single haploid (23X) sperm, in which the haploid genome duplicates (> Fig. 20.6) [88]. The remaining group (4-15%) of complete moles are also androgenetic but are formed by dispermy, i.e., fertilization of an ovum lacking functional maternal chromosomes by two spermatozoa. Accordingly, the complete mole, being paternally derived, constitutes a total allograft in the mother. The opposite pathogenesis of a complete mole occurs in parthenogenesis, meaning that the maternal set of chromosomes duplicates itself in oocytes, and ovarian teratomas are believed to result from this process.

Fig. 20.6

Chromosomal origin of a complete hydatidiform mole. A single sperm fertilizes an empty egg. Reduplication of its 23X set results in a completely homozygous diploid genome of 46XX. A similar process follows fertilization of an empty egg by two sperms with two independent sets of 23X or 23Y. Note that both karyotypes 46XX and 46XY can ensue

The karyotype of a partial mole is nearly always triploid (69 chromosomes) (> Fig. 20.7) with a maternal chromosome complement. Conversely, not all triploid conceptuses demonstrate histological features of a partial mole because the triploids are composed of different groups with distinct pathogenesis [46]. The percentage of partial moles among triploid conceptuses depends on the histologic criteria for the diagnosis and on the type of cytogenetic assays employed. When triploidy is present in a partial mole, the chromosomal complement usually is 69,XXY or 69,XXX and rarely 69,XYY. These abnormal conceptuses result from the fertilization of an egg with a haploid set of chromosomes by either two sperms, each with a set of haploid chromosomes, or by a single sperm with a diploid genome of 46,XY [88]. This condition is known as diandric or androgenetic (paternally derived) triploidy in which two of the three haploid sets are of paternal origin. Diandric triploids at early stages of development frequently show features of an early partial mole, but only a subgroup will go on to develop the complete phenotype of a partial mole. A conceptus with a diploid 46XX maternal genome due to failure of the first meiotic division and a haploid paternal set of chromosomes results in an abnormal, triploid (69XXX or 69XXY) fetus [134]. This is referred to as a digynic (maternally derived) conceptus in which two of the three haploid sets are of maternal origin. There is no agreement as to the percentage of digynic triploids among all triploid placentas,

Chromosomal origin of the triploid, partial

hydatidiform mole. A normal egg with a 23X haploid set is fertilized by two sperm that carry either sex chromosome, to result in 69 chromosomes with a sex configuration of XXY, XXX, or XYY. A similar result can be obtained by fertilization of a sperm carrying the unreduced paternal genome 46XY (resulting sex complement, XXY only)

but it is believed that digynic triploids generally do not present as a molar pregnancy. In conclusion, most welldocumented partial moles are (diandric) triploids, but not all triploid conceptuses are associated with partial moles.

Genetic studies of choriocarcinoma have shown that most choriocarcinomas are diploid [40], and that choriocarcinomas with aneuploidy may be associated with a poorer prognosis. Several studies have demonstrated the diandric (androgenetic) origin of choriocarcinoma following a complete hydatidiform mole [43, 88].

The cytogenetic studies of GTD other than molar pregnancy and choriocarcinoma such as PSTT and epithelioid trophoblastic tumor have not been as well studied because of the rarity of these neoplasms. However, new techniques such as fluorescence in situ hybridization, interphase cytogenetics, and polymorphism of oligonucleotide repeat sequences (microsatellites) have been performed on fixed tissue. Although the majority of GTD can be diagnosed by pathologists on morphological grounds alone, the application of these techniques may become more and more important in diagnosis and management of GTD. For example, microsatellite markers that differ in maternal or paternal origins have been used to confirm a complete mole. Both fluorescence in situ hybridization using chromosome-specific markers and polymerase chain reaction using polymorphic markers have been employed to assist in differentiating a hydropic abortus from a partial mole, and a partial mole from a complete mole [13, 97].

Serum Markers

Treatment of GTD is based on determining, if possible, the specific histological type of trophoblastic lesion, monitoring serum hCG titers, and instituting chemotherapy when appropriate. hCG has proved to be an ideal marker for all forms of GTD and measurement of serum hCG levels is an integral part of the management of this disease. hCG is a glycoprotein composed of two polypeptide chains, alpha and beta, attached to a carbohydrate moiety. The configuration of hCG is similar to other gonadotropins, particularly luteinizing hormone (LH). The α -polypeptide chain in all these hormones is identical; it is the difference in the beta chain that gives the hormones their unique immunologic specificity and biologic function. Accordingly, beta-hCG is the most specific marker for GTD. hCG is produced mainly by syncytiotrophoblast, and it is almost invariably detectable in the serum if trophoblastic tissue is present and when sensitive assays are used. In addition to syncytiotrophoblast, implantation site intermediate trophoblastic cells can also produce a variant of hCG that is hyperglycosylated. It has been reported that this hyperglycosylated hCG inhibits apoptosis in intermediate trophoblastic cells while promoting cell invasion and growth.

In normal pregnancy, beta-hCG peaks to 50,000-100,000 mIU/mL at about 10 weeks gestation and decreases to 10,000-20,000 mIU/mL by 20 weeks, remaining at that level until term. Levels as high as 600,000 mIU/mL have been reported in early pregnancy. In molar gestations, betahCG levels at diagnosis are variable, but most show a markedly elevated hCG titer, which is a useful diagnostic feature. Levels greater than 2 million mIU/mL have been reported. beta-hCG titers are generally higher in complete than partial moles [28]. Choriocarcinoma, almost invariably, produces very high level of beta-hCG and a case with a level of 11 million mIU/mL has been reported [59]. In contrast to the high levels in hydatidiform moles and choriocarcinoma, beta-hCG levels are much lower in PSTTs and epithelioid trophoblastic tumors [150]. Nevertheless, beta-hCG levels are very useful in monitoring patients with these tumors [25].

Beta-core fragment of hCG in urine has been reported to be an even more sensitive marker being detected in patients whose serum hCG levels are near to or below the limit of detection [136]. Also recently, a sensitive radioimmunoassay (RIA) and immunoradiometric assay

(IRMA) have been developed [22, 25] that can measure serum beta-hCG to a level of 0.5 mIU/mL. The assay can detect beta-hCG production from as few as 1,000 trophoblastic cells, thus permitting follow-up to complete disappearance of trophoblastic tissue. Disappearance of beta-hCG from the serum as measured by half-life shows two components, one with a half-life of 6 h and a slower component with a half-life of about 30 h. Since heterophilic antibodies are known to interfere with the measurement of serum analytes, concurrent serum, and urine testing for hCG has been recommended to be used as routine policy in the diagnosis and follow-up of the patients with GTD [138]. Except for hCG, the utilization of other trophoblastic markers including hPL, inhibin, activin, and progesterone in the detection and follow-up of GTD has not yet been established [141].

Staging and Prognostic Factors

Several systems including the modified International Federation of Gynecology and Obstetrics (FIGO) staging system, the World Health Organization (WHO) prognostic index score system, and the National Institute of Health (NIH) classification of metastatic GTD have been developed to predict prognosis and guide treatment (reviewed in [163]). The FIGO system uses an anatomic staging system, which is summarized in **2** Table 20.3. Within each stage, patients with no risk factors are assigned to substage A, those with only one risk factor to substage B, and those with two risk factors are assigned to substage C. The NIH classification is a clinical classification and is based on a variety of clinical features and serum hCG levels that segregates patients into good and poor prognosis (> Table 20.4). The WHO scoring system divides patients into low-, intermediate-, and high-risk groups based on the total score of a variety of prognostic features (Table 20.5). Based on the WHO system, patients

Table 20.3

International Federation of Gynecology and Obstetrics (FIGO) staging of gestational trophoblastic disease

Stage	Definition
L	Confined to uterine corpus
II	Metastases to pelvis and vagina
Ш	Metastasis to lung
IV	Distant metastasis

with nonmetastatic (stage I) and low-risk metastatic (stages II and III, World Health Organization score < 7) gestational trophoblastic neoplasm (GTN) can be treated with single-agent chemotherapy, and the survival rate approaches 100%. In contrast, patients with high-risk metastatic GTN (stage IV, WHO score \geq 7) requires initial multiagent chemotherapy with or without adjuvant radiation and surgery, and the survival rate is 80–90% [106, 114].

In addition to the diagnosis of choriocarcinoma, poor prognostic factors include metastatic disease at diagnosis, cerebral or hepatic metastases, symptoms for more than 4 months, failure of prior chemotherapy, and a pretreatment serum beta-hCG titer of more than 100,000 mIU/mL. More recently, the critical beta-hCG level has been reduced to 40,000 mIU/mL by some investigators. Metastatic disease limited to the lungs or vagina is not a poor prognostic sign. In contrast, although it is difficult to assess precisely the prognostic significance of extrapulmonary metastases, patients with CNS metastases have an approximately 50% remission rate compared with involvement of other visceral organs. Development of CNS metastases during the course of treatment confers an even worse prognosis. Patients with hepatic metastases also have a poor prognosis, but multiagent chemotherapy appears to increase the survival rate. Choriocarcinoma diagnosed after a term gestation has a worse prognosis than choriocarcinoma diagnosed after a mole.

Table 20.4

Clinical classification of malignant trophoblastic disease

Nonmetastatic GTD
Metastatic GTD
Good prognosis
Low hCG level (<40,000 mIU/ml serum beta-hCG)
Symptoms present for less than 4 months
No brain or liver metastasis
No prior chemotherapy
Pregnancy event is not term delivery (i.e., mole, ectopic,
or spontaneous abortion)
Poor prognosis
High pretreatment hCG level (>40,000 mIU/ml serum
beta-hCG)
Symptoms present for more than 4 months
Brain or liver metastasis
Prior chemotherapeutic failure
Antecedent term pregnancy

GTD, gestational trophoblastic disease; hCG, human chorionic gonadotropin.

Table 20.5

World Health Organization scoring system based on prognostic factors^a

	Score			
Prognostic factors	0	1	2	4
Age (years)	≤39	>39		
Antecedent pregnancy	Mole	Abortion	Term	
Interval ^b	4	4–6	7–12	>12
hCG (IU/L)	$< 10^{3}$	103–10 ⁴	10 ⁴ -10 ⁵	>10 ⁵
ABO groups (female		0 × A	В	
× male)		A×O	AB	
Largest tumor (including uterine tumor)		3–5 cm	>5 cm	
Site of metastasis		Spleen, kidney	GI tract, liver	Brain
No. of metastases identified		1–4	4-8	>8
Prior chemotherapy			Single drug	Two or more drugs

^aThe total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: \leq 4, low risk; 5–7, middle risk; and \geq 8, high risk.

^bInterval time (months) between end of antecedent pregnancy and start of chemotherapy.

hCG, human chorionic gonadotropin; GI tract, gastrointestinal tract.

Pathogenesis of Gestational Trophoblastic Disease

The pathogenesis of GTD is largely unknown as few molecular studies have been performed [155]. This is in part due to the relative rarity of GTD and the lack of appropriate experimental models. The most well-studied gestational trophoblastic lesion is hydatidiform mole and, to a lesser extent, choriocarcinoma [88]. Development of a hydatidiform mole appears to be associated with an excess of paternal haploid set of chromosomes. The higher the ratio of paternal/maternal chromosomes, the greater the molar change. Complete moles show a 2:0 paternal/maternal ratio, whereas partial moles show a 2:1 ratio. This hypothesis is best supported by the following two studies. First, a mouse model in which molecularly engineered mice that were either androgenetic or gynogenetic (parthenogenetic) were created by microtransfer of male or female pronuclei into enucleated oocytes. Androgenetic embryos transplanted to

a foster mother developed a bulky, hypertrophic placenta similar to complete moles in humans, whereas the gynogenetic embryos developed only a small placenta with a secondarily stunted embryo. Another study using the mouse embryonic fibroblasts as the cell model demonstrates that paternal and maternal genomes confer opposite effects on proliferation, cell-cycle progression, senescence, and tumor formation [54]. In comparison with biparental fibroblasts, androgenetic fibroblasts whose genomic complement is exclusively from paternal origin exhibit highly proliferative activity, spontaneous transformation, and formation of tumors at low passage number, while the gynogenetic fibroblasts with exclusive maternal genomic complement show decreased proliferation and increased senescence. The molecular mechanism underlying this observation is the differential expression of imprinted genes. For example, the maternally expressed and paternally imprinted genes such as p57^{kip2} decrease cellular proliferation. In contrast, the paternally expressed growth factor, Igf2, is essential for the long-term proliferation of all genotypes [54]. Therefore, it is likely that a similar mechanism is also involved in the pathogenesis of complete and partial hydatidiform moles. In rare familial/recurrent hydatidiform moles, which account for 2% of all molar cases, mutations have been detected in the maternal gene, NALP7, which plays a role in inflammation and apoptosis [108, 162].

As previously discussed (> Table 20.1), there are at least three distinctive types of GTN including the most common type, choriocarcinoma, and the less common ones, PSTT and epithelioid trophoblastic tumor. Molecular analysis on GTN is largely based on the identification and characterization of trophoblastic markers in various types of GTN, and the reference of their unique gene expression patterns to different trophoblastic subpopulations in normal early placentas (reviewed in [145]). The main conclusion from those studies is that following neoplastic transformation of trophoblastic stem cells, presumably the cytotrophoblast, specific differentiation programs dictate the type of trophoblastic tumor that develops () Fig. 20.8). These patterns of differentiation in GTN recapitulate the stages of early placental development. For example, choriocarcinoma is composed of variable amounts of neoplastic cytotrophoblast, syncytiotrophoblast, and intermediate (extravillous) trophoblast, and resembles the previllous blastocyst, which is composed of a similar mixture of trophoblastic subpopulations. On the other hand, the neoplastic cytotrophoblast in PSTT differentiates mainly into intermediate (extravillous) trophoblastic cells in an implantation site, whereas the neoplastic cytotrophoblast in epithelioid trophoblastic tumor differentiates into

Relationship of trophoblastic neoplasms to different subpopulations of intermediate trophoblastic cells. Exaggerated placental site and placental site trophoblastic tumor are related to the differentiation of implantation site intermediate trophoblast, whereas placental site nodule and epithelioid trophoblastic tumor are related to chorionic-type intermediate trophoblast. EVT: extravillous trophoblast (equivalent to intermediate trophoblast), PSTT: placental site trophoblastic tumor, ETT: epithelioid trophoblastic tumor

chorionic-type intermediate (extravillous) trophoblastic cells in chorion laeve. This model suggests that choriocarcinoma is the most primitive trophoblastic tumor, whereas PSTT and epithelioid trophoblastic tumor are relatively more differentiated. Furthermore, it explains the histologic mixture of choriocarcinoma and PSTT and/or epithelioid trophoblastic tumor in some GTNs.

Clinicopathological Features, Behavior, and Treatment of Molar Placentas

A hydatidiform mole is an abnormal placenta characterized by enlarged, edematous, and vesicular chorionic villi accompanied by villous trophoblastic hyperplasia. It is subdivided into complete hydatidiform mole and partial hydatidiform mole based on morphologic, cytogenetic, and clinicopathological features. Although typical complete and partial moles are easily distinguished on histologic examination, the routine use of ultrasound in pregnancy has led to the clinical diagnosis and evacuation of moles much earlier in gestation, often in the first trimester. As a result, the classical features of complete and partial moles that in the past were based on examination of specimens obtained in the second trimester are not as apparent, making the histopathologic diagnosis more difficult [43]. In addition, a variety of other genetic abnormalities such as trisomy and monosomy may be associated with abnormal placentas that display minor degrees of

hydropic change and trophoblastic proliferation but do not qualify as moles. Although recent studies have proposed new and expanded criteria for the diagnosis of these early moles and abnormal placentas, the criteria are subtle and difficult to reproduce, making the histologic diagnosis somewhat subjective. Furthermore, with the recognition that the genetic alterations that underlie these various lesions are distinctly different, one can legitimately question whether the diagnosis should be based on genetic as well as morphologic assessment. At present there is insufficient data to provide a definitive answer. Genetic analysis is costly, labor-intensive, and is not available in most pathology laboratories. However as these techniques become cheaper and more widespread it is likely that genetic analysis will complement histopathologic evaluation in the diagnosis of difficult cases [13, 97]. The ratio of complete versus partial moles varies among studies and most reports show that complete moles outnumber partial moles [13, 28, 45, 65, 97, 121, 167]. Clinical, pathologic, and cytogenetic differences separate the two forms of hydatidiform mole, yet all molar pregnancies have the potential for persistent GTD [3], although the risk is much higher in complete than in partial hydatidiform moles.

Complete Hydatidiform Mole

Complete hydatidiform mole is characterized by hydropic swelling of the majority of villi, and a variable degree of trophoblastic proliferation and atypia. Fetal tissue usually is not present. Most complete hydatidiform moles have a 46, XX karyotype [43]. In a study analyzing 26 complete moles, all of them show diandric (paternal-only) genomes and the lesions include 24 homozygous and 2 heterozygous moles [13]. Early complete moles may lack hydropic swelling but trophoblastic proliferation and atypia are present.

Clinical Features

As discussed above, complete moles are being diagnosed now at an earlier gestational age than in the past (8.5-12 weeks versus 16-18 weeks) because of the routine use of sonography in pregnancy. Pelvic ultrasonic examination discloses a diagnostic snowstorm pattern but high resolution sonography typically reveals a complex intrauterine mass with many small cysts. This pattern, especially when associated with a markedly elevated beta-hCG level, is clinically diagnostic of molar pregnancy. Consequently, a complete mole now rarely presents with the classic signs and symptoms such as excessive uterine size, hyperemesis, theca lutein ovarian cysts, hyperthyroidism, or preeclampsia. The majority of patients present with vaginal bleeding or are discovered by sonography. While a presumptive diagnosis of an incomplete or missed abortion is usually made, serum beta-hCG levels greater than 100,000 mIU/mL should prompt the physician to consider the diagnosis of molar pregnancy. In the past, excessive uterine enlargement for the gestational age occurred in approximately two thirds of patients. Occasionally, the initial clinical manifestation is sudden passage of molar vesicles. Preeclampsia (pregnancy-induced hypertension with edema and proteinuria) occurs in up to one fourth of patients with complete mole. In contrast to nonmolar gestations, in which preeclampsia occurs typically in the last trimester, in molar gestations preeclampsia occurs in the first trimester. Thus, early onset of preeclampsia, especially when coupled with excessive uterine enlargement, suggests the presence of a molar pregnancy. Additional clinical signs of established molar pregnancy include hyperemesis gravidarum, hyperthyroidism, pulmonary embolization of trophoblast, and massive ovarian enlargement due to benign theca lutein cysts (hyperreactio luteinalis) [43]. Usually with complete mole the beta-hCG titer is markedly elevated.

Although these clinical signs and symptoms permit the diagnosis of a molar pregnancy before evacuation, the clinical presentation is quite variable. Up to 80% of cases are first diagnosed by histological study of spontaneously passed or curetted tissue. Hydatidiform moles also can be found unexpectedly in elective abortion specimens of asymptomatic patients and may be rarely detected in the fallopian tube and ovary. A primary mole involving the adnexa should be discriminated from the hydropic change that is frequent in an aborting ectopic pregnancy and from invasive mole with extension into the broad ligament.

Gross Findings

In typical cases, massively enlarged, edematous villi give the characteristic grape-like appearance to the placenta

Fig. 20.9

Complete hydatidiform mole. (a) A hysterectomy specimen shows an enlarged uterus with molar tissue protruding into the uterine cavity. (Reprint from [146] with permission from Churchill Livingstone Elsevier.) (b) In a well-developed complete mole, the hydropic villi range from a few millimeters to more than 1 cm in diameter (> Fig. 20.9). However, the specimen volume of contemporary complete moles is significantly less than in the past and in very early complete moles grossly hydropic change may be absent. In advanced mole, which is now rarely encountered, swollen villi may range from a few millimeters to as large as 3.0 cm in diameter but usually average about 1.5 cm. Rarely, fetal development may occur in complete mole. After suction curettage, molar villi may collapse and a large amount of bloody tissue may obscure the edematous villi, especially if a mole is extracted early in pregnancy when villous enlargement is less striking. In this instance, there may be no gross evidence of molar enlargement. Histological evaluation of the tissue adherent to the gauze that collects suctioned uterine contents is necessary to establish the diagnosis. Immersing the gross tissue in saline or formalin can resuspend collapsed villi.

Microscopic Findings

Complete moles have two key features: trophoblastic proliferation and villous edema. Many villi display central cistern formation characterized by a prominent central space that is entirely acellular (\bigcirc *Fig. 20.10*). Smaller villi usually are present but these, too, are edematous. The villous stroma has a distinctive appearance with a pale blue-grey appearance having widely separated spindle cells beneath the villous surface, and edematous central cistern. Villous stroma of a complete mole contains numerous but inconspicuous CD34-positive blood vessels. All hydatidiform moles display some degree of haphazard trophoblastic proliferation on the villous surface. This trophoblastic proliferation in complete hydatidiform mole is circumferential around the villus (\bigcirc *Fig. 20.11*). Columns and streamers of cells composed of a mixture of

Fig. 20.10

Early complete hydatidiform mole. Villi have extensive stromal edema with central cisterns (*C*). The periphery of the villi expands into bulbous projections with more prominent stromal cells. There is a large amount of proliferative trophoblast in this field (Courtesy of Dr. B. Ronnett)

• Fig. 20.11 Complete hydatidiform mole. Enlarged villi with circumferential proliferation of trophoblast

Fig. 20.12 Trophoblast in a complete mole. A mixture of cytotrophoblast (CT), intermediate trophoblast (IT), and syncytiotrophoblast (ST) grows from the surface of a villus (V)

cytotrophoblast, syncytiotrophoblast, and villous intermediate trophoblast project randomly from the villous surface (> Fig. 20.12). The amount of proliferative trophoblast in moles varies greatly. It may be marked, affecting most villi, or it may be subtle and only focally present, emphasizing the need for thorough sampling. Large sheets of trophoblast including villous intermediate trophoblast that appear to be unattached to villi also may be present. These result from tangential sectioning, or they represent detached fragments of the trophoblast from the implantation site. Trophoblastic islands, structures seen in the normal early placentas, are rarely present in complete moles. The trophoblast of a complete mole always displays cytologic atypia. At times it may be as marked as in choriocarcinoma () Fig. 20.12). In addition, a linear distribution of atypical intermediate trophoblast overlying fibrin is a feature that occurs in trophoblastic lesions as opposed to an abortus.

Fig. 20.13

An early complete hydatidiform mole. The villi are not particularly hydropic and the trophoblastic hyperplasia and atypia are not marked. The circumferential proliferation of villous trophoblastic cells that project randomly from the villous surface is characteristic. This case has been molecularly confirmed as an androgenetic complete mole (Courtesy of Dr. B. Ronnett)

As noted previously, the typical morphologic features of a complete mole may be absent or very subtle in molar specimens evacuated in the first trimester (\bigcirc *Fig. 20.13*). These complete moles are referred to as "early complete moles" that do not have the typical clinical presentation or classic sonogram appearance. The histologic features of an early complete mole are: (1) redundant or polypoid bulbous terminal villi; (2) hypercellular villous stroma with primitive stellate cells; (3) a labyrinthine network of villous stromal canaliculi; (4) focal hyperplasia of cytotrophoblast and syncytiotrophoblast on both villi and the undersurface of the chorionic plate; (5) atypical trophoblast lining the villi and in the implantation site [72, 107]; and (6) increased villous stromal apoptosis [75].

Exaggerated placental site. The lesion is associated with a complete hydatidiform mole. The intermediate trophoblastic cells extensively infiltrate the endomyometrium. The nuclei are enlarged and show cytologic atypia

The implantation sites associated with a complete hydatidiform mole almost always show a morphological feature similar to an exaggerated placental site. As with the trophoblastic hyperplasia on the villous surface, the cells are more abundant and atypical than what is encountered with an abortus and for that matter an exaggerated placental site (**>** Fig. 20.14). The immunostaining pattern for the markers of implantation site intermediate trophoblast is identical between the molar implantation site and an exaggerated placental site except the Ki-67 labeling index in a mole is elevated as compared to no Ki-67 labeling index in a nonmolar exaggerated placental site, suggesting that these two types of lesions are different despite their similar morphologic features [104, 151]. Interestingly, as compared with the normal placentas, complete moles exhibit a higher level of apoptosis in cytotrophoblast, indicating a complex but delicate regulation of the cell population in complete moles.

Differential Diagnosis (See section **Partial** Hydatidiform Mole)

The differential diagnosis of complete moles is discussed in the section of partial moles.

Behavior and Treatment

In the past, when the complete moles were not diagnosed early, 2 and 12% of patients experienced severe respiratory distress immediately after uterine evacuation of a hydatidiform mole. This phenomenon usually is attributed to massive deportation of trophoblast to the lungs, an exaggeration of a physiologic process occurring in normal pregnancy. The most serious complication after molar evacuation is persistent or metastatic GTD and the risk of developing choriocarcinoma. Postmolar trophoblastic disease may represent a persistent mole in the uterine cavity or it may be an invasive mole or a choriocarcinoma. Persistent GTD occurs in approximately 17-20% of women who have undergone evacuation [140] and in 3–5% of women who have undergone hysterectomy [44]. The risk of development of choriocarcinoma following a complete mole is about 2-5% in the United States [26, 33] and 13% in Japan [95]. Prediction of the behavior of complete hydatidiform moles based on biomarkers is notoriously difficult. The capricious nature of molar pregnancy should never be underestimated. In the past, a number of clinical, morphologic, and immunohistochemical studies have attempted to predict the prognosis of complete moles but no reliable features have emerged. More recently, Cheung et al. have found that higher mRNA and protein expression levels of Nanog, a transcription factor involved in embryonic stem cell development, are associated with worse clinical outcome in hydatidiform moles, i.e., increased risk for developing persistent GTD [148, 161]. Further studies including large case control studies or prospective cohorts are required to confirm this finding. It is recommended that follow-up with serial serum betahCG titers using sensitive assays and radiographic imaging remain the mainstay in managing patients with complete hydatidiform mole.

After treatment with chemotherapy there is minimal increase in the risk of spontaneous abortion or congenital anomalies and many patients have successful term pregnancies. In general, patients with molar pregnancy can be reassured that they can anticipate a normal future reproductive outcome after appropriate treatment [11]. A chest radiograph before treatment and 4 weeks later should be performed to exclude metastases. Following evacuation of a mole, careful beta-hCG monitoring is mandatory since it is the most reliable and sensitive method for the early detection of persistent GTD. The titers of beta-hCG should fall to normal between 10 and 170 days after evacuation of a mole, and most patients will have normal titers by 60 days postevacuation. Persistent GTD after molar pregnancy is heralded by plateauing beta-hCG titers for 2–4 weeks, rising beta-hCG titers, persistent uterine disease such as abnormal bleeding, or evidence of metastases. Initial therapy for persistent disease is usually methotrexate, dactinomycin, or a combination of the two. Multiagent chemotherapy that includes etoposide (VP-16) is used for the treatment of high-risk patients and for those who fail to respond to conventional forms of chemotherapy.

Partial Hydatidiform Mole

Partial hydatidiform mole features an intimate admixture of two populations of villi: enlarged, edematous villi and normal-sized villi that may be fibrotic. Partial molar pregnancies may have a grossly identifiable embryo or fetus with congenital anomalies.

Partial moles are usually the result of diandric triploidy; however, not all triploid conceptuses are partial moles. In a study analyzing 12 partial moles, all partial moles show diandric, monogenic genomes including 11 heterozygous and one homozygous lesions [13].

Clinical Features

Patients with partial moles may have signs and symptoms similar to those seen in complete moles, but usually this is less likely. Uterine size is generally small for dates. Enlargement in excess of that expected for the gestational age is uncommon. Frequently, patients with partial moles appear to have a missed abortion, and vaginal bleeding is the main presenting symptom. Forty-two percent of patients with partial moles are at risk of pre-eclampsia, which tends to occur later than in complete mole but it can be equally severe [68]. Serum beta-hCG levels often are in the low or normal range for gestational age. Only a few patients with partial moles show markedly elevated beta-hCG titers such as those seen with complete moles.

Gross Findings

The volume of tissue is generally small, less than 100 or 200 mL. The villi may be grossly evident and recognizable

Fig. 20.15 Partial hydatidiform mole. Hydropic villi mixed with smaller, "normal-appearing" villi

as molar, yet are smaller than those found in a complete mole. For early partial moles, these gross features may not be apparent. In some cases a fetus or fetal membranes is present. When a fetus is found, it often shows gross congenital anomalies.

Microscopic Findings

Partial mole shows features in some villi that are similar to those seen in complete moles, but the molar change is focal (\bigcirc *Fig. 20.15*). By definition, there should be a mixture of edematous villi and small, relatively normal-sized villi. Central cisterns are less conspicuous than in complete moles. Smaller villi usually show stromal fibrosis similar to that seen in missed abortions (\bigcirc *Fig. 20.16*). Trophoblastic hyperplasia is less marked than in complete

Partial hydatidiform mole. A mixture of enlarged villi and small, normal-sized, and fibrotic villi. There is mild haphazard trophoblastic hyperplasia and a scalloped villous surface with trophoblastic infoldings forming inclusions (arrow)

mole. Generally it is focal and shows little, if any, atypia, consisting of small, haphazard tufts of trophoblast, often syncytiotrophoblast, emanating from the surface of some of the abnormal villi. Another feature commonly encountered in partial mole is a scalloped outline of the enlarged villi, yielding a pattern of trophoblastic invaginations into the villous stroma. When the invaginations do not show continuity with the surface trophoblast, they appear as inclusions within the stroma (\bigcirc *Figs. 20.15* and \bigcirc *20.16*). Invaginations are not exclusive for partial moles and may, on occasion, be found in other conditions including complete mole and nonmolar hydropic abortus.

Partial moles with triploidy often are associated with the presence of a fetus (usually abnormally formed) or its amnion, in contrast to the absence of fetal structures in most complete moles. Fetal demise with subsequent degeneration of fetal structures may make identification of fetal tissue difficult. A subtle clue is the presence of a functioning villous circulation containing nucleated red cells, a feature that requires fetal development. In contrast, the embryo associated with a complete mole usually dies before organogenesis and, therefore, fetal structures are not present in the specimen, and fetal erythrocytes are not present within placental vessels. One concern in the diagnosis of an apparent partial mole is that the specimen represents a twin gestation with a fetus and a complete mole. Such twin pregnancies may occur [82], but probably are an infrequent occurrence relative to singleton gestations of a partial mole. In summary, a partial mole is optimally diagnosed when the following four microscopic features are present: (1) two populations of villi (one hydropic and one small and fibrotic, (2) enlarged villi with central cavitation, (3) irregular villi with geographic, scalloped borders with trophoblast inclusions, and (4) minimal trophoblast hyperplasia (usually focal and involving syncytiotrophoblast) [44, 168].

Differential Diagnosis

In a practical sense, the most important diagnostic issue when encountering specimens with abnormal villous morphology is recognition of complete hydatidiform mole since this lesion has a higher risk to develop persistent GTD than partial hydatidiform moles and hydropic abortus. However, diagnosis of hydatidiform moles by histology can be complicated by overlap of morphological criteria for complete mole, partial mole, and a nonmolar hydropic abortus. Nevertheless, the diagnosis of complete versus partial moles is usually relatively straightforward, although it can be difficult when an early complete hydatidiform mole is encountered. The pathological features of partial as compared to complete moles are summarized in **2** Table 20.6. Evidence of a fetus or embryo including villous erythrocytes strongly favors the diagnosis of partial mole, although the rare event of a twin gestation with one conceptus being a complete mole should be borne in mind.

Morphological distinction of a hydatidiform mole from an abortus with abnormal villous morphology may be problematic, and there is a considerable degree of interobserver variance in making this distinction [20]. Placentas with genetic abnormalities other than triplody,

Table 20.6

Pathologic features and behavior of complete and partial moles

Feature	Complete	Partial
Karyotype	46,XX, 46,XY	69,XXY, 69,XXX
Embryo/fetus	Absent	Present
Villous outline	Round	Scalloped
Villous stromal apoptosis	Prominent	Limited
Hydropic swelling	Marked; cisterns present	Less pronounced and focal
	All villi involved	Cisterns less prominent
		Small fibrotic villi can be present
Trophoblastic proliferation	Circumferential; Variable, may be marked	Focal and minimal
Trophoblastic atypia	Often present	Absent
Implantation site	Exaggerated ^a	Normal or occasionally exaggerated
P57 (kip2) staining	Negative	Diffusely positive
Behavior	17–20% develop pGTD	<4% develop pGTD

^aExaggerated implantation site indicates an increase in the number and the extent of intermediate trophoblastic cells.

pGTD, persistent gestational trophoblastic disease.

such as trisomy, can display morphologic changes suggestive of partial mole and can be misinterpreted as such by morphologic diagnosis alone [20]. However, some clues may be useful in assisting the differential diagnosis. Spontaneous abortions often are associated with failure of development or early demise of the embryo, the so-called blighted ovum or hydropic abortus. These specimens show some villous edema with hydropic swelling, features shared with molar placentas. The hydropic abortus usually is a smaller specimen, however. The villi in a hydropic abortus are enlarged only slightly and do not assume the large dimensions found in complete or partial moles. Cisterns can be seen in nonmolar abortions but they are focally distributed. Hyperplasia of villous trophoblast is not evident in these cases. The proliferative trophoblast on the villous surface of early pregnancy also must be

distinguished from the trophoblastic hyperplasia of molar pregnancy. The trophoblast proliferating from the villous surface of an abortus shows polar distribution characterized by proliferation of trophoblast at the distal end of the villus that implants into the basal plate. Similarly, villi with trophoblastic islands can be regarded as polarized villi that are also associated with a nonmolar abortus. This directional orientation contrasts with the irregular or circumferential proliferation of molar trophoblast. In comparing abortion specimens with a non-molar etiology to partial mole it was found that partial moles display at least three of the following histologic features: two discrete populations of villi, circumferential mild trophoblastic hyperplasia, trophoblastic inclusions, prominent scalloping of villi, or cistern formation. In contrast, a non-triploid abortus villi display at most two of these features of partial moles [20]. Irregular trophoblastic hyperplasia from the villous surface is an especially critical feature for diagnosing molar pregnancy.

When large aggregates of atypical or proliferating trophoblast are encountered without any villi, the differential diagnosis should include choriocarcinoma or PSTT. Care must be taken to be certain that sampling is adequate since villi may be sparse and fragmented. Even complete mole can have limited villi in the sections if much of the tissue has been spontaneously aborted or if dealing with repeated curettage following primary evacuation. The entire specimen should be processed. Limited examination of a uterine, vaginal, or pulmonary lesion may show only trophoblast, but deeper sectioning may reveal molar villi.

Immunohistochemical stains with the p57kip2 antibody can be helpful in the differential diagnosis of complete hydatidiform moles. Expression of p57kip2, a paternally imprinted gene, is either absent or low in trophoblast in cases of complete moles in contrast to diffuse staining in partial moles and non-molar placentas (> Figs. 20.17–20.19) [17, 21]. Importantly, assessment of p57 immunoreactivity should be performed only in villous trophoblast and stroma cells rather than intermediate trophoblastic cells in the endomyometrium as the latter may reexpress p57 due to a mechanism related to "epigenetic relaxation" in a complete mole. The accuracy of p57 staining in the diagnosis of complete moles has been recently validated by molecular genetic studies [97, 132]. Besides the p57 expression pattern, the stromal apoptotic index has been shown to be significantly higher in very early complete mole than in very early partial mole or normal placental tissues, which can be potentially useful in differential diagnosis [75].

Given the fact that complete and partial moles are characterized by distinct molecular genetic features, ploidy

p57 immunostaining of a complete hydatidiform mole. The villous stromal cells and cytotrophoblastic cells (dashed arrow) do not show p57 immunoreactivity while the intermediate trophoblastic cells (IT) (arrow) are positive for p57

analysis has proven valuable in distinguishing a diploid complete mole from a triploid partial mole and diploid hydropic abortus from a triploid partial mole [175]. Flow cytometry and digital imaging systems are frequently employed to analyze ploidy; however, ploidy assays cannot be used to diagnose hydatidiform moles per se or to distinguish a diploid complete mole from a diploid hydropic abortus. Recently, the multiplex short tandem repeats (microsatellite markers) DNA analysis has gained wide acceptance in genotyping products of conception with abnormal villous morphology [89]. The assay can be performed using commercially available kits such as those used in practicing forensic medicine and the genomic DNA from villi and maternal tissues can be conveniently

prepared from paraffin sections. Analyzing microsatellite markers provides a useful adjunct tool in the differential diagnosis among complete mole, partial mole, and nonmolar hydropic abortus.

In summary, it has been well known that diagnosis based solely on morphology suffers from unsatisfied interobserver reproducibility in distinguishing hydatidiform moles from nonmolar specimens with hydropic villi and subclassification of hydatidiform moles as complete hydatidiform mole, partial hydatidiform mole, or early complete hydatidiform mole. Moreover, chorionic villi associated with chromosomal abnormalities that are not triploid, such as trisomy, may display hydropic change and abnormal villous morphology that mimic a partial mole [20]. These abnormal placentas associated with hydropic abortus are not associated with an increased risk of GTD and therefore the

Abnormal villous morphology. The H&E shows irregularly shaped and variably sized villi with a trophoblastic inclusion, suggesting a partial hydatidiform mole (PHM). Similar to a PHM, the villous stromal cells and cytotrophoblast are diffusely positive for p57. However, genotyping analysis demonstrated biparental diploidy, consistent with a non-molar abortus (Courtesy of Dr. B. Ronnett)

differential diagnosis is clinically important. A logistic approach in differential diagnosis of specimens with abnormal villous morphology has been proposed [97]. In that study, it is recommended that morphologically abnormal villi should be assessed for p57 immunostaining, which serves as a triage assay for the diagnosis of complete hydatidiform moles. When the diagnosis by routine morphology is equivocal, morphologic features together with a negative p57 result indicate a complete hydatidiform mole with a rare exception that the complete hydatidiform mole retains the maternal allele of chromosome 11 in which the *p57* gene resides. Molecular genotyping is then applied to validate a diagnosis of complete hydatidiform mole by demonstrating androgenetic diploidy and to resolve p57-positive cases into diandric triploid partial hydatidiform mole, biparental diploid nonmolar specimens, and the rare complete hydatidiform mole with aberrant p57 expression [98]. All genotyped nonmolar specimens demonstrated biparental diploidy, while partial hydatidiform moles demonstrated diandric triploidy.

Behavior and Treatment

Several studies have shown that partial moles are rarely followed by persistent or metastatic GTD with risk estimates ranging from 0 to 4% [9, 12, 47, 50, 82, 95, 100, 115, 140, 183]. Misinterpretation of complete moles as partial moles is a major factor contributing to the overestimated frequency of persistent GTD after partial mole in previous studies. Although the risk to develop persistent GTD or GTN is relatively low in partial mole, there are several case reports demonstrating the association of a partial mole and GTN. For example, invasive mole and metastatic pulmonary lesions have been reported in association with a partial mole [50], and choriocarcinomas have been reported in 3 of 3,000 patients with partial moles. In addition, an in situ or intraplacental choriocarcinoma arising in a partial mole have also been reported [99]. The magnitude of the risk of repeated partial moles is not known, although repetitive partial moles do occur. Therefore, despite the fact that development of persistent GTD following a partial mole is uncommon, follow-up of patients after evacuation of a partial mole is warranted.

Invasive Mole

Invasive mole is a hydatidiform mole in which hydropic villi invade the myometrium or blood vessels or, more rarely, are deported to extrauterine sites. Although invasive mole is not a true neoplastic disease, it is often clinically considered to be malignant since the lesion can invade the myometrium and metastasize.

Clinical Features

Invasive mole is a possible sequela of a hydatidiform mole, complete or partial. It is unusual for invasive mole to present primarily, although invasive mole may occur simultaneously with intracavitary molar pregnancy. Pathological diagnosis requires demonstration of molar villi
invading the myometrium or deported to extrauterine sites. In histologically verified cases the lesion most often is confined to the uterus, with distant spread occurring in 20–40% of cases. Typically this involves the lungs, but the vagina, vulva, and broad ligament are also well recognized. Rare examples of spread to other sites such as the paraspinal soft tissue have been reported. The diagnosis usually is made on a hysterectomy specimen. However, invasive mole is rarely confirmed histologically since hysterectomy is rarely performed in patients with persistent beta-hCG titers after removal of an intrauterine mole and since metastatic lesions of GTD usually are treated successfully with cytotoxic chemotherapy without biopsy.

Gross Findings

In the uterus, invasive mole is an erosive, hemorrhagic lesion extending from the uterine cavity into the myometrium. Invasion can range from superficial penetration to extension through the wall, with perforation or involvement of the broad ligament. Molar vesicles often are grossly apparent.

Microscopic Findings

Microscopically, the diagnostic feature is the presence of molar villi along with trophoblast in the myometrium or at an extrauterine site (> Fig. 20.20). Trophoblastic proliferation with atypia accompanies the enlarged villi and is as variable as in noninvasive mole, ranging from slightly proliferative with minimal atypia to marked trophoblastic proliferation with extreme atypia. Hydropic swelling tends not to be as marked as in noninvasive mole. Molar villi usually are no more than 4-5 mm in diameter. In metastatic sites, the diagnosis is based on the presence of villi. Careful searching may be necessary to identify villi within a lesion seemingly composed entirely of highly proliferative trophoblast. Lesions at distant sites usually are composed of molar villi confined within blood vessels without invasion into adjacent tissue. The molar villi at the extrauterine sites are the result of intravascular deportation.

Differential Diagnosis

Since the pathological diagnosis of invasive moles requires identification of molar villi and trophoblast either within the myometrium or at an extrauterine site, there are few lesions that enter into the differential. Recurettage of the

endometrium after diagnosis of a mole may show proliferative trophoblast with villi but this does not represent an invasive mole unless myometrial invasion is found. If post-molar curettage yields only trophoblast, the diagnosis of invasive mole is not established. Two forms of placenta accreta, specifically placenta increta or percreta, represent normal placenta that has implanted without an intervening decidual layer and invaded myometrium. In contrast to invasive mole, however, the villi in accreta are not hydropic and the trophoblast does not show the proliferative activity found in a mole.

Invasive mole must be discriminated from choriocarcinoma. Both invasive mole and choriocarcinoma after a hydatidiform mole are manifested by a plateau or elevation in the beta-hCG titer. Furthermore, both can give rise to secondary lesions. Consequently, it is often not possible clinically to distinguish between these lesions. A repeat curettage may yield more molar tissue, obvious choriocarcinoma, or scant fragments of trophoblast unaccompanied by villi but lacking unequivocal features of choriocarcinoma. In the latter instance a diagnosis of atypical trophoblast is appropriate, accompanied by a description and the reasons why a diagnosis of residual mole or choriocarcinoma was not made. When more molar tissue is found, a diagnosis of persistent hydatidiform mole is made.

Behavior and Treatment

Invasive mole is the most common form of persistent or metastatic GTD after hydatidiform mole, which occurs six to ten times more frequently than choriocarcinoma. Using modern chemotherapy, death from invasive mole is unusual. Most patients, even with distant spread survive. The risk of progression to choriocarcinoma is no greater than that after complete mole.

Invasive mole is the clinical diagnosis given to many patients with extrauterine disease or abnormally persistent beta-hCG titers after molar pregnancy and no residual hydatidiform mole within the uterine cavity. In such instances, there is, however, a possibility that persistent beta-hCG levels may be due to choriocarcinoma. In these cases, the clinical term persistent GTD or gestational trophoblastic neoplasia is used without attempting to discriminate between invasive mole and choriocarcinoma.

Clinicopathological Features, Behavior, and Treatment of Trophoblastic Tumors and Tumor-like Lesions

Choriocarcinoma

Gestational choriocarcinoma is a highly malignant epithelial tumor arising from the trophoblast of any type of gestational event, most often a hydatidiform mole. Choriocarcinoma is for all practical purposes limited to reproductive-age women but rare examples in postmenopausal women have been reported. It consists predominantly of a biphasic proliferation of mononucleate trophoblast and syncytiotrophoblast that morphologically recapitulates the primitive trophoblast of the previllous stage during placental development. Chorionic villi are not a component of this tumor with an exception of intraplacental choriocarcinoma (see below). Molecular genetic study based on restriction fragment length polymorphism analysis using a minisatellite DNA probe suggests that the pathogenesis of choriocarcinoma varies, some being androgenetic and some gynogenetic [6]. However, the case number in that study is limited to permit from conclusions. The absence of Y chromosome has been demonstrated in the vast majority of choriocarcinomas, indicating that the shortfall of Y chromosomal complements in choriocarcinomas may simply be due to the genetic basis of their precursor lesions, complete hydatidiform moles in which most of cases had the genotype of XX [178].

Clinical Features

Theoretically, choriocarcinoma may arise in the trophoblast of the primitive blastocyst during implantation, but most cases of choriocarcinoma appear to follow a recognizable gestational event. Indeed, "in situ" or intraplacental choriocarcinoma can be found in a third-trimester placenta [29, 38] with a transition from normal-appearing cytotrophoblast to choriocarcinoma. The more abnormal the pregnancy, the more likely that choriocarcinoma may supervene. Hertig and Mansell found an incidence of 1 in 160,000 normal gestations, 1 in 15,386 abortions, 1 in 5,333 ectopic pregnancies, and 1 in 40 molar pregnancies [55]. In that series, one half of the cases of choriocarcinoma were preceded by hydatidiform mole, with 25% following abortion, 22.5% following normal pregnancy, and 2.5% following ectopic pregnancy [55].

The signs and symptoms of choriocarcinomas are protean. Abnormal uterine bleeding is one of the most frequent presentations of choriocarcinoma, but uterine lesions may be restricted to the myometrium and remain asymptomatic. Not all patients have a demonstrable lesion in the uterus after an intrauterine gestation. Many examples of metastatic choriocarcinoma without a primary uterine tumor have been described and in those cases, it is highly likely that the neoplasm undergoes regression in the uterus. Although the majority of choriocarcinomas develop shortly after the preceding gestation (> Table 20.7), long latency (>10 years) between the gestation and diagnosis can occur [127, 165]. Because of its rarity, the diagnosis of a postpartum choriocarcinoma can be delayed and the mean duration from onset of symptoms to treatment is 7 weeks [117]. Sometimes, symptoms related to metastases are the first indication that a choriocarcinoma is present, and the lungs are the most frequent sites for metastasis. Thyrotoxicosis and hemorrhagic events in the central nervous system, liver, and gastrointestinal or urinary tracts also occurs in choriocarcinoma. Although rare, gestational choriocarcinoma may coexist with an intrauterine

Table 20.7

Clinical features of gestational trophoblastic tumors

Features	Choriocarcinoma	PSTT	ETT
Clinical presentation	Persistent GTD after hydatidiform mole	Missed abortion	Abnormal vaginal bleeding
Last known pregnancy or GTD	Usually within months	Variable, can be remote	Variable, can be remote
History of mole	\sim 50% of cases	${\sim}10\%50\%$ of cases	${\sim}10\%{-}50\%$ of cases
Serum beta-hCG	High (>10,000 IU/mL)	Low (<2,000 IU/mL)	Low (<2,000 IU/mL)
Clinical behavior	Aggressive if untreated, curable in most patients after treatment	Self-limited, persistent, or aggressive	Self-limited, persistent, or aggressive
Response to chemotherapy	Excellent	Variable	Variable

Choriocarcinoma. *Left*: Choriocarcinoma in the uterus. The tumor forms a large, hemorrhagic mass that involves the endometrium and myometrium. (Reprint from [146] with permission from Churchill Livingstone Elsevier.) *Right*: Liver metastasis from choriocarcinoma. Multiple, circumscribed, and hemorrhagic masses are evident

pregnancy, either as an incidental microscopic finding or a concurrent disease with the diagnosis of choriocarcinoma during pregnancy. Gestational choriocarcinoma also may be primary in the fallopian tube, and in this extremely rare instance, the tumor probably is a sequela of an ectopic pregnancy.

Gross Findings

Uterine choriocarcinoma generally is a dark red, hemorrhagic mass with a shaggy, irregular surface and variable amounts of necrosis (**>** *Fig. 20.21*). Occasionally, a lesion may lack significant hemorrhage and appear as a fleshy,

Choriocarcinoma. The tumor forms a circumscribed mass within the myometrium. Hemorrhage is present in the right lower corner

tan-gray mass with necrosis. The size of uterine lesions varies greatly, ranging from tiny, microscopic foci to huge, necrotic tumors. Metastases beyond the uterus appear well circumscribed and hemorrhagic. For the rare intraplacental choriocarcinoma, the diagnosis based on gross specimens is very difficult as the lesion may be very small and can mimic non-malignant conditions, such as placental infarction or even an old blood clot.

Microscopic Findings

Choriocarcinoma is characterized by masses and sheets of trophoblastic cells that invade surrounding tissue and permeate vascular spaces (\bigcirc *Figs. 20.22–20.26*). Choriocarcinoma is generally not associated with chorionic villi with the rare exception of choriocarcinoma arising within a placenta. Central hemorrhage and necrosis with viable tumor constituting only a thin peripheral rim

Choriocarcinoma. Syncytiotrophoblast (ST) lining vascular spaces and capping cytotrophoblast (CT) and intermediate trophoblast (IT). There is an alternating arrangement of multinucleated ST with intervening clusters of mononucleate IT and CT

is a characteristic feature. The interface with normal tissue, if preserved, is circumscribed and appears expansile or pushing (**>** *Fig. 20.22*).

An intimate mixture of cytotrophoblast, intermediate trophoblast, and syncytiotrophoblast forms the cellular population of choriocarcinoma (\bigcirc *Fig. 20.23*) [92]. The cytotrophoblast and intermediate trophoblast tend to grow in clusters and sheets, separated by syncytiotrophoblast, forming the characteristic dimorphic growth pattern (\bigcirc *Fig. 20.23*). These patterns of growth recapitulate the relationship of the trophoblast to the maternal-placental circulation of the early implanting previllous blastocyst. A network of syncytiotrophoblast intimately admixed with cytotrophoblast and intermediate trophoblast in many cases. The percentage of intermediate trophoblast in choriocarcinomas is highly variable ranging from 1 to 90%

Fig. 20.24 Choriocarcinoma with inconspicuous syncytiotrophoblast.

Occasionally, choriocarcinoma is composed predominately of cytotrophoblast and intermediate trophoblast with indistinct or attenuated syncytiotrophoblast (*arrow*) forming monotonous and cohesive sheets. Although syncytiotrophoblast is inconspicuous, these cells have dense, eosinophilic cytoplasm and pyknotic nuclei. This pattern may simulate a poorly differentiated carcinoma

of the mononucleate trophoblastic cellular population [149], and a recent study has demonstrated that choriocarcinoma is composed predominantly of a mixture of syncytiotrophoblast and intermediate trophoblast with only a small proportion of cytotrophoblast [92]. The intermediate trophoblastic cells in a choriocarcinoma tend to be larger with more abundant cytoplasm (> Fig. 20.23). They are usually located adjacent to the cytotrophoblast, assuming a zonal pattern of differentiation from cytotrophoblast. Occasionally, choriocarcinoma appears predominately composed of cytotrophoblast and intermediate trophoblast forming a monotonous and cohesive sheet or mass with indistinct or attenuated syncytiotrophoblast (> Figs. 20.24 and **2**20.25). This monomorphic variant may cause a problem in the

Fig. 20.25

Monomorphic choriocarcinoma in the cervix. Mononucleate trophoblast (cytotrophoblast and intermediate trophoblast) is present and syncytiotrophoblast is indistinct in this section. However, syncytiotrophoblast appears in deeper sections and displays an alternating (biphasic) pattern of syncytiotrophoblast and mononucleate trophoblast (*inset*)

differential diagnosis. Careful search for syncytiotrophoblast, deeper sectioning of the paraffin blocks, and immunostaining for beta-hCG may reveal syncytiotrophoblast in focal areas. Beta-hCG staining can be very useful in demonstrating attenuated or indistinct syncytiotrophoblast.

One of the unique morphological features of choriocarcinoma is the lack of new blood vessel formation (angiogenesis) in the center of the tumor (\bigcirc *Fig. 20.26*) although blood vessels stemming from the surrounding stroma can be detected in the periphery of a choriocarcinoma. Instead, the tumor cells within a choriocarcinoma establish intricate pseudovascular network and blood-lakes that are lined by trophoblastic cells rather than by endothelial cells. Those trophoblast-lined pseudovascular channels likely communicate with true blood vessels outside the

Choriocarcinoma. (a) H&E stain shows high magnification of choriocarcinoma cells. (b) Trichrome stain demonstrates almost undetectable connective tissue within the choriocarcinoma. (c) CD34 staining reveals no evidence of endothelium-lined blood vessels in the tumor except in the tumor–stroma interface. The blood supply of choriocarcinoma in this specimen is derived from trophoblastic cells creating blood-filled channels and lakes that communicate with the circulation in the soft tissue surrounding the tumor

choriocarcinoma. The generation of microvascular-like channels by neoplastic cells was termed "vasculogenic mimicry," a term used to underscore their de novo generation without involvement by endothelial cells [37]. The vasculogenic mimicry can only be seen in a sizable choriocarcinoma usually obtained from a hysterectomy specimen (> Fig. 20.26) and may not be obvious in small biopsy samples. In contrast to angiogenesis occurring in other solid tumors, the pseudovascular channels in choriocarcinoma are devoid of adequate stromal support, which contributes to hemorrhage and necrosis in the center of the tumor. Accordingly, it is not uncommon that only a small amount of viable choriocarcinoma tissue remains in a lesion and thus extensive sampling and sectioning may be required to identify the typical morphological features of choriocarcinoma.

There may be considerable cytological atypia in the trophoblast with pleomorphic-enlarged nuclei, abnormal mitotic figures, and bizarre cellular configurations. Nuclear chromatin is coarsely granular, with an uneven distribution, and nucleoli may be present (**)** *Fig. 20.26*). Enlarged, multinucleated intermediate trophoblastic cells with two or several nuclei also occur, and they are

distinguished from syncytiotrophoblast by their cytoplasm, which lacks the dense eosinophilia and vacuolization and by positive CD146 (Mel-CAM) immunostaining [149].

It is not uncommon for choriocarcinoma to display focal differentiation of a PSTT and/or an epithelioid trophoblastic tumor. The choriocarcinoma component can be discrete or it can merge imperceptibly with areas of PSTT or epithelioid trophoblastic tumor. To report those mixed GTN, we recommend using a term of "choriocarcinoma with PSTT or epithelioid trophoblastic tumor" to accentuate the clinical importance in recognizing the choriocarcinoma component, which requires cytotoxic chemotherapy. Further studies are required to determine the treatment response and clinical outcome in the mixed GTNs.

Differential Diagnosis

In general, the diagnosis of choriocarcinoma requires the presence of the biphasic pattern of trophoblastic growth (syncytiotrophoblast and mononucleate trophoblast) and invasion of the tumor typically associated with necrosis

Table 20.8

Morphological features of gestational trophoblastic tumors

Features	Choriocarcinoma	PSTT	ETT
Cellular population	Dimorphic; syncytiotrophoblast alternating with mononucleate trophoblast	Monomorphic; implantation site intermediate trophoblastic	Monomorphic; chorionic-type intermediate trophoblastic
Cell size and shape	Irregular, highly variable	Large and pleiomorphic	Smaller, round, and uniform
Cytoplasm	Variable pale to amphophilic	Abundant and eosinophilic	Eosinophilic or clear
Growth pattern	Circumscribed mass with central necrosis/ hemorrhage	Confluent sheets, masses or infiltrating single cells	Epithelioid nests or cords or solid masses
Tumor border	Circumscribed; pushing	Infiltrating	Circumscribed; expansile
Cellular necrosis	Extensive	Usually absent	Extensive
Calcification	Absent	Absent	Usually present
Vascular invasion	Tumor thrombi	From periphery to lumen	Absent
Fibrinoid change	Absent	Present	Present
Mitosis	High; 2–22/10 HPF	Variable; 0–6/10 HPF	Variable; 1–10/10 HPF
Associated chorionic villi	Absent	Absent	Absent

into the endomyometrium. The presence of detached fragments of biphasic trophoblastic tissue alone may be insufficient to diagnose choriocarcinoma unless very early placentas and trophoblastic hyperplasia associated with a complete hydatidiform mole can be excluded. Assessment of endomyometrial invasion should be thoroughly evaluated and deeper sections may be needed to demonstrate the invasive pattern associated with choriocarcinoma. Thus, choriocarcinoma must be distinguished from the normal trophoblast of early gestation, from molar pregnancies, as well as from PSTT, epithelioid trophoblastic tumor, and from other forms of epithelial malignancy. The differential diagnosis is primarily based on morphological grounds (> Table 20.8). Occasionally, normal trophoblast of an early gestation is found in curettings without associated villi. In this circumstance, the trophoblast should be present only in small quantities and deeper sections may reveal chorionic villi. Normal trophoblast of an early gestation, although proliferative, does not show atypical features including marked cellular enlargement and nuclear abnormalities found in choriocarcinoma (> Fig. 20.27). Thus, large amounts of trophoblast showing atypia should be viewed suspiciously for choriocarcinoma. Most importantly, fragments of normal trophoblast in curettings do not show tumor necrosis or destructive invasion. As a general rule, choriocarcinoma should not be diagnosed in the presence of villi. Proliferative trophoblast in association with villi usually indicates either an abortion or hydatidiform mole. The differential diagnosis of these lesions is discussed under "Hydatidiform mole." Rarely, gestational choriocarcinoma arises within a normally developing placenta, with the neoplasm intimately associated with well-formed, mature nonmolar villi [184]. If the diagnosis is in doubt, a chest radiograph and careful monitoring of beta-hCG levels should help resolve the problem.

Discriminating choriocarcinoma from other carcinomas either within the uterus or at other sites usually is not a problem. On occasion a biopsy may show a few syncytiotrophoblastic cells, or the entire lesion is composed of mononucleate trophoblastic cells, a pattern that can mimic a poorly differentiated carcinoma (\bigcirc *Figs. 20.24* and \bigcirc *20.25*). When this differential diagnosis arises, the clinical history may reveal a previous molar pregnancy or another suspicious pregnancy event that can assist in the diagnosis. Serum beta-hCG levels and immunohistochemical localization of beta-hCG, hPL, and HSD3B1 in syncytiotrophoblast can be useful (\bigcirc *Fig. 20.28*; \bigcirc *Table 20.2*).

Choriocarcinoma has been described as a primary tumor arising in a number of different sites besides the uterus and gonads. In women of reproductive age, however, pure choriocarcinoma that appears to be an extrauterine primary tumor probably represents

Normal trophoblast in an early gestation. The trophoblastic cells in an early placenta may exhibit "biphasic" growth as seen in choriocarcinoma (*inset*). Unlike choriocarcinoma, the normal trophoblastic cells, although proliferative, do not show atypical features including marked cellular enlargement and nuclear abnormalities. Normal trophoblast does not display tumor cell necrosis or destructive invasion. Large amounts of trophoblast with atypia should be viewed suspiciously for choriocarcinoma. Moreover, the presence of chorionic villi is important to establish the diagnosis of an early gestation. Deeper sections can be useful in identifying villi if they are absent in the original sections

gestational choriocarcinoma in which the index pregnancy is undetected. True primary choriocarcinoma at an unusual site may be an extragonadal germ cell tumor, or it may be derived from dedifferentiation of an ordinary carcinoma [1]. Primary somatic tumors of the gastrointestinal tract, bladder, breast, lung, or endometrium rarely show choriocarcinomatous differentiation, and these show transitions from ordinary carcinoma to the trophoblastic component. Since somatic tumors also may produce beta-hCG without showing choriocarcinoma histology, the

Fig. 20.28 Syncytiotrophoblast in choriocarcinoma.

Syncytiotrophoblast surrounds nests of mononucleate trophoblastic cells. In this case, syncytiotrophoblast is strongly positive for beta-hCG. In choriocarcinoma with inconspicuous syncytiotrophoblast, immunostaining with an anti-hCG antibody can be very useful in establishing the diagnosis by highlighting syncytiotrophoblast

classic biphasic growth pattern should be present before rendering the diagnosis of choriocarcinoma.

The differential diagnosis of choriocarcinoma and PSTT and epithelioid trophoblastic tumor will be discussed in the following specific sections and is summarized in **7** *Tables 20.7* and **7** *20.8*.

Clinical Behavior and Treatment

Metastasis of choriocarcinoma most frequently occurs in brain and liver, and the majority of therapeutic failures have liver and/or brain metastases. High beta-hCG level is a risk factor for predicting the occurrence of brain and liver metastases [182]. Kidney and abdomen, including intestinal tract, are the other common sites of spread, but almost any organ, including the skin, may be involved. Lymph nodes contain tumor on occasion, often as tertiary metastatic lesions from other organs. Vaginal involvement has been reported in 16–32% of patients. There have been a few isolated reports of metastatic choriocarcinoma occurring in the mother and child of a term pregnancy [39, 184]. In most cases, the infant is disease-free, however.

In untreated cases, death from choriocarcinoma most commonly results from hemorrhage or pulmonary insufficiency. Fatal hemorrhage usually occurs in the central nervous system or lungs, but intraperitoneal and gastrointestinal hemorrhages also can cause death. Exsanguination may occur after biopsy of a vaginal metastasis. Pulmonary insufficiency can be due either to a large tumor burden or to the effects of irradiation and cytotoxic chemotherapy. An interval of less than 4 months since the antecedent pregnancy, a pretreatment beta-hCG level <40,000 mIU/mL, and absence of brain or liver metastases appear to be the significant predictors of a favorable outcome in postterm choriocarcinoma [137].

In the past, gestational choriocarcinoma usually was fatal. Before cytotoxic chemotherapy was available, hysterectomy and, in some instances, irradiation were the only forms of treatment. The absolute 5-year survival for patients treated by hysterectomy alone was 32%. Survival rates have improved dramatically since the introduction of cytotoxic chemotherapy combined with accurate and sensitive assays for beta-hCG to monitor the course of the disease. The chemotherapy regimens such as EMA/CO (etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine) are highly effective in eradicating choriocarcinoma cells and, thus, choriocarcinoma represents one of the few cancers that are potentially curable by chemotherapeutic agents alone. The overall survival for choriocarcinoma at the present time approaches 100% [63], although some patients develop non-operable diseases with recurrent and chemoresistant choriocarcinoma. New therapeutic regimens have been proposed to salvage these unfortunate patients [145, 172].

The principles of management of choriocarcinoma are similar to those for GTD after hydatidiform mole; betahCG monitoring and chemotherapy are essential. In following the patients with beta-hCG, a measurement of urinary hCG is important due to the possible falsepositive serum hCG titers [138]. Hysterectomy can reduce the length of hospitalization and the amount of chemotherapy needed to induce remission. Resection of pulmonary metastases may have therapeutic value in patients with persistent but limited pulmonary disease, if there is no evidence of tumor at other sites and the hCG titer is low. Irradiation combined with chemotherapy will give a 50% remission rate for cerebral metastases but irradiation to other sites generally is not useful.

Placental Site Trophoblastic Tumor

The PSTT is a relatively uncommon form of GTD accounting for less than 3% of GTD cases [53, 125]. The tumor is composed of neoplastic implantation site intermediate trophoblastic cells that resemble those infiltrating into the endometrium and myometrium of the placental site during early pregnancy. Molecular genetic data together with immunohistochemical findings support the trophoblastic nature of PSTT [120, 160]. The neoplasm lacks the biphasic pattern seen in choriocarcinoma, and the epithelial-like growth pattern of epithelioid trophoblastic tumor. The PSTT was originally termed atypical chorioepithelioma by Marchand in 1895, but because of its rarity, it was periodically rediscovered and renamed. Terms that have been used include atypical choriocarcinoma, syncytioma, chorioepitheliosis, and trophoblastic pseudotumor [80]. PSTT has been thought to develop as a result of neoplastic transformation of cytotrophoblastic cells and the transformed cells assume the differentiation toward implantation site intermediate trophoblast [145]. Both benign and malignant PSTTs do not demonstrate significant karyotypic abnormalities [62, 177]. Interestingly, more than 85% of patients with PSTT have had a female antecedent gestation either by history or genetic analysis. Furthermore, PSTTs lack Y chromosomes based on a molecular genetic analysis, suggesting a role of the paternally derived X chromosome in the pathogenesis of PSTT [36, 61, 77, 83, 178]. Alternatively, this shortfall of Y-chromosomal complements in PSTTs may reinforce the notion that the majority of PSTTs are derived from previous molar gestations.

Clinical Features

Patients usually are in the reproductive age group (19–62 years with an average of 30 years) and can present with either amenorrhea or abnormal bleeding, often accompanied by uterine enlargement [53, 80, 180] and frequently are thought to be pregnant. When uterine enlargement ceases, the diagnosis of a missed abortion is made. Serum levels of beta-hCG are generally low (<1,000 mIU/mL). Rarely, PSTT is associated with virilization, nephrotic syndrome, and erythrocytosis [14, 181]. In contrast to choriocarcinoma, which is preferentially associated with a complete mole, PSTT occurs commonly following a normal pregnancy but spontaneous abortions and

hydatidiform moles have preceded the diagnosis of PSTT [32, 105, 125]. Usually, the relationship to the previous gestation is uncertain, because the PSTT can be diagnosed long after the last known pregnancy. Patients with PSTT can present either with amenorrhea or with abnormal bleeding [125, 153]. Rare examples of primary tubal and ovarian PSTT have been reported [5, 164], and metastasis to ovary has been documented [103]. The clinical features of PSTT as compared with choriocarcinoma and epithelioid trophoblastic tumor are summarized in *Table 20.7*.

Gross Findings

Most of the tumors are well circumscribed, and they can be polypoid, projecting into the uterine cavity or may predominantly involve the myometrium. The sectioned surface is usually soft and tan, containing only focal areas of hemorrhage or necrosis, if present. Invasion frequently extends to the uterine serosa and, in rare instances, to the adnexal structures including broad ligament [7].

Microscopic Findings

The predominant cell type in PSTT is the implantation site intermediate trophoblast. The microscopic features of PSTT are summarized in **>** *Table 20.8*. Most of the cellular population is monomorphic in contrast to the mixture of cell types in choriocarcinoma (**>** *Fig. 20.29–20.33*). PSTT is composed of large, polygonal implantation site intermediate trophoblastic cells with irregular, hyperchromatic

Fig. 20.29

Placental site trophoblastic tumor. The tumor is composed of a confluent mass of large, polygonal implantation site intermediate trophoblastic cells with irregular, hyperchromatic nuclei and dense eosinophilic to amphophilic cytoplasm with occasional vacuoles

Fig. 20.30

Placental site trophoblastic tumor. Tumor is composed of a confluent mass of a monomorphic intermediate trophoblast in contrast to the mixture of cytotrophoblast, syncytiotrophoblast, and intermediate trophoblast in choriocarcinoma. The implantation site intermediate trophoblastic cells characteristically separate muscle bundles as they invade the myometrium

Fig. 20.31 Placental site trophoblastic tumor. Implantation site intermediate trophoblastic cells may assume a spindle shape and, therefore, can be confused with leiomyosarcoma

nuclei and dense eosinophilic to amphophilic cytoplasm with occasional vacuoles (> Fig. 20.29). PSTT also contains scattered multinucleated implantation site intermediate trophoblastic cells that can be mistaken for syncytiotrophoblast. The tumor cells often aggregate into confluent sheets; however, at the periphery of the tumor the trophoblast cells invade singly or in cords and nests, characteristically separating individual muscle fibers and groups of fibers (> Fig. 20.30). Although most of the implantation site intermediate cells are polyhedral, many of them assume a spindle shape especially where they are closely apposed to myometrial cells (> Fig. 20.31). Occasionally, PSTT is composed almost entirely of single cells or small nests of cells without forming sheets or masses. The individual neoplastic cells extensively infiltrate the endomyometrium and penetrate the uterine wall deeply. Although some tumors appear to cause relatively little tissue destruction, others are associated with extensive necrosis, a microscopic feature that is often associated with malignant behavior (see below). It is not uncommon for a PSTT to also exhibit histological features of

Fig. 20.32

Placental site trophoblastic tumor. Vascular invasion by implantation site intermediate trophoblast resembles that of the normal implantation site. The neoplastic cells surround and invade a blood vessel, extending into the vascular lumen. The vessel wall has been replaced by fibrin. In some vessels, a dense eosinophilic fibrionoid deposit can be identified in the vascular wall (*inset*)

choriocarcinoma and epithelioid trophoblastic tumor, and these tumors are termed mixed choriocarcinoma and PSTT or mixed PSTT and epithelioid trophoblastic tumor. Too few of these mixed cases have been studied to determine their clinical behavior.

As in the normal placental site, abundant extracellular eosinophilic fibrinoid material is present in the tumor. The neoplasm displays a characteristic form of vascular invasion in which blood vessel walls are extensively replaced by trophoblastic cells and fibrinoid material (\bigcirc *Fig. 20.32*), as observed in the normal placental site (\bigcirc *Fig. 20.4c*). These "transformed" blood vessels are unique among all human solid tumors and are diagnostic for PSTT. Decidua or an Arias-Stella reaction may be present in the adjacent, uninvolved endometrium. Villi are almost never identified.

PSTT is immunoreactive to the protein markers expressed in implantation site intermediate trophoblast

Malignant placental site trophoblastic tumor. As in a benign PSTT, malignant PSTT grows in masses and sheets and the cells are large with abundant eosinophilic cytoplasm. However, the tumor cells in a malignant PSTT exhibits a higher level of nuclear atypia

(**7** *Table 20.2*), because the tumor may likely arise from transformation of trophoblastic stem cells, presumably cytotrophoblast, undergoing differentiation toward the implantation site trophoblast (**7** *Fig. 20.6*). For example, PSTT is diffusely positive for hPL, CD146 (Mel-CAM), HLA-G, CD10, and Mucin-4 that are expressed in normal implantation site intermediate trophoblastic cells [84, 92, 149]. Expression of these markers can be useful in the differential diagnosis of PSTT from other mimickers.

Differential Diagnosis

The differential diagnosis of PSTT includes exaggerated placental site, choriocarcinoma, epithelioid trophoblastic tumor, and epithelioid smooth muscle tumor. The most difficult differential diagnosis is that of an exaggerated placental site. Both lesions are characterized by an exuberant infiltration of implantation site intermediate trophoblastic cells. Moreover, the immunophenotype of both lesions is similar. The histologic features that favor the diagnosis of PSTT include confluent masses of trophoblastic cells, unequivocal mitotic figures, and absence of chorionic villi () Table 20.8). In contrast, the exaggerated placental site is microscopic in size, lacks mitotic activity, is composed of intermediate trophoblastic cells separated by masses of hyaline, and usually is admixed with decidua and chorionic villi (> Table 20.8). In addition, an exaggerated placental site contains larger numbers of multinucleated trophoblastic cells than PSTT. Immunostaining for Ki-67 to assess proliferation activity in the implantation site intermediate trophoblastic cells has been shown to be superior to the mitotic index as a diagnostic adjunct in the differential diagnosis of an exaggerated placental site versus a PSTT [151]. The use of immunohistochemistry in the differential diagnosis of PSTT is discussed in the section **()** Immunohistochemical Approach for Differential Diagnosis and in **>** Fig. 20.53. Briefly, the Ki-67 labeling index is significantly elevated (>10%) in PSTT but is near zero in the normal and exaggerated implantation site. A diagnosis of a PSTT should be strongly considered if there are Ki-67-labeled implantation site intermediate trophoblastic cells. Although the Ki-67 index in molar implantation site, which is morphologically indistinguishable with exaggerated placental site, can be 10% or higher, the diagnosis of a PSTT versus a complete hydatidiform mole usually is not a problem. The Ki-67 labeling in the implantation site intermediate trophoblastic cells should be carefully assessed using stringent morphologic criteria since implantation site intermediate trophoblastic cells can closely resemble other cell types in a placental site. Many Ki-67-positive cells in the placental site or PSTT are natural killer cells and activated T lymphocytes, which can be positive for Ki-67. A double-staining technique utilizing MIB-1 antibody to determine the Ki-67 proliferative index and markers to identify implantation site intermediate trophoblastic cells such as HSD3B1, HLA-G, and Mel-CAM (CD146) can be very useful in distinguishing an exaggerated placental site from a PSTT [93, 144].

In contrast to the biphasic pattern of choriocarcinoma, PSTT is composed of a relatively monomorphic population of trophoblast. The multinucleated intermediate trophoblastic cells in PSTT should not be confused with syncytiotrophoblast in choriocarcinoma. In contrast to the interlacing pattern of elongated syncytiotrophoblast in choriocarcinoma, the multinucleated intermediate trophoblastic cells in PSTT are usually polygonal or round. Additionally, PSTT is diffusely (>50%) positive for hPL, but only focally positive for beta-hCG (mostly confined to the multinucleated intermediate trophoblastic cells). Ki-67 labeling index in intermediate trophoblastic cells is also helpful in the differential diagnosis of PSTT versus choriocarcinoma [151]. The Ki-67 index in intermediate trophoblastic cells of PSTT is significantly lower (<30%) than choriocarcinoma (>40%).

The differential diagnosis of epithelioid smooth muscle tumor can at times present a problem because of the infiltrative pattern of PSTT within the myometrium (**)** *Fig. 20.31*). The distinctive pattern of vascular invasion and the deposition of fibrinoid material in PSTT are helpful morphological clues (**)** *Fig. 20.32*). Positive staining for HSD3B1, cytokeratin 18, and hPL as well as the negative staining for smooth muscle markers are helpful in this differential diagnosis [93, 144]. The use of immunohistochemistry in the differential diagnosis of PSTT is discussed in the last section (**)** Immunohistochemical Approach for Differential Diagnosis) of this chapter.

Poorly differentiated carcinoma and metastatic melanoma can sometimes be confused with PSTT. The pattern of prominent blood vessel invasion, characteristic myometrial invasion, and extensive deposition of fibrinoid material (> Figs. 20.30 and > 20.32) are key diagnostic features of PSTT. Immunohistochemical stains for HSD3B1, hPL, and HMB-45 help to distinguish PSTT from poorly differentiated carcinoma and melanoma (see section Immunohistochemical Approach for Differential Diagnosis). Typically, in choriocarcinoma the serum beta-hCG levels are high, ranging from 1,000 mIU/mL to over 1,000,000 mIU/mL, whereas in PSTT the levels are significantly lower, often less than 1,000 mIU/mL. A recent study further demonstrates that the percentage of hCG free beta-subunit is a reliable serum marker for PSTTs and can be used to rule out other trophoblastic neoplasms and non-trophoblastic tumors that produce hCG [25].

The differential diagnosis of PSTT from epithelioid trophoblastic tumor is considered in the section describing the latter lesion.

Behavior and Treatment

PSTTs often invade through the myometrium to the serosa, and therefore perforation at the time of curettage may occur. These tumors may also directly invade into the broad ligament and ovary. Despite deep myometrial invasion, most cases of PSTT are self-limited [18, 53, 125] and some patients have been cured by curettage alone.

Approximately 10-15% of PSTT are clinically malignant, and patients have died despite intensive multiagent chemotherapy. The mortality rate in patients with PSTT is about 15-30%, which may be overestimated because benign cases are generally not reported [53, 58, 125]. The outcomes of patients with FIGO stage I-II disease after hysterectomy are excellent; while those with FIGO stage III-IV diseases have a 30% survival [18]. A recent large retrospective study demonstrates that the probabilities of overall and recurrence-free survival 10 years after first treatment are 70% and 73%, respectively. Patients with stage I disease had a 10-year probability of overall survival of 90% and the probability of overall survival at 10 years was 52% for patients with stage II disease and 49% for stage III and IV disease [139]. In one report, metastases at presentation occur in more than 30% of cases and recurrences develop in more than 30% of cases [35]. The overtly malignant tumors have had widely disseminated metastases resembling choriocarcinoma in their distribution with lung, liver, abdominal cavity, and brain involved. Metastases have the same histological appearance as the primary tumor and may develop several years after the initial diagnosis, as one fatal case recurred 5 years after hysterectomy. In general, PSTTs with multiple metastases have poor prognosis.

Because these tumors are composed of neoplastic implantation site intermediate trophoblastic cells that contain only small amounts of beta-hCG, serum levels of beta-hCG are usually in the range of 1,000 to 2,000 mIU/ mL. These levels are much lower than those in choriocarcinoma. Despite the low level of serum beta-hCG in patients with PSTT, it is the best available marker to monitor the course of the disease [130]. Of note, the marker cannot be used to diagnose PSTT versus other trophoblastic diseases [52]. It is important to emphasize that the disease may still progress even if beta-hCG levels are low [58]. For those patients with undetectable or very low serum levels of beta-hCG, urinary or serum beta-core fragment of betahCG may be a better method to monitor treatment as the percentage is much higher in PSTTs than in choriocarcinoma and other carcinomas that produce beta-hCG [23].

It is difficult to predict with certainty the behavior of PSTT [154]. However, some studies have found that several clinical parameters may be associated with a poor clinical outcome in PSTT patients and they include FIGO stage [18, 56, 131], metastatic involvement [125], long interval from the antecedent pregnancy [8, 53, 56, 125], age > 35, hCG > 1,000 mIU/mL, depth of invasion [8, 131], and p53 immunoreactivity [109]. For example, based on multivariate analysis, investigators have found that the only significant independent predictor of overall

and recurrence-free survival is time since antecedent pregnancy. In that report, a cutoff point of 48 months since antecedent pregnancy could differentiate between patients' probability of survival (<48 months) or death $(\geq 48 \text{ months})$ with 93% specificity and 100% sensitivity, and with a positive predictive value of 100% and a negative predictive value of 98% [139]. Some studies showed that a high mitotic count was an adverse prognostic indicator in PSTT patients [8, 56] but it has also been shown that there is no correlation between clinical outcome and DNA ploidy, histopathological features, immunohistochemical features, and S-phase fraction [40, 41]. In our experience, malignant PSTTs as compared with benign cases generally are composed of larger masses and sheets of cells, many with clear instead of amphophilic cytoplasm. They have more extensive necrosis, prominent nuclear atypia and higher mitotic activity (> Fig. 20.33). Our preliminary findings suggest that the Ki-67 labeling index may be a reliable indicator of prognosis as the index is usually higher than 50% in malignant tumors.

The treatment of choice for patients whose disease is confined to the uterus is hysterectomy [35, 58, 131]. In some patients with localized PSTT who desire preservation of fertility, more conservative surgical therapy may be considered [85, 91, 118, 128]. Curettage and local excision may be therapeutic, but if uterine disease persists, as evidenced by persistently elevated serum beta-hCG levels, hysterectomy is indicated. For patients with more extensive or metastatic disease, chemotherapy in addition to surgery is indicated although the clinical outcome is variable [18, 30, 35, 112, 166, 171]. Combination chemotherapy usually results in a high response rate and long-term remission even in patients with recurrent, metastatic PSTT, but only a few patients achieve a complete response [10, 18, 67, 133]. In general, EMA/CO is the first line chemotherapy regimen and EMA/EP can be used in EMA/CO refractory cases [113]. In conclusion, with the use of dose-intensive chemotherapy, imaging techniques to define disease spread, surgery for localized disease, and the close surveillance with serologic measurement of the beta-hCG level, most patients with PSTT can be cured.

Epithelioid Trophoblastic Tumor

The term "epithelioid trophoblastic tumor" was introduced to describe an unusual type of trophoblastic tumor that is distinct from PSTT and choriocarcinoma with features resembling a carcinoma. The tumor was originally termed "atypical choriocarcinoma" and was described in the lungs of patients with antecedent choriocarcinoma following intensive chemotherapy [70, 96]. Similar lesions referred to as "multiple nodules of intermediate trophoblast" were subsequently reported in the uteri of patients following evacuation of hydatidiform moles [159]. Subsequently, similar tumors were observed in the uterus without history of antecedent GTD [150]. The relatively recent recognition of epithelioid trophoblastic tumor as a distinctive form of trophoblastic disease is in part due to its rarity and because many of the morphologic features of epithelioid trophoblastic tumor are more reminiscent of a carcinoma than of a trophoblastic tumor [150]. Epithelioid trophoblastic tumor is very rare, and experience with this tumor has been limited to approximately 59 cases reported so far [27, 49, 70, 78, 87, 90, 94, 96, 101, 109, 110, 119, 126, 150, 159, 170, 173, 174]. The trophoblastic nature of this tumor has been confirmed using molecular approaches [120, 160]. Based on morphologic, ultrastructural, and immunohistochemical studies, epithelioid trophoblastic tumor appears to develop from neoplastic transformation of cytotrophoblastic cells that differentiate toward chorionic-type intermediate trophoblastic cells [96, 145, 155].

Clinical Features

Based on an analysis of published 52 cases, Palmer et al. reported that 67% of patients present with abnormal vaginal bleeding, 36% had evidence of antecedent molar pregnancy, and 35% presented with metastases [124]. Mean age at diagnosis is 38 years and the mean interval between the preceding gestation and the diagnosis of epithelioid trophoblastic tumor is 76 months. hCG levels are usually low (<1,000 mIU/mL) [49, 150], but high levels of hCG can be present in some cases. Extrauterine epithelioid trophoblastic tumor without an identifiable trophoblastic lesion in the uterus has also been described, [49, 86, 150], and the origin of such tumors is not clear. It is well recognized that choriocarcinoma can develop after a long latent period without evidence of disease in the uterus, thus it is conceivable that extrauterine epithelioid trophoblastic tumors develop in a similar fashion. Rarely, epithelioid trophoblastic tumor can occur in an extrauterine site including broad ligament [78], gall bladder [90], and (para)adenxal tissue [116, 126]. Epithelioid trophoblastic tumor can be seen in association with choriocarcinoma and PSTT [150, 159]. Like PSTT, a recent molecular genetic study on a small series of epithelioid trophoblastic tumors demonstrates a balanced chromosomal profile without detectable gain or loss in the genome, suggesting that DNA copy number alterations as

seen in most solid tumors are not a characteristic feature of this tumor [176].

Gross Findings

In one study, 30% of 14 epithelioid trophoblastic tumors were located in the uterine corpus, 50% in the lower uterine segment or endocervix, and the remaining 20% in extrauterine sites including the small bowel and lungs [150]. In cases in which a hysterectomy was performed, tumor size varied from 0.5 to 4.0 cm. All were solitary, discrete nodules that deeply invaded the cervix or myometrium. The cut surface was solid or cystic. Solid areas were typically tan to brown with varying amounts of hemorrhage and necrosis (\bigcirc *Fig. 20.33*). Metastatic epithelioid trophoblastic tumors show similar gross features (\bigcirc *Figs. 20.34* and \bigcirc 20.35).

Microscopic Findings

Epithelioid trophoblastic tumors are nodular and generally well circumscribed although focal infiltrative features can be present at the periphery. The tumors are composed of a relatively uniform population of mononucleate trophoblastic cells typically arranged in nests and cords and masses of cells that are intimately associated with an eosinophilic, fibrillar, hyaline-like material, and necrotic debris (**)** Figs. 20.36–20.40). This hyaline-like material, composed of type IV collagen and fibronectin of oncofetal and adult types, is either located within the nests or surrounds them, coalescing to form large aggregates. This dense eosinophilic material and necrotic debris can simulate keratin (> Figs. 20.38-20.40). The extensive areas of necrosis that surround islands of viable tumor cells create a "geographic" pattern () Fig. 20.36). Typically, a small blood vessel is located within the center of tumor nests. Blood vessels within the tumor are preserved with occasional deposition of amorphous fibrinoid material in the wall. A lymphocytic infiltrate often surrounds the tumor (> Fig. 20.38). In most cases, apoptotic cells are diffusely distributed throughout the tumor.

 A lobectomy specimen shows a discrete nodule with yellowish and necrotic cut surface

Epithelioid trophoblastic tumor. Tumor in a hysterectomy specimen contains nests of atypical mononucleate trophoblastic cells. Large areas of genographic necrosis and extensive calcification are characteristic features of the tumor, which lacks the typical dimorphic pattern of choriocarcinoma

Calcification is common in epithelioid trophoblastic tumors but not in PSTT or choriocarcinoma, and this morphological feature is unique among all GTDs (**>** *Fig. 20.36*).

Chorionic-type intermediate trophoblast is the predominant cell population in the epithelioid trophoblastic tumor [145,150]. These cells contain round, uniform nuclei and eosinophilic or clear (glycogen-rich) cytoplasm surrounded by a well-defined cell membrane, morphological features characteristic of the intermediate trophoblastic cells in fetal membrane (chorion laeve; **)** *Fig.* 20.5). For the most part, the cells are larger than cytotrophoblastic cells but smaller than the implantation site intermediate trophoblastic cells. The tumor cell nuclei have finely dispersed chromatin and prominent or inconspicuous nucleoli. Ultrastructurally these cells are transitional between cytotrophoblast and syncytiotrophoblast but differ from

the implantation site intermediate trophoblast [96]. Occasionally, larger cells resembling implantation site intermediate trophoblastic cells can be found among the smaller tumor cells or embedded in the extracellular hyaline matrix. The mitotic index varies from 0 to 9 mitoses per 10 high power fields (×40) with an average of 2 mitoses per 10 high power fields [150]. Although most epithelioid trophoblastic tumors display a uniform architectural pattern, focal areas resembling placental site nodule, PSTT, and choriocarcinoma can occasionally be identified within the tumor. Furthermore, epithelioid trophoblastic tumor can be associated with a concurrent germ cell tumor such as teratoma [2], indicating epithelioid trophoblastic tumor may arise, although rarely, from a non-gestational event.

A unique feature of epithelioid trophoblastic tumor, among all GTDs, is its ability to replace and re-epithelialize the endocervical and/or endometrial surface epithelium (\bigcirc *Fig. 20.41*) [34, 150]. When this tumor involves the

cell carcinoma

lower uterine segment and endocervix, the intraepithelial extension can mimic squamous carcinoma in situ. The tumor cells usually stratify into two to three layers, however, and are larger than cervical squamous cells with abundant eosinophilic cytoplasm and large hyperchromatic, pleomorphic nuclei.

The immunohistochemical features of the epithelioid trophoblastic tumor are similar to those of chorionic-type intermediate trophoblast (**7** Table 20.2). The "classic" implantation site intermediate trophoblastic markers including hPL and CD146 (Mel-CAM) are only focally expressed. The immunophenotype of the epithelioid trophoblastic tumor contrasts with the PSTT, which is diffusely positive for CD146 (Mel-CAM) and hPL. Furthermore, epithelioid trophoblastic tumor exhibits similar morphological features and gene expression profile to the intermediate trophoblastic cells in a placental site nodule [153, 158], suggesting that the epithelioid

Fig. 20.39 Epithelioid trophoblastic tumor. At high magnification, the dense eosinophilic debris is prominent within the tumor

trophoblastic tumor represents the neoplastic counterpart of the placental site nodule. Indeed, synchronous epithelioid trophoblastic tumor and placental site nodule in the same specimens can be occasionally observed [150, 158] and transformation of a placental site nodule into a malignant epithelioid trophoblastic tumor has been recently documented [170]. The morphological and immunohistochemical features of extrauterine epithelioid trophoblastic tumors are similar to those in the uterus [49].

Like PSTT, epithelioid trophoblastic tumor can present as a mixed lesion containing either a PSTT or a choriocarcinoma (\bigcirc *Fig. 20.42*). It has been proposed that these mixed tumors can result from aberration in the trophoblastic differentiation program in which the neoplastic cytotrophoblast (stem) cells differentiate into implantation site intermediate trophoblastic cells to form the PSTT component, and into chorionic-type intermediate trophoblastic cells to form the epithelioid trophoblastic component, or they remain relatively undifferentiated to form the choriocarcinoma component [145]. According to this model (\bigcirc *Fig. 20.8*), choriocarcinoma

Epithelioid trophoblastic tumor. Dense eosinophilic material surrounds nests of tumor cells. The tumor is frequently accompanied by an abundant lymphocytic infiltration

is the most primitive trophoblastic tumor, whereas PSTT and epithelioid trophoblastic tumor are relatively more differentiated. This hypothesis explains the existence of trophoblastic tumors with a mixed histological pattern including choriocarcinoma and PSTT and/or epithelioid trophoblastic tumor. This new model also helps to explain the findings previously reported by Mazur who originally described epithelioid trophoblastic tumor as tumors after intense chemotherapy of metastatic choriocarcinomas in the lung. In these cases, it is plausible that chemotherapeutic agents direct choriocarcinoma cells to differentiate into an epithelioid trophoblastic tumor phenotype, which is more refractory to chemotherapy than the original choriocarcinoma. As a result, the epithelioid trophoblastic tumor outgrew the choriocarcinoma after chemotherapy.

Differential Diagnosis

The differential diagnosis of epithelioid trophoblastic tumor includes PSTT, placental site nodule, choriocarcinoma, epithelioid smooth muscle tumor, and keratinizing

Fig. 20.41

Epithelioid trophoblastic tumor. An endocervical gland is replaced by epithelium from an epithelioid trophoblastic tumor. There is an abrupt transition between the tumor and the endocervical epithelium (*arrow*) (Reprinted by permission of [150])

squamous cell carcinoma of the cervix [150, 174]. Epithelioid trophoblastic tumors exhibit a nodular growth pattern, and the border between the tumor and the myometrium is expansile. In contrast, the cells of PSTT infiltrate the myometrium by insinuating themselves between muscle bundles and fibers. In addition, the cells in epithelioid trophoblastic tumor are smaller than in PSTT (> Fig. 20.43) and tend to grow in nests and cords, a pattern usually not observed in PSTT. In epithelioid trophoblastic tumors, there is extensive geographic necrosis accompanied by dystrophic calcification and the tumor cells are surrounded by fibrillar eosinophilic material instead of the more homogeneous fibrinoid material found in PSTT. Blood vessels in epithelioid trophoblastic tumor are often surrounded by tumor cells but vascular invasion is not a striking feature in contrast to the vascular invasion in PSTT, where tumor cells and hyaline material replace the vessel walls (> Fig. 20.32). If calcification is detected, the lesion is most likely an epithelioid trophoblastic tumor rather than a PSTT. Finally, immunostains can be useful in difficult cases

A mixed PSTT and epithelioid trophoblastic tumor. (a) H&E stain. PSTT area (*above the dash line*) has higher cellularity than the epithelioid trophoblastic tumor component (*below the dashed line*) that shows geographic necrosis and abundant eosinophilic matrix deposition. (b) Immunostain with an anti-hPL antibody. hPL immunoreactivity is confined to the PSTT area. (c) Histological features from PSTT and epithelioid trophoblastic tumor (ETT) areas

(see section **②** Immunohistochemical Approach for Differential Diagnosis and **③** *Fig. 20.53* for details).

The differential diagnosis of placental site nodule versus epithelioid trophoblastic tumor is considered in the section of placental site nodule.

As compared with choriocarcinoma, the cells in an epithelioid trophoblastic tumor are aggregated into nests and cords. In addition, epithelioid trophoblastic tumor is not associated with marked hemorrhage as is the case with choriocarcinoma. Immunostains for beta-hCG can be helpful in the differential diagnosis. Beta-hCG immunostains highlight the dimorphic trophoblastic population of cells in choriocarcinoma with hCG-negative cytotrophoblast and intermediate trophoblast alternating with beta-hCG-positive syncytiotrophoblast. In contrast, beta-hCG-positive cells are randomly distributed as single mononucleate cells or small clusters of cells in epithelioid trophoblastic tumor.

Epithelioid smooth muscle tumors usually display areas composed of typical smooth muscle cells in addition to epithelioid areas. In addition, epithelioid smooth muscle tumors are positive for muscle markers including desmin and smooth muscle actin, which are not expressed by epithelioid trophoblastic tumors. Conversely, epithelioid trophoblastic tumors are positive for HSD3B1 and cytokeratin 18, which are not expressed in smooth muscle tumors [93].

Distinction between an epithelioid trophoblastic tumor and a keratinizing squamous cell carcinoma of the cervix can be challenging [129, 150]. The differential diagnosis is particularly difficult because of the tendency of epithelioid trophoblastic tumor to grow in the lower uterine segment and cervix and involve the endocervical epithelium. In this situation, immunostains are particularly helpful. The application of commercially available antibodies in the differential diagnosis is described in the section \heartsuit Immunohistochemical Approach for Differential Diagnosis and \heartsuit *Fig. 20.54*.

The morphological distinction between a pulmonary epithelioid trophoblastic tumor and a primary squamous cell carcinoma of the lung can be extremely difficult, especially in a postmenopausal patient [49, 86, 150]. Useful clues that support the diagnosis of epithelioid trophoblastic tumor include (1) lack of cytoplasmic eosinophilia

Comparison of cytological features of PSTT and epithelioid trophoblastic tumor. PSTT (*left*) is composed of implantation site intermediate trophoblastic cells. The epithelioid trophoblastic tumor (ETT) (*right*) is comprised of chorionic-type intermediate trophoblastic cells which are smaller and have round, uniform nuclei, eosinophilic to clear cytoplasm, and a well-defined cell membrane. The cells in PSTT are larger and polygonal with atypical nuclei. They infiltrate into smooth muscle

and intercellular bridges that are frequently observed in differentiated squamous cell carcinoma; and (2) infiltration of alveolar spaces by highly atypical tumor cells and preservation of the alveolar septa, features not frequently seen in squamous cell carcinoma [49]. As in squamous cell carcinomas of the cervix, primary squamous cell carcinoma of the lung rarely reacts with antibodies to HSD3B1 and cytokeratin 18 [93].

Behavior and Treatment

Experience with epithelioid trophoblastic tumor is limited because only 59 cases have been reported to date. Generally, the behavior of epithelioid trophoblastic tumor is similar to that of PSTT. For the most part, epithelioid trophoblastic tumors behave in a benign fashion. Although most reported cases lack long-term follow-up, metastasis occurs in approximately 25% of patients and death in 13% [124]. Because the number of tumors that have behaved in an aggressive fashion is small and follow-up for many cases has been short, we have been unable to identify any feature that predicts outcome.

Although serum beta-hCG levels are variable and generally low in patients with epithelioid trophoblastic tumors, serum beta-hCG levels have been used successfully to monitor treatment. For those patients with undetectable or very low serum levels of beta-hCG, urinary beta-core fragment of beta-hCG may be useful [136]. Hysterectomy and lung resection have been used successfully, but the effectiveness of curettage of early lesions requires further evaluation. Unlike choriocarcinoma, epithelioid trophoblastic tumor appears to be only partially responsive to chemotherapy since tumors may recur or metastasize despite intensive chemotherapy [90, 96, 150, 159]. Recurrent disease can be late and complex [90]. Nonetheless, combined chemotherapy regimen such as EMA/CO has been used successfully in treating metastatic epithelioid trophoblastic tumor [170].

Exaggerated Placental Site (Reaction)

This lesion is defined as an exuberant infiltration of the myometrium by implantation site intermediate trophoblast. The distinction between a normal and exaggerated placental site is somewhat arbitrary since there are no reliable data quantifying the amount and extent of trophoblastic infiltration at different stages of normal gestation. The exaggerated placental site can occur in a normal pregnancy or an abortion from the first trimester. The incidence is approximately 1.6% of spontaneous and elective abortions from the first trimester based on a review of the surgical pathology files at the Johns Hopkins Hospital. In normal pregnancy and abortion, the apparent exaggerated placental site may actually only represent a fortuitous increase in the amount of placental site removed by curettage. Nonetheless, it is an important entity since it can mimic proliferative trophoblast seen in trophoblastic neoplasms.

The exaggerated placental site is characterized by an extensive infiltration of the endometrium and myometrium by implantation site intermediate trophoblastic cells, many of which are multinucleated (> Figs. 20.44 and 20.45). Despite the massive infiltration by trophoblastic cells, the overall architecture of the placental site is not disturbed. Endometrial glands and spiral arteries may be completely engulfed by trophoblastic cells but there is no necrosis. Similarly, the smooth muscle cells of the myometrium are separated by cords, nests, and individual trophoblastic cells that diffusely infiltrate the myometrium without producing necrosis () Fig. 20.44). Cytologically, the trophoblastic cells in an exaggerated placental site are identical to the implantation site intermediate trophoblastic cells in the normal placental site. They contain abundant eosinophilic cytoplasm with hyperchromatic and irregular nuclei (> Fig. 20.45). In many cases, there are large numbers of multinucleated implantation site intermediate trophoblastic cells (> Fig. 20.45). Mitotic activity is absent. The associated chorionic villi are morphologically unremarkable.

The trophoblastic cells in the exaggerated placental site display an identical immunophenotypic profile to the implantation site intermediate trophoblastic cells found in the normal placental site (**)** Table 20.2). These findings indicate that the differentiation of implantation site intermediate trophoblastic cells is unaltered in an exaggerated placental site, and suggests that an exaggerated placental site is a normal variation of an implantation site. Despite the profuse infiltration of implantation site intermediate trophoblast in an exaggerated placental site, the Ki-67 indices of implantation site intermediate trophoblast are near zero [151]. Complete hydatidiform moles are always accompanied by exaggerated placental sites in which the implantation site intermediate trophoblastic cells are often more atypical than those in the exaggerated placental sites that are not associated with complete moles.

Fig. 20.44

Exaggerated placental site. The lesion is characterized by an increased number of implantation site intermediate trophoblast exceeding that normally seen in the implantation site. Note large number of multinucleated giant cells, characteristic of this lesion

Based on our previous study [151] and recent experience, the Ki-67 labeling index in molar exaggerated placental site ranges widely from 5% to 30% or even higher. It is debatable whether the molar exaggerated placental site with high Ki-67 labeling index represents trophoblastic hyperplasia associated with a complete mole or it is a PSTT arising from a complete mole. The answer depends on future molecular genetic studies to demonstrate the clonal event of implantation site intermediate trophoblast in molar exaggerated placental site.

The most important differential diagnosis of an exaggerated implantation site is PSTT, which is discussed in the section describing that entity. Although exaggerated placental site and PSTT share similar morphological and immunohistochemical features, the lack of genetic link between both lesions has been documented [31]. Occasionally, implantation site intermediate trophoblastic cells that infiltrate the myometrium may resemble the atypical smooth muscle cells found in symplastic leiomyomas.

Exaggerated placental site. Mixture of mononucleate and multinucleated implantation site intermediate trophoblastic cells. The latter are more commonly seen in an exaggerated placental site than in a PSTT. Unlike PSTT, the trophoblastic cells in an exaggerated placental site are widely spaced, lacking confluent growth or necrosis. There is no mitotic activity

The presence of chorionic villi, the infiltrative growth pattern of the trophoblastic cells, characteristic vascular invasion pattern, and positive stains for HSD3B1, cytokeratin, and hPL support the diagnosis of an exaggerated implantation site.

Exaggerated placental site probably represents a physiologic process that resolves spontaneously after curettage. Exaggerated placental site that is not associated with a hydatidiform mole does not carry an increased risk of persistent GTD. No specific treatment or follow-up is required. Thus, to distinguish an exaggerated placental site from a normal placental site may not be critical in routine pathology practice because of the subjective morphological criteria in defining this condition and the lack of clinical significance of exaggerated placental site. However, the report of an exaggerated placental site in curettage specimens may indicate that PSTT has been considered as a differential diagnosis in those cases.

Placental Site Nodule

Placental site nodules (or plaques) are small, wellcircumscribed nodular aggregates of chorionic-type intermediate trophoblastic cells that are embedded in a hyalinized stroma. Placental site nodules have been thought to represent a portion of uninvoluted placental site from remote gestations in the uterus. However, the constituent cells in placental site nodules are more closely related to the intermediate trophoblast of chorion laeve (chorionic-type intermediate trophoblast) than to the intermediate trophoblast of a placental site (implantation site intermediate trophoblastic cells) [158]. Based on morphological and immunohistochemical studies, the placental site nodule appears to represent the benign counterpart of the epithelioid trophoblastic tumor.

Patients are in the reproductive age group. Placental site nodules are typically incidental findings in uterine or endocervical curettings, cervical biopsies, and occasionally in hysterectomy specimens. In addition, placental site nodules can also be detected in fallopian tubes, presumably a consequence of prior tubal pregnancy [7, 42, 66, 111]. In one study, 40% of placental site nodules were present in the endocervix, 56% in the endometrium, and 4% in the fallopian tube [158]. The diagnosis of placental site nodule has been made in a variety of clinical settings including evaluation of cervical intraepithelial neoplasia following an abnormal cervical smear (35%), dysmenorrhea and metromenorrhagia (30%), recurrent spontaneous abortion (5%), retained products of conception (5%), postcoital bleeding (2.5%), and infertility (2.5%) [158]. Many patients have a prior history of therapeutic abortion and cesarean section. A significant number of patients have had a history of a tubal ligation [16, 60, 158]. The antecedent pregnancy has been reported to have been as short as 2 months to as long as 108 months prior to the diagnosis, suggesting that these lesions can persist in the uterus for a long period of time.

Placental site nodules are usually small, ranging from 1 to 14 (average 2.1) mm. Occasionally, multiple and sizable (>5 mm) placental site nodules can be found. When grossly visible, placental site nodules appear as a yellow-white and necrotic-appearing nodule in the endometrium or superficial myometrium [74].

Microscopically, placental site nodules are small nodular or plaque-like lesions with rounded, wellcircumscribed borders (> Figs. 20.46-20.50). The nodules are surrounded by a thin rim of chronic inflammatory cells and, occasionally, decidualized stroma. The nodules typically are composed of chorionic-type intermediate trophoblast (> Fig. 20.5). The trophoblastic cells are arranged in a haphazard pattern, dispersed singly, in small clusters and cords, or occasionally diffusely throughout the nodule (> Fig. 20.50). Mitotic figures are absent or rare. Often these cells occupy the outer portion of the nodule with a central hyalinized extracellular matrix (> Figs. 20.46-20.48). The trophoblastic cells within the placental site nodule share several features with chorionic-type intermediate trophoblast in normal fetal membranes (> Fig. 20.49) [158]. They are haphazardly distributed in an eosinophilic hyaline matrix with scattered large hyperchromatic nuclei easily visible at low magnification. The cells vary in size; many have relatively small uniform nuclei and a few have large, irregular, and hyperchromatic nuclei. Multinucleated cells are

Fig. 20.47

Placental site nodule. The nodule is composed of hyalin material that contains scattered chorionic-type intermediate trophoblast. There are two distinct populations of trophoblastic cells, one with eosinophilic cytoplasm and one with clear or vacuolated cytoplasm

occasionally present. The cytoplasm of the larger trophoblastic cells is abundant and eosinophilic to amphophilic, whereas the smaller cells contain glycogen-rich clear cytoplasm (\bigcirc *Fig. 20.49*).

Rarely, placental site nodules demonstrate morphologic and immunostaining features suggestive of an epithelioid trophoblastic tumor but they are quantitatively and qualitatively insufficient to render the diagnosis of epithelioid trophoblastic tumor [94, 158, 170]. We have tentatively used "atypical placental site nodules" to describe and report those lesions. Although there are no criteria and quantitative measures in defining what is "atypical," atypical placental site nodules usually contain more abundant lesional tissues in curettage or biopsy specimens and appear more cellular than placental site nodules [94, 158, 170]. Specifically, these lesions are intermediate in size between placental site nodules, which rarely exceed 4 mm in diameter and the larger epithelioid trophoblastic tumors. Atypical placental site nodules tend to have higher cellularity and the trophoblastic cells are arranged in more cohesive nests and cords than the typical placental site nodules (\bigcirc *Fig. 20.51*) [146, 153, 154]. Also, the Ki-67 labeling index in usual placental site nodules is higher. These findings suggest that atypical placental site nodules are

Fig. 20.48

Placental site nodule in endocervical curettings. (a) At low magnification, the lesion appears as a discrete nodule containing a trophoblastic layer that surrounds a core of eosinophilic acellular material. (b) The chorionic-type intermediate trophoblastic cells are dispersed singly and in small clusters and cords. The trophoblastic cells can occasionally be detected in cervical cytological specimens where they appear as relatively large cells with abundant cytoplasm and degenerated, smudged nuclei (*inset*) intermediate between a placental site nodule and an epithelioid trophoblastic tumor and may represent a transition from a benign placental site nodule to an epithelioid trophoblastic tumor. Based on the histologic and immunohistochemical features as well as the intimate association of some epithelioid trophoblastic tumors with placental site nodules, we have speculated that the epithelioid trophoblastic tumor represents the neoplastic counterpart of the placental site nodule [94, 170]. The clinical behavior of atypical placental site nodules is currently not known because only a few cases have been reported so far but the few cases in which we have follow-up information have behaved in a benign fashion.

Fig. 20.49

Placental site nodule. Chorionic-type intermediate trophoblastic cells form small nests and cords with distinct cell borders. Mitotic figures are rare but can be seen

Placental site nodule. On some occasions, the trophoblastic cells are arranged in a haphazard pattern, dispersed in small clusters and cords, or sometimes diffusely throughout the nodule. The eosinophilic extracellular matrix is not prominent in this case (compared to **?** *Figs. 20.47* and **?** *20.46*). Each nest is accompanied by hyalinized material, a characteristic finding in placental site nodules

The trophoblastic cells in the placental site nodule exhibit an immunophenotype similar to that of trophoblastic cells in the chorion laeve (fetal membrane; **)** *Fig. 20.5*) but distinct from the implantation site intermediate trophoblast (**)** *Table 20.2*). For example, they are only focally positive for hPL and CD146 (Mel-CAM), and are negative for mucin-4, in contrast to the intermediate trophoblastic cells in the implantation site, where these antigens are highly and diffusely expressed [92, 146, 149, 153]. Immunoreactivity for beta-hCG is usually absent. In contrast to implantation site intermediate trophoblastic cells in placental site nodules are positive for p63 [84, 156]. Similar to the chorionic-type intermediate trophoblastic cells found in chorion laeve (fetal membrane) of normal pregnancy, there is a low level of proliferation in the cells of placental site nodules as indicated by a few scattered Ki-67-labeled nuclei [158]. In contrast, in the normal implantation site and even in exaggerated placental sites the Ki-67 index of implantation site intermediate trophoblastic cells is zero [151].

A placental site nodule may be confused with a PSTT, epithelioid trophoblastic tumor, and a non-trophoblastic lesion, notably invasive squamous carcinoma of the cervix [153, 179]. Their microscopic size, circumscription, extensive hyalinization, and paucicellularity are features that separate them from PSTT. In difficult cases, immunostaining is helpful. The application of immunohistochemistry in assisting the diagnosis of placental site nodule is described in the section **>** Immunohistochemical Approach for Differential Diagnosis. As previously mentioned, the differential diagnosis between placental site nodule and cervical squamous carcinoma may arise in cervical biopsies from patients who are being evaluated for cervical neoplasia. Circumscription of the lesion, abundant eosinophilic extracellular deposit, and lack of mitotic activity favor a placental site nodule. Immunoreactivity for HSD3B1 and p16 are particularly useful in the differential diagnosis [93, 94]. Specifically, placental site nodule is positive for HSD3B1 but is negative for p16, while cervical squamous intraepithelial lesion and carcinoma are positive for p16 and is always negative for HSD3B1.

The distinction of an epithelioid trophoblastic tumor from a placental site nodule is usually not difficult as placental site nodules are microscopic lesions with sharply circumscribed borders [158]. Epithelioid trophoblastic tumors are larger and display substantial necrosis. The placental site nodule is much less cellular than epithelioid trophoblastic tumor (\bigcirc *Fig. 20.52*). In addition, the lesional cells in a placental site nodule in contrast to an epithelioid trophoblastic tumor are bland and mitotic activity is low or absent. If calcification is present, the lesion is most likely an epithelioid trophoblastic tumor rather than a placental site nodule. Moreover, cyclin E is usually expressed in an epithelioid trophoblastic tumor but rarely in a placental site nodule (\bigcirc *Fig. 20.52*) [94].

Placental site nodules are benign non-neoplastic lesions. Because of their small size and circumscription, the lesions are usually removed completely by the surgical procedure that led to their discovery. Neither local recurrence nor progression to persistent GTD has been documented in placental site nodules [153, 179]. Accordingly, no specific treatment or follow-up is necessary for this lesion. The behavior of atypical placental site nodules has not yet been studied.

Atypical placental site nodule. The lesion is intermediate between a placental site nodule and an epithelioid trophoblastic tumor. These atypical placental site nodules tend to have higher cellularity and the trophoblastic cells are arranged in more cohesive nests and cords than the typical placental site nodule. The Ki-67 labeling index in this case is approximately 15–20%, which is higher than in a conventional placental site nodule

Chorangiocarcinoma

Chorangiocarcinoma is discussed in this chapter because this lesion is likely of trophoblastic origin. Chorangiocarcinoma is an exceedingly rare placental lesion and only four cases have been reported so far in the literature [4, 48, 69, 169]; it has argued that the incidence is actually higher [73]. The tumor is usually an incidental finding in a term or a near-term placenta. Grossly, it is a discrete intraplacental lesion resembling a placental infarct. Microscopically it is a lesion characterized by an abnormal trophoblastic proliferation in conjunction with a hypervascular chorangiosis (or chorangioma) in the stroma of chorionic villi (\bigcirc *Fig. 20.53*). The unique morphologic feature of a proliferation in both epithelial and vascular components of chorionic villi distinguishes chorangiocarcinoma from other trophoblastic tumors and tumor-like lesions. The cells in the epithelial compartment form solid masses with massive central coagulation necrosis surrounded by a few (three to six) layers of viable epithelial tumor cells. At low magnification, the necrotic areas may occupy most of the tumor. The epithelial cells are highly proliferative with frequent mitotic figures. They express low-molecular-weight cytokeratin (such as cytokeratin 18), beta-hCG, and HSD3B1, supporting their trophoblastic origin [93]. The vascular component is similar to chorangiosis or a chorangioma with numerous intercalated vascular channels in the villous stroma.

Comparison of a placental site nodule (a, c, e) and an epithelioid trophoblastic tumor (b, d, f). (a, b): H&E sections at low magnification. (c, d) H&E sections at higher magnification. (e, f) Cyclin E immunostain (Reprinted by permission from [94])

The pathogenesis in the development of chorangiocarcinoma is undetermined. The lesion may represent a chorangioma with associated trophoblastic hyperplasia, a true trophoblastic neoplasm with a reactive chorangiosis response, a reactive lesion of trophoblastic cells and villous vascular channels, or a collision tumor of chorangioma and choriocarcinoma. The clinical experience with chorangiocarcinoma is very limited but the available data from the reported cases reveal that patients have an uneventful postpartum course and do not develop persistent GTD [48, 69, 73, 169].

Immunohistochemical Approach for Differential Diagnosis

Diagnosis of trophoblastic tumors and tumor-like lesions is usually straightforwardly based on clinical and morphological features (**>** *Tables 20.7* and **>** *20.8*). However; the diagnosis can be challenging in certain cases, especially in small biopsy and curettage specimens [110]. To assist in differential diagnosis, we have developed an algorithmic approach, termed "trophogram," using a three-tiered stepwise immunohistochemical staining procedure [144]

Chorangiocarcinoma. (a) The tumor is characterized by an abnormal trophoblastic proliferation (*left*) and hypervascular chorangiosis (*right*) in the stroma of the chorionic villi. (b, c) The cells in the epithelial compartment form solid masses with massive central coagulative necrosis which is surrounded by a few (three to six) layers of viable epithelial (presumable trophoblastic) tumor cells. (d) Immunohistochemical features of chorangiocarcinoma. The viable tumor cells in the epithelial component are positive for low-molecular-weight cytokeratin (such as cytokeratin 18) and HSD3B1 (a trophoblast-associated marker), a finding supporting the tumor cells are of trophoblastic origin. The percentage of Ki-67 labeled epithelial cells is high (>90%) in the viable epithelial cells. In contrast, the vascular/chorangiosis component is negative for cytokeratin and HSD3B1 but is positive for vimentin

(\triangleright Fig. 20.54). The antibodies utilized in the algorithm are all commercially available and are listed in \triangleright Table 20.9. The first tier in the algorithm discriminates a trophoblastic versus a non-trophoblastic lesion. The second tier determines if the lesion is related to implantation site intermediate trophoblast (i.e., exaggerated placental site and PSTT), to chorionic-type intermediate trophoblastic cells (i.e., placental site nodule and epithelioid

trophoblastic tumor), or a choriocarcinoma. The third tier distinguishes a benign tumor-like lesion versus a trophoblastic neoplasm (\bigcirc *Fig. 20.54*). An example of how the algorithm can be used in the diagnosis of a PSTT is illustrated in \bigcirc *Fig. 20.55*.

Using the algorithm, immunoreactivity of HSD3B1 and low-molecular-weight cytokeratin (e.g., cytokeratin 8 or 18) should first be assessed to determine if the lesion

Trophogram is an immunohistochemistry algorithm designed to assist in the differential diagnosis of trophoblastic tumors and tumor-like lesions. A three-tier sequential staining procedure that utilizes a panel of commercially available antibodies listed in **7** Table 20.9. The first tier discriminates a trophoblastic versus a non-trophoblastic lesion. The second determines if the lesion is a choriocarcinoma, a lesion related to implantation site intermediate trophoblast or a lesion related to chorionic-type intermediate trophoblastic cells. The third tier distinguishes a benign tumor-like lesion versus a true trophoblastic neoplasm. EPS, exaggerated placental site; PSTT, placental site trophoblastic tumor; PSN, placental site nodule; ETT, epithelioid trophoblastic tumor; LMW, low molecular weight

Table 20.9

Commercial antibodies used	in the trophogram

Marker	Antibody source	Application
HSD3B1	Abnova (3C11-D4 ^a)	Distinguish GTD from most non-GTD
Cytokeratin	Ventana (CAM5.2)	Exclude mimickers of mesenchymal origin
p63	Neomarker (4A4)	Distinguish ETT vs. PSTT
hPL	Dako (polyclonal)	Distinguish PSTT vs. ETT
beta-hCG	Dako (polyclonal)	Highlight ST in choriocarcinoma
Cyclin E	Zymed (HE12)	Distinguish ETT vs. PSN
Ki-67	Dako (MIB-1)	Distinguish ETT vs. PSN; PSTT vs. EPS

^aClone or name for the monoclonal antibody which may be obtained from other commercial sources.

GTD, gestational trophoblastic disease; ETT, epithelioid trophoblastic tumor; PSTT, placental site trophoblastic tumor; PSN, placental site nodule; EPS, exaggerated placental site; ST, syncytiotrophoblast.

The algorithm in the diagnosis of a PSTT. Hematoxylin-and-eosin section shows a tumor composed of large, atypical cells forming confluent masses and cords. The differential diagnosis includes PSTT, exaggerated placental site, epithelioid trophoblastic tumor, smooth muscle neoplasm, and poorly differentiated carcinoma. Immunohistochemistry demonstrates that the tumor cells are diffusely positive for HSD3B1, indicating trophoblastic origin. The trophoblastic lesion was then stained with hPL followed by Ki-67 and is diffusely positive for hPL, indicating that it is derived from the implantation site intermediate trophoblastic cells. The Ki-67 labeling index is approximately 15%, confirming its neoplastic nature. The combination of morphologic and immunohistochemical findings indicate that the case is a PSTT. EPS, exaggerated placental site; PSTT, placental site trophoblastic tumor; PSN, placental site nodule; ETT, epithelioid trophoblastic tumor; LMW, low molecular weight

in question is trophoblastic. Diffuse and intense HSD3B1 and low-molecular-weight cytokeratin immunoreactivity strongly suggests trophoblast origin [93]. It should be noted that HSD3B1 must be used in conjunction with low-molecular-weight cytokeratins because the latter are expressed in a wide variety of adenocarcinomas. Thus, cytokeratin should be used to further support the diagnosis of a trophoblastic lesion in HSD3B1-positive cases. Once the diagnosis of a trophoblastic lesion is established and hydatidiform mole is excluded, choriocarcinoma should be considered because it is the most common malignant trophoblastic neoplasm. The presence of beta-hCGstained syncytiotrophoblast supports the diagnosis of choriocarcinoma. In choriocarcinomas where the syncytiotrophoblastic component is attenuated, beta-hCG-positive syncytiotrophoblast tends to lie between or envelop masses of mononucleate trophoblastic cells. Syncytiotrophoblast in choriocarcinoma should not be mistaken for betahCG positive multinucleated intermediate trophoblastic cells in PSTT and epithelioid trophoblastic tumor. The multinucleated intermediate trophoblastic cells are usually polygonal or round in shape with centrally located nuclei, whereas syncytiotrophoblast have an irregular often serpentine shape with dense, amphophilic cytoplasm and multiple hyperchromatic nuclei. A beta-hCG immunostaining can help demonstrate the characteristic growth pattern. Furthermore, choriocarcinoma has very high proliferative activity and accordingly the Ki-67 labeling index in mononucleate tumor cells in choriocarcinoma (Ki-67 index usually >40%) is significantly higher than that in most PSTTs and epithelioid trophoblastic tumors (Ki-67 index usually <30%). Of note, some malignant PSTTs and epithelioid trophoblastic tumors may have unusually high Ki-67 labeling index and thus the Ki-67 index is useful but not diagnostic of choriocarcinoma. Other immunohistochemical markers including HLA-G, Mel-CAM, p63, cytokeratin, and inhibin are not useful in the differential diagnosis of choriocarcinoma versus other trophoblastic tumors [71].

If choriocarcinoma has been ruled out, both hPL and p63 antibodies should be applied to determine if the lesion is related to implantation site intermediate trophoblast or chorionic-type intermediate trophoblast. hPL is diffusely positive (usually >50% of lesional cells) and p63 is always negative (or very focally positive) in PSTT and exaggerated placental site. In contrast, hPL is either negative or focally positive in epithelioid trophoblastic tumors and placental site nodules but p63 is diffusely positive (usually >50% of lesional cells) [84, 156, 185]. Of note, the antibody to p63 should be the one that recognizes all the p63 isoforms. If necessary, the Ki-67 labeling index can be used to distinguish an epithelioid trophoblastic tumor from a placental site nodule or a PSTT from an exaggerated placental site. The Ki-67 index in placental site nodule is generally low (<8%), while the index in epithelioid trophoblastic tumor is above 12%. Similarly, the Ki-67 index is near zero (<1%) in exaggerated placental site while it is usually above 10% in PSTT. One important pitfall in determining Ki-67 labeling index is that presence of NK cells and lymphocytes in the endomyometrium, which are proliferative and can result in an apparent increased Ki-67 labeling index [151]. Accordingly, it is important that the Ki-67 labeling index be exclusively evaluated in trophoblastic cells. Morphologically, trophoblastic cells tend to have enlarged and highly pleomorphic (degenerated) nuclei, whereas inflammatory cells usually have smaller and uniform nuclei, but at times distinction between trophoblastic cells and inflammatory cells may be difficult. The Ki-67 labeling index is more reliable in distinguishing PSTT from exaggerated placental site rather than epithelioid trophoblastic tumor from placental site nodule because the diagnostic margin of Ki-67 labeling index between epithelioid trophoblastic tumor and placental site nodule is relatively narrow in some cases. To address this potential concern, Mao et al. has recently reported that cyclin E immunoreactivity is useful in the discrimination

between epithelioid trophoblastic tumors and placental site nodules [94]. Cyclin E is expressed in the nuclei of many epithelioid trophoblastic tumors but rarely in placental site nodules.

It should be emphasized that the sequence in applying the immunostaining scheme outlined in **>** Fig. 20.54 should be followed when applying the trophogram in the differential diagnosis of trophoblastic tumors and tumor-like lesions. For example, p63 immunoreactivity is informative only in the context of distinguishing trophoblastic tumors and tumor-like lesions that are related to either implantation site intermediate trophoblastic cells (PSTT and exaggerated placental site) or chorionic-type intermediate trophoblastic cells (epithelioid trophoblastic tumor and placental site nodule). p63 immunostaining is not useful in distinguishing trophoblastic versus nontrophoblastic lesions because it is expressed in several types of squamous carcinomas [57]. Likewise, cyclin E immunoreactivity is applicable only for distinguishing epithelioid trophoblastic tumors from placental site nodules. It is not useful in other diagnostic settings because a variety of neoplastic diseases express cyclin E.

A variety of hematologic neoplasms involves the female reproductive organs, including a number of different types of lymphomas and lymphoid leukemias, myeloid sarcomas and myeloid leukemias, and rare histiocytic neoplasms. When the female reproductive organs are affected by one of these disorders in the setting of widespread disease, the diagnosis is usually straightforward, but in the uncommon instance in which the female genital tract is the presenting site of a hematologic neoplasm, diagnosis may be problematic, and special problems in differential diagnosis may arise.

Lymphoid Neoplasms of the Female Reproductive Organs

Lymphoma rarely presents with involvement of the female reproductive organs. When it does, the ovaries are most commonly affected, followed by the uterine cervix, uterine corpus, vagina, vulva, and fallopian tubes. Nearly all cases are non-Hodgkin's lymphoma of B-lineage, with diffuse large B-cell lymphoma being the most common type throughout the female reproductive organs. T-cell lymphoma is very uncommon and the natural killer (NK)-cell lymphoma and Hodgkin's lymphoma are exceptional [21, 40]. Rare cases of lymphoma arising in the setting of HIV infection or iatrogenic immunosuppression [37, 42, 58] and a few cases of women with a family history of hematologic neoplasia have been described [23]. Endemic Burkitt's lymphoma is known to have a tendency to involve the ovaries.

Ovarian Lymphoma

Primary Ovarian Lymphoma

Overall, fewer than 1% of lymphomas present with ovarian involvement [14, 21, 22] and fewer than 1.5% of neoplasms arising in the ovary are lymphomas. However, in countries where Burkitt's lymphoma is endemic, approximately 50% of malignant ovarian neoplasms in childhood are Burkitt's lymphoma [78].

Clinical Features

Patients range in age from 18 months to 74 years [21], with a peak incidence in the thirties or forties [14, 21, 90]. Occasionally lymphoma develops during pregnancy [21, 49]. Rare patients have been HIV+ [42]. The presenting complaints are generally nonspecific symptoms related to

the presence of a mass [14, 61, 90]. A minority have fatigue, weight loss, fever, or abnormal vaginal bleeding [14]. Rarely the lymphoma is an incidental finding [90].

Pathologic Features

Ovarian lymphomas range from microscopic [90] to large masses up to 25 cm in diameter with an average size of 11–14 cm [21, 90]. The external surfaces are usually intact and may be smooth or nodular. On sectioning, the tumors may be soft and fleshy or firm and rubbery, depending on the degree of cellularity and associated sclerosis. They are usually white, tan, or gray-pink and a minority has cystic degeneration, hemorrhage or necrosis [21]. Very rare cases of lymphoma in association with, possibly arising from, a teratoma have been described [53].

The most common lymphoma is diffuse large B-cell type, followed by Burkitt's lymphoma and follicular lymphoma [14]. Adolescents and children almost always have diffuse, aggressive lymphomas, including Burkitt's lymphoma, B lymphoblastic lymphoma and diffuse large B-cell lymphoma [40] while adults may have indolent or aggressive lymphomas. Ovarian lymphoma may preferentially spare corpora lutea, corpora albicantia, follicles, and a peripheral rim of cortical tissue but otherwise typically obliterates normal ovarian parenchyma. Lymphoma is rarely associated with hyperplasia and luteinization of the adjacent stroma [21].

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma in the ovary, as in other sites is composed of centroblasts, immunoblasts, multilobated cells, or a mixture of these. In the ovary, associated sclerosis is common and tumor cells may grow in cords and nests, simulating carcinoma [78], or be elongate and grow in a storiform pattern, mimicking a sarcoma (\bigcirc *Fig. 21.1a–c*). A few diffuse large B-cell lymphomas have a component of follicular lymphoma [61, 90]. Tumor cells are CD20+, and in the few cases studied, expression of bcl6, CD10, and bcl2 is common [90].

Burkitt's Lymphoma

Ovarian Burkitt's lymphoma is most commonly encountered among children and adolescents [40]. Burkitt's lymphoma is more often bilateral than other ovarian lymphomas [41]. It is hypothesized that Burkitt's lymphoma occurring in pregnancy has a tendency to involve hormonally stimulated organs, such as the ovary [49].

Both sporadic and endemic Burkitt's lymphoma may present with ovarian involvement [13, 43], and ovarian

Ovary, diffuse large B-cell lymphoma with spindle neoplastic cells. (a) Low power shows a thin layer of uninvolved tissue at the surface of the ovary. The neoplastic cells grow in a storiform pattern. (b) High power shows atypical cells with elongate, usually blunt-ended nuclei admixed with cells with round or lobated nuclei; there is interstitial sclerosis. The neoplastic proliferation spares a small epithelial inclusion gland. (c) Neoplastic cells are CD20+ confirming B lineage; they also expressed CD45, the leukocyte common antigen (not shown) (immunoperoxidase technique on a paraffin section)

involvement in the setting of immunodeficiency (HIV infection) has been described [42]. The histologic features are the same as those found in other sites. There is a diffuse proliferation of medium-sized, uniform cells with round nuclei containing stippled chromatin and several small nucleoli per cell in each nucleus. A moderate quantity of cytoplasm which is deep blue with Giemsa or Wright stain is present. Mitoses are numerous. Many scattered pale tingible body macrophages in a background of dark neoplastic cells impart a starry sky pattern at low power (**>** *Fig. 21.2a and b*). Occasionally, neoplastic cells are somewhat more pleomorphic, chromatin may be more

vesicular, and there is only a single nucleolus within each nucleus. In some cases, designated Burkitt's lymphoma with plasmacytoid differentiation, there is slightly more cytoplasm and tumor cells contain monotypic cytoplasmic immunoglobulin [13, 43]. Children with Burkitt's lymphoma usually have typical morphology, while Burkitt's lymphoma with plasmacytoid differentiation is usually found in the setting of immunodeficiency. As in other sites, the characteristic immunophenotype is monotypic IgM+, CD20+, CD10+, CD5–, bcl6+, bcl2–, Ki67 \sim 100% +, and the neoplastic cells harbor a translocation involving c-myc [10, 13, 40, 43]. Endemic Burkitt's lymphoma typically

Ovary, Burkitt's lymphoma. (a) Low power shows scattered pale tingible body macrophages in a background of dark neoplastic cells, creating a "starry sky" pattern. (b) High power shows fairly uniform, medium-sized lymphoid cells with round nuclei, stippled chromatin, and numerous mitoses; the appearance is typical of Burkitt's lymphoma

contains Epstein-Barr virus (EBV), while a minority of cases of sporadic Burkitt's lymphoma and immunodeficiency-associated Burkitt's lymphoma in HIV+ patients are positive for EBV [13, 43].

Follicular Lymphoma

Ovarian follicular lymphoma mainly affects older patients. They may be entirely follicular or may have conspicuous diffuse areas. They are composed of a variable admixture of centrocytes (small cleaved cells) and centroblasts (large non-cleaved cells). Follicular lymphomas of all three grades (grade 1: 0–5 centroblasts/average high power field (HPF); grade 2: 6–15 centroblasts/average HPF; grade 3: >15 centroblasts/average HPF) occur in the ovary (\triangleright *Fig. 21.3a–d*) [41, 90].

Rare Lymphomas

Rare cases of CD30+ anaplastic large cell lymphoma of T lineage, and B and T lymphoblastic lymphoma presenting with ovarian involvement have been reported [33, 40, 76, 90]. Morphology, in conjunction with expression of terminal deoxynucleotidyl transferase (TdT) distinguishes precursor B and T-cell neoplasms from mature B and T-cell lymphomas.

Staging, Treatment and Outcome

At laparotomy there is involvement of one or both ovaries with approximately equal frequency. Staging discloses extraovarian spread in most cases, often involving pelvic or paraaortic lymph nodes and occasionally peritoneum, other genital organs, or distant sites [14, 21]. Ovarian lymphoma has traditionally been considered an aggressive tumor with a poor outcome, but improvements in therapy in recent years appear to be associated with a prognosis similar to that of lymph nodal lymphomas of comparable stage and histologic type [14, 51, 90].

Secondary Ovarian Lymphoma

Among patients with disseminated lymphoma and lymphoid leukemias, the ovary is a relatively common site of involvement, although it may be asymptomatic. Seven to twenty five percent of women dying with lymphoma have ovarian involvement [3, 21]. Any type of lymphoma may spread to the ovary, but mediastinal large B-cell lymphoma has a distinct tendency to involve the ovary (**>** *Fig. 21.4a and b*) [12, 79, 97]. Acute lymphoblastic leukemia that relapsed in the ovaries during bone marrow remission has been reported [7, 93]. The ovaries were usually not the only site of relapse; there is frequent involvement of the peritoneum, omentum, fallopian tubes, lymph nodes, and central nervous system [7, 93].

Differential Diagnosis

The differential diagnosis of ovarian lymphoma is broad; it includes dysgerminoma, metastatic carcinoma, and primary small cell carcinoma of hypercalcemic and pulmonary types, adult granulosa cell tumor [61], spindle cell

Ovary, follicular lymphoma. (a) The ovary is replaced by a vaguely nodular-appearing proliferation of atypical lymphoid cells. (b) The atypical cells are mostly small with irregular nuclei; very few large cells are present. (c) The atypical cells are B cells (CD20+); they also expressed the follicle center-associated antigen bcl6 (not shown). (d) CD21 highlights follicular dendritic meshworks; the follicular architecture is more readily appreciated than on routinely stained sections (c, d, immunoperoxidase technique on paraffin sections)

sarcoma, undifferentiated carcinoma, and myeloid sarcoma [21]. Immunohistochemical studies readily confirm or exclude lymphoma. In contrast to lymphomas in the lower genital tract (see below), the differential diagnosis with inflammatory processes is only rarely problematic.

The main problem in differential diagnosis is distinguishing diffuse large B-cell lymphoma from nonlymphoid neoplasms because large lymphoid cells can have varying morphology and may overlap in size and shape with other types of neoplastic cells. Burkitt's lymphoma is a highly cellular tumor with a characteristic histologic appearance. Recognition of follicular lymphoma is facilitated by its, at least, partially follicular growth pattern. Selected features that aid in differential diagnosis are presented in **>** *Table 21.1*.

Lymphoma of the Fallopian Tube

Primary Lymphoma of the Fallopian Tube

One case of primary tubal marginal zone B-cell lymphoma associated with salpingitis [63], one possible case of primary tubal follicular lymphoma (**)** *Fig. 21.5a and b*), [20] and a bilateral primary tubal peripheral T-cell lymphoma [24] have been described.

Ovarian involvement by mediastinal large B-cell lymphoma. (a) Gross examination of the bisected ovarian tumor shows fleshy white tissue. (b) High power shows discohesive neoplastic cells with round or irregular nuclei and scant cytoplasm. A few cells are multilobated and rare cells are multinucleated

Table 21.1

Differential diagnosis of ovarian diffuse large B-cell lymphoma

Non-lymphoid tumor	Problem	Differential features	Usual immunophenotype of non-lymphoid tumor
Dysgerminoma	DLBCL composed of IBs: IBs have size, shape and prominent nucleoli, similar to cells of dysgerminoma	Dysgerminoma: Sheets and nests of tumor cells, fibrous trabeculae with lymphocytes, and histiocytes; nuclei flattened along one side, fine chromatin, abundant clear PAS+ cytoplasm, distinct cell borders: not seen in DLBCL	PLAP+, Oct4+, CD117+, CD45–, CD20–
Carcinoma	DLBCL with sclerosis can have cord-like or nested pattern resembling carcinoma	Cohesive growth, nuclear molding, lumen formation, mucin production favor carcinoma; follicles favor small cell carcinoma, hypercalcemic variant	Cytokeratin+, CD45–, CD20–
Spindle cell sarcoma	DLBCL with sclerosis can have spindle cell morphology	Sarcoma lacks admixed CBs and IBs; tumor cells usually more elongate	Mesenchymal markers (varied)+, CD45–, CD20–
Adult granulosa cell tumor	CBs and IBs have large pale vesicular nucleoli that could mimic cells of AGCT; AGCT can have a diffuse pattern, like DLBCL	Trabecular, insular, micro- or macrofollicular pattern, Call-Exner bodies, more pale, evenly dispersed chromatin, and nuclear grooves favor AGCT	Inhibin+, calretinin+, CD45–, CD20–
Myeloid sarcoma	Large lymphoid cells and primitive myeloid cells overlap morphologically; their patterns of growth are similar	Myeloblasts are slightly smaller than large lymphoid cells; they have more finely dispersed chromatin and usually smaller nucleoli. Some cells may have pink cytoplasm, suggesting myeloid differentiation. Bone marrow exam may show myeloid leukemia. Eosinophilic myelocytes may be present	Lysozyme+, MPO+/–, CD68+/–, CD34+/–, CD117+

DLBCL, diffuse large B-cell lymphoma; IB, immunoblast; CB, centroblast; AGCT, adult granulosa cell tumor; MPO, myeloperoxidase.

Secondary Tubal Involvement by Lymphoma

Tubal involvement is relatively common among patients with lymphoma of the ovaries [61]. Most are diffuse large B-cell lymphoma or Burkitt's lymphoma [86]; follicular lymphoma, peripheral T-cell lymphoma and lymphoblastic lymphoma/leukemia have also been reported [7, 61, 67, 86]. Tubal infiltration is also seen at autopsy in cases of disseminated lymphoma [30].

Fig. 21.5

Fallopian tube, follicular lymphoma. (a) Whole mount section shows tube with transmural involvement by crowded lymphoid follicles. (b) High power shows a portion of one of the neoplastic follicles; it is composed of small cleaved cells (centrocytes) with few admixed large noncleaved cells (centroblasts). Small lymphocytes are present at the periphery of the follicle

Uterine Lymphoma

Primary Uterine Lymphoma

Less than 1% of extranodal lymphomas arise in this site [22]. Lymphoma arises more often in the cervix than in the corpus, with a 10:1 ratio in one series [87], although other series have not shown such a striking excess of cervical lymphomas [40].

Clinical Features

Uterine lymphoma affects adults over a broad age range [28], with a mean and a median age in the fifth decade [17, 23, 28, 50, 71]. The most common presenting symptom is abnormal vaginal bleeding [1, 8, 9, 11, 21, 23, 28, 50, 86]. Less common complaints are dyspareunia, perineal, pelvic, or abdominal pain. A few patients have systemic symptoms such as fever or weight loss [17, 21, 71]. Because lymphomas are typically not associated with ulceration, uterine lymphoma is only occasionally detected on a Papanicolaou smear.

Pathologic Features

Cervical lymphomas typically produce bulky lesions identifiable on pelvic examination. The classic appearance is diffuse, circumferential enlargement of the cervix ("barrelshaped" cervix) (> Fig. 21.6). The lymphoma may also form a discrete submucosal tumor [8, 28], a polypoid or multinodular lesion [9, 25, 28], or a fungating, exophytic mass; ulceration is unusual [28]. The tumors have been variously described as fleshy, rubbery, or firm, and whitetan to yellow [28]. Extensive local spread to sites such as vagina, parametria, or even pelvic side walls is common [9, 11, 23, 28] and invasion into the urinary bladder is described [38]. Patients commonly exhibit hydronephrosis secondary to ureteral obstruction [11, 21, 28]. Lymphomas of the uterine corpus are usually fleshy or soft, pale gray, vellow, or cream-colored. They may form a polypoid mass or diffusely infiltrate the endometrium, sometimes with deep invasion of the myometrium [21, 28].

The microscopic appearance of the lymphomas is similar to that of the same types of lymphoma seen in nodal and other extranodal sites. In the cervix, there is often a band of uninvolved normal tissue just beneath the surface epithelium, and the overlying epithelium is usually intact. In a large biopsy or hysterectomy specimen, deep invasion of the cervical wall is usually seen. In small biopsies, squeeze artifact is often prominent.

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma is the most common type of primary uterine lymphoma by far, in both the corpus

and the cervix [1, 9, 23, 25, 38, 86, 87], accounting for about 70% of cases [17, 86]. Neoplastic cells may be centroblasts, immunoblasts, or multilobated large lymphoid cells, or a combination of these. Cervical lymphomas are frequently associated with prominent sclerosis [25, 41, 86], which may be associated with a cord-like arrangement or spindle-shaped tumor cells [28]. The spindle cell pattern may be sufficiently prominent to mimic a sarcoma resulting in usage of the terms "spindle cell variant" [5] and "sarcomatoid variant" [35]. Rare examples of intravascular large B-cell lymphoma presenting with involvement of the uterus and adnexa have been described [81, 94]. Microscopic examination revealed large atypical lymphoid cells filling the lumens of blood vessels (> Fig. 21.7a and b). One case had the unusual feature of CD5 coexpression by the large atypical CD20+, CD79a+ B cells; neoplastic cells were also positive for EBV [94].

Fig. 21.6

Uterine cervix, lymphoma. Gross examination shows circumferential expansion of the cervix, so-called barrel-shaped cervix

Follicular Lymphoma

Follicular lymphoma is the second most common type of uterine lymphoma; follicular lymphomas of all three grades have been reported [40]. These are also often associated with sclerosis. Neoplastic follicles are often found in a perivascular location as they invade into the wall of the cervix (\bigcirc *Fig. 21.8a–f*) [28].

Extranodal Marginal Zone Lymphoma (MALT Lymphoma)

A few cases of marginal zone B cell lymphoma arising in the endometrium or in the cervix have been described [21, 23, 40, 84, 86, 87].

Fig. 21.7

Uterine cervix, intravascular large B-cell lymphoma. (a) The exocervix has multiple blood vessels containing neoplastic cells. (b) High power shows a dilated blood vessel filled by large, atypical, pleomorphic lymphoid cells. The neoplastic cells were CD20+ and CD3– (not shown), consistent with B-lineage

Uterine cervix, follicular lymphoma. (a) Low power shows atypical lymphoid follicles invading deep into the wall of the cervix. The surface epithelium is intact and uninvolved by the lymphoid infiltrate. (b) Higher power shows crowded, ill-defined follicles composed of a monotonous population of small atypical lymphoid cells. Immunostains show follicles composed of B cells (c, CD20+) surrounded by T cells (d, CD3+). B cells co-express the follicle center-associated marker CD10 (e) as well as bcl2 (f); these immunohistochemical results confirm a diagnosis of follicular lymphoma (c-f, immunoperoxidase technique on paraffin sections)

In 1997 three cases of a distinctive type of low-grade endometrial B-cell lymphoma was described [84]. All affected women were in their sixties and the lymphomas were all incidental findings and confined to the uterus. On microscopic examination all were composed of large nodules with a monotonous population of small lymphoid cells with slightly irregular nuclei and scant cytoplasm adjacent to and sometimes surrounding endometrial glands. Immunohistochemical analysis showed B cells with aberrant coexpression of CD43. The immunoglobulin heavy chain genes were clonally rearranged. Follow-up, when available, was uneventful. The authors were reluctant to subclassify these lymphomas as marginal zone type because of lack of certain features that would support that diagnosis including absence of conspicuous lymphoepithelial lesions, lack of a marginal zone pattern, and lack of reactive follicle centers. In addition, only limited immunophenotyping could be performed. Subsequently, a case with identical histologic features was reported in which neoplastic cells were CD20+, bcl2+, without expression of CD5, bcl6, or cyclin D1. The cellular nodules were associated with altered CD21+ follicular dendritic cell meshworks [33]. This case was interpreted as an endometrial marginal zone lymphoma. These cases are best classified as endometrial marginal zone lymphomas, albeit with distinctive clinical and pathologic features (\heartsuit *Fig. 21.9a–c*).

Fig. 21.9

Endometrium, marginal zone lymphoma. (a) Crowded nodules of small lymphoid cells extensively replace the endometrium and extend superficially into the myometrium. (b) Nodules of small, bland lymphoid cells scattered among endometrial glands. (c) Lymphoid cells are predominantly B cells (CD20+). B cells co-expressed CD43 and were associated with CD21+ follicular dendritic meshworks (not shown) crowded nodules of small lymphoid cells (immunoperoxidase technique on a paraffin section)

Rare Lymphomas

A few cases of Burkitt's lymphoma [40, 64] and rare cases of B lymphoblastic lymphoma [40], peripheral T cell lymphoma [39], and cervical extranodal NK/T-cell lymphoma [86] have been reported. The uterus is rarely the site of involvement by B-cell post-transplantation lymphoproliferative disorder [58]. Although Hodgkin's lymphoma in the female genital organs is vanishingly rare, a case of classical Hodgkin's lymphoma, lymphocyte depletion type, confirmed with immunophenotyping showing CD15 and CD30 expression by the neoplastic cells, has been reported [40].

Staging, Treatment, and Outcome

Although most uterine lymphomas are large at the time of diagnosis (the primary endometrial marginal zone lymphomas are an exception), the majority are localized (Ann Arbor stage I or stage II), with stage I more frequent than stage II [8, 87]. The type of therapy has varied. In a few cases, young women have been successfully treated using combination chemotherapy and some have preserved fertility [21, 25]. Uterine lymphoma has a relatively good prognosis [9, 21, 59, 86]. Between 70% and 90% of patients are alive and free of disease at last follow-up [8, 17]. Most prognostic information on uterine lymphoma is related to lymphoma arising in the cervix. The 5-year survival for cervical lymphoma is estimated to be approximately 80% [50, 87]. There is not enough information to draw definite conclusions about the prognosis of the rare endometrial lymphomas. However, those with localized disease tend to do well, including, in particular, the endometrial marginal zone lymphomas [23, 84]. Those with advanced disease presenting with endometrial involvement have a worse prognosis [28].

Secondary Uterine Lymphoma

Secondary involvement of the uterus in cases of disseminated lymphoma or lymphoid leukemia is not unusual; it may be asymptomatic or accompanied by vaginal bleeding or discharge [21, 40, 86]. In contrast to primary uterine lymphoma, in which the cervix is much more often involved than the corpus, when the uterus is secondarily involved, the corpus is involved at least as often as the cervix. Lymphomas secondarily involving the uterus are also of more varied types than in primary cases, with less of a predominance of diffuse large B-cell lymphoma. They include diffuse large B-cell lymphoma, follicular lymphoma, chronic lymphocytic leukemia, lymphoblastic lymphoma [21, 40, 86], T lymphoblastic leukemia [46] and extranodal NK/T-cell lymphoma [57]. The prognosis is much less favorable than that of primary uterine lymphoma [57, 87].

Uterine involvement is relatively common in patients dying with lymphoid leukemias. In one autopsy study, 25% of patients with acute lymphoblastic leukemia and 14% with chronic lymphocytic leukemia had involvement of the uterus [3].

Placental Involvement by Lymphoid Neoplasms

Approximately 0.1% of women have a malignancy during pregnancy, subsets of which are lymphomas or leukemias. Rarely, lymphoma or leukemia may be detected in the placenta of these patients [6, 34, 52, 54, 62]. Some of the women have been treated successfully, while others have succumbed to their disease. In most instances placental involvement does not lead to spread of the neoplasm to the fetus, although rarely this does occur [6, 52], sometimes with fatal consequences for the newborn [6].

On gross examination, white nodules or white granular areas or infarcts may be present [54, 62]. On microscopic examination, there is a variably dense infiltrate of neoplastic cells in the intervillous space (maternal circulation). In very rare cases, neoplastic cells are also found within the chorionic villi, involving blood vessels (fetal circulation) [6, 52] or the cord blood [85]; involvement of fetal circulation has rarely been associated with spread of the malignancy to the fetus, resulting in death within a few months of delivery [6]. This underscores the importance of careful gross and microscopic examination of the placenta in the setting of maternal malignancy.

The lymphomas and lymphoid leukemias have been of a variety of types, sometimes classified with older nomenclature [34]. Aggressive lymphomas of B and T lineage have been documented to involve the placenta [54]. Rare cases of mediastinal large B-cell lymphoma [62], anaplastic large cell lymphoma (ALK-positive) [54], and Epstein–Barr virus-positive aggressive NK-cell leukemia/lymphoma involving the placenta have been described [6]. An example of B-lymphoblastic leukemia, in which neoplastic cells were detected in cord blood, has been reported [85].

Vaginal Lymphoma

Primary Vaginal Lymphoma

Clinical Features

Lymphoma rarely arises in the vagina [21, 71, 89]. As in other parts of the female reproductive organs, primary

vaginal lymphoma affects patients over a broad age range; their mean age is in the forties. Patients present with vaginal bleeding, discharge, pain, dyspareunia or urinary frequency. Some note a mass. The lesion may compress the urethra and cause anuria [95] or bladder distension [89]. The tumors typically result in ill-defined thickening or induration of the vaginal wall, often with invasion of adjacent structures such as the cervix and the rectovaginal septum [89]. As in the uterine cervix, surface epithelium is usually intact, so that Papanicolaou smears are generally negative [72].

Pathologic Features

The pathologic features are similar to those of cervical lymphoma. Nearly all of the lymphomas are diffuse large B-cell type [21, 40, 89]. Rare cases of follicular lymphoma [11, 28, 40], Burkitt's lymphoma, lymphoplasmacytic lymphoma [40], T-cell lymphoma [21, 72], and marginal zone lymphoma [95] have been reported. As in the cervix, vaginal diffuse large B-cell lymphomas are often associated with marked sclerosis and may be "sarcomatoid." Only a few of these cases have been studied in detail, but they have been CD20+, CD5-, CD10-, bcl6+, MUM1-, CD138-, Epstein-Barr virus (EBV)-, HHV-8-, with somatic mutation of both immunoglobulin and bcl6 genes. These features suggest that the so-called spindle cell variant of diffuse large B-cell lymphoma corresponds to an early germinal center stage of B cell maturation [5]. Rare primary vaginal lymphomas positive for EBV have been reported [15].

Staging, Treatment, and Outcome

Primary vaginal lymphoma typically presents with localized disease (Ann Arbor stage IE or IIE). Treatment has not been uniform, but vaginal lymphoma appears to have a favorable prognosis [11, 15, 71, 72, 89, 95]. In one series of eight cases of diffuse large B-cell lymphoma, for example, only one patient died of lymphoma [89].

Secondary Vaginal Lymphoma

Secondary involvement of the vagina by malignant lymphoma, including relapse of lymphoma in the vagina and involvement of the vagina in the setting of widespread disease, is more common than primary vaginal lymphoma [21]. The prognosis is much less favorable than for primary disease [72, 89].

Vulvar Lymphoma

Primary Vulvar Lymphoma

Primary vulvar lymphoma is exceedingly rare. Patients are adults who present with a nodule, swelling, or induration of the vulva [21, 88]. In rare cases the lymphoma has presented as a mass in the region of Bartholin's gland [82], or as a clitoral mass [40]. Patients appear to be, on average, older than patients with lymphoma arising in other parts of the reproductive tract [40]. A few patients have been HIV+ or iatrogenically immunosuppressed [21, 36, 37, 88]. Diffuse large B-cell lymphoma is the most common type [21, 48, 82, 88]. Other types are rare. Several cases of lymphoplasmacytic lymphoma have been reported [40] and a case of T-cell post-transplantation lymphoproliferative disorder has been described [37]. Vulvar lymphoma is, overall, relatively aggressive, but occasional patients have long disease-free survival.

Secondary Vulvar Lymphoma

Secondary involvement of the vulva by lymphoma at relapse or in the setting of widespread disease is rare. The lymphomas have been of various types [40]. Mycosis fungoides may involve the vulva but, typically, skin elsewhere is also involved [86].

Nonneoplastic Lymphoid Proliferations

Two entities, so-called lymphoma-like lesion and leiomyoma with lymphoid infiltration, stand out as distinctive nonneoplastic lymphoid proliferations that because of their typically extensive, tumor-like nature may mimic lymphoma.

Lymphoma-Like Lesions

In a small proportion of cases of inflammation of the lower reproductive tract, the lymphoid component is dense and extensive and contains numerous large lymphoid cells, potentially raising the question of malignant lymphoma. The cervix, and less often the endometrium and the vulva can be involved by these "lymphoma-like lesions" [27, 47, 96]. Lymphoma-like lesions almost always occur in women of reproductive age, and may be associated with abnormal vaginal bleeding. They are superficially located, and are often associated with erosion or ulceration of the overlying epithelium. In the cervix, they typically extend no more than 3 mm into the wall, and only rarely extend beyond the deepest endocervical glands. Large masses are very uncommon. The lesions are composed of a polymorphous cellular infiltrate composed of small and large lymphoid cells including immunoblasts, often with admixed plasma cells, and neutrophils. Lymphoma-like lesions involving the cervix or endometrium, typically, are found in a background of usual-appearing chronic cervicitis or endometritis, respectively. Large cells (CD20+ B cells) may form aggregates, which may represent follicle centers. Sclerosis is absent (> Fig. 21.10). When follicle centers are present, they are CD20+, CD10+, bcl6+, and bcl2-, consistent with reactive follicles. Plasma cells are polytypic (mixture of κ + and λ +). A few cases have occurred in the setting of Epstein-Barr virus infection or pelvic inflammatory disease [27, 47, 96]. In contrast, lymphoma of the lower reproductive tract usually produces a gross abnormality of the involved organ often with extension of the process into adjacent structures. On microscopic examination, lymphomas are composed of a monomorphous population of lymphoid cells (often with sclerosis), tend to invade deeply, sparing a narrow subepithelial zone, and often spread in proximity to blood vessels [96]. In some cases it may be difficult to distinguish

Fig. 21.10

Uterine cervix, lymphoma-like lesion. The infiltrate involves the surface epithelium and is composed of loose aggregates of large cells with admixed small lymphocytes, plasma cells, and neutrophils. The large cells were mostly CD20+ B cells; small cells were mostly CD3+ T cells (not shown) between lymphoma-like lesions and lymphoma. In such cases rebiopsy may be helpful, as lymphoma-like lesions may resolve spontaneously.

Leiomyoma with Lymphoid Infiltration

Uterine leiomyoma with lymphoid infiltration is a rare lesion that has been described in women between 25 and 53 years of age. On gross examination, the myomas range from 2 to 12 cm in diameter; they may be grossly typical [75], while others are described as soft (**>** *Fig. 21.11a*)

Fig. 21.11

Leiomyoma with lymphoid infiltrate. (a) Gross examination of a cross section of the uterus shows one small, white, discrete typical leiomyoma (*right*) and one yellow-tan leiomyoma with lymphoid infiltration (*left*). (b) The leiomyoma is extensively involved by a lymphoid infiltrate; the adjacent myometrium is uninvolved. The infiltrate contains multiple lymphoid follicles, mainly near the periphery of the leiomyoma

[65, 69]. On microscopic examination a moderate or marked infiltrate of small lymphocytes with scattered larger lymphoid cells, histiocytes, variable numbers of plasma cells and rarely eosinophils, is present. In some cases, reactive follicles may be observed. The infiltrate does not contain neutrophils [19, 65, 69, 75] and is typically confined to the leiomyoma (> Fig. 21.11b), but occasionally extends for a short distance into the adjacent myometrium [19, 75]. Immunohistochemical analysis has shown B cells (CD20+, CD79a+) in follicles and T cells (CD3+, CD45RO+) outside follicles. In several cases, there is a predominance of CD8+ or TIA-1+ T cells, consistent with a cytotoxic phenotype [69, 75]. In a single case, molecular analysis revealed clonal rearrangement of the T-cell receptor gamma chain gene [75]; the significance of this is uncertain as the patient was well with no evidence of lymphoma 3 years later. Occasionally, clonal B or T-cell populations may be found in inflammatory processes, and they are not necessarily indicative of lymphoma.

The etiology of this reactive process is not known, but several patients have had an intrauterine contraceptive device that could have played a role in initiating a chronic inflammatory process [19]. One patient had clinical features suggesting an underlying autoimmune disease [75]. Several patients had been treated with gonadotropinreleasing hormone (GnRH) agonists [75]. Prominent vascular damage within the leiomyomas in addition to lymphoid infiltration has been described in association with luteinizing hormone-releasing hormone therapy [65]. It is possible that the degenerative changes associated with such therapy may elicit an inflammatory response within leiomyomas [65, 69].

In all cases of leiomyoma with lymphoid infiltration follow-up, when reported, has been uneventful [19, 75]. One of the patients in the original series [19] had a large lipoma excised several months after the diagnosis of leiomyoma with lymphoid infiltration; the lipoma had multiple lymphoid aggregates. This patient was well with no evidence of lymphoma 8 years later (unpublished data).

The differential diagnosis of leiomyoma with lymphoid infiltration includes uterine lymphoma, but the polymorphous nature of the infiltrate and its confinement to the leiomyoma help to distinguish it from lymphoma. Inflammatory pseudotumor produces a mass lesion within the uterus, but it is composed of fibroblasts and myofibroblasts, rather than smooth muscle cells, and has an infiltrate that includes neutrophils. Pyomyomas are leiomyomas with marked neutrophilic infiltrate with suppurative necrosis and should not be confused with leiomyoma with lymphoid infiltration.

Differential Diagnosis of Lymphoma of the Lower Reproductive Tract

The differential diagnosis of lymphoma of the lower reproductive tract includes chronic inflammatory processes, carcinoma, sarcomas, and others. Lymphomas, particularly lymphomas with sclerosis, are prone to artifactual distortion by crush artifact, compounding the difficulty in reaching the correct diagnosis. Like many cervical lymphomas, idiopathic retroperitoneal fibrosis is a sclerosing process that may result in ureteral obstruction; the presence of many B cells outside follicles and atypical lymphoid cells favor lymphoma, but recognizing atypical lymphoid cells may be difficult if crush artifact is extensive. Features useful in differential diagnosis of selected entities are presented in **>** Table 21.2.

Myeloid Neoplasms of the Female Reproductive Organs

The female reproductive organs are rarely involved by myeloid sarcoma, a mass-forming lesion composed of primitive myeloid elements. Myeloid sarcoma was initially described with the name of chloroma, because there was sometimes a sufficiently high myeloperoxidase content to impart a green color to the neoplasm. Subsequently, the term granulocytic sarcoma was put forward, to encompass those tumors that lacked a green color [74]. The WHO Classification uses the term myeloid sarcoma for tumor masses composed of myeloblasts or immature myeloid cells, present in extramedullary sites and in bone. The designation monoblastic sarcoma is used for the uncommon myeloid sarcomas composed of monoblasts [4].

Clinical Features

Myeloid sarcomas involve the reproductive organs in patients from early childhood to advanced age, with a median age of approximately 40 years [26]. It occurs in three settings: (1) known acute myelogenous leukemia; (2) chronic myeloproliferative diseases or related disorders; and (3) with no other evidence of hematopoietic disease [60]. Nearly half of the patients have a prior history of a myeloid neoplasm, which is usually acute myeloid leukemia, but which has occasionally been a chronic myeloproliferative disease or a myelodysplastic syndrome/ myeloproliferative disorder; these cases thus represent relapse or progression of the patients' prior myeloid neoplasms. Myeloid sarcoma in a patient with a chronic

Table 21.2

Differential diagnosis of lower female genital tract lymphoma

Diagnosis	Features against lymphoma	Features supporting lymphoma
Lymphoma-like lesion	Absence of mass	Mass present
	Superficial location	Deep extension
	Erosion	Subepithelial sparing, no erosion
	Mixed infiltrate	Monomorphous infiltrate
	Absence of sclerosis	Presence of sclerosis
	Evidence of PID or EBV infection	
Carcinoma, especially small cell carcinoma and lymphoepithelial	Cohesive growth, nuclear molding in best preserved areas	Discohesive tumor cells
cell carcinoma	Obliteration of normal structures, e.g., endometrial or endocervical glands	Tumor cells: CBs, IBs, or multilobated cells
	Presence of SCIS or ACIS	Sparing of normal structures
	Cytokeratin+ atypical cells	No SCIS or ACIS
		CD45+, CD20+ neoplastic cells (for B-cell lymphoma)
Spindle cell sarcoma	Absence of admixed CBs, IBs, multilobated cells	CBs, IBs, or multilobated cells admixed with spindle cells
	CD45-, CD20- neoplastic cells	CD45+, CD20+ neoplastic cells (for B-cell lymphoma)
Endometrial stromal sarcoma,	Characteristic tongue-like growth	Closely packed tumor cells
low-grade	Evenly but loosely distributed cells	Blood vessels usually not prominent
	Small arterioles conspicuous	CD45+, CD20+, CD10-/+ (for B-cell
	Foam cells may be admixed	lymphoma)
	CD45–, CD20–, CD10+	
Embryonal rhabdomyosarcoma	Pediatric patient	Adult patient
	Alternating hyper- and hypocellular areas	Even distribution of atypical cells
	Myxoid background	Sclerotic background
	Desmin+, myogenin+, Myo-D1+ neoplastic cells	CD45+, CD20+ neoplastic cells (for B-cell lymphoma)
Extramedullary hematopoiesis, especially with erythroid	Homogeneous dark chromatin characteristic of erythroid elements	Vesicular or stippled chromatin characteristic of lymphoid cells
predominance	Presence of megakaryocytes and maturing myeloid elements	Absence of other hematopoietic cell lines
	Evidence of concurrent myeloproliferative disorder	

PID, pelvic inflammatory disease; EBV, Epstein-Barr virus; SCIS, squamous cell carcinoma in situ; ACIS, adenocarcinoma in situ; IB, immunoblast; CB, centroblast.

myeloproliferative disorder often coincides with blast crisis [60]. In the FAB classification, the leukemias have included M1, M2, M3, M4 [26], and M5 types [29]. Several have been associated with acute myeloid leukemia with abnormal marrow eosinophilia (AML, M4 eo) [16, 26]. Nearly all patients with myeloid sarcoma and no evidence of bone marrow disease will eventually develop

overt leukemia [60]. However, in a few patients with isolated myeloid sarcoma who are treated aggressively with a combination of chemotherapy and radiation, there may be long survival without the development of acute leukemia [31, 55]. In general, patients have not had conditions predisposing to the development of myeloid neoplasia, although one patient had prior chemotherapy

for breast cancer [73]. A few patients with acute myeloid leukemia and myeloid sarcoma involving the reproductive organs were exposed to radiation at Hiroshima or Nagasaki [45]. Most cases involve either the ovaries or the uterus. Vaginal and vulvar myeloid sarcomas are rare [26, 66].

Pathologic Features

Microscopic examination reveals a diffuse infiltrate of discohesive atypical cells that may spare certain normal structures, such as endometrial glands, or developing follicles in the ovary. A single-file pattern of growth is common. Mitoses are frequent. The neoplastic cells are medium-sized, with oval to irregular, sometimes distinctly indented nuclei with fine chromatin and small nucleoli. Cytoplasm ranges from very scant to moderate in quantity, sometimes with a pink color, reflecting the presence of myeloid granules. Scattered apoptotic cells are often present. A minority of cases show geographic necrosis. Scattered eosinophil precursor cells may be identified [26, 66]. The lesions may be subclassified as blastic, immature or differentiated based on the degree of cellular differentiation [4, 26]. The blastic type is composed mainly of myeloblasts, the immature type contains promyelocytes in addition to myeloblasts, and the differentiated type contains, in addition, more mature cells in the neutrophil series [4].

Immunophenotyping on paraffin sections typically shows neoplastic cells that are positive for myeloperoxidase, lysozyme, CD117, CD43, and often for CD34 and CD68. CD45 (leukocyte common antigen) is usually positive, but may be dimly expressed or even negative on paraffin sections, potentially leading to difficulty in recognizing such lesions as hematologic [4, 26, 70]. B and T-cell specific antigens are not expressed. Tumor cells are also positive for chloroacetate esterase. Monoblastic sarcomas are lysozyme+, CD68+, but do not express myeloperoxidase [4].

Ovarian Involvement by Myeloid Neoplasia

Leukemia rarely presents initially in the ovary, but infiltration of the ovary at autopsy is quite common. In an autopsy study of 1,206 patients with leukemia who died between 1958 and 1982, there was ovarian involvement by acute myelogenous leukemia in 11% and by chronic myelogenous leukemia in 9% [3] The authors noted a significant reduction in extramedullary tumor during the later years of the study and attributed this to more aggressive therapy.

The diagnosis of ovarian myeloid sarcoma is appropriate when immature myeloid cells form an ovarian tumor. Among patients with clinically evident myeloid sarcoma, the ovary is rarely involved. None of the 21 women with myeloid sarcoma studied by Neiman et al. [60] and only 1 of 9 women studied by Meis et al. [55] had involvement of the adnexa.

A few women and very rarely children have had what apparently was isolated ovarian myeloid sarcoma or ovarian myeloid sarcoma as the first manifestation of acute myeloid leukemia [16, 20, 66, 67]. The ovary can also be a clinically apparent, but usually not an isolated, site of relapse following chemotherapy for acute myelogenous leukemia [66].

The tumors can be unilateral or bilateral and range up to 19 cm in diameter (mean, 10–12 cm). They are typically solid, soft, and white or red-brown, but cystic degeneration, hemorrhage, or necrosis may be seen [20, 67]. A few cases have had a distinct green color on gross inspection [66], thus warranting a designation of chloroma.

Uterine Involvement by Myeloid Neoplasia

Myeloid sarcoma of the uterus is uncommon [66]. In two combined series of patients with myeloid sarcoma from a variety of sites, one of 30 women had myeloid sarcoma involving the corpus, and one had cervical involvement [55, 60]. Patients have been adults, with a mean age in the sixth decade, who typically present with abnormal vaginal bleeding, sometimes accompanied by abdominal pain [28, 29, 70, 73, 80]. Several patients had cervical smears positive for malignancy, although a specific diagnosis was not made [20, 80]. One was considered positive for malignant lymphoma or leukemia [80] and in one, the diagnosis of lymphoma was suggested [20]. The cervix is involved more often than the corpus, but both may be involved simultaneously [28, 73]. In only a minority of cases is tumor confined to the uterus [28]. In most cases tumor involved other reproductive organs, including the vagina [20, 80], vulva [80], ovaries, or fallopian tubes [26, 29], sometimes with parametrial involvement [20], with or without extension to the pelvic side walls [70]. Bulky pelvic masses may be associated with hydroureter [73]. Staging in some cases has revealed concurrent involvement of sites outside the reproductive tract, including lymph nodes [26, 28, 80], gastrointestinal tract [80], breast [26], or mediastinum [26]. Bone marrow examination may reveal acute myeloid leukemia [26]. Among those

without acute myeloid leukemia at presentation, progression to acute myeloid leukemia is common [20, 28, 29]. One woman with chronic myelogenous leukemia developed granulocytic sarcomas of the breast and the endometrium, shortly after blast crisis [80]. One patient with a history of breast cancer treated with chemotherapy developed an isolated therapy-related uterine monoblastic sarcoma expressing CD45, CD43, CD68, and lysozyme associated with a translocation of the mixed – lineage leukemia gene at 11q23 [73]; acute myeloid leukemia with 11q23 abnormalities can arise as a complication of chemotherapy that includes DNA topoisomerase II inhibitors.

On gross examination, the lesions appear as nodules, ulcers, or large masses, often extending into the vagina or paracervical soft tissue [20]. The tumors range from graytan or gray-blue to green [28]. On microscopic examination, the immature granulocytes tend to infiltrate around, rather than destroy normal structures, a pattern that is also seen in cases of lymphoma. The histological appearance is similar to myeloid sarcoma in other sites.

The correct diagnosis was often not rendered on initial biopsy, particularly in earlier reports, when routine immunophenotyping was less prevalent and fewer antibodies were available for paraffin section immunohistochemistry. The most common misdiagnosis was malignant lymphoma [28]. One cervical biopsy was initially interpreted as small-cell squamous cell carcinoma and in another, the tumor was not recognized [20].

Involvement of the uterus in other forms of myeloproliferative disorders is very unusual. Extramedullary hematopoiesis may be seen in the endometrium, involving the endometrial stroma, or less often elsewhere in the reproductive tract. In approximately half of the cases, there is an associated hematologic neoplasm [83]. This author has seen an unpublished case of chronic idiopathic myelofibrosis in which there was extensive extramedullary hematopoiesis ("myeloid metaplasia") in the endometrium (**>** *Fig. 21.12*).

Vaginal and Vulvar Involvement by Myeloid Neoplasia

Patients with acute myelogenous leukemia occasionally have leukemic infiltration of the vagina [20]. In addition, a handful of cases of myeloid sarcoma of the vagina have been documented (\bigcirc *Fig. 21.13a and b*). Oliva and coworkers described three cases in women aged 66, 73, and 76 years, presenting with postmenopausal bleeding, an abnormal Papanicolaou smear and the presence of

Fig. 21.12

Endometrium, extramedullary hematopoiesis. Several megakaryocytes with large, dark, atypical nuclei are scattered in the endometrial stroma. A loose cluster of nucleated red blood cells is present near the bottom of the image

a mass. One of them had a prior history of acute myeloid leukemia, one presented with vaginal myeloid sarcoma, but was found to have acute myeloid leukemia when a marrow biopsy was performed, and one had apparently isolated myeloid sarcoma. At last follow-up, one was alive with disease, and two had died [66]. Another case was described in a 48-year-old woman who presented with vaginal pain and leukorrhea; physical examination revealed an isolated vaginal mass that was green. Evaluation revealed a tumor that was CAE+, CD43+, CD45+, lysozyme+, and negative for CD20, CD3, S100, and cytokeratin. Despite treatment, the patient rapidly developed overt leukemia, classified as acute myeloid leukemia, M5a. Cytogenetic analysis revealed a complex karyotype. The patient developed myeloid sarcomas in other sites, including the breast and thigh, and she died of leukemia 10 months after presentation [29]. One 39-year-old patient with Down's syndrome presented with symptoms related to a myeloid sarcoma of the cervix and vagina [20]. Another case is presented without details in the large series of myeloid sarcomas reported by Neiman et al. [60].

A myeloid sarcoma presenting as a mass in the vulva of an elderly woman has been described; additional work-up showed that she had acute myeloid leukemia [18]. In another case, a woman with a myelodysplastic/myeloproliferative disorder developed what appeared to be a rash of the clitoris, but that proved to be myeloid sarcoma; acute myeloid leukemia developed two months later [26].

Vagina, myeloid sarcoma. (a) An infiltrate of primitive, discohesive neoplastic cells with finely dispersed chromatin and scant cytoplasm permeates the fibromuscular stroma. (b) The neoplastic cells are positive for myeloperoxidase (immunoperoxidase technique on a paraffin section)

The prognosis of myeloid sarcoma in the reproductive tract is difficult to assess because only small numbers of patients have been studied over many years and treatment has varied. There are only a few sizable series [26, 66], and follow-up has often been short. Among patients presenting initially with isolated myeloid sarcoma, progression to acute myeloid leukemia is common [26] even among patients who are treated aggressively [29]. In general, patients with myeloid sarcoma of the female reproductive organs have had a poor prognosis, which will likely improve with advances in therapy for acute myeloid leukemia. Occasional patients, including those with isolated myeloid sarcoma and those with more widespread disease at presentation do achieve long-term disease-free survival [26, 66].

Differential Diagnosis

The majority of cases of myeloid sarcoma in some large series were initially misdiagnosed, most often as malignant lymphoma [55, 60]. This occurs less often currently because of greater use of immunophenotyping and larger number of antibodies available for paraffin section immunohistochemistry. Compared to lymphoma, myeloid sarcoma is generally composed of cells with more finely dispersed chromatin, often with more cytoplasm than a lymphoid cell with the same size nucleus. The cytoplasm may have a distinct red color. The identification of eosinophilic myelocytes in some cases is very helpful in making a diagnosis of a tumor of primitive myeloid origin. Establishing a diagnosis of myeloid sarcoma is not difficult in a patient who has been previously diagnosed with an acute myeloid leukemia that has been well characterized by flow cytometry. In those cases in which a myeloid sarcoma represents the first presentation with disease, it is essential to confirm this unusual diagnosis with immunohistochemistry. Using a panel of antibodies to myeloidassociated antigens, such as lysozyme, myeloperoxidase, CD68, CD34, and CD117, in conjunction with markers of B cells (such as CD20), T cells (such as CD3), and in selected cases, markers of non-hematolymphoid cells, such as cytokeratin and S-100. It should be noted that certain T-lineage-associated antigens, such as CD43, are not lineage-specific and may be expressed in myeloid sarcomas. Monoblastic sarcomas may express CD4 (usually more faintly than mature T helper cells), as well as CD56, usually considered an NK cell marker, so that judicious interpretation of unusual or unexpected immunophenotypic results is required (See **>** *Table 21.1*).

Differentiating pyometra from myeloid sarcoma of the endometrium can at times be difficult. Some myeloid sarcomas show differentiation to mature forms. In the setting of severe acute inflammation degenerated neutrophils may have nuclei that lose their distinctive lobation and appear round, and thus may potentially be mistaken for primitive cells. A diagnosis of myeloid sarcoma should only be made if there is a convincing population of well-preserved primitive myeloid elements.

Histiocytic Neoplasms of the Female Reproductive Organs

Langerhans Cell Histiocytosis

Clinical Features

Langerhans cell histiocytosis, previously known as histiocytosis X, occurs in one of the three clinical syndromes: (1) eosinophilic granuloma, which is characterized by unifocal disease; (2) Hand–Schüller–Christian disease which is a chronic progressive multifocal disease typically involving one organ system, and (3) Letterer– Siwe disease, an aggressive, fulminant disorder with multifocal, multisystem involvement by Langerhans cell histiocytosis [56, 92].

Langerhans cell histiocytosis occasionally involves the reproductive organs, most often the vulva and infrequently the vagina or cervix [32, 44]. Endometrial and ovarian involvement has also been reported rarely [2]. Uterine involvement is almost always accompanied by vulvar or vaginal lesions, or both [20, 32]. There appears to be a strong association between diabetes insipidus and the presence of mucocutaneous lesions of Langerhans cell histiocytosis, particularly in the female reproductive tract [32]. Langerhans cell histiocytosis frequently has manifestations in other sites, prior to, or subsequent to, the reproductive organ involvement [2], in particular, in the form of bony lesions [32, 68]. Isolated Langerhans cell histiocytosis involving the reproductive organs is rare [77].

Langerhans cell histiocytosis in the reproductive tract falls into one of the four patterns [2, 68]:

- 1. Isolated genital disease, some with local recurrence but no distant involvement.
- 2. Isolated genital disease with subsequent dissemination to other sites most often bone, accompanied in some cases by diabetes insipidus.
- 3. Initial presentation with oral or skin disease, and subsequent genital and multiorgan disease.
- 4. Initial presentation with diabetes insipidus and subsequent genital and multiorgan disease.

Patients with Langerhans cell histiocytosis involving the reproductive tract range from 1 to 85 years; most have been young adults [2, 32]. The presenting complaints are usually vulvar pruritus or dyspareunia [32, 44]. The lesions can be single or multiple [32, 77] They are white or yellow-brown ulcers, papules, ulcerated nodules [32, 91], erythematous plaques, red papules [77], or irregular friable masses [20] and may mimic primary syphilis, squamous cell carcinoma, lymphogranuloma venereum [32], herpes simplex viral infection, or melanoma [20]. The lesions in the cervix are yellow-brown, brown or red papules [20, 32].

Pathologic Features

Microscopically they consist of submucosal nodules or sheets of Langerhans cells with pale, deeply creased, or folded nuclei with delicate nuclear membranes, pale chromatin and relatively abundant pale pink cytoplasm. There is often an admixture of eosinophils and lymphocytes in some areas, as well as neutrophils in some cases (Fig. 21.14a and b). The cellular infiltrate is often associated with ulceration and a scale crust [32]. On microscopic examination, Langerhans cell histiocytosis can be confused with an inflammatory disorder, lymphoma, or carcinoma, but the presence of numerous Langerhans cells admixed with eosinophils should suggest the correct diagnosis. The Langerhans cells have a distinctive immunophenotype: they express both S-100 protein and CD1a. They are also variably positive for CD45, CD68, and lysozyme and negative for CD30, myeloperoxidase, and B- and T-cell specific markers. Like other histiocytes and monocytes, they may be CD4+. Immunohistochemical studies thus play an important role in confirming the diagnosis [68, 92]. It is uncertain whether Langerhans cell histiocytosis derives from neoplastic transformation of mature Langerhans cells in squamous epithelium or other tissues, or whether Langerhans cell histiocytosis is derived from an abnormal marrow-derived cell that assumes characteristics of Langerhans cells [56].

Treatment and Outcome

The behavior of Langerhans cell histiocytosis involving the reproductive organs is difficult to predict. Because of their rarity and variable behavior, uniform therapy has not been employed. Occasionally, small vulvar lesions may remit spontaneously, although nodular lesions do not [32]. The lesions may be treated initially with simple excision or with topical hydrocortisone. If these methods are unsuccessful, local radiation therapy may be effective, but may be followed by recurrences. In a few cases, systemic steroids or chemotherapy (methotrexate, vincristine, vinblastine, and others) have been used [2, 32, 44]. Since Langerhans cells

Vulva, Langerhans cell histiocytosis. (a) Low power shows sheets of pale histiocytes, aggregates of small lymphocytes and occasional eosinophils beneath squamous mucosa. (b) High power shows Langerhans cells with large, oval nuclei with nuclear folds and abundant pale pink cytoplasm, with a few admixed small lymphocytes and eosinophils

play an important role as antigen-presenting cells in the immune response, immunomodulatory agents such as interferons have been tested as treatment for Langerhans cell histiocytosis. Dramatic responses of cutaneous and anogenital Langerhans cell histiocytosis have been described with interferons and thalidomide [56], although response is not always sustained. Thalidomide may be effective because it is an inhibitor of tumor necrosis factor (TNF), which plays a role in generating Langerhans cells from marrow precursors [77]. Whatever the therapy, incomplete responses, local recurrences, and distant relapses are common [68, 77, 91].

The views expressed in this chapter are those of the authors and do not necessarily reflect official policy or position of the Armed Forces Institute of Pathology, the Department of the Army, the Department of Defense, or any other Department or Agency within the U.S. Government.

R. J. Kurman, L. Hedrick Ellenson, B. M. Ronnett (eds.), Blaustein's Pathology of the Female Genital Tract (6th ed.), DOI 10.1007/978-1-4419-0489-8_22, © Springer Science+Business Media LLC 2011

The most common benign mesenchymal tumor of the gynecologic tract is a leiomyoma. The most frequent malignant mesenchymal neoplasms of this anatomic region in pediatric and adult patients are rhabdomyosarcoma and leiomyosarcoma, respectively. Because these entities are well-recognized and expertly covered elsewhere in this textbook, they are not discussed in this chapter. Instead, this section concentrates on the myriad of other less common mesenchymal processes that occasionally affect the female reproductive organs. We attempt to cover the better documented and most relevant entities as comprehensively as space allows, and include brief comments and/or references for rarer lesions. Supplemental data from the Armed Forces Institute of Pathology Tumor Registry is included for selected topics. It is important to remember that some of the entities under discussion have only recently been recognized and remain works in progress. Readers are directed to standard soft tissue tumor texts for additional reading.

Soft Tissue Tumors and Tumor-like Lesions with Benign Behavior

Aggressive (Deep) Angiomyxoma

Aggressive angiomyxoma was characterized as a distinct clinicopathologic entity in 1983 [292]. In earlier literature, examples were sometimes classified as myxomas, vascular myxomas, or edematous or soft fibromas.

Clinical Features

Aggressive angiomyxoma has a predilection for adult females, with a peak incidence in the 4th and 5th decades (\bigcirc *Fig. 22.1*) [44, 92]. However, a recent review of 71 examples in the AFIP files revealed a broader age range than has generally been appreciated for this entity. Women 60 years of age and older comprised 18% of the total cases. This is a surprisingly high figure and probably reflects case referral bias, but it nonetheless stresses the point that postmenopausal status does not strongly militate against the diagnosis. In contrast, a diagnosis of aggressive angiomyxoma in a prepubertal girl should be viewed with suspicion. One purported example in an 11-year-old is more consistent with a superficial angiomyxoma [229, 323].

Most patients present with a slow-growing pelvicoperineal mass that is either asymptomatic or associated with dull regional pain, a pressure-like sensation, or dyspareunia. Tumor size is often significantly

Fig. 22.1

Age distribution for patients with AAM (aggressive angiomyxoma), AMF (angiomyofibroblastoma), CAF (cellular angiofibroma), and SAM (superficial angiomyxoma/cutaneous myxoma), AFIP data

underestimated by physical examination, and preoperative clinical impressions generally revolve around a Bartholin gland cyst, vaginal cyst, hernia, or lipoma. The bulk of the process is frequently concealed within the deep soft tissues, and more than 50% of resected neoplasms in the AFIP files are ≥ 10 cm in size.

CT imaging demonstrates a hypo- or iso-attenuated mass that tends to grow around pelvic floor structures and generally does not cause significant disruption of the vaginal or rectal musculature [247]. T1-weighted MR images show a hypo- to iso-intense mass, whereas high signal intensity is evident in T2-weighted images [51, 64, 247]. Both T2-weighted MR and enhanced CT images often demonstrate a distinctive swirled or layered internal architecture [247]. These imaging techniques can accurately assess tumor extent and determine whether the pelvic diaphragm has been traversed, information critical for selecting an optimal surgical approach [247].

Pathologic Findings

Gross examination usually reveals a large mass, commonly >10 cm and not infrequently >20 cm. Small tumors under 5 cm make up <10% of examples in the AFIP files. The lesions often have a lobular gross appearance with adherence to fat, muscle, and other regional structures. A soft to moderately firm or rubbery consistency is often present, and the cut surface is generally described as glistening or myxedematous with a pink or reddish-tan color. Focal hemorrhage and cystic change are sometimes noted.

Aggressive angiomyxomas generally have fairly uniform, low to moderate cellularity, and they contain relatively small, stellate-shaped and spindled cells, set in a loosely collagenous, myxedematous matrix with scattered vessels of varying caliber and a variety of entrapped regional structures () Figs. 22.2 and () 22.3). The tumor cells have scant eosinophilic cytoplasm with poorly-defined borders and relatively bland nuclei with an open chromatin pattern and a small, central nucleolus. Multinucleated tumors cells are sometimes present. Mitotic figures are infrequent. A characteristic finding, evident in most cases, is the presence of loosely organized collections of welldeveloped myoid (myofibroblastic vs. true smooth muscle) cells situated around larger nerve segments and vessels [92, 123, 285]. These cells are generally immunohistochemically distinct from the smooth muscle of vessel walls (see ≥ Figs. 22.4e and ≥ 22.4f) [92]. While the tumor name implies the presence of abundant myxoid matrix, aggressive angiomyxomas are typically only weakly positive for mucosubstances, and edema appears to be a major component of the noncollagenous stroma [92, 292].

The neoplastic cells often have moderate to diffuse nuclear immunoreactivity for estrogen and progesterone receptor proteins (**>** *Fig. 22.4*) [92, 206]. The cells have

diffuse cytoplasmic reactivity for vimentin and variable levels of reactivity for desmin and actins. CD34 expression is less frequently observed and generally only a focal finding. Immunoreactivity for \$100 protein is absent. In our experience, the small, stellate-shaped and spindled tumor cells typically have greater reactivity for the D33 desmin antibody (DAKO) than the DE-R-11 antibody (DAKO). The larger well-developed myoid cells, noted above, that often reside around nerves and vessels have stronger and more uniform immunoreactivity for both actins and desmin than the more prevalent population of smaller tumor cells with less abundant cytoplasm. Most, but not all, conventional cytogenetic analyses of aggressive angiomyxoma have demonstrated aberrations involving chromosome 12, and in several studies, its HMGA2 (HMGIC) gene has been implicated [211, 239, 308]. In some tumors (the exact percentage is unresolved), this results in aberrant nuclear HMGA2 (HMGIC) protein expression, a finding that has also been noted in several other soft tissue entities (including uterine leiomyomas) but is reportedly absent in normal vulvovaginal soft tissue, as well as several key soft tissue tumors (e.g., angiomyofibroblastoma) that enter into the differential diagnosis [211, 235, 239].

Differential Diagnosis

The differential diagnosis for aggressive angiomyxoma includes superficial angiomyxoma, angiomyofibroblastoma,

Fig. 22.2

Aggressive angiomyxoma. Low (a) and medium (b) power views. Note the evenly spaced, small delicate tumor cells embedded in loosely collagenous matrix, the scattered larger vessels, and the proliferation of eosinophilic myoid cells around some of the nerves and vessels

Fig. 22.3

Aggressive angiomyxoma. A proliferation of well-developed myoid cells is present around a nerve segment (a) and several vessels (b). Figures (c) and (d) are high power views of the small neoplastic cells of aggressive angiomyxoma. Note the scant cytoplasm, indistinct cell borders and nuclei with small but distinct nucleoli. Two lymphocytes are present as a size reference in figure (c). Multinucleated tumor cells are illustrated in figure (d)

cellular angiofibroma, myxoid and edematous smooth muscle tumors, pelvic fibromatosis, and low-grade myxofibrosarcoma (myxoid malignant fibrous histiocytoma). A detailed review of most of these entities is provided elsewhere in this chapter. Hydropic (edematous) and myxoid smooth muscle tumors usually feature larger tumor cells with spindled morphology, abundant eosinophilic cytoplasm (in which longitudinal cytoplasmic striations may be highlighted with a Masson trichrome stain), and sometimes, juxtanuclear vacuoles. True myxoid smooth muscle tumors contain abundant hyaluronic acid, a feature not seen in aggressive angiomyxoma. Myxofibrosarcoma (myxoid malignant fibrous histiocytoma) predominantly affects adults in the later decades of life. This entity has more pronounced mitotic activity and cytologic atypia, even in lower grade

examples, than is present in aggressive angiomyxoma. Also, myxoid sarcomas usually contain a complex microvascular network with branching and curvilinear capillaries that is notably absent in most benign soft tissue tumors.

Sometimes physiologic conditions, such as childhood asymmetric labium majus enlargement (a.k.a., prepubertal vulvar fibroma or fibrous hyperplasia) [8, 155, 317] and vulvar hypertrophy with lymphedema [313], can also be confused with aggressive angiomyxoma, especially when one is confronted with a biopsy sample unaccompanied by relevant clinical information. Recognition that these poorly-demarcated processes are largely centered in the superficial soft tissues and the absence of many characteristic features of aggressive angiomyxoma, such as a perivascular/perineural myoid proliferation, are important

Fig. 22.4

Aggressive angiomyxoma immunohistochemistry. (a) desmin reactivity in the small neoplastic cells; (b) nuclear immunoreactivity for estrogen receptor protein; (c, d) desmin expression in perineural myoid cells; (e) desmin expression in perivascular myoid cells (note the actual vessel walls are negative); and (f) α -smooth muscle actin is expressed by the perivascular myoid cells and the smooth muscle cells of the vessel wall

first steps in their identification. Additional helpful features include the presence of immunoreactivity for CD34 and absence of desmin expression by the fibroblastic element in childhood asymmetric labial enlargement and the presence of dilated tortuous lymphatics in vulvar hypertrophy with lymphedema.

Behavior and Treatment

Aggressive angiomyxoma has a local recurrence rate that exceeds 35% [44, 92, 123]. As a result, complete excision is preferable if this can be accomplished without undo morbidity. In instances where complete removal would be associated with high morbidity or when preservation of fertility is desired, incomplete removal may be acceptable if the risks of recurrence and additional surgical intervention are understood [44]. All patients require long-term follow-up with periodic imaging analysis, because the tumors are generally slow growing and recurrences are difficult to detect by physical examination. Adjuvant radiation and chemotherapy have no proven role in the management of this tumor. There are anecdotal reports of dramatic responses to hormonal therapy [gonadotropin-releasing hormone (GnRH) agonist] and this may have a role in selected instances, but additional investigation is needed [94, 205].

There are two reports of metastasizing aggressive angiomyxomas. We do not regard the comments and illustrations accompanying the initial case report [280] as convincing, and suspect this patient's pelvic tumor is an unrelated myxoid sarcoma [229]. The most recent case report [25] is more difficult to dismiss, but in the absence of additional similar observations, its significance remains unclear. Certainly, the vast majority of aggressive angiomyxomas do not appear to have metastatic potential.

Superficial Angiomyxoma

Clinical Features

Superficial angiomyxoma (cutaneous myxoma) is a benign mesenchymal neoplasm of the dermis and subcutis that has potential for local recurrence [7, 37, 41, 93]. The process has a wide anatomic distribution and a broad age range, with an overall peak incidence in the 4th to early 5th decade [7, 37]. However, female patients with genital lesions commonly present in their late teens and early 20s [93]. On rare occasion, this tumor is associated with skin pigmentation abnormalities, endocrine overactivity, cardiac myxoma, psammomatous melanotic schwannoma, and other tumor types (Carney complex) [28, 293]. The process has been underrecognized in the vulvoperineal region. In AFIP files, approximately 13% of all cases of superficial angiomyxoma diagnosed in female patients involved this region.

Pathologic Findings

The tumors involve the dermis and subcutis, where they form lobular or multinodular masses that are usually <2.5 cm and only rarely >5 cm [41]. They contain abundant hyaluronic acid and a sparse to moderately cellular population of stellate-shaped and spindled cells with pale eosinophilic cytoplasm and mildly pleomorphic nuclei with "smudgy" chromatin and occasional cytoplasmic-nuclear invaginations (> Figs. 22.5 and > 22.6). Focal multinucleation is common. The myxoid matrix disrupts the mesenchymal element, forming paucicellular pools and cleft-like spaces. The degree of vascularity is variable, but large caliber vessels as seen in aggressive angiomyxoma are typically absent. Scattered inflammatory cells (e.g., polymorphonuclear leukocytes, lymphocytes and plasma cells) are a frequent finding. Adnexal epithelial inclusions, sometimes with cystic change and peripheral buds of basaloid epithelium, are occasionally encountered [7, 41, 93].

The neoplastic cells are vimentin and CD34 positive [93]. Some weak cytoplasmic reactivity for S100 protein can be seen, and there may be limited actin expression. This entity lacks nuclear reactivity for estrogen and progesterone receptor proteins [93]. Negative results are obtained for glial fibrillary acidic protein and desmin.

Differential Diagnosis

Superficial angiomyxoma has similarity to aggressive angiomyxoma only in name. It is easily distinguished from the latter by its superficial location, small size, abundant alcian blue (pH 2.5)-positive hyaluronic acid content, different tumor cell morphology and immunoprofile.

Behavior and Treatment

Superficial angiomyxoma has a documented recurrence rate of >30%, so complete excision with attention to

■ Fig. 22.5 Superficial angiomyxoma (cutaneous myxoma). Note the multinodular growth pattern, abundant myxoid matrix and presence of paucicellular cleft-like spaces

margins is advisable. There are no reports of metastases. When this process is multifocal, encountered in childhood, or evident in a patient with other unusual clinical findings (e.g., prominent facial skin pigmentation, cardiac symptoms or endocrine abnormalities), evaluation for the Carney complex is recommended.

Angiomyofibroblastoma

Clinical Features

Angiomyofibroblastoma is a benign soft tissue tumor that primarily occurs in the subcutaneous tissue of the vulva. Rare examples have involved the vagina, usually near the introitus [101, 106, 183]. Affected individuals are frequently in the 4th through 7th decades of life, with a peak incidence in the 5th decade [106, 183, 229]. Patients usually present with a relatively small, painless mass.

Fig. 22.6

Superficial angiomyxoma. (a) tumor nodules often have peripheral cleft-like spaces filled with hyaluronic acid; (b) cystic epithelial inclusions may be present; (c) tumor cells frequently have smudgy chromatin, and multinucleation and cytoplasmic-nuclear invaginations are common; and (d) tumor cells often express CD34

Pathologic Findings

Gross examination generally reveals a well-demarcated mass under 5 cm in size with a soft to rubbery consistency, pinkish tan to yellow color, and mucoid or myxedematous cut surface. Areas grossly consistent with fat may be present.

Microscopic features include relatively sharp margination, low to moderate cellularity, and abundant vasculature that consists predominantly of small capillary-sized vessels and venous segments, sometimes with focal hyalinization (**>** *Figs. 22.7a* and **>** *22.7b*). The cellularity often varies from one region to the next, and some areas may contain abundant myxedematous, loosely collagenized stroma. A polymorphic population of epithelioid, spindled, and multinucleated tumor cells with low level nuclear atypia and a low mitotic rate is typically present. Some epithelioid cells may have abundant eosinophilic cytoplasm, imparting a plasmacytoid appearance. There is a tendency for tumor cells to exhibit focal corded, nested, and trabecular growth patterns and for the cells to aggregate around the vasculature. Adipose tissue is present in >50% of AFIP cases, and in a small percentage, this is a prominent or even dominant feature, as documented in the lipomatous variant of angiomyofibroblastoma (\bigcirc *Figs. 22.7c* and \bigcirc *22.7d*) [38, 183]. Large caliber vessels and mediumsized nerve segments, as seen in aggressive angiomyxoma, are typically absent.

Angiomyofibroblastomas are immunoreactive for vimentin, and they usually express desmin [101, 106, 183, 226] and estrogen and progesterone receptor proteins [183]. There is variable, but generally minimal, reactivity for actins. CD34 expression is notably uncommon in conventional examples, but it is encountered with some

Fig. 22.7

Angiomyofibroblastoma. Medium and high power views of a conventional (a, b) and lipomatous (c, d) angiomyofibroblastoma. Note a tendency for epithelioid tumor cells to aggregate around the vasculature

frequency in the lipomatous variant [38, 183]. Some vaginal tumors with desmin and CD34 expression that have been reported as angiomyofibroblastomas are, in our opinion, more consistent with superficial cervicovaginal myofibroblastomas [108, 184, 226]. S100 protein expression and nuclear immunoreactivity for HMGA2 (HMGIC) are absent [235].

Differential Diagnosis

The differential diagnosis for angiomyofibroblastoma revolves primarily around aggressive angiomyxoma and cellular angiofibroma. Aggressive angiomyxomas typically present as large deep-seated masses with a "pushing" infiltrative border. They incorporate a variety of regional structures, including large vessels and nerves that are sometimes bordered by loosely organized collections of spindled myoid (smooth muscle-like) cells. The small neoplastic cells of aggressive angiomyxoma are generally more monomorphic and uniformly distributed than the cells of angiomyofibroblastoma. Although it has been stated in the literature that there are tumors with hybrid features of aggressive angiomyxoma and angiomyofibroblastoma [123], we have yet to encounter a resection specimen where distinction between the two was not possible.

Angiomyofibroblastoma and cellular angiofibroma have some overlapping features, as both present as relatively small superficial masses with high vascularity, both may be dominated by spindled cells, and both can contain fat. However, cellular angiofibroma lacks a prominent epithelioid tumor cell population with a tendency to aggregate around vessels, it can have more pronounced mitotic activity, it often has more notable perivascular hyalinization, and it is much less likely to have desmin expression.

Behavior and Treatment

Angiomyofibroblastoma is typically cured by simple local excision. There is a single unique case report of an angiomyofibroblastoma with sarcomatous transformation (angiomyofibrosarcoma) in an elderly female [230]. The sarcomatous component resembled myxofibrosarcoma (myxoid malignant fibrous histiocytoma).

Cellular Angiofibroma

Clinical Features

Cellular angiofibroma [156, 229, 237] (angiomyofibroblastoma-like tumor) [182] is a recently described benign superficial soft tissue tumor of the vulvoperineal and inguinal regions. Vaginal examples have been reported, but in our experience, these are usually located at the introitus. The process generally affected individuals in the 4th through 8th decades of life, with a median age in the 40s [156]. Most lesions are painless.

Pathologic Findings

Gross examination usually reveals a small (often <3 cm) well-demarcated mass with a cut surface similar to angiomyofibroblastoma.

Histologically, the tumors are generally wellcircumscribed, and they contain a moderately cellular spindle cell population associated with numerous, rather uniformly distributed, small to medium sized vessels, oftentimes with perivascular hyaline fibrosis (**)** *Fig. 22.8*). Myxedematous matrix associated with wispy collagen, foci with thick eosinophilic collagen bundles, variable amounts of fat

Fig. 22.8

Cellular angiofibroma. Medium (a, c) and high (b, d) power views of two different cases. Note the appearance of the spindled tumor cells and numerous thick-walled vessels

(present in up to 50% of cases), and a variety of degenerative changes (including hemorrhagic, cystic, and pseudoangiomatous stromal changes) may be present. Mitotic activity is usually sparse, but in exceptional cases, it can be relatively brisk [156]. Atypical mitotic figures are not present. Tumor cell nuclei generally have minimal or only low level atypia, but rare examples may have small areas where atypia is more pronounced. Tumor necrosis is absent.

There are notable differences in the reported immunoprofile for this tumor, and further study is needed to resolve some of these discrepancies. Strong diffuse reactivity is consistently present for vimentin, and CD34 expression has been reported in close to half of the cases [63, 156, 182]. Actin and desmin expression are seen in <20% and <10% of tumors, respectively. Estrogen and progesterone receptor proteins have been documented in up to 50% of cases.

Differential Diagnosis

Cellular angiofibroma has some morphologic overlap with both angiomyofibroblastoma and spindle cell lipoma, and these are the key considerations in the differential diagnosis of this entity [156, 182, 237]. Features that aid in distinguishing angiomyofibroblastoma from cellular angiofibroma are documented in the preceding text. Spindle cell lipoma is notably uncommon in the vulvar region. It generally features a greater adipocytic component, less pronounced vasculature, and more ropy collagen than cellular angiofibroma. Its spindle cell component also more consistently expresses CD34.

Behavior and Treatment

Cellular angiofibroma is optimally managed by complete local excision. Special attention to margins is advisable for those rare examples with a high mitotic rate and more pronounced atypia. Local recurrences are very uncommon [182, 207], and there are no reports of metastasis.

Granular Cell Tumor

In the older medical literature, this entity is often referred to as "granular cell myoblastoma." A few recent publications use the designation "granular cell schwannoma," reflecting the currently accepted cell of origin, but most authors continue to favor the above terminology.

Clinical Features

It has been estimated that 5-16% of all granular cell tumors occur in the vulvar region [52, 190, 223, 229]. The labia majus are most frequently involved, but other areas, including the mons pubis, clitoris, perineum and perianal region, may also be affected [148, 223, 329]. Approximately 70-80 cases arising in the female genital region are documented in the literature, and AFIP files contain an additional 62 examples (5.1% of all cases diagnosed in females). We have encountered an age range of 14-73 years, with a peak incidence in the 4th decade. Patients usually present with an asymptomatic mass, though occasionally pain or pruritus are present. The process is commonly misdiagnosed clinically, and in some instances, it can grossly resemble squamous cell carcinoma. Granular cell tumors occur with increased frequency in African-Americans, they are multifocal in 3-20% of cases, and rarely, they may be familial [178, 190, 198, 223, 255, 261]. Once a diagnosis has been rendered, some authors advocate a detailed clinical history and thorough physical examination to rule out the presence of other clinically occult lesions, as they can sometimes affect anatomically sensitive sites, such as the airways [9, 52, 190, 191]. Rarely, granular cell tumors have been reported to involve the vagina, uterine cervix and ovaries [107, 114, 261]. The vast majority of granular cell tumors are benign, with malignant behavior documented in no more than 1-2% of cases [89, 148, 190, 261, 266].

Pathologic Findings

More than 75% of gynecologic-related granular cell tumors in the AFIP files are <2 cm in size; examples \geq 5 cm are exceptional. Epidermal or mucosal ulceration is occasionally present. The lesions have a firm consistency, and the cut surface often demonstrates a radially symmetrical, circumscribed or stellate-shaped, whitish-tan to yellowish mass.

Histologically, granular cell tumors feature large epithelioid and focally spindled neoplastic cells with abundant coarsely granular eosinophilic cytoplasm (**>** *Fig. 22.9*). Nuclei are hyperchromatic and generally fairly uniform in size, but foci with mild to moderate pleomorphism are occasionally encountered. Nucleoli may be present or inconspicuous. Usually, mitotic figures are only rarely encountered. The tumors may form relatively well-demarcated masses with little stromal reaction, or they can have an infiltrative, stellate-shaped appearance with prominent

Fig. 22.9

Granular cell tumor. (a, b) medium and high power views of a granular cell tumor with pseudoepitheliomatous hyperplasia of the overlying squamous epithelium; (c) a high power view of the neoplastic Schwann cells demonstrating granular cytoplasm and nuclei with small nucleoli and scattered cytoplasmic-nuclear invaginations; and (d) both nuclear and cytoplasmic immunoreactivity for S100 protein is present

desmoplasia. Some examples are intimately associated with small nerve trunks. The bulk of cases involve the dermis and subcutis, and >25% of cases induce pseudoepitheliomatous hyperplasia of the overlying squamous epithelium. This can be misinterpreted as an invasive squamous cell carcinoma, especially in undersampled or superficially biopsied lesions where the granular cell population is not readily apparent [295, 329].

Attention should be paid to the tumor growth pattern and margins [9]. Although data are limited, there is some evidence suggesting gynecologic granular cell tumors with a well-defined nodular appearance and "pushing" border may have little potential for local recurrence when marginally excised. In contrast, tumors with an infiltrative edge seem to carry substantial risk for local recurrence.

Malignant granular cell tumors are often large, and they usually have extensive and conspicuous cytologic abnormality, not merely focal atypia. Rarely, the malignant potential of a granular cell tumor can be difficult to predict, because prominent atypia may be absent. However, in most instances, a combination of the following histologic features help with prognostication: tumor necrosis, prominent spindling of the tumor cells, prominent nuclear pleomorphism, many large vesicular nuclei with macronucleoli, many cells with a high n/c ratio, and >2 mitoses/10 HPFs (especially if mitotic activity is widespread and accompanied by atypical mitotic figures). Fanburg-Smith et al. [89] regard the presence of three or more of these findings as an indication of malignant potential. Granular cell tumors meeting one or two of these criteria were interpreted as atypical, but no atypical

tumors (only nine examples with follow-up) were demonstrated to have metastatic potential.

Granular cell tumors have immunoreactivity for S100 protein (nuclear and cytoplasmic), CD68, calretinin, and vimentin. They are nonreactive for keratins, EMA, actins, desmin, chromogranin, and HMB-45.

Differential Diagnosis

The differential diagnosis for granular cell tumor includes true histiocytic, "fibrohistiocytic," melanocytic, myogenic and epithelial tumors with granular cytoplasm. Most of these tumors can be easily ruled out with the immunoresults noted above. Histiocytic tumors often feature mononucleated cells with reniform nuclei, as well as multinucleated giant cells. When histiocytes are present en masse, "windowing" may be noted between the cells due to abundant surface pilopodia. Histiocytic proliferations commonly express CD68 and CD163, and some have immunoreactivity for CD45RB and other markers, such as CD1a or S100 protein. Benign fibrohistiocytic tumors are usually superficial (most are dermal-based), they commonly have a stellate configuration, and they feature a more heterogenous population of cells than granular cell tumor. The scattered S100 protein-positive cells randomly distributed in some fibrohistiocytic tumors are usually nonlesional dendritic cells.

Behavior and Treatment

The vast majority (\geq 98%) of granular cell tumors are benign. Many gynecologic authors recommend conservative wide local excision for these tumors to minimize the risk of local recurrence. However, simple local excision may prove adequate for examples with well-defined nodular growth. The most important prognostic factor for malignant granular cell tumors is tumor size [89]. These neoplasms tend to affect older patients than benign granular cell tumors, and they often behave as high-grade malignancies with a tendency to metastasize to regional lymph nodes, the lungs and bones. As a result, they warrant aggressive intervention. The possibility of multiple independent lesions should always be considered before assuming metastasis in the setting of granular cell tumor.

Schwannoma (Neurilemoma)

While there are rare reports of schwannoma involving the vulva [137, 325], vagina [78], uterine cervix [135, 189],

uterine body, fallopian tubes [77], broad and round ligaments, and ovaries, most schwannomas occurring in the vicinity of genital organs arise in the pelvic retroperitoneum [151, 167, 309]. Vulvar schwannomas most commonly affect the labia [271], but other sites including the clitoris [54, 150] may be affected. Most schwannomas are of the classical type, but infrequent examples are plexiform [54, 271, 331, 333] (usually superficial) or cellular [325] (usually deep-seated).

Clinical Features

Superficial schwannomas often present as a firm, welldemarcated, nodular mass. Retroperitoneal examples may be incidentally discovered during evaluation for unrelated problems. Central degeneration and cystic change are frequent imaging findings [151]. Plexiform schwannomas may have a multinodular, "bag of worms" appearance when imaged. Symptoms are often absent, but sometimes patients report pain radiating along the course of the affected nerve segment.

Pathologic Findings

The lesions are sharply demarcated and moderately firm. The cut surface ranges from gray-white to yellow. Hemorrhagic foci and cystic areas with brownish liquid are sometimes present. These tumors lack the whorled cut surface common to smooth muscle neoplasms.

Histologically, the process is encapsulated. Deepseated examples may be bordered by a thick rind of fibrous tissue with patchy chronic inflammation, and there may be adherence to adjacent structures. The lesions contain spindled Schwann cells with alternating patterns of growth (> Fig. 22.10). Antoni A areas have minimal myxoid matrix and more pronounced cellularity. These areas can have fascicular growth, as well as foci with nuclear palisading and Verocay body formations. Antoni B foci have myxoid matrix, lower cellularity and less ordered growth. Thick-walled vessels and perivascular xanthoma cells are frequent findings in schwannomas, and central cystic and hemorrhagic degeneration may be noted. Varying degrees of nuclear atypia (often viewed as "degenerative") can be present. Mitotic figures are generally uncommon, but they may be evident. Mitotic activity has much less clinical significance in a schwannoma than in a neurofibroma.

Cellular schwannomas are usually deep-seated, and they tend to be larger than conventional schwannomas [325].

Fig. 22.10

Schwannoma. (a) a low power view demonstrating encapsulation and central cystic degeneration; (b) neoplastic Schwann cells with tapered nuclei and prominent nuclear palisading; (c) thick-walled vessels and (d) perivascular xanthoma cells

These tumors feature a prominent Antoni A component, and oftentimes, they have $\leq 10\%$ Antoni B growth. Verocay bodies are generally absent. Because of high cellularity, focal nuclear atypia, and mitotic activity (usually ≤ 4 mitoses/10 HPFs), cellular schwannomas can be confused with sarcomas [325].

All schwannomas should have extensive nuclear and cytoplasmic immunoreactivity for S100 protein. Some examples also express GFAP. Infrequently, focal keratin expression is noted and is thought to be due to keratin antibodies crossreacting with GFAP epitopes. Schwann cells are nonreactive for actins and desmin.

Behavior and Treatment

Schwannomas are usually cured by local excision, and recurrences are very uncommon (<5%). Deep-seated

examples can be difficult to excise because of proximity and adherence to regional structures, such as major vessels and the ureters, and removal is sometimes complicated by substantial blood loss [167, 325]. Malignant transformation of a true schwannoma is an extremely rare event.

Neurofibroma and Neurofibromatosis-1

Clinical Features

Neurofibromatosis-1 (NF1) is an autosomal dominant disorder that affects approximately 1 in 3,000 individuals [264]. The process has virtually 100% penetrance, and it is progressive, but there is marked variation in expressivity [264]. Approximately half of the patients have an affected parent, and the other half represent new mutations. Excellent reviews [134, 264] that include a summary of
diagnostic criteria for this disorder are included in our references [134]. Six to eighteen percent of female patients with NF1 are reported to develop neurofibromas in the vulvar region [32, 47, 112, 276]. However, <1% are documented to have vaginal involvement. While there are a few reports of neurofibromas involving the uterine cervix [36, 47, 112, 122, 321], other sites, such as the uterine body [122, 335], fallopian tubes and ovaries [122, 138], are only very rarely affected.

Clitoral and preputial neurofibromas are often congenital, and in many cases, they are the presenting sign of NF1 in the pediatric population [26, 138, 297]. These lesions may be clinically confused with ambiguous genitalia, but they have a firmer consistency than hormonally-induced phallus enlargement [26, 297]. Careful examination often reveals the patients to have multiple cutaneous café-au-lait spots, but other diagnostic manifestations of NF1 may be absent in this age group and may not become evident until at or around the time of puberty [26, 32, 233, 265, 276, 297]. For many pediatric patients, clinical confirmation of NF1 hinges on documentation of an affected first degree relative [297].

Vaginal and cervical neurofibromas are usually diagnosed in early adulthood and are rarely seen outside of the setting of NF1. Approximately 30% of vaginal neurofibromas are detected during pregnancy or manifest as an obstructive complication during delivery [269]. Many patients with vaginal neurofibromas have co-existing bladder and/or vulvar disease [26, 47, 119, 265, 297]. For some individuals, urinary tract signs or symptoms are the presenting feature [47].

Localized cutaneous neurofibromas of the vulva are encountered throughout life but are uncommon before the age of 20. These tumors may be sporadic, or they may be associated with NF1.

Pathologic Findings

Localized, plexiform, and diffuse neurofibromas have all been reported in the genital region (**)** *Fig. 22.11*). Most clitoral and deep-seated genitourinary tract neurofibromas associated with NF1 are either plexiform neurofibromas or neurofibromas with an admixture of diffuse and plexiform features. Plexiform neurofibromas grossly distort nerve segments and impart a macroscopic "bag of worms" appearance. Diffuse neurofibromas form illdefined, typically large, expansile masses with an offwhite color. Localized neurofibromas may be ill-defined or discrete, depending on how much of the process is intraneural. These latter lesions may form a solid mass with a rubbery consistency or they may be soft and fluctuant due to abundant myxoid matrix. Very rarely, neurofibromas may be pigmented.

Neurofibromas contain neoplastic S100 proteinpositive Schwann cells admixed with other nerve sheath elements (i.e., neurofilament protein-positive neuraxons, CD34-positive intraneural fibroblasts, and occasional EMA-positive perineurial cells). The Schwann cells usually have elongate bipolar cytoplasmic processes and wavy, tapered, dark-staining nuclei. Growth tends to be more random than in a schwannoma, and myxoid matrix is often more widely distributed. Nuclear palisading and Verocay bodies are usually not present. Mitotic figures are absent or extremely sparse in almost all instances. When high cellularity or significant nuclear atypia is accompanied by notable mitotic activity and/or necrosis, malignancy warrants strong consideration.

Diffuse neurofibromas often have Schwann cells with shorter cytoplasmic processes and less tapered (more ovoid) nuclei than are encountered in most other neurofibroma types. These cells tend to grow in a permeative, diffuse fashion with random or sometimes vague storiform orientation. Entrapment of regional structures is characteristic, and many examples contain small abnormal nerve twigs that give rise to Wagner-Meissner-like bodies (> Fig. 22.11d). As noted above, this neurofibroma variant can be seen in association with a plexiform neurofibroma. When a diffuse neurofibroma involves skin, it can sometimes be confused with dermatofibrosarcoma protuberans (DFSP), an error compounded by the fact that both processes contain cells with immunoreactivity for CD34 (> Fig. 22.12). However, in diffuse neurofibroma, there is a dual population of cells, delicate CD34positive fibroblast-like cells and S100 protein-positive Schwann cells, and the latter component is absent in DFSP.

The postpartum microneuroma is a form of traumatic neuroma linked to parturition and should not be confused with a true neurofibroma [304]. These small (usually ≤ 1 mm) incidental cervical lesions consist of disorganized, but otherwise relatively unremarkable, nerve twigs that often satellite around a larger nerve segment.

Behavior and Treatment

Localized neurofibromas that cause cosmetic concern or are subject to constant irritation are generally managed by conservative resection. The recommended treatment for clitoral neurofibromas is clitoroplasty with preservation of the neurovascular bundle and glandular tissue [297]. When neurofibromas are extensive, functionally

Neurofibromas. Figures (a, b) depict an intraneural neurofibroma with abundant myxoid matrix. Note the dark staining, tapered and focally undulating, Schwann cell nuclei in figure (b). Figures (c, d) illustrate a diffuse neurofibroma from the vagina of an NF1 patient. Note vaginal epithelial changes in figure (c) reminiscent of that encountered with granular cell tumors, and the presence of Wagner-Meissner-like bodies (d)

Neurofibroma. CD34 (a) and S100 protein (b) results for a diffuse neurofibroma. CD34 highlights numerous delicate fibroblast-like spindled cells, and S100 protein highlights the neoplastic Schwann cell population

compromising and symptomatic, more aggressive intervention may be required. However, complete excision can be very difficult to achieve and may be impossible for many large plexiform neurofibromas of the genitourinary region [49]. Sudden growth in a pre-existing neurofibroma warrants immediate attention because of the risk of malignant transformation.

Nodular Fasciitis

Clinical Features

Nodular fasciitis typically presents as a rapidly growing mass of less than 2 months duration. The process may be asymptomatic or accompanied by mild pain or tenderness. The number of reported examples involving the vulva is small, totaling only 12 cases through 1998 [13, 240]. However, 26 examples of vulvar nodular fasciitis are present in the AFIP files (1.1% of cases diagnosed in females). A predilection for the labia, especially the labia majus, has been noted. Patients documented in the literature have ranged in age from 7 to 51 years. AFIP patients have ranged from 8 to 58 years with a peak incidence in the 4th decade and a median age of 34 years.

Pathologic Findings

Nodular fasciitis generally forms a well-circumscribed mass, usually <3 cm and almost always <5 cm in size.

The median size for AFIP cases is 1.9 cm. The lesions have a cut surface that varies in appearance from myxoid, sometimes with focal cystic change, to fibrous.

Histologically, nodular fasciitis tends to form a lobulated mass with a relatively uniform population of plump "activated" (myo)fibroblasts with minimal atypia and no pleomorphism (\bigcirc *Fig. 22.13*). These spindle cells tend to be arranged in a loose, "feathery," tissueculture-like growth pattern with scattered small areas of mucoid degeneration. More compact growth is sometimes present, especially at the tumor periphery. A sprinkling of intralesional lymphocytes is common, and occasional osteoclast-like giant cells may be encountered in the areas with mucoid degeneration. Mitotic figures can be abundant, but they are not atypical. Some later stage examples have central hyalinized (keloid-like) collagen.

The spindle cell population is usually immunoreactive for α -smooth muscle actin and muscle-specific actin, and it is generally negative for desmin [218]. No reactivity is present for S100 protein, CD34, or keratins. The osteoclast-like giant cells are readily highlighted with CD68 (KP-1).

Differential Diagnosis

Because of cellularity and mitotic activity, nodular fasciitis can be misinterpreted as a spindle cell sarcoma. However, helpful clues to correct classification are the small size and lobular contour of the mass, presence of areas with mucoid degeneration, lack of significant nuclear atypia or pleomorphism, and absence of atypical mitotic figures.

Nodular fasciitis. Note the loose tissue culture-like growth pattern and areas with mucoid degeneration (a). Scattered osteoclast-like giant cells are present in figure (b) and its inset

Behavior and Treatment

Nodular fasciitis is a benign self-limiting condition, usually cured by simple local excision. Local recurrence is encountered in no more than 1–2% of cases and usually occurs shortly after an incomplete initial procedure. When a recurrence develops at the site of a previously diagnosed nodular fasciitis, the original specimen should be reevaluated to insure accuracy of the initial interpretation.

Desmoid Tumor (Musculoaponeurotic Fibromatosis)

Clinical Features

Desmoid tumors are rare with an estimated incidence of 2.4–4.3 new cases per 10^6 population per year [262]. These lesions have a wide anatomic distribution, but the single most common location is the anterior abdominal wall. Tumors at this site have a very strong female predilection (in AFIP files, the F:M ratio is >8:1). They usually occur between the ages of 18 and 40 and often develop during gestation or within the first year after childbirth. As a result, desmoids are one of the more common fibrogenic neoplasms encountered by gynecologists. Much more rarely, gynecologists may also be confronted with pelvic desmoids located in the iliac fossa or lower pelvic region [61, 100, 169, 200, 202, 228, 281]. These tumors also have a female predominance and occur over the same age range as abdominal wall desmoids. However, in AFIP files, they are more than 20 times rarer than abdominal

wall desmoids. Although no clear link between pelvic desmoids and pregnancy or childbirth has been established in the literature, on recent review of in-house material, we noted a possible association with gestation in up to 40% of cases. Most desmoid tumors are sporadic, but some cases are associated with familial adenomatous polyposis/ Gardner syndrome.

Pathologic Findings

Regardless of the anatomic site, desmoid tumors share certain gross and microscopic findings. They form poorlycircumscribed, firm masses that are often intimately associated with fascia and muscle. On cut section, they have a coarsely trabeculated off-white appearance. Histologically, the process is moderately cellular, infiltrative and composed of spindled cells with only mild nuclear atypia and no significant pleomorphism (> Fig. 22.14a). The neoplastic cells often have small, but distinct, central nucleoli. Mitotic activity is variable but usually low. Abundant collagenous or myxocollagenous matrix is present, and the lesional cells are generally arranged in loose fascicular and broad storiform growth patterns. The vasculature tends to consist of evenly spaced, thin-walled vessels with slit-like or rounded lumens. Immunoreactivity is typically present for α -smooth muscle actin and musclespecific actin, and some cases may have a small amount of reactivity for desmin. The vast majority of tumors also have at least focal nuclear staining for β-catenin (> Fig. 22.14b) [23, 40].

Desmoid tumor. A medium power view (a) of a desmoid tumor illustrating broad fascicular growth, and a high power view (b) demonstrating nuclear and cytoplasmic immunoreactivity for β-catenin

Behavior and Treatment

Desmoid tumors have a strong propensity for local recurrence and are optimally managed by complete excision with wide tumor-free margins. In instances where this cannot be achieved without undo morbidity, lesser intervention is often advocated, because desmoid tumors do not metastasize [202]. In cases where tumor-free margins are not achieved, radiation therapy may be beneficial [158]. Other forms of therapy, including hormonal therapy [326], have also been tried with varying degrees of success. Radical surgery is generally reserved for cases where all other reasonable treatment options have been exhausted.

Genital Rhabdomyoma

In the past, genital rhabdomyomas were often regarded as a subtype of fetal rhabdomyoma. However, most soft tissue experts now view them as a separate and distinct tumor type.

Clinical Features

Approximately 39 genital rhabdomyomas have been documented in the literature [19, 73, 121, 154, 160, 175, 296]. More than 80% of tumors have involved the vagina, where they form an asymptomatic polypoid mass, typically in the 1–3 cm size range. The remaining cases are equally divided between the portio vaginalis/uterine cervix and vulva. Patients have ranged in age from 8 to 54 years, but the overwhelming majority present in their 4th and 5th decades. Tumors involving the vulva tend to manifest much earlier in life (age range: 8–24 years) [154].

Pathologic Findings

Gross examination typically reveals a polypoid or cauliflower-like mass with a mucosal surface. The average tumor size is approximately 2 cm. Histologic examination reveals fibrous stroma with interlacing collections of large strap-like cells admixed with scattered plump epithelioid cells with abundant eosinophilic cytoplasm (**>** *Fig. 22.15*). Close inspection usually reveals occasional tumor cells with cytoplasmic cross-striations (> Fig. 22.15b inset), highlightable with Masson trichrome and phosphotungstic acid-hematoxylin (PTAH) stains. The neoplastic cells usually have one large centrally located nucleus with a vesicular chromatin pattern and a prominent central nucleolus. Occasional multinucleated cells may be present. Anaplasia and mitotic activity are absent. No subepithelial "cambium" layer effect, as seen with botryoid rhabdomyosarcomas, is present.

Immunoreactivity is present for muscle-specific actin, desmin, myoglobin, and nuclear regulatory proteins for skeletal muscle differentiation (especially myogenin, personal observation). No reactivity is present for epithelial markers.

Vaginal rhabdomyoma. Low (a) and high (b) power views. Note the abundant eosinophilic cytoplasm and nuclear features. Cross striations are evident in the figure (b) inset

Differential Diagnosis

In childhood, the key consideration in the differential diagnosis is the botryoid variant of embryonal rhabdomyosarcoma. This tumor classically contains a hypercellular subepithelial cambium-like layer of neoplastic cells. The process has infiltrative growth, significant nuclear atypia and mitotic activity. In older patients, a mesodermal stromal polyp would commonly be a leading consideration until skeletal muscle differentiation is confirmed. When the myogenic features become apparent, fleeting consideration might be given to a heterologous element from an adenosarcoma or carcinosarcoma, but no epithelial component is present and the mesenchymal cells lack malignant cytomorphologic features.

Behavior and Treatment

Genital rhabdomyomas are benign tumors, typically cured by simple local excision.

Glomus Tumor

There are rare reports of glomus tumor involving the labia minus [163, 174], clitoris [157, 290], periurethral area [290], and uterine cervix [6], and AFIP files contain an additional four examples. Patients have ranged in age from 27 to 67 years. The lesions are usually solitary and ≤ 1 cm in size, but rarely, they may be multifocal or measure up to 3 cm. The classic clinical scenario for vulvar examples is intense (sometimes incapacitating) nonradiating pain, unrelated to the menstrual cycle and localized to a specific "trigger" spot. Overlying erythema may be noted.

Histologic examination reveals a well-demarcated nodular mass composed of epithelioid and sometimes focally spindled (modified/specialized) smooth muscle cells organized around numerous vascular spaces (**>** *Fig. 22.16*). The epithelioid cells often have a "fried egg" appearance with a central, hyperchromatic, round nucleus and pale to eosinophilic cytoplasm with a distinct cell border. So-called "degenerative" atypia is occasionally present. Mitotic figures are rarely encountered. The tumor cells

Glomus tumor. Medium (a) and high (b) power views. Note a tendency for aggregation around the vasculature. Also note the "fried egg" appearance of the tumor cells, with round, centrally located, nuclei and distinct cell borders

have strong immunoreactivity for muscle-specific actin and α -smooth muscle actin, but they are usually negative for desmin. Many S100 protein-positive nerve twigs may be present in the background, but tumor cells are negative for this marker. There is no immunoreactivity for keratins, synaptophysin or chromogranin.

Complete local excision is curative.

Benign Tumors and Tumefactions of Blood Vessels

A wide variety of benign vascular lesions may affect the gynecologic tract. Lesions of the vulva, ranging from reactive vascular tumefactions secondary to infection (e.g., bacillary angiomatosis) [194] to vascular malformations and neoplasms [91], are similar in appearance to those encountered in other cutaneous sites and are not included in this chapter. Many of the more common vulvar lesions (e.g., juvenile hemangioma, lobular capillary hemangioma/pyogenic granuloma and angiokeratoma) [57] are discussed elsewhere in this textbook.

Vaginal angiomas are usually classified as capillary or cavernous hemangiomas, and much less frequently, are arteriovenous in nature [60, 65, 79, 132, 144, 263]. Most vaginal hemangiomas are small, isolated lesions that are detected incidentally. However, infrequently, they may be more extensive with coexisting vulvar, urethral, cervical or pelvic involvement. When widespread, the process is often classified as an angiomatosis. As with other vascular lesions of the gynecologic tract, rapid growth can occur during pregnancy. The most common benign vascular lesions of the uterine cervix are also capillary and cavernous hemangiomas [5, 65, 87, 133]. These lesions may be incidentally discovered (e.g., during colposcopy or in a hysterectomy specimen for an unrelated medical condition), or they may cause abnormal vaginal bleeding. Grossly, they are usually <4 cm in size and have a red-purple color and soft to spongy consistency. Cervical hemangiomas have been reported over a wide age range, but the peak incidence is in the 3rd decade of life. Only rarely are they identified before puberty. We are aware of one report of bacillary angiomatosis affecting the uterine cervix [194].

Benign vascular lesions of the uterus proper can be asymptomatic or they may be associated with abnormal vaginal bleeding, infertility, spontaneous abortions, and fetal wastage. They can cause life-threatening complications during pregnancy, delivery and surgical procedures (e.g., myomectomy) [50, 67, 109, 303, 322]. Most vascular lesions of the uterus are detected in the 3rd through 5th decades and generally are either cavernous hemangiomas (a.k.a. cavernous angiomatosis of the uterus) [59, 67, 109, 173, 303, 310, 322] or arteriovenous malformations [199]. The former are often viewed as congenital and commonly exhibit widespread involvement of the uterus. The latter are either congenital or acquired (usually post-traumatic) and tend to be more localized ("tumor-like") in their distribution [109]. The distinction can have clinical relevance, because bleeding from arteriovenous malformations can be more difficult to control [59]. Spectral Doppler analysis is a valuable clinical tool in distinguishing the two processes [59].

Ovarian hemangiomas occur over a wide age range and fall into two general groups: those associated with abdominopelvic (hem)angiomatosis[185] and those occurring as localized lesions [10]. The former are often symptomatic, whereas the latter are frequently asymptomatic. Localized ovarian hemangiomas are usually unilateral, and they most commonly involve the medullary and hilar regions. They generally exhibit cavernous, or less commonly, capillary features. A small number of cases have been associated with ascites, an elevated serum CA-125, stromal luteinization and hormonal function [110, 126, 272, 334]. We are aware of one report of an infantile cellular hemangioma ("hemangioendothelioma") of the ovary in a newborn [257].

Patients with vascular abnormalities of the gynecologic tract may have other important physical findings that aid in their recognition. Some patients may have coexisting hemangiomas or vascular malformations involving the skin, deep soft tissue, or other organ systems [67, 109, 144, 303], and a few individuals have been documented to have Klippel-Trénaunay-Weber syndrome [59], tuberous sclerosis [109], hereditary hemorrhagic telangiectasia [109], and blue rubber bleb nevus syndrome [289].

Benign vascular lesions of the gynecologic tract have been treated in a variety of ways, ranging from clinical observation to local ablative therapy to resection of the affected organ. The treatment approach is influenced by the type, size and location of the vascular lesion, symptomatology, a desire to preserve fertility, and other factors.

Other Benign Soft Tissue Lesions Involving the Gynecologic Tract

Other benign soft tissue tumors and tumor-like lesions reported to involve the gynecologic tract include proliferative fasciitis, ischemic fasciitis [273], massive localized lymphedema as encountered in morbid obesity [229], lipoma [31, 72, 220], lymphangioma, and ganglioneuroma [95]. Rosai-Dorfman disease, which usually follows an indolent course, has also been documented [224].

Borderline/Low-Grade Soft Tissue Neoplasms and Mesenchymal Tumors with Varying Behavior

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) commonly develops in early to mid adult life and initially manifests

as a small cutaneous plaque-like lesion that over time progresses to form a protuberant, multinodular mass. The rate of growth can be quite variable with long intervals of relative stasis, separated by periods of slow or more rapid enlargement. This process has a strong predilection for the trunk and limb girdle regions (old-fashioned bathing suit distribution), and more than two dozen examples have been reported to affect the vulva [11, 27, 113, 118, 232, 277, 316, 332]. Patients with vulvar involvement have ranged in age from 19 to 83 years with a median age in the early to mid 40s.

Most examples of DFSP arise in the dermis and subsequent spread to the subcutis, and occasionally, deeper structures. Histologically, the tumor is composed of relatively uniform spindled fibroblast-like cells arranged in a monotonous, tight storiform pattern (> Figs. 22.17 and **22.18**). Other cellular elements such as lymphocytes, giant cells, and xanthoma cells are rarely seen. Hemorrhage, hemosiderin deposition, and necrosis are uncommon in conventional examples that have not been previously manipulated. The overlying epidermis is usually attenuated, as opposed to the acanthotic appearance commonly associated with fibrous histiocytomas. A frequent finding of diagnostic importance is the entrapment of fat and adnexa within the tumor. Myxoid matrix is present in some examples, though this is usually a focal finding, and rare cases (approximately 1-5%) may contain scattered melanin-laden spindled, epithelioid and dendritic cells (so-called Bednar tumors) (> Fig. 22.18c). There is generally minimal cellular pleomorphism. While mitotic activity can be quite variable, the overall mitotic rate is often relatively low.

A small percentage of DFSPs contain areas with solid fascicular growth, morphologically indistinguishable from classic adult-type fibrosarcoma (> Fig. 22.18d). These lesions are referred to as DFSP with fibrosarcomatous transformation (DFSP-FS) [1, 213, 332]. Criteria for diagnosis have varied considerably in the literature. Some authors require the fibrosarcomatous element to comprise 5-10% of the tumor area (without stipulating a minimum size in cm, but with the notation it must be more than a rare microscopic focus), whereas others require the fibrosarcomatous element to make up 25-30% of the tumor area or for it to be ≥ 1 cm in size. Histologically, the fibrosarcomatous component often arises in the subcutis, and it frequently (though not always) has increased cytologic atypia, greater cellularity, and more mitotic activity than adjacent areas of DFSP with storiform growth. Very rarely, DFSP can also harbor foci with substantial pleomorphism, mimicking malignant fibrous histiocytoma (pleomorphic undifferentiated sarcoma).

Fig. 22.17

Dermatofibrosarcoma protuberans (DFSP). These low (a) and medium (b) power views demonstrate a well-developed storiform growth pattern and infiltration and entrapment of fat

The typical spindled tumor cells of DFSP are immunoreactive for CD34 (**?** *Fig. 22.18b*) and negative for S100 protein. Focal actin expression is sometimes observed. Areas with fibrosarcomatous transformation often have diminished expression of CD34. The melanin-laden spindled and dendritic cells encountered in pigmented DFSP (Bednar tumor) are immunoreactive for S100 protein, HMB-45, and Melan A (best observed with a red chromogen if the cells have not been bleached).

DFSP generally harbors either a supernumerary ring chromosome with low level amplification of sequences from chromosomes 17 and 22, or it contains a linear t(17;22) [197, 284]. The former is more common in adults, whereas the latter is common in pediatric patients. Both genetic events produce a *COL1A1/PDGF* β chimeric gene. There is wide variation in the break point on the *COL1A1* gene (from chromosome 17) but consistent involvement of exon 2 of the *PDGF* β gene (from chromosome 22). The resultant chimeric protein product is processed to mature PDGF- $\beta\beta$, which leads to continuous autocrine and paracrine activation of the PDGFR β protein-tyrosine kinase, promoting cell proliferation and tumor growth [278].

DFSP is a tumor of "indeterminate" or low malignant potential. Less than 3% of conventional examples give rise to metastases. However, when fibrosarcomatous transformation is present, the risk of metastasis increases to 10–15% [1, 213]. The risk of metastasis is also believed higher when malignant fibrous histiocytoma-like areas are present, though this has not, to date, been adequately studied. A wide local excision is generally recommended, because invasion beyond grossly apparent margins is common, and there is a very strong propensity for recurrence [210, 268]. A 3 cm margin of normal-appearing tissue, with the inclusion of underlying fascia, has been advocated by some to minimize the risk of recurrence. However, using this approach, skin grafting may be required to cover the surgical defect, so management needs to be individualized. A growing number of patients have been successfully treated with Mohs' micrographic surgery [75, 116, 204, 288]. Long-term follow-up is required for all cases, and periodic screening for metastases (chest x-ray, etc.) is indicated when increased risk is documented. Imatanib mesylate, a potent inhibitor of several protein-tyrosine kinases, including PDGF receptors, has had a beneficial effect for some patients with locally advanced or metastatic disease [204].

Solitary Fibrous Tumor/ Hemangiopericytoma

The term "hemangiopericytoma" was originally used to describe a neoplasm of purported pericytic lineage composed of plump epithelioid or ovoid cells intimately associated with numerous thin-walled, branching (staghorn-like) vessels [81]. However, features diagnostic of pericytes are not faithfully reproduced in most of these tumors, and the above morphologic pattern can be encountered in a variety of other mesenchymal neoplasms, making the diagnosis one of exclusion. Solitary fibrous tumor shares many clinicopathological features with hemangiopericytoma [139] and many experts use the two terms synonymously [111]. Others continue to attempt to separate these

Dermatofibrosarcoma protuberans. Figure (a) is a high power view of the spindled neoplastic cells with a monotonous, tight, storiform growth pattern. Figure (b) illustrates immunoreactivity for CD34. Figure (c) contains scattered melaninladen cells, as encountered in pigmented DFSP (Bednar tumor). Figure (d) demonstrates the fascicular growth that characterizes fibrosarcomatous transformation of DFSP

processes, pointing out that classic solitary fibrous tumors tend to have more spindle cells, a greater amount of collagen, and less pronounced vascularity than classic hemangiopericytomas. That said, it is clear there are tumors where the morphologic distinction is blurred, and since the criteria for assessing malignant potential are essentially identical for the two lesions, this debate presently has little clinical relevance.

Clinical Features

Female genital tract hemangiopericytomas/solitary fibrous tumors (HPC/SFT) have been documented primarily in the vulvovaginal region [105], with rare examples noted in the uterus [53, 318], cervix, broad ligament, paraovarian tissue, and fallopian tube [24, 336]. Age range

at presentation is wide, but most patients are in the 4th through 8th decades of life. Vulvovaginal tumors usually present as asymptomatic, slow-growing masses, while pain or bleeding typically herald the presence of a uterine or cervical tumor. One high-molecular-weight insulin-like growth factor II-secreting uterine tumor caused hypoglycemia [318]. HPC/SFTs also arise in the soft tissue of the pelvic fossa and retroperitoneum [81, 82, 139] and because of proximity to the gynecologic tract, they may also be encountered in gynecologic practices.

Pathologic Findings

There is considerable variation in tumor size, with most examples measuring between 3 and 15 cm in greatest dimension [24, 81]. Macroscopically, HPC/SFTs tend to

form well-circumscribed, nodular masses that typically have a firm consistency and gray-white, whorled cut surface. Hemorrhage or myxoid change is sometimes observed. Histologically, the cellular variant of SFT (classic HPC) consists of ovoid to fusiform cells with round to oval nuclei and scanty, pale eosinophilic cytoplasm with ill-defined cell borders (> Fig. 22.19a). The neoplastic cells are intimately arranged around a myriad of thin-walled, partially collapsed, branching capillaries. Scattered larger vessels within the lesion often have a staghorn-like appearance. Perivascular collagen deposition is a common finding. The conventional SFT (fibrous HPC) (**)** Fig. 22.19b) characteristically exhibits hyper- and hypocellular areas. Hypercellular regions feature bland fusiform and elongated spindle cells (+/- some epithelioid cells) arranged haphazardly around hemangiopericytomatous vessels, in short fascicles or vague storiform arrays. The mitotic rate is generally low. Paucicellular regions contain abundant hyalinized collagen or myxoid matrix. Perivascular collagenization can be a prominent feature. Lipomatous HPC (fat-forming variant of SFT) [82] and giant cell angiofibroma (giant-cell-rich variant of SFT) [128, 139] have features of both conventional and cellular SFT [111]. The former, however, has a variable number of mature adipocytes, whereas the latter possesses multinucleated stromal giant cells found within the interstitium or lining ectatic pseudovascular spaces. Immunohistochemically, conventional SFT shows strong reactivity for CD34, bcl-2, and CD99 and variable reactivity in a small percentage of cases for EMA, smooth muscle actin, and nuclear beta-catenin [40, 139]. Keratin, desmin and S100 protein

are usually absent. Tumors with classic HPC morphology are also usually CD34-positive, but less consistently so than conventional SFTs [82, 336]. There is a trend for atypical/malignant HPC/SFTs to have diminished CD34 expression.

Differential Diagnosis

HPC/SFT warrants separation from a number of highly vascular, site-specific, spindle cell lesions of the vulvovaginal region. Cellular angiofibroma shares with HPC/SFT perivascular collagen deposition, the occasional presence of some hemangiopericytoma-like vessels, and CD34-positive tumor cells. However, multipatterned architecture, prominent hemangiopericytomatous vasculature, and pericellular collagen deposition are not features common to cellular angiofibroma. Angiomyofibroblastoma typically lacks hemangiopericytomatous vessels and its spindle and epithelioid tumor cells (which often express desmin) have a notable tendency to concentrate around lesional vessels in corded and nested arrays. Endometrial stromal sarcoma and synovial sarcoma (especially monophasic fibrous and poorly-differentiated examples) can contain a hemangiopericytoma-like vascular component. However, both of these tumors tend to be more infiltrative than HPC/SFT, and they often have more pronounced nuclear atypia and mitotic activity. Additionally, concentration of tumor cells around arterioles is a distinct feature of endometrial stromal sarcoma. In comparison with HPC/SFT, endometrial stromal sarcoma

Fig. 22.19

Hemangiopericytoma (a) and Solitary fibrous tumor (b). It is now widely recognized that these tumor types can sometimes have overlapping histologic features

shows stronger expression of CD10 and progesterone receptor protein, and it is estrogen receptor proteinpositive and CD34-negative [22]. Synovial sarcomas typically have focal keratin and EMA expression, and they are usually CD34-negative. Synovial sarcomas also feature an t(X;18) with SYT/SSX fusion transcripts.

Behavior and Treatment

Most HPC/SFTs behave in a benign fashion [81, 82, 120]. Recurrent or metastatic disease is reported in 6–15% of cases overall [81, 311], and the 5-year survival rate is >85% [82]. Histologic criteria for assessing malignant potential are imprecise and prognostication can be problematic, so complete excision with negative margins and long-term follow-up are generally recommended [311]. Features associated with aggressive behavior include large tumor size (>5 cm vs. >10 cm), infiltrative margins, high cellularity, nuclear pleomorphism, \geq 4 mitoses/10 HPFs and necrosis [81, 120, 311]. Patients with large tumors containing a histologically malignant component should be considered for additional therapeutic intervention beyond surgery alone, as they may benefit from adjuvant therapy.

Inflammatory Myofibroblastic Tumor

This rare mesenchymal lesion has also been referred to in the literature as an inflammatory pseudotumor, plasma cell granuloma and plasma cell pseudotumor. It has been documented in a wide variety of anatomic sites, including the uterus [20, 97, 115, 161, 258, 279]. Recent evidence that the process often harbors clonal chromosomal aberrations involving 2p23 with various associated fusion gene transcripts (including *TPM3-ALK*, *TPM4-ALK* and others) supports the view this is a neoplastic rather than reactive process [33, 125, 186].

Reported examples in the uterus have affected individuals ranging in age from 6 to 60. Patients may present with findings related to mass effect, or the clinical picture can be dominated by constitutional signs or symptoms, including fever, weight loss, erythema of the face and extremities, malaise and fatigue.

Gynecologic examples have ranged in size from 1 to 12 cm and have exhibited polypoid growth within the endometrial cavity or diffuse involvement of the uterine wall. The cut surface can have a white, fibrous, whorled appearance similar to a smooth muscle tumor, or it can be smooth, soft and fish flesh-like or even gelatinous. Histologically, the process features spindled and stellate-shaped cells with amphophilic or eosinophilic cytoplasm and a prominent nucleus with an "open" chromatin pattern and conspicuous central nucleolus (\bigcirc *Fig. 22.20*). The lesional cells should lack significant hyperchromasia and pleomorphism. The mitotic rate is variable, but generally low, and bizarre mitotic figures are absent. The tumor cells may be loosely arranged due to a moderate amount of myxoid matrix, widely dispersed due to abundant fibrosclerotic stroma, or closely packed with broad storiform and fascicular growth. A prominent lymphoplasmacytic inflammatory infiltrate is a nearly universal finding.

Immunohistochemical results vary in the literature and may reflect methodological differences or case heterogeneity. In general, at least focal actin expression is common. Desmin expression is more variable, and when present, it is often observed in only a small percentage of cells. While there is inconsistency in ALK-1 expression amongst purported inflammatory myofibroblastic tumors (IMTs) from various anatomic sites [97, 219], uterine examples are typically positive for this marker [258]. Focal keratin reactivity has been noted in many IMTs, but to our knowledge, it has not yet been reported in a uterine tumor. IMTs are negative for CD34 and S100 protein, and they are usually negative for CD117 and estrogen receptor protein [258].

ALK (anaplastic lymphoma kinase) gene locus rearrangement can often be detected with FISH, and RT-PCR can be used to detect the *ALK* gene fusion partners that include, but are not limited to, *TPM3* (tropomyosin 3), *TPM4* (tropomyosin 4), and *CLTC* (clathrin heavy-chain gene).

In the past, most IMTs of the uterus were classified as smooth muscle tumors, often a myxoid leiomyoma or leiomyosarcoma. Clues for recognition as an IMT lay in the nuclear features of the neoplastic cells (i.e., the open chromatin pattern and distinct central nucleolus), the prominent lymphoplasmacytic inflammatory infiltrate, and a more blunted expression of myogenic markers than would generally be expected in a true smooth muscle neoplasm.

IMTs can be locally aggressive, and they have a documented propensity for local recurrence if incompletely excised, so complete surgical excision is generally advocated. While there are rare reports of IMTs outside of the gynecologic tract giving rise to metastases [219], this appears to be a very uncommon event, and the process is usually viewed as being more of a local problem, so radical intervention should be avoided whenever possible. There is some evidence to suggest that *rare* examples of IMT may, over time,

Inflammatory myofibroblastic tumor of the uterus. Medium (a) and high (b) power views demonstrating the loose growth pattern, lymphocytic infiltrate, and spindled neoplastic cells with amphophilic cytoplasm and large nuclei with an "open" chromatin pattern and prominent nucleoli. Figures (c) and (d) illustrate immunoreactivity for ALK-1 and desmin, respectively

transform to fully malignant neoplasms, but at present, it is difficult to predict in which cases this will occur.

Postoperative Spindle Cell Nodule

Controversy exists as to whether postoperative spindle cell nodules (POSCN) [56, 165, 201, 256] are a unique (reactive versus neoplastic) exuberant fibroblastic/ myofibroblastic proliferation or part of the morphologic spectrum of inflammatory myofibroblastic tumor (IMT). Current data, in our opinion, are insufficient to definitively resolve this issue. By definition, POSCNs are temporally associated with some type of local trauma, including instrumentation. They usually occur in middle-aged and elderly patients, and they often present as polypoid or nodular, mucosal-based masses, sometimes with substantial infiltration of underlying stroma. The fibroblastic/myofibroblastic population has many morphologic and immunohistochemical similarities to that encountered in IMTs, including occasional ALK-1 expression. Inconsistently reported differences from IMTs include more substantial mitotic activity, more prominently edematous stroma, less plasma cells, and a lack of ganglion-like myofibroblastic cells. POSCNs of the gynecologic tract have generally responded well to conservative local excision.

Perivascular Epithelioid Cell Tumor (Myomelanocytic Tumor)

Perivascular epithelioid cell tumors (PEComas) are a family of mesenchymal neoplasms with shared cytomorphologic

and immunohistochemical features, namely the presence of epithelioid and spindled cells with lightly eosinophilic to clear cytoplasm, that may have an intimate relationship with vasculature and characteristically co-express melanocytic and myoid markers [84, 85, 103]. The prototypic tumors of this group are angiomyolipoma (renal and extrarenal variants), lymphangiomyomatosis, and clear cell "sugar" tumor of the lungs. PEComa, not otherwise specified (NOS), is a more recent addition to this family. This latter tumor has been documented in a wide variety of sites, but the single most common location is the uterus. A striking female predilection has been noted for all perivascular epithelioid cell tumor variants. Whereas angiomyolipoma and lymphangiomyomatosis have a strong association with the tuberous sclerosis complex (TSC), <10% of patients with PEComas, NOS, of gynecologic and soft tissue origin have clinical evidence of tuberous sclerosis.

Clinical Features

Within the gynecologic tract, the uterine corpus is by far the most commonly affected site with 37 cases documented, to date. PEComas in this location have affected patients ranging in age from 7 to 79 years (median, 37 years). Abnormal uterine bleeding is the most frequent presenting feature, but pain and hemoperitoneum have also been reported. There are four published examples of PEComa involving the uterine cervix (age range: 25–48 years), and rare examples have also occurred in the pelvis, vulva, vagina, broad ligament and ovary.

Pathologic Findings

The tumors have ranged in size from 1 to 30 cm. They often have a well-circumscribed appearance, but they may be frankly infiltrative, sometimes possessing tonguelike extensions reminiscent of an endometrial stromal sarcoma [314]. Histologically, the process features epithelioid and varying numbers of spindled cells with pale eosinophilic to clear (sometimes described as "moth-eaten") cytoplasm (**)** Fig. 22.21a). In some instances, the eosinophilic cytoplasm condenses around the nucleus and retracts from portions of the cell membrane, leaving skeins of cytoplasm that impart a spider-like appearance. Tumor cell nuclei are round to oval in epithelioid cells and more elongate in the spindle cell population. In most instances, the nuclei are relatively uniform with only low level atypia, but some tumors have significant atypia and pleomorphism. Scattered multinucleated giant cells may be encountered. Mitotic figures are often difficult to find, but they may be abundant and atypical in malignant examples.

The tumors characteristically feature a diffuse, intrinsic network of small capillaries, and some examples have hyalinized arterioles or other thick-walled vessels. Intimate growth of tumor cells around the vessels may be observed. The neoplastic cells exhibit a combination of nested, fascicular and sheetlike growth patterns. Occasional examples may have abundant fibrotic or hyalinized stroma.

Immunoreactivity is always present for HMB-45 (\bigcirc *Fig. 22.21b*) or Melan A (a definitional characteristic with the former being more frequently expressed than the latter), and there is usually reactivity for α -smooth muscle actin (70–80%) [84, 85, 103]. Immunoreactivity may also

Fig. 22.21

Perivascular epithelioid cell tumor (PEComa) of the uterine cervix. The neoplastic cells (a) and cytoplasmic immunoreactivity for HMB-45 (b) are depicted

be present for h-caldesmon, desmin (\approx 50%), musclespecific actin (>30%), microphthalmia transcription factor, and estrogen and progesterone receptor proteins. A small percentage of cases have been reported to express S100 protein, TFE-3, and rarely, keratins [84, 85, 103]. Negative results are usually obtained for CD34 and CD117.

Differential Diagnosis

The main considerations in the differential diagnosis are a uterine epithelioid smooth muscle tumor, and to a lesser extent, an unusual metastatic malignant melanoma or clear cell sarcoma. While most experts acknowledge some morphologic and immunohistochemical overlap between uterine smooth muscle tumors and PEComas, true epithelioid smooth muscle tumors typically lack the rather distinctive vascular network encountered in PEComas, and they usually contain some foci with conventional smooth muscle morphology (e.g., well-defined spindling, prominent and more homogeneous cytoplasmic eosinophilia, elongate cigar-shaped nuclei, and juxtanuclear vacuoles). Since HMB-45 expression has been documented in "normal" myometrium, as well as subsets of smooth muscle (and endometrial-type stromal) tumors [282], and because clear cell change is not unique to PEComas, some experts have argued that the presence of either of these findings in an otherwise conventional smooth muscle tumor is insufficient evidence to warrant classification as a PEComa [84, 85].

Metastatic malignant melanoma and clear cell sarcoma feature widespread nuclear atypia with prominent macronucleoli, notable mitotic activity, and often, strong nuclear and cytoplasm reactivity for S100 protein. Oftentimes, these tumors have more widespread reactivity for melanocytic markers than PEComas. Additionally, clinical history can be very helpful, and from a genetic standpoint, only clear cell sarcoma has a t(12;22)(q13;q13) with an *EWS-ATF1* fusion gene.

Discussion with Comments on Behavior and Treatment

There is debate amongst experts as to whether gynecologic PEComas warrant separate classification from smooth muscle tumors [84, 282, 314]. Support for this separation includes morphologic, immunohistochemical (including elevated phospho-p70S6K and decreased phospho-AKT expression, consistent with loss of TSC1/2 function), and genetic (evidence of the tuberous sclerosis complex in

a small percent of patients)[29, 85, 314] findings that more closely linked these tumors to other members of the perivascular epithelioid cell tumor family than true smooth muscle neoplasms [168]. Additionally, current evidence suggests that the histopathologic criteria (e.g., the mitotic threshold) for prognosticating gynecologicrelated PEComas differs from that presently used for epithelioid smooth muscle tumors.

Criteria for distinguishing benign from malignant PEComas of the gynecologic tract are still in a state of evolution. Folpe et al. [103] proposed classifying soft tissue and gynecologic PEComas as malignant when two or more of the following features were present: tumor size >5 cm, infiltrative growth, high nuclear grade and cellularity, coagulative tumor necrosis, vascular invasion, and mitotic activity >1 mitotic figure/50 HPFs. Tumors were considered of uncertain malignant potential if either large size or nuclear pleomorphism was encountered without other worrisome features. Tumors with no worrisome features were considered to have very low risk for aggressive behavior and were provisionally labeled benign. A more recent comprehensive review [84] restricted to gynecologic PEComas suggests the most reproducible criteria for defining malignancy in this location are: large size (as a continuous variable with the most effective threshold being 5 cm and the probability of malignancy increasing through 10 cm), coagulative necrosis, and mitotic activity (benign tumors usually have ≤ 1 mitosis/ 50 HPFs and almost always have ≤ 1 mitosis/10 HPFs). Other criteria, such as significant nuclear pleomorphism, are probably also relevant but require additional study. It is important to note that the absence of mitotic activity does not guarantee benignancy. When PEComas metastasize, they generally spread to the lungs, liver, bones and lymph nodes. Ovarian and omental metastases are also documented. Multifocal, morphologically benign, disease (a.k.a., PEComatosis) has been reported [88].

Recent observations consistent with mTOR activation and loss of TSC1/2 function in some PEComas, presents an avenue for further study to see if mTOR inhibitors, such as rapamycin, have a role in the treatment of these tumors [85, 168].

Malignant Soft Tissue Tumors

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma is a rare malignancy that usually arises in sites other than the gynecologic tract [246]. In children, it often affects the head and neck region, and in adolescents and adults (peak incidence: 3rd decade), the thigh and buttock are the most common locations. To date, approximately 30 cases have been diagnosed as primary tumors in the vulva, vagina [39, 46, 241], uterine cervix [2, 83, 102, 104, 142, 176, 270], uterine corpus [35, 129, 162, 234, 259], and broad ligament [124, 225, 267]. AFIP files contain an additional 7 unpublished gynecologic examples, as well as slides from two published cases, representing 7.4% of our female accessions for this entity.

Clinical Features

Most gynecologic examples of alveolar soft part sarcoma involve the uterine cervix or uterine corpus, these two sites being affected with nearly equal frequency. A smaller number of cases are documented in the vagina, and other locations are only rarely affected. Patients have ranged in age from 8 to 62 years, and their tumors have varied in size from 0.2 to 9.8 cm. The average patient age is in the early 30s, and the average tumor size approximates 3 cm. The most common clinical signs are a mass lesion, abnormal intermenstrual bleeding, and menometrorrhagia. Some examples have been incidentally noted in hysterectomy specimens removed for other reasons.

Pathologic Findings

The lesions tend to be well-circumscribed and solid with a grayish-white to yellowish-tan color, occasionally punctuated with foci of hemorrhage. Some examples are polypoid.

Histologically, the tumors contain numerous vessels, and the larger examples may have occasional well-developed fibrous septa (> Fig. 22.22). The neoplastic cells have epithelioid morphology with relatively abundant granular eosinophilic to focally clear, glycogen-rich, cytoplasm. In up to 80% of cases overall and approximately 65% of gynecologic examples, PAS-positive, diastase-resistant cytoplasmic crystals can be found (> Fig. 22.22c), and in most of the remaining cases, globular or granular cytoplasmic material with similar staining properties may be evident [225, 259]. Tumor cell nuclei are large and vesicular with prominent central macronucleoli. This process typically has a very low mitotic rate, often <1 mitotic figure/10 high power fields. The neoplastic cells may be present individually, in small aggregates, or in classic, large, alveolar-like nests.

The characteristic cytoplasmic crystals have recently been demonstrated to consist of a complex of monocarboxylate transporter 1 (MCT1) and its chaperone, CD147 [179]. By ultrastructural analysis, the crystals have an internal lattice pattern with a periodicity of ≈ 100 Å. They are usually membrane-bound, but occasionally, they may be free floating in the cytosol.

Alveolar soft part sarcoma has been shown to have a nonreciprocal translocation involving the *TFE3* gene of Xp11.2 and the *ASPL* gene of 17q25 [142, 180]. With the exception of nuclear immunoreactivity for TFE3 (the result of aberrant ASPL/TFE3 fusion protein accumulating in the nucleus) (**)** *Fig. 22.22d*) [16, 162, 267], immunostaining has little value in the diagnosis of alveolar soft part sarcoma, except to rule out other potential considerations in the differential diagnosis. The neoplastic cells are reported to be variably positive for vimentin, desmin, and actins. They are negative for chromogranin, synaptophysin, myogenin, Myo-D1, and with rare exception, S100 protein, keratins (focal +/- dot-like reactivity reported in two cases) and HMB-45 (focally positive with a negative S100 protein result in two cases) [225, 246, 267].

Differential Diagnosis

The differential diagnosis for alveolar soft part sarcoma includes paraganglioma, metastatic renal cell carcinoma, malignant melanoma, an epithelioid smooth muscle tumor, and PEComa. Paragangliomas are glycogen-poor, and they have immunoreactivity for chromogranin and synaptophysin. Rare renal cell carcinomas (encountered primarily in pediatric and adolescent patients) have the same ASPL-TFE3 gene fusion and nuclear TFE3 immunoreactivity as seen in alveolar soft part sarcoma, but in this setting, the t(X;17) is balanced, and the tumors commonly have pseudopapillary growth, psammoma bodies, renal cell carcinoma antigen expression, and in approximately half of the cases, focal reactivity for EMA or keratin [14-16]. Malignant melanomas have greater anaplasia, more obvious mitotic activity, and frequent immunoreactivity for S100 protein, Melan-A and HMB-45. Epithelioid smooth muscle tumors often have (at least focally) a spindle cell component that is lacking in alveolar soft part sarcoma, and they generally have strong reactivity for *a*-smooth muscle actin. Perivascular epithelioid cell tumors (PEComas) tend to have an admixture of spindled and epithelioid cells with pale to clear "moth-eaten" cytoplasm, and they generally co-express melanocytic and smooth muscle markers. None of the considerations in the differential diagnosis have the characteristic cytoplasmic crystals encountered in most examples of alveolar soft part sarcoma.

1188

Fig. 22.22

Alveolar soft part sarcoma. Note the nested growth pattern, high vascularity, and fibrous septa in figure (a). Figure (b) is a high power view demonstrating large alveolar-like nests of tumor cells. Note the granular eosinophilic cytoplasm with focal clearing and the large nuclei with distinct nucleoli. These tumors typically have a low mitotic rate. Figure (c) illustrates the characteristic PAS/D positive cytoplasmic crystals. Figure (d) demonstrates nuclear immunoreactivity for TFE-3

Behavior and Treatment

In most instances, alveolar soft part sarcoma is a slowly progressive disease that ultimately metastasizes to the lungs, brain and skeleton and usually proves fatal. However, there is a suggestion in the literature that examples arising in the uterine body or cervix (but not other gynecologic sites) may have a much more favorable prognosis (only one metastasis thus far reported), perhaps related to small tumor size (<5 cm) and resectability [162, 225, 267]. Before a definite statement can be made in this regard, longer follow-up is required, because for patients presenting with a localized soft tissue primary, the median interval to first metastasis in one large series was 6 years, and almost 40% of these patients did not present with metastatic disease until ≥ 10 years after initial diagnosis [192]. Before accepting an alveolar soft part sarcoma as primary in the gynecologic tract, careful clinical evaluation to rule out a metastasis is recommended. Treatment should be directed at complete resection. Evaluation of regional lymph nodes is advisable, although nodal metastases are a relatively uncommon event. The value of adjuvant therapy is uncertain.

Epithelioid Sarcoma

Defined as a distinct clinicopathologic entity by Enzinger in 1970, the classical (or "distal-type") epithelioid sarcoma is a neoplasm of uncertain histogenesis that primarily

affects individuals in the 2nd through 4th decades (mean age: 27 years) and has a strong predilection for the extremities (upper > lower), especially the distal portions [48, 80]. The tumor characteristically features an admixture of epithelioid and spindled cells with a notable tendency for pseudogranulomatous growth. More recently, a "proximaltype" variant of epithelioid sarcoma has been proposed [130, 140]. These tumors have a predilection for the truncal, pelvicoperineal and genital regions of a somewhat older age group, and they feature large atypical epithelioid or rhabdoid cells, with little tendency for pseudogranulomatous growth. Tumors in this latter category often have more aggressive clinical behavior than conventional ("distal-type") epithelioid sarcomas, and some examples have been interpreted in the literature as "atypical" epithelioid sarcomas or malignant extrarenal rhabdoid tumors [130, 252].

Clinical Features

Female genital tract epithelioid sarcomas present over a wide age range, but the peak incidence is in the 3rd through 5th decades of life [17, 130, 215, 254, 301, 305]. The tumors most commonly affect the labia majus, followed in frequency by the labia minus, clitoris, and Bartholin gland region. Clinically, the process often manifests as an asymptomatic nodular mass with a variable growth rate. Some examples mimic a Bartholin gland cyst or abscess.

Pathologic Findings

Macroscopically, the process presents as a single or multinodular fleshy, whitish mass. Foci of necrosis and hemorrhage are sometimes observed. Superficial tumors usually measure <5 cm in size, while deep-seated examples may be larger. Microscopically, classical examples of epithelioid sarcoma consist of a variable admixture of mild to moderately atypical, medium to large-sized epithelioid and plump spindled cells with a strong tendency to aggregate around zones of necrosis, necrobiosis, hyalinization or myxoid change, producing a rather characteristic multinodular, garland-like (pseudogranulomatous) growth pattern () Figs. 22.23a and) 22.23b) [48, 80]. The cytoplasm of the cells is often eosinophilic and glassy, and the nuclei are round to oval and somewhat hyperchromatic, but with a relative abundance of euchromatin. A single, relatively small but distinct, central

nucleolus is often present. Pleomorphism is usually not pronounced, but occasionally, it is evident. Some examples contain neoplastic cells with focal rhabdoid, or rarely, signet ring-like (mucin-negative) morphology. Mitotic activity varies but is generally low. Dystrophic calcification or metaplastic bone formation is noted in <20% of cases.

In contrast, most proximal-type ("large-cell" variant) epithelioid sarcomas (> Figs. 22.23c and > 22.23d) feature large epithelioid cells with abundant amphophilic or eosinophilic cytoplasm and prominent, markedly atypical, nuclei. The nuclei may be pleomorphic and hyperchromatic with small or inconspicuous nucleoli, or they may be large and vesicular with macronucleoli [130]. Some examples contain numerous cells with a rhabdoid appearance due to large hyaline cytoplasmic inclusions that laterally displace the nucleus. Multinodular and sheetlike growth patterns predominate. Necrosis is common, but pseudogranulomatous architecture is seldom observed. When intralesional hemorrhage is prominent, a pseudoangiosarcomatous pattern may be present. While rhabdoid cells can be encountered in both types of epithelioid sarcoma, they are a much more common component of the "large-cell" variant. A very rare "fibroma-like" variant of epithelioid sarcoma with relatively bland morphology, abundant collagen, and focal storiform or whorled (fibrous histiocytomalike) growth has also been described.

Epithelioid sarcomas are usually immunoreactive for vimentin, keratins (especially CK 8 and 19), and EMA, and 1/2 to 2/3 of cases express CD34 [214]. Some examples also have focal reactivity for muscle-specific actin. Classical epithelioid sarcomas are usually negative for S100 protein and desmin. Proximal-type epithelioid sarcomas immunohistochemically differ from classical (distal-type) tumors in that they occasionally have desmin expression (primarily encountered in the rhabdoid cells), and by one account, they more commonly lack nuclear immunoreactivity for INI1. [130, 217]

Differential Diagnosis

The differential diagnosis for epithelioid sarcoma revolves primarily around a granulomatous inflammatory reaction, squamous and adnexal carcinomas, malignant melanoma, and malignant extrarenal rhabdoid tumor. Epithelioid sarcoma is usually readily distinguished from a granulomatous reaction, because the latter has less pronounced mitotic activity and considerably less cytologic atypia. Mononuclear histiocytes are generally smaller in size than the tumor cells of epithelioid sarcoma, and they often have reniform nuclei and finely vacuolated or granular cytoplasm.

Epithelioid sarcoma. Figures (a) and (b) illustrate a conventional epithelioid sarcoma with a garland-like growth pattern (a) and an admixture of spindled and epithelioid tumor cells with low to moderate nuclear atypia (b). Figures (c) and (d) depict a proximal-type epithelioid sarcoma with sheet-like growth and focal necrosis. The tumor cells have abundant cytoplasm (with focal rhabdoid morphology). There is increased nuclear atypia, but nucleolar prominence was not a notable finding in this example

Multinucleated giant cells are commonly encountered in granulomatous reactions but are uncommon in epithelioid sarcomas. While epithelioid sarcomas typically express keratins and EMA, histiocytic cells (for practical purposes) lack these markers and often have reactivity for CD163, CD68 (KP-1), lysozyme and/or CD45RB.

Distinguishing epithelioid sarcoma from carcinoma can be difficult in some instances. The presence of surface epithelial dysplasia and malignant change, cytoplasmic keratinization and intercellular bridge formation, and immunoreactivity for CK5/6 (especially if widespread) and p63 are features that can help support a diagnosis of squamous carcinoma [98]. Similarly, cytologic and architectural atypia within adjacent adnexa and the identification of a tumor component with a myoepithelial immunophenotype (e.g., a combination of keratin, GFAP, actins, calponin, S100 protein and p63) can help support classification as an adnexal neoplasm. Intracellular mucin is not a feature of epithelioid sarcoma and implies glandular differentiation. Lastly, immunoreactivity for CD34 is uncommon in carcinomas but is expressed in many epithelioid sarcomas.

Malignant melanomas usually have nuclear and cytoplasmic immunoreactivity for S100 protein, and many express HMB45, Melan A, tyrosinase, and/or microphthalmia transcription factor. Malignant melanomas only rarely express keratin. Since focal, weak, cytoplasmic-only, S100 protein expression is, on rare occasion, encountered in epithelioid sarcoma, this antibody should not be used as a sole discriminator between the two entities, but instead, it should be included as one component of an immunohistochemical panel.

Malignant extrarenal rhabdoid tumor (MERT) is characterized by the presence of: (1) round or polygonal cells with abundant globular eosinophilic cytoplasm and vesicular nuclei with prominent nucleoli, (2) PASpositive hyaline or globoid intracytoplasmic inclusions, (3) immunoreactivity for keratin, EMA, and vimentin, and (4) absence of immunostaining for S100 protein (usually), desmin, MyoD1, myogenin, GFAP, and neurofilament protein. However, most experts do not regard these criteria as sufficient to define a specific clinicopathologic entity, because all of the above features may be encountered in carcinomas, mesotheliomas, and a variety of sarcomas, including synovial sarcoma and epithelioid sarcoma. It is our view that MERTs, as diagnosed in the adult segment of the population, are a heterogenous group of biologically aggressive neoplasms united by a common end-stage morphologic pattern. As a result, we rarely render this diagnosis, and only when all other alternate considerations have been exhausted. Distinguishing this process from a proximaltype epithelioid sarcoma can be extremely difficult, as there are many shared morphologic and immunohistochemical features (including loss of nuclear reactivity for INI1) [147], and this has occasionally led to the same tumor being diagnosed differently by different experts. While criteria for separating these entities are soft, the following findings favor a diagnosis of proximal-type epithelioid sarcoma: the presence of foci bearing a strong resemblance to classical-type epithelioid sarcoma and cytoplasmic immunoreactivity for CD34 and desmin [130, 243].

Behavior and Treatment

Classical (distal-type) epithelioid sarcoma often follows a rather slow but relentless clinical course punctuated by local recurrences and eventual regional lymph node and distant metastases, if incompletely excised. In the largest series to date [48], 77% of tumors recurred, 45% metastasized (most commonly to the lungs, followed in frequency by the regional lymph nodes, scalp, and bones), and 31% of patients died of disease. Factors implicated in aggressive behavior include proximal location, older age and male sex, increased tumor size and depth, high mitotic rate, necrosis, vascular invasion, and inadequate excision [30, 48, 98, 136]. Based on our review, between 40% and 50% of reported vulvar epithelioid sarcomas (most exhibited proximal-type morphology) have recurred or metastasized, and nearly 45% of patients died of disease. For classical epithelioid sarcoma, a wide or radical resection with careful evaluation of regional lymph nodes is often advocated. Encouraging results are reported in several series when surgical treatment is combined with adjuvant radiation therapy [30, 48, 136]. The role of multiagent chemotherapy is more ambiguous.

Proximal (large-cell)-type epithelioid sarcomas often behave more aggressively than classical epithelioid sarcomas [98, 130, 140]. These tumors are frequently resistant to multimodal therapy, and early tumor-related deaths are common. As such, the behavior of this tumor has notable similarities to malignant extrarenal rhabdoid tumor, and this has led some experts to regard distinction between the two as being largely academic [17].

Synovial Sarcoma

Synovial sarcomas have been documented in a wide variety of anatomic sites and organ systems, and recognition has been enhanced in recent years by the identification of a characteristic t(X;18), detectable in >90% of cases. Rare examples have involved the vulva [12, 146, 227, 324], vagina [251], fallopian tube [216], ovary [286] and true pelvis [99]. Patients with gynecologic-related tumors have ranged in age from 23 to 72 years old. Individuals with vulvar primaries usually presented in their 4th decade. These neoplasms are histologically similar to synovial sarcomas in other sites (> Fig. 22.24). They are generally classified as biphasic, monophasic fibrous, or poorly-differentiated. Tumors in the last category may be pure, but more often, they are admixed with one of the first two patterns. Biphasic examples contain epithelial cells, spindled fibroblast-like cells, and often, small numbers of epithelioid or "transitional" cells. The epithelial cells vary in appearance from cuboidal to columnar and exhibit corded, nested, or glandular growth. Monophasic fibrous tumors feature an abundance of delicate spindled cells and rare to scattered epithelioid cells, but they lack a clearly defined epithelial component. Poorly-differentiated synovial sarcomas represent a form of tumor progression, encountered in <20% of cases [312]. Relatively large epithelioid cells with increased nuclear atypia and mitotic activity usually predominate, but some poorly-differentiated tumors exhibit a small cell (Ewing sarcoma/PNET-like) pattern or a high-grade spindle cell pattern reminiscent of a malignant peripheral nerve sheath tumor [312]. Poorly-differentiated synovial sarcomas characteristically have a high mitotic index with >10 mitoses/10 HPFs.

Synovial sarcomas are usually immunoreactive for keratins (e.g., AE1/AE3, CK7, CK19), EMA, and vimentin,

Synovial sarcoma, monophasic fibrous (a–c) and biphasic (d–f) types. Note the microcalcifications in figures (a) and (c) and an admixture of spindled and epithelioid ("transitional") neoplastic cells in figure (b). The epithelioid cells typically have strong immunoreactivity for keratins (c). There is considerable variation in the morphology of the epithelial component in biphasic synovial sarcomas (d, e), but the spindled neoplastic element tends to look the same from one case to the next. Figure (f) is a keratin cocktail immunostain

and many examples express calretinin. They are typically negative for CD34. In problematic cases, FISH can be used to document gene rearrangement, and RT-PCR can be used to identify SYT-SSX fusion transcripts. Care should be taken not to confuse this neoplasm with benign processes such as endometriosis or hidradenoma papilliferum, or other malignancies of the gynecologic tract, including carcinosarcoma and adenosarcoma.

Synovial sarcomas range from intermediate to high grade. The most frequent sites of metastases are the lungs, lymph nodes, and bone. Treatment decisions are influenced by a variety of factors, including tumor size, tumor grade, patient age, and resectability [21, 127, 242]. This is one of the more chemotherapy sensitive soft tissue sarcomas [146, 216].

Angiosarcoma

Angiosarcomas only rarely affect the gynecologic tract. These tumors tend to fall into three clinicopathologic subgroups: those of vulvar and vaginal origin, uterine examples, and tumors primary to the ovaries. Angiosarcomas of the vulva/lower abdominal wall [43, 117, 131, 170, 187, 195, 248] and vagina [45, 203, 221, 306] are usually postirradiation tumors, developing 4–29 years after treatment for a carcinoma of the vulva, uterine cervix, or endometrium. Most patients are in the 7th and 8th decades of life, and they often present with a painless, purplish-red lesion in an area with radiodermatitis. The tumors may form illdefined patches or plaques, they may be papulonodular, and some examples may be ulcerated. Sometimes there is accompanying lymphedema.

Uterine angiosarcomas primarily affect peri- and postmenopausal women (peak incidence: 6th decade), and they present with vaginal bleeding, anemia, weight loss, and a pelvic/abdominal mass [212, 222, 244, 274, 328]. There is usually no history of prior radiotherapy. A few examples have occurred in association with benign smooth muscle proliferations [74, 300]. The tumors are typically large and deeply invasive on presentation.

In contrast with the other two groups, ovarian angiosarcomas primarily affect young patients between the ages of 20 and 40 years (peak incidence: 3rd decade) [62, 193, 231, 238, 244]. Abdominal pain and distention and intraabdominal hemorrhage are the key presenting features. There are no recognized predisposing factors, although rare cases have occurred in association with dermoid cysts, as well as mucinous and serous tumors [70, 159, 231, 244].

Angiosarcomas have a broad morphologic spectrum (**)** *Fig. 22.25*), but almost all cases will contain some areas with interanastomosing vasoformative channels featuring atypical endothelial cells with mitotic activity and architectural disarray (including the piling and detachment of neoplastic cells). Destructive growth and necrosis are common. Some examples feature endothelial cells with prominent epithelioid morphology, and others may have frank spindling. Immunoreactivity is usually present for CD31 and factor VIIIrAg, whereas CD34 expression is more variable. Focal keratin reactivity may be encountered, especially in epithelioid angiosarcomas.

The prognosis for angiosarcoma is generally poor, with survival time often measured in months. The best chance for cure is with small, low-stage lesions.

Malignant Peripheral Nerve Sheath Tumor (Malignant Schwannoma, Neurofibrosarcoma)

Malignant peripheral nerve sheath tumors (MPNST) have been reported in the vulva [181, 196, 302], uterine cervix [83, 166], uterine corpus, and ovaries. However, it is difficult to substantiate some of these cases, due to lack of an association with a nerve, absence of S100 protein expression and no clinical history of NF1. Without fulfilling at least one of these often used criteria, the diagnosis of MPNST is, at best, presumptive. In general, 40–50% of MPNSTs occur in the setting of NF1, although <5% of all patients with this disorder ultimately develop a MPNST [76, 149]. MPNSTs in NF1 patients arise on average more than a decade earlier than in patients without NF1 [76, 291, 319, 330], and tumors occurring in the former group are often more aggressive [76, 291, 330]. Five to ten percent of MPNSTs are radiation-induced [149, 291, 330], and this patient group also has a poorer prognosis. Most MPNSTs are associated with a major nerve trunk or arise within a large, long-standing plexiform neurofibroma. MPNSTs have a strong tendency to metastasize to the lungs, but regional lymph node metastases are very uncommon [76, 149, 330].

In the setting of NF1, MPNSTs are often heralded by rapid growth or the onset of pain in a pre-existing neurofibroma. MPNSTs of the uterine cervix may present as polypoid masses associated with abnormal vaginal bleeding.

Histologically, these tumors are either spindled or spindled and epithelioid cell neoplasms with high cellularity, nuclear atypia, and mitotic activity. Many highgrade examples have areas with geographic necrosis. Some tumors contain a peculiar glomeruloid-like vascular proliferation, and up to 10–15% of cases (all anatomic sites) are reported to have foci with divergent (usually chondro-osseous, rhabdomyoblastic, or rarely, angiosarcomatous) differentiation [76, 149]. At least half of cases are reported to express S100 protein, but this is often a focal finding [149].

Fig. 22.25

Angiosarcoma. These tumors can vary considerably in appearance, even within a given tumor, as illustrated in this example. Note the presence of vasoformative growth in figure (a) and more solid fascicular growth in figure (b) Most MPNSTs require aggressive surgical intervention with wide margins, because they have a very high local recurrence rate when incompletely excised, a low salvage rate when allowed to recur, a resistance to adjuvant radiotherapy (especially when total dosage is <60Gy) and chemotherapy, and a high mortality rate [76, 149, 291, 302, 330].

Ewing Family Tumors (EFT): Ewing sarcoma (EWS)/Peripheral Primitive Neuroectodermal Tumor (pPNET)

EFTs have been reported as primary neoplasms in the vulva [208, 275, 315], vagina [208, 315], uterine cervix [3, 42, 83, 250, 287, 307], uterine body [249, 283], ovaries [96, 164, 171], broad ligament [188], and rectovaginal septum [253]. Some of the cases are very well documented with a combination of immunohistochemistry and either molecular genetics or cytogenetic studies. Some are less well documented but contain solid presumptive evidence for the diagnosis. However, others are not convincing. A major point of confusion has been the misinterpretation of uterine and ovarian tumors with CNS-type neural differentiation as being part of this category. Classic peripheral (bone/soft tissue-type) PNET/EWSs do not exhibit mats of neuropil or ganglion cell, ependymal, astrocytic or medulloepithelial differentiation. In addition, for practical purposes (extremely rare exceptions noted), these tumors do not contain areas with frank

epithelial differentiation, although there are now several molecularly confirmed pPNET/EWSs associated with small composite areas of endometrioid adenocarcinoma in uterine and ovarian sites. Most uterine primitive neuroectodermal tumors with CNS-type differentiation that present as polypoid intracavitary masses in postmenopausal women are thought to have a Mullerian derivation [68, 143], whereas most ovarian neuroectodermal tumors with similar differentiation (especially those associated with teratoma) have a germ cell origin [164, 172, 315]. Primitive neuroectodermal tumors with CNS-type differentiation are usually CD99-negative, and they lack the characteristic cytogenetic abnormalities detected in peripheral (bone/soft tissue-type) PNET/EWSs [164, 188].

EFTs of the gynecologic tract become clinically apparent through abnormal vaginal bleeding or mass effect. The better documented cases of vulvar origin have occurred at or below the age of 40, with most examples occurring between 10 and 30 years of age. Vaginal tumors have generally been diagnosed in patients in their early to mid 30s. Cervical tumors often occur between the ages of 20 and 45. Uterine body and ovarian tumors have affected individuals from 2nd to 8th decades, but classic examples often occur before 40 years of age. Some EFTs in postmenopausal women have been associated with a minor element of (usually low grade) endometrioid adenocarcinoma [96, 283].

EFTs are typically composed of a rather monomorphic population of small epithelioid cells that vary somewhat in appearance depending on the degree of neuroectodermal differentiation (\bigcirc *Fig. 22.26*). The more primitive

Fig. 22.26

Two tumors from the Ewing sarcoma/peripheral primitive neuroectodermal tumor family. Tumors in this group form a morphologic continuum with the less differentiated neoplasms conforming to classical Ewing sarcoma morphology (a) and the more differentiated tumors with focal (pseudo)rosette formation showing progression to pPNET morphology (b)

examples with classical EWS morphology are composed of sheets of round cells with scant, clear to lightly eosinophilic, glycogen-rich, cytoplasm. Examples with classical pPNET morphology often contain slightly larger cells that may have focal tapered cytoplasmic processes or spindling and can be glycogen-poor or glycogen-negative. These latter tumors have a notable tendency to form occasional Homer Wright (pseudo)rosettes, and much more rarely, Flexner-Wintersteiner rosettes. Mitotic activity is quite variable and can be either low or high. The neoplastic cells usually exhibit strong membranous reactivity for CD99, nuclear reactivity for FLI-1, and cytoplasmic reactivity for vimentin. There can be some reactivity for synaptophysin, Leu-7, and S100 protein (especially at the pPNET end of the spectrum), and a small amount of patchy reactivity for keratins is present in >30% of cases overall. The tumor cells are typically negative for chromogranin, GFAP, desmin, and actins. Approximately 85-90% of cases harbor a t(11;22) (q24;q12) translocation (usually type 1 or 2) that fuses the EWS gene on chromosome 22 to the FLI-1 gene on chromosome 11 [188, 208]. This translocation can be detected in fresh tissue with cytogenetics. Indirect evidence of the gene fusion can also be detected in processed tissue via RT-PCR. Fluorescence in situ hybridization provides an alternate investigative approach and is of special value for the 10-15% of cases containing a variant translocation (e.g., t(21;22) (q22;q12)) that may not be detected with some RT-PCR tests. In the gynecologic tract, demonstration of one of the characteristic translocation abnormalities is the gold standard for EFT diagnosis [208].

There is speculation that EFTs of the vulva and vagina may have a better prognosis than similar tumors arising elsewhere in the gynecologic tract [208]. However, there are too few cases with too limited follow-up for any conclusive statement in this regard. EFTs are typically both chemo- and radiation therapy sensitive, and some gynecologic examples have shown dramatic response to conventional pPNET/EWS multimodality therapy [3, 253, 307].

Other Malignant or Potentially Malignant Soft Tissue Tumors that May Arise in the Gynecologic Tract

Additional soft tissue tumors that very rarely arise in the gynecologic tract include pleomorphic undifferentiated sarcoma/malignant fibrous histiocytoma [66, 232, 320], liposarcoma [34, 236, 298], osteosarcoma [69, 86, 145], chondrosarcoma [55, 299], and pleomorphic rhabdomyosarcoma [90, 245]. Before accepting any of the above as pure primary tumors, the possibility of a metastasis, direct extension from adjacent anatomy, or origin within another type of gynecologic neoplasm (e.g., a malignant mixed Mullerian tumor, teratoma, etc.) must be strongly considered. Other reported tumors include paraganglioma [58, 141, 209], (psammomatous) melanotic schwannoma [71], Kaposi sarcoma [4, 18, 177, 260], epithelioid hemangioendothelioma [294], and Langerhans cell histiocytosis [153]. In our opinion, all gastrointestinal stromal tumors (GISTs) involving the gynecologic tract must be assumed to be direct extensions from adjacent bowel or metastases [152, 327].
