Preface

The advances in the field of gynecologic pathology since the publication of the last edition of this text in 2001 have been significant and the progress that the senior editor has witnessed since the first edition of this book appeared in 1977 has been truly remarkable. To cite just one example, in the first edition, Herpes virus type 2 was thought to cause cervical cancer and the nomenclature for cervical cancer precursors was cervical dysplasia and carcinoma in situ (CIS), with the emphasis placed on the distinction of severe dysplasia from CIS since a diagnosis of severe dysplasia resulted in a cone biopsy whereas the diagnosis of CIS resulted in a hysterectomy. Since then, the terminology and, in turn, the management of the precursor lesions has evolved to cervical intraepithelial neoplasia 1-3 (CIN 1-3) with treatment of all grades of CIN, to low- and high-grade squamous intraepithelial lesions (LSIL and HSIL respectively) in which LSIL is generally not treated, as it is recognized as a manifestation of human papillomavirus (HPV) infection, whereas HSIL is managed by LEEP excision, as it is recognized as the immediate precursor of cervical cancer. Along with these changes in terminology and treatment, the recognition that high-risk human HPVs represent the etiologic agents that cause essentially all cervical and vaginal cancers and a substantial fraction of vulvar carcinomas led to the development of prophylactic vaccines in preventing HPV infections. As a consequence the management of this disease will change again. In fact, the efficacy of these vaccines in preventing cervical cancer precursors has the potential, in the future, of eradicating a cancer that affects over 500,000 women yearly worldwide and the recent award of the Nobel Prize in Medicine to Professor zur Hausen for his identification of HPV 16 DNA in cervical cancer specimens is testimony to this truly remarkable achievement.

Examination of the trajectory of advances in gynecologic pathology over the last 35 years since the first edition of *Blaustein's Pathology of the Female Genital Tract* highlights the significant contributions made by a number of different disciplines including molecular biology and epidemiology. In fact, the application of molecular biologic methods in conjunction with histopathologic classifications based on the natural history of disease ushers in a new approach for surgical pathology in general and gynecologic pathology in particular, which undoubtedly will continue to evolve in the future. Thus, the publication of this 6th edition of the Blaustein text marks the transition in diagnosis from a largely morphological activity to one based upon an integrated assessment using microscopy, immunohistochemistry and molecular biology. Finally, the emerging role of digital technology that makes an ever-increasing amount of data available at our fingertips will undoubtedly change the way we access information in the future. It is not difficult to envision that the next edition of this text will be on an electronic reader of some type instead of in the form of a textbook.

As with previous editions of the Blaustein text, the 6th edition maintains our commitment to producing a comprehensive text that covers the field of gynecologic pathology in depth while not sacrificing its utility as a "deskside" text that can be referred to in every day practice. Accordingly, significant changes have been made to inform the reader of advances in research that have occurred since the last edition while at the same time enhancing its usefulness in the everyday practice of gynecologic pathology. To accomplish this latter goal we have increased the number of photomicrographs, nearly all of which are now in color. Discussions of differential diagnosis have also been significantly expanded. Both the text and the photomicrographs emphasize the importance of immunohistochemistry and newly emerging molecular techniques as adjuncts to morphology in routine clinical diagnosis. To avoid the text becoming too ponderous we have reduced its size by asking contributors to delete sections they deemed no longer relevant while retaining older material that they regarded as "classic" or that described large series of cases with clinicopathologic data that are still relevant today. Similarly, given the ability to obtain references easily on the Internet, many older references have been deleted with emphasis on including those published since 2000. Unlike the last edition in which embryology, anatomy, epidemiology, immunohistochemistry, molecular biology and gross processing were separate chapters, these subjects have been incorporated into the individual chapters by organ site. This has resulted in a more streamlined format that integrates these various disciplines with the histopathology. Finally, two separate chapters, one on soft tissue tumors and the other on hematologic disorders involving the female reproductive organs, have been added because these are subspecialty areas in their own right and are authored by experts in these fields.

The publication of this text has depended on the assistance of many individuals to whom the authors are greatly indebted. In particular, in an effort to achieve a degree of uniformity in the quality of the images among the various

chapters, Mr. Norman Barker, Associate Professor and Director of Pathology, Digital Imaging and Computer Graphics at Johns Hopkins reviewed and digitally edited all of the photomicrographs, many of which required his considerable expertise (particularly those images that were scanned from Kodachrome slides). We feel this has been successfully accomplished and are grateful for his efforts. Finally, there are many people, including fellows, our colleagues in the Divisions of Gynecologic Pathology at Johns Hopkins and Cornell and individuals from other disciplines who, through our collaboration with them, have enhanced our understanding of the pathobiology of neoplasms of the female reproductive organs. They are far too numerous to specifically mention but their influence on us has been considerable. To all these people we wish to express our thanks.

Anatomy

The external female genitalia include the mons pubis, labia majora and minora, prepuce, frenulum, clitoris, and vestibule. The orifices of the paraurethral (Skene) and Bartholin glands, as well as those of the minor vestibular glands and the urethral meatus, open into the vestibule (> Fig. 1.1). After menarche, the mons pubis and lateral aspects of the labia majora acquire increased amounts of subcutaneous fat and develop the coarse, curly pubic hair. During adolescence, the labia develop pigmentation and the clitoris undergoes some enlargement. Histologically, the entire vulva, with the exception of the vulvar vestibule, is covered by keratinized, stratified squamous epithelium [245]. The labia majora contain both smooth muscle and fat, whereas the labia minora are devoid of adipose tissue but are rich in elastic fibers and blood vessels [167]. Within the lateral aspects of the labia majora, sebaceous glands are associated with hair follicles but open directly to the surface epithelium toward the medial aspect. Similar sebaceous glands are seen on the perineum posterior

Fig. 1.1

External anatomy of the vulva and the Hart's line. The line of Hart is the junction between the nonkeratinized mucous membrane epithelium of the vestibule, the thinly keratinized epithelium of the medial aspects of the labia minora, the posterior aspects of the labia majora, and the perineal body to the vestibule. The labia minora typically do not contain glandular elements, except sebaceous glands near the junction with the interlabial sulcus and near the inferior and lateral aspects. The apocrine glands of the labia majora, prepuce, posterior vestibule, and perineal body, like the apocrine glands of the axilla, are activated at menarche, whereas the eccrine sweat glands, primarily involved in heat regulation, function before puberty [189]. The vestibule is bounded medially by the external portion of the hymen ring, posteriorly and laterally by the line of Hart, and anteriorly by the frenulum of the clitoris. The mucosa of the vestibule is glycogenated in women of reproductive age, or under estrogen influence, and resembles vaginal mucosa. The linea vestibularis, seen in approximately one quarter of newborn female infants, is located in the posterior portion of the vestibule, and is a white streak or spot in the midline of the posterior vestibule extending nearly to the posterior commissure [109]. The squamous epithelium of the vestibule merges with the transitional epithelium at the urethral meatus, and with the duct openings of the paraurethral glands (Skene), the major vestibular (Bartholin) glands, and the minor vestibular glands.

The paired Skene's glands, homologous of the prostate in females [80], are composed of pseudostratified mucussecreting columnar epithelium, open to the external surface on both sides of the urethral meatus and along the posterior and lateral aspects of the urethra itself. The ducts are lined by transitional epithelium. The major vestibular glands of Bartholin are bilateral racemose, tubuloalveolar glands, with acini composed of simple, columnar, mucussecreting epithelium () Fig. 1.2). Each gland is drained just external to the hymen ring of the vestibule posterolaterally. The Bartholin duct, approximately 2.5 cm in length, has three types of epithelial linings depending on the location within the duct. It is lined proximally by mucus-secreting epithelium, distally by transitional epithelium, and, at its exit, by squamous epithelium. The minor vestibular glands are composed of acini lined by simple columnar mucus-secreting epithelium. They lie within 1-2.5 mm of the superficial epithelium and communicate with the vestibular surface. Squamous metaplasia often occurs within these glands and may obliterate them completely, resulting in the formation of a vestibular cleft. These minor glands ring the vestibule and extend from the frenulum on both sides of the meatus, around the external base of the hymenal ring, to the fourchette [38]. Specialized anogenital sweat glands (mammary-like) have been found within the vulvar interlabial sulcus, in the medial aspects of the labia majora, and in lesser numbers within the perineum and about the anus. These glands, with long and wide coiled ducts that

Fig. 1.2

Bartholin duct and gland. The terminal Bartholin duct has a transitional epithelial-type lining that merges with the simple columnar mucus-secreting epithelium of the Bartholin gland acini. The glands are tubuloalveolar and racemose and the surrounding fibrous stroma is somewhat more cellular than the peripheral stroma

open to the surface, have a simple columnar epithelium with apical snouts and myoepithelium beneath the glandular epithelium [232, 233].

The clitoris, which has no glands, is covered by thinly keratinized stratified squamous epithelium. Within the stroma of the clitoris are two conjoined corpora cavernosa, which branch near the base of the clitoris and lie along the pubic rami as divided crura. They are invested in a loose fibrous sheath containing abundant nerves and with an incomplete center septum. The dermis, subepithelium, and stroma of the vulva are rich in collagen, blood vessels, and myofibroblastic-type cells that are frequently immunoreactive for desmin [242]. Myxoid-like changes are present within the subepithelial stroma and have been reported extending from the ectocervix to the vulva. Atypical-appearing multinucleated cells may be observed in this subepithelial myxoid area [1]. Sparse numbers of inflammatory cells including lymphocytes, a few plasma cells, and mast cells are normally present in the perivascular spaces and interstitium.

The femoral and inguinal lymph nodes receive lymphatic drainage from the entire vulva except the clitoris, which has a minor secondary lymphatic pathway [97, 135]. Delicate intercommunicating lymphatic vessels extend to the labia minora, clitoral prepuce, and vestibule, bypassing the clitoris. The lymphatic bed of the labia

majora drains in an anterosuperior direction toward the mons, joining the lymphatic vessels from the labia minora and prepuce, and then into the ipsilateral inguinal and femoral nodes. Some contralateral flow also may occur into the superior medial nodes of the femoral group. The superficial inguinal lymph nodes, consisting of 8-10 nodes on each side, divided into a superior oblique and an inferior ventral group, are the major nodes that drain the vulva and therefore are included in a radical vulvectomy [150]. The superior oblique group is found about the Poupart ligament, and the inferior ventral group lies above the junction of the saphenous vein and fascia lata. Lymphatic drainage from the clitoris and midline perineum proceeds bilaterally in more than 67% of cases and may bypass the superficial nodes [94]. A second minor lymphatic pathway from the glans clitoris joins the lymphatics of the urethra, traverses the urogenital diaphragm, and merges with the lymphatic plexus on the anterior surface of the bladder. From there, drainage is into the internal iliac, obturator, and external iliac nodes. No direct pathway of lymphatic flow from the clitoris to the pelvic nodes could be demonstrated by in vivo colloid injection [94]. Lymphatic flow from other sites on the vulva usually proceeds to the ipsilateral groin and pelvic lymph nodes. This finding correlates with the observation that in cases of clitoral carcinoma, in which the inguinofemoral lymph nodes are free of tumor, it is highly unlikely that the pelvic nodes are involved.

The superficial and deep external pudendal arteries branch from the femoral artery. The internal pudendal arteries branch from the internal iliac arteries. These branches from the femoral and internal iliac arteries provide the major blood supply to the vulva via the anterior and posterior labial branches. The clitoris, including the crura and corpora cavernosa, is supplied separately by the deep arteries of the clitoris, whereas the anterior vaginal artery supplies blood flow to the vestibule and the Bartholin glands. The venous return parallels the arterial supply. The nerve supply to the vulva includes sensory nerves, special receptors, and autonomic nerves to the vessels and various glands. The major nerves of the vulva derive from the anterior (ilioinguinal) and posterior (pudendal) labial nerves [123]. The clitoris is innervated by the dorsal nerve of the clitoris and the cavernous nerves of the clitoris, which also supply the vestibule [212].

Developmental Abnormalities

The clitoris in an adult women measures 16.064 mm in length, with a transverse diameter of 3.46 mm and longitudinal diameter of 5.161.4 mm. It is slightly larger in parous

women. Height and weight do not influence clitoral size [236]. Clitoral hypertrophy may occur as an isolated finding or in association with generalized vulvar enlargement. Clitoral enlargement in a newborn suggests adrenogenital syndrome, exogenous maternal androgen therapy, or some form of hermaphroditism. A clitoral mass from an infant has been identified with chromosomal mosaicism in which the clitoral skin had a hyperdiploid chromosomal abnormality with normal chromosomes being found in the ovary; this is an example of ambiguous genitalia resulting from a somatic cell mutation with maldevelopment of the clitoris [211]. Clitoral enlargement also has been reported associated with lipodystrophy (Lawrence-Seip syndrome) [193]. In addition to developmental abnormalities, a variety of tumors including granular cell tumors, hemangiomas, and vascular, neural, and smooth muscle tumors may cause clitoral enlargement [171, 220].

Hypertrophy and asymmetry of the labia minora may occur without demonstrable etiology and, in some cases, may be associated with chronic irritation, as may be seen in women wearing indwelling urethral catheters. True hypoplasia occurs infrequently and may be a sign of defective steroidogenesis. Slight fusion of the labia minora may be seen in infants without apparent cause and typically responds to topical estrogen cream. Labial fusion, like clitoral hypertrophy, also may be present with intersex disorders. In these situations, the defect is developmental, but such fusion also may be acquired secondary to lichen sclerosus (LS), lichen planus (LP), or inflammatory conditions, with subsequent adhesion formation [107]. A low transverse vaginal septum may occlude the vaginal lumen and result in hematocolpos with the onset of menstruation. Excision of the septum is the usual therapy of choice. Imperforate hymen is remarkably rare, with a reported frequency of 0.014%, and usually is discovered at the onset of menarche between 10 and 18 years of age. Limited surgical excision of the hymen is the usual treatment. Duplication of the vulva is extremely rare and usually is associated with duplication of the internal müllerian system and rectum as well. In müllerian agenesis, the hymen and vagina usually are represented by only a depression in the vestibular area. Congenital absence of the clitoris and external genitalia has also been described. The urethra may open into the vagina rather than into the vestibule. Ectopic urethral orifices are seen occasionally adjacent to the hymen [107].

Inflammatory Diseases of Vulvar Skin

Inflammatory diseases of vulvar skin can be generally categorized into infectious and noninfectious groups

(**)** *Table 1.1*). Further classification of infectious diseases according to etiologic agents is summarized in **)** *Table 1.2*. The most prevalent infectious diseases of the vulva in North America include human papillomavirus (HPV), typically manifested as condyloma acuminatum,

Schistosomiasis
Demodex

HIV, human immunodeficiency virus.

Table 1.3

Infectious diseases of the vulva

Disease	Causative microorganism	Salient features	Diagnostic methods
Condyloma acuminatum	Papillomavirus	Acanthosis, hyperkeratosis, parakeratosis, papillomatosis, perinuclear halo (koilocyte)	Histopathology, Immunohistochemistry, Molecular hybridization
Herpes genitalis	Herpes simplex hominis type II	Intranuclear inclusions	Cytopathology, culture, serology, Immunohistochemistry
Syphilitic chancre	Treponema pallidum	Ulceration, chronic inflammation, vasculitis	Dark-field, fluorescence, silver stain, serology
Condyloma lata	Treponema pallidum	Like chancre, with epithelial hyperplasia	Same as syphilitic chancre
Molluscum contagiosum	DNA poxvirus group	Intracytoplasmic inclusions	Cytopathology, histopathology
Granuloma inguinale	Calymmatobacterium granulomatis	Donovan bodies, granulomatous reaction without caseation, pseudoepitheliomatous hyperplasia	Giemsa stain, silver stain
Lymphogranuloma venereum	Chlamydia (TRIC agent)	Granulomatous reaction without caseation	Serology
Tuberculosis	Mycobacterium tuberculosis	Acid-fast bacilli (AFB), granulomatous reaction with caseation	AFB stain, AFB culture, PCR
Chancroid	Hemophilus ducreyi	Granulomatous reaction without caseation	Culture, Gram stain

herpes genitalis, syphilis, and molluscum contagiosum (**>** *Table 1.3*). Clinical diagnosis does not necessarily require specific organism characterization in all these conditions.

Human Papillomavirus Infection

General Features

Human papillomavirus (HPV) infection is responsible for benign tumors, that is, condylomata acuminata and precursor lesions of certain types of vulvar carcinoma (i.e., vulvar intraepithelial neoplasia, VIN) [56, 118, 185]. (The latter types are described in **2** Chap. 2, Premalignant and Malignant Tumors of the Vulva.) Condylomata acuminata (genital warts) are predominately sexually transmitted benign neoplasms that may involve the vulva, vagina, cervix, urethra, anal canal, and perianal skin [164]. The prevalence of HPV infection varies greatly, depending on the population studied. In most studies, clinically evident vulvar involvement is less common than cervical HPV infection [69, 124]. Molecular biologic methods have identified HPV-6 as the most common HPV type in typical genital condylomata acuminata. HPV-11 has been found in approximately one fourth of genital warts [25, 255]. These two HPV types are responsible for over 90% of condyloma acuminata.

Clinical Features

Condylomas present as papillary, verrucous, or papular lesions of the skin and mucous membrane that are nearly always multiple and frequently confluent (\bigcirc *Fig. 1.3*). Most lesions are asymptomatic unless secondarily infected. Condylomata acuminata are commonly associated with vaginitis, pregnancy, diabetes mellitus, oral contraceptive use, poor perineal hygiene, immunosuppression, and sexual activity with multiple partners or a partner exposed to other partners [8, 39, 151, 169]. Approximately 30–50% of women with vulvar condyloma acuminatum have associated cervical HPV infection [240]. The presence of vulvar condyloma acuminatum in children may be related to sexual abuse [58, 163, 254].

Approximately 40–60% of children with laryngeal papillomatosis are born from mothers with a history of genital HPV infection [70]. However, the true incidence of infection of the larynx of the newborn infant, from a mother with genital papillomavirus infection is

Fig. 1.3 Condylomata acuminata. Involvement of vulva and perianal region

unknown but is probably low. No correlation has been shown between the volume of maternal wart tissue and occurrence of infantile laryngeal papillomatosis. Employing DNA hybridization techniques, it has been observed that approximately one half of laryngeal papillomas contain HPV-11 [59, 216]. This finding supports the view that laryngeal papillomas of infancy and childhood are acquired at the time of vaginal delivery.

Gross Findings

Condylomata acuminata usually present as discrete papillary growths, with a central stalk or as large sessile lesions. On the cervix, vagina, or vulva, condyloma acuminata may present as slightly raised rough areas with irregular borders. Small lesions are best appreciated with application of 3–5% acetic acid for 3–5 min on colposcopic examination. Lesions that are detectable by colposcopic

Fig. 1.4 Condyloma acuminatum. Verrucous epidermal hyperplasia with broad rounded papillation

magnification only, or by performing HPV testing on the tissue in question, are considered subclinical [48, 91].

Microscopic Findings

Acanthosis, dyskeratosis, parakeratosis, hyperkeratosis, and a prominent granular layer are seen. A superficial chronic inflammatory infiltrate often is present in the dermis. Typical perinuclear cytoplasmic "halos," with "raisinoid" pyknotic nuclei or slightly enlarged nuclei (koilocytosis), are commonly present in the superficial epithelial cells, and binucleated and multinucleated squamous cells often are found (\bigcirc *Figs.* 1.4 and \bigcirc 1.5). Parabasal hyperplasia with accentuated intracellular bridges may be seen. Enlarged parabasal cells with "foamy" or "ground glass"-appearing nuclear chromatin may be present. In situ hybridization studies on cervical tissue have demonstrated the presence of HPV DNA in condylomata [159].

Fig. 1.5

Condyloma acuminatum. Parabasal hyperplasia is present. Above the basilar layer, koilocytotic cells with prominent perinuclear halos are found in the more superficial epithelium

Differential Diagnosis

Condylomata acuminata at times may be difficult to distinguish from VIN. Condylomata typically are verrucous or papillary and display koilocytosis, parabasal hyperplasia, accentuated intracellular bridges, dyskeratosis, accentuation of the granular layer, and hyperkeratosis. Mitotic figures are infrequently found. In contrast, the presence of flat macular growth, abnormal mitoses, cytologically atypical nuclei, marked variation in nuclear size and shape, and hyperchromasia are characteristics of VIN lesions. Unlike VIN, condylomas usually are diploid; however, atypia may be seen related to tetraploidy or octoploidy. Unlike VIN, this atypia is characterized by large nuclei, with moderate nuclear pleomorphism and some degree of hyperchromasia, but without abnormal mitosis. A high-grade VIN lesion induced by oncogenic HPV often correlates with aneuploidy [153, 194], which is rare in common condyloma.

Typical condylomas will be HPV antigen positive by immunoperoxidase techniques in approximately 50% of cases, whereas VIN will be immunoreactive in less than 10% of cases; however, such testing is not of value in distinguishing these two entities [98]. In a given case of VIN, a spectrum may be found from typical VIN 3 to adjacent changes that may have the morphologic changes of condyloma acuminatum. As a matter of practice, the first diagnosis given on the pathology report is that of the most serious lesion identified, with subsequent diagnosis following. In our present state of understanding, it is acceptable to classify flat condylomata acuminata (condyloma plana) of the vulva as VIN 1 (see **2** Vulvar Intraepithelial Neoplasia in Chap. 2). Regressing or early flat condylomata acuminata also may resemble lichen simplex chronicus (LSC) or squamous cell hyperplasia; however, the prominent granular layer, accentuated intracellular bridges, parabasal hyperplasia, and koilocytosis are typically lacking. If this cannot be resolved by histopathologic examination, molecular biologic methods such as Hybrid Capture 2, polymerase chain reaction (PCR), or in situ hybridization, to detect HPV, may be applicable and are of value in establishing the diagnosis of HPV-associated changes when virus is identified [86].

Vulvar vestibular papilloma is differentiated from condylomata in that the epithelium lacks hyperkeratosis and other typical microscopic features of condyloma. Moreover, vestibular papilloma are confined to the vulva vestibule [17, 77]. Fibroepithelial polyps may have the shape of large condylomas; however, the epithelium also lacks the microscopic features of condyloma. Condylomata lata may resemble condylomata acuminata clinically; however, on biopsy, the deep inflammatory infiltrates with plasma cells and the presence of spirochetes on a Warthin–Starry silver stain distinguishes these lesions.

Clinical Behavior and Treatment

The natural history of HPV infection of the vulva usually is one of a long protracted course and may be influenced by immunologic factors [6]. Regression has been noted after pregnancy. Presentation following radiation therapy has been observed [169]. Progression of condyloma acuminatum of the vulva to VIN and malignant transformation to squamous cell carcinoma have been observed [227]. Oncogenesis secondary to papillomavirus is well recognized in experimental animals. The association of vulvar and vaginal condylomata acuminata with invasive squamous cell carcinoma has been documented in women with immunosuppressive conditions such as Fanconi anemia and Hodgkin disease [242] (see **O** Chap. 2, Premalignant and Malignant Tumors of the Vulva).

The topical application of dilute podophyllin [21] or the judicious application of concentrated halogenated acetic acid (trichloroacetic acid) is the common approach to the treatment of small vulvar condylomata. Electrodesiccation, surgical excision, cryosurgery, hot wire electroloop excision, laser ablation, and interferon have been used for large lesions [6, 23, 49, 116, 206, 239].

Herpesvirus Infection

General Features

The causative agent is the herpes simplex virus (HSV) (var. hominis type 2), although in some instances the type I virus may be involved. The incidence of herpesvirus infection in the USA has been reported as 126 per 100,000; approximately 600,000 new cases of genital herpes occur each year in the USA. The prevalence of the HSV-2 antibody among women in the USA is 26%, although genital herpes has been diagnosed in only a small proportion (10–25%) of individuals with HSV-2 antibodies. Herpes simplex virus type I is becoming a more frequent cause of genital herpes, especially among young women. Although approximately 20% of the US population has been infected by HSV 2, the frequency of vulvar involvement is unknown [3, 127, 137, 161].

Clinical Features

The initial clinical presentation frequently includes dysuria or urinary retention with vulvar pain that may be incapacitating. Systemic symptoms, including generalized malaise and fever, are frequently seen along with a mild inguinal lymphadenopathy. The sequential appearance of vesicles, pustules, and painful shallow ulcers that often are infected secondarily with bacteria characterize the clinical findings. The vesicles usually are asymptomatic, whereas the ulcers are extremely painful (> Fig. 1.6). The lesions can involve the anus, urethra, bladder, cervix, and vagina, as well as the vulva. The acute ulcers heal in approximately 16 days [137, 234]. Of the women who are culture positive for HSV, diagnostic genital vesicles and ulcers are present in approximately two thirds; the remainder of the women have nondetectable or atypical lesions or are asymptomatic [122, 234].

Microscopic Findings

An early intact herpes simplex vesicle extends deeply into the epidermis. The histologic transformation of the HSVinfected epithelial cell begins with a homogenization of the nuclear chromatin resulting in a "ground glass" appearance, which then progresses to the more typical eosinophilic intranuclear inclusion body [75]. The characteristic intranuclear inclusions are seen at the periphery of the lesion (\bigcirc *Figs.* 1.7 and \bigcirc 1.8). Subsequently, the cells undergo karyorrhexis and lysis. A biopsy taken in the late ulcerative phase, therefore, does not always show the intranuclear inclusions. Cytologic evaluation of the scraping of the base and edges (Tzank preparation) of a fresh ulcer, or freshly opened vesicle, usually will show the multinucleated cells with viral cytopathic effects characteristic of HSV infection. Cytologic examination of vesicular aspirate is an effective method of identifying the cytopathic changes of HSV and is almost as sensitive

Fig. 1.6

Fig. 1.8

Herpes simplex. High-power view of viral-infected cells with multinucleation and homogenized "ground glass" intranuclear viral inclusions

as virus isolation. Moistening the ulcer with a salinesoaked sponge and then scraping the ulcer with a wooden spatula may improve the diagnostic yield from ulcerative lesions. Whether the sample is from an ulcer or a freshly opened vesicle, the specimen should be smeared on a clean slide, rapidly fixed in 95% ethanol, or with spray fixative, and stained with Papanicolaou stain. Morphologic changes seen with HSV infection are not reliable in separating primary from secondary infection or in distinguishing HSV type I from type II infection. Development of serologic assays to detect antibodies to herpes simplex virus (HSV) glycoproteins (g)G1 and (g)G2 has allowed accurate definition of the seroprevalence of HSV-2 from HSV-1. Furthermore, herpes zoster can involve the vulva and may have similar cytologic findings.

Adjunctive Methods

HSV-specific fluorescein conjugated antiserum may be placed on smears of ulcers or vesicles to identify HSV antigens. Immunoperoxidase techniques, employing HSV-specific antibodies, may be of value if the histopathologic findings are nonspecific and can be employed on paraffin-embedded tissue. Isolation of HSV, whether type I or type II, can be achieved by the inoculation of tissue culture monolayers, such as WI-38 human embryonic lung fibroblasts or monkey kidney cells. Both types of HSV produce characteristic cytopathic changes on these cell lines, which are confirmed by direct immunofluorescence employing monoclonal antibodies to HSV [122]. Virus isolation can be achieved within 4 days [249]. Rapid viral culture over 24 h, followed by a search for HSV antigen using an immunoperoxidase technique, can give results in less than 2 days.

Polymerase chain reaction (PCR) technique, employing HSV-specific primers, is another approach to the positive identification of HSV infections [52, 199, 225]. Serologic studies on acute and convalescent serum samples are of value in distinguishing primary from recurrent infection. In primary infection, significant rises (more than fourfold dilution) are found. In recurrent infection, the patient is seropositive at presentation and antibody titers will not rise consistently. Serologic methods are not reliable in separating HSV type I from type II [249]. Asymptomatic viral shedding of HSV has been documented in 1.5–3% of women who are seropositive for HSV type II [122]. HSV infection may have some oncogenic potential; however, this relationship remains to be defined [100, 117].

Clinical Behavior and Treatment

Recurrent episodes of herpatic vulvitis are common after primary infection; recurrences decrease in frequency over time, whether or not acyclovir is given prophylactically. Acyclovir may reduce the severity of infection if given early in the course of illness [107, 137].

Varicella (Herpes Zoster) (Vulvar Shingles)

Varicella infection of the vulva is rare. The prodromal pain within the vulva, without apparent physical findings, may simulate vestibulitis. The subsequent development of vesicles and ulcers assists in making the distinction because vestibulitis is not associated with vesicles and ulcers. The patients usually are postmenopausal or immunosuppressed, and the vesicles are characteristically unilateral [11, 111]. The cytologic findings from scrapings of opened vesicles, as well as the histologic findings, are those of a herpesvirus infection. Therapy with famciclovir is reported to reduce pain significantly if begun within 48 hours of the presentation of the rash [175, 230]. The protracted neuralgia and recurrent bouts of vesicles are as described for shingles.

Cytomegalovirus Infection

Cytomegalovirus (CMV) vulvitis, like herpes type II vulvitis, presents with an ulcerated vulvovaginitis.

The histopathologic findings are similar, although the viral inclusions are both intranuclear and intracytoplasmic. Viral inclusions also may be seen involving vascular endothelial cells, as well as the epithelial cells. CMV infection has been associated with vulvar ulcers in a woman with acquired immunodeficiency syndrome (AIDS). Culture or immunoperoxidase studies using specific antibodies to CMV, or PCR employing CMV-specific primers, are necessary to establish the diagnosis [71].

Epstein–Barr Virus Infection

Epstein–Barr virus (EBV) has been cultured from painful ulcers on the labia minora during primary infection of infectious mononucleosis. The ulcers slowly healed over a few weeks [223]. EBV infection may be a sexually transmitted disease [223].

Molluscum Contagiosum

Molluscum contagiosum is a moderately contagious viral disease that, in adults, is often related to intimate or sexual contact [67]. Molluscum contagiosum usually is asymptomatic; however, perianal lesions frequently become pruritic or secondarily infected. The lesions are small, smooth papules (3–6 mm in diameter) with a central punctum or umbilication. They generally are multiple and separate, although they may be single. Rare plaque formations, made up of 50–100 individual clustered lesions, also have been described. The incubation period varies between 14 and 50 days. Clinical diagnosis usually does not require biopsy.

Cytologic identification of the typical eosinophilic intracytoplasmic inclusion bodies (Henderson-Paterson bodies) within scrapings from the interior of the molluscum papule is adequate to confirm the diagnosis. Histologic examination demonstrates marked acanthosis and the characteristic intracytoplasmic viral inclusions in recent infections (**>** Figs. 1.9 and **>** 1.10). With aging, the cytoplasmic bodies take on a more basophilic appearance preceding lysis of the cell [67]. The central dimple of the lesion is seen histologically if the lesion is carefully bisected. Within the dermis, there often is a marked vascular response with endothelial proliferation and perivascular inflammation. Electron microscopy has demonstrated that the virus is spherical, ellipsoidal, or brick shaped and contains a DNA core with a two-layered protein coat measuring 210-300 nm [148]. Most lesions regress spontaneously; untreated lesions may persist for

years, during which time they may be spread by close contact or autoinoculation.

Syphilis

Clinical Features

Syphilis is a venereal disease caused by the spirochete Treponema pallidum. The primary lesion is the chancre, a painless, indurated, shallow, clean-based ulcer with raised edges. The chancre usually presents within 3 weeks after initial contact; the range, however, is 7-90 days. If secondarily infected, the chancre may become soft and painful and show an ulcerated surface. Although chancres are generally single, they may be multiple. Chancres may occur on inconspicuous surfaces, such as the cervix, anal mucosa, or oral pharynx. In approximately 50% of women and 30% of men the primary lesion is never seen. Lymphadenopathy presents 3-4 days after the chancre. The nodes are nontender, freely movable, and rubbery [27]. Left untreated in the primary phase, the chancre will heal within 2-6 weeks and typically does not leave a scar [155, 244]. The secondary stage of the disease will become evident within 6 weeks to 6 months. At this point, the patient may present with a skin rash that often involves mucous membranes as well as the palms of the hands and soles of the feet [27]. On occasion, the secondary lesions are papular, especially about the vulva, presenting as elevated plaques up to 3 cm in diameter. These are known as condylomata lata, which clinically may mimic condylomata acuminata (**)** Fig. 1.11). Such lesions also may occur on other mucocutaneous borders. The tertiary gumma of syphilis is rarely seen on the vulva.

Microscopic Findings

If syphilis were not considered in the clinical differential diagnosis, the diagnosis may be quite difficult from histologic material alone. The primary chancre is characterized by ulceration of the epidermis with acute and chronic inflammation within the dermis. There is a marked perivascular inflammatory response, characterized by the presence of large numbers of plasma cells. Histologic examination of condylomata lata reveals marked acanthosis and hyperkeratosis (\bigcirc *Figs. 1.12* and \bigcirc *1.13*). The inflammatory response within the dermis is similar to that in the primary chancre with a marked, predominantly plasma cell inflammatory infiltrate. The arteritis in both lesions may be sufficiently severe to result in obliteration of the smaller vessels. Dieterle, Warthin–Starry, or Steiner

stains for spirochetes are always of value if there is any suspicion of syphilis (**>** *Fig. 1.14*), but may be negative with active infection. Serologic studies for syphilis should be performed if syphilis is considered clinically or from the pathologic findings [165].

Fig. 1.11 Condyloma lata. Multiple papules are present

Fig. 1.12

Condyloma lata. Marked psoriasiform epidermal hyperplasia with scales in the cornified layer. (Courtesy of R.J. Kurman, M.D., Baltimore, MD.)

Adjunctive Methods

The primary chancre, as well as the condyloma latum and other secondary lesions, are rich in spirochetes. Therefore, when a chancre or secondary lesion of syphilis is suspected, an attempt to identify spirochetes within the lesion should be made. This examination is accomplished either through dark-field examination of serum expressed from the base of the ulcer or by the fluorescent conjugated antibody technique, which employs a dried smear preparation. The organism measures up to 15 mm in length and 0.20 mm in thickness; it is spiral in shape, with 6–14 coils. Motility, characterized by flexion, rotation about the long axis, and random movement are noted on darkfield examination of fresh sera from an active lesion.

Fig. 1.13

Condyloma latum. Prominent acanthosis is present with a marked dermal perivascular inflammatory cell infiltrate that consists primarily of plasma cells and lymphocytes, with some neutrophils These methods for identification of spirochetes are far more sensitive and specific than is silver stain on paraffin-embedded tissue. The chancre may be present for weeks before serologic tests become reactive. More than 70% of patients with dark-field-positive lesions have a reactive serology at the time of initial diagnosis. The most common serologic testing methods are based on the identification of reagin. These tests become positive approximately 1 month after the disease is contracted. Common reagin testing methods employ microflocculation testing and include the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) [252]. These two tests have similar specificity and can be quantitated to evaluate the course of the disease and response to therapy. The fluorescent treponemal antibody-absorbed (FTA-ABS) test, still the "gold standard," is highly sensitive and is ordered if the reagin tests are nonreactive, weakly reactive, or if there is a possibility of a false-positive result. Biologic false positives can occur in lupus erythematosus, virus infection, cirrhosis of the liver, pregnancy, malaria, and other inflammatory or autoimmune diseases. Treponemal enzyme immunoassays (EIAs) are an appropriate alternative to the use of combined Venereal Disease Research Laboratory/rapid plasma

• Fig. 1.14 Secondary syphilis. Warthin–Starry stain shows spirochetes in the dermis

reagin and Treponema pallidum hemagglutination assay (TPHA) tests for screening for syphilis. If a treponemal EIA is used for screening an alternative treponemal test, such as TPHA, should be used for confirmatory testing. The fluorescent treponemal antibody-absorbed test is probably best reserved for specimens giving discrepant results [64].

Once the FTA-ABS becomes positive, it can remain so forever in the life of the patient. Although newer technologies, such as PCR and immunoblotting, have been used in detection of syphilis, serologic tests with RPR/ VDRL and FTA-ABS are still the current tests of choice [252]. If the FTA-ABS is positive, spinal fluid serologic evaluation will be necessary to rule out neurosyphilis. A false-positive FTA-ABS is rare and, if detected, requires *T. pallidum* mobilization testing and careful follow-up [155].

Clinical Behavior and Treatment

Approximately 30% of patients with primary syphilis will undergo spontaneous remission of the disease. Those who are not treated or who do not achieve spontaneous remission may progress to tertiary syphilis with its wellrecognized cardiovascular and central nervous system effects. Untreated syphilis may prove fatal in 10% of those afflicted. Penicillin or another appropriate systemic antibiotic is the treatment of choice.

Granuloma Inguinale

Granuloma inguinale (donovanosis; granuloma venereum) is caused by Calymmatobacterium granulomatous, a gramnegative, heavily encapsulated rod considered to be in the bacterial family Enterobacteriaceae. Granuloma inguinale occurs with approximately equal frequency in men and women. Primary lesions may occur on the vulva, vagina, or cervix and may present as painless papules or necrotizing ulcers with rolled borders and a friable base. Inguinal adenopathy usually is absent [26]. The lesions usually appear within 1 week to 1 month of exposure; anal coitus or fecal contamination of the vulva or vagina has been incriminated as the mode of transmission [155, 244]. Granuloma inguinale extends primarily by local infiltration, although lymphatic permeation may occur during later stages of the disease. Chronic lymphatic infiltration and fibrosis frequently result in a massive brawny edema of the external genitalia. There is controversy as to the true origin of the edema, because dye injection studies suggest that the lymphatic drainage is intact. With involvement of the cervix, the disease may advance via the cervical lymphatics to involve parametrial tissue [191].

The clinical diagnosis of granuloma inguinale depends on the identification of the Donovan bodies within the tissue; this is best accomplished by preparing smears or a biopsy from the edge of the ulcer and pressing this biopsy tissue between two slides. The tissue imprints are air dried, fixed in methanol, and stained with Giemsa stain. Any antibiotic treatment may obscure the diagnosis, necessitating biopsy at a later date to identify organisms. Histologically, the main portion of the lesion consists of granulation tissue associated with an extensive chronic inflammatory cell infiltrate and endarteritis. An ulcer usually is covered with a fibrinous exudate, and necrosis may be present. The surface epithelium, adjacent to the ulcer, may show prominent pseudoepitheliomatous hyperplasia. Necrosis and microabscesses may be seen within the epidermis [191]. Within the granulation tissue there is a dense mixed inflammatory cell infiltrate, consisting predominantly of plasma cells and mononuclear cells with few lymphocytes, which extends into the dermis. Large vacuolated histiocytes that contain the characteristic encapsulated bacilli, Donovan bodies, within their cytoplasm frequently are present () Fig. 1.15); they can be demonstrated with a Warthin-Starry stain or Giemsa stain. The Donovan bodies may be found extracellularly, as well as intracellularly, and may appear coccoid, coccobacillary, or bacillary [26, 191]. Ultrathin plasticembedded sections, as well as electron microscopy, may be of value in diagnosis [26, 191].

Calymmatobacterium granulomatous may be cultured by special techniques. The diagnosis depends on the clinical findings and documenting the organism within a tissue specimen or by culture. Syphilis, chancroid, and herpesvirus infection usually are included in the differential diagnosis [113].

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is caused by Chlamydia, and occurs approximately three times more frequently in men than in women. The disease has three phases: (1) erosion of the skin, (2) adenitis, and (3) fibrosis and destruction [26]. Lympho-granuloma venereum is spread primarily via the lymphatics. The initial ulcers, which generally are not tender or painful, often are ignored. Adenitis may evolve into painful superficial groin nodes, or buboes, that frequently rupture through the skin with exudation of a purulent discharge. The third phase of the disease often results in stricture and fibrosis of the vagina and rectum [246]. During this phase, chronic lymphatic obstruction is responsible for the characteristic nonpitting edema of the external genitalia. The histology of LGV is not diagnostic and reveals no characteristic identifiable organisms by the usual modes of investigation. Smears and biopsy specimens should be evaluated for organisms (spirochetes, Donovan bodies, etc.) to rule out other diseases with a similar presentation. Histologically, giant cells may be seen along with lymphocytes and plasma cells (> Fig. 1.16). Older lesions may exhibit extensive fibrosis of the dermis and sinus tracts. The diagnosis is based on the typical clinical presentation, along with positive complement fixation tests. Culture, as well as other specific immunohistochemical tests, can assist in the diagnosis of LGV. Treatment is systemic tetracycline or doxycycline [155, 244].

Chancroid

Chancroid is relatively rare and presents with a genital ulcer that usually is tender, nonindurated, and has a friable purulent erythematous base. Primary lesions may be single or multiple and tend to be small, measuring approximately 1–2 mm in diameter. Coalescence of the lesions leads to ulcers approaching 3 cm in diameter. Tender inguinal adenopathy with flocculent nodes may be present. The incubation period may be as short as 10 days [228]. The clinical differential diagnosis includes

Fig. 1.16 Lymphogranuloma venereum (LGV). An intense superficial and deep chronic inflammatory infiltrate is present, composed predominantly of lymphocytes and plasma cells

herpesvirus infection and primary syphilis [113, 228]. Chancroid is caused by the organism Haemophilus ducreyi, a gram-negative, nonmotile bacillus, which in culture grows in pairs and parallel chains. Skin tests and biopsies may not be diagnostic. Identification of the organism by culture is necessary for accurate diagnosis [228]. Selective agar medium has been developed for the organism, which has improved culture isolation. Recent advances in nonculture diagnostic tests using PCR have enhanced our ability to diagnose chancroid [170, 228]. Histologic examination of the tissue demonstrated a granulomatous-type reaction with chronic inflammatory cells consisting primarily of lymphocytes and plasma cells, and the presence of the gram-negative organisms, which may be present in large numbers and in parallel chains [112].

HIV-Associated Vulva Ulcers

Human immunodeficiency virus (HIV) infectionassociated vulva ulcers are usually painful and multiple. A recent study revealed that about 60% of vulva ulcerations have no proven etiologic agent. The rest of the patients are positive for HSV II, unusual or mixed bacteria, and rarely cytomegalovirus, *Chlamydia trachomatis*, and *Gardnerella vaginalis*. Human immunodeficiency virus may play a local role in causation or exacerbation [126].

Vulvar Apthosis

Vulvar apthus ulcers have been reported, but are rare. Vulvar apthosis manifests as painful, shallow ulcers typically with a gray-white base. Most ulcers are less than 5 mm and heal within 7 to 10 days. These ulcers as with oral aphthae, have a much higher predilection for white adolescents who are not sexually active. As with oral apthosis, the etioology is unclear. Risk factors for these ulcers include stress, infections, vitamin deficiency, and family history [95].

Tuberculosis

Tuberculosis of the vulva is rare. It usually is associated with tuberculosis of other genital sites, primarily the fallopian tube, and endometrium. Genital involvement usually is associated with pulmonary tuberculosis. Autoinoculation by hematogenous or direct spread therefore is the most common method of transmission to the vulva. Primary inoculation or sexual transmission of tuberculosis is very uncommon. Immunosuppression may play a role in susceptibility, as a case of vulvar tuberculosis has been described in a renal transplant patient [224]. The usual organism is Mycobacterium tuberculosis; however, atypical mycobacteria also have been incriminated. Diagnosis usually can be made by biopsy of the involved tissues. Caseating granulomas with Langhans giant cells are found, and acid-fast stains usually reveal the mycobacterium (> Fig. 1.17). Confirmation of the diagnosis can be made by culture techniques. Appropriate long-term systemic antibiotics are the recommended therapy. Giant cells of the foreign body type are encountered frequently in vulvar tissues in which a previous biopsy has been performed. These giant cells, associated with noncaseating granulomas, often result from embedded suture occasionally seen in prior biopsied areas, and should not be confused with tuberculosis. Vulvar

Fig. 1.17
 Vulvar tuberculosis. Caseating granulomas with Langhans giant cells

ulceration, secondary to sarcoidosis, has been reported and should be included in the differential diagnosis of granulomatous ulcerations of the vulva [54, 114].

Fungal Infection and Miscellaneous Infectious Diseases

Chronic inflammatory conditions of the vulvar and perianal skin without concomitant ulceration often are caused by fungal infections, although a variety of irritants, unrelated to infection, may be responsible [144]. Candida and dermatophytes are frequent pathogens. Such conditions rarely require biopsy, and accurate diagnosis generally can be accomplished by microscopic examination of skin scrapings placed in 10% potassium hydroxide, or by appropriate culture methods. Topical antifungal creams are the usual therapy. Chronic and acute vaginitis related to trichomonas, Chlamydia, Candida species, or other infectious agents may be associated with inflammation of the vulva, especially the vulvar vestibule. The histologic findings usually are not diagnostic. Vulvar candidiasis usually can be diagnosed by employing silver stains for fungus, with recognition of the fungal organisms within the keratin, or superficial epithelium. Bacterial infections may produce clinical findings similar to those seen with fungal infections.

Erythrasma is a chronic bacterial infection of the genitocrural area that shows a coral-red fluorescence under Wood's light. The disease is most common in obese diabetes. Scrapings of these lesions, when stained with Gram stain, demonstrate the causative gram-positive bacteria, *Corynebacterium minutissimum*, in rods, filaments, and coccoid forms [113].

Parasitic Infections

Enterobius vermicularis (pinworm, seatworm) is a relatively common intestinal parasite. The female worm measures 8-13 mm in length and 0.5 mm in diameter. The male is approximately one fourth as long as the female, with the same diameter. Infected children frequently present with complaints of severe vulvovaginal pruritus, which may awaken them at night. Other complaints include lower abdominal pain, diarrhea, restlessness, and nocturia. Studies for fungus and bacteria are not diagnostic, and examination of the vulvar vestibule and vagina reveals marked inflammation. Occasionally, an adult female helminth found on the vestibule or perineal areas is brought to the laboratory. More commonly, the pathologist is presented with a cellulose-tape-slide preparation for identification of the typical embryonated eggs of E. vermicularis. A granuloma secondary to Enterobius eggs has been reported involving the vulva [222]. Vulvar schistosomiasis, usually Schistosoma mansoni, is well documented, and primary skin lesions on the vulva from penetration of the infective cercariae may be seen. When biopsied, the parasite may be found within the epidermis [146]. Cutaneous myiasis of the vulva, secondary to infestation of the larval form of the muscoid fly and sarcophaga, has been reported. Recognition of the larva extracted from the vulvar tissues is diagnostic [43, 119].

Noninfectious Papulosquamous Dermatoses

Papulosquamous dermatoses often have a common component of epidermal hyperplasia in which the hyperplasia is somewhat psoriasiform. **>** *Table 1.4* summarizes most of the entities in this group.

To establish a standardized system of nomenclature based on histopathological findings, the International Society for the Study of Vulvovaginal Disease (ISSVD) and International Society of Gynecological Pathologists (ISGP) recommended that all lesions be classified as nonneoplastic epithelial disorders or as lichen sclerosus, or other dermatoses. Diagnoses as kraurosis vulvae, leukoplakia, and atrophic vulvitis have generally been abandoned. Historically, the term dystrophy was proposed to describe a clinically related group of disorders of vulvar epithelium, which presented as white lesions, and that

Table 1.4

Noninfectious papulosquamous disorder

Seborrheic dermatitis	
Spongiotic dermatitis Acute, subacute, and chronic atopic/contact dermatitis Irritant contact dermatitis Eczema	
Nutritional deficiency

Lichen simplex chronicus (LSC)	
Lichen planus (LP) (hypertrophic form)	
Lichen sclerosis (hypertrophic form)	
Acanthosis nigricans	

microscopically were characterized by benign alterations of the epithelial and dermal architecture. Two basic clinical varieties of dystrophy were recognized by the ISSVD in 1976: lichen sclerosus and hyperplastic dystrophy. When both clinical varities coexisted on different areas of the same vulva, it was recommended that the lesion be classified as a mixed dystrophy. The term mixed dystrophy is now recognized to refer to lichen sclerosus associated with variable lichen simplex chronicus and this reflects the spectrum of changes seen in lichen sclerosus, rather than the presentation of two distinctive epithelial disorders. The various forms of nonneoplastic epithelial disorders of the vulva cannot be reliably distinguished on the basis of their clinical appearance alone; all may be white, scaly, and fissured (> Fig. 1.18). Although biopsy may not be necessary in all cases, especially in children with typical findings of lichen sclerosus, one or more biopsies to sample the entire lesion usually are very informative. On the basis of the histologic findings, the pathologist can separate white lesions of a neoplastic type from nonneoplastic epithelial disorders.

Lichen Sclerosus (Lichen Sclerosus et Atrophicus)

Clinical Features

The term Lichen Sclerosus Atrophicus is now referred to as Classic Lichen Sclerosus [102].

In children, symptoms include dysuria, painful defecation, and rectal bleeding [20, 181]. Lichen sclerosus can lead to anal fissures and strictures and to genital and perianal ulcers, which may resemble evidence of child sexual abuse. In adult women, the clinical findings typically include thinned and whitened epithelium, which usually is symmetric and involves the labia minora, clitoris, prepuce, frenulum, perineal body, and vulvar vestibule. Perirectal involvement is common. In advanced cases, loss and agglutination of the labia minora, frenulum, prepuce, and adhesions of the clitoris are found [181]. Stenosis of the introitus is common. In men, the glans penis and prepuce frequently are involved, and distal urethral stricture and phimosis may occur. Under these circumstances, the condition is clinically known as balanitis xerotica obliterans.

Gross Findings

The vulvar lesions of lichen sclerosus typically are pale white, flat, plaque-like areas that in advanced cases may be associated with thinned parchment-like epithelium and focal areas of ecchymosis and superficial ulceration (see \triangleright *Fig. 1.18*). The vaginal mucosa is not involved.

Microscopic Findings

The microscopic findings of lichen sclerosus can vary considerably, related to age of the lesion, excoriation, and treatment [32, 158]. The principal histologic changes show a sandwich appearance, including epidermis with blunting or loss of the rete ridges, a zone of homogeneous collagenized subepithelial edema of variable thickness, and a band of lymphocytic infiltration beneath this zone (> Fig. 1.19). The homogeneous zone usually shows a reduction or absence of elastic fibers. The epithelium is thinned, but hyperkeratosis may be present in some cases and is believed to be superimposed lichen simplex chronicus [102]. The basal cell layer often is disorganized, and spongiosis may be evident. There is both an absence of melanosomes in the keratinocytes and a disappearance of the melanocytes. The lack of pigment, as well as edema, contributes to the white clinical appearance. Mitotic figures are rare or absent. In some cases, the mechanical trauma of rubbing and scratching will have produced bullous areas of lymph edema and subepithelial lacunae filled with erythrocytes. Areas of ulceration and acute inflammation also may be seen.

 Fig. 1.18
 Lichen sclerosus (LS). White epithelium with focal subcutaneous ecchymosis is seen. The labia minora are somewhat atrophic

Differential Diagnosis

See Differential under "Lichen planus".

■ Fig. 1.19 Lichen sclerosus. Hyperkeratosis is present along with loss of rete pegs and homogenization of the dermis

Ultrastructural Findings

Ultrastructural studies have shown that collagen metabolism is abnormally active and the number of capillaries is reduced. The basal lamina is thickened and discontinuous. Degenerate dermal and collagenous material and formation of a hybrid of elastocollagenous bundles can be found between the cells of the epidermis, and melanocytes are rare [149].

Immunohistochemical and Related Studies

The presence of an elastase-type protease in vulvar fibroblasts from lichen sclerotic tissue has been reported that may be responsible for the loss of elastic tissue [84]. An increased concentration of collagenase inhibitor also has been reported. Tissue studies of glucose metabolism as well as alkaline phosphatase and adenosine triphosphatase have shown a surprisingly high rate of activity, equal to that seen in hyperplastic specimens and greater than that found in normal menopausal skin. The cell cycle protein Ki-67 is present in the basal and many parabasal epithelial cells involved by lichen sclerosus [209]. An apparent premature maturation of all cells above the basal layer has been reported, based on their high concentration of involucrin [32]. There is a growing body of evidence that an autoimmune mechanism may be involved. Patients with lichen sclerosus have been noted to have an increased number of organ-specific antibodies and more autoimmune disease than the normal population [29, 30]. However, the correlation is inconclusive [208]. On a histologic level, direct immunofluorescence studies have shown a deposit of fibrin along the dermoepidermal junction in 75% of the specimens studied [84, 208]. With an indirect fluorescent technique, IgM and C3 were concentrated along the basal lamina of the epithelium [84, 208]. Studies of the T cells within lichen sclerosus have identified monoclonal T cells that are predominantly cytotoxic CD8+ responsible for the destruction of basal keratinocytes [188].

Clinical Behavior and Treatment

Lichen sclerosus sometimes is associated with vulvar squamous carcinoma; however, it is not considered to be a premalignant intraepithelial neoplasm (see O Chap. 2, Premalignant and Malignant Tumors of the Vulva). In a report of vulvar squamous cell carcinoma, 61% of the patients had lichen sclerosus. Until the time of the tumor diagnosis, 43 of the 47 cases with lichen sclerosus were not recognized to have vulvar lichen sclerosus [128]. Among patients with symptomatic vulvar lichen sclerosus, 9% developed VIN lesions and 21% invasive squamous cell carcinoma. Symptomatic lichen sclerosus preceded the carcinoma by a mean of 4 years. Squamous cell carcinomas associated with lichen sclerosus were located more commonly on the clitoris in an older age group, and were of the conventional squamous cell carcinoma type [32, 33]. Aneuploidy has been reported, which correlates with elevated p53 expression [31, 32]. In cases where lichen sclerosus is associated with vulvar squamous cell carcinoma, squamous cell hyperplasia usually is observed adjacent to the carcinoma [198]. Differentiated (simplex) type VIN and non-HPV-related squamous cell carcinoma have been associated with vulvar lichen sclerosus [250].

Traditional management has relied on the long-term topical application of testosterone or progesterone. Recent studies have reported good results with topical, superpotent corticosteroids for a short period [30, 53, 134]. In children, clearing or improvement of the anogenital lesions has been reported at puberty. However, this improvement has not been associated with menarche or pregnancy [93, 133]. Topical testosterone had been reported to arrest the symptoms and progress of the disease; however, it cannot be used in children because it is systemically absorbed. It is rarely used today. The recommended and accepted treatment according to the Guidelines for the management of lichen sclerosus as published on behalf of the British Association of Dermatologists is the ultrapotent topical corticosteroid ointment clobetasol propionate [160]. Current therapy using highpotency topical corticosteroids produces symptomatic relief and, in some cases, resolution of lichen sclerosus [36]. Opinion varies as to the ideal long-term therapy; most dermatologists advocate high-potency topical corticosteroids, but with reduced frequency. Lichen sclerosus is not a disease that requires vulvectomy or is cured by local excision or ablative treatment, however, some patients with persistent itch unresponsive to topical treatment, have responded to laser therapy or cryotherapy [160]. Women with lichen sclerosus, however, require continued therapy and follow-up because, over time, it is associated with a small but significant risk of vulvar differentiated (simplex) type VIN and squamous cell carcinoma in postmenopausal women. In these cases, tumor development occurs in the field of lichen sclerosus, and typically is associated with visible tumor or hyperplastic changes that indicate biopsy to establish the diagnosis of tumor. With improved therapy, it is expected that the frequency of tumor may be decreased.
Lichen Simplex Chronicus (Formerly Squamous Cell Hyperplasia or Hyperplastic Dystrophy)

Lichen simplex chronicus (LSC) is now considered to be equivalent to squamous cell hyperplasia by the International Society for the Study of Vulvovaginal Disease (ISSVD) and dermatopathologists [136, 178]. The microscopic diagnosis of lichen simplex chronicus, however, includes the finding of a superficial dermal chronic inflammatory infiltrate with vertical collagen streaks in the papillary dermis (\bigcirc *Fig. 1.20*). A recent study revealed that the expression of retinoid acid receptor-alpha, a modulator of epithelial cell proliferation and differentiation, is decreased and the distribution of the receptor is changed in lichen sclerosus and squamous cell hyperplasia [16].

Gross Findings

The involved vulvar area usually is symmetric, and may be confined to a focal area, usually involving the labia majora. The involved area appears gray-white or reddened. The skin markings often are accentuated, a sign of intradermal edema and chronic rubbing; excoriation and fissures frequently bear witness to the intensity of the

Fig. 1.20

Lichen simplex chronicus (LSC). The epithelium is slightly thickened; however, no hyperkeratosis is present. Within the superficial dermis, there is a prominent chronic inflammatory cell infiltrate. In this example, there is minimal fibrosis within the superficial dermis itching. There is shrinkage, stenosis, and agglutination of the labia.

Microscopic Findings

The histopathologic features of lichen simplex chronicus are epidermal acanthosis with superficial dermal fibrosis and variable superficial dermal chronic inflammation (> Fig. 1.20). Hyperkeratosis and parakeratosis may be present. There is typically an inflammatory infiltrate, predominately of lymphocytes in the superficial dermis. The changes are otherwise nonspecific, and the diagnosis is arrived at by exclusion of other dermatoses. The individual squamous cells are regular with distinct intercellular bridges. The nuclei are round to oval and contain finely distributed chromatin. Nucleoli may be prominent; however, there is progressive maturation of the cells as they approach the superficial layers. Mitotic figures, if present, are normal and confined to the basal layer. Hyperkeratosis may be seen associated with accentuation of the granular layer. Although parakeratosis may be present in otherwise typical areas of hyperplasia, its presence should prompt a careful search for cellular atypia and VIN of the differentiated type (see > Vulvar Intraepithelial Neoplasia in Chap. 2). In the absence of atypia or lichen sclerosus, there is no evidence of risk of carcinoma from this process. The diagnosis of lichen simplex chronicus is one of exclusion.

Differential Diagnosis

The differential diagnosis of LSC includes chronic candidiasis or dermatophyte infection of the vulva that usually can be differentiated by a silver stain for fungus or periodic acid-Schiff (PAS) stain for the organisms. The fungal organisms usually are present in the keratin layer. The finding of inflammatory exocytosis, with neutrophils within the epithelium, is a clue for fungal infection. Regressing or early flat condylomata acuminata also may resemble LSC. However, the prominent granular layer, accentuated intracellular bridges, parabasal hyperplasia, and koilocytosis typically are lacking. If this cannot be resolved by histopathologic examination, molecular biologic methods, such as PCR or in situ hybridization, may be helpful in establishing the diagnosis of HPV-associated changes when virus is identified. Psoriasis or lichen planus may be included in the differential diagnosis; however, they represent distinct entities that are clinically and histologically identifiable.

Clinical Behavior and Treatment

Treatment is based on limiting or preventing exposure of the vulva to potential irritants in conjunction with the use of topical corticosteroids and antipruritics. Symptoms usually abate within 2–3 weeks [36]. Occasionally, local excision or laser ablation of the hyperplastic area may be effective in unresponsive cases. Combined treatment of 0.1% tacrolimus ointment and psoralen plus (PUVA) may be a good option in extensive cases of lichen sclerosus or when other treatment options have failed, and has a good tolerability and safety profile [231].

Lichen Planus

General Features

Lichen planus (LP) has a wide age distribution; however, it presents most commonly in women more than 40 years of age [130, 141]. Vulvar pruritus and burning are common symptoms; however, the patient may be asymptomatic. White, lacelike plaques (Wickham's striae) involving the oral and vaginal mucosa also may be present. Involvement of all three sites is referred to as the vulvovaginal-gingival syndrome reported by Pelisse. The syndrome is recognized as an erosive form of LP [173]. Patients with this condition experience vulvar pain, dyspareunia, and burning. Postcoital bleeding also has been reported [138, 173]. LP can result in severe introital and vaginal adhesions, scarring, and stenosis.

Gross Findings

The clinical appearance may be highly variable on the vulva, ranging from delicate reticulated papules to an erosive desquamative process involving the vagina and vulva. Within the vulva, the erosive process is typically confined to the vulvar vestibule and commonly involves the vagina. With advancing disease, there is loss and agglutination of the labia minora and prepuce, associated with thinned epithelium, postinflammatory hypopigmentation, and shrinkage with stenosis of the vaginal introitus. In advanced stages, it may be difficult to distinguish LP from advanced lichen sclerosus (LS). Vaginal involvement with adhesions and synechiae clinically characterizes LP, as does the finding of mucous membrane lesions outside the vulva.

Microscopic Findings

The histopathologic features may be highly variable depending on the age of the lesion as well as its location. Mucous membrane lesions may differ considerably from those occurring on vulvar skin [113]. In the skin, there are two important microscopic features: a bandlike chronic inflammatory infiltrate that is predominantly lymphocytic, with no or rare plasma cells. The inflammation is lichenoid, involving the upper dermis and immediate overlying epidermis (> Fig. 1.21). Liquefaction necrosis of the basal epithelial cells is seen, and these cells typically are admixed with chronic inflammatory cells. Degenerated keratinocytes result in the formation of colloid bodies (civatte bodies). Within the vulvar skin, the involved epithelium may show acanthosis, wedgeshaped hypergranulosis, and hyperkeratosis. Usually, parakeratosis is not present. Immunofluorescent studies often reveal fibrin deposition at the dermal-epidermal junction and, occasionally, granular IgM; rarely C3 and IgG deposits are also present. The cluster of necrotic keratinocytes (colloid bodies) positive for IgM in up to 87% of cases and, sometimes, C3 and IgG deposits may be helpful for the diagnosis [226]. The epithelial changes are variable within mucous membranes and include thinning

Fig. 1.21

Lichen planus (LP). The epithelium is somewhat thinned with loss of rete ridges. A prominent granular layer is evident without significant hyperkeratosis in this example. There is a prominent bandlike chronic inflammatory infiltrate consisting almost entirely of lymphocytes, which is lichenoid and involves the basal layer of the epithelium, with ulceration and bullous formation. In contrast to the findings within the skin, plasma cells may be evident with mucosal involvement.

Differential Diagnosis

Well-developed lichen sclerosus (LS) can be distinguished from LP by the absence of the lichenoid inflammatory infiltrate at the dermal-epidermal junction in LS. Colloid bodies also are common in LP. LP typically involves mucosal as well as nonmucosal sites, whereas LS typically does not involve the vagina or oral mucosa. In advanced cases, mucosal involvement may be the most important distinguishing feature. Cicatricial pemphigoid and LP may both cause scarring and stenosis of the vulvar vestibule and vagina. Lichen planus has the characteristic lichenoid inflammatory pattern with colloid bodies within the epithelium. Cicatricial pemphigoid forms subepithelial blisters and has abundant eosinophils in the vesicles and in the dermis. Immunofluorescence demonstrates linear IgG and C3 deposits, which are usually absent in LP. Morphea (scleroderma) may be included in the differential diagnosis in that a band-like chronic inflammatory infiltrate may be seen with epithelial thinning; however, the inflammation is typically perivascular and around skin adnexa in the deep dermis, frequently with plasma cells. The interface liquefaction changes seen in LP typically are not seen in morphea. Morphea usually involves other sites, especially the trunk. Sclerosus of the dermis in morphea results in dermal thickening and loss of fat about skin appendages, as well as loss of skin appendages.

Clinical Behavior and Treatment

Adhesion formation can lead to scarring and agglutination of the labia minora [130]. The cause of erosive LP is unknown, although increasing evidence suggests that LP is a T-cell–mediated disease, representing an autoimmune response to altered self antigens or heterogeneous foreign antigens. C Topical cortical steroids are the usual form of treatment; fluorinated corticosteroids may be needed initially to provide relief. The most frequent first-line treatment was an ultrapotent topical corticosteroid, 0.05% clobetasol propionate ointment, which led to symptomatic improvement in 84 (94%) of 89 women, with 63 (71%) being symptom free while receiving treatment [51]. Additional therapy may include topical or oral cyclosporine, oral dapsone, and oral griseofulvin [61, 130].

Psoriasis

Psoriasis is inherited as an autosomal dominant trait (diathesis) with incomplete penetrance. Psoriasis affects approximately 2% of the population of the USA. On the vulva, the disease typically involves the lateral aspects of the labia majora and genitocrural areas [192]. The lesions present as sharply demarcated, silvery-topped erythematous papules and plaques on skin. When this loose silvery scale is removed, several punctuate bleeding points can be seen (Auspitz sign). In the vulva and other intertriginous areas, the silvery scales are lost. The sharply demarcated, bright red erythematous plaques are the main clinical finding. The lesions frequently are symmetric and may persist for years. At times, new psoriatic lesions develop at sites of trauma within 7-30 days after the trauma. This is referred to as Koebner phenomenon. Reiter's syndrome of the vulva, which is in the spectrum of psoriasis, rarely affects women [62].

Microscopic Findings

Hyperkeratosis, parakeratosis, uniform psoriasiform hyperplasia (elongation of the rete ridges to an even length) with club-shaped tips of rete ridges, diminution of the granular layer, and collections of polymorphonuclear leukocytes within the epidermis (Munro abscesses) are the epidermal changes (\bigcirc *Fig. 1.22*). Mitotic activity increases within the epidermis above the basal layer, reflecting the significantly increased rate of epithelial turnover. The dermal papillae are clubbed and edematous. Prominent tortuous vessels are seen within the papillae, and there is a minimal chronic inflammatory cell infiltrate with the dermis [113].

Differential Diagnosis

The major differential diagnosis includes seborrheic dermatitis and chronic eczema. The latter two conditions also show psoriasiform hyperplasia; however, the rete ridges typically are not elongated to an even length as in the psoriasis. In seborrheic dermatitis, the subcorneal neutrophils are typically distributed around follicular ostia. Because psoriasis and seborrheic dermatitis have a similar clinical presentation, the differential diagnosis between these two diseases can be very difficult [192].

Fig. 1.22

Psoriasis. Prominent uniform acanthosis is present. An intracorneal neutrophil collection (Munro abscess) is evident. The dermal papillae are clubbed and infiltrated by chronic inflammatory cells

Contact Dermatitis

Vulvar contact dermatitis may be of an allergic type, which is a cell-mediated response to sensitizing agents such as nickel or rubber, or an irritant related to exposure to chemical or physical agents that damage the skin. Urinary incontinence is a common cause of irritation. Irritant dermatitis is the more common of the two. The lesions typically are confined to the area of exposure and usually persist for some time after the exposure [179]. The pathologic findings may be quite variable, depending on the severity and duration of the process and whether there is an associated allergic response. The most constant histopathologic findings are spongiosis with microvesiculation. The superficial perivascular inflammatory response consists predominantly of lymphocytes and histiocytes; eosinophils may be present. Superficial erosion or ulceration may be present and, in long-standing contact dermatitis, epithelial thickening with parakeratosis, and hyperkeratosis simulating lichen simplex chronicus also occurs.

Atopic Dermatitis

Women with atopic dermatitis may have involvement of the vulva, with associated pruritus and burning [179]. The physical findings may be limited to dryness and scaling, but thickening of the skin with localized excoriation may be evident if the vulva has been irritated by scratching. Vulvar biopsies are rarely performed on these patients. The pathologic findings often are typically squamous cell hyperplasia or are nonspecific. Spongiosis can at times be present. Within the dermis, lymphocytes and macrophages are present and the density of the infiltrate tends to correlate with the severity and chronicity of the process. Eosinophils and mast cells also may be identified. Immunofluorescent studies have demonstrated IgE on epidermal Langerhans cells [166, 221].

Fixed Drug Eruption (Dermatitis Medicamentosa)

Fixed drug eruptions constitute a complex group of cutaneous manifestations of drug-hypersensitive reactions that are subclassified as types I through IV. Type I is mediated through IgE antibodies and usually presents as urticaria. Type II is mediated through IgG and IgM antibodies and may be manifested as drug purpura or a bullous drug eruption. Type III is related to immune complexes and may be expressed as a maculopapular eruption, exanthem, urticaria, or vasculitis. Type IV is cell mediated and may be manifested as contact dermatitis, an exanthem, or a maculopapular eruption.

Fixed drug eruptions usually appear at the same place on reexposure to the same drug. Multiple reexposure may elicit lesions at new places in addition to the original locations. After discontinuation of the drug, the lesion may heal with prominent postinflammatory hyperpigmentation of the skin; however, this does not appear on the mucosa. The most common histopathologic findings of a fixed drug reaction are similar to erythema multiforme, that is, interface vacuolar changes with necrotic keratinocytes and scattered eosinophils in the dermis. Histologic findings in drug eruption are usually nonspecific and are only suggestive or supportive of a drug eruption. Patch testing, indirect and direct Coombs tests, and other specific laboratory testing, as well as a detailed clinical history, are necessary to precisely diagnose such cases [156].

Miscellaneous Inflammatory Dermatoses

A few special dermatoses, which are not classified into other categories in this chapter, are summarized in *Table 1.5.*

Table 1.5

Miscellaneous inflammatory dermatoses (noninfectious)

Plasma cell vulvitis
Granulomatous diseases
Sarcoidosis
Vulvitis (chelitis) granulomatosa
Crohn disease
Behçet syndrome
Pyoderma gangrenosum
Vulvodynia (Vulvar vestibulitis, Vulvar vestibular
syndrome)
Fox-Fordyce disease
Fixed drug eruption (drug-induced erythema multiforme)

Plasma Cell Vulvitis (Vulvitis of Zoon)

Plasma cell vulvitis usually presents with symptoms of pruritus and burning. It is characterized by erythematous macules that usually have focal hemorrhagic areas and may appear orange in color. The lesions may be multiple [104, 251]. On microscopic examination the epithelium is thinned, with flattening of rete ridges and lack of a granular layer or keratinized surface. Parabasal keratinocytes have a horizontal orientation with marked spongiosis. The inflammatory infiltrate is lichenoid in type, consisting predominantly of plasma cells. Prominent dermal blood vessels are evident with associated intradermal hemorrhage and hemosiderin [113, 146]. The differential diagnosis includes syphilis, because of the perivascular plasma cell infiltrate, as well as lichen planus and other chronic dermatoses. The etiology is unknown; however, local irritation and poor hygiene may be contributing factors. Perineal hygiene, supportive care, and topical and intralesional corticosteroids are the usual treatment [251]. Use of etretinate has been reported in plasma cell vulvitis [196]. At present, topical tacrolimus can be considered an alternative treatment for plasma cell vulvitis only in cases resistant to conventional therapies [238].

Fox–Fordyce Disease

Fox–Fordyce disease is a disorder of the apocrine glands; 90% of cases occur in women. The disease generally begins at puberty and presents as a pruritic papular eruption usually involving the axilla, vulva, and perianal regions.

Fig. 1.23
Fox–Fordyce disease. Dilated apocrine glands show inspissated secretion

On microscopic examination, the center of the papule often contains a hair follicle and an apocrine sweat gland duct plugged by keratin. There may be an associated rupture of the intraepithelial portion of the duct with subsequent vesicle formation within the epidermis caused by spongiosis. These vesicles can be seen when serial sections are performed [187]. Transverse histologic sections to make the diagnosis have also been reported [218]. Chronic inflammatory changes are present in the dermis, and there is dilatation of the apocrine gland acini (> Fig. 1.23). In addition, there is epidermal acanthosis and spongiosis. Deposition of mucin may be found in the ducts, glands, and tissues surrounding the skin appendages. Fox–Fordyce disease is a chronic condition that may progress somewhat during pregnancy or after menopause; however, no definite therapy is known. In women of reproductive age, oral contraceptives may relieve symptoms and reduce somewhat the severity of the process. Systemic antibiotics and topical, as well as locally injected, corticosteroids and antipruritics relieve symptoms. Isotretinoin has been used in treating this condition [152]. Hidradenitis suppurativa as well as folliculitis may complicate the clinical course.

Vulvodynia (Formerly Known as Vulvar Vestibulitis or Vulvar Vestibular Syndrome)

General Features

Vulvodynia formerly known as, Vulvar vestibulitis, was renamed at the ISSVD Terminology and Classification Consensus Among Health Care Providers in 2003. Vulvodynia is described as "vulvar discomfort, ... a burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder." Vulvodynia is divided into two categories: (1) vulvar pain related to a specific disorder and (2) vulvodynia, a condition in which the vulva has a normal appearance other than some erythema (\bigcirc *Table 1.6*).

Microscopic Findings

As seen in the table, vulvar pain related to a specific disorder, can be infectious, inflammatory, neoplastic or neurologic. This group has histopathologic features that include areas of mild to moderate inflammatory response, characterized by a superficial chronic inflammatory infiltrate that is composed predominantly of lymphocytes resembling female urethral syndrome [80]. Many cases also have plasma cells within the infiltrate, but leukocytes and eosinophils are rare. The stromal tissue beneath the vestibular epithelium is involved most prominently, and the inflammatory process may surround the minor

Table 1.6

vestibular glands. Inflammatory cells occasionally are found within the glandular epithelium or within the acini or ductal lumina [184]. These patients rarely have clinically or morphologically evident condyloma acuminatum or VIN [243]. The group under vulvodynia has essentially histologically unremarkable tissues.

Clinical Behavior and Therapy

The natural history of vulvodynia is poorly understood, and no long-term controlled prospective studies have been reported to date [90]. Local excision of the vestibule has been advocated; however, the recurrence rate, with followup for as long as 5 years, reveals that recurrent symptoms after surgery are relatively common, occurring in more than one half the cases in some series. Biofeedback therapy appears effective in many patients as does cognitivebehavioral therapy [18, 81]. Antibiotics produce no response, nor can the symptoms be reliably alleviated by corticosteroids. Nonvaporization laser ablation of the superficial submucosal ectatic blood vessels has been proposed, especially in cases having recurrent symptoms after surgery [142]. Interferon has been advocated, with some response [24]. The administration of interferon and biofeedback training of the lower pelvic muscles are treatments used as a first choice before more aggressive treatment [24]. A low-oxalate diet has been proposed but has not been proven to be of value. More than one half of these patients initially obtain some relief from topical therapy. Management of symptoms is long term and supportive.

Vulvitis Granulomatosa (Chelitis Granulomatosa)

Vulvitis granulomatosa is of unknown etiology, related to cheilitis granulomatosa (Miescher–Melkersson–Rosenthal syndrome) and Crohn's disease [88, 89]. Clinically, the labia majora are indurated, swollen, and erythematous without tenderness. The labia minora, as well as the perineum and perianal areas, also may be involved. Mild regional lymphadenopathy typically is present. The process remains localized but is slowly progressive. Histopathologic findings include dermal edema and a chronic granulomatous inflammatory infiltrate composed of histiocytes and giant cells, as well as lymphocytes and plasma cells. The infiltrate involves the dermis and extends to the epithelium. The differential diagnosis includes other granulomatous inflammatory processes [89]. Treatment of this condition is with intralesional steroids.

Factitial Vulvitis

Factitial vulvitis is an uncommon disorder that may present as a mild chronic inflammatory process, often with associated superficial ulceration [179]. The pathologic findings often are nonspecific.

Behçet Syndrome

Behçet syndrome refers to the triad of oral aphthous ulcers, genital ulcers, and ophthalmologic inflammation [203]. Ocular changes may be absent in mild cases. Other findings include acne, cutaneous nodules, thrombophlebitis, encephalopathy, and colitis [203]. Behçet syndrome causes deep ulcerations on the vulva that may result in fenestration of the labia and lead to gangrene of the labia. The ulcerations characteristically heal and relapse, and are associated with simultaneous oral ulcers. Histologically, necrotizing arteritis frequently is seen and can be considered a cardinal pathologic finding. A chronic inflammatory infiltrate may be perivascular or involve the vessel wall with homogenization of the arterial media [113]. Endothelial cell swelling also occurs and may result in arteriolar occlusion as well as venous thrombosis.

Crohn's Disease

Crohn's disease is a chronic noncaseating granulomatous disease of unknown etiology that can involve, besides the gastrointestinal tract, the vulva and the perineum in adults and children [229, 237]. Cutaneous ulcerations occur in areas where there is close apposition of skin, such as the vulva and inframammary areas. When Crohn's disease involves the vulva, the resulting ulcers often are slit shaped, multiple, deep, and secondarily infected. Vulvar and perianal erythema, induration, or ulceration may be the presenting signs [172, 237]. Involvement of the colon, rectum, or small bowel is not always present when the vulva is involved. Perianal fistulas, as well as fistulas to other sites in the female genital tract, are complications. When perianal draining sinuses and abscesses occur, they often drain fluid resembling small bowel contents.

Microscopically, the disease is characterized by a noncaseating granulomatous inflammation within the

dermis, which usually is deep and associated with fissures and sinus tracts. Studies for acid-fast bacteria and fungi are negative. A marked granulation tissue response frequently is seen surrounding the ulcers, but significant lymphadenitis is rare [113].

Pyoderma Gangrenosum

Pyoderma gangrenosum is a progressive necrotic and ulcerative condition of the skin, of uncertain etiology. Most case reports of pyoderma gangrenosum occur on the legs and are associated with idiopathic bowel disease such as chronic ulcerative colitis. Other associations include hematologic malignancy, connective tissue disease, and liver disease. Pyoderma gangrenosum of the vulva may present some time after treatment for colitis, ileostomy, or abdominal perineal resection of the colon and rectum.

The microscopic findings reveal epithelial ulceration with severe acute and chronic inflammation. If the biopsy is from the ulcer edge, the sharply demarcated ulcer is adjacent to hyperplastic squamous epithelium. Organisms are not identified within the inflammatory process. Systemic corticosteroid therapy with aggressive local excision, followed by skin grafting, may be necessary in addition to the treatment of the underlying disease [180].

Necrotizing Fasciitis (Includes Synergistic Bacterial Infection)

Postoperative, posttraumatic, or necrotizing fasciitis is a life-threatening condition that usually is secondary to a polymicrobial infection after episiotomy or other types of vaginal, vulvar, or abdominal surgery [13, 219]. Diabetes mellitus, arteriosclerosis, obesity, hypertension, and prior irradiation predispose to necrotizing fasciitis [4]. The clinical presentation is that of a rapidly progressing inflammatory process that may initially appear as mild cellulitis or edema with inflammation. Delay in diagnosis without therapy carries a nearly 50% mortality. Prompt radical excision of the infected tissue and broad-spectrum systemic antibiotic therapy offers the only chance of cure [219].

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic inflammatory disorder of the apocrine glands [85]. Deep-seated, painful, subcutaneous nodules are found in areas containing apocrine glands, especially the axilla and vulva. The lesions commonly progress subcutaneously, producing confluent masses that subsequently ulcerate the epidermis and result in draining sinuses and extensive scarring. The condition may coexist with Fox–Fordyce disease. Total excision of involved areas may be necessary in advanced cases, although laser ablation and unroofing the sinuses has been reported to be effective [213]. Long-term isotretinoin therapy also has been reported to be effective in some cases [99]. Histologically, in the early stage hidradenitis suppurativa demonstrates a perifolliculitis with an acute and chronic inflammatory infiltrate within the dermis. The later stages of the disease result in destruction of the epithelial appendages with sinus tract formation [113] (\bigcirc Fig. 1.24).

Mites and Lice

A variety of mites are capable of producing local and limited chronic skin infections of the perineal area,

Fig. 1.24

Hidradenitis suppurativa. There is a severe acute and chronic inflammatory cell infiltrate within the dermis with involvement and destruction of the skin appendages

including scabies [41, 154]. Mites must be specifically considered, because definitive diagnosis sometimes is difficult [41]. Mites are small arachnids and belong to the order Acarina; they differ from lice, which are insects. Mites have a fused head and thorax, devoid of primary segmentation, and four pairs of legs. Mites burrow within the subcorneal area of the epidermis, inducing severe pruritus. The overt skin lesions are papular and, when examined under a magnifying lens, reveal an adjacent burrow. Scrapings from the burrow or specimens obtained from the patient's clothing can be fixed in an alcoholether-acetic acid-formalin mixture and analyzed microscopically for mites, eggs, and fecal material. Lice are associated with irritation of the skin from secondary infection of feeding sites. The pubic louse, Phthirus pubis, class Insecta, is the usual offender and can be diagnosed by identifying the louse and nits on the hair shaft.

Spider Bite

A brown recluse (Loxosceles reclusa) spider bite on the vulva has been reported, associated with ulceration and infection of the vulva. Although secondary protracted infection may occur with such ulcers, slow and progressive healing over several months is the usual clinical course [139].

Bullous Diseases

Although virtually any dermatologic disease can involve the vulva, the following bullous diseases bear discussion, as they may first be observed and biopsied by the gynecologist. Definitive diagnosis of most bullous diseases requires clinical and pathologic correlation, and in some cases the clinical findings are essential in distinguishing these cutaneous diseases that otherwise have very similar or identical histopathologic findings. Some of the bullous diseases have immunologic components, and others are nonspecific (**7** Table 1.7). The key histopathologic features and differential diagnosis of bullous and bullouslike diseases are summarized in (**7** Table 1.8).

Pemphigus (Pemphigus Vulgaris)

Pemphigus vulgaris initially may present on the vulva as recurrent superficial ulcers and erosions. Associated oral lesions usually are present in these patients, and rectal and vaginal lesions may occur [15, 179]. The disease was life threatening before the era of steroid treatment. Biopsy of a fresh vulvar vesicle usually is diagnostic. Microscopic

Table 1.7 Noninfectious bullous dermatoses

Immunobullous dermatoses	Nonimmunobullous dermatoses
Bullous pemphigoid	Benign familial pemphigus (Hailey– Hailey)
Cicatricial pemphigoid	Darier disease (keratosis follicularis)
Pemphigus	Erythema multiforme
Dermatitis herpetiformis	Lichen planus and lichenoid vaginitis
Linear IgA dermatosis	Lichen sclerosus (LS)
Herpes gestationis	Pruritus, urticaria, papules and plaques of pregnancy (PUPPP)
Bullous lupus erythematosus	

findings include acantholysis with suprabasal vesicle formation and eosinophils in the vesicular fluid and the superficial dermis (**>** *Fig. 1.25*). Direct immunofluorescent studies of perilesional skin demonstrate IgG deposited at the epidermal intercellular junctions. Circulating antibodies to epidermal intercellular spaces can be detected with indirect immunofluorescent method against monkey esophageal epithelium; the titer correlates with the clinical activity of the disease. Therapy includes high systemic doses of corticosteroids and cytotoxic agents, plasma pheresis, and supportive measures [28, 87, 217].

Pemphigus Vegitans

This rare variant of pemphigus may present as a localized, indurated, inflamed area with vesicles. The pathologic as well as immunofluorescent and immunologic findings are similar to pemphigus vulgaris, although intraepidermal eosinophilic abscesses and verrucous epidermal hyperplasia are prominent [179, 248]. The presence of eosinophils, as well as the localized and self-limited character of the disease, distinguish it from pemphigus vulgaris.

Pemphigoid (Bullous Pemphigoid)

Pemphigoid can involve the vulva and is characterized by moist, tender ulcers that involve the labia minora, majora, and perianal areas. At times, fluid-filled tense bullae also are present. Biopsies of fresh ulcers, including normal adjacent skin, typically show the characteristic subepidermal bullae (see **>** *Table 1.8*). In advanced stages, biopsy of ulcerated areas may show only granulation tissue [120].

Cicatricial pemphigoid, unlike bullous pemphigoid, results in scarring and stenosis. Both bullous pemphigoid and cicatricial pemphigoid can be the result of a drug hypersensitivity reaction [235]. The disease presents as erosions, erythema, and small blisters of the vulva, perianal, and anal mucosa associated with chronic burning pain and painful ulcers. The origin of the recurrent scarring of the vulva may not be apparent until the presentation of ocular involvement secondary to cicatricial pemphigoid [74]. Severe cicatrization with shrinkage, suggesting advanced vulvar lichen sclerosus or lichen planus, characterizes the process. In contrast to lichen sclerosus or lichen planus, cicatricial pemphigoid is associated with small blisters and a positive Nikolsky phenomenon (slippage and detachment of the superficial epidermis from the underlying dermis when the examining finger is slid over the skin surface).

Microscopically, there is subepidermal blister formation with a mixed inflammatory cell infiltrate within the dermis (**>** *Fig. 1.26*). Eosinophils are prominent. Direct immunofluorescence demonstrates linear IgG, and complement C3, along the basement membrane. Immunoglobulins IgA and IgM may or may not be present [76, 120]. Systemic corticosteroids and immunosuppressive drugs may be of value [87, 121]. If the condition is drug related, the offending medication should be discontinued.

Herpes Gestationis

This vesiculobullous disease is unique to pregnant women, with an estimated incidence of approximately 0.6 per 100,000 pregnancies. Patients have a strong association with HLA-DR3 and -DR4. Presenting signs and symptoms often are severe pruritus and a macular erythematous rash that leads to blistering and superficial ulcerations. The lesions may involve the vulva and pubic area in addition to the trunk and upper thigh. The process usually presents in the second trimester, and spontaneous regression follows soon after delivery, although regression may occur in the late third trimester.

Histopathologic findings include a subepidermal blister that may contain eosinophils, neutrophils, lymphocytes, and histiocytes. There is a perivascular superficial dermal inflammatory infiltrate that also is rich in lymphocytes and eosinophils. Immunofluorescent studies

Table 1.8

Differential diagnosis of vesticular bullous and bullous-like diseases of the vulva

	Location of vesicle		Acantholysis of	Significant		
Disease	Subepidermal	Intraepidermal suprabasal	suprabasal cells	systemic manifestations	ImmvLnoflvLOresce.nl localization	
Pemphigus vulgaris	No	Yes	Yes	Yes	lgG Intercellular	
Pemphigus vegitans	No	Yes	Yes	No	lgG Intercellular	
Pemphigoid (bullous) (cicatricial pemphigoid)	Yes	No	No	Yes, localized scarring (sometimes debilitating)	IgG linear along basement membrane IgA, IgM, C ₃ , C ₅ may be in basement membrane	
Herpes gestationis	Yes	No	No	Yes	C ₃ Linear along basement membrane. IgG may also be present. IgM, IgA is rare	
Polymorphic eruption of pregnancy, pruritic urticarial plaques and papules in pregnancy (PUPPP)	Yes	No	No	Yes	Negative	
Darier disease	No	Yes Yes Yes,	Yes, 3+ dyskeratosis	Yes	Negative

Hailey-Hailey	No	Yes	Yes, 4+ No dyskeratosis	No	Negative	
Localized acantholytic disease of the vulva	No	Yes	Yes	No	Negative	
Benign chronic bullous disease of childhood (linear IgA disease)	Yes	No	Microabscesses in dermal papillae	No, flu-like symptoms may precede presentation	lgA linear along basement membrane (C ₃ , IgA, IgG, IgM also may be present)	
Dermatitis herpetiformis	Yes	No	No	No, severe pruritus in some cases	IgA deposits in the tips of dermal papillae and/or along the basement	

demonstrate C3 as a linear basement membrane deposit. Serologic studies demonstrate circulating complementfixing IgG antibodies in 25% of the cases. The antibodies bind to 180-kDa hemidesmosome antigen (BPAg2) [214]. The main differential diagnosis is bullous pemphigoid, which is usually not associated with pregnancy. Prurigo of pregnancy, pruritic folliculitis of pregnancy, and polymorphic eruption of pregnancy may be included in the differential of dermatosis associated with pregnancy, but these are not bullous diseases, and the immunofluorescent studies are negative [146].

Darier Disease (Keratosis Follicularis)

Darier disease is inherited as an autosomal dominant trait with the gene locus mapped to chromosome 12q, although

Fig. 1.25

Pemphigus (pemphigus vulgaris). Suprabasal vesicle formation is evident with prominent acantholysis. (Courtesy of B. Smoller, Little Rock, AR)

Fig. 1.26

Bullous pemphigoid. A subepidermal bulla is evident, with intact epithelium separated from the underlying dermis. An intense inflammatory infiltrate of lymphocytes, neutrophils, and eosinophils is seen within the dermis with some inflammatory cells within the bulla (Courtesy of B. Smoller, Little Rock, AR)

spontaneous cases also may occur. This disease affects anytime after late childhood. The disease has a seborrheic distribution and frequently involves the vulva. Although it usually is not considered a bullous disease, it is listed herein because microscopic intraepidermal acantholysis is a common observation. On clinical examination, the lesions are crusted, hyperkeratotic papules that often appear darker than the surrounding skin. The papules may be secondarily infected [113, 192].

Warty dyskeratoma. Acantholysis of the suprabasal epithelial cells, with intraepithelial clefts extending from the basal layer through the granular layer. (Courtesy of B. Smoller, Little Rock, AR)

Histologically, acantholysis of the suprabasal epithelial cells results in clefts that extend from the basal layer through the granular layer. Acantholytic cells are seen within the clefts. Corps ronds and nuclear grains can be found in the granular layer along microscopic findings with individual dyskeratotic cells. Hyperkeratosis, acanthosis, and papillomatosis are seen along with keratotic plugs. Rarely, epithelial basal cell budding into the adjacent dermis may be seen. The inflammatory cell infiltration within the dermis usually is minimal, unless the lesions are secondarily infected [113]. The main differential diagnosis is warty dyskeratoma, Hailey–Hailey disease, and localized acantholytic disease of the vulva (see **>** *Table 1.8*).

Warty Dyskeratoma

Warty dyskeratoma of the vulva typically presents with a histologic picture essentially identical to that of Darier disease. Unlike Darier disease, which is multifocal and may involve the trunk and extremities as well as the face, warty dyskeratoma typically involves the head, neck, or vulva as a solitary lesion. Histologically, warty dyskeratoma has more prominent villous-like projections into the acantholytic space (\bigcirc *Fig. 1.27*). Other distinguishing clinical features are that Darier disease usually is congenital, and is carried as an autosomal dominant, whereas warty dyskeratoma is not (see \bigcirc *Table 1.8*) [50].

Erythema Multiforme (Stevens–Johnson Syndrome)

Vulvar involvement has been reported in association with Stevens–Johnson syndrome, which is the severe form of erythema multiforme. Involvement of the mouth, eyes, and skin, with associated high fever and other systemic symptoms, characterizes the syndrome. The most common cause of the Stevens–Johnson syndrome is drug therapy. Herpesvirus infection is typically associated with a recurrent minor form of erythema multiforme in which the recurrence may be prevented by prophylactic use of systemic antiviral therapy (e.g., Valtrex). Other causes include mycoplasma infection, malignancy, or radiotherapy [202].

The histopathologic features are complex, depending on the age of the lesion. Major features include interface vacuolar dermatitis with necrotic keratinocytes and intraepithelial vesicle formation. Separation of the epithelium from the dermis is associated with hydropic degeneration of the basal keratinocytes (see **2** *Table 1.8*). Within the dermis, there is a prominent chronic inflammatory infiltrate consisting of lymphocytes and histiocytes. Extravasated red blood cells may be present within the dermal inflammatory process, as well as within the epidermis. Nonspecific intravascular complement C3 and IgM deposits may be seen within the superficial dermal vessels by immunofluorescent staining [146]. There are case reports of "introital adenosis" occurring 1-3 years after the diagnosis of Stevens-Johnson syndrome, characterized clinically by erosions within the vulvar vestibule and medial aspects of the labia minora. On histopathologic examination, glandular epithelium has been identified within these areas, associated with submucosal inflammation [22, 143]. The epithelium was described in one case as columnar epithelium of tuboendometrial type, having secretory and ciliated-type cells [143]. The term mucinous metaplasia of the vulva has been used to describe these changes, which is consistent with columnar cell metaplasia [46, 60].

Hailey–Hailey Disease (Familial Benign Pemphigus)

Hailey–Hailey disease is inherited as an autosomal dominant trait with the gene locus mapped to chromosome 3q; approximately one third of patients, however, have no family history of the disease. Onset of the disease often occurs during adolescence. Intertriginous areas usually are involved, but several cases in which the lesions are

Fig. 1.28

Hailey–Hailey disease (benign familial pemphigus). Acantholysis is present in the suprabasal area and lower dermis. The mid- and upper epidermis remain intact, although some acantholysis is present (Courtesy of B. Smoller, Little Rock, AR)

confined exclusively to the vulva have been reported [241]. The usual clinical presentation is recurrent clusters of vesicles that develop, rupture, and result in crusted, moist papules that later coalesce to form plaques.

Histologically, there is acantholysis with resultant suprabasalar lacunae. Acantholytic cells that maintain their nuclear details remain attached to each other in the acantholytic space, giving a dilapidated brick-wall appearance. The acantholysis is more marked than in Darier disease (> Fig. 1.28) [113]. Basal cells maintain their orientation to the basement membrane. Rarely, corps ronds are seen in the granular layer. In contrast to Darier disease there is minimal, if any, dyskeratosis in Hailey-Hailey disease. Strands of epidermal cells may proliferate into the dermis, but little dermal inflammatory infiltrate exists unless secondary infection is present. **•** Table 1.8 summarizes the major distinguishing features of Darier disease, Hailey-Hailey disease (familial benign pemphigus), pemphigus vulgaris, pemphigus vegetans, and warty dyskeratoma. Recently, squamous cell carcinoma arising in Hailey-Hailey disease of the vulva has been reported [45].

Benign Chronic Bullous Disease of Childhood (Linear IgA Disease)

This disease commonly involves the lower abdominal, pelvic, inguinal, and genital areas, presenting as clusters

of annular lesions or "clusters of jewels" that usually are pruritic and typically evolve over the course of 24 h. The annular lesions evolve to tense bullae that, if ruptured, ulcerate and become crusted. Patients may have fever and anorexia. In some cases the eruption is preceded by a bacterial or viral infection [63, 247], and other cases are drug induced, vancomycin being one of the more common offenders [115]. Because of the location and abrupt appearance of the lesions, they may be mistaken for evidence of child abuse. Biopsy of an early bullous lesion reveals subepithelial vesicles that contain predominantly neutrophils within the vesicular fluid. Microabscesses may occur within the epidermis. The diagnostic finding is the identification of a linear deposition of IgA in the basement membrane (see > Table 1.8). Other immunoglobulins and complement C3 also may be found [113]. The antigen of the linear IgA disease is a 97-kDa molecule, which is identical to the carboxyl terminal of 180-kDa (BPAg2), located at the basement membrane [96]. The differential diagnosis includes dermatitis herpetiformis and bullous pemphigoid. Dermatitis herpetiformis is distinguished by having granular IgA at the dermal papillae, whereas bullous pemphigoid has linear IgG basement membrane deposits [113]. Therapy includes systemic antiinflammatory drugs including dapsone, colchicine, and intravenous immunoglobulin therapy [5, 112, 183].

Depigmentation and Hypopigmented Disorders

In adult women, the vulvar skin, especially that of the perineal body and lateral labia majora, usually is more pigmented than the general body surface. Biopsies of the normal vulva show dendritic melanocytes scattered along the basal layer of the epithelium as well as squamous keratinocytes containing variable concentrations of melanin granules. Areas of the vulvar skin that appear hypopigmented therefore are clinically remarkable. Three basic conditions result in vulvar hypopigmentation: vitiligo, albinism, and postinflammatory depigmentation (leukoderma).

Vitiligo

Vitiligo is an inherited disorder in which the melanocytes are lost from areas of skin that were previously normally pigmented. This condition frequently affects the vulva, and biopsies from vitiliginous areas show a remarkable absence of both basilar melanocytes and melanin granules. A Fontana stain for melanin pigment in the basal keratinocytes can be used to support the diagnosis [113].

Albinism

Albinism, an inherited genetic disorder, is characterized by an inability of the melanocytes to produce pigment. There is an absence of melanin granules in the keratinocytes. Large pale cells may be present within the basal layer, representing incompetent melanocytes.

Postinflammatory Depigmentation (Leukoderma)

In areas of previous ulceration, recently healed skin will temporarily lack a normal population of melanocytes, a condition referred to as postinflammatory depigmentation, or leukoderma. This disorder is common after herpes infection, syphilitic ulceration, burns, and deep laser or cryotherapy. Histologically, the skin appears thinned, metabolically active, and lacks the usual amount of pigment. On careful microscopic inspection, some melanin usually is evident.

Pigment Disorders of Melanocytic Origin and Nevi

In a prospective study of 301 women, 37 (12%) were found to have a pigmented lesion of the vulva. All these women were white, and only 26% of the patients were aware that they had a pigmented lesion. More than 50% of the pigmented lesions were lengito simplex (lentigines); seven patients had nevi, of which one had the histologic features of a dysplastic nevus, five patients had postinflammatory hyperpigmentation, two cases represented hemangiomas, and one patient had a pigmented lesion that proved to be VIN with ulceration [197].

Lentigo Simplex

The most common hyperpigmented lesion occurring on the vulva is lentigo simplex (lentigines), which may occur on the mucous membranes as well as on the skin. The lesion is typically small, 4 mm or less in diameter, flat, and uniformly pigmented. Clinically, lentigines closely resemble junctional nevi and, therefore, are frequently biopsied. Except for the rare leopard syndrome, in which thousands of lentigines are present all over the body, lentigo simplex is essentially devoid of clinical significance. In contrast to lentigo simplex, solar lentigines usually are seen on sun-exposed areas only [12].

Histologically, lentigo simplex is a localized circumscribed area of slightly hyperplastic epidermis that contains an increased number of normal-appearing melanocytes along the side and tips of the elongated rete ridges associated with basilar hyperpigmentation. Extreme degrees of epidermal pigmentation may be present, with numerous squamous cells exhibiting cytoplasmic melanin granules, usually in highest concentration near the epithelial–stromal junction (\bigcirc *Fig. 1.29*). There may be mild acanthosis and slight clubbing of the rete ridges, and heavily pigmented melanophages may be present in the upper dermis. At times, a minimal superficial dermal

Fig. 1.29

Lentigo simplex. Note the heavy concentration of deeply pigmented basalar keratinocytes at the tips of the accentuated rete ridges. Increased solitary melanocytes along the site of the retes are present (Taken from Atlas of Vulvar Disease [244]) inflammatory cell infiltrate is noted, but this is by no means constant.

Vulvar Melanosis

Vulvar melanosis is characterized by prominent brown to black pigmented macular areas with irregular borders that may be solitary or multiple, located on the labia minora or labia majora as well as on the vaginal introitus and perineum. The pigmented areas vary in size and may cover much of the vulva skin. Vulvar melanosis typically occurs in women of reproductive age and is more common on the squamous mucosa portion of the vulva [68, 201].

The microscopic findings are essentially similar to lentigo simplex, with intense basilar keratinocytic hyperpigmentation, although epithelial hyperplasia usually is not seen. The lesions typically are larger than those of lentigo, which characteristically are not more than 4 mm in diameter. The pigmentation may be intense within the basal layer with slight or no increase in the number of melanocytes. The melanocytes are typically arranged in single solitary units within the dermal–epidermal junction [68, 201].

Congenital and Giant Nevomelanocytic Nevi

Congenital nevi are found in approximately 10% of newborns and usually are less than 4 mm in diameter. Giant nevomelanocytic nevi (20 cm or more in diameter) (garment type), although rare, carry an increased risk of developing malignant melanoma in prepubertal individuals.

Junctional, Compound, and Intradermal Nevi

Vulvar melanocytic nevi may be junctional, compound, or intradermal. These nevomelanocytic types occur on the vulva with nearly equal distribution [42]. Clinically they usually are well defined, papular, uniformly pigmented, and typically less than 10 mm in diameter [197]. Nevus cells are somewhat larger than melanocytes and have round or ovoid nuclei. Dendrites are not present, and intercellular connections are not visible. The cells may lie singly within the dermis, but more commonly they tend to form nests. Unless they contain melanin, their cytoplasm is clear without granules or fibrils.

In pure junctional nevi, which are identified relatively infrequently on the vulva, the nevus cells are located within the epidermis and at the dermal–epidermal junction. Individual cells, or cell nests, bulge downward from the tips of the rete ridges. There is no connective tissue noted between the nevus cells and the adjacent squamous keratinocytes. Such nevi are young and somewhat undifferentiated.

With age, the nevus becomes a compound nevus with melanocytes located in the epidermis and the dermis. The basement membrane of the epidermis surrounding the nests disappears, and collagen and elastic fibers envelop the nests, pushing the epidermis upward. During this process, the lesion is clinically elevated above the level of the surrounding skin. Further differentiation results in complete enclosure of the nevus cells and nests by connective tissue elements such that they are entirely intradermal; no activity is seen at the dermoepidermal junction. These nevi are referred to as intradermal (\bigcirc *Fig. 1.30*). Most nevi biopsied on the vulva are either compound or intradermal in type. With time, nevi may regress completely or may result in a fibrous papule or acrochordon [177].

• Fig. 1.30 Intradermal nevus. Nests of nevus cells are evident within the dermis

Atypical Vulvar Nevi

The so-called atypical vulvar nevus has many clinical and histopathologic features in common with acquired dysplastic nevi. The atypical vulvar nevus occurs in young women ranging from 20 to 30 years of age. Although not considered specifically as dysplastic by some authors, or associated with dysplastic nevi in other sites, the atypical vulvar nevus demonstrates prominent variable-sized junctional melanocytic nests and lentiginous spread. Because of their intertriginous location, vulvar nevi are subjected to chronic irritation and rubbing, and therefore some of the atypicality is probably reactive. Although some features may suggest a diagnosis of melanoma, the lesion is small, well circumscribed, has maturation toward the dermis and lacks pagetoid spread, necrosis, or mitotic activity in the dermis [2, 44] (> Fig. 1.31). A zone of eosinophilic fibrosis may be present in the superficial dermis [82].

Dysplastic Nevi

Dysplastic melanocytic nevi are seen most often in young women of reproductive age. Rare on the vulva, they present as pigmented, elevated lesions greater than 0.5 cm in diameter with irregular borders. Microscopic examination reveals large epithelioid or spindle-shaped nevus cells with nuclear pleomorphism and prominent nucleoli. The nevus cells are clustered in intraepithelial nests and are present in skin appendages, including hair shafts and the ducts of sweat glands [2, 44, 177]. They often have a lowpower microscopic appearance of a large junctional nevus, with a dermal component that has spindle- or epithelioidtype nevus cells in nests or isolated within the papillary and reticular dermis. Three features distinguish a dysplastic nevus from melanoma. (1) Symmetric growth, which is evident on microscopic examination of a full cross section of the nevus, can be determined by visualizing a line drawn perpendicular to the surface of the center of the nevus. The halves should be mirror images of each other. (2) The most atypical cells are present in the superficial levels of the nevus, with smaller and more uniform cells in the deeper areas. (3) Rare pagetoid spread of single melanocytes with little or no involvement of the upper one third of the epithelium is seen and is usually present at the center of the lesion [2, 44, 177, 190]. In addition to malignant melanoma, a lesion of the dysplastic nevus syndrome should be included in the differential diagnosis. Individuals with dysplastic nevus syndrome have multiple large nevi, usually more than 0.5 cm in diameter, which may be found on the vulva and on the trunk and

Fig. 1.31

Atypical vulvar nevus. This acquired atypical nevus has marked variation in size and shape of the nests at the dermal epidermal junction with cytologic atypia characterized by hyperchromasia at this power. Small, benign-appearing nevus cells are present within the dermis, superficial and junctional areas (Taken from Atlas of Vulvar Disease [244])

extremities. Individuals with dysplastic nevus syndrome have a high risk of subsequent malignant melanoma, whereas women with isolated atypical nevi of the vulva do not. Vulvar nevi are influenced by hormonal changes. They appear more active or atypical during pregnancy. Quite a few nevi are removed during pregnancy or at the time of the delivery because of the changes in color or size induced by pregnancy.

Acanthosis Nigricans and Pseudoacanthosis Nigricans

Acanthosis nigricans has been reported involving the vulva, although other sites where skin folds are found,

including the axilla and submammary area, are more commonly involved. The clinical presentation is a diffuse, velvet-like, brown to gray-black skin change that is characteristically symmetric and may involve all the keratinized epithelium of the vulva, including the inguinal gluteal folds as well as the medial aspects of the upper thighs. Within the vulva, the pigmentation usually involves the labia majora and the lateral labia minora as well as the pubis [146]. In adults, acanthosis nigricans may be associated with adenocarcinoma of the stomach or other visceral malignancies. Its presentation should prompt the search for gastric and other tumors, especially if it occurs with sudden onset and is associated with pruritus and the appearance of multiple seborrheic keratosis (Leser–Trelet syndrome) [125].

A second variant of this type of skin change recognized in adults is pseudoacanthosis nigricans. This lesion has been reported in obese individuals as well as those with autoimmune or endocrine disorders or lipodystrophy.

A third variant of acanthosis nigricans occurs in children. It is not associated with any of the disorders described in adult variants [207]. The microscopic features are characterized by prominent papillomatosis with acanthosis and hyperkeratosis. Keratinous horn cysts may be seen within the epidermis. Increased melanin typically is seen within the basal layer. No significant inflammation or distinctive dermal changes are found.

Cysts

Bartholin Cyst and Abscess

The Bartholin ducts are prone to obstruction at their vestibular orifice. Such obstruction results in subsequent accumulation of secretion with associated cystic dilatation of the duct [176, 204]. The content of an uninfected Bartholin cyst is a mucoid, clear, translucent liquid that, when cultured, fails to grow bacteria. The secretion stains with mucicarmine, PAS before and after diastase digestion, and Alcian blue at pH 2.5, consistent with sialomucin. The epithelium lining the cyst may be squamous, transitional, or low cuboidal mucinous epithelium. In some cases it is flattened and otherwise not classifiable (> Fig. 1.32). Generally, there is minimal, if any, inflammatory response within the adjacent tissue. The epithelium of the cyst is immunoreactive for carcinoembryonic antigen (CEA). Bartholin cysts may be recurrent, and occasionally are associated with primary infection of the Bartholin gland, in which case they require marsupialization. In postmenopausal women, recurrent cysts or

a palpable mass after cyst drainage may require excision of the gland because of the possibility of associated carcinoma of the Bartholin gland (see O Chap. 2, Premalignant and Malignant Tumors of the Vulva). Bartholin adenocarcinomas, when present, tend to be in the tissues adjacent to the cyst wall.

Bartholin abscess is an acute process often associated with Neisseria gonorrheal infection, although it may be related to Staphylococcus or to other anaerobic organisms. The patient presents with tenderness and swelling in the Bartholin gland area. Microscopically, the Bartholin duct abscess demonstrates a striking acute inflammatory reaction within the stroma surrounding the duct. A purulent exudate is present within the lumen of the abscess wall. Excision, drainage, and antibiotics are the treatments of choice. Occasionally, the infection subsides without abscess formation or becomes chronic. Bartholin duct cysts, resulting from distal obstruction of the duct secondary to chronic inflammation and scarring, may be a late sequela of chronic infection. Mucocele-like changes have been reported in the Bartholin glands.

Keratinous Cyst (Epithelial Inclusion Cyst)

Keratinous cysts frequently are seen on the vulva; generally, these cysts are located on the labia majora and may involve the clitoris. Typically, they are superficial and range in size from 2 to 5 mm, but may be larger. They may occur at any age, even in newborns. Milium,

Mucous Cyst

Mucous cysts usually are seen within the vestibule and are lined by mucus-secreting, cuboidal to columnar epithelium without peripheral muscle fibers or evidence of myoepithelial cells (**)** *Fig. 1.34*). Squamous metaplasia may be present. Histochemical studies demonstrate that

a type of small keratinous cyst, has been reported in the

vulva [105]. Keratinous cysts usually contain a white to

pale yellow, grumous or cheesy material without hair.

Foreign body-type giant cells may be seen in the tissue

adjacent to the cyst wall, secondary to keratinous material

leaking into the adjacent dermis. The lining of the cyst is

characterized by a relatively flattened, stratified squamous

epithelium that is immunoreactive for high molecular

weight keratin (**>** *Fig. 1.33*). Whether these cysts represent

primary keratinous cysts, unrelated to sebaceous glands,

or are actually occluded sebaceous glands that have under-

gone squamous metaplasia is debatable. Step sections

through the cysts may show communication with the

surface epithelium or underlying or adjacent sebaceous

glands in some cases. An unusually high frequency of

vulvar keratinous cyst has been reported in Nigerian

children, related to female circumcision [92]. Such cysts

are not considered premalignant, although carcinoma

may arise in keratinous cysts. Treatment of asymptomatic

small cysts usually is not necessary; however, surgical

excision may be necessary for diagnosis or if the cyst is

enlarging, symptomatic, or secondarily infected.

Fig. 1.32
Bartholin cyst. The dilated duct has a flattened transitional type epithelial lining

Fig. 1.33 Keratinous cyst. Stratified squamous epithelial lining is evident

the epithelial cells lining the cyst stain with both Alcian blue and Mayer mucicarmine, whereas the epithelial lining of cysts of mesonephric origin does not exhibit these reactions [72, 162]. The cysts probably develop from occlusion of minor vestibular glands [72]. Electron microscopic studies of mucinous cysts of the vestibule have demonstrated that these cysts have an epithelium consistent with an origin from urogenital sinus endoderm [195]. Because the vulvar vestibule arises embryologically primarily from the urogenital sinus, the origin of these cysts from minor vestibular glands is not inconsistent with a urogenital sinus origin.

Mucinous metaplasia of the vulva has been described, presenting as a solitary depressed red area of the labium minus [46]. In one reported case, this condition responded to topical estrogen cream. The finding of columnar cell metaplasia of the nonkeratinized squamous epithelium of the vulva vestibule or vagina, to columnar epithelium of mucinous or tuboepithelial type, also has been described after Stevens–Johnson syndrome as well as after laser and 5-fluorouracil (5-FU) therapy [143].

Apocrine Hidrocystoma/Cystadenoma of the Vulva

Apocrine hidrocystoma is a well-circumscribed cyst, lined by epithelium with apocrine differentiation. The lining cells have abundant pink cytoplasm with apical snoutlike

Fig. 1.34

Mucous cyst of the vestibule. Simple columnar mucussecreting cells rest on the basement membrane. Note absence of underlying smooth muscle layer (Courtesy of R.J. Kurman, M.D., Baltimore, MD) secretion. When the lining cells form micropapillary projections into the cystic space, the lesion is termed apocrine cystadenoma (\bigcirc *Fig.* 1.35). The lesion typically arises in the apocrine gland-rich region, which includes the vulva [83].

Ciliated Cysts of the Vulvar Vestibule: Vestibular Adenosis

Cysts lined with tuboendometrial epithelium resembling mullerian-type epithelium have been reported in the vulvar vestibule in women with chronic inflammation associated with Stevens–Johnson syndrome or with extensive laser or 5-FU therapy [106, 143, 210]. The cysts are believed to be acquired as the müllerian system does not contribute to the development of the vestibule. They are distinguished from endometriosis by the absence of

Fig. 1.35

Apocrine cystadenoma. A well-circumscribed cystic space lined by epithelium with apocrine differentiation. The epithelial cells form micropapillary projections into the cystic lumen (Courtesy of R.J. Kurman, M.D., Baltimore, MD) associated endometrial stroma or hemosiderin-laden macrophages. In the vagina, such changes, when associated with 5-FU, slowly regress over time by a process of squamous metaplasia. In the vestibule, such cysts may be followed; if persistent or symptomatic, they can be excised.

Mesonephric-like Cyst (Wolffian-like Duct Cyst)

Mesonephric-like cysts are encountered occasionally on the lateral aspects of the vulva and the vagina. They are thin walled, translucent, and contain clear fluid. The lining epithelium is cuboidal to columnar and is not ciliated. Immunohistochemical techniques show smooth muscle in the submucosal area [103].

Mammary-like Cysts (Hidrocystoma)

Hidrocystoma originates in mammary-like glands involving the main collecting duct of anogenital mammary-like sweat glands. It is characterized by a peripheral basal layer of myoepithelial cells and a luminal layer of cuboidal to columnar cells. The luminal layer has discrete apical decapitation secretion. Cutaneous glands, including mammary-like glands, and dartos muscles surround the cysts. The mammary-like cysts may have similar alterations resembling eccrine, apocrine, and mammary glands, and most likely represent involution cysts of mammary-like glands [233].

Cyst of the Canal of Nuck (Mesothelial Cyst)

Cysts of the canal of Nuck are generally found in the superior aspect of the labia majora or inguinal canal and are believed to arise from inclusions of the peritoneum at the inferior insertion of the round ligament into the labia majora. As such, they are analogous to the hydrocele of the spermatic cord. These cysts can achieve substantial size and must be distinguished from an inguinal hernia, with which they are associated in approximately one third of cases [205].

Benign Solid Tumors and Tumor-like Lesions

Benign solid tumors of the vulva are rare. They may be divided into those that are of epithelial origin (squamous and glandular) and those that originate from vulvar soft tissue (mesenchymal origin).

Benign Squamous Epithelial Tumors

Fibroepithelial Polyp (Acrochordon)

A fibroepithelial polyp, or "skin tag," is a relatively uncommon benign polypoid tumor of the vulva. In contrast to the vestibular papilloma, the fibroepithelial polyp occurs on the hair-bearing skin of the vulva. These tumors vary in their clinical appearance from small, flesh-colored or hyperpigmented, papillomatous growths resembling condylomata to large pedunculated tumors that often are hypopigmented. On cut section, fibroepithelial polyps are soft and fleshy. Small tumors may resemble intradermal nevi; large lesions may present cosmetic problems but generally are clinically insignificant. They usually arise in hair-bearing skin but may be found on the labia minora [35]. The origin is most probably from a regressing nevus.

Histologically, fibroepithelial polyps may be of two types, one that is predominantly epithelial and another that is primarily stromal. The epithelial surface varies from a thickened layer with papillomatosis, hyperkeratosis, to an attenuated flattened layer exhibiting multiple primary folds (\bigcirc *Fig. 1.36*). The connective tissue stalk is composed of loose bundles of collagen with a moderate number of blood vessels. The stroma may be edematous and hypocellular. The stromal cells usually have relatively uniform nuclei; however, marked atypia may be seen in some cases [35].

Fig. 1.36

Fibroepithelial polyp. This polyp is primarily stromal, with prominent vessels within the central stalk. The epithelial surface is keratinized, stratified squamous epithelium. No inflammation or glandular elements are evident

Vulvar Vestibular Papilloma (Micropapilloma Labialis)

The vestibular papilloma is a benign papillary lesion that is composed of a delicate fibrovascular connective tissue core covered by squamous epithelium, histologically similar to a fibroepithelial polyp. In contrast to a fibroepithelial polyp, vestibular papilloma typically occurs on the vestibule and may be single or multiple. They are relatively common lesions. When multiple, they also may involve the medial aspects of the labia minora and posterior medial labia majora, forming clusters of papules. They occur almost exclusively in women of reproductive age. Vestibular papillae are small, usually less than 5 mm in length, with a diameter of 1-2 mm. Solitary lesions usually are seen adjacent to the hymen, whereas multiple papillomas typically occur in clusters, usually on the lateroposterior aspects of the vestibule. They may be asymptomatic and associated with pruritus. In some cases, they may be seen in women with vulvar vestibulitis. Vulvar vestibular papilloma, associated with vestibular pruritus, burning, or dyspareunia, has been identified as a clinical complexity. The etiology of vestibular papillomatosis is unknown in most cases. No significant association with HPV has been demonstrated [17, 55, 157]. These papillae may be an anatomic variant, the female homologue of pearly penile papules.

On microscopic examination, vestibular papillae typically have features of an angiofibroma with stratified nonkeratinized squamous epithelium, which is glycogenrich in women of reproductive age. They may have a thin keratin layer. The papillae have a fibrovascular core, often with a prominent central vessel. Usually inflammation is not present. The glycogen-rich squamous epithelium should be distinguished from HPV changes by having normal-sized nuclei whereas the koilocytes have enlarged atypical nuclei. Other features of HPV infection, including dyskeratosis, parabasal hyperplasia, accentuation of intracellular bridges, and multinucleation, are not identified in glycogen-rich epithelium. In situ hybridization and PCR for HPV may be performed if the findings are equivocal.

Seborrheic Keratosis

Seborrheic keratosis is a benign epithelial growth characterized by acanthosis, papillomatosis, hyperkeratosis, and epithelial invaginations forming horn cysts. The lesions are raised with irregular borders occurring on hair-bearing skin of the vulva. They vary from pale brown to brownish black and appear to be stuck onto the skin surface. Although clinically insignificant, their gross appearance often mimics that of a nevus or melanoma. Seborrheic keratosis of genital skin has been associated in a few studies with human papillomavirus (HPV) infection but is not generally considered a lesion caused by HPV [9, 131]. Multiple seborrheic keratosis presenting over a short period of time may be associated with internal malignancy (Leser–Trelat syndrome) [125]. This association is especially strong when associated with acanthosis nigricans.

On low-power examination, the entire lesion appears to be above a straight line drawn from the normal epidermis at one side of the lesion to the normal epidermis at the other side. Both mature squamous cells and basal type cells are noted in strands and cords surrounding numerous horny keratin cysts (\bigcirc *Fig. 1.37*). Varying degrees of hyperpigmentation may be present.

Fig. 1.37

Seborrheic keratosis, pigmented. When pigmented, these lesions may mimic vulvar intraepithelial neoplasia (VIN) or melanoma on the vulva. The melanocytic hyperplasia and hyperpigmentation are present primarily in the basal layers. A keratin pearl is present

Keratoacanthoma

Keratoacanthoma is composed of glassy squamous epithelial proliferation in which horny masses of keratin are pushed upward while tongues of squamous epithelium invade the dermis, resembling squamous cell carcinoma. These tumors commonly occur on sun-exposed skin and may arise on hair-bearing skin of the vulva. They are rapidly growing but are usually self-limited. Keratoacanthoma is generally accepted as a well-differentiated squamous cell carcinoma, keratoacanthoma type. Metastasis of keratoacanthoma has been reported [113, 78]. Complete excision with a clear histologic margin is the treatment of choice.

Glandular Tumors

Papillary Hidradenoma (Hidradenoma Papilliferum)

Clinical Features

Papillary hidradenoma is a benign tumor of apocrine sweat gland origin, composed of epithelial and myoepithelial cells lining complex delicate fibrovascular branching stalks. Papillary hidradenoma usually presents as a small, dome-shaped tumor less than 2 cm in size. The lesion generally arises from the interlabial sulci, or from the lateral surface of the labia minora. The tumors usually are asymptomatic; however, ulceration of the overlying surface may produce bleeding. Papillary hidradenomas have not been described before puberty, and almost all cases have occurred in Caucasian women [14]. There is evidence that they arise from specialized anogenital mammary-like "sweat" glands [232].

Microscopic Findings

Histologically, under low-power examination, the tumor simulates a well-differentiated adenocarcinoma (\bigcirc *Fig. 1.38*). Stromal compression often results in the formation of a well-circumscribed pseudocapsule. At times, epithelial cells become entrapped within the compressed connective tissue, creating a pseudoinfiltrative appearance. The tumor is composed of numerous tubules and acini lined by a single or double layer of cuboidal cells, the outer layer representing myoepithelial cells (\bigcirc *Fig. 1.39*). At times, the cells lining the lumen of the adenomatous structures are large and pale. An inflammatory reaction is unusual unless secondary infection is present. Mitotic figures are rare, and only mild degrees of cellular and nuclear pleomorphism are present.

Fig. 1.38

Papillary hidradenoma. This well-circumscribed adenomatous dermal tumor has no connection to skin surface. At low magnification, this benign tumor can be misinterpreted as adenocarcinoma

\

■ Fig. 1.39 Papillary hidradenoma. High-power examination shows tubules and acini lined with a single or double layer of bland cuboidal to columnar cells with underlying myoepithelial cells

Clinical Behavior and Treatment

Clinically, the hidradenoma is benign; however, an intraductal carcinoma resembling mammary-type apocrine epithelium has been described arising in a hidradenoma [174]. Local excision, including the base of the mass, is a sufficient therapy. Many names, including clear cell hidradenoma, clear cell myoblastoma, solid cystic hidradenoma, eccrine acrospiroma, eccrine sweat gland adenoma of clear cell type, and apocrine hidradenoma, have all been used for this entity [113]. Nodular hidradenoma is generally considered a tumor of eccrine sweat gland origin because it contains eccrine enzymes. Isolated examples of this tumor have been reported on the vulva [57].

Histologically, nodular hidradenoma is composed of a well-circumscribed lobulated mass with occasional cystic spaces. Tubular structures, sometimes branching, are often found in the solid areas. The cells are usually the mixtures of pink polyhedral cells and clear cells. The proportion of these two types of cells varies. In addition, secretory cells, dermal and epidermal ductal cells, and immature basaloid cells can be found in this tumor. The relatively small nucleus is round to oval and may exhibit an irregular outline. The chromatin frequently is clumped, and a single small nucleolus often is seen. Mitotic figures are not uncommon (\bigcirc Fig. 1.40) [113]. Wide local excision is considered adequate therapy.

Syringoma

The syringoma is a benign tumor of eccrine duct origin characterized by multiple, small, relatively uniform epithelial-lined tubules and cysts within a fibrous stroma. It is assumed to be an adenoma of the eccrine ducts. These lesions occur on the vulva as well as the eyelids, cheeks, axillae, and abdomen. Clinically, multiple clustered fleshcolored papules are noted within the deeper skin layers of the labia majora bilaterally. They often are asymptomatic, although pruritus may occur [34].

Histologically, the tumor lacks a clearly defined border. Within the dermis, numerous small, dilated duct spaces are seen. These spaces usually are lined by two rows of epithelial cells that appear flat, secondary to pressure atrophy. The comma-like formation of these glandular spaces is characteristic (\bigcirc *Fig. 1.41*). The stroma has a desmoplastic appearance.

Mixed Tumor of the Vulva (Pleomorphic Adenoma, Chondroid Syringoma)

Mixed tumor of the vulva is a rare neoplasm that usually presents as a solid, subcutaneous tumor involving the labia majora or the Bartholin gland area or both. The histopathologic findings are similar to those of mixed tumors of the parotid and other salivary glands. The tumor consists of epithelial cells arranged in tubules or nests, mixed with a fibrous stroma containing chondromatous, osseous, and myxoid elements. These stromal-like elements are believed to arise from pluripotential myoepithelial cells that, in the vulva, are found in the Bartholin glands, sweat glands, and accessory breast tissue [200]. These tumors are benign, but local recurrence may occur. Malignant mixed tumors have

Fig. 1.40 Nodular hidradenoma (clear cell hidradenoma). High power view of the sheets of large clear cells

Fig. 1.41

Syringoma. The comma pattern of the eccrine structures is easily appreciated (Courtesy of V. Vincek, Gainesville, FL)

been reported [168]. When metastasis occurs from a malignant mixed tumor, it is usually composed of only epithelial elements. There are insufficient cases of vulvar mixed tumors to determine its natural history in this site. Wide local excision, with free margins, is the recommended therapy of choice for both the primary tumor and local recurrences.

Trichoepithelioma

Trichoepithelioma is a benign tumor of follicular origin that is rare in the vulva [40]. The tumor presents as single or multiple cutaneous nodules with normal-appearing overlying epithelium. On microscopic examination, the tumor is composed of complex interconnected nests of basaloid cells, which form small cysts containing keratin "horn cysts." The cells in trichoepithelioma are monomorphic without hyperchromasia or nuclear atypia. Occasionally, a granulomatous reaction with giant cells is present next to ruptured horn cysts. Hair or hair-forming elements are rare. Trichoepithelioma is distinguished from basaloid carcinoma or basal cell carcinoma in that it is not infiltrative, contains "horn cysts" and granulomas, may exhibit hair-forming elements, and is not associated with an intraepithelial neoplastic component. Local excision is therapeutic.

Proliferating Trichilemmal Tumor/Cyst (Pilar Tumors)

Proliferating trichilemmal tumor/cyst is rare on the vulva, occurring in the dermis of the labium majus, where it presents as a slowly growing solid mass that may have a cystic cavity in the center of the tumor [7, 186]. It is thought to arise from the cells of the outer root sheath of a hair follicle. Microscopic examination reveals a lobulated proliferation of squamous epithelium with a pushing border. The tumor may show no connection with the overlying epithelium. An eosinophilic glassy layer of collagen (vitreous layer) may surround some of the lobules. The tumor cells are palisaded peripherally and have increased cytoplasm in the cells toward the center of the lobules with abrupt changes into eosinophilic amorphous keratin, resembling keratinization of the follicular infundibulum (trichilemmal keratinization). Some degree of nuclear pleomorphism and cytologic atypia, as well as individual cell keratinization, forming squamous "eddies" may be present. Focal calcification within the amorphous keratin may occur.

Trichoblastic fibroma also has been described on the vulva [79]. Local excision is therapeutic.

Adenoma of Minor Vestibular Glands

Adenoma of minor vestibular glands is a rare benign tumor. These lesions are small, ranging from 1–2 mm to 1 cm. The tumor is composed of multiple lobular clusters of small glands lined by mucin-secreting columnar epithelium. Some may represent a nodular hyperplasia. Most cases have been found incidentally in vestibulectomy specimens excised for vulvar vestibulitis [73, 182].

Endometriosis

Vulvar endometriomas develop from ectopic endometrial epithelium. Endometrium implanted in an episiotomy incision at the time of delivery, as well as menstrual endometrium implanting in a small area of trauma, has been implicated in the etiology of this condition (see Ochap. 13, Diseases of the Peritoneum). The clinical appearance is variable, ranging from bluish-red cystic masses to amorphous deep-seated nodules. Endometriomas of the vulva usually are located near the posterior fourchette. Cyclic enlargement and regression often are noted. Fineneedle aspiration may be of value in the diagnosis, demonstrating benign glandular and stromal cellular elements [140].

Histologically, both endometrial glands and stroma are present with a fibrotic response. A foreign body– giant cell reaction and hemosiderin-laden macrophages may be noted, especially in cases in which the onset was preceded by recent surgery.

Angiokeratoma

Angiokeratoma is a variant of hemangioma and occurs almost exclusively on the scrotum and vulva; however, it has been described as presenting as an ulcerated tumor of the clitoris [147]. Somewhat larger than senile hemangioma, these lesions often are purple to brown-black in color and occur primarily in women of childbearing age. Their peculiar appearance often prompts excisional diagnostic biopsy, although they usually have no clinical significance [47]. Multiple lesions may be associated with Fabry's disease [244].

Histologically, the dilated endothelial-lined channels are separated by strands and cords of squamous epithelial cells representing downgrowth from the overlying epithelium, which is often hyperkeratotic (**)** *Fig. 1.42*). Varying degrees of acanthosis and papillomatosis are present, along with a mild inflammatory reaction in the deep dermis. Angiosarcomas and Kaposi sarcoma are included

in the differential diagnosis of vascular tumors [132]. These malignant tumors typically are more cellular and have greater cellular atypia. In addition, they have less well-formed vascular spaces that are usually slitlike and which are infiltrative with poorly defined margins.

Pyogenic Granuloma (Granuloma Pyogenicum)

Pyogenic granuloma is a variant of hemangioma that may occur anywhere on the skin. It is analogous to the epulis tumor of pregnancy. Most of the pyogenic granulomas that occur on the vulva do so during gestation. Although previously thought to be secondary to a superficial wound infection, this tumor is recognized as a form of hemangioma characterized by rapid growth. Because the surface is easily traumatized, the lesion often is secondarily infected. Histologically, a thin ulcerated epidermis is noted covering a mass of granulation tissue. Capillaries are numerous, and secondary inflammatory changes frequently are found within the stroma (> Fig. 1.43). Around the periphery of the lesion, there may be a downward growth of the epidermis producing a "collarette." The overall architecture appears lobulated (lobular capillary hemangioma) with a few thickened fibrous septae separating the vascular proliferation.

Lymphangioma Circumscriptum

Lymphangioma circumscriptum is a relatively rare condition that is benign and thought to be secondary to a localized developmental defect of the dermal lymphatics or a

Fig. 1.43

Pyogenic granuloma. Superficial ulceration of the mucosa is present, with a chronic inflammatory infiltrate. Within the submucosa, multiple endothelial-lined vascular spaces are seen surrounded by a delicate fibrous stroma, resembling granulation tissue

malformation. Initial presentation may be in childhood; however, vulvar cases have been described initially presenting in women in their thirties. The lesion is characterized by multiple clustered blebs and vesicles that are white to purple. The lesions may be small, but may exceed 2 cm in diameter [37, 101, 215]. The blebs of lymphangioma circumscriptum may become secondarily infected, ulcerated, and macerated, resulting in pain and cellulitis. The diagnosis usually is made by the clinical appearance and by biopsy.

The microscopic findings reveal distinctive subepidermal cystic spaces containing lymph that is eosinophilic and acellular. These endothelial-lined cysts, which may be multiloculated, are located immediately beneath the basal epithelial layer in the papillary dermis (\bigcirc *Fig.* 1.44). Dilated lymphatic spaces can be found in the reticular dermis. Some of these deeper lymphatics may be surrounded by a prominent peripheral smooth muscle layer. The overlying epithelium usually is unremarkable but may be eroded or hyperkeratotic. Treatment includes surgical excision or laser therapy [101].

Miscellaneous Tumors and Tumor-like Lesions

Verruciform Xanthoma

Verruciform xanthoma is a benign lesion that clinically mimics a malignant tumor. It is a tumor of mucosal origin and is most commonly seen in oral cavity and, rarely, in anogenital mucosa as well as in the vulvar mucosa. Histologically, the lesion has verruciform hyperplasia with the expended dermal papillae/submucosa, which is filled with foamy histiocytes [129]. Patients with verruciform xanthoma may have autoimmune diseases.

Nevis Lipomatous Superficialis

This distinctive benign tumor of adipose tissue presents as a nodule within the dermis with normal overlying epithelium. This tumor has been considered a hamartoma of fat. Microscopic examination reveals adipose tissue within the superficial dermis, distinct from the underlying adipose tissue. tissue in the vulva may present as an amorphous enlargement of the labia, usually first noted in association with pregnancy [232]. Benign cystic disease (fibrocystic disease), as well as fibroadenomas, lactating adenomas, and intraductal papillomas, have been described [232]. Cystosarcoma phyllodes, a tumor arising in these mammary-like tissues of the vulva is rare (\bigcirc *Figs.* 1.45 and \bigcirc 1.46). Adenocarcinoma of the mammary-like tissue of the vulva has been reported [110, 232]. Surgical removal of symptomatic mammary-like tissue is advocated except when such tissue is discovered during pregnancy, in which case therapy should be deferred until after puerperal regression is complete.

Mammary-like Tissue Within the Vulva

The findings of mammary-like tissue in the vulva is not well understood, but it is currently considered to be ectopic in nature [232, 233]. Clinically, mammary-like

Fig. 1.46

Phyllodes tumor of the vulva. Marked stromal expansion with spindle cells and proliferation of epithelial cells forming papillary structures (Courtesy of R.J. Kurman, M.D., Baltimore, MD)

Salivary Glandlike Tissue

Salivary glandlike tissue has been observed in the vulva [145].

Idiopathic Vulvar Calcinosis

Although not a cystic condition, vulvar calcinosis may resemble keratinous cysts on clinical presentation, presenting as small (usually 2 mm or less), firm, subcutaneous nodules involving the majora and fourchette. The vulvar cases reported have occurred predominantly in adolescent women. Histologic examination demonstrates normalappearing overlying epithelium with basophilic acellular superficial subcutaneous nodules measuring from less than 0.1 mm to approximately 2 mm, associated with a chronic inflammatory infiltrate, mast cells, and foreign body giant cells. The acellular material stains with Von Kossa stain and contains acid mucopolysaccharides [10]. The process is rare, benign, and of uncertain etiology but appears similar to idiopathic scrotal calcinosis [19].

Vulvar Amyloidosis

Nodules within the vulva have been described related to involvement of the vulva in a woman with systemic amyloidosis, which may mimic giant condyloma.

Benign Lesions of the Urethra

Urethra Prolapse

Prolapse of the urethral mucosa may occur at any age, but it is most common in premenarchal children and in postmenopausal women. Redundancy of the mucosa and laxity of the supporting periurethral fascia contribute to the formation of prolapse, which is aggravated by increased abdominal pressure; it may be related to relative lack of estrogen. The prolapsed urethra may present as a large red polypoid mass covered with urethral mucosa with edematous vascular submucosa, protruding from the urethra and mimicking a urethral neoplasm. Histologically, the urethral mucosa may exhibit ulceration, and the underlying connective tissue is generally filled with an inflammatory infiltrate. Vascular engorgement usually is present. Cryosurgery is an effective method of treatment [107].

Urethral Caruncles

Caruncles are sessile or polypoid masses that arise at the urethral meatus in postmenopausal women. They may represent localized areas of prolapse, and are by far the most common lesions of the urethra. Caruncles often are asymptomatic but may cause bleeding or dysuria. Clinical differentiation from urethral carcinoma may be impossible; therefore, excision is indicated for diagnosis. Recurrences may be observed [253]. Histologically, the submucosa of the urethral caruncle may contain large venous channels that often are dilated and engorged. A myxomatous or granulomatous pattern may be present in the supporting tissue, which often is densely infiltrated with chronic inflammatory cells. Excision, with hemostatic control of the base of the lesion, is the treatment of choice.

Malacoplakia of the Urethra

Malacoplakia is a chronic granulomatous inflammatory process that usually involves the bladder if the urethra is involved. The lesion presents as a polypoid mass at the urethral meatus.

On microscopic examination the lesion contains foamy histiocytes, lymphocytes, granulocytes, and plasma cells. The diagnostic Michaelis–Gutmann bodies are seen within the cytoplasm of the histiocytes as inclusions having a blue-gray color (**)** *Fig. 1.47*). The inclusions may appear laminated or targetoid. With PAS stains, the Michaelis–Gutmann bodies usually stain pink to red (see **)** Chap. 3, Diseases of the Vagina). Many of the adjacent histiocytes also contain PAS-positive cytoplasmic material. Excision may be diagnostic and curative for small

Fig. 1.47

Malacoplakia of the urethra. Round inclusions are present in some of the histiocytes (Michaelis–Gutmann bodies), which are approximately the size of the nuclei of the histiocytes and have a dark periphery and pale center (Courtesy of R.J. Kurman, M.D., Baltimore, MD) lesions within the urethra, although recurrences are not uncommon. Antibiotics also may be of value.

Periurethral Cysts

Periurethral cysts can be subclassified according to their epithelial lining, and are similar to cysts of the vulvar vestibule. The cysts can be classified into four types: epithelial inclusion, mucous, mesonephric-like, and urothelial.

Epithelial Inclusion (Keratinous) Cysts

Epithelial inclusion cysts have a squamous epithelial lining, and may arise secondary to trauma or surgical procedures that entrap epithelium (see vulvar keratinous cysts).

Mucous Cysts

Mucous cysts have a columnar, endocervical-type epithelial lining and may have associated squamous epithelium, secondary to squamous metaplasia. The cytoplasm of the columnar epithelium contains mucin. These cysts appear essentially identical to the mucous cysts of the vulvar vestibule, although they have been referred to as müllerian cysts.

Mesonephric-like Cysts

Mesonephric-like cysts have a low cuboidal epithelium that does not stain with mucin.

Urothelial Cysts

Urothelial cysts usually are seen in infants and are rare in adults. They are believed to arise from the Skene ducts or from proximal urothelial ducts. These cysts have a urothelial epithelial lining, although those near the urethra meatus may have a squamous epithelial lining.

Suburethral Diverticulum

Suburethral diverticula originate from the upper two thirds of the posterior urethral wall and may extend cephalic to involve the region beneath the vesicle neck. Although a congenital etiology has been proposed for some cases, most are thought to begin as an infection in one of the tubular periurethral glands, followed by abscess formation with eventual breakthrough into the urethral lumen.

Urethral Condyloma Acuminatum

Urethral condyloma acuminatum may present like a caruncle or urethral carcinoma, and usually is seen in women of reproductive age and not in older individuals. In children, urethral and periurethral condylomata may be polypoid and clinically may suggest sarcoma botryoides. In adult women, they usually are associated with other lower genital infections, especially vulvar vestibular condyloma acuminatum. Some patients may have symptoms of urethritis associated with urethral condyloma acuminatum. In these patients, the condylomas may be in the mid- or upper urethra. On biopsy they have a stratified squamous epithelium within which typical features of mucosal HPV infection are seen, including koilocytosis, multinucleation, and parabasal hyperplasia. HPV types 6 and 16 have been observed in urethral condylomas.

Vulvar Intraepithelial Neoplasia

(Vulvar Squamous Intraepithelial Lesion, Dysplasia, Carcinoma In Situ)

General Features

The incidence of vulvar intraepithelial neoplasia (VIN) (dysplasia, carcinoma in situ) has nearly doubled when comparing recorded cases between 1973-1976 and 1985-1986 and is becoming more frequent in young women 20-35 years of age (30, [87]). The true incidence of VIN probably is higher, because generally only a subset, carcinoma in situ (VIN 3) cases, is reported. Approximately 50% of these women have other neoplasia involving the genital tract, most often cervical intraepithelial neoplasia (CIN). Approximately one half of these women have a history of a preexisting or concomitant sexually transmitted disease, of which condylomata acuminata is the most frequent. There is an association between VIN and cigarette smoking. Most patients are symptomatic, often with pruritus. Current terminology for squamous intraepithelial lesions (dysplasia, carcinoma in situ, vulvar intraepithelial neoplasia (VIN), as proposed by the World Health Organization [WHO]) is summarized in **Table 2.1** [175]. Lesions of the vulva that are pigmented and papular or verrucoid have been clinically termed bowenoid papulosis by some authors [166], but they are histologically indistinguishable from other forms of intraepithelial neoplasia and behave in a similar fashion. The separate term bowenoid papulosis therefore is not included in the WHO classification.

Clinical Features

Vulvar pruritus and irritation are the most common presenting symptoms. In some cases, the patients observe the lesion and seek medical assistance. Approximately one third of the patients are asymptomatic [174]. The lesions of VIN typically have a raised surface and are macular or papular (\bigcirc *Figs. 2.1–2.4*). The most common sites of VIN on presentation are the labia minora and the perineum. Aproximately one third of VIN cases have perianal involvement, and such lesions may extend into the anus. Approximately two thirds of VIN lesions are multifocal [174].

Although the clinical appearance of VIN lesions can be highly variable, at presentation, approximately one half of patients with VIN have white lesions, or lesions that are

Table 2.1

Classification of squamous intraepithelial lesions of the vulva (vulvar intraepithelial neoplasia [VIN]/dysplasia, carcinoma in situ)

Low-grade vulvar intraepithelial neoplasia (VIN 1) (Mild dysplasia) (Low-grade squamous intraepithelial lesion (LSIL)0: a squamous intraepithelial lesion in which nuclear abnormalities are confined to the lowest one third of the epithelium

High-grade vulvar intraepithelial neoplasia (VIN 2) (Moderate dysplasia) (High-grade squamous intraepithelial lesion (HSIL)): a squamous intraepithelial lesion in which nuclear abnormalities involve the lower two thirds of the epithelium

High-grade vulvar intraepithelial neoplasia (VIN 3) (Severe dysplasia)) (High-grade squamous intraepithelial lesion (HSIL)): a squamous intraepithelial lesion in which nuclear abnormalities extend into the upper third of the epithelium, but not involving the full thickness

High-grade vulvar intraepithelial neoplasia (VIN 3) (Carcinoma in situ); includes differentiated (simplex) type VIN (High-grade squamous intraepithelial lesion (HSIL, differentiated type)): a squamous intraepithelial lesion in which nuclear abnormalities involve the full thickness of the epithelium or in which the lower portion of the epithelium is replaced by a lesion resembling grade 1 squamous cell carcinoma

Source: From ref. [92].

distinctly aceto-white, after the application of topical 3-5% acetic acid. Approximately one quarter of the lesions are pigmented (**>** Figs. 2.3 and **>** 2.4). VIN 3 is, in fact, the second most common pigmented vulvar lesion. Pigmented VIN usually occurs in keratinized vulvar skin. The remainder of VIN lesions may be pink, gray, or red. Lesions involving the nonkeratinized mucous membrane of the vestibule appear red. Such red lesions have been called erythroplasia of Queyrat, but like bowenoid, papulosis are not designated separately and are included within the VIN category. The lesions may be macular (**)** Fig. 2.1) or papular (**)** Fig. 2.2). In approximately three quarters of cases, they are multiple, and in the majority of the remainder of cases, VIN is a solitary lesion. Solitary lesions appear to be more common in older women and are more commonly associated with invasive squamous carcinoma [24]. Confluent growth of VIN is relatively uncommon [148,174] (see SFigs. 2.1 and ≥ 2.4). The anal skin and squamous mucosa of the anal canal are the most frequently involved secondary sites.

Vulvar intraepithelial neoplasia (VIN). Multiple macular and plaquelike aceto-white areas are present on the labia majora

Fig. 2.2 Vulvar intraepithelial neoplasia (VIN). Multiple pigmented papules are present on the labia majora

Fig. 2.4 Vulvar intraepithelial neoplasia (VIN). Confluent distribution of pigmented, slightly raised, rough-surfaced areas involving the labia majora and minora

Microscopic Findings

The epithelial cells of VIN have a high nuclear: cytoplasmic ratio and lack cytoplasmic maturation above the basal and parabasal layers. Mitotic activity is present above the basal layer, and the mitotic figures are often abnormal in appearance. Multinucleation and dyskeratosis, including formation of intraepithelial squamous pearls, may be seen (\bigcirc *Figs. 2.5* and \bigcirc *2.6a, b*). Nuclear pleomorphism and hyperchromasia are present; however, nucleoli are uncommon. Radial dispersion of nuclear chromatin and coarse nuclear chromatin are seen in the epithelial cells of VIN, corresponding to an increased number of interchromatinic

Fig. 2.5

VIN 2, warty type. In the lower two thirds of the epithelium cells are crowded and lack maturation. Nuclei are hyperchromatic and pleomorphic. Within the upper third of the epithelium there is cellular maturation with prominent koilocytosis and perichromatinic granules. The so-called individual cell keratinization seen within the epithelium is attributed to the presence of aggregated intracytoplasmic tonofilaments that may be produced in the process of abnormal cell division.

Parakeratosis is seen when keratinocytes fail to form granules of prekeratin and retain nuclear material at the epithelial surface. Both intracellular and extracellular pigment granules may be distributed throughout the epidermis. In pigmented VIN lesions, dermal melanophages are often prominent beneath the basal layer and within the dermal papillae. VIN involves the skin appendages in more than 50% of the cases studied. Skin appendage involvement by VIN should be differentiated from early invasion (compare **)** *Fig. 2.6b, c* to **)** *Fig. 2.7*). Skin appendages as deep as 2.7 mm in hair-bearing areas may be involved with VIN [144]. In non-hair-bearing areas, the skin appendages and minor vestibular glands are more superficial. The thickness of the epithelium involved by VIN may range from 0.10 to 1.90 mm, with a mean of 0.52 mm [12].

Microscopic Grading

The World Health Organization classification of vulva intraepithelial neoplasia is subdivided into three grades: VIN 1 mild dysplasia, VIN 2 moderate dysplasia, VIN 3 severe dysplasia, and carcinoma in situ/VIN 3. Differentiated (simplex) VIN is included in the VIN 3 category [92]. In this chapter, and in the most recent American Registery of Pathology Fascicle on cervix, vagina and vulva, the term "high-grade VIN" encompasses VIN 2 and VIN 3, and "low-grade VIN" encompasses VIN 1 and flat condylomas [92,175]. This terminology is relatively commonly used and is applicable provided one's clinicians understand its use and appropriate ICD9 coding is used.

Grading of VIN lesions should be performed based on the findings in the most severe, highest grade area. When the cellular epithelial abnormalities of VIN are confined to the lower third of the epithelium, low-grade VIN (VIN 1) is reported (\bigcirc *Fig. 2.8*). Flat condyloma acuminatum of the vulva may be included in the low-grade VIN category because the biologic difference between low-grade VIN and flat condyloma is unknown and the morphologic distinction is unreliable. Flat condyloma acuminatum with koilocytosis and minimal evidence of proliferation or atypia, with atypia limited to the lower one third of the epithelium, are classified as "low-grade VIN." This practice eliminates the need for such terms as "atypical condyloma acuminatum, or flat condyloma acuminatum" that are not recommended. In the occasional case with

VIN 3 with superficial invasion. (a) Squamous differentiation within the VIN is manifested by rounded foci of cells with eosinophilic cytoplasm near the basal layer. This is a useful feature in identifying early invasion. (b) Small clusters of invasive squamous cell carcinoma are present in the superficial dermis. (c) A small tongue of invasive squamous carcinoma is noted at the base of the dermal papillae. Note the loss of palisading of the basal cells, as compared to those in the adjacent dermal papillae

VIN 3, involving a skin appendage. Increased cellularity and disarray with lack of maturation is seen within the epithelium

Fig. 2.8

VIN 1, warty type. Crowding of the basal and parabasal cells with some cellular disarray and loss of maturation within the lower one third of the epithelium. Koilocytotic cells are present on the surface typical condyloma acuminatum associated with low- or high-grade VIN, a diagnosis of "low-grade VIN, with condyloma acuminatum, or 'high-grade VIN (VIN 2–3)' with condyloma acuminatum" is appropriate.

A lesion is classified as high-grade VIN (encompassing VIN 2 and VIN 3) if the cellular abnormalities extend through at least one half of the epithelium and may involve essentially the full thickness of the epithelium, not including the surface layers above the granular zone (\bigcirc *Figs. 2.5*, \bigcirc *2.9* and \bigcirc *2.10*). Abnormal mitoses are nearly always present in high-grade VIN lesions and may be seen in all but the most superficial layers of the epithelium. Lack of abnormal mitoses, or lack of mitosis above the basal layer, should raise the question as to whether a lesion belongs to the high-grade VIN. VIN lesions are predominately VIN 2 or 3; VIN 1 lesions are relatively rare. Ki-67 (MIB-1) demonstrates nuclear reactivity throughout most of the epithelium (\bigcirc *Fig. 2.9b*).

Differentiated VIN is a relatively rare lesion associated with prominent eosinophilic cytoplasm with nuclear chromatin changes including chromatin clearing and prominent nucleoli. Differentiated VIN is classified as a high-grade VIN lesion (\bigcirc *Fig. 2.11*). Differentiated VIN is commonly seen adjacent to invasive squamous cell vulvar carcinoma and may be associateed with lichen sclerosus (see \bigcirc *Fig. 2.6*) (see following, \bigcirc Histologic Subtypes of VIN).

The International Society for the Study of Vulvovaginal disease (ISSVD) has proposed that VIN not be graded, and used only to describe high-grade VIN lesions only (VIN 2 or VIN 3). The ISSVD has also recommended that the term low-grade VIN (VIN 1, or mild dysplasia) not be used and that such lesions be classified as flat condyloma acuminatum, or given an appropriate descriptive term [147]. Issues regarding the recommendation to not use the term VIN 1 are challenged by evidence that low-grade VIN lesions are associated with high-risk human papillomavirus (HPV) in approximately 40% of cases studied, and prospective studies on such cases regarding clinical behavior remain to be performed [152].

Histologic Subtypes of VIN

VIN has been subclassified into at least three types – warty (condylomatous), basaloid, and differentiated (simplex) on the basis of cellular features. Interobserver reproducibility for subtyping VIN lesions is fair (kappa, 0.31–0.42) [160]. An individual patient may have more than one histologic type in different VIN lesions, and occasionally both basaloid and warty types may be seen in a single а h b C

Fig. 2.9

VIN 3, basaloid type. (a) Prominent acanthosis and basaloid type neoplastic keratinocytes involve the full thickness of the epithelium. VIN 3 (carcinoma in situ), basaloid type.
(b) Complete replacement of the epithelium with overlying parakeratosis resembles carcinoma in situ of the cervix.
(c) Immunohistochemical study for Ki-67 demonstrates full epithelial thickness reactivity

Fig. 2.10

VIN 3, warty (condylomatous) type. (a) The surface shows hyperkeratosis. A prominent granular layer is evident. (b) Marked cellular disarray with prominent nuclear pleomorphism. Several multinucleated keratinocytes are present

VIN 3, differentiated type with invasive squamous carcinoma. The epithelium is composed of keratinocytes with abundant cytoplasm. The nuclei are enlarged and contain prominent nucleoli

lesion. Mixtures of basaloid and warty patterns are particularly frequent, and in some cases, both patterns may be seen in a single excised lesion. These "mixed" cases can be classified according to the predominant component or simply as VIN, basaloid/warty type. A rare pagetoid type of VIN is also recognized [125]. Some VIN lesions are not readily classifiable into one of these groups.

Warty (condylomatous) VIN lesions have an epithelial surface that is typically undulating or "spiked" surface with a warty/condylomatous appearance and is often keratinized with hypergranulosis and parakeratosis. There is usually prominent acanthosis with rete pegs that are relatively wide and extend deeply into the dermis. Dermal papillae are thinned and may be seen close to the surface. The cells show evidence of maturation with prominent parabasal hyperplasia. The epithelial cells have well-defined cell membranes and prominent eosinophilic cytoplasm. Individual cell keratinization and small cells with eosinophilic cytoplasm or "corps ronds" are often identified. Multinucleated epithelial giant cells are often observed. The nuclei are enlarged and pleomorphic, with coarsely granular chromatin and increased nuclear-cytoplasmic ratio. Nucleoli are not prevalent. Koilocytes, are cells with hyperchromatic, shrunken nuclei surrounded by a clear halo separating the nucleus from the cytoplasm cytoplasm, are characteristic (see **>** *Figs. 2.5* and **>** *2.10*). The warty type of VIN has larger cells with greater nuclear pleomorphism than basaloid VIN. Abnormal mitosis usually can be identified [117] (see **>** *Fig. 2.10b*).

The basaloid type of VIN has a thickened epithelium with a relatively smooth and flat surface without the

undulated and spiked appearance of warty VIN. Hyperkeratosis is often present, but less extensive than that is seen in warty VIN. The epithelium lacks cellular maturation and is typically nearly entirely composed of atypical parabasal type cells. These cells are relatively small, uniform cells with hyperchromatic and coarse nuclear chromatin. Nucleoli are rare, and mitosis is common;abnormal mitoses are usually found. Although there is little or no maturation of the keratinocytes, some keratinization or parakeratosis, as well as koilocytosis may be seen near the surface (see \triangleright *Fig. 2.9*).

Both warty and basaloid VIN may have intraepithelial growth that extends into adjacent hair follicles and other skin adnexal structures. This is a relatively frequent finding and should be distinguished from invasive squamous cell carcinoma. Both basaloid and warty VIN may be identified adjacent to, and associated with, invasive squamous cell carcinomas. The invasive carcinoma may be of the basaloid or warty types corresponding to the VIN type, although the converse may occur with basaloid VIN adjacent to warty carcinoma or warty VIN adjacent to basaloid carcinoma (see Invasive Squamous Cell Carcinoma). Although basaloid VIN and basaloid carcinoma are often related to oncogenic HPV, nine (7%) of reported "differentiated" VIN cases in one study were basaloid VIN lesions that were negative for HPV and did not express p16INK4a, but did express p53 [60].

Differentiated VIN (VIN 3, differentiated/simplex type) has a thickened epithelium that is typically associated with elongation and anastomosis of rete ridges. Parakeratosis is usually present, associated with prominent intracellular bridges. The keratinocytes of differentiated VIN are large and pleomorphic with relatively large amounts of eosinophilic cytoplasm, as compared to the other two types of VIN (> Fig. 2.11). Keratin pearl formation within the rete may be seen. The nuclear chromatin is vesicular rather than coarse, and the nuclei have prominent nucleoli, usually most prominently in the basal and parabasal keratinocytes. A distinctive feature is the prominent increased eosinophilic cytoplasm within the keratinocytes in the basal and parabasal layers that is sometimes limited to the base of rete ridges [71,94,175,183]. Keratin pearl formation is common in differentiated VIN but is not common in other VIN lesions. In a study of 12 patients with differentiated VIN, 10 had squamous cell hyperplasia in the epithelium adjacent to the tumor, and four patients had associated lichen sclerosus. In this study, only one of the 12 patients had evidence of human papillomavirus (HPV); however, p53 was expressed in the suprabasal cells in ten of the 12 patients [183]. All the patients in this study were postmenopausal; three had a prior history of vulvar squamous cell carcinoma, and one patient had concurrent superficially invasive vulvar squamous cell carcinoma.

Pagetoid VIN is a very rare lesion with reports limited to a few cases [125]. It is characterized by a pagetoid growth pattern of neoplastic intraepithelial epithelial cells in groups and nests within otherwise normal-appearing epithelium. The cells of pagetoid VIN may resemble Paget disease of cutaneous type, or superficially spreading melanoma, having relatively pale cytoplasm and larger nuclei than the adjacent normal keratinocytes with relatively clear chromatin and evident nucleoli. Pagetoid VIN can be distinguished from Paget disease or melanoma in situ by immunohistochemical study in that unlike Paget disease, or melanoma in situ, the cells are not immunoreactive for CK 20, carcinoembryonic antigen (CEA), S-100 or Melan A but are immunoreactive for cytokeratin-7 [125].

Differential Diagnosis

The differential diagnosis of warty or basaloid VIN includes basal cell carcinoma, superficial spreading malignant melanoma, Paget disease, pagetoid urothelial intraepithelial neoplasia, and multinucleated atypia of the vulva.[30, 103,172]

Immunohistochemical methods to assist in distinguishing melanoma and Paget disease from VIN are summarized in **>** *Table 2.2.* Multinucleated atypia of the vulva

is characterized by multinucleated keratinocytes, without significant nuclear atypia, within the lower to middle epithelial layers. The possibility that a podophyllin effect on condylomata acuminata of the vulva could result in these lesions being misinterpreted as VIN is highly improbable because the changes from a single application of podophyllin regress within 1–2 weeks. Mitotic arrest with cells in metaphase seen after podophyllin contrasts with the abnormal mitotic figures seen in VIN. Nuclear karyorrhexis is rarely present in VIN, whereas it is found in most of the condyloma cases. In VIN, in contrast to the podophyllin effect, nuclear size tends to be vary, and the nuclear chromatin is usually coarse with little cellular swelling (see **)** Chap. 1, Benign Diseases of the Vulva).

Differentiated VIN should be differentiated from repair or reaction related to erosion or superficial ulceration including pseudoepitheliomatous (pseudocarcinomatous) hyperplasia, trapped epithelium at a prior biopsy site, or granulomatous or decidual change in the immediately adjacent underlying epithelium. A similar lesion to differentiated VIN, but lacking the distinctive increased eosinophilic cytoplasm of the base of the rete ridges, has been designated by some as atypical squamous cell hyperplasia because this lesion has similar nuclear atypia but histologically resembles squamous cell hyperplasia more closely than it does in VIN[93] (see O Chap. 1, Benign Diseases of the Vulva). Despite the association with keratinizing squamous cell carcinoma, there are no longitudinal studies demonstrating that squamous cell hyperplasia alone, as already defined here, is a precursor of squamous cell carcinoma. When associated with lichen sclerosus, follow-up studies suggest that associated squamous cell hyperplasia is probably a precursor to squamous cell carcinoma in some cases; however, the association between differentiated VIN, squamous cell hyperplasia, and squamous cell carcinoma requires further study [132]. Squamous cell hyperplastic-type lesions do not express p53, and this in part distinguishes these otherwise benign lesions from differentiated VIN [88,183].

Adjunctive Studies

Evidence for HPV, nearly always type 16, in VIN is predominately found in the warty and basaloid types, based on molecular biologic studies, and has been demonstrated in most cases [134]. In differentiated VIN, HPV is infrequent [134,148]. Alterations in the p16/pRb/Cyclin D1 pathway occur in VIN lesions as demonstrated by immunohistochemical methods. Epigenetic silencing of p16INK4a has been reported in approximately two thirds of basaloid or warty VIN lesions [137]. Immunohistochemical expression of p16INK-4a was demonstrated in 92% of high-grade VIN lesions in one study, and these cases had nearly the full thickness expression of p16INK in the involved epithelium. In low-grade VIN lesions, two of ten were immunoreactive, and in these cases, the reactivity was limited to the intraepithelial neoplastic predominately within in the lower half of the epithelium [133]. Oncogenic HPV is usually present in high-grade warty and basaloid VIN lesions, with type 16 being the usual type identified. Oncogenic HPV is significantly less common in VIN of differentiated type [94,134,148]. Approximately a third of cases demonstrated overexpression of Cyclin D1 in a series or 13 cases of VIN. None of these cases demonstrated lack of pRb protein [93]. Differentiated VIN lesions usually express p53 in the basal and some parabasal cells and are not associated with oncogenic HPV [88,183]. Cellular proliferation analysis employing immunohistochemical studies for BCL 2 and Ki-67 (MIB-1) does not appear to be of much value in the diagnosis of VIN lesions although Ki-67 may have some value in grading and identifying low-grade lesions [96].

Most high-grade VIN lesions contain DNA aneuploid populations of cells [59,178]. DNA analysis by microspectrophotometry of multifocal lesions suggests that separate lesions arise from separate stem cells, forming distinguishable clones. Large confluent lesions may result from centrifugal growth from a single cell line or by confluence of separate and distinct clones [178]. In single VIN lesions, approximately half have different stem cells by DNA microspectrophotometry, suggesting that such lesions may undergo clonal evolution[178]. The cells of VIN are immunoreactive for some low and high molecular-weight keratins and keratin expression provides some evidence of lack of cellular maturation in VIN [53].

Immunohistochemical studies for cellular proliferation employing BCL 2 and Ki-67 (MIB-1) have not been demonstrated to be of significant value in the diagnosis of VIN lesions.

Clinical Behavior and Treatment

The clinical course of VIN following treatment has been well studied; however, there are relatively few long-term studies of untreated VIN [85,86]. There is evidence that untreated VIN 3 will progress to invasive squamous cell carcinoma, and this has been reported with invasion being observed within 8 years of the diagnosis of VIN [85,86]. VIN associated with vulvar invasive squamous cell carcinoma diagnosed within excised VIN lesions is reported in 2-20% of larger series that have specifically looked for this association [24,80]. In evaluation of epithelial changes adjacent to vulvar squamous cell carcinoma, 60-80% of superficially invasive carcinomas and 25% of deeply invasive carcinomas have adjacent VIN [184]. Differentiated (simplex) VIN was reported associated with vulvar squamous cell carcinoma in seven of 12 (58%) patients in one study [183]. This study suggests that there is a stronger association between differentiated VIN and squamous cell carcinoma than there is between the other recognized VIN types and invasion. There are no known differences in clinical behavior between warty and basaloid VIN. Squamous cell carcinoma, in the other VIN types, also occurs most commonly in postmenopausal women, although it may occur in women of reproductive age [69]. Spontaneous regression of VIN has been observed in young women; however, no long-term controlled prospective studies have evaluated this event specifically [30,58]. Regression appears to be most common in young women and those who are pregnant, whereas women of advanced age, those who are severely immunosuppressed, and women with Fanconi anemia are at a greater risk for invasion [23,179].

Conservative therapy is now recommended for VIN, and most cases are managed with local excision; laser ablation also may be appropriate for selected patients, especially when the VIN lesion involves the non-hairy skin or mucous membrane areas (e.g., the vulvar vestibule and perianal areas). Topical imiquimod has gained some application in the treatment of vulvar condyloma acuminatum and VIN lesions [156,163]. Women who are cigarette smokers appear to have a higher frequency of recurrence of VIN lesions, and cessation of smoking is recommended [176].

Squamous Cell Carcinoma

Approximately 95% of malignant tumors of the vulva are squamous cell carcinomas. Vulvar squamous cell carcinoma has an overall incidence of approximately 1.5 per 100,000 women in the USA; this rate increases with advancing age to as high as 20 per 100,000 in older women [155]. The American Cancer Society reports over 3,400 new cases of vulvar squamous cell carcinoma in the USA annually [4]. Unlike VIN, the incidence of vulvar squamous cell carcinoma in the USA has not increased significantly since 1973 [155]. The mean age at presentation is 60–74 years [92,155]. Vulvar carcinoma may occur in younger women and adolescents, and has been described in a 12 year old [2,124].

Epidemiologic studies of women with vulvar carcinoma have identified an increased risk with prior or current vulvar VIN, condyloma acuminatum, and cervical carcinoma. In these cases, oncogenic human papillomavirus is usually a significant factor. Vulvar lichen sclerosus is also associated with an increased life-time risk of vulvar carcinoma, which does not appear directly related to oncogenic HPV. In addition, factors including older age, number of life-time sexual partners, cigarette smoking, immunodeficiency, chronic granulomatous disease, most notably granuloma inguinale, diabetes mellitus, achlorhydria, poor perineal hygiene, and genital granulomatous disease have been associated [128,146]. Occupational risk is reported in women cotton mill workers, and women with industrial exposure to industrial oils, as well as those working in the dyeing and cutlery industries. Topical exposure to arsenicals also increases risk. A possible increased frequency has been suggested for women with blood group A, but findings remain inconclusive [128]. Vulvar carcinoma may occur during pregnancy, although parity does not appear to be a significant risk factor.

Current evidence supports the view that women at risk for vulvar carcinoma can be separated into two groups: those who have associated HPV squamous lesions, specifically VIN, and those with vulvar disease not associated with HPV including known vulvar dermatoses (especially lichen sclerosus) and those related to other conditions, such as chronic granulomatous disease. One case related to hidradenitis suppurativa has been reported [146]. The frequency of oncogenic HPV associated vulvar squamous cell carcinoma is different between young and older women. HPV, usually type 16, is reported in less than one fifth of vulvar carcinomas in older women (mean age 77 years), whereas approximately four fifths of the vulvar squamous carcinomas identified in younger women (mean age 50 years) are HPV associated. The histopathologic type of invasive carcinoma also differs. In the older women vulvar squamous cell carcinomas are usually well differentiated and highly keratinized. In younger women, the tumors are usually warty or basaloid carcinomas [43,93,157].

Older women with vulvar carcinoma (mean age, 77 years) typically do not have associated VIN or a history of heavy cigarette smoking. Their tumors rarely contain HPV, and typically they are well-differentiated keratinizing squamous cell carcinomas (**)** *Table 2.3*) [91,93,157]. Suppressed immunocompetence is recognized as a risk factor in these women [23,179]. Women with HPV-related cervical neoplasia with low CD 4 counts who are treated with triple combination antiretroviral therapy can have decreased

plasma human immunodeficiency virus-1 (HIV-1) levels, increased CD 4 cell counts, and partially restored immune function. This restored immune function is associated with regression of cervical lesions in these women [74].

Women with differentiated, non-HPV-related, vulvar squamous cell carcinoma often have associated vulvar dermatoses, especially lichen sclerosus [20]. Primary evidence based on p53 mutation analysis and clonal studies suggests that squamous cell hyperplasia of the vulva is probably not a precursor of non-HPV-related vulvar squamous cell carcinomas [88]. Women with vulvar lichen sclerosus who develop squamous cell carcinoma tend to be older; their primary tumors more commonly involve the clitoris and are typically not associated with VIN of the warty or basaloid types. VIN was identified in 5% of the cases in one series [20]. It is recognized that there is an under reporting of skin diseases related to vulvar carcinoma. Squamous carcinomas associated with lichen sclerosus express tumor suppressor gene product p53 in nearly one half the cases and cytokine transforming growth factor-beta (TGF-b) in one third of the cases as compared to 19% and 9%, respectively, for nonlichen sclerosus-related tumors. Approximately one half of these lichen sclerosus-associated tumors are associated with a prominent fibromyxoid stromal response, as compared to nonlichen sclerosus-related tumors [20]. From a literature review of a cohort of symptomatic women with vulvar lichen sclerosus, it was reported that 9% subsequently presented with VIN and 21% with vulvar squamous cell carcinoma. The carcinoma presented 1-23 years (mean, 4 years) after the onset of symptoms [20].

Stage IA Invasive Squamous Cell Carcinoma (AJCC T1a, M0, N0; FIGO Stage IA)

General Features

The majority of vulvar squamous cell carcinomas in the USA are stage 1, being 2 cm or less in diameter and clinically confined to the vulva without evidence of extension to other sites or lymph node metastasis. Stage 1 vulvar carcinomas are divided into two subgroups based on depth of invasion. A stage IA vulvar carcinoma is a superficially invasive squamous cell carcinoma with a depth of invasion of 1 mm or less and a diameter of 2 cm or less. The staging of vulvar carcinoma as recommended by the American Joint Committee on Cancer (AJCC) is as summarized in O *Tables 2.4* and O *2.5* (American Joint Committee on Cancer 2010) [5].

A stage IA (FIGO Stage IA; AJCC T1a) carcinoma of the vulva is defined as a single lesion measuring 2 cm or

Table 2.4

American Joint Committee on Cancer (AJCC) staging of vulvar carcinoma when pathologic staging is performed, it is designated "pT"; clinical staging is designated "T"

TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
Tis: Carcinoma in situ (preinvasive carcinoma)
T1: Tumor confined to the vulva or vulva and perineum, 2 cm or less in greatest dimension. (Stage T1 N0 M0)
T1a: Tumor confined to the vulva or vulva and perineum, 2 cm or less in greatest dimension, and with stromal invasion no greater than 1 mm. ^a
T1b: Tumor confined to the vulva or vulva and perineum, 2 cm or less in greatest dimension, and with stromal invasion greater than 1 mm. ^a
T2: Tumor of any size with extension to adjacent perineal structures (lower/distal1/3 urethra, lower/distal1/3 vagina, anal involvement, with negative nodes (FIGO uses the classification T2/T3. This is defined as T2 in TNM)
T3: Tumor of any size with extension to any of the following: upper/proximal 2/3 of urethra, upper/proximal 2/3 vagina, bladder mucosa, rectal mucosa, or fixed to pelvic bone (FIGO uses the classification T4 for this group. This is defined

as T3 in TNM)

^aThe depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

Source: From AJCC Cancer Staging Manual, 7th ed. Springer, New York, Dordrecht, Heidelberg, London, 2010 [5].

less in diameter with a depth of invasion of 1 mm or less regardless of the presence of vascular invasion. Tumors with more than one site of invasion are not included in this stage [89,180]. It is recommended that the term "microinvasive carcinoma" not be used in reporting vulvar carcinoma because there is no agreement on the definition of the term. When the term is used, it usually refers to vulvar squamous cell carcinomas with a depth on invasion or thickness of 5 mm or less. In a multivariate

Table 2.5

FIGO staging: carcinoma of the vulva 2009

Stage I	Tumor confined to the vulva (Stage I, T1 N0 M0).
	Stage IA: Lesions 2 cm or less in size, confined to the vulva or perineum, and with stromal invasion of 1.0 mm or less, no nodal metastasis. ^a (Stage T1a)
	Stage IB T1b: Lesions greater than 2 cm in size, with stromal invasion greater than 1.0 mm, confined to the vulva or perineum, with negative nodes. ^a (Stage T1b)
Stage ll	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus, with negative nodes (Stage T2 N0 M0)
Stage III	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguinal– femoral nodes
IIIA	(i) with 1 lymph node metastasis (of 5 mm or less) or
IIIA	(ii) 1–2 lymph node metastasis(es) (<5 mm)
IIIB	(i) With two or more lymph node metastasis (of 5 mm or > 5 mm), or
IIIB	(ii) With three or more lymph node metastasis (<5 mm)
IIIC	With positive nodes with extracapsular spread.
Stage IV	Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina) or distant structures
IA	Tumor involves any of the following:
IVA (i)	Upper urethra and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone; or,
IIVA (ii)	Fixed, or ulcerated inguinal-femoral lymph nodes;
IVB	Any distant metastasis including pelvic lymph nodes

^aThe depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

FIGO ref: Pecorelli S, Denny L, Ngan H, Pecorelli S, Hacker N, Bermudez A, Mutch D, Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obstet*. 2009;105:103–104.

retrospective analysis of 78 cases of "microinvasive" vulvar squamous carcinoma fulfilling this 5 mm criteria, 28 (36%) were pathologic stage IA, 40 (51%) pathologic stage 1B, six (8%) pathologic stage II, and four (5%) pathologic stage III [184]. The term "microinvasion" is not recommended by the World Health Organization, the International Society for the Study of Vulvovaginal Disease (ISSVD), or the AJCC. Reporting the diameter of the tumor, the depth of invasion, the thickness of the tumor, the presence or absence of vascular space involvement, and the status of surgical margins clearly defines the tumor and its extent. These findings will influence treatment options and are included in the College of American Pathologists Vulvar Cancer protocol for synoptic reporting [31,171].

Gross Findings

Stage 1 invasive vulvar squamous cell carcinoma may present as an ulcer, a red, brown, or black macule or papule, or a white hyperkeratotic plaque. The invasive carcinoma may be associated with VIN and clinically present as a VIN lesion. Although the presence of invasion associated with VIN may be heralded by the finding of an associated ulcer, irregularly contoured elevated mass, abnormal vascularity, or marked hyperkeratosis, no specific clinical findings definitively separate VIN from VIN with squamous carcinoma [24].

Tumor diameter alone in stage 1 vulvar carcinoma is not a reliable predictor of lymph node status. In a study of 190 patients with vulvar carcinomas 2 cm in diameter or smaller, 36 (19%) had lymph node metastasis. Of those with node metastasis, the relative 5-year survival was 78.6%, compared with 97.9% survival at 5 years for those with negative nodes [78].

Microscopic Findings

The identification of a squamous cell carcinoma arising in VIN lesion, or in differentiated VIN, includes (1) Isolated neoplastic squamous cells with increased eosinophilic cytoplasm and atypical nuclei with prominent nucleoli within the adjacent dermis. (2) Loss of the orderly palisaded orientation of the basal keratinocytes of the dermal papillae. (3) Irregular nests of neoplastic squamous cells with disorderly orientation within the dermis. (4) Dyskeratosis and keratin pearl formation in the basal and parabasal layers. (5) Focal dermal reaction with fibrosis (dermal desmoplasia) or edema locally evident in the area of invasion [92,139]. Immunohistochemical study of laminin may also be of some value in that continuous reactive laminin is usually seen about nests of VIN, but discontinuous reactivity of laminin is identified about invasive squamous epithelium [48,92].

In a study of 78 cases of vulvar squamous cell carcinoma with invasion of 5 mm or less, of 40 patients with inguinal lymph node dissections, five had concurrent lymph node metastases. Concurrent lymph node metastases were compared to tumor depth of invasion, tumor thickness, tumor horizontal spread, estimated tumor volume, tumor histologic squamous tumor type, tumor grade, primary pattern of invasion, multi-focality of tumor of the vulva, presence of perineural invasion, presence of angiolymphatic invasion, histologic type of VIN, as well as the presence of lichen sclerosus. In this detailed study, only tumor depth of invasion was statistically significant in correlating with the presence of lymph node metastases (p = 0.027, n = 78, ANOVA). All additional correlations between these findings and lymph node metastasis were not statistically significant (p > 0.05) [184].

In that the staging of a stage IA invasive vulvar carcinoma is based upon the "depth of invasion of the tumor" (> Fig. 2.12). This measurement requires a calibrated ocular or comparable measuring device, as does the measurement of the thickness of the tumor. The measurement of the "depth of invasion" for staging stage 1 vulvar carcinoma is defined as the measurement from the epithelial dermal (stromal) junction of the most superficial adjacent dermal papillae to the deepest point of invasion (> Fig. 2.12). The measurement from the surface of the tumor, or from the base of the granular layer if a keratin layer is present, to the deepest point of invasion is defined as the "thickness of the tumor." Both measurements are valuable, because in cases in which the tumor is ulcerated the thickness may be 1 mm or less and the depth of invasion may be well beyond 1 mm, and a thickness measurement alone would underestimate the depth of invasion (**>** Fig. 2.12). Methods of measurement require a description along with the measurement within the pathology report [31,171,174].

There can be some difficulties in measuring the depth of invasion in some cases, especially if there is tangential sectioning of the specimen, or the surface epithelium is distorted, disrupted, or folded. In some cases, the depth of invasion can be more readily calculated by measuring the thickness of the tumor and subtracting the epithelial measurement from the surface to the epithelial–dermal (stromal) junction of the immediately adjacent dermal papillae. The measurement should be made from "...the epithelial-stromal junction of the adjacent most superficial dermal papilla," and in some cases, the immediately Premalignant and Malignant Tumors of the Vulva

Fig. 2.12

Squamous cell carcinoma; measurement for the depth of invasion. (a) The depth of invasion is measured from the epithelial-dermal junction of the adjacent-most superficial dermal papillae to the deepest point of invasion. This measurement is applicable whether or not the surface epithelium is ulcerated or keratinized. This is the AJCC recommended method of measuring vulvar squamous cell carcinomas in determining if a tumor is Stage T1a, or T1b (From *AJCC Cancer Staging Manual*, 6th ed. New York: Lippincott, Williams & Wilkins; 2002, with permission. Figure © E.J. Wilkinson, 2007). If the tumor is keratinized, the thickness of tumor is measured from the granular layer to the deepest point of invasion. For squamous cell carcinomas the convention is to measure from the bottom of the granular layer. For melanoma the convention is to measure from the top of the granular layer. If the epithelium is not keratinized the thickness of tumor is measured from the surface of the tumor to the deepest point of invasion (Figure © E.J. Wilkinson, 2007.). (b) Melanoma and squamous cell carcinoma; measurements for tumor thickness when the tumor is ulcerated. The tumor thickness is measured from the surface of the ulcerated tumor to the deepest point of invasion. For melanomas, the level of invasion is measured and expressed as Clark's Levels. For squamous cell carcinoma the depth of invasion is a more accurate measurement of the true depth of the tumor, as measured from the epithelial dermal junction of the adjacent dermal papillae to the deepest point of invasion (Figure © E.J. Wilkinson, 2007.) (from Wilkinson EJ and Stone IK, Atlas of Vulvar Disease. Wolters Kluwer/ Lippincott-Williams Wilkins, 2008 (ref: 174)

adjacent dermal papillae is not applicable for various reasons, including that it is not the most superficial dermal papillae, which may be the second papillae over on either side of the tumor. The issue is also not of such importance when the depth of invasion is obviously over 1 mm. In some cases, levels of the block containing the section of tumor with the apparent deepest point of invasion may be worth obtaining to identify the best-orientated section with the deepest point of invasion. In rare cases, the involved epithelium may not have dermal papillae, and in such cases, a measurement from the epithelial-dermal (stromal) junction of the adjacent epithelium uninvolved by tumor should be representative. In general, with a welloriented specimen with a tumor less than 3 mm in depth, and totally excised with intact noninvolved epithelium adjacent to the tumor, the measurements of depth of invasion and tumor thickness can be made reliably (> Figs. 2.12 and > 2.13). In larger tumors, the diameter and dimensions of the tumor may be too great to include an adjacent dermal papillae; however, this often can be

overcome by appropriate sectioning. With a partially excised tumor, or when the tumor is superficially biopsied, these tumor measurements cannot be made reliably. When marked acanthosis is present, the thickness of the epithelium may give an overestimate of the depth of invasion. If the tumor is ulcerated, the thickness measurement may underestimate the true tumor size. The College of American Pathologists has recommended that the following information be included in the surgical pathology report [31,171].

- 1. Depth of invasion of the tumor in millimeters and thickness of the tumor in millimeters
- 2. Method of measurement of the depth of invasion and thickness
- 3. Presence or absence of vascular space involvement by tumor
- 4. Diameter of the tumor (as measured from the gross surgical specimen)
- 5. Clinical measurement of the tumor diameter, when available.

Squamous cell carcinoma. The depth of invasion is 0.7 mm from the most superficial adjacent dermal papillae to the deepest point of invasion

When there is a question as to whether invasion is present and additional sectioning does not resolve the question, it is recommended that invasion not be diagnosed.

Clinical Behavior and Treatment

Patients who have had stage 1A invasive vulvar squamous cell carcinoma that was treated who have recurrence, or have a second primary squamous cell carcinoma of the vulva, risk regional lymph node metastasis and death from recurrence. In a study of 28 women with Stage 1A vulvar carcinoma, none had recurrence of squamous cell carcinoma 240 months of follow-up [184]. In a series of 26 women with VIN and associated superficially invasive squamous cell carcinoma, ten (38%) of these patients experienced recurrence of VIN or superficially invasive squamous cell carcinoma, all within 36 months of treatment [76]. Three of these ten women subsequently presented with frankly invasive vulvar squamous cell carcinoma. Of the patients without recurrence of VIN or superficially invasive carcinoma, none had regional lymph node or distant metastases and none died of tumor. In another study of 40 patients with T1a (stage 1A) vulvar carcinomas, none had regional lymph node metastasis; however, two patients had vulvar recurrence, and one of them had a groin node metastasis associated with the recurrence [100].

There are relatively limited data specifically evaluating tumors with a depth of invasion of 1.1 mm to 2 mm. In two relatively small studies specifically examining tumors with invasion of 1–2 mm, without vascular space involvement, none had node metastasis [13,122,184]. In a multivariate analysis performed by Yoder et al., six of 19 (31%) of cases with 1.1–2.0 mm depth of invasion had recurrence of vulvar squamous cell carcinoma [184]. Of these cases, however, recurrence did not influence survival and those women with tumors having a depth of invasion of 2.0 mm or less of invasion had 100% overall survival at 240 months [184]. Until more data are available on tumors that invade between 1 and 2 mm, the evidence that women with such tumors have limited risk of regional lymph node metastasis should be considered when node assessment is considered in such patients. Recurrence is a recognized risk, and treatment with wide local excision/partial vulvectomy in these patients is generally accepted.

Women with tumors having a depth of invasion of 2.1–3 mm or less have significant risk of regional lymph node metastasis, recurrence of tumor, and reduced survival. With this depth of invasion, there is inguinal lymph node metastasis in approximately 10% of cases. In one study on women with tumors having a depth of invasion between 2.1 and 3.0 mm, five of 16 (31%) cases had recurrent squamous cell carcinoma. These women had a 93% survival at 258 months, whereas women with tumors greater than 3.1 mm of invasion had 79% survival at 231 months [184]. Selected patients with tumors with a depth of invasion of 2.1–3 mm may be treated by wide local excision with ipsilateral regional node dissection [63].

Vulvar squamous cell carcinomas with a depth of invasion exceeding 3.1 mm are associated with an increased risk of recurrence and death. In one study of tumors exceeding 3 mm invasion, five of 15 (33%) cases had recurrence of tumor with an overall survival of 79% at 231 months [184]. In a study evaluating both depth of invasion and tumor thickness, more than 40% of the cases had groin metastasis when the thickness of the tumor exceeded 4 mm [13]. Women with vulvar squamous carcinomas with a 5 mm depth of invasion, have been found to have inguinal lymph node metastasis in approximately 15% of cases (**)** *Fig. 2.14*).

The type of surgery for vulvar squamous cell carcinomas with a depth of invasion less that 5 mm does not appear to influence recurrence of squamous cell carcinoma. In a study of 78 patients with tumors of 5 mm in depth of invasion or less, 44 (56%) underwent wide local excision (partial vulvectomy), of which three had adjuvant radiation, seven (9%) had total (simple) vulvectomy, and 27 (35%) had total vulvectomy with inguinal–femoral lymph node dissection (radical vulvectomy); one of whom had adjuvant radiation therapy. No association was identified between recurrent squamous cell carcinoma and the type of surgical procedure performed [184].

Percent of women who underwent lymphadenectomy with inguinal lymph node metastasis plotted against the depth of invasion of their tumor. The frequency of lymph node metastasis rises rapidly with depth of invasion beyond 1 mm (Reprinted by permission of E.J. Wilkinson)

Surgical margin assessment correlates with recurrence in women treated with vulvar squamous cell carcinoma. The presence of VIN at a surgical margin has borderline statistical significance related to recurrence of VIN. Of 19 cases with VIN at a surgical margin, six (58%) had recurrence of VIN. In contrast, only four of 59 (91%) women with margins free of VIN or squamous cell carcinoma had recurrence of VIN. In this study, two cases had invasive squamous cell carcinoma at a surgical margin, and both had recurrence, or persistent, squamous cell carcinoma [184]. This study identified a strong association between the type of surgery performed and surgical margin involvement by either VIN or invasive squamous cell carcinoma. Of 19 cases with VIN at the margin of excision, 15 (79%) were found in cases treated with wide local excision. Of the 78 cases in this study, 44 cases were treated by wide local excision and of these, 15 had VIN at a surgical margin, and two had invasive squamous cell carcinoma at the margin [184].

For now, it is safe to say there is a diminishing small risk of inguinal lymph node metastasis with tumors that are stage IA (T1a1) with a depth of invasion of 1 mm or less. For patients with stage IA carcinoma of the vulva, the recommended therapy is wide local excision without vulvectomy. Total excision of a lesion suspected of being a stage IA invasive carcinoma is necessary to assure that an associated deeper squamous carcinoma is not immediately adjacent to the apparently superficially invasive focus. The surgical specimen typically encompasses the apparent VIN lesion and any associated hyperkeratotic or ulcerative lesions. The specimens are usually not more than 2-3 cm in greatest dimension, usually with 1 cm or less clinically negative margins. Sampling of the ipsilateral groin nodes, or bilateral groin nodes if the tumor is midline, has been suggested. For stage IA (T1a) vulvar carcinomas, the probability of node metastasis is extremely small, and node sampling or resection is not contributory in most cases [92,170,184]. Based on analysis of published series, the current treatment of these patients is partial deep vulvectomy (deep local excision) without lymphadenectomy [67,68,100,184].

Invasive Squamous Cell Carcinoma

Clinical Features

Women presenting with vulvar carcinoma may have a wide variety of presenting complaints relevant to the vulvar tumor, especially if the tumor is more advanced. Pruritus, burning, pain, bleeding, discharge, dyspareunia, dysuria, unpleasant odor, or palpation or observation of a mass have all been reported. A past medical history of vulvar intraepithelial neoplasia (VIN), condyloma acuminatum, lichen sclerosus, or other chronic inflammatory diseases of the vulva may be present. Mental confusion and disorientation related to hypercalcemia have been reported associated with vulvar squamous cell carcinoma. After the ovary, the vulva is the second most common gynecologic tumor site associated with hypercalcemia. Vulvar squamous carcinomas with associated hypercalcemia usually are large, well differentiated, and without bony metastasis [112]. Surgical excision of the tumor results in the serum calcium levels returning to normal, and if mental symptoms related to the hypercalcemia were present, these also regress. The hypercalcemia results from secretion by the tumor of parathyroid hormone (PTH) or PTH-like substance.

Invasive squamous carcinoma may present as a lesion associated with VIN, as a focal ulcer or hyperkeratotic area in a field of vulvar lichen sclerosus, an exophytic papillomatous mass, or as an endophytic ulcer. The tumor is usually located on the labium minus or majus; however, the clitoris is primarily involved in less than one fifth of cases. Typically, the tumor is solitary (\bigcirc *Figs. 2.15* and \bigcirc *2.16*); less than 10% are multifocal.

Fig. 2.15 Squamous cell carcinoma. The tumor involves the medial aspect of the left anterior labium majus and clitoris

Fig. 2.16

Squamous cell carcinoma. The tumor presents as a nodular mass on the right posterior labia majus. There is associated lichen sclerosus

Microscopic Findings

Vulvar squamous cell carcinoma is typically contiguous with adjacent vulvar skin or mucosa, and that epithelium may be involved with VIN, lichen sclerosus, chronic inflammation, or other changes [28]. The invasive tumor typically lacks the usually orderly palisaded orientation of the basal epithelial cells with the underlying dermis. The adjacent dermis often has edema, desmoplastic change, and/or an associated inflammatory cell infiltrate that is typically not in direct contact with the invasive epithelial cells, but within the reactive dermis immediately below and adjacent to the tumor. Some prominent vascularity may be present within the dermis immediately below the tumor. The tumor may invade with a broad pushing pattern, or have variable degrees of "finger-like" growth within the dermis, including single tumor cells within dermis. The tumor growth pattern influences the risk of regional metastasis in tumors exceeding 1 mm in depth of invasion [184]. A grading system for infiltrative patterns of vulvar carcinoma has been proposed [184]. Capillary-like vascular space invasion by the tumor may be evident and in such cases the tumor can usually be found attached to the lining of the capillary-like space. The tumor is composed of neoplastic squamous epithelial cells that may have variable eosinophilic cytoplasm with nuclei that exhibit variable degrees of anisonucleocytosis with nuclear chromatin abnormalities including clumped and radially dispersed chromatin. Nucleoli are usually present, and mitotic figures including abnormal mitotic figures may be evident, especially near the epithelial-dermal junction.

A number of grading systems for vulvar squamous cell carcinomas have been proposed. However, to date no uniform grading system has been unanimously accepted. An effective grading system must reflect clinical behavior, preferably include three grades only as applied in most other grading systems in gynecologic pathology, and be applicable to the various subtypes of vulvar squamous carcinoma including warty, basaloid, and keratinizing types. The difficulty is that with current systems, basaloid carcinomas would be graded G3 or G4, which would not necessarily predict behavior. The American Joint Committee on Cancer (AJCC) recommends that histopathologic grading of vulvar carcinoma be recorded as follows: GX, grade cannot be assessed; G1, well differentiated; G2, moderately differentiated; G3, poorly differentiated; and G4, undifferentiated (American Joint Committee on Cancer 2010) [5]. The Gynecologic Oncology Group (GOG) advocates a system according to the percentage of undifferentiated cells. The latter are small cells with scant cytoplasm showing little or no differentiation and infiltrating the stroma in either

elongated cords or small clusters [78]. Grade 1 tumors have no undifferentiated cells (\bigcirc *Figs. 2.16–2.18*), grade 2 tumors contain less than 50% undifferentiated cells, grade 3 tumors (\bigcirc *Fig. 2.19*) have greater than 50% but less than 100%, and grade 4 is essentially entirely composed of undifferentiated cells. The risk of recurrence is reportedly higher with increasing grade [78,81,142].

In addition to tumor staging (as summarized in Tables 2.4, 2.5, and 2.6), the AJCC staging system reports regional lymph node status (as N) and the presence or absence of metastases (as M) (> Table 2.6). All lymph node tissues should be submitted for microscopic analysis. The microscopic evaluation of lymph nodes for detection of metastatic cell squamous carcinoma may be augmented by immunohistochemistry using a polyclonal cytokeratin antibody. Pathologic findings included in the College of American Pathologists (CAP) guidelines for evaluation of vulvar squamous cell carcinoma are the same for deep and superficial invasive squamous cell carcinomas (see Stage 1a Invasive Squamous Cell Carcinoma, Microscopic Findings) [31,171]. The CAP Surgical Pathology Cancer Case Summary/Checklist provides a synoptic approach to reporting vulvar cancer cases for either excisional biopsies or resections. In addition to tumor staging, the checklist includes macroscopic observations including specimen type, type of lymphadenectomy if performed, specific tumor site, and tumor size. Microscopic features to record include the histological type of tumor, the histologic grade, the pathologic stage (pTNM/FIGO), tumor depth of invasion, tumor border features, surgical margin status, presence or absence of venous/lymphatic invasion by tumor. Additional pathologic findings, including the pathologic findings in the adjacent vulvar skin or mucosa, and any additional comments can be added [31,171].

Chromosomal and Immunohistochemical Studies

Cytogenetic studies on vulvar carcinomas have demonstrated that they are genetically complex with multiple chromosomal rearrangements [175]. Nonetheless, they remain karyotypically stable in culture. The tumors typically are heterogeneous with multiple, but closely related, clonal populations. Both development and progression are apparent sequelae of altered gene expression. A study of vulvar carcinomas employing flow cytometry and image analysis demonstrated a high frequency of aneuploidy with a predominance of tumors within the hypotetraploid range [44].

Immunohistochemical studies employing monoclonal antibodies to MIB-1 (Ki-67), a proliferation-associated marker, have demonstrated two distinct tumor labeling patterns, diffuse and localized, that appear to be associated with prognosis; the diffuse pattern is associated with poor prognosis [75]. Quantitation of Ki-67 (MIB-1) and Ag-NOR do not appear to predict the presence or absence of inguinal-femoral lymph node metastasis, although a correlation was found between the mitotic index and the Ki-67 expression [50]. In vulvar squamous cell carcinoma associated with lichen sclerosus, it has been observed

Fig. 2.17 Invasive keratinizing squamous cell carcinoma, well differentiated. Tongues of well-differentiated squamous epithelium with keratinization are evident

• Fig. 2.18 Invasive keratinizing squamous cell carcinoma, well differentiated. The cells have abundant cytoplasm and large, round nuclei with prominent nucleoli

Invasive squamous cell carcinoma, moderately to poorly differentiated. Small nests and cords of invasive squamous cell carcinoma are present without keratinization

Table 2.6

Lymph node status and metastasis staging using the American Joint Commission on Cancer (AJCC) staging system

pNX: Regional lymph nodes cannot be assessed
pN0: No regional lymph node metastasis
pN1: Regional lymph node metastasis with the following features:
pN1a: One or two (1 or 2) lymph node metastasis each less than 5 mm (FIGO IIIA)
pN1b: One (1) lymph node metastases 5 mm or greater (FIGO IIIA)
pN2: Regional lymph node metastasis with the following features:
pN2a: Three or more or more lymph node metastases each less than 5 mm (FIGO IIIB)
pN2b: Two or more lymph node metastases 5 mm or greater (FIGO IIIB)
pN2c: Lymph node metastasis with extracapsular spread (FIGO IIIC)
pN3: Fixed or ulcerated regional lymph node metastasis (FIGO IVA)
Distant Metastasis (pM)
pMX: Distant metastasis cannot be assessed
pM0: No distant metastasis
pM1: IVB Distant metastasis (includes pelvic node metastasis) (FIGO IVB)

Source adapted from ref. American Joint Committee on Cancer 2010.

that Ki-67 expression is increased in squamous hyperplasia adjacent to the squamous cell carcinoma. These findings may imply premalignancy or a reactive process related to the carcinoma [140]. In addition, p53 is expressed in the neoplastic component when differentiated VIN is also associated [183]. Immunohistochemical expression of p16INK-4a is commonly expressed in vulvar squamous tumors and VIN associated with oncogenic HPV [129,133].

Histologic Subtypes of Vulvar Squamous Cell Carcinoma

Squamous cell carcinoma of the vulva can be subdivided into several morphologically distinct subtypes (> *Table 2.3*). Histologically, invasive squamous cell carcinomas that are not otherwise specified (NOS) usually are well-differentiated tumors, but moderately and poorly differentiated varieties are found in 5–10% of the cases (see > *Figs. 2.13* and > *2.16–2.19*).

Basaloid Carcinoma

An increased prevalence of human papillomavirus (HPV), mainly type 16, has been observed with certain types of invasive squamous carcinomas of the vulva. Among these are basaloid carcinomas, which occur in younger women (mean age, 54 years), compared with typical keratinizing squamous cell carcinomas (mean age, 77 years). HPVassociated vulvar squamous cell carcinomas can be distinguished histopathologically from non-HPV-related tumors, with agreement between observers noted in 67% of cases [160]. Basaloid carcinomas frequently are associated with adjacent VIN, usually of the basaloid type. In contrast to typical keratinizing squamous cell carcinomas, basaloid carcinomas are associated with synchronous or metachronous squamous neoplasms of the cervix and vagina [93]. On gross examination, basaloid carcinomas are similar to typical keratinizing squamous cell carcinomas. Microscopically, they are characterized by variablesized nests of immature squamous cells with little, if any, squamous maturation. Some tumors are composed of small, irregularly shaped nests and cords of cells surrounded by a densely hyalinized stroma. The basal-type cells within the nests and cords resemble those in the classic type of carcinoma in situ of the cervix (> Figs. 2.20-2.22). Characteristically, the cells are ovoid and relatively uniform in size, with scant cytoplasm and a high nuclear cytoplasmic ratio, and therefore they appear undifferentiated. Nuclei contain evenly distributed coarsely granular chromatin, creating a stippled appearance. A moderate degree of

Basaloid carcinoma. A prominent desmoplastic stroma is present

Fig. 2.22 Basaloid carcinoma. The tumor is composed of relatively small cells with hyperchromatic, nuclei

Fig. 2.21

Basaloid VIN with basaloid carcinoma. The basaloid VIN within the overlying epithelium has similar cellular features to the basaloid invasive tumor within the superficial and deep dermis. The tumor is composed of immature-appearing keratinocytes without significant maturation or keratinization

mitotic activity usually is evident. Occasionally, the cells in the center of a nest show evidence of maturation and contain more abundant cytoplasm. Small foci of keratinization may be evident in the center of the nests, and keratin pearls occasionally are present. Desmosomes usually are not evident. HPV-16 can be detected in approximately 70% of basaloid squamous carcinomas (**>** *Fig. 2.22*) [93]. Although basaloid carcinoma is reported to be associated with decreased survival in one age-controlled study [118], no evidence of decreased survival was observed in relatively large study [93].

Basaloid squamous carcinoma must be distinguished from basal cell carcinoma, but at times this may be difficult. In contrast to basaloid carcinoma, basal cell carcinomas tend to be more circumscribed and have a lobular appearance. The characteristic palisading of the outermost layer of cells in the nests of basal cell carcinoma is lacking in basaloid carcinoma. The differential diagnosis of basaloid carcinoma also includes metastatic small cell carcinoma and Merkel cell tumor. These tumors have a more diffusely infiltrative pattern characterized by poorly defined nests, trabeculae, and individual cells invading the stroma rather than the broad anastomosing bands and well-defined nests typical of basaloid carcinoma. Small cell tumors usually are immunoreactive for neuroendocrine markers; Merkel cell tumors have a characteristic perinuclear cytoplasmic "dot" demonstrated by immunohistochemical study with cytokeratins.

Warty Carcinoma (Condylomatous Carcinoma)

Warty carcinoma is found predominantly in younger women (mean age, 55 years) and presents clinically as a verrucoid or papillary tumor that may resemble condyloma acuminatum. Occasionally warty carcinoma or verrucous carcinoma may arise in association with condyloma acuminatum [42,43]. On microscopic examination, warty carcinoma has multiple papillary projections with a keratinized epithelial surface and fibrovascular cores (\triangleright *Figs. 2.23* and \triangleright *2.24*). Cytologic atypia is seen,

especially within the basal and parabasal cells, where there is nuclear pleomorphism and nuclear hyperchromasia. Multinucleation may be present. Mitotic figures usually can be found and sometimes may be atypical. Cytoplasmic perinuclear clearing similar to koilocytosis in VIN is present in a substantial number of cells; it is the most characteristic feature. At the junction between the exophytic portion of the tumor and the underlying stoma, irregularly shaped nests of epithelium are present that may be associated with keratin pearls and dyskeratotic cells. In this area, the tumor resembles a keratinized squamous cell carcinoma. In some cases, these areas are small and focal. Warty carcinoma is frequently associated with HPV type 16 [42,93,157].

The clinical course of warty carcinoma appears generally good; however, lymph node metastasis may occur. The prognosis appears intermediate between that of verrucous carcinoma and squamous cell carcinoma of the usual type [157]. Approximately 80% of warty and basaloid carcinomas have adjacent warty or basaloid VIN. About one quarter of the warty and basaloid carcinomas are associated with other genital tract squamous neoplasias[93].

Fig. 2.23

Warty (condylomatous) carcinoma. (a) The tumor has welldifferentiated neoplastic keratinocytes with keratinization. At the deep margin, the tumor is composed of irregularly shaped, varying sized nests that infiltrate the stroma in a haphazard fashion. (b) The cords of neoplastic cells are separated by a fibrovascular stroma. Keratinization is present

Fig. 2.24

Warty (condylomatous) carcinoma. Cells with pleomorphic nuclei and vacuolated cytoplasm resembling koilocytes are present within the neoplastic epithelium (Courtesy of R.J. Kurman, M.D., Baltimore, MD.)

Verrucous Carcinoma

Verrucous carcinoma is a highly differentiated squamous carcinoma that has a verrucous pattern and invades with a pushing border in the form of bulbous pegs of neoplastic cells [17]. The term giant condyloma of Buschke-Lowenstein is considered to be a synonym for verrucous carcinoma, but it is confusing and therefore is not recommended [175]. Squamous cell carcinomas at times may have some of the architectural features of verrucous carcinoma, but if they lack a high degree of differentiation, or have a nonpushing pattern of invasion, they should not be designated verrucous carcinoma. Verrucous carcinoma is a papillary exophytic growth that may have the appearance of an exophytic, broad-based condyloma acuminatum, and distort or completely obscure the vulva (> Fig. 2.25). Secondary infection may be associated with a malodorous discharge. Regional lymph nodes usually are not enlarged.

Condyloma acuminatum may be adjacent to verrucous carcinoma, and rarely the tumor may merge into a typical squamous cell carcinoma [42,43]. "Vulvar acanthosis with altered differentiation" has been proposed as a probable precursor of vulvar verrucous carcinoma. It is characterized as a noninvasive squamous lesion with variable verrucoid growth with acanthosis and parakeratosis. There is associated loss of the granular layer and pale cytoplasm of the superficial keratinocytes. These changes were reported adjacent to vulvar verrucous carcinoma in seven cases in a study of nine verrucous carcinomas from seven patients. Neither this lesion nor the verrucous carcinomas in this study was associated with human papillomavirus [110]. Verrucous carcinoma may be associated with HPV, typically type 6 or variants of type 6.

The microscopic features of vertucous carcinoma include prominent acanthosis with a pushing tumor–dermal interface and bland cytologic features (\bigcirc *Fig. 2.26*)

Fig. 2.25 Verrucous carcinoma. At the stromal interface the tumor displays rounded, bulbous tongues of very well differentiated squamous epithelium

• Fig. 2.26 Verrucous carcinoma. There is a well-defined tumorstromal interface with a pushing, growth pattern. The keratinocytes are very well differentiated

(see Ohap. 3, Diseases of the Vagina). Large bulbous nests of squamous epithelium characterize the deep margin. There is minimal nuclear pleomorphism, with the greatest degree of nuclear atypia nearest the dermal interface. The nuclei may have coarse chromatin and variable-sized nucleoli, distinguishing them from normal adjacent keratinocytes. Mitotic figures are rare and when present are normal. The abundant cytoplasm of the tumor cells is eosinophilic, without dyskeratosis. Koilocytosis is not a feature of this tumor. Parakeratosis or hyperkeratosis usually is present and may be prominent. There is an absence of fibrovascular cores separating the bulbous epithelial downgrowths. An inflammatory infiltrate within the dermis usually is present. These tumors typically are diploid.

The differential diagnosis includes the typical variety of squamous cell carcinoma, warty carcinoma, and condyloma acuminatum. Squamous cell carcinoma of the usual type (keratinizing squamous carcinoma) has greater nuclear pleomorphism and a more irregular pattern of infiltration of the stroma compared with the bulbous nests of verrucous carcinoma. Warty carcinoma, despite its verruciform appearance, has fibrovascular cores within the papillary fronds, unlike verrucous carcinoma. In addition, these tumors display greater nuclear atypia, "koilocytosis," and, at their deep margin, invade like typical squamous cell carcinomas. Condyloma acuminatum is characterized by a complex branching papillary architecture with vascular papillae, lacks bulbous downgrowths, and typically shows koilocytosis, although in vulvar condylomas koilocytosis may be quite subtle.

Verrucous carcinomas may recur locally after excision. Lymph node metastasis is extremely rare, and its presence should prompt reevaluation of the lesion for areas of the usual type of squamous cell carcinoma. Wide local excision and total vulvectomy without lymph node dissection are the most common methods of therapy. If the tumor is excised completely, the prognosis is excellent. The role of radiotherapy in vulvar verrucous carcinomas is not well studied, but it may be applicable in very advanced cases.

Giant Cell Squamous Carcinoma

Squamous cell carcinoma with tumor giant cells is a variant of squamous cell carcinoma characterized by multinucleated tumor giant cells, large nuclei with prominent nucleoli, and prominent eosinophilic cytoplasm (**?** *Fig. 2.27*). This tumor variant is relatively rare and is associated with a poor prognosis. The most important differential diagnosis is malignant amelanotic melanoma, which commonly forms multinucleated tumor giant cells [177]. Melanomas typically have intranuclear inclusions and prominent nucleoli.

Unlike giant cell carcinoma, melanomas are typically immunoreactive for S-100, melanoma antigen (HMB 45), and Melan-A and negative for cytokeratin [177].

Spindle Cell Squamous Cell Carcinoma

Spindle cell carcinoma of the vulva/sarcomatoid squamous cell carcinoma may mimic a sarcoma or be associated with sarcoma-like stroma (**>** *Fig. 2.28*) [32,33,153].

Fig. 2.27

Giant cell carcinoma of the vulva. Multinucleated tumor giant cells are evident. The cells contain nuclei with prominent nucleoli and abundant eosinophilic cytoplasm

Fig. 2.28

Spindle cell (sarcomatoid) squamous cell carcinoma. The tumor is composed of fascicles of spindle-shaped neoplastic squamous cells, showing moderate nuclear pleomorphism These tumors must be distinguished from mesenchymal spindle cell tumors, including leiomyosarcoma, malignant fibrous histiocytoma, and fibrosarcoma, as well as spindle cell malignant melanoma and transitional cell carcinoma with spindle cell features. The neoplastic cells of spindle cell carcinoma, unlike all the mesenchymal tumors and melanoma, are immunoreactive for keratin [135]. Spindle cell carcinoma may be associated with tumor giant cells, which are also immunoreactive for keratin [135].

Acantholytic Squamous Cell Carcinoma (Adenoid Squamous Carcinoma; Pseudoangiomatous Carcinoma)

The acantholytic squamous tumor forms rounded spaces, or pseudoacini, lined with a single layer of squamous cells. Dyskeratotic and acantholytic cells are sometimes present in the central lumen (**>** *Fig. 2.29*). These changes are focal in most cases and may occur within otherwise well-

Fig. 2.29

Acantholytic squamous cell carcinoma. Nests of poorly differentiated squamous cell carcinoma are arranged in a crude acinar manner. Some of the central acini are vacuolated differentiated squamous tumors. Acantholytic squamous cell carcinomas have been reported to have a prognosis similar to squamous carcinoma of the usual type; however, some recent reports describe a more aggressive behavior for this tumor type [79,136].

Adenosquamous carcinoma, is a term used sometimes for acantholytic squamous cell carcinoma but may be better considered as a distinct tumor in that adenosquamous carcinoma should have a distinct secretory, glandular cell component. It has been reported as being associated with a poorer prognosis that the usual squamous cell carcinomas, but in one case had arisen in a hidradenoma [10]. As with Bartholin gland adenosquamous carcinomas, such tumors in the Bartholin gland have a poorer prognosis than squamous cell carcinomas. In the Bartholin gland, this is considered partly because of the higher frequency of lymph node metastasis (see **Q** Bartholin Gland Tumors).

Papillary Squamous Cell Carcinoma

This tumor is rare and has similar morphologic features to papillary squamous cell carcinoma of the cervix. The tumor is exophytic with an expansile and deep pushing infiltrative pattern within the dermis. Although there is very limited experience with this tumor, with negative nodes it can be managed by deep wide excision [97].

Lymphoepithelioma-Like Carcinoma

These tumors may occur rarely on the vulva in older individuals. They are composed of nests or syncytial groups of epithelioid-appearing cells mixed with, and surrounded by, a dense lymphocytic infiltrate (\bigcirc *Fig. 2.30*) (see \bigcirc Chap. 6, Carcinoma and Other Tumors of the Cervix). The epithelial cells are immunoreactive for high molecular-weight cytokeratins, which distinguishes them from inflammatory processes and malignant large cell lymphomas. Lymphomas, including Ki-1 lymphomas, which are immunoreactive for lymphocytic markers, contain an immunophenotypic monoclonal population of neoplastic lymphocytic cells. The therapy is wide local excision with or without local radiation therapy [22].

Plasmacytoid Squamous Carcinoma

Plasmacytoid squamous carcinoma is a rare tumor of the vulva, with one case reported in a 92-year-old woman who had been treated previously for multiple

Lymphoepithelial like carcinoma. The tumor cells are small, uniform and lack maturation. The cells are in nests and syncytial groups mixed with, and surrounded by a prominent lymphocytic infiltrate

vulvar squamous and verrucous carcinomas. The patient's prior tumors were all treated by local excision. The plasmacytoid tumor presented as a 3 cm polypoid vulvar mass superior but adjacent to the urethra. The surface of the tumor was ulcerated [158]. On gross examination, the tumor was submucosal, somewhat yellow in color, and abutted the overlying epithelium. No evidence of VIN or other related HPV changes were identified adjacent to the tumor. On microscopic examination, approximately 60% of the tumor cells had plasmacytoid features with cells having epithelioid differentiation. These cells lacked the nuclear characteristic "clock face" appearance of plasma cells, but did have prominent amphophilic cytoplasm with an eccentrically placed nucleus. In addition, these cells were more than twice the size of normal plasma cells. The tumor cells were immunoreactive for cytokeratin 5, AE3, and high molecularweight cytokeratin 903. Some cells expressed AE1. In addition, the cells were reactive for p63, CD138, and VS38, but negative for Kappa or Lambda light chains. Other immunohistochemical studies performed were negative.

The differential diagnosis of vulvar plasmacytoid squamous cell carcinoma includes metastatic or primary melanoma, myoepithelial tumors, neuroendocrine tumors, or plasmacytoma. In addition metastatic plasmacytoid urothelial carcinoma and lobular breast carcinoma must be considered. These tumors can be distinguished by immunohistochemical studies, and clinical history is often contributory in metastatic cases.

The treatment was deep partial vulvectomy. Within 6 months postoperative the patient presented with a right

inguinal enlarged lymph node with several pulmonary nodules. The patient died with metastatic tumor in less than 1 year of diagnosis [158].

Clinical Behavior and Treatment of Vulvar Squamous Cell carcinoma

Factors that may be of significance in prognosis and in the probability of lymph node metastasis include the diameter of the tumor, the presence of vascular space invasion, and tumor ulceration. Confluent growth, defined as anastomosing cords or tumor, or tumor in the dermis exceeding 1 mm³, does not correlate with the occurrence of node metastasis but is not found in tumors having 1 mm or less of invasion [170]. When controlled for age, survival with vulvar carcinoma decreased with advancing age, higher stage and grade, increasing tumor thickness, prominent fibromyxoid dermal response, infiltrative pattern of growth, and basaloid tumor type [118].

Inguinofemoral lymph node status and the diameter of the tumor are independent prognostic factors. The overall 5-year relative survival, related to stage, as reported in a series of 588 patients with vulvar carcinoma is as follows: stage I, 98%; stage II, 87%; stage III, 75%; and stage IV, 29% [78]. The distance between the tumor and the surgical margin is a significant predictor of local recurrence. A surgical margin of 8 mm or less from the invasive carcinoma is associated with a 50% risk of local recurrence [73]. In a GOG study of 121 patients with stage I vulvar carcinoma with a tumor thickness of 5 mm or less, without vascular space invasion, and with negative lymph nodes, 19 patients (15.7%) experienced recurrence, and there were seven deaths (5.8%) from tumor. Of the seven deaths, five were related to recurrence in the groin nodes [154]. Tumors with a depth of invasion greater than 1 mm require more extensive surgery, including groin node dissection [63,67,170]. Terminology for surgical procedures and characterization of depth of invasion of vulvar tumors has been developed by the International Society for the Study of vulvovaginal Disease (ISSVD) and is shown in **⊘** *Table 2.7* [84].

Vulvar carcinoma typically spreads by direct extension and lymphatic metastasis and tends to recur locally. Although distant metastasis is less common. Direct extension may include involvement of bone and metastasis may include bone metastasis. The reliability of clinical evaluation in the determination of whether tumor is present in inguinal nodes has a false-positive rate less than 10% but a false-negative rate of approximately 20% [16]. It is recognized that pathologic evaluation of lymph nodes for metastasis also may be falsely negative.

Table 2.7

Surgical procedures and characterization of depth of invasion of vulvar tumors

Vulvectomy
Partial vulvectomy: Removal of a part of the vulvar/ perineal integument independent of depth
Total vulvectomy: Removal of the whole vulva and appropriate integument of the perineum independent of depth
Depth of excision
Superficial: Removal of the most superficial layer with a variable amount of dermis and subcutaneous tissue
Deep: removal of the vulva to the superficial aponeurosis of the urogenital diaphragm and/or pubic periosteum

Developed by the International Society for the Study of Vulvovaginal Disease (ISSVD) [84].

In assessing groin nodes, fine-needle aspiration may be the first step if clinically suspicious nodes are present because the technique is rapid, safe, cost-effective, and will detect gross metastasis. Current therapy attempts to define high- and low-risk groups and requires individualization of therapy [81]. Sentinel lymph node identification methods employing technetium-99 m-labeled noncolloid have been employed to attempt to select and sample sentinel lymph nodes and possibly avoid inguinofemoral lymph node resection if the sentinel lymph node, or nodes, are free of metastatic tumor [1,39,105]. Many patients are now offered immediate reconstructive surgery as part of the initial procedure [63]. Radiation techniques are now available that allow skin-sparing treatment of the groin nodes and have been used successfully in both primary and adjunctive treatment.

Basal Cell, Adenoid Basal Cell, Metatypical Basal Cell, and Sebaceous Cell Carcinoma of the Vulva.

Basal Cell Carcinoma

Although basal cell carcinomas of the skin are extremely common, they account for only 5–7% of vulvar carcinomas [56,119]. They are found primarily in elderly white women (mean age, 70–76 years), whose symptomatology consists of pruritus, irritation, soreness, or bleeding. The tumors usually present as an ulcer, an area of pigmentation or depigmentation, or as a mass [56,107,170].

Most of these tumors are confined to the labia majora, and approximately one half are of infiltrative type. Basal cell carcinomas are not associated with human papillomavirus.

The histologic pattern resembles that of basal cell carcinomas occurring elsewhere on the skin (**>** *Fig. 2.31*).

Fig. 2.31

Basal cell carcinoma. (a) The tumor is composed of relatively small uniform cells in club shaped nests with a palisade orientation of the cells at the tumor-stromal interface.
(b) The basal cell carcinoma has an infiltrative pattern, with focal cribriform formation (Courtesy of R.J. Kurman, M.D., Baltimore, MD.)

The tumor is composed of small elongated cells with deeply basophilic nuclei and may have a large variety of architectural patterns, ranging from slight palisading of the basal layer of the epidermis to the formation of large club-shaped

Sebaceous carcinoma. The tumor is composed of cords and nests of basaloid-appearing cells. These cells are associated with sebaceous cells in pagetoid nests in the parabasal areas and in larger clusters near the epithelial surface (Courtesy of R.J. Kurman, M.D., Baltimore, MD.)

masses of pleomorphic basal cells. The connective tissue adjacent to the tumor frequently contains a chronic inflammatory cell infiltrate and occasionally shows a mucoid or myxomatous change.

Primary treatment is wide local excision [1]. Local recurrence occurs in approximately 9–20% of cases [119]. Metastasis to regional lymph nodes occurs but is rare [11]. The overall prognosis of patients with these tumors is excellent, with only a rare death reported [11].

Adenoid Basal Cell Carcinoma

Adenoid basal cell carcinoma is a variant of basal cell carcinoma in which tubular and glandlike differentiation is seen within a tumor that otherwise is a characteristic basal cell carcinoma.

Metatypical Basal Cell Carcinoma (Basosquamous Carcinoma)

Metatypical basal cell carcinoma, or basosquamous carcinoma, represents a mixture of both squamous and basal cell neoplastic elements. Unlike basal cell carcinomas, basosquamous carcinomas are locally aggressive and metastasize rarely, and should be managed like squamous cell carcinoma related to the stage of the tumor.

Sebaceous Cell Carcinoma

Sebaceous cell carcinoma is a rare tumor of the vulva that may be associated with vulvar intraepithelial neoplasia. The tumor has features of basosquamous cell carcinoma with sebaceous differentiation (\triangleright *Fig. 2.32*) [21].

Glandular Tumors of the Vulva (Primary Adenocarcinomas of the Vulva)

Adenocarcinomas of the vulva are relatively rare. Many previous reports have been shown retrospectively to represent benign hidradenomas or foci of adnexal Paget disease. Adenocarcinoma in situ has been reported arising within vulvar papillary hidradenoma [143]. Most adenocarcinomas of the vulva arise as primary malignant tumors of the Bartholin gland; however, they also may arise from sweat glands or from other skin appendages, the urethra, the Skene gland, and from Paget disease [169]. Paget disease and Paget-like neoplastic lesions, including pagetoid urothelial intraepithelial neoplasia (PUIN), are described here.

Paget Disease

Clinical Features

Clinically, vulvar Paget disease can present as either an erythematous lesion, often involving the vestibule and adjacent areas, or an eczematous lesion that appears as a red to pink area with white islands of hyperkeratosis and usually involving hair-bearing skin (\bigcirc *Figs. 2.33* and \bigcirc *2.34*). The extent of involvement can be very focal, or extensive, extending about the anus, medial aspects of the upper thigh, or other contiguous sites [123].

Pruritus is present in more than half the patients, and was present for a median duration of 2 years before the diagnosis in a study of 100 patients [55]. Almost all patients are postmenopausal Caucasian women, with a median age of 70 years [55]. Paget disease may occur in younger women of reproductive age. Vulvar pruritus or pain may bring the patient to the attention of the physician. Because of its clinical resemblance to a dermatosis, these patients may be treated with various topical medications for some time before the diagnosis is made by biopsy.

Vulvar Paget disease and pagetoid urothelial intraepithelial neoplasia (PUIN) have recently been subclassified by Wilkinson and Brown into two distinct types, specifically cutaneous Paget disease and noncutaneous Paget disease based upon the origin of the neoplastic cells summarized as follows: [173]

Paget disease, primary type. An eczematoid, slightly raised and white area is present on the medial anterior surface of the right labium majus, an eroded, red, ulcerated area is present on the left labia majus

Primary Cutaneous Paget Disease

Primary vulvar cutaneous Paget disease is subdivided into three distinct groups (> *Table 2.8*).

Primary cutaneous Paget disease can be an intraepithelial neoplasm or primary vulvar intraepithelial Paget disease. It characterized by an intraepithelial proliferation of atypical glandular-type cells and may be considered as an adenocarcinoma in situ (\bigcirc *Fig. 2.35*). Histopathologic features are characterized by relatively large cells, with prominent cytoplasm, that are within the squamous epithelium. These cells are generally larger than the adjacent keratinocytes and have large nuclei with prominent nucleoli. Their cytoplasm is finely granular and amphophilic to basophilic, and may be vacuolated, in contrast to the eosinophilic more homogeneous cytoplasm of keratinocytes. The neoplastic cells are typically clustered in groups or dispersed as single cells within the basal and

Fig. 2.34

Paget disease, primary type, partial deep vulvectomy. The white and eczematoid epithelial changes reflect the Paget disease that involves the perineal body and left labia majus (photo courtesy R. Foss, PA, Gainesville, FL.)

Table 2.8

Classification of primary and secondary vulvar Paget disease [169]

Primary Paget disease (primary cutaneous Paget disease)
Paget disease as an intraepithelial neoplasm/in situ Paget disease
Paget disease as an intraepithelial neoplasm with invasion/invasive primary Paget disease.
Paget disease as a manifestation of an underlying cutaneous neoplasm.
Secondary Paget disease: (Paget disease of noncutaneous origin)
Paget disease as a manifestation of anal-rectal adenocarcinoma
Paget disease related to other adenocarcinomas.
Paget disease as a manifestation of urothelial in situ or invasive carcinoma/pagetoid urothelial intraepithelial neoplasia (PUIN).

Paget disease, primary type. Large numbers of Paget cells within the basal and parabasal areas with Paget cells extending into the upper epithelium. Paget cells are present singly and in nests. Their pale cytoplasm differentiates them from surrounding keratinocytes. The nuclei of the Paget cells are larger, and their nuclear chromatin coarser, than in the adjacent keratinocytes

parabasal areas, and also in various layers within the epithelium, so-called pagetoid spread. They may form small acinar groupings within the surface squamous epithelium and involve the epithelium surrounding hair shafts and skin appendages. Mitotic figures may be present but are not frequent (\bigcirc *Fig. 2.35*). Paget cells can be identified on cytologic examination of scrapings from saline-moistened areas. Proliferative epithelial lesions may be associated with Paget disease, including manifesting with a marked verrucoid papillomatous appearance of the epithelium that may resemble warty changes (\bigcirc *Fig. 2.36*) [14].

Primary cutaneous Paget disease can present as a primary vulvar intraepithelial Paget disease with invasion. Dermal, or submucosal, invasion by intraepithelial Paget cells is well documented and has been reported in 12% in a series of 100 cases [55]. Vulvar Paget disease is therefore properly classified as a form of intraepithelial neoplasia that may become invasive.

Primary cutaneous Paget disease can present as a manifestation of a primary underlying adenocarcinoma of the vulva. Vulvar Paget disease associated with an underlying primary invasive adenocarcinoma of the vulva has been reported in 4% of vulvar Paget disease cases in one series [55]. Cases with associated adenocarcinoma of the Bartholin gland and squamous cell carcinoma of the vulva have been reported. Primary vulvar adenocarcinoma is identified beneath Paget disease in

Fig. 2.36

Paget disease, primary type. The tumor has a papillomatous, appearance and there is an associated superficial dermal chronic inflammatory cell infiltrate. Paget cells are present within the basal and parabasal epithelium (Case courtesy Dr. Michael J. Goldfischer, Hackensack University Medical center, Hackensack, NJ.)

approximately 10-20% of the cases reported. Its origin may be from primary invasive Paget disease or adenocarcinoma of the Bartholin gland, specialized anogenital glands, or other vulvar glandular structures. Early investigators noted underlying adnexal adenocarcinoma beneath the skin in the vicinity of Paget disease in many extramammary cases. This finding led some to conclude that Paget cells in the epidermis represented an intradermal migration of neoplastic cells from an underlying cutaneous tumor, as occurs in the breast. This has been documented in a case of eccrine carcinoma of the vulva with pagetoid spread of the tumor cells within the vulvar skin, with resulting Paget disease of the involved skin [65]. This is a rare occurrence and is not the usual finding. The origin of such underlying adenocarcinomas associated with Paget disease does not appear to be usually associated with sweat gland tumors in that epidermal growth factor (EGF), which is typically present in approximately three fourths of eccrine or apocrine sweat gland tumors, was absent in vulvar Paget disease in a study of 17 cases [3]. Vulvar Paget disease may be of noncutaneous origin, and there are two major groups of such cases. One group is Paget disease as a manifestation of an associated adjacent primary anal, rectal, or other noncutaneous adenocarcinoma. The second group of noncutaneous Paget disease represents those cases that are a manifestation of bladder or other urothelial carcinoma. Wilkinson and Brown have proposed that this Paget-like neoplasm of the vulva be

classified as pagetoid urothelial intraepithelial neoplasia (PUIN) to characterize this neoplasm as a manifestation of bladder (urothelial) neoplasia, and not of glandular origin [18,173].

Cases of Paget disease as a manifestation of an associated adjacent primary noncutaneous adenocarcinoma, include Paget disease associated with in situ or invasive rectal adenocarcinoma or colonic adenocarcinoma (> Fig. 2.37), or intraepithelial extension from an adjacent cervical adenocarcinoma. Perianal involvement by Paget disease is associated with a high frequency of adenocarcinoma or squamous carcinoma of the rectum and may present with perianal pruritus, pain and burning, or bleeding after defecation [99]. Primary perianal Paget disease may involve the vulva and should be distinguished from primary cutaneous vulvar Paget disease. Although cutaneous primary vulvar Paget disease involving the perianal area cannot be distinguished by routine histologic examination from primary anal Paget disease involving the vulva, the distinction can be made employing immunohistochemistry. Primary noncutaneous perianal Paget disease is immunoreactive for cytokeratin 20 and negative for gross cystic disease fluid protein-15 (GCDFP-15). It is also associated with rectal Paget disease and, in most reported cases, with rectal adenocarcinoma (> Table 2.8) [113]. Adenocarcinoma of the cervix manifesting as vulvar Paget disease has been reported [37]. In such cases, the immunohistochemistry would reflect a cervical adenocarcinoma, depending on cellular type, and

Fig. 2.37

Paget disease, secondary type, of anorectal adenocarcinoma origin. The Paget lesion is focally contiguous with the invasive anal adenocarcinoma that invades the dermis and focally involves the overlying epithelium would have a high probability of containing human papillomavirus, especially types 16 or 18. Paget cells typically are HPV negative.

Paget disease of urothelial origin, pagetoid urothelial intraepithelial neoplasia (PUIN), is a cutaneous manifestation of bladder (urothelial) neoplasia: urinary tract malignancy has been reported with genital Paget disease, and the original report of extramammary Paget disease by Crocker in 1889 was of a man with penile and scrotal Paget disease associated with bladder carcinoma [113]. It has recently been recognized, however, that Paget-like vulvar mucosal and dermal changes associated with urothelial neoplasia can be recognized as a distinct entity [173]. In these cases, there is involvement of the vulvar vestibule, including the periurethral area, which is manifested as an erythematous lesion.

The cells of PUIN have the cytologic features of urothelial carcinoma in situ, with which PUIN is most commonly associated (\bigcirc *Figs. 2.38* and \bigcirc *2.39*) [18,173]. Of key importance regarding the recognition of PUIN (Pagetoid intraepitheral neoplasia) is that this vulvar neoplasm is a manifestation of bladder urothelial neoplasia and is not associated with underlying adenocarcinoma.

Differential Diagnosis and Adjunctive Studies

The PUIN cells do not contain mucin, PAS-positive material, CEA, or GCDFP-15 as do the Paget cells of primary cutaneous Paget disease, or noncutaneous Paget disease related to adenocarcinoma anorectal area, or other nonvulvar primary site [172]. The cells of PUIN are immunoreactive for cytokeratin 7 and may be cytokeratin 20 positive and uroplakin III positive, as are one half of the primary urothelial carcinomas (**>** *Table 2.2*) [18,173].

Paget cells of primary cutaneous Paget disease, or noncutaneous Paget disease related to adenocarcinoma anorectal area, or other nonvulvar primary site are positive for PAS (diastase resistant), mucicarmine, aldehydefuschin, and Alcian blue. The cells stain pink against a background of greenish-blue with Movat stain. In addition, Paget cells of cutaneous type, as well as the cells and secretions of normal eccrine and apocrine glands, are rich in carcinoembryonic antigen (CEA) and gross cystic disease fluid protein-15 (GCDFP-15), and typically are negative for S-100 protein, HMB-45, and Melan-A [173]. Paget cells of cutaneous type are immunoreactive for cytokeratin 7 [37,172,173]. These reactions distinguish typical cutaneous Paget cells from PUIN, VIN, superficial spreading malignant melanoma, and pagetoid reticulosis. They may also be useful in evaluation of margins in permanent sections [61]. Melanoma is distinguished by being immunoreactive for S-100, HMB-45, and Melan-A, which are typically not identified in Paget cells [77,120]. Paget cells, however, may contain granules of melanin, demonstrable with Fontana–Mason stain, probably produced by neighboring melanocytes and engulfed secondarily by the Paget cell. Paget cells have not been demonstrated to be associated with common oncogenic or non-oncogenic genital human papillomaviruses [150]. Estrogen receptor expression, p53 immunoreactivity, and DNA ploidy do not appear predictive of clinical behavior or recurrence; however, DNA nondiploid Paget disease has been associated with an increased risk of recurrence, as compared to diploid Paget disease, in one study [138].

Fig. 2.38

Pagetoid urothelial intraepithelial neoplasia (PUIN); Paget disease, secondary type, of urothelial origin. The epithelium has pagetoid urothelial cells throughout the full thickness, but most concentrated in the basal and parabasal areas. The "clefts" between the neoplastic urothelial cells and the adjacent epithelial keratinocytes are characteristic of PUIN

Clinical Behavior and Treatment

The treatment and prognosis of Paget disease of the vulva depends on the type as described herein. For primary cutaneous Paget disease, prognosis depends on whether the lesion is intraepithelial only, or if there is an associated invasive Paget disease. For primary intraepithelial Paget disease, the lesion is usually a slowly progressive, indolent, superficial process. Accordingly, local excision of the visible lesion to the fascia, with 2 cm clinically visibly clear margins of excision, is sufficient. In cases associated with invasive Paget disease, or with underlying skin appendage or vulvar glandular adenocarcinoma, as determined by histopathologic evaluation, treatment includes ipsilateral inguinal-femoral lymphadenectomy. If the tumor extends to the margins of excision, or the excision is deemed inadequate in the face of invasive disease, more extended partial or total vulvectomy may be needed [9,37,55]. Recurrent vulvar Paget disease, occurring peripheral to an excised intraepithelial Paget lesion, does not appear to be associated with any significant risk of underlying adenocarcinoma and can be treated by a more conservative approach, such as superficial excision, or topical therapy, including imiquimod [54,72,99].

In the patient with vulvar primary cutaneous Paget disease, clinically normal-appearing skin may contain Paget cells. A careful topographic study [66] demonstrated

Fig. 2.39 Pagetoid urothelial intraepithelial neoplasia (PUIN); Paget disease, secondary type, of urothelial origin. Large neoplastic intraepithelial urothelial cells are present throughout the epithelium

that the outline of the histologically involved area was highly irregular and of much greater extent than the visible lesion. In addition, multicentric foci, some occurring in grossly normal-appearing skin, were noted; this accounts for the frequent "recurrences" of disease despite seemingly adequate excision. These clinically normalappearing areas of skin, however, are not associated with underlying skin appendage adenocarcinoma or invasive primary cutaneous Paget disease. In the author's experience, when invasive primary cutaneous Paget disease or cutaneous Paget disease associated with an underlying skin appendage carcinoma (type 1c) is present, the adenocarcinoma is within the dermis of the skin or mucosa clinically involved with the Paget disease. In such cases, excision to the fascia of these clinically involved areas, to excise the Paget disease and the potential underlying adenocarcinoma, is necessary.

The depth of invasion influences prognosis in such cases. When the depth of dermal invasion was 1 mm or less, no nodal metastasis or death from tumor was observed in seven such patients, whereas all three patients with tumor invasion beyond 1 mm had inguinofemoral node metastasis [37]. Frozen section evaluation of clinically normal-appearing skin margins adjacent to primary cutaneous Paget disease has not been demonstrated either to improve survival or to reduce recurrence. In a study of 12 patients with involved margins following surgery, seven (58%) had recurrence, whereas recurrence was seen in one of four patients (25%) with negative margins [37]. Recurrences of primary cutaneous intraepithelial Paget disease after excision of the primary lesion have not demonstrated a significant risk of associated underlying adenocarcinoma. Recurrences at the site of the original tumor or remote from it can be treated by local superficial excision. Intraepithelial Paget disease has no significant risk of lymph node metastasis or death [37,55]. The issues regarding margin assessment specifically relate to primary cutaneous Paget disease. Margin assessment for Paget disease of noncutaneous origin, including PUIN, needs to be addressed. One study has reported reduced E-cadherin expression in primary vulvar Paget disease as correlating with disease progression [49].

In cases of perianal Paget disease, it is necessary to evaluate the rectum and the anus to determine if the lesion is a manifestation of underlying rectal Paget disease or rectal or anal adenocarcinoma. In such cases, therapy is directed toward treatment of the rectal or anal carcinoma, and the vulvar Paget disease can be treated as an intraepithelial neoplasm, with local superficial excision, or more conservatively. In vulvar Paget disease associated with other adjacent adenocarcinomas, such as cervical adenocarcinoma, the treatment is focused on the primary adenocarcinoma and the associated Paget disease is treated as an intraepithelial neoplastic process, with superficial excision. The prognosis in such cases is dependent on the stage and behavior of the associated adenocarcinoma.

Therapy for vulvar PUIN is directed toward the bladder urothelial neoplasm, and the vulvar pagetoid intraepithelial urothelial neoplastic process is treated conservatively, as an intraepithelial neoplasm. Total vulvectomy and excision to the deep fascia is not indicated in this circumstance [173].

Adenocarcinoma of Cloacogenic Origin (Mucinous Adenocarcinoma Arising in the Surface Epithelium of the Vulva); Cloacogenic Carcinoma (Cloacogenic Adenocarcinoma)

All these rare tumors of the vulva have features of glandular tumors of the colon, and their origin is uncertain. They are usually solitary, but may involve more than one site. The tumor presents as a cutaneous mass and are polypoid, excoriated and/or inflamed [46,181]. They appear to be primary mucinous tumors of the vulvar epithelium and within the vulvar vestibule this may be a probable explanation. Benign-appearing mucinous glandular elements have been reported in the dermis deep to the tumor in one case [187]. It is also possible that they arise from some remnant of the early colaca within the vulva, as the term implies.

On microscopic examination the tumor may be entirely confined to the epithelium, with a verrucoid, or papillary appearance and with neoplastic colonic-type glandular epithelial cells on the surface of the tumor. They may resemble colonic villous adenoma when a predominant intraepithelial component is present. The neoplastic mucinous epithelium is in continuity with the overlying epithelium. If invasion is present, it is in continuity with the overlying neoplastic epithelium. The tumor is not associated with an underlying dermal glandular neoplasm as may be seen with Paget disease. The invasive adenocarcinoma resembles mucinous colonic carcinoma, with neoplastic colonic type epithelium with goblet cells and intracytoplasmic mucin. Apocrine differentiation is not observed [181,187].

On immunohistochemical study, these tumors are reported as being reactive with mucicarmine, Alcian blue pH 5, and immunoreactive for polyclonal CEA, cytokeratin 17, CAM 5.2, and p53 antigen. In addition, S-100 and chromogranin are also reported as immunoreactive in some neoplastic epithelial cells, evidence of the presence of endocrine cells. The tumors are not reactive for monoclonal CEA and estrogen receptor (ER) and progesterone receptor (PR). Electron microscopic studies have provided additional evidence of a colonic type epithelium within these tumors [46,181,187].

Although there is limited experience, treatment of tumors that are entirely intraepithelial would be more conservative than for invasive tumors. For these deeper tumors, risk of lymph node metastasis is limited although regional lymph node involvement is apparently rare. Treatment with partial deep vulvectomy (deep local excision) has reportedly been effective [181]. Gynecologic oncology consultation is recommended because of the very limited experience with these tumors.

Bartholin Gland Tumors

General Features

A wide variety of tumors may arise from the Bartholin gland. The criteria for the diagnosis of a tumor of Bartholin gland origin are that (1) the neoplasm must arise at the site of Bartholin gland, (2) be consistent histologically with a primary neoplasm of Bartholin gland, and (3) not be metastatic. Adenocarcinomas account for approximately 40% of Bartholin gland carcinomas, but others include squamous cell carcinoma (40%), adenoid cystic carcinoma (15%), transitional cell carcinoma (less than 5%), adenosquamous carcinomas [40].

Clinical Features

Carcinoma of the Bartholin gland usually presents as an enlargement in the gland area and may present as an apparent Bartholin cyst. The average age of women with this tumor is 50 years, with most between 40 and 70 years.

Gross Findings

Bartholin gland tumors are typically solid, deeply infiltrative, and occupy the site of the gland, occasionally obscuring its presence. They range from 1 to 7 cm in diameter.

Microscopic Findings

Adenocarcinomas of the Bartholin gland usually are nonspecific in type, but mucinous and papillary types have been described. The tumors usually contain intracytoplasmic mucin and are immunoreactive for CEA. Fine-needle aspiration cytology may be of value in diagnosis.

Differential Diagnosis

The differential diagnosis of Bartholin gland adenocarcinoma includes adenocarcinoma of skin appendage origin and metastatic adenocarcinoma. These tumors typically do not involve the Bartholin gland, and the tumor type may not be consistent with a primary tumor of the Bartholin gland.

Other Primary Bartholin Gland Carcinomas

Squamous cell carcinomas arising in the Bartholin gland have the same microscopic appearance as those arising elsewhere in the vulva. These tumors are typically immunoreactive for CEA.

Adenoid cystic carcinomas arising in the Bartholin gland are similar to those occurring in salivary glands, the upper respiratory tract, and skin. They are composed of uniform, small cells arranged in cords and nests with a cribriform pattern [36]. Variable-sized cysts filled with amphophilic or eosinophilic acellular basement membrane-like material also may be encountered (\diamond *Figs. 2.40* and \diamond *2.41*). Keratin and S-100 antigen are detectable by immunohistochemical techniques. The S-100 reactivity may demonstrate a myoepithelial cell element.

The differential diagnosis of adenoid cystic carcinoma includes adenocarcinoma, basal cell carcinoma, metastatic atypical carcinoid, and small cell carcinoma. Metastatic small cell carcinoma arising in the vagina has been reported as presenting as a Bartholin mass [104]. Adenocarcinomas lack the uniform acinar arrangement and intraluminal basement membrane material of adenoid cystic carcinoma. Basal cell carcinomas are more solid and lack the cystic spaces and the intracystic basement membrane-like material. Metastatic carcinoids and small cell carcinomas are more solid, have fewer lumens, contain argyrophil cells, and stain for neuron-specific enolase (NSE) in most cases. Carcinoid tumors almost always react with antibodies against chromogranin and other neuroendocrine markers.

Adenosquamous carcinoma of the Bartholin gland contains a mixture of squamous cells with intracellular bridges and glandular cells that typically contain mucin.

Fig. 2.40 Adenoid cystic carcinoma. Relatively small cells surrounding sharply punched-out cystic spaces

Transitional cell carcinoma arising in the Bartholin gland is composed of uniform polyhedral or rounded epithelial cells often lining broad papillary fronds. Rare areas of glandular or squamous differentiation may be found. The differential diagnosis of primary transitional cell carcinoma of the Bartholin gland includes poorly differentiated squamous cell carcinoma and adenocarcinoma. If more than rare foci contain glands or show keratinization, the tumor is of mixed cell type and should be so designated, listing the different tumor types.

Clinical Behavior and Treatment

The primary treatment for Bartholin gland carcinoma is wide local excision to the fascia, hemivulvectomy, or total vulvectomy. Ipsilateral or bilateral inguinofemoral lymph node dissection is necessary, regardless of the type of primary excision [35,95,168]. Adjunctive radiation

Fig. 2.41

Adenoid cystic carcinoma. The tumor is composed of relatively small hyperchromatic cells arranged in wellcircumscribed nests within the stroma. Well-defined cystic spaces are evident in this tumor. The surrounding stroma is desmoplastic (Courtesy of R.J. Kurman, M.D., Baltimore, MD.)

therapy to the vulva and regional lymph nodes also has been advocated [35].

Approximately 20% of carcinomas of the Bartholin gland are associated with metastases to the inguinofemoral lymph nodes. The overall 5-year survival of patients with Bartholin gland carcinomas is approximately 50% when the groin nodes are free of tumor, but decreases to 18% when two or more nodes are involved [168]. If the groin nodes are involved there is a 20% probability that pelvic lymph node metastasis also will be involved, but if the groin nodes are free of metastasis, there is essentially no risk of pelvic node metastasis.

Therapy for adenoid cystic carcinoma of the Bartholin gland is wide local excision with ipsilateral inguinofemoral lymphadenectomy [36]. Local recurrence is well documented and, when the tumor involves the margin, adjuvant radiotherapy may be beneficial. Survival is better with adenoid carcinoma than with other forms of carcinoma of the Bartholin gland.

The treatment of vulvar adenosquamous carcinoma is similar to that of squamous cell carcinoma. Adenosquamous carcinomas have a poorer prognosis than squamous cell carcinomas, partly because of the higher frequency of lymph node metastasis.

Mammary Gland-like Adenocarcinoma Arising in the Vulva

Specialized anogenital mammary-like glands, found typically in the interlabial sulcus, are thought to be the origin of vulvar mammary-like (breast-like) adenocarcinomas [162]. Other benign and malignant tumors, including papillary hidradenomas as well as fibrocystic-like disease, have been described within these specialized glands. The origin of these tumors had been previously thought to be ectopic breast tissue; however, current opinion is that these glands are not ectopic tissue, but rather normal anatomic elements composed of specialized anogenital mammary-like glands. The adenocarcinomas arising from these glands have histopathologic features very similar to those of primary mammary adenocarcinomas, and a few have been associated with breast adenocarcinoma. Most have a pattern of growth of infiltrating, welldifferentiated adenocarcinoma. In some cases, an intraductal carcinoma component has been identified.

Metastases to inguinal lymph nodes from adenocarcinomas of vulvar mammary-like tumors have been observed. These adenocarcinomas contain secretory material similar to that of breast adenocarcinomas, including alpha-lactalbumin and milk fat globulin protein, and also may contain estrogen and progesterone receptors.

Metastatic adenocarcinoma to the vulva can be distinguished from primary adenocarcinomas if mammary-like glands or in situ adenocarcinoma is present. In the absence of mammary-like tissue, the distinction may not be possible. Treatment of primary adenocarcinoma arising within vulvar specialized anogenital glands is extended wide local excision and ipsilateral inguinofemoral lymphadenectomy.

Carcinomas of Sweat Gland Origin

Carcinomas of vulvar sweat gland origin, including Skene glands, are rare, comprising less than 1% of all vulvar

carcinomas [169]. Patients typically present with a painless vulvar mass. In addition to undifferentiated sweat gland adenocarcinomas, ductal eccrine carcinoma, eccrine porocarcinoma, eccrine hidradenocarcinoma, clear cell hidradenocarcinoma, and apocrine carcinomas have been reported [169]. Adenosquamous carcinoma has been reported arising in a hidradenoma [10].

Sebaceous carcinoma of the vulva has also been reported, which may be associated with VIN [52,169]. Adenocarcinomas of the vulva may arise from the Skene glands [149].

Mucinous adenocarcinoma with focal squamous and neuroendocrine differentiation has been reported arising in the labium majus. This tumor expressed chromogranin A, protein gene product 9.5, serotonin, and vasoactive intestinal polypeptide [64].

Malignant Melanoma

General Features

Melanomas account for approximately 9% of all malignant tumors of the vulva, and vulvar melanoma accounts for approximately 3% of all melanomas in women and approximately 8-10% of all vulvar malignant neoplasms [25,41,82]. Melanomas occur predominantly in white women. The age-specific incidence in a comprehensive Swedish study is 75 years of age or older, occurring in 1.28 per 100,000. In women 60-74 years old, the incidence was 0.56; in those 45-59, 0.19. In those 30-44 it was 0.08, and 0.02 or less in women under 29 years of age [126]. Vulvar melanoma has been reported in children [19,47]. Vulvar bleeding was the most common symptom of 198 patients studied, being recorded in 35% of the patients. A vulvar mass was observed in 28%, an ulcer in 5%, and a mole in 5% [126]. Pruritus occurred in 15%, irritation and or burning in 14%, and discomfort with urination in 12%.

Vulvar melanomas may arise from a preexisting benign or atypical pigmented lesion [106,182]. Melanomas occur on the clitoris, labia minora, and labia majora with approximately equal frequency, although approximately one third of the cases arise at mucosal-cutaneous sites on the vulva. Of the cases available with data on site within the vulva, 90 melanomas occurred on glabrous skin, 69 on hairy–glabrous skin, and 23 on hairy skin. The mass usually is polypoid or nodular (40%) and, although generally pigmented, was nonpigmented in 27% in one series [126]. Satellite nodules may be present, and were observed in 20% of 198 cases [126].

Vulvar melanomas are of three distinct histopathologic types: superficial spreading melanoma () Figs. 2.42–2.44), nodular melanoma () Figs. 2.45 and **2**.46), and mucosal-lentiginous (mucosal/acral lentiginous) melanoma (**)** Figs. 2.48 and **)** 2.49 [127]. Some vulvar melanomas are mixed or otherwise unclassifiable. This group comprised approximately one quarter of the cases in one study [126]. Thin melanomas have also been reported [38]. The relative frequency of these types differs in various reports [41,165,167]. Mucosal/acral lentiginous melanoma was the most common type identified in the Karolinska series, observed in 52% of the cases, where as nodular melanoma accounted for 20% and superficial spreading melanoma 4% of the 198 cases reported [126].

Some of the variation in the type of vulvar melanoma reported may relate to differences in the criteria used to distinguish superficial spreading melanoma from nodular melanoma. Superficial spreading melanoma usually can be differentiated from nodular melanoma by evaluating the adjacent epithelium. If the radial growth of a melanoma or atypical melanocytes involves four or more adjacent rete ridges, the tumor should be classified as superficial spreading melanoma (see \bigcirc *Fig. 2.44*).

There is some variation in the frequency of melanoma type related to the vulvar anatomic site of the tumor. In one large series, mucosal/acral lentiginous melanomas were seen with similar frequency in glabrous, hairy– glabrous, and hairy skin, whereas nodular melanomas were seen primarily in glabrous and hairy–glabrous skin and less frequently in hairy skin. In contrast, superficial spreading melanomas were seen predominately in hairy skin [126].

Microscopic Findings

Mucosal–lentiginous (mucosal/acral lentiginous) melanomas have both vertical growth, as is seen in nodular melanoma, and radial growth, as is seen in superficial spreading melanoma, and may be in situ or superficially invasive (\bigcirc *Figs 2.48* and \bigcirc *2.49*). Atypical melanocytes usually can be identified within the epithelium adjacent to mucosal–lentiginous and superficial spreading melanomas. Malignant melanomas may consist predominantly of epithelioid, dendritic (nevoid), or spindle cell types, either pure or mixed, within a given tumor. The cells may contain no melanin, or variable amounts, ranging from minimal to very large quantities. The histopathologic features vary considerably, and certain features can be correlated with the subtype of the melanoma. In the

Fig. 2.42 Malignant melanoma. A superficial spreading malignant melanoma with vertical growth within the field of a superficially spreading malignant melanoma (Courtesy of Linda S. Morgan, M.D., Gainesville, FL.)

invasive area of mucosal–lentiginous melanoma the cells may be dendritic and spindle like, with deeper and more central areas of invasion having more significant cytoatpyia (\bigcirc *Fig. 2.49*). Within the invasive area of a superficial spreading melanoma, the malignant melanocytic cells usually are large and have relatively uniform nuclei with prominent nucleoli. Similar melanocytic cells can be found within the adjacent epithelium, representing the radial growth phase of the tumor. Junctional melanocytes are numerous and distributed within the epithelium in a pagetoid distribution.

In nodular melanomas, an intraepithelial component may be present in addition to an invasive component, but without an adjacent radial growth phase. The cells of nodular melanomas may be polygonal (epithelioid) or

Superficial spreading malignant melanoma. Pagetoid spread of the melanoma cells into the upper third of the epidermis. Markedly atypical melanocytic cells are at the epithelial-dermal junction. No invasion is present

Fig. 2.45

Nodular melanoma, partial deep vulvectomy. The tumor is deeply pigmented and clearly demarcated from the adjacent vulvar epithelium. The tumor is deeply invasive (Courtesy R. Foss, PA, Gainesville, FL.)

Fig. 2.44 Superficial spreading melanoma. The tumor displays vertical, invasive, growth

spindle shaped (see \bigcirc *Fig. 2.46*). The polygonal cells contain abundant eosinophilic cytoplasm, large nuclei, and prominent nucleoli. The dendritic cells have tapering cytoplasmic extensions resembling nerve cells and show moderate nuclear pleomorphism. Spindle cells have smaller, oval nuclei and may be arranged in sheets or bundles (see \bigcirc *Fig. 2.47*). Mucosal/acral lentiginous melanomas of the vulva arise most commonly within the vestibule. They may show little or no pagetoid spread

Nodular melanoma. The tumor is deep within the dermis, with overlying epithelium that does not have an intraepithelial melanocytic lesion

and are characterized by melanoma cells within the junctional zone. When there is extension into the adjacent dermis growth is in a diffuse pattern (see \bigcirc *Figs. 2.48* and \bigcirc *2.49*). The melanoma cells in the junctional area are relatively uniform with little nuclear pleomorphism, however with deeper invasion the cellular features may be more distinctive for melanoma. Within the subepithelial tissue, the tumor cells usually evoke a desmoplastic response.
Differential Diagnosis

Superficial spreading malignant melanoma must be distinguished from Paget disease, VIN, and dysplastic nevi. The cells of Paget disease usually are larger than superficial spreading melanoma, have more cytoplasm, and are clustered with occasional gland formation. Squamous cell carcinomas with tumor giant cells, or those predominantly composed of spindle cells, may resemble malignant melanoma. Typical squamous cell carcinoma may be identifiable adjacent to the giant cell or spindle cell component, which may establish the diagnosis. Spindle cell tumors of soft tissue origin, large cell lymphomas, pagetoid reticulosis, Kaposi sarcoma, and metastatic tumors, including choriocarcinoma, may be included in the differential diagnosis. In these cases, review of the clinical history and physical and radiologic findings, as well as thorough sectioning of the submitted tissue and appropriate immunohistochemical studies, as discussed next, usually will contribute evidence to establish the diagnosis. It should be emphasized that when faced with a poorly differentiated vulvar tumor that defies classification on initial microscopic examination, melanoma should be placed first on the list of the differential diagnosis.

Paget disease can be distinguished from melanoma with histochemical and immunohistochemical studies for mucin, CEA, S-100 protein, HMB-45 (or Melan-A), and cytokeratins. Paget cells, regardless of origin, are immunoreactive for cytokeratin and primary cutaneous Paget disease, and Paget disease of anorectal origin also typically contain cytoplasmic mucin, with mucicarmine stain, and are immunoreactive for CEA, whereas melanomas are not (see **)** Table 2.2). Pagetoid reticulosis and Kaposi sarcoma will typically express CD 45 and related lymphoproliferative markers. Melanomas usually are immunoreactive for S-100 protein, HMB-45, and Melan-A, whereas the nonmelanocytic tumors, including Paget, PUIN, VIN, squamous cell carcinoma, pagetoid/bowenoid reticulosis, and Kaposi sarcoma, are negative [173]. When the diagnosis of vulvar melanoma is difficult to resolve, the immunohistochemical studies should include epithelial markers, to identify squamous, glandular, and transitional cell neoplasms (e.g., AE1/3, cytokeratins 7 and 20, epithelial membrane antigen (EMA), CEA, GCDFP-15); hematopoietic markers, to identify lymphomas including Ki-1 lymphomas, pagetoid/bowenoid reticulosis, etc. (e.g., CD 45); muscle markers for leiomyosarcoma or rhabdomyosarcoma (e.g., desmin, smooth muscle actin); fibrohistiocytic markers (e.g., alpha-1-antitrypsin, alpha-1-antichymotrypsin); neural and neuroendocrine tumor markers (e.g., S-100,

Fig. 2.47

Malignant melanoma, amelanotic, spindle cell type. The overlying epithelium has in situ melanoma with neoplastic cells in the basal and parabasal epithelium. The invasive melanoma consists of spindle-shaped neoplastic cells. No melanin pigment is identified and the tumor is deeply invasive

Fig. 2.48

Mucosal-lentiginous melanoma, in situ. This variant of malignant melanoma is characterized by a radial component with a lentiginous pattern at the mucosalsubmucosal interface. In this case, the basal epithelium of the vulvar vestibule is involved. The melanoma cells are relatively obscured by the associated inflammatory cells. Pagetoid spread is not evident. This type of malignant melanoma usually is found within the vulvar vestibule

Fig. 2.49

Mucosal-lentiginous melanoma. The melanoma involves the overlying mucosal epithelium predominately in the basal layer in a lentiginous pattern. No significant pagetoid growth is identified. Invasive melanoma is evident at the mucosal-submucosal interface with deep submucosal involvement

chromogranin, synaptophysin, CD56); and melanoma markers (e.g., HMB-45, Melan-A, S-100).

Clinical Behavior and Treatment

Both the level of invasion of a malignant melanoma (Clark level) and its thickness have prognostic significance [127]. The Clark classification of cutaneous melanomas into five levels of invasion is well accepted and can be applied to melanomas of the vulva arising in keratinized skin, though they require some interpretation when arising within mucocutaneous areas such as the vulvar vestibule whereas the Breslow measurements for thickness are readily applicable in both sites [15]. A level I melanoma is a melanoma in situ; level II melanoma extends into the superficial papillary dermis; and level III melanoma fills and expands the papillary dermis; level IV melanoma

invades the reticular dermis; and level V melanoma invades beyond the reticular dermis into fat or other deeper tissues.

Thickness measurements for cutaneous malignant melanomas as proposed by Breslow require measurement from the deep border of the granular layer of the overlying epithelium to the deepest point of tumor invasion [15]. If a lesion is less than 0.76 mm in thickness, it has little or no metastatic potential. This is also generally accepted for tumors with a thickness of 1 mm or less. Correlations between the thickness and the level of a vulvar melanoma can be made. Level I melanomas have no measurable thickness. In one study, level II melanomas had a thickness from 1 to 2 mm, and level IV melanomas had a thickness exceeding 2 mm, but did not involve subcutaneous fat or adjacent deeper structures.

Factors that adversely influence survival include a tumor thickness exceeding 2 mm, Clark level IV, a mitotic count exceeding 10 mm², surface ulceration, and a minimal or absent inflammatory reaction [182]. Vascular space invasion and tumor necrosis also are associated with a poorer prognosis and are seen more commonly with large melanomas. No recurrences of vulvar melanoma have been observed when the thickness was 0.75 mm or less [182]. An excellent prognosis has been associated with melanomas at Clark level II or less, and those with a thickness of 1.49 mm or less. A tumor volume of less than 100 mm³ also correlates with an excellent prognosis. Other adverse prognostic factors reported include central location of the tumors, tumor ulceration, vascular space involvement, and a high mitotic rate [159].

Vulvar melanomas may recur locally, or in the cervix, urethra, vagina, or rectum. Distant metastasis may be the first sign of recurrence. Metastases to the lungs, brain, urinary bladder, bone marrow, and abdominal wall have all been observed. The prognosis after recurrence is guarded, with a 5-year survival of approximately 5%. The usual treatment for vulvar melanomas with a thickness of 0.75 mm or less is wide local excision with a 1 cm circumferential and 1-2 cm deep margins. This is also acceptable treatment for some melanomas with a thickness of 1 mm or less, although there is limited data available for vulvar melanomas with a thickness between 0.76 and 1.0 mm. Melanomas 1.1-4 mm thick require 2 cm surgical margins with deep margins of at least 1-2 cm. Melanomas with a thickness greater than 4 mm are usually treated by wide excision to the fascia or partial or total vulvectomy [159]. Depending on the size of the

tumor, the surgical procedure may include bilateral inguinal lymphadenectomy [182]. Radical vulvectomy does not appear to improve survival when compared to radical local excision with bilateral groin lymphadenectomy. Regional lymph node metastasis, as well as the number of lymph nodes with metastatic tumor, significantly influence survival [120].

Other Malignant Tumors of the Vulva

Malignant Blue Nevus

Malignant blue nevus is a rare tumor but has been reported as a primary vulvar tumor, reported arising in the labium majus of a 28-year-old woman. This patient had an ovarian metastasis from this tumor 15 years after therapy. Malignant blue nevus typically has significant nuclear atypia, but a low mitotic rate [151].

Yolk Sac Tumor (Endodermal Sinus Tumor)

Yolk sac tumor is a germ cell tumor occurring in ovary and testis (see O Chap. 16, Germ Cell Tumors of the Ovary). Its occurrence in extragonadal sites is rare. In the vulva, vagina, and pelvis, the tumor is reported primarily in children and young women [57]. The characteristic histopathological features are quite variable although Schiller-Duval bodies and eosinophilic hyaline droplets are classic features. These features may not be evident in cases with other patterns including reticular, micropapillary, microcystic, and hepatoid. The eosinophilic droplets are PAS positive, diastase resistant, and express alpha-fetoprotein (AFP) on immunohistochemical study. The histologic appearance does not appear to influence prognosis in tumors of the ovary, but there are insufficient cases within the vulva to evaluate this relationship. The variable patterns of growth may resemble adenocarcinoma, which is the primary differential diagnosis. Immunoperoxidase studies to demonstrate the presence of alpha-fetoprotein (AFP) and an elevated serum level of AFP support the diagnosis. Recommended therapy for vulvar yolk sac tumor is wide local excision and chemotherapy [57]. Platinum-based chemotherapy has markedly improved survival in patients with this tumor [57].

Primary Malignant Lymphoma

The vulva is the second most common site, after the cervix, for malignant lymphoma involving the genital tract

(see O Chap. 22, Soft Tissue Lesions Involving Female Reproductive Organs). These tumors predominately are found in women of reproductive age, and postmenopausal women, but may occur in children. The tumor may present as a Bartholin mass, clitoral enlargement, ulcerated or destructive neoplasm, or mimic other vulvar tumors [121,161,164]. Lymphomas involving the vulva are usually of the diffuse, B cell large cell type. Other tumor types have also been reported including diffuse mixed cell lymphoma, follicular large cell lymphoma, and peripheral T cell lymphoma. Kappa-positive lymphoplasmacytic lymphoma and angiocentric small and large mixed cell lymphoma, as well as plasmocytoma, have also been reported in the vulva [161,164]. Lymphoma involving the vulva may also represent metastatic involvement [164]. The diagnosis of lymphoma is confirmed by specific immunoperoxidase and/or flow cytometry studies including specific markers for lymphocytes, such as CD 45, and T and B cells, and studies for specific lymphocyte markers including specific molecular studies for gene rearrangements to identify the neoplastic cell population as lymphoma.

The differential diagnosis includes inflammatory conditions and dermatoses as well as lymphoepithelioma-like carcinoma [22]. Dermatoses and benign inflammatory processes, unlike lymphomas, contain mixed populations of lymphocytes and other inflammatory cells. Lymphoepithelioma-like carcinomas contain epithelial cells that express high molecular-weight cytokeratins and lack evidence of a monoclonal lymphocytic population [22]. Large cell lymphomas, including Ki-1 lymphomas, may mimic poorly differentiated carcinoma. Immunoperoxidase studies, including CD45 (LCA); and specific lymphocyte markers as well as epithelial markers are of value to distinguish these types. Appropriate aggressive chemotherapy is the treatment of choice for most lymphomas. Prognosis is dependent on the lymphoma type and stage of the tumor [161].

Merkel Cell Tumor

Merkel cell tumor of the vulva is rare, occurring predominately in older women [26,34,62,141]. These tumors typically present as an intradermal nodule or nodules with erythema of the overlying skin [34]. These tumors may be associated with VIN or squamous cell carcinoma. Both squamous differentiaition and glandular differentiation have been reported in one case. Three distinctive histopathologic types of Merkel cell tumor are recognized, namely the trabecular or carcinoid-like type, the intermediate cell type, and the small cell or oat cell-like type (> Figs. 2.50 and > 2.51). The distribution of these types among vulvar tumors has not been determined. The histopathologic features are that of a poorly differentiated neoplasm within the dermis and composed of a diffuse population of relatively small, uniform, hyperchromatic cells usually without prominent nucleoli (see) Figs. 2.50 and (2.51). In some cases, the tumor may have pagetoid growth. Immunocytochemistry demonstrates a distinctive perinuclear cytoplasmic dot with low molecular-weight cytokeratin-specific antibodies such as AE1/3, Cam 5.2, and cytokeratin 20. The tumors are usually immunoreactive for neuron-specific enolase (NSE) [26,62]. Chromogranin may be negative. These tumors usually contain membrane bound neurosecretory granules that can be demonstrated by electron microscopy; ACTH production by a Merkle cell tumor with demonstrated neurosecretory granules has been reported.

The differential diagnosis includes other small cell tumors, of either primary or metastatic origin, including but not limited to neuroendocrine tumors, primitive neuroectodermal tumor (PNET), basal cell carcinoma, and basaloid squamous cell carcinoma. When pagetoid spread is present Paget disease, melanoma, or lymphoma must also be considered (see **P**aget Disease). Immunohistochemical findings will not distinguish Merkle cell tumor from a metastatic tumor of similar reactivity and morphology, but clinical history usually will. PNET expresses CD99 and lymphomas usually express CD 45; neither of these are expressed in Merkle cell tumor.

Merkel cell tumors are clinically very aggressive, with regional node metastasis and subsequent widespread metastasis often occurring within a year of diagnosis [26,62]. For local disease, therapy includes wide local excision (partial deep vulvectomy) with a 2 cm margin of excision with sentinel lymph node biopsy. If the sentinel node demonstrates metastatic tumor, regional lymphadenectomy and postoperative local radiation therapy to the primary and regional sites is recommended. If there is systemic disease, chemotherapy is recommended [26,29,62].

Metastatic Tumors

Metastatic tumors comprise approximately 8% of all tumors of the vulva. Tumors from other sites of the genital tract are the most common tumors that metastasize to the vulva, with squamous carcinoma of the cervix being the most frequent, followed by carcinomas of the endometrium and ovary. Other common primary tumor sites include the bladder and urethra [102]. The vulva may be involved by direct extension of tumors arising in the

Fig. 2.50

Merkel cell carcinoma. The tumor is within the dermis and composed of a diffuse population of relatively small, uniform cells with hyperchromatic nuclear chromatin. Prominent eosinophilic fibrovascular stroma is present between irregular- shaped groups of cells

Fig. 2.51 Merkel cell carcinoma. The tumor cells are relatively small and uniform with little cytoplasm and nuclei with dispersed chromatin. Nucleoli are not prominent

vagina, urethra, bladder, or rectum. Other primary tumors that have metastasized to the vulva including malignancies of breast, kidney, lung, stomach and gestational choriocarcinoma, melanoma, and neuroblastoma [102,111,131,145].

Low-grade endometrial stromal sarcoma has been reported metastatic to the clitoris [7]. Malignant

lymphomas also may metastasize to the vulva and the Bartholin gland [121,161,164]. Metastatic myeloid sarcoma presenting as a mass involving the labia majora has been reported as a presenting symptom of acute myeloid leukemia [51]. Eosinophilic granuloma has been reported involving the vulva [83]. Metastatic tumors typically involve the dermis and overlying epithelium and consequently are often associated with ulceration. Patients with metastatic carcinoma to the vulva have a poor prognosis. Treatment is primarily palliative; radical surgical approaches are not indicated.

Tumors of the Urethra

Urethral Carcinoma

Urethral carcinoma constitutes less than 1% of malignancies affecting the female genitalia and occurs almost exclusively in elderly women. Urethral bleeding, frequency, and dysuria are the most frequent presenting complaints. Tumors in the distal urethra usually give rise to symptoms early in their course (see **?** *Table 2.9*). Most of these tumors arise in the distal urethra and are squamous cell carcinomas. Squamous cell carcinomas and transitional cell carcinomas may be papillary, forming papillomas or papillary carcinomas, or nonpapillary, presenting as carcinoma in situ of urothelial or squamous type or as solid high-grade urothelial carcinomas or squamous cell carcinomas. Urothelial (transitional cell) carcinomas may be seen in the distal as well as proximal urethra and have been described arising within a urethral diverticulum [6,108].

A pagetoid variant of urothelial carcinoma in situ has been described that primarily involves the bladder but is also described in the urethra [116]. Pagetoid urothelial intraepithelial neoplasia (PUIN) involving the urethral meatus and the vulvar vestibule, and clinically resembling vulvar Paget disease, has recently been described (see Paget Disease) [173]. Primary urothelial carcinomas express cytokeratin 7 and usually cytokeratin 20. In addition, uroplakin III is reported to be expressed in more than one half of primary urinary tract urothelial carcinoma cases studied and in approximately two thirds of the metastasis from urinary tract urothelial carcinomas [18].

Adenocarcinomas of the urethra are relatively rare, accounting for approximately 10% of all primary urethral carcinomas. They occur in the proximal urethra as well as within urethral diverticula [6]. Histopathologic types of adenocarcinoma include columnar/mucinous, clear cell, and colloid types [98,108,185]. Of these, clear cell adenocarcinoma of the urethra is of special interest in that this

Table 2.9

American Joint Committee on clinical staging of urethral carcinoma primary tumor (T), urethra

TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
Ta: Noninvasive papillary, polypoid, or verrucous carcinoma
Tis: Carcinoma in situ
T1: Tumor invades subepithelial connective tissue
T2: Tumor invades any of the following: periurethral muscle (in males includes corpus spongiosum and prostate)
T3: Tumor invades any of the following: anterior vagina, bladder neck
T4: Tumor invades other adjacent organs
Regional lymph nodes (N) related to urethral carcinoma are staged as follows:
NX: Regional lymph nodes cannot be assessed
NO: Ro regional lymph node metastasis
N1: Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2: Metastasis in a single node more than 2 cm in greatest dimension, or in multiple nodes
Distant Metastasis (M)
MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis

Source: From [5].

tumor occurs in adults with a wide age range, has distinct immunohistochemical and morphologic features suggesting Müllerian differentiation, and appears to have a generally better prognosis, even with more advanced stages [45]. These tumors do not express prostate-specific antigen (PSA) or prostate acid phosphatase, and have tubulocystic, papillary, and diffuse patterns of growth similar to clear cell carcinomas of the female genital tract [45]. In one series, two thirds of the cases arose in a urethral diverticulum [115]. The differential diagnosis of these clear cell tumors includes metastatic tumor, mesonephric carcinoma, and nephrogenic metaplasia [108,185].

Primary adenocarcinomas arising in Skene glands and a periurethral cyst have also been reported [108,109]. Skene gland tumors are thought to arise from the luminal secretory cells of these glands and have been demonstrated to express PSA and prostate acid phosphatase, reflecting the homology between Skene periurethral glands and the prostate [149]. Both urethral squamous carcinomas and adenocarcinomas are usually immunoreactive for CEA. The staging system for tumors of the urethra proposed by the AJCC is summarized in **2** *Table 2.9* [5].

The prognosis related to urethral carcinoma is relatively poor. Survival is better with tumors in the distal urethra, where 5-year survival may exceed 50%. Tumors in the proximal portions of the urethra have a poorer prognosis, and those patients with tumors involving the entire urethra have the poorest prognosis [108]. Survival in urethral carcinoma is influenced by the fact that up to one half of the women with urethral carcinoma have metastasis to superficial or deep pelvic nodes when first seen. Improved early detection, and individualized surgical and radiotherapy techniques, promise to substantially increase survival.

Other Malignant Tumors of the Urethra

Non-Hodgkin's lymphoma, [8,130], carcinosarcoma [90], and sarcomas have all been reported arising within the urethra. Urethral caruncles with atypical stromal cells, and a florid proliferation of reactive lymphoid cells, are the primary differential diagnosis in regard to lymphomas and sarcomas in this location [186]. Immunohistochemical studies to distinguish lymphocytic populations distinguish these benign processes from lymphoma. The atypical stromal cells in the urethral caruncles are immunoreactive for vimentin in approximately two thirds of the cases, and express alpha-smooth muscle actin in one half of cases [186].

A number of metastatic tumors may involve the urethra, either by direct mucosal growth or by lymphatic or vascular metastasis [108]. Metastatic involvement of the urethra from bladder carcinoma is observed in 8–16% of cases [27,101]. In these cases, direct mucosal-related metastasis and/or lymphatic metastasis may occur. Bladder neck involvement by the primary bladder carcinoma is the most significant risk factor for urethral involvement [27]. Metastatic tumors from vulvar, vaginal, cervical, or anal carcinomas, as well as endometrial and, rarely, ovarian carcinomas, may occur [70]. Metastatic ovarian carcinoma has been reported presenting as a urethral caruncle [70].

Gross Description, Processing and Reporting of Vulvar specimens

Vulvar Biopises

Vulvar biopsies may be diagnostic, where only a sampling of the lesion in question is made, or complete excisional, where the clinician attempts to excise the entire lesion. Diagnostic biopsies may be punch biopsies, such as performed with a Keyes punch biopsy, shave biopsies, or partial excisional biopsies, where a scalpel is used to excise a representative section of the lesion in question. Punch biopsies are usually preferred to evaluate inflammatory processes, such as lichen sclerosus, whereas excisional biopsies are preferred if the lesion is considered neoplastic and issues regarding possible invasive tumors are made. Shave biopsies are also useful for neoplastic lesions, provided issues such as depth of a tumor are not an issue. In general, vulvar biopsies should be handled like skin biopsies, and in all cases, effort should be made to keep the specimen well orientated so that on sectioning, right angle sections of the epithelial-dermal are made, to clearly identify the epithelial-dermal or mucosal stromal interface.

Several methods are in common use to assess both deep as well as lateral resection margins. Orientation is aided if the surgeon places a suture on one edge of the epithelium for orientation, or uses India ink, or tattoo dye to facilitate the recognition of the surface of the lesion. For lateral and deep margins one or more colored inks or dyes can be used to define the margins. Specimens should be sectioned into approximately 2 mm slices, with the plane of section at right angles to the surface of the specimen, and the entire specimen submitted for evaluation, unless it is very large in which case it is handled as any other partial vulvectomy. In most cases, several slices can be placed into a single cassette. Small punch biopsies are submitted totally and, when necessary, bisected perpendicular to the epithelial surface.

It is useful to request at the time of submission that the paraffin block(s) be cut at multiple levels. For example, cutting three sections from each block. This will usually give an excellent view of the lesion in question. This practice also shortens the turnaround time, since without it small biopsies frequently are sectioned inadequately the first time they are cut, often with only one section made. Remounting the block and cutting again to make additional slides takes more time than obtaining multiple levels at the onset, and may result in loss of valuable tissue.

Large Operative Specimens

Wide Local Excision (Partial Deep Vulvectomy) and Superficial Vulvectomy

Most specimens are highly variable in their composition, since these procedures are tailored to the extent of the lesion. Recently, wide local excision has been performed for Stage IA (<1 mm) invasive tumors, whereas laser techniques and/or topical medications are often used to treat vulvar intraepithelial neoplasia (VIN 3) or residual Paget disease once invasion has been excluded. The operative specimens may include all or part of the labia minora, labia majora, clitoris, perineal body, and perianal tissue without subcutaneous fat.

The gross description should specify the features and extent of the lesion as well as the anatomic structures involved. Since intraepithelial lesions are subtle, careful attention must be paid to coloration and surface texture. The lesions typically are red, brown, or white and often are roughened. They should be measured, and distances from the lesion to the resection margin should be recorded.

Because the disease process often is multifocal and difficult to discern with the naked eye, all surgical resection margins must be examined microscopically. This requires sections through all obvious lesions to rule out invasive carcinoma and sections from all the lateral resection margins. Sections parallel to the surgical margins (shave biopsies) often are taken to evaluate the excision lines, a method that uses fewer sections than those taken perpendicular to the line of resection. Multiple perpendicular sections, however, have the advantage that the central lesion, margin, and intervening areas can be included in one slide and tumor "close to" the margin is much easier to evaluate. To facilitate sectioning, pin the specimen on a corkboard or a block of paraffin and fix for 2–3 h before sectioning [31,171].

The surgical pathology report should include the microscopic diagnosis, extent of the involvement, and adequacy of the surgical resection margins (see: CAP synoptic reporting in this chapter) [31,171].

Total Vulvectomy: Superficial or Deep

The specimen includes the entire vulva. When superficial (skinning vulvectomy) is performed, the specimen consists of skin and minimal subcutaneous tissue. If deep, the excision includes the skin or mucosa, as well as the subcutaneous fat and skin adnexa, since the surgical dissection is carried down to the deep fascia. Superficial vulvectomy is used on occasion for extensive vulvar intraepithelial neoplasia. Total deep vulvectomy is performed primarily for larger invasive tumors, where deep partial vulvectomy is not considered adequate, or for extensive vulvar Paget disease where there may be serious concern for underlying or associated adenocarcinoma.

The gross description is similar to that outlined for the superficial vulvectomy. Although Paget disease of the vulva usually is an intraepithelial lesion, at times, it may be invasive or associated with an underlying sweat gland, Bartholin, or other carcinoma, and, therefore, the underlying subcutaneous tissue is removed. The specimen should be pinned, fixed, and then sectioned at approximately 0.5 cm intervals in order to evaluate adequately the underlying dermis for an invasive carcinoma. Microscopic involvement of Paget disease may exceed the visible extent of the lesion on gross examination. Occult foci of Paget disease also may be present within normal-appearing skin, and consequently the entire deep and lateral resection margins must be thoroughly evaluated in a similar manner as described for the superficial vulvectomy specimen. The surgical pathology report should include the microscopic diagnosis, extent of involvement, adequacy of the resection margins, and whether an underlying carcinoma is present (see: CAP synoptic reporting in this chapter) [31,171].

Total Deep Vulvectomy with En-Block Lymphadenectomy (Radical Vulvectomy, with Lymphadenectomy)

The specimen consists of the vulva, inguinal skin, subcutaneous tissue, femoral and inguinal lymph nodes, and portions of the saphenous veins. The procedure is performed for advanced invasive squamous carcinomas and has been somewhat superseded by total deep vulvectomy with separate incisions for inguinal–femoral lymphadenectomy.

The gross description should include the size, location, and depth of penetration of the primary lesion, and all resection margins, including the perirectal and vaginal margins. Examination often is aided if the specimen is first pinned out and fixed for a short period. Sections should include the tumor, showing the maximum depth of invasion, labia majora and minora, clitoris, resection margins including the vaginal margin, and all lymph nodes. Sections should evaluate the status of the skin immediately adjacent to the primary lesion, as preinvasive disease often is present. Separation of lymph nodes into superficial and deep groups requires communication with the gynecologic surgeon. Invasive vulvar neoplasms, in contrast to intraepithelial lesions, tend to be solitary and, consequently, evaluation of resection margins can be limited to the margins near the tumor. Because the specimen contains a considerable amount of fatty tissue, identification of lymph nodes may be difficult. In the fresh state, lymph nodes are recognized by palpation. The fatty tissue should be bread loafed at 1–2 cm intervals to allow adequate palpation and sectioning of node bearing tissue to identify as many nodes as possible. Location of lymph nodes is facilitated by an understanding of the lymphatic drainage of the vulva [31,171].

The surgical pathology report should include the microscopic diagnosis, tumor grade, dimensions, location and maximum depth of invasion, presence of lymphatic invasion, number and location of the involved lymph nodes, and status of resection margins [31,171] (see: CAP synoptic reporting in this chapter).

106

The vagina, like other orifices that interface between the external environment and the interior milieu, acts as a barrier to many potentially invasive microorganisms. It is, thus, not surprising that the vagina is the site of a variety of infections, both sexually and nonsexually transmitted, and this, in fact, represents the predominant type of pathology of this organ. In contrast, neoplasms are relatively unusual in this site, which is somewhat unexpected in view of the relationship between infection (e.g., human papilloma virus infection) and the development of carcinoma of the vulva and cervix.

Because of its profound effects on the development of the vagina, the pathology of in utero diethylstilbestrol (DES) exposure has been integrated into the Developmental Disorders and Malignant Neoplasms sections of this chapter. This well-intended therapy for women with a history of early pregnancy loss had serious and wholly unexpected consequences that prompted research that elucidated many interrelationships among embryology, anatomy, physiology, and neoplasia of the vagina. The astute reader will note, however, that the failure to identify many aspects relating to the pathogenesis of numerous other diseases of the vagina reflects our current state of ignorance.

Development

The müllerian ducts first appear as funnel-shaped openings of the coelomic epithelium in the mesonephric ridge at about postconception day 37 [50]. They grow caudally as paired tubes, extending to meet the posterior wall of the urogenital sinus. At about day 54, the caudal portions of the müllerian ducts fuse, forming a straight uterovaginal canal that is lined by simple columnar epithelium. The uterovaginal canal continues to elongate caudally until about day 66. Shortly thereafter, the epithelium from the caudal tip of the canal to the external cervical os changes to a stratified squamous type; this results from a migration of squamous cells from the urogenital sinus, rather than from squamous metaplasia of the native müllerian columnar epithelium [242]. Continued stratification of the squamous epithelial lining progressively occludes the more caudal portion of the canal, leading to the development of a solid vaginal plate. In the 16th week, the squamous epithelium of the vagina and ectocervix begins to mature, becoming glycogenated and thickened. Desquamation subsequently results in the canalization of the vaginal plate. Vaginal development is essentially complete by the 18th-20th week. A band of subepithelial stroma extending from the endocervix to the vulva has been described, but the role of the vaginal stroma in induction of mucosal changes remains unclear [50, 247]. In the past, our knowledge of vaginal embryology was derived from classic dissections of the fetus. Several experiments of nature in humans (in utero exposure to DES, transverse vaginal septation, and partial vaginal agenesis) and in mice (testicular feminization syndrome and agenesis of the lower vagina [50]) as well as studies using human fetal grafts transplanted into the nude mouse [51] have provided the opportunity for elegant studies of altered development. Such studies reaffirm that the vagina is of dual origin, with a native lining of müllerian columnar cells that are retained unless there is a contribution of squamous cells from the urogenital sinus.

Anatomy

The vagina is a partially collapsed, midline, tubular structure that extends from the vestibule of the vulva to the uterine cervix. The vagina is posterior to the urinary bladder and anterior to the rectum, with an angle of more than 90° between the axis of the vagina and that of the uterus (\bigcirc Fig. 3.1). In an adult, the vagina is about 9 cm in length. Its caliber and length are unrelated to sexual activity or symptoms of dyspareunia [309]. The anterior and posterior walls are in contact with each other, with the exception of the cranial (proximal) end where the vagina surrounds the ectocervix. Here, there are vaultlike recesses between the vaginal walls and the cervix, termed fornices, which are deepest posteriorly. In contrast to the slack anterior and posterior walls, the lateral walls are relatively rigid, resulting in a somewhat compressed lumen with an H shape in transverse sections.

The vagina is in contact anteriorly with the uterine cervix, the base of the bladder, and the urethra. The proximal third of the urethra is separated from the vagina by loose connective tissue; it enters into the vaginal wall distally, where their fasciae fuse into a single dense layer. Posteriorly, the upper fourth of the vaginal wall is bounded by peritoneum, and forms the anterior part of the cul-desac or pouch of Douglas. The rectovaginal septum connects the adventitia of the middle half of the vagina with the rectum, whereas the perineal body and anal and rectal sphincters separate the remaining more caudal portion from the anal canal. Laterally, each ureter, crossed by the uterine artery and vein, runs just above the lateral fornix. Caudally (distally), the levator ani and bulbocavernosus muscles partially surround the vagina, which ultimately opens into the vestibule (> Fig. 3.2).

Blood is supplied to the vagina primarily by branches of the internal iliac artery, including the uterine, vaginal, middle rectal, and internal pudendal arteries. Extensive

Fig. 3.2 Vagina, uterus, and supporting structures of the pelvis

anastomoses provide alternate routes of flow, which minimize the possibility of ischemic damage. A complex network of veins surrounds the vagina, forming a plexus with the uterine, pudendal, and rectal veins, which drain into the interior iliac vein.

The lymphatic drainage of the vagina is complex and variable. The lymphatics of the proximal anterior vagina

and vaginal vault join those of the cervix and drain primarily into the external iliac lymph nodes. The posterior portion of the vagina drains into the inferior gluteal, sacral, and anorectal lymph nodes, whereas the distal part of the vagina, like the vulva, drains into the femoral lymph nodes. It is important to note that, as a consequence of extensive anastomotic channels, any pelvic, anorectal, or 108

femoral node may be involved in the lymphatic drainage of any part of the vagina.

The innervation of the vagina is principally from the superior hypogastric plexus of the autonomic nervous system. This plexus bifurcates and is joined by branches of the second through fifth sacral nerves, forming the pelvic plexuses.

Histology and Physiology

The vaginal wall consists of three layers: mucosa, muscularis, and adventitia (\bigcirc *Fig. 3.3a* and *b*). The vaginal mucosa is thrown into ill-defined laterally oriented folds or rugae of about 2–5 mm thickness (\bigcirc *Fig. 3.4*). The thickness of the folds varies according to location and hormonal stimulation. The mucosal lining is a stratified squamous epithelium that is normally glycogenated and nonkeratinizing. Subdivision of the epithelium into layers is somewhat arbitrary but useful as it provides a basis for understanding the variable appearance of squamous cells in vaginal cytologic smears (\bigcirc *Fig. 3.5*). The basal layer consists of a single layer of

columnar cells, with the principal axis of the cells perpendicular to the basement membrane. The nuclei are oval and uniformly hyperchromatic, and are surrounded by relatively scant cytoplasm, resulting in a high nuclear/ cytoplasmic ratio. The parabasal layer usually consists of two to five layers of cells of cuboidal shape, with a centrally located, round, and uniformly hyperchromatic nucleus. Mitoses usually are confined to the basal and parabasal layers. The intermediate layer is of variable thickness. The cells in this layer contain moderate quantities of slightly flattened cytoplasm and oval nuclei with finely dispersed chromatin. The long axis of both nucleus and cytoplasm is parallel to the basement membrane. The superficial layer also varies in thickness. The cells contain pyknotic nuclei, which are small, round, and hyperchromatic. The cytoplasm is abundant, with an orientation similar to intermediate cells. The three-dimensional configuration of these cells is that of a highly attenuated disk, resulting in a flattened appearance when viewed in cross section.

Variable quantities of glycogen may be present in the intermediate and superficial cell layers. The glycogen accumulates initially in a perinuclear location within

Fig. 3.3

Vaginal wall. The vaginal muscularis is composed of ill-defined and variably sized smooth muscle bundles (a). The adventitia contains numerous blood vessels and nerves within adipose tissue (b)

Fig. 3.4

Vaginal mucosa. The mucosa is composed of ill-defined, laterally oriented folds or rugae

intermediate cells, resulting in a clear zone around the nucleus. This appearance may cause confusion with the perinuclear clearing of koilocytes. However, the presence of nuclear membrane irregularity in koilocytes and the characteristic location of these normal cells in the middle rather than superficial third of the epithelium are helpful distinguishing features. Melanocytes have been identified as a normal constituent of the basal layer in about 3% of women.

The lamina propria, which lies beneath the squamous epithelium, consists of a loose fibrovascular stroma containing elastic fibers and nerves. A band of stroma extends from the endocervix to the vulva, which may contain atypical polygonal to stellate stromal cells with scant cytoplasm. Some of these cells are multinucleated or have multilobulated nuclei (\bigcirc *Figs. 3.6* and \bigcirc *3.7*). The muscularis consists of

Fig. 3.5

Mature vaginal squamous epithelium. The epithelium is composed of a basal layer, several layers of parabasal cells, and multiple layers of intermediate and superficial cells that progressively accumulate glycogen

Fig. 3.6

Lamina propria of the vagina. Beneath the squamous epithelium of the vagina is a poorly defined zone containing large, stellate, or spindle stromal cells. This zone extends in irregular fashion from the cervix to the vulva 110

poorly delineated, inner circular, and outer longitudinal bundles of smooth muscle. Some of the outer longitudinal layers of muscle pass into the lateral pelvic wall to contribute to the inferior portion of the cardinal ligaments, whereas fibers of the bulbocavernosus form a sphincter around the distal vagina. The adventitia is a thin coat of dense connective tissue that merges with the loose connective tissue of the surrounding pelvis, which contains the lymphatic and venous plexuses and nerve bundles.

The squamous cells of the vagina contain intranuclear steroid receptors and represent a target tissue for sex steroids. The thickness and maturation of the epithelium varies throughout the menstrual cycle. Because the vagina is rarely biopsied but frequently sampled cytologically, the latter procedure has contributed greatly to our knowledge of normal and aberrant maturation. During the proliferative phase, the epithelium progressively proliferates and matures fully in response to estrogens. The addition of progesterone during the secretory phase is associated with an arrest of maturation at the intermediate cell level and a decrease in epithelial thickness. Although glycogen is found in the intermediate and superficial cells throughout the menstrual cycle, it is particularly abundant during pregnancy. Transient vaginal atrophy is found in some women postpartum, particularly in those who are lactating [313]. After menopause, a gradual reduction in the thickness of

Fig. 3.7

Multinucleate stromal cells of the lamina propria. Scattered bizarre, floret-type multinucleate cells are often admixed with other stellate or spindle cells in the superficial portion of the lamina propria. These may be the source of bizarre cells identified in some vaginal fibroepithelial (mesodermal) stromal polyps the epithelium occurs, first with a loss of superficial cells followed by intermediate cells, such that the mucosa of late menopausal women may be reduced to only six to eight layers of parabasal cells (\bigcirc *Fig. 3.8*). As a consequence, a normal postmenopausal atrophic pattern may be confused with a high-grade intraepithelial lesion, unless care is taken to identify other nuclear abnormalities. Newborn infants, having been exposed to maternal steroids in utero, have a fully mature-appearing epithelium that rapidly regresses to atrophy within about 4 weeks. A gradual maturation of the epithelium follows the onset of menarche. Exposure of the postmenopausal vagina to estrogen leads to squamous maturation comparable to that observed in the proliferative phase of reproductive-age women. It is interesting to note that, in one study, the time required for

Fig. 3.8 Vaginal atrophy. The epithelium is reduced to only a few layers of parabasal and basal cells

a vaginal squamous cell to make the transition from progenitor cell through desquamation was about 5 days for both cycling and postmenopausal women [11].

There are few data concerning vaginal function during coitus or parturition [174]. Distension and lengthening of the proximal two thirds of the vagina occurs during the early phases of sexual response, followed by constriction of the distal third. The anterior portion of the levator ani, the pubococcygeus muscle, appears to be involved in orgasmic function, but the mechanism is speculative [174, 257]. Functional MRI has provided evidence that the vagus nerve may be either a primary or secondary pathway for nerve impulse conduction during vaginal orgasm [136]. Even the source of vaginal fluids that are present during arousal has been disputed. Glands are not normally present in the vagina, and candidate sources include secretions from sebaceous, sweat, Bartholin, and Skene glands or the endocervix. Fine droplets appear scattered throughout the rugal folds of the vaginal wall during arousal, followed by a rapid coalescence [174]. The fluid is believed to represent a transudate resulting from associated vasoconstriction within the venous plexus [174]. The fluid is usually acidic, with a pH around 4.6, but the pH rises during the sexual response. This fluid contains a variety of enzymes, enzyme inhibitors, and immunoglobulins, which may play a role in the liquefaction of coagulated semen and capacitation of spermatocytes or have antimicrobial activity. The immunoglobulin A levels are highest during the late proliferative phase [115], but the significance of this observation is unclear. During pregnancy and immediately postpartum, edema, vascular congestion, and loss of collagen have been noted in the lamina propria, which may serve to increase elasticity of vaginal tissues during delivery.

Developmental Disorders

Lesions Related to In Utero Exposure to DES

Diethylstilbestrol and the chemically related drugs hexestrol and dienestrol are synthetic, nonsteroidal estrogens that were administered frequently to gravid women who were thought to be at high risk for early pregnancy loss during the 1940s through the 1960s. An estimated five to ten million Americans received DES during pregnancy or were exposed to the drug in utero [95]. In 1971, the rare development of clear cell adenocarcinoma of the vagina in young women was linked to their in utero exposure to these drugs [113]. Subsequently, a number of nonneoplastic changes were identified in the genital tract of daughters of women exposed to DES, such as adenosis, cervical ectropion, various types of cervicovaginal ridges, and structural abnormalities of the uterine corpus and fallopian tube. DES was soon thereafter withdrawn from the market for use during pregnancy. Consequently, the population exposed in utero now averages about 55 years in age, with the youngest persons about 35 years old.

Gross Structural Changes of the Vagina and Cervix

Approximately one fifth of DES-exposed women demonstrate gross structural changes in the cervix or vagina [112]. Descriptive designations have included coxcomb (hood), collar (rim), pseudopolyp, and ridge. The pseudopolyp is caused by a peripheral concentric cervical band that gives the portio vaginalis central to it the appearance of a protruding cervical polyp; however, the presence of the external os at its center differentiates it from a true polyp. The cervix may be hypoplastic, the vaginal fornices may be obliterated, or the vagina may be traversed by a ridge (septum) consisting of fibrous connective tissue covered by squamous epithelium (\bigcirc *Fig.* 3.9). The natural history of the structural abnormalities is not well understood, although some ridges have been observed to disappear as the cervix and vagina undergo remodeling with age.

Vaginal Epithelial Changes: Adenosis and Squamous Metaplasia

Vaginal adenosis and metaplastic squamous epithelium vaginal epithelial changes (VECs) - are common in DESexposed females. In the pre-DES era, vaginal adenosis was a clinical rarity, detected only occasionally in women, usually in their 30s or 40s, who often complained of an excessive mucous discharge from the vagina. The demographics are again changing. During the past decade, adenosis caused by DES exposure has become rare, although acquired adenosis in adult women with vaginal dysplasia treated with topical 5-fluorouracil occasionally have been reported [64, 98]. Clinically, adenosis should be suspected when the vaginal mucosa contains red granular spots or patches () Fig. 3.9) and does not stain with an iodine solution. On colposcopy, adenosis appears as glandular or metaplastic epithelium replacing the native squamous epithelium of the vaginal mucosa.

112

Fig. 3.9

Adenosis in a woman exposed to DES in utero. There is a nodular deformity and ridge in the cervix visible in the upper portion of the photograph. The friable red granular epithelium that replaces much of the mucosa reflects regions of adenosis, most of which is of the tuboendometrioid type

Adenosis involves the upper third of the vagina in 34% of DES-exposed women, the middle third in about 10%, and lower third in about 2% of exposed women. Mucinous columnar cells, which resemble those of the normal endocervical mucosa, comprise the glandular epithelium most frequently encountered as adenosis (62% of biopsy specimens with vaginal adenosis) (\bigcirc *Fig. 3.10*) [240]. Tuboendometrial adenosis with dark and light cells, often ciliated and resembling the lining cells of the fallopian tube and endometrium, is found in 21% of specimens with adenosis. These cells usually are found in glands in the lamina propria and not on the surface of the vagina. In most biopsy specimens, metaplastic squamous cells replace adenosis to some degree (\bigcirc *Fig. 3.11*),

indicating the manner by which adenosis regresses. Reserve cell proliferation progresses through immature and mature stages of squamous metaplasia, with intercellular pools of mucin and droplets remaining as the final vestiges of adenosis. Eventual maturation of the metaplastic squamous epithelium with acquisition of glycogen makes it indistinguishable from the normal (native) squamous epithelium.

The Embryologic Basis of Vaginal Adenosis and Cervical Ectropion

The DES experience and the experimental studies it has fostered have provided insights into the development of the normal lower genital tract and the effects caused by prenatal DES exposure [239]. In brief, the embryonic squamous epithelium of the urogenital sinus normally extends up the vagina and exocervix, replacing the original columnar (müllerian) epithelium lining these organs. Recent experimental work has suggested that inhibition of p63 by DES may alter the urogenital sinus and müllerian duct epithelial differentiation and result in adenosis [143]. Further, the stroma of the vaginal wall (like the uterine corpus and fallopian tube) induces the growth of a tuboendometrial-type epithelium, while the stroma of the superficial endocervix favors mucinous columnar epithelium. In DES-exposed fetal organs, the stromal components of the uterine wall fail to segregate normally into an outer layer of smooth muscle and an inner layer of endometrial stroma [242].

Vaginal adenosis is not limited exclusively to women exposed to DES in utero, but has also been reported in 2–10% of non-exposed females who have no known risk factors [32, 229]. Adenosis may occur following topical treatment of squamous dysplasia with 5-fluorouracil [92], but the mechanism by which it induces glandular metaplasia remains unclear.

Imperforate Hymen

Imperforate hymen probably represents the most common significant congenital anomaly of the vagina. Its frequency is reported to be about 1 in 2,000 female patients. The presence of a thick mucoid secretion that distends the vagina may provide a clue to diagnosis in the neonate, but often an imperforate hymen is not recognized until puberty, when there is abdominal pain and retention of menstrual

Fig. 3.11

Adenosis. The mucinous glands display partial replacement by metaplastic squamous epithelium. With increasing age, mature squamous metaplasia obliterates all evidence of the adenosis

detritus [220]. If it is not corrected promptly, infertility may result from endometriosis and pelvic adhesions associated with retrograde menstruation [311]. The treatment is surgical, with either a central incision or local excision [3]. No detailed pathologic description of this condition has been reported.

Vaginal Agenesis

Complete vaginal agenesis is relatively rare, occurring in about 1 in 5,000 female births [63, 82, 296]. As an isolated defect it results from incomplete caudal development and fusion of the lower part of the müllerian ducts (müllerian dysgenesis). The external genitalia usually appear normal, except for the introitus, where a short blind pouch may be present [311]. Therapy usually involves construction of an artificial vagina. Although this rarely results in a specimen for pathologic examination, the defect often is associated with the absence of the uterus and fallopian tubes (müllerian agenesis or Mayer-Rokitansky-Kuster-Hauser syndrome) [72] and with anomalies of the urinary tract [202]. The latter syndrome provides insight into embryologic development and demonstrates that an intact mesonephric duct is required for the growth and caudal lengthening of the müllerian duct during fetal life [163, 164]. Because the gonads are not of müllerian origin, they usually are normal. About 25% of women with vaginal agenesis have a uterus, and they may have complications from retrograde menstruation.

Transverse Vaginal Septum

A transverse vaginal septum is uncommon, with an estimated prevalence of about 1 in 50,000 women [220], and may occur anywhere within the vagina, but most frequently at the junction of the cranial and middle third. It presumably results from incomplete migration or excavation of the vaginal plate. A complete vaginal septum results in obstructive symptoms similar to an imperforate hymen, whereas a partial septum may allow passage of menstrual flow but cause dyspareunia or lacerate during childbirth. The microscopic appearance of the septum is typically that of a fibrovascular stroma covered on two surfaces by epithelium. Although the caudal surface is covered by a stratified nonkeratinizing squamous epithelium, the cranial aspect is covered typically by glandular epithelium, as might be predicted from the embryologic development.

Miscellaneous Congenital Disorders

Complete duplication of the vagina with a septum including muscularis extending to the introitus is rare, and typically is accompanied by cervical and uterine duplication [14]. Longitudinal septa that lack a muscular layer are more common; they often are clinically asymptomatic. Congenital rectovaginal fistulas often are associated with an imperforate anus. Typically, the anus opens into the posterior caudal portion of the vagina, near the fourchette. 114

Infectious Inflammatory Disorders

The normal vaginal flora is varied and changes from birth through menarche to menopause. Although it has long been evident that lactobacilli split glycogen to form lactic acid, thus reducing the pH of the vagina, this does not provide a complete explanation for the regulation of the vaginal flora. The ecosystem reflects a delicate balance that includes the interplay of steroid hormones, vascularity, vaginal acidity, and glycogen. It can be upset easily by mechanical, chemical, or hormonal manipulation. Approximately 10⁹ obligate anaerobic and 10⁸ facultative bacteria are present in a gram of vaginal secretion, of which lactobacilli probably are the most common [171]. Three hundred and forty-five organisms were represented in 52 specimens collected from healthy adults, including the following anaerobes: Peptococcus, Bacteroides, Peptostreptococcus, Lactobacillus, Eubacterium spp.; and aerobes: Stapylococcus epidermidis, Corynebacterium spp., and Lactobacillus sp [14]. The proportion of aerobic organisms decreases about 100-fold during the week before menses. During pregnancy, more lactobacilli and yeast, but fewer anaerobic bacteria, are present [157]. On the third day after parturition, there is a dramatic increase in the number of anaerobic bacteria. Postmenopausal women also have a relatively larger proportion of anaerobes, with more lactobacilli recovered from those treated with estrogen [149]. Organisms that at times are associated with vaginitis may colonize the vagina of healthy, asymptomatic women.

Vaginitis

Vaginitis is one of the most common reasons for a patient to visit her gynecologist, accounting for more than ten million office visits each year [132]. Abnormal colonization or invasive infection has been reported for practically all major types of organisms, including viruses, bacteria, fungi, and parasites. It is difficult to determine the most common organism responsible for vaginitis because frequency lists vary according to age, sexual activity, and method of microbial identification [265]. Currently, more than 20 bacterial, viral, and protozoan agents are considered to be responsible for sexually transmitted diseases (STDs) (> Table 3.1). Because the notification that one has an STD frequently evokes a strong emotional response, it is important to remember that the distinction between sexually and nonsexually transmitted disease is at times arbitrary. Whereas many infectious agents make use

Table 3.1

Sexually transmitted pathogens

Bacterial agents
Neisseria gonorrhoeae
Chlamydia trachomatis
Mycoplasma hominis
Ureaplasma urealyticum
Treponema pallidum

Molluscum contagiosum virus
Protozoan agents
Trichomonas vaginalis
Entamoeba histolytica
Giardia lamblia
Ectoparasites
Pediculus pubis
Sarcoptes scabiei

of the opportunity afforded by close apposition of mucous membranes or secretions to spread, there is variability in the stringency of their demands.

The clinical diagnosis of vaginitis is frequently based on the presence of a vaginal discharge. Reliance on this finding alone may lead to overdiagnosis, as the production of vaginal fluid is a physiologic event caused by transudation of fluid through the vaginal wall, with additional contributions by cervical and uterine secretions, exfoliated epithelial cells, bacteria, and bacterial products. This event is particularly noticeable at mid-cycle when cervical mucus becomes watery and profuse and often is interpreted erroneously as a "discharge." Other relatively nonspecific criteria of vaginitis include subjective assessment of the color, odor, quantity, or quality of the discharge. In contrast to discharge caused by vaginitis, normal vaginal secretions are floccular rather than homogeneous, and neither malodorous nor associated with pruritis. Although accurate diagnosis of vaginitis does not require a biopsy, some infectious agents cause highly specific tissue reactions, with which the pathologist should be familiar.

Candida

Candida probably is the most common potential or active pathogen in the female genital tract. It can be isolated from the vagina of about 20% of asymptomatic healthy women, and about 70% of women will have a symptomatic candidal infection at some time during their lives [267]. C. albicans is found frequently in the colon of healthy individuals, and spread from the contaminated perineum probably is the usual method of introduction of the organism into the vagina [267]. Interestingly, fomites from bathtubs or toilet seats do not appear to be a common mechanism for transmission [9]. Sexual transmission plays a role in some patients, resulting from either oralgenital or less likely penile-genital transmission [30]. Factors associated with an increased risk of developing symptomatic infection include pregnancy, oral contraceptive use, antibiotic therapy, diabetes mellitus, and antibiotic use. Changes in the vaginal flora likely play a role in the development of candidiasis.

Vulvar pruritis is the typical presenting symptom, often accompanied by a white, granular vaginal discharge. The vagina appears reddened, and superficial erosion of the mucosa may be evident after the removal of a pseudomembrane of adherent granular debris.

Saline or potassium hydroxide suspensions of a discharge containing blastospores and pseudohyphae permit a presumptive microscopic diagnosis to be made immediately. Unfortunately, the sensitivity of the wet prep exam is only about 65% [180], and the morphologic appearance is not entirely specific. In one study, Papanicolaou-stained smears demonstrated the organism in 46% infected patients, compared with 85% for the wet prep and 94% for culture [179]. In daily practice, it is the experience of the examiner that seems to be the most critical determinant for accurate recognition of the organism. Definitive identification of the fungus is generally made by culture or polymerase chain reaction [173].

Biopsies, which are rarely obtained, contain relatively dense infiltrates of primarily mononuclear inflammatory cells and congested blood vessels in the stroma, with exocytosis of neutrophils into the overlying epithelium (\bigcirc *Fig. 3.12*) [130]. *Candida* are generally not identifiable unless the discharge remains adherent, where the organisms are visualized as yeast and pseudohyphae intertwined among the desquamated squamous cells (\bigcirc *Fig. 3.13*) [19]. First-line therapy of topical imidazole derivatives for 5–7 days has been used for the past 20 years, but the recent introduction of triazols permits equal efficacy with single-dose therapy [267]. However, recurrent infection remains common and may result from either failure to

Fig. 3.12

Vaginitis caused by *Candida* or *Trichomonas*. The histologic changes, including variably dense infiltrates of mononuclear inflammatory cells in the stroma and neutrophils in the epithelium, are similar for both organisms

respond to medical therapy or endogenous reinfection by the identical strain of organism [300].

Candidal species other than *C. albicans* are responsible for about 10–20% of cases of fungal vaginitis [238, 267], and infection with *C. tropicalis* or *C. glabrata* is associated with a high rate of recurrence [238]. *C. glabrata* typically produces milder symptoms than *C. albicans* [21], but *C. glabrata* has been reported to cause a severe ulcerative vaginitis-simulating malignancy [37]. The microscopic appearances of most *Candida* species are similar, but *C. glabrata* produces only yeasts (blastospores), which are slightly smaller than those of *C. albicans* [21].

Bacterial Vaginosis

Organisms such as *Trichomonas* and *Candida* have long been known to produce vaginitis; however, until recently

Fig. 3.13

Candida vaginitis. Yeast and pseudohyphae are present in a mat of exfoliated superficial squamous cells. *Candida* are usually not identified in biopsies of the vagina unless desquamated cells remain adherent to the intact mucosal surface (periodic acid–Schiff [PAS] stain)

there have been a substantial number of women who have a copious vaginal discharge or pruritis in the absence of a readily identifiable pathogen. In the past, this condition was designated nonspecific vaginitis, but the term bacterial vaginosis currently is preferred because evidence of inflammation is typically absent [171]. Gardnerella, a gram-negative bacillus, has been isolated from women with vaginosis at a higher rate than asymptomatic women and thus was considered to be responsible for nonspecific vaginitis [87]. However, more recent studies cast doubt on this concept, because this organism and "clue" cells have been identified at times with similar frequency in healthy women without vaginal discharge [269]. Currently, it is believed that bacterial vaginosis is not an infection by a single organism, but rather an overgrowth of multiple colonizing bacteria including Gardnerella and a variety of anaerobes [216, 286, 303]. The flora typically found in affected women includes not only disproportionately

large numbers of Gardnerella vaginalis, but also abundant Prevotella bivia, Mycoplasma hominis, Mobiluncus mulieris, and Mobiluncus curtisii [287]. In an animal model, the inoculation of Gardnerella and Mobiluncus together caused the clinical disease, although neither alone was capable of doing so [172]. The diagnosis of bacterial vaginosis is made if three of the following four criteria are present: (1) homogeneous, thin, malodorous discharge, (2) vaginal pH 4.5, (3) vaginal epithelial cells with numerous attached bacteria ("clue" cells) (> Fig. 3.14), and (4) fishy odor on alkalinization of vaginal secretions [7, 56, 255]. The diagnosis usually is confirmed by elimination of other pathogens, combined with identification of gram-negative to gram-variable bacilli and "clue" cells on wet mount or smears, or by culture [284]. The identification of squamous cells coated by large numbers of coccobacilli in a cervical vaginal cytology specimen represents a moderately sensitive and highly specific method for screening for bacterial vaginosis [56, 94]. No specific histopathologic features have been described.

Efforts to restore the local environment by topical administration of acetic acid, estrogen, or fermented milk products have been ineffective. In contrast, antimicrobial therapy with metronidazole or intravaginal clindamycin produces clinical cure in most women, further supporting the concept that anaerobes acting with Gardnerella produce bacterial vaginosis [269]. The initiating cause remains unknown, but sexual transmission occurs in many instances [150, 198]. Although bacterial vaginosis was previously thought to carry no appreciable morbidity, it recently has been associated with a 3- to 15-fold increased risk of upper genital tract infection, including salpingitis and endometritis [116, 138, 206, 276]. In addition, the anaerobic bacteria cultured from the endometrium and fallopian tubes of women with asymptomatic endometritis or symptomatic salpingitis were those associated with bacterial vaginosis [138, 268]. During pregnancy, bacterial vaginosis significantly increases the likelihood of premature onset of labor and chorioamnionitis [118, 176, 196, 268].

Trichomonas Vaginalis

Trichomoniasis is responsible for more than 2.5 million infections per year in the United States and about 180 million infections worldwide [285]. It is found in about 10% of asymptomatic women, and almost 50% of those attending STD clinics [275]. The organism is almost always sexually transmitted [320], although trichomonads

reportedly may survive in tap water, soap water, and chlorinated swimming pools. The mechanism by which *Trichomonas* causes disease is unknown, but the organisms are found both in the vaginal lumen and adherent to squamous, but not columnar, epithelial cells [235]. Invasion of the squamous mucosa does not occur. *Trichomonas* is a strict anaerobe and there is frequently an alteration in the associated vaginal flora, with increased anaerobic bacteria [298]. Although the role of sex steroids is unclear, infection is generally lower in women taking oral contraceptives [24].

Symptoms of infection include vaginal discharge, intense pruritis, and dyspareunia, with exacerbations often temporally related to menses. However, in one study, only 17% of culture-positive women noted pruritis, and more than one third did not even complain of a vaginal discharge [178]. When present, the vaginal discharge usually is copious, homogeneous, yellow green to gray, and malodorous. Typically, the vaginal mucosa is erythematous and punctate hemorrhages may be present, particularly on the cervical mucosa, leading to what is unfortunately described as a "strawberry cervix."

The diagnosis usually is made by the microscopic identification of motile organisms accompanied by many neutrophils in a saline preparation. The protozoan is ovoid, about 10–20 mm in diameter, with polar flagella. Active motility, in the form of a jerky swaying motion, is

provided by the flagella and undulating membrane. If the wet prep diagnosis is based on the presence of motile organisms, the specificity approaches 100%. Trichomonads also may be found in Papanicolaou-stained vaginal smears in about 70% of cases (> Fig. 3.15), a sensitivity similar to that of the wet prep [160]. Several recently introduced molecular amplification methods appear to provide both high sensitivity and specificity when applied to distal vaginal secretions [60, 106, 167, 314]. Culture methods are available, expensive, and generally unnecessary. The organism is not detectable in biopsy specimens from culture-positive women, although an inflammatory response of variable intensity may be seen, including dilated vessels in the stroma, accompanied by dense infiltrates of plasma cells and lymphocytes (> Fig. 3.12). The ectocervical as well as vagina mucosa is commonly spongiotic (> Fig. 3.12) [134]. Neutrophils frequently are present in large numbers among the squamous cells, sometimes forming intraepithelial abscesses. There may be irregular acanthosis of the epithelium, with pseudepitheliomatous hyperplasia. A fibrinopurulent exudate composed of necrotic debris, neutrophils, and lymphocytes is found in the foci of ulceration. Metronidazole provides effective therapy, although recurrence is common if the typically asymptomatic male partner is not also treated. Unfortunately, the frequency of resistance to metronidazole is increasing [289].

Fig. 3.15

Trichomonas vaginitis. Papanicolaou-stained cytologic preparation of vaginal secretions containing several of the nucleated, ovoid protozoans, as well as three intermediate squamous cells and inflammatory cells

Acquired Immunodeficiency Syndrome

Slightly more than one million persons in the US are living with human immunodeficiency virus (HIV)/acquired immunodeficiency virus syndrome (AIDS). Woman account for about one quarter of newly reported cases, and heterosexual contact represents the mode of transmission in about 28% of all cases in the United States. It is the fifth leading cause of death among American women 25– 44 years of age. There are no gross or histopathologic changes of AIDS specific to the vagina.

Most HIV infections resulting from heterosexual contact have occurred in women who reported only vaginal intercourse [210]. The virus has been identified in both semen and cell-free seminal fluid [155]. Certain STDs are considered to be risk factors for sexual transmission of HIV, particularly those that cause ulceration of the vaginal mucosa, facilitating HIV exposure to vascular channels, as well as providing a large number of CD4 lymphocytes and macrophages that contain or could bind HIV at the site of injury [40]. It is estimated that a fivefold to tenfold increase in risk of heterosexual transmission of HIV is present in those with genital ulcers [302]. A twofold to fivefold increase in risk is associated with the presence of an inflammatory or exudative STD, presumably reflecting the presence of microscopic ulcerations or increased concentrations of CD4 lymphocytes in the discharge [153, 302]. Localization of simian immunodeficiency virus (SIV) in dendritic cells of the monkey vagina has been demonstrated in an experimental model, suggesting that heterosexual transmission of HIV may occur across an intact mucosa [183]. Nevertheless, the precise mechanism by which heterosexual transmission of HIV occurs remains to be defined.

Group B Streptococcus

Group B streptococci (*Streptococcus agalactiae*) can be found in 5–35% of normal females [119, 319] and thus are considered to be part of the normal vaginal flora. These bacteria frequently are sexually transmitted [115], although they also can ascend from the lower intestinal tract, which may serve as a reservoir [195]. Although group B streptococcal colonization of the vagina or urethra usually causes little morbidity to the adult female, a vaginitis at times may occur [115]. Histopathologic changes resulting from vaginal infection by group B streptococci have not been well described. More significantly, this organism is a frequent cause of abortion, chorioamnionitis, premature rupture of membranes, perinatal death, and intrapartum and postpartum bacteremia [233, 276]. For reasons that currently are unknown, only a small proportion of colonized mothers or infants develop symptomatic infection [276].

Actinomycetes

Actinomycetes have been implicated in upper genital tract infections in women with intrauterine contraceptive devices and also are found in the vagina of about one quarter of women without such devices. These organisms represent part of the normal oral and colonic flora, from which it may be introduced into the vagina. Vaginitis subsequently occurs when overgrowth is favored by the presence of a foreign body [53]. Actinomycetes are recognized in Papanicolaou-stained smears and tissue sections as a dense mass of fine, blue, filamentous bacteria, usually radiating from a central core (\triangleright *Fig. 3.16*).

Malacoplakia and Xanthogranulomatous Pseudotumor

Malacoplakia and xanthogranulomatous pseudotumor of the vagina are closely related entities resulting from infection by gram-negative bacilli, usually *Escherichia coli* [156, 271]. Typically, yellow polypoid nodules arise from the vaginal mucosa, at times accompanied by a discharge.

Fig. 3.16

Actinomycetes. Papanicolaou-stained cytologic preparation with a dense collection of fine, blue, filamentous bacteria, which appear to radiate from a central core

119

The microscopic findings are identical to those described in other body sites, and include the presence of large collections of histiocytes with abundant granular to pale foamy cytoplasms (von Hansemann cells), with interspersed plasma cells and lymphocytes. Both intracellular and extracellular, concentrically laminated basophilic masses (Michaelis–Gutmann bodies) are present in variable numbers. The clinical suspicion of tumor may lead the pathologist to the misdiagnosis of a rare neoplasm such as a granular cell tumor, unless care is taken to consider this lesion. The correct diagnosis may be confirmed by the finding of numerous gram-negative rodlike bacteria on tissue Gram stain, on silver stain, or by electron microscopy.

Tuberculosis

Genital tract tuberculosis is no longer frequent in the United States, but remains a significant problem in Third World nations. The vagina is involved in about only 1% of these women, and patients present with localized ulceration [199]. Characteristic microscopic features include necrotizing granulomata containing Langhans giant cells underlying an ulcerated epithelium [41].

Emphysematous Vaginitis

Emphysematous vaginitis is a rare entity (about 200 reported cases), characterized by multiple, discrete, gasfilled cystic cavities in the vaginal mucosa. Most patients present with symptoms of vaginal discharge, although some are aware of popping sounds associated with the rupture of the cysts during intercourse. The dramatic presentation and physical findings have prompted an interest disproportionate to the frequency or significance of the disease. There is evidence that it is an unusual manifestation of a common infection in an immunocompromised host [127, 288]. No single organism has been identified as the causative agent, although both Trichomonas vaginalis and Gardnerella vaginalis have been implicated [88]. Chemical analyses of the lesions have disclosed a wide variety of gases, including ammonia, hydrogen sulfide, nitrogen, oxygen, carbonic acid, and trimethylamine. The microscopic findings are variable, with cysts in the stroma lined by either multinucleated giant cells, squamous cells, or both. A scattering of chronic inflammatory cells accompanies the cysts [88, 140]. Bacterial or protozoan production of gas with transmucosal passage into the stroma has been suggested, but the pathogenesis remains obscure [88].

Unusual Types of Bacterial Vaginitis

Occasionally, vaginitis may be caused by bacteria that are commonly pathogenic in other sites. *Shigella vulvovaginitis* has been identified primarily as a cause of a chronic, sanguinous, and purulent vaginal discharge in children, un-associated with intestinal infection [54, 232]. Haemophilus influenzae, Coryne bacterium diphtheria, and *Neisseria meningitidis* also rarely cause vaginitis in children [31, 68, 69, 274], but the histologic changes have not been documented. Staphylococcal infection of the vagina after systemic antibiotic therapy was reported more than 30 years ago and thought to result from a disturbed indigenous flora [148] (see section **>** Toxic Shock Syndrome).

Parasitic Vaginitis

Parasitic infection of the vagina, although currently rare in the United States, almost certainly will be encountered more commonly because of more frequent global travel.

Vaginal amebiasis caused by *Entamoeba histolytica* has been reported in Mexico, South Africa, and India, where the infection is endemic [107, 117, 188, 297]. Most patients present with a bloody vaginal discharge. The gross appearance mimics carcinoma, with one or more ulcerated, necrotic growths typically involving the vagina and cervix. Microscopically, the lesions are characterized by ulceration of the epithelium with replacement by a fibrinopurulent exudate containing trophozoites 15–60 micrometers in diameter. In cytologic preparations they appear somewhat larger than histiocytes, and approximate the size of parabasal cells. Positive staining with periodic acid–Schiff (PAS) stain or acid phosphatase provides further support for the diagnosis.

Eggs of *Enterobius vermicularis* or *Trichuris trichiura* usually are found after incidental contamination of the vagina associated with intestinal infestation by these worms [187]. Eggs and worms of *Schistosoma mansoni* and *hematobium* have been identified in pelvic tissues including the vagina, presumably reflecting anastomoses between hemorrhoidal and hypogastric veins [91]. They elicit a striking host inflammatory response, ultimately resulting in dense fibrosis.

Toxic Shock Syndrome

General Features

In 1978, Todd et al. described an acute, potentially lifethreatening disease characterized by fever, hypotension, headache, confusion, rash, vomiting, diarrhea, and oliguria. The disease was termed toxic shock syndrome (TSS) because it was associated with infection with strains of *Staphylococcus* that produced a unique epidermal toxin [290]. By 1980, more than 98% of cases had been related to the use of tampons during menses [75]. The incidence is about 6 cases per 100,000 menstruating women per year. Although *S. aureus* rarely inhabits the vagina normally, it has been isolated from about 75% of women with TSS [55, 177]. More recently it has become evident that children or adults with any focal staphylococcal infection are also at risk for TSS, and about 11% of all reported cases are nonmenstrual [236].

Pathogenesis

There is a strong relationship between localized infection with S. aureus and the development of TSS. Studies of patients with TSS as well as experimental systems have revealed that some staphylococci elaborate a protein of about 22 kDa termed toxic shock syndrome toxin 1 (TSST-1), which produces essentially all the systemic biologic effects [20]. TSS can also occur in the absence of this toxin, and other staphylococcal enterotoxins (such as Staphylococcal exotoxin B), streptococcal exotoxins, and endotoxins from gram-negative bacteria have been implicated in some cases of TSS [230, 236]. The mechanism by which tampon use during menses predisposes to TSS remains somewhat unclear, but it is believed that microulcerations of the vaginal mucosa caused by tampons (see below, > Tampon Ulcer) permit the growth of toxin-producing staphylococci. A diminished host immune response to the toxin, access of toxin through a denuded endometrial mucosa, and the normal menstrual phase decrease in lactobacilli that are inhibitory to the growth of staphylococci may facilitate the process [75, 252]. A multifactorial sequence is supported by the observation that about 10% of healthy women are colonized vaginally by Staphylococcus aureus, and 85% of women have antibodies to TSST-1 [205], whereas other women have recurrent episodes of the illness. A dramatic reduction in the incidence of TTS occurred when Rely superabsorbent tampons were withdrawn from the market in 1980 [142].

Clinical Features

The diagnosis of TSS is based on a constellation of clinical features, as follows: fever, hypotension, palmar or diffuse

erythroderma followed by desquamation, hyperemia of conjunctivae or mucous membranes of vagina or pharynx, and multisystem dysfunction including vomiting; diarrhea; impaired renal, cerebral, or hepatic function; cardiopulmonary dysfunction; thrombocytopenia; elevated creatine phosphokinase; and decreased serum calcium and phosphate [55]. Vaginal erythema, erosions, or vaginitis, sometimes accompanied by a purulent exudate, typically are present [304]. Abdominal or bilateral adnexal tenderness is present in about half of cases [109].

Gross and Microscopic Findings

The disease is systemic, with pathologic abnormalities described in lung, liver, and kidney, as well as genital tract [1, 205]. Ulceration and discoloration of the vaginal and cervical mucosa are present focally. Microscopically, there is extensive desquamation of the epithelium, with underlying subacute vasculitis, perivascular inflammatory cell infiltrates, and platelet thrombi [1, 205]. Rare grampositive cocci have been found in the fibrinopurulent exudate associated with ulcers. Deep tissue invasion by the organisms has not been described [205].

Clinical Behavior and Treatment

The spectrum of severity of TSS varies from a relatively mild to a rapidly fatal illness, with a mortality rate of about 4% [277]. The treatment includes beta-lactamase-resistant anti-staphylococcal antibiotics, and aggressive, supportive measures for systemic manifestations related to shock [236]. Intravenous immunoglobulin therapy also has been effective, supporting the concept that the symptoms of TSS result from a toxin that may be neutralized by infused antibodies [13].

Noninfectious Inflammatory Diseases

The vagina is occasionally the site of involvement by a systemic disease, a generalized disease of squamous mucosa, or by extension from a disease elsewhere in the pelvis. In one recent study of chronic vaginitis, the most common diagnoses were as follows: contact dermatitis (21%), recurrent vulvovaginal candidiasis (21%), atrophic vaginitis (15%), and vulvar vestibulitis syndrome (13%) [200].

Desquamative Inflammatory Vaginitis

Idiopathic desquamative inflammatory vaginitis is the term that has been applied to an unusual process in which bright red, well-delineated areas replace portions of the normal mucosa of the cranial half of the vagina. It must be distinguished from other disorders causing erosion such as pemphigus vulgaris, lichen planus, and pemphigoid [191]. A pseudomembrane at times replaces the ulcerated mucosa. A copious purulent to hemorrhagic vaginal discharge is present, smears of which display numerous neutrophils and a high proportion of parabasal cells. The women usually are premenopausal and have normal serum estrogen levels. In rare cases in which biopsies have been performed, a nonspecific mixed inflammatory cell infiltrate has been reported [192]. The etiology is unknown, and no single bacterial or viral agent has been identified by culture. Nevertheless, the replacement of long gram-positive bacilli by gram-positive cocci in the vaginal discharge of some affected women suggests an infectious etiology. Treatment with clindamycin and topical steroids results in clinical improvement in more than 95% of patients [266].

Ligneous Vaginitis

Ligneous vaginitis is one localized manifestation of a rare, inherited, and potentially life-threatening systemic disease in which afflicted individuals develop pseudomembranous lesions of mucosal surfaces in the acute phase [161]. Recent research indicates that it reflects a severe type 1 plaminogen (PLG) deficiency due to a variety of mutations in the PLG gene [283]. Clinical manifestations often include ligneous conjunctivitis, ligneous gingivitis, and occasional involvement of the respiratory or gastrointestinal tract. The chronic phase is characterized by asymptomatic sessile or pedunculated yellow-white to red firm masses. Histologically, these represent subepithelial accumulations of amorphic, eosinophilic material that represents fibrin and collagen [161], which may be accompanied by granulation tissue or chronic inflammatory cell infiltrates (> Fig. 3.17).

Allergic Reactions to Seminal Fluid

A few women display allergic reactions after exposure to seminal fluid [152]. The severity of the response varies from localized vulvovaginal urticarial reactions to generalized urticaria and bronchospasm. The onset of symptoms

Fig. 3.17

Ligneous vaginitis. Extensive stromal deposition of amorphic, eosinophilic material is characteristic of a longstanding lesion and is frequently accompanied by overlying pseudoepitheliomatous hyperplasia

immediately follows contact with seminal fluid, and the duration of the reaction is between 2 and 72 h.

Crohn Disease

About 20% of females with Crohn disease have vaginal symptoms [100]. Rectovaginal fistulas occur in some patients with Crohn disease [70], and they represent the site of about 9% of fistulas in women with this disease [5]. In situ squamous carcinoma of the vagina has been reported rarely [224].

Bullous Dermatoses

Vaginal stenosis may develop as a sequela of severe bullous erythema multiforme (Stevens–Johnson syndrome) in which extensive vulvar and vaginal ulceration occurred [101]. Acantholytic intraepithelial bullae may be found when there is vaginal involvement by familial benign chronic pemphigus (Hailey–Hailey disease) [295].

Giant Cell Arteritis and Polyarteritis

Giant cell arteritis is not always limited to the temporal arteries, and may be associated with either limited visceral, or much more rarely, generalized organ involvement [216]. A pan-arteritis, with fragmentation and destruction of the internal elastic lamella and phagocytosis of elastic material by multinucleated giant cells may be seen in the vagina as part of limited female genital tract involvement [16]. Arteritis limited to the genital tract is most commonly found in the cervix and endometrium and has a favorable prognosis in the absence of an elevated sedimentation rate [74]. The frequency of involvement of the vagina has not been determined, since vaginal tissues are infrequently sampled in the course of most surgical procedures.

Thrombotic Thrombocytopenic Purpura

Massive, acute hemorrhagic necrosis of the vagina has been reported as one of the initial manifestations of thrombotic thrombocytopenic purpura [85]. The disease usually is characterized by the pentad of fever, microangiopathic hemolytic anemia, thrombocytopenia, neurologic symptoms, and renal dysfunction. Numerous thrombi are found microscopically in the vaginal stroma, accompanied by superficial hemorrhage, necrosis, and sloughing of the epithelium.

Lesions That Follow Trauma, Surgery, and Radiation

Atrophic Vaginitis

Atrophy of the squamous epithelium of the vagina, accompanied by a loss of glycogen and an increase in the pH, are physiologic events in postmenopausal women that reflect estrogen deprivation. The response also includes a change in the vaginal flora, with a reduction in the lactobacilli that ordinarily inhibit other potential pathogens. The thin epithelium seems to offer little resistance to an altered flora, which may include streptococci, staphylococci, E. coli, and diphtheroids. As a result, minor trauma may facilitate a transition from simple atrophy to atrophic vaginitis. Many patients are asymptomatic, but there may be minor vaginal bleeding, pruritis, dysuria, or dyspareunia, accompanied at times by a watery discharge. Atrophy of the vagina produces a pale-appearing mucosa, with petechiae and loss of rugal folds. Microscopically, there is a variable reduction or a loss of the superficial and intermediate cell layers. Small ulcers with acute inflammation and granulation tissue may be interspersed among regions of intact epithelium. Elsewhere, the submucosa is infiltrated by lymphocytes and plasma cells (> Fig. 3.18). Although the histologic changes are relatively straightforward, occasionally there may be a confusion of atrophy with

Fig. 3.18

Atrophic vaginitis. In addition to profound atrophy of the epithelium, there is dense infiltration of the stroma by chronic inflammatory cells

a high-grade squamous intraepithelial lesion (see below, Vaginal Intraepithelial Neoplasia). There usually is a good response to estrogen replacement, with epithelial cell maturation and a return to premenopausal flora and pH. Antibiotic therapy rarely is necessary.

Tampon Ulcer

Although tampons have been in use for 60 years, there had been little interest in their effects on the vagina until about 1980, when mucosal ulceration and TSS were related to their use. In several series of cases, the women presented with abnormal vaginal discharge or intermenstrual bleeding. Typically, a single ulcer with an irregular border of granulation tissue was identified in one of the vaginal fornices. After neoplasms and infectious etiologies were excluded, a more detailed history revealed the frequent use of tampons. Microscopically, some of the ulcers contained fibrillar foreign bodies within the exudate [125]. The lesions healed spontaneously within 2-3 months after discontinuation of tampon usage [125]. Subsequently, Friedrich studied the vagina during tampon use, and characterized a sequence of clinically asymptomatic, colposcopic, and microscopic changes as follows: (1) mucosal dehydration, (2) layering or intraepithelial cleavage, and (3) microulceration [78]. Ultrastructural findings include a widening of the intercellular spaces separating squamous cells and a marked reduction in the number of desmosomes. He suggested that these changes resulted from a fluid shift across the vaginal epithelium due to the absorbent qualities of the tampon. This hypothesis explains the higher frequency of mucosal alteration with the use of superabsorbent tampons. However, this explanation may be incomplete because a colposcopic study demonstrated an inverse relationship between vaginal drying and the quantity of blood absorbed by different tampon types [255]. The great frequency with which tampons induce clinically inapparent vaginal microulcerations helps to explain their relationship to staphylococcal infections and the development of TSS. The observation that vaginal colonization by Staphyloccous aureus has increased from about 12% in 1980 to 23% in 2005 should be viewed with alarm [253].

Postoperative Spindle Cell Nodule

In 1984, Proppe et al. described a lesion of the lower genitourinary tract that closely simulated a sarcoma histologically but was benign [225]. The term postoperative spindle cell nodule was applied to the lesion because typically it arose within 1-3 months of surgery in the region, and usually presented as polypoid, poorly defined nodules. Lesions of similar histologic appearance have been reported in the urinary tract in the absence of a clinical history of surgery or instrumentation [318]. Similarly, these lesions may occur in the vagina in the absence of surgery. The microscopic appearance is characterized by intersecting fascicles of plump spindle cells with a delicate network of small blood vessels, sometimes accompanied by extravasated blood or hemosiderin (> Fig. 3.19). Superficial ulceration may be present, and chronic inflammatory cells are scattered in the deeper portions of the lesions. The spindle cells have oval, elongated nuclei with evenly dispersed chromatin and abundant eosinophilic bipolar cytoplasmic processes. Because mitotic figures are numerous and the lesions are poorly circumscribed, they may easily be confused with sarcoma. Helpful distinguishing features include the lack of nuclear pleomorphism or nuclear hyperchromasia, an absence of abnormal mitotic

Fig. 3.19

Postoperative spindle cell nodule. The spindle cells have oval, elongated nuclei with evenly dispersed chromatin and bipolar eosinophilic cytoplasmic processes. Extravasated red blood cells are a characteristic finding

figures, and the clinical history of a recent surgical procedure in the region of the lesion [225]. Local recurrence has not been reported, even after incomplete resection [225]. Recently, it has been suggested that this lesion should be included in the category of inflammatory myofibroblastic tumor (IMT), but most IMTs are not associated with prior surgery, and about 33% of them recur following local excision [185].

Vaginal Vault Granulation Tissue

Vaginal vault granulation tissue is a common finding after hysterectomy. One or more small, red, and soft granular to polypoid lesions may be seen grossly, which microscopically are composed of ulcerated, edematous, and granulation tissue containing numerous neutrophils superficially and lymphocytes and plasma cells in the deeper stroma. Occasionally, scattered bizarre stromal cells may cause confusion with a malignant neoplasm (**)** *Fig. 3.20*), particularly if the hysterectomy has been performed for a cervical or corpus tumor.

Fistula

Vesicovaginal and ureterovaginal fistulas may occur as a complication of hysterectomy, resulting from ischemic necrosis secondary to interruption of the vascular supply [280]. The surgical correction usually yields small fragments of tissue with variable amounts of granulation

Fig. 3.20

Granulation tissue. Polypoid, edematous, and vessel rich tissue (a) contains numerous inflammatory cells, scattered bizarre stromal cells and prominent endothelial cells, which may simulate malignancy (b) tissue, fibrosis, chronic inflammation, and little or no epithelium. Rarely, calculi are present. These are composed of urinary salts that develop in the vagina because of continuous leakage of urine from a vesicovaginal fistula. Vesicovaginal fistula and vaginal laceration also may be a consequence of coitus.

Radionecrosis

Radiation therapy to the vulva, vagina, or uterine cervix may cause necrosis, ulceration, or stenosis of the vagina [246]. The mechanism by which this injury develops reflects the sensitivity of endothelial cells to radiation, with thrombosis and subsequent stenosis or obliteration of small blood vessels, stromal fibrosis, and epithelial ulceration. The formation of granular to polypoid masses, particularly in the vaginal vault, may clinically simulate recurrent cervical carcinoma. In addition to the vascular changes, dense infiltrates of plasma cells, granulation tissue, and bizarre stromal cells with pleomorphic, hyperchromatic nuclei may be sprinkled through the stroma. Even in the absence of a gross lesion, one may anticipate extreme atrophy of the vaginal squamous mucosa as a consequence of radiation therapy combined with cessation of ovarian function (**)** *Fig. 3.21*). Careful examination of nuclear detail helps to distinguish radiation atrophy from intraepithelial carcinoma. Atrophic cells have high nuclear/cytoplasmic ratios such as those of intraepithelial carcinoma, but have a regular, round to oval nuclear shape with a uniform distribution of chromatin that may appear smudged, in contrast to the irregular nuclear contours and clumped chromatin of vaginal intraepithelial neoplasia. Occasionally, radiation may result in partially obliterated vascular channels lined by plump endothelial cells containing large nuclei with vesicular chromatin, which simulate cords of invasive carcinoma. The distinction may be assisted by immunohistochemistry. Although a positive immunostaining reaction is not always present, the localization of factor VIII antigen in the atypical cells coupled with the absence of staining for keratins provides evidence for reactive endothelial rather than epithelial cells.

Vaginal Prolapse

Cystocele, rectocele, and vaginal prolapse may occur after multiple vaginal deliveries. The surgical correction may include removal of elliptical fragments of vaginal mucosa in which variable degrees of acanthosis, hyperkeratosis, or parakeratosis are present (\bigcirc *Fig. 3.22*).

Fig. 3.21

Radiation change. Long-term consequences of irradiation to the vagina include atrophy of the squamous epithelium, edema, fibrosis within the stroma, and obliteration of vascular channels

Fig. 3.22 Vaginal prolapse. Acanthosis and hyperkeratosis of the squamous epithelium are present

Fallopian Tube Prolapse

Prolapse of the fallopian tube into the vagina is a relatively uncommon complication of either vaginal or abdominal hysterectomy [29, 262]. Patients often present with abdominal pain, vaginal discharge, or vaginal bleeding. A red, granular mass or nodule usually is present at the vaginal apex, which grossly may be confused with granulation tissue or carcinoma. Manipulation of the prolapsed tube typically causes extreme pain. Microscopically, a complex pattern of tubular, glandular, and papillary structures may be present (> Fig. 3.23). Nuclear crowding and stratification are common, and ciliated or secretory columnar cells of typical tubal type may be difficult to locate (> Fig. 3.24) [262]. Fimbriae are rarely identifiable, and both a diligence and an awareness of the condition are required to avoid the misdiagnosis of adenocarcinoma. There is often associated inflammation and granulation tissue, and when prominent, this may

Fig. 3.24

Fallopian tube prolapse. While the architectural complexity raises the possibility of malignancy, most cells are ciliated confirming that the structure is fallopian tube

be confused with either aggressive angiomyxoma or angiomyofibroblastoma [181, 299].

Cysts

Cysts of the vagina are relatively uncommon. Several classifications for cystic lesions have been proposed, reflecting a combination of good microscopic descriptions, an incomplete knowledge of embryology, and an assumption that histologic differentiation mirrors histogenesis [131, 139]. A functional classification scheme follows: squamous inclusion cysts, mesonephric cysts, müllerian cysts, and Bartholin gland cysts.

Squamous Inclusion Cyst

Squamous inclusion cysts are probably the most common of the vaginal cysts, resulting from the entrapment of fragments of mucosa during repair of a vaginal laceration or episiotomy and thus more commonly occur in the distal portion of the vagina [131]. These cysts are often asymptomatic and vary from a few millimeters to several centimeters in diameter. The microscopic appearance is that of a cyst wall formed by a stratified squamous epithelium, lacking rete ridges, with a central mass of keratin from desquamated cells (\triangleright *Fig. 3.25*).

Mesonephric Cyst

Mesonephric cysts, also termed Gartners duct cysts, are most often located along the anterolateral wall of the

Fig. 3.25

Squamous inclusion cyst. The cyst is lined by stratified squamous epithelium and contains keratinaceous debris

Fig. 3.26

Mesonephric cyst. The cyst is typically small and lined by a simple cuboidal epithelium, lacking cilia or intracellular mucin

vagina, following the route of the mesonephric duct. It is assumed that mesonephric cysts result from secretion by small isolated epithelial remnants after incomplete regression of the mesonephric duct. Mesonephric cysts are lined by low cuboidal, non-mucin-secreting cells, which are devoid of cytoplasmic mucicarmine or PAS-positive material (\bigcirc *Fig. 3.26*).

Müllerian Cyst

The genesis of the müllerian cysts is poorly understood; perhaps some are derived from islands of adenosis [131]. They are located anywhere within the vagina are grossly indistinguishable from mesonephric duct cysts, and are

usually less than 2 cm in diameter. The distinction is made on microscopic examination. Müllerian cysts may be lined by any of the epithelia of the müllerian duct, including mucinous endocervical, endometrial, and ciliated tubal types (**>** *Fig. 3.27*). Tall columnar mucin-secreting cells of endocervical type are most common, and squamous metaplasia may be observed.

Bartholin Gland Cyst

Bartholin gland cysts occur in the region of the ducts of Bartholin glands, near the opening of the primary duct into the vestibule. The pathogenesis is incompletely understood, but usually involves occlusion of the duct, associated with either a highly viscous thick mucoid secretion or infection of the gland [131]. The cyst may enlarge rapidly and cause dyspareunia. The cyst lining varies from mucin secreting to squamous or "transitional," reflecting the different types of epithelium lining the duct and gland (*Fig. 3.28*). Histochemical and ultrastructural studies of

Müllerian cyst. The cyst is lined by cuboidal or columnar cells, which may be endocervical, tubal, or endometrial type. Note the cilia along the apical border of scattered cells the mucinous cells of normal Bartholin glands, as well as these cysts, reveal no differences from the cells of the endocervix [248]. The Bartholin gland is of urogenital sinus origin, whereas the cervix is of müllerian derivation; therefore, the weakness of a histogenetic classification of vaginal cysts based on histologic features is reinforced further by this observation. Cysts of identical histologic appearance may occur elsewhere in the vestibule, reflecting the presence of numerous minor vestibular glands of urogenital sinus origin. The treatment of vaginal cysts usually is excision, although marsupialization may be indicated for some Bartholin gland cysts.

Benign Neoplasms

Squamous Papilloma

Squamous papillomas may be single but are frequently multiple. These lesions usually are only a few millimeters in diameter, and most commonly occur in clusters near the hymenal ring, resulting in a condition referred to as squamous papillomatosis [144]. The lesions usually are asymptomatic, but may be associated with vulvar burning or dyspareunia. Squamous papillomas may be difficult to distinguish from condylomas by gross inspection. Colposcopic and microscopic examination reveal the squamous papilloma to be composed of a single papillary frond with a central fibrovascular core (\bigcirc *Fig. 3.29*). It lacks the complex arborizing architecture, acanthosis, and cellular atypia (koilocytes) of the condyloma.

Fig. 3.29 Squamous papilloma. In contrast to a condyloma, this lesion lacks koilocytes and complex branching papillae

Condyloma Acuminatum

An extensive discussion of the features of condylomas is provided in O Chap. 1, Benign Diseases of the Vulva, and O Chap. 4, Benign Diseases of the Cervix. As the biologic and pathologic characteristics of vaginal condylomas are similar to those in the cervix and vulva, they are not described here.

Müllerian Papilloma

Müllerian papilloma is a rare benign neoplasm, first described by Ulbright et al., which typically occurs in the

Fig. 3.30 Müllerian papilloma. Complex, branching, thick fibrovascular cores (a) are covered by a bland low columnar epithelium (b)

vagina (and cervix) of young girls, usually less than 5 years of age. As these lesions are typically exophytic papillary growths, patients most commonly present with vaginal bleeding. Microscopically, it is composed of a complex arborizing papillae with fibrovascular cores lined by bland-appearing epithelial cells, typically low columnar to cuboidal, which may sometimes form both solid masses and glandular lumina (**>** *Fig.* 3.30) [294]. Although similar tumors displaying an exophytic growth pattern and covered by mucin-secreting, hobnail, or eosinophilic cells have been described in both the vagina and cervix of young girls as mesonephric müllerian papillomas [10, 44, 165, 175, 254, 279], the morphologic, immunophenotypic, and ultra-structural features, including microvilli, perinuclear arrays

of microfilaments, tonofilaments, and complex cytoplasmic interdigitations, support a müllerian origin. These tumors are considered benign, although rare instances of recurrence and malignant transformation have been reported [2, 62].

Fibroepithelial Polyp (Mesodermal Stromal Polyp)

The fibroepithelial stromal polyp is a benign proliferation that most likely represents a reactive process that arises from the distinctive subepithelial myxoid stroma of the distal female genital tract rather than representing a neoplastic process; cells with a similar histologic appearance have been described in a band-like subepithelial stromal zone extending from the endocervix to the vulva of normal females and may represent the origin of these atypical cells. The fibroepithelial stromal polyp may occur at any age, with the age range extending from newborn to 77 years, but are most frequent during reproductive years with a mean age at diagnosis of about 40 years [34, 182, 186, 201, 203, 226]. The lesions usually are asymptomatic and are discovered incidentally, during pelvic examination, on the lateral wall of the lower third of the vagina. The size varies but they usually measure less than 5 cm, and the gross configuration may be that of a single edematous soft polyp resembling an acrochordon, a papillary lesion with fingerlike projections, or a cerebriform mass (> Fig. 3.31). Although usually single, multiple polyps may occur, particularly during pregnancy; about 25% of patients with fibroepithelial stromal polyps are pregnant at the time of diagnosis. Microscopically, these polypoid

 Fig. 3.31
 Fibroepithelial stromal polyp. Cross section shows a homogeneous fibrous core

lesions have a fibroblastic stroma and a centrally located fibrovascular core, and are covered by a variably thickened stratified squamous epithelium. The most histologically distinctive component of these lesions is the stroma, which can vary from edematous and hypocellular with bland spindle-shaped cells with indistinct cytoplasm to lesions that are hypercellular and contain cells with markedly enlarged hyperchromatic nuclei. When the latter features are florid, which more commonly occur during pregnancy, these changes can mimic malignancy, particularly sarcoma botryoides; however, the fibroepithelial polyp lacks a "cambium layer," small undifferentiated stromal cells, rhabdomyoblasts, or invasion of the overlying squamous epithelium, which are typical features of sarcoma botryoides. Most fibroepithelial polyps occur in women over the age of 20, whereas sarcoma botryoides is confined almost always to children less than 5 years of age. Moreover, the presence of stellate and multinucleate cells, which are typically located near the epithelial stromal interface, as well as the lack of an interface between the lesional stromal cells and the overlying squamous epithelium are characteristic findings, even in floridly pseudosarcomatous lesions (> Fig. 3.32). However, the distinction from sarcoma is made primarily on the basis of superficial location, small size, lack of an identifiable lesional margin, extension of abnormal stromal tissue to the mucosal-stromal interface, and the presence of scattered multinucleate stromal cells [200]. The stromal cells are typically positive for desmin, vimentin, estrogen receptor, and progesterone receptor; actin is less commonly positive [104, 182, 186]. The immunolocalization of steroid receptors in these bizarre cells and frequent relationship to pregnancy, during which there may be multiple polyps (and following which they usually regress) supports the premise that fibroepithelial polyps are hormonally induced.

Leiomyoma

Benign smooth muscle tumors of the vagina are uncommon. The mean age at detection is about 40 years, with a reported range of 19–72 years [253]. The tumor may occur anywhere within the vagina, however, it more commonly involves the lateral aspect and is usually in a submucosal location. Vaginal leiomyomas vary from 0.5 to 15 cm in diameter, but are usually less than 5 cm [282]. Because most are relatively small, they often are asymptomatic. Larger tumors may produce pain, hemorrhage, dystocia, or dyspareunia.

The gross and microscopic appearances of vaginal leiomyomas resemble those of their uterine counterparts.

Fig. 3.32

Fibroepithelial stromal polyp. The stroma varies in appearance from bland and hypocellular (a) to stroma with markedly atypical cells (b). Note the lack of an interface between the stromal cells and the overlying epithelium and the presence of multinucleate stromal cells near the epithelial–stromal interface

They are well-circumscribed, firm masses that occasionally may contain foci of edema or hyalinization. Microscopically, they are well circumscribed without evidence of infiltration and are composed of interlacing fascicles of spindle-shaped cells, with elongated, oval nuclei with no mitotic activity or nuclear pleomorphism. Of the 60 cases of smooth muscle tumors of the vagina reviewed by Tavassoli and Norris, only 7 contained more than five mitoses per ten high-power fields (HPF). Five patients developed recurrence after local excision. All the recurrent tumors were in the subset with high mitotic activity and generally moderate to marked nuclear atypia [282]. Accordingly, it is recommended that the diagnosis of vaginal leiomyoma be reserved for those tumors that are histologically well circumscribed, are cytologically bland, and have fewer than five mitoses per ten HPF. However, it also should be noted that increased mitotic activity in the absence of aggressive behavior may be present in vaginal leiomyomas during pregnancy.

Rhabdomyoma

Rhabdomyoma is a rare benign tumor displaying wellformed skeletal muscle differentiation, about 20 cases of which have been reported arising within the vagina [96, 103, 123]. The average age at diagnosis is about 45 years, with a range extending from 34 to 57 years. Patients typically present with a solitary polypoid to nodular mass that varies from 1 to 11 cm in diameter. Symptoms are typically related to a mass lesion and include dyspareunia; bleeding is less common as the overlying mucosa is usually intact.

Microscopically, rhabdomyomas are located in the submucosa and are composed of a somewhat fascicular proliferation of benign-appearing fetal- or adult-type skeletal muscle cells surrounded by variable quantities of fibrous stroma (> Fig. 3.33). The cells are of spindle to oval shape, with plump oval nuclei and abundant granular, eosinophilic cytoplasm. Mitotic activity and nuclear pleomorphism are absent. The diagnosis is confirmed by identification of intracytoplasmic fibers with cross-striations (> Fig. 3.34), staining for which may be enhanced by phosphotungstic acid hematoxlin (PTAH) or trichrome preparations. Immunohistochemistry and electron microscopy usually are not needed to confirm the presence of skeletal muscle differentiation [96]. It is important not to confuse vaginal rhabdomyoma with embryonal rhabdomyosarcoma (see below), but this is generally not difficult because genital rhabdomyoma lacks nuclear atypia, mitotic activity, and a cambium layer; in addition it occurs in an older-age population. The behavior of rhabdomyoma is benign, and local excision provides adequate therapy.

Spindle Cell Epithelioma (Benign Mixed Tumor)

Tumors that histologically bear some resemblance to salivary gland neoplasms are classified as spindle cell epitheliomas or benign mixed tumors. These neoplasms are rare, and usually present as a slowly growing, painless, wellcircumscribed, submucosal mass that may occur anywhere in the vagina, but most frequently near the hymenal ring [25, 263]. The mean age at diagnosis is 30 years. They range in size from 1.5 to 5 cm and often are diagnosed preoperatively as a polyp or cyst.

Microscopically, the neoplasm is a well-circumscribed, unencapsulated mass located near, but not connected to, the overlying epithelial surface and is characterized by a biphasic proliferation of spindle and epithelial cells (> Figs. 3.35 and > 3.36). The spindle cell proliferation is variably cellular and loosely fascicular with paler hypocellular zones containing fibroblastic-type cells separating the cellular areas into interconnecting islands. The epithelial component, which may be only focally present, includes nests of bland-appearing glycogenated, stratified squamous cells and occasional glands lined by a mucinsecreting epithelium [83]. Eosinophilic hyaline globules, which likely represent condensation of the stromal matrix, are characteristic. The spindle cells are positive for keratin and smooth muscle actin [190], the combination of which led to the former designation of these lesions as mixed tumors. The behavior is benign and local excision is curative; one case of a recurrence has been reported 8 years following initial excision [316].

Fig. 3.33

Vaginal rhabdomyoma. At low magnification, a nonencapsulated mass of plump, elongated cells is covered by a slightly thickened squamous epithelium

Endometriosis

It is not uncommon for endometriosis to involve the vagina, either superficially implanted in the squamous mucosa or involving the deep stroma, particularly of the

Fig. 3.34

Vaginal rhabdomyoma. At higher magnification, cross striations can be seen in the eosinophilic cell cytoplasm (hematoxylin and eosin stain) (a); the cross striations are further enhanced with phosphotungstic acid-hematoxylin stain (b)

Fig. 3.35

Spindle cell epithelioma (benign mixed tumor of vagina). The tumor often has a biphasic spindle cell population composed of hypo- and hypercellular zones

Fig. 3.36

Spindle cell epithelioma (benign mixed tumor of vagina). A nest of stratified squamous epithelial cells is surrounded by irregular fascicles of spindled stromal cells

rectovaginal septum [86, 133, 169, 301, 312]. A complete discussion of endometriosis is provided in **O** Chap. 13, Diseases of the Peritoneum.

Miscellaneous Benign Tumors and Tumor-Like Lesions

In addition to those tumors that are highly characteristic for the vagina, sporadic cases of benign neoplasms and tumor-like processes have been reported, including adenomatoid tumor [159], villous adenoma (**2** *Fig. 3.37*) [73], mature cystic teratoma [145], Brenner tumor

Fig. 3.37

Villous adenoma of the vagina. The lesion presented as a polypoid mass. It is histologically identical to a villous adenoma in the colon

[33], hemangioma [97], granular cell tumor [139], neurofibroma [58], paraganglioma [215], glomus tumor [270], blue nevus [289], and eosinophilic granuloma [320]. Thyroid and parathyroid glands have been described in the vaginal wall of a 3-year-old girl, but probably these represented monodermal differentiation within a benign vaginal teratoma [145].

Malignant Neoplasms

Vaginal Intraepithelial Neoplasia

In contrast to the high prevalence of intraepithelial lesions of the cervix and vulva, vaginal intraepithelial neoplasia (VAIN) is relatively rare. The reason for this discrepancy is unknown, but may be related to a lesser susceptibility of the vaginal mucosa to HPV infection than the cervical transformation zone. However, similar to the cervix, the range of HPV types that can affect this area is greater than those that occur in the vulva [270]. Understanding the reasons for this difference may prove pivotal to understanding carcinogenesis involving the squamous epithelium of the lower female genital tract. The terminology for intraepithelial neoplasia of the vagina continues to evolve, reflecting conceptual refinements, and parallels that for the cervix and vulva. Squamous intraepithelial lesion (SIL) and dysplasia represent alternative systems of nomenclature for intraepithelial neoplasia, reflecting differing social, political, and scientific efforts to best characterize the processes. Irrespective of terminology (VAIN), SIL displays nuclear atypia coupled with some loss of squamous

General Features

The incidence of in situ carcinoma of the vagina is reported to be about 0.20 cases per 100,000 in Caucasian females and 0.31 cases per 100,000 in black females; this is less than 1% of the incidence for the same disease in the cervix [47, 110]. The highest incidence rates are observed in women over the age of 60, with the mean age at diagnosis of VAIN 3 about 53 years. These figures are 10 or more years greater than the age of detection of cervical intraepithelial neoplasia (CIN) 3 [121]. Risk factors for the development of VAIN paralleled that of the cervix and include immunosuppression, HPV infection, or squamous neoplasia elsewhere in the lower genital tract, irradiation, and in utero exposure to DES, although this latter factor is controversial [26]. During the mid-1970s, it was first suggested that DES-exposed offspring might be at risk for increased rates of dysplasia because of the extent of metaplastic tissue present in both the cervix and vagina. Multiple studies of prevalence rates subsequently conducted indicated that the frequency of dysplasia in both the exposed and unexposed populations was approximately the same. In 1984, the DESAD Project amplified its findings on the frequency of dysplasia. The incidence rates were slightly higher in exposed women. The new occurrence of squamous cell dysplasia in women under observation developed twice as frequently in DES-exposed women in contrast to those that were never exposed in utero [23, 241]. Some believe that the DESAD findings may not be valid, and that the increased rates of dysplasia, especially of mild form, may be caused by over- or misinterpretation of the HPV-infected tissue for dysplasia [238], especially as the DESAD study was conducted before many of the histologic intricacies of HPV infection were fully appreciated. Regardless of interpretation, DES itself is not believed to be the etiologic cause of dysplasia. Possibly, the metaplastic squamous epithelium, which is more extensive in the vagina in DES-exposed women, may be more susceptible to agents that give rise to dysplasia, but even this is speculative.

Almost 75% of women with VAIN have preceding or coexisting squamous carcinomas of the cervix or vulva [18, 128, 129, 151, 260]. These observations have generated the concept of a field effect, in which the squamous epithelium of the entire lower female genital tract is at risk for neoplastic transformation. This hypothesis is appealing, because

the squamous epithelia of these sites do share a common embryonic derivation from the urogenital sinus, and all are susceptible to infection by various HPVs. Radiation therapy for cervical carcinoma results in exposure of the vagina to ionizing radiation, and women who have had pelvic radiation for benign as well as malignant diseases are at increased risk for development of VAIN [18, 89, 151].

Gross Findings

Women with VAIN are usually asymptomatic, and in most instances there is no grossly identifiable lesion in the vagina. Occasionally, the epithelium appears raised, roughened, and white or pink (\bigcirc *Fig. 3.38*). More often, the patient presents with an abnormal Papanicolaou smear and the diagnosis is confirmed by a colposcopically directed biopsy subsequent to an abnormal cytologic diagnosis in which sampling of the vagina as well as the cervix has been performed, or in vaginal samples after hysterectomy. The process is multifocal or diffuse in almost half of the cases, and usually is located in the upper third of the vagina [18, 151, 184, 251].

Microscopic Findings

The microscopic features of VAIN are analogous to those of CIN (see **O** Chap. 5, Precancerous Lesions of the

Fig. 3.38 Dysplasia of the vaginal vault. It appears as an irregular raised white plaque with a granular surface

Cervix), and similarly the term VAIN comprises lesions classified as condyloma (low-grade VAIN, VAIN I) and lesions classified as vaginal intraepithelial neoplasia (highgrade VAIN, VAIN II-III). Histologically, low-grade VAIN parallels CIN I and includes exophytic and flat condyloma. Exophytic condyloma is characterized by verucopapillary growth, acanthosis, and superficial koilocytotic atypia (> Fig. 3.39); this lesion is highly associated with HPV types 6 and 11. Flat condyloma shares the superficial distribution of koilocytotic atypia but lacks exophytic growth (**)** Fig. 3.40). High-grade VAIN is characterized histologically by the presence of nuclear abnormalities including enlargement with irregular shape, hyperchromasia, and irregular condensation of chromatin at all levels of the epithelium. Lesions that exhibit maturation at the surface are classified as VAIN II, whereas those with minimal maturation correspond to VAIN III (> Figs. 3.41 and ≥ 3.42). SIL (VAIN) lesions nearly always display some loss of squamous maturation as well as disordered maturation, frequently including increased mitotic activity, abnormal mitotic figures, acanthosis, and dyskeratosis.

The differential diagnosis of SIL (VAIN) includes atrophy, radiation change, and immature squamous metaplasia in women with adenosis, all of which may display loss of glycogen and a relative increase in cellularity. The distinction rests primarily on the characteristic nuclear features of SIL (VAIN), which are absent in the other conditions. Radiation changes include nuclear enlargement, smudged

Fig. 3.39

VAIN I (low-grade SIL, exophytic condyloma). There is papillomatosis and irregular acanthosis of this epithelium in addition to koilocytosis and nuclear features of intraepithelial neoplasia. The extensive cytoplasmic differentiation is diagnostic of VAIN I (low-grade SIL) chromatin, multinucleation, and vacuolization of cytoplasm, with lack of mitotic activity [80]. Occasionally, there may be significant nuclear atypia associated with inflammatory and reactive processes, but usually this is expressed as regular nuclear enlargement with vesicular chromatin and moderate-sized nucleoli. Such changes are referred to as reactive squamous atypia.

Clinical Behavior and Treatment

The natural history of SIL (VAIN) is uncertain. In one study, about 5% of SIL (VAIN) progressed to invasive carcinoma, with sequential changes documented by serial biopsies [251], but this figure probably significantly underestimates the biologic potential of VAIN because many lesions were treated [261]. Therapy generally is local excision, although topical 5-fluorouracil, laser vaporization, vaginectomy, and irradiation also have been successfully used [166, 272, 315]. In a study of 94 women with VAIN,

Fig. 3.40

VAIN 1 (low-grade SIL, flat condyloma). This lesion shows striking superficial koilocytotic atypia but lacks exophytic growth. The nuclear features of intraepithelial neoplasia are evident, including nuclear enlargement, pleomorphism, coarse chromatin, and irregular nuclear contours. Koilocytosis is also present 70% achieved remission after a single treatment of any type, but 24% required additional therapy with chemosurgery or upper vaginectomy; 5% progressed to invasive squamous carcinoma in spite of therapy and close follow-up [261].

Fig. 3.41

VAIN 2 (high-grade SIL). This intraepithelial process is characterized by enlargement and pleomorphism of nuclei, but preservation of some features of cytoplasmic differentiation is noted in cells of the intermediate and superficial layers

Fig. 3.42

VAIN 3 (high-grade SIL). Cytoplasmic differentiation is limited to the uppermost layers of the squamous epithelium. The remaining cells have a high nuclear/ cytoplasmic ratio, with a longitudinal nuclear axis perpendicular to the basement membrane

Squamous Cell Carcinoma

General Features

Squamous cell carcinoma represents about 80% of malignant neoplasms primary to the vagina [48, 217]. The incidence in the United States is about 1,000 cases each year. The incidence is 0.42 cases per 100,000 in Caucasian women and 0.93 per 100,000 in black women [47, 217], which is about 1/50th the incidence of cervical squamous cell carcinoma [189]. Only 1% of malignant neoplasms of the female genital tract are classified as squamous cell carcinoma originating in the vagina [217]. The incidence reflects both the relative rarity of squamous cell carcinoma at this site and the extremely rigid criteria for diagnosis of vaginal as compared with cervical carcinoma, which results in underestimation of its true frequency. The International Federation of Gynecology and Obstetrics (FIGO) staging of vaginal cancer is analogous to that of cervical cancer and is based on clinical rather than pathologic examination () Table 3.2). To be considered a primary tumor of the vagina, the neoplasm must be located in the vagina, without clinical or histologic evidence of involvement of the cervix or vulva. Thus, bulky tumors located in the upper vagina that have extended onto the portio vaginalis of the cervix are classified as primary cervical carcinoma. Similarly, squamous cell carcinoma occurring in the vagina within 5 years of therapy for cervical carcinoma is considered to be recurrent cervical carcinoma rather than a new primary carcinoma of the vagina [212]. It is thus not surprising that only 10-20% of vaginal malignancies are classified as primary neoplasms of the vagina [80]. The risk factors for invasive squamous carcinoma of the vagina are the same as those for SIL (VAIN)

Table 3.2

FIGO staging of vaginal carcinoma (1978)

Stage	Clinical status
0	Intraepithelial
-	Limited to vaginal wall
=	Extends to subvaginal tissue but not to pelvic side wall
Ш	Extends to pelvic side wall
IV	Extends beyond the true pelvis or involves mucosa of the bladder or rectum (bullous edema does not consign the patient to stage IV)
IVa	Adjacent organs involved
IVb	Distant organs involved

[26, 251]. In a case control study of VAIN and invasive squamous carcinoma of the vagina, significant risk factors also included prior vaginal discharge, condyloma acuminata, or irritation, prior abnormal cervical vaginal cytology, and prior hysterectomy. Surprisingly, early age at first intercourse, multiple sexual partners, and a history of smoking were not associated with an elevated risk of neoplasia [26]. Occasionally, squamous cell carcinomas also have been reported in young women with congenital absence of the vagina 8 to 25 years after the creation of a neovagina [120, 250].

Clinical Features

The mean age at diagnosis of invasive vaginal squamous carcinoma is 64 years [144]. The presenting symptoms usually are painless vaginal bleeding or discharge, dysuria, or frequency [6]. There is a relationship between duration of symptoms and the size and spread of tumor. Unfortunately, about 20% of patients with vaginal cancer delay more than 7 months from onset of symptoms to initiation of therapy [219]. Most of the tumors arise in the upper third of the vagina [219], with 57% involving the posterior wall and 27% located on the anterior wall [218].

Gross Findings

Vaginal squamous carcinomas vary in size from clinically occult to larger than 10 cm. The gross configuration is similarly variable and includes polypoid, fungating, indurated, and ulcerated lesions (\triangleright *Fig. 3.43*).

Microscopic Findings

Squamous cell carcinomas of the vagina resemble those arising in the cervix (> Fig. 3.44). Histologic grade using either the method of Broders or Reagan and Wentz has not been related to prognosis [61, 207]. Microinvasive carcinoma is not currently a defined entity in the vagina; however, superficially invasive tumors, with less than 3 mm of stromal invasion and no vascular space invasion, appear to have a low likelihood of nodal metastasis [218]. The distinction of early invasive carcinoma from intraepithelial carcinoma is based on a constellation of findings, including the presence of angulated narrow cords of squamous cells at the stromal interface, frequently with acquisition of more abundant eosinophilic cytoplasm, and a desmosplastic or inflammatory host response. Unfortunately, these features are not present in every case of early invasive squamous carcinoma.

Fig. 3.44

Squamous cell carcinoma of the vagina. Irregular nests of neoplastic cells with highly pleomorphic nuclei infiltrate the stroma. Keratin pearl formation is evident

Clinical Behavior and Treatment

Historically, the survival rates for women with squamous cell carcinoma of the vagina were low. However, recent studies indicate a considerably better prognosis, with rates comparable to those of cervical carcinoma when corrected for stage of disease [61, 208, 222]. In a review of 300 women with vaginal carcinoma treated over a 40-year interval at one institution, the overall 5- and 10-year survival rates were 60% and 49%, respectively [36]. The most important prognostic indicators included FIGO stage, tumor size, and location in the vagina (with better outcomes for those with lesions in the upper vagina). Results from the National Cancer Data Base between 1985 and 1994 and the FIGO 6th annual report of results of treatment in gynecologic cancer support the prognostic importance of stage [17, 48]. The relative 5-year survival rate for stage I disease was 73%, 53% for stage II tumors, and only 36% for stages III and IV [48]. Unfortunately, relatively few women are diagnosed with tumors confined to the vagina. Direct spread into the soft tissues of the pelvis or to the mucosa of the bladder or rectum occurs early because the wall of the vagina is thin and is separated from these organs by only a few millimeters of connective tissue. Consequently, at initial diagnosis, most tumors have invaded the soft tissues surrounding the vaginal wall and about 20% extend to the pelvic sidewall [36]. As discussed in the section on anatomy, the lymphatic drainage of the vagina is complex and variable, and any of the inguinal or pelvic lymph nodes may be the site of metastasis, although there is some relationship to the location of the tumor within the vagina [170].

Radiation therapy, including brachytherapy and external beam radiation, is the modality used primarily to treat vaginal squamous carcinoma, although radical vaginectomy may be indicated in selected instances. Although metastases may be discovered ultimately in the lungs or supraclavicular lymph nodes, recurrent disease is typically local and occurs within 2 years of diagnosis [144]. In one large study, local recurrences were identified at 5 years in 23% and distant metastases in 15% of patients [36]. Only 12% of the women who suffered a recurrence survived for 5 years.

Verrucous Carcinoma

The use of the term verrucous carcinoma should be reserved for those rare vaginal tumors that display the characteristic features described by Ackerman [4, 49]. Grossly, they are exophytic, fungating masses with a coarsely granular or undulating surface. Microscopically, the characteristic feature of verrucous carcinoma is the presence of squamous cells with bland cytologic features. At the deep margin of the tumor, the squamous cells invade in a pushing fashion as broad bulbous masses, creating a so-called baggy pants appearance. On the surface of the tumor, hyperkeratosis and acanthosis are common. The distinction of verrucous carcinoma from condyloma or pseudoepitheliomatous hyperplasia may be difficult and may not be possible in a superficial biopsy specimen. Some authors have indicated that verrucous carcinoma does not display the koilocytosis or surface papillae formed of fibrovascular cores covered by squamous cells, which are typical of condylomata or warty carcinomas [124, 144], but other investigators disagree [65, 162]. This issue, however, is not of primary importance because the diagnosis rests on the presence of bland cytologic features in the broad bulbous masses of squamous cells at the stromal interface. Verrucous carcinomas display a relatively indolent growth potential, with frequent local recurrence after incomplete excision. Lymph node metastasis occurs rarely, if ever. Because verrucous carcinomas not only are resistant to therapeutic irradiation but may actually transform to conventional squamous carcinoma after radiation therapy, the treatment is usually wide local or radical surgery [4, 141]. Tumors with a mixed pattern of both verrucous and conventional squamous carcinomas behave with the aggressiveness of typical squamous cancer and should be classified as such.

Warty Carcinoma

Squamous cell carcinomas in which many of the cells contain nuclear abnormalities and perinuclear cytoplasmic cavitation similar to the koilocytes in intraepithelial neoplasms have been designated warty carcinoma. These changes are not typically present in verrucous carcinoma. In addition, warty carcinomas have greater nuclear pleomorphism than verrucous carcinomas, as well as multinucleation, and an infiltrative pattern at the stromal interface. A detailed clinicopathologic analysis of warty carcinomas in the vagina has not been reported. Preliminary data from similar tumors in the vulva indicate that they behave in a low-grade malignant fashion, although metastases to regional lymph nodes occur occasionally (see Chap. 2, Premalignant and Malignant Tumors of the Vulva) [146].

Papillary Squamotransitional Cell Carcinoma

During the past decade, there has been increased recognition that lesions involving the lower genital tract may bear a close resemblance to those arising from urothelium. In

addition to transitional cell metaplasia [311], malignant neoplasms have been reported, primarily in the cervix [135, 230], but with occasional cases originating in the vagina [15, 71, 249]. The diagnostic terminology has been varied, including papillary squamous carcinoma, transitional cell carcinoma, and mixed squamous and transitional (squamotransitional) cell carcinoma, reflecting the less than unambiguous histologic features that discriminate such epithelia [135]. Immunohistochemical studies have usually demonstrated the presence of cytokeratin CK-7 and the frequent absence of CK-20 in the papillary genital tract tumors, unlike the profile of transitional cell carcinomas of the urinary bladder, which typically react with both CK-7 and CK-20 [135].

The presenting symptom of papillary squamotransitional cell carcinoma is usually either abnormal bleeding or abnormal cervical-vaginal cytology. The gross tumor configuration is described as papillary, polypoid, or exophytic. The neoplasm is characterized microscopically by the presence of predominantly narrow fibrovascular cores covered by a multilayered epithelium that may resemble either transitional cells, squamous cells, or both (> Fig. 3.45). Cytologic atypia is usually present in cells having oval nuclei, with frequent hyperchromasia and the occasional presence of longitudinal intranuclear grooves. Koilocytosis is rare, but mitoses are distributed throughout the epithelium. Often stromal invasion is not identifiable within the papillae of a superficial biopsy and must be sought at the deeper stromal interface. The invasive component may be identical to either conventional squamous or transitional cell carcinoma and usually elicits a desmoplastic host response.

The biologic behavior remains incompletely defined and has been described as either indolent or similar to that of conventional squamous carcinoma [135, 230]. Some of the cases have followed treatment of primary papillary transitional cell carcinomas of the urinary tract or have been associated with transitional cell metaplasia, suggesting the possibility of an extended urogenital field at risk for transitional cell neoplasia [71].

Clear Cell Adenocarcinoma

General Features

From the 1970s through the 1990s, most cases of vaginal clear cell adenocarcinoma occurred in young women with a documented history of DES exposure in utero. The median age at the time of diagnosis in the DES-exposed US population was 19 years, and the risk of tumor development was

Fig. 3.45 Papillary squamotransitional cell carcinoma. The tumor closely resembles a papillary urothelial cell carcinoma

higher when the drug was started early in pregnancy. Fortunately, clear cell adenocarcinoma developed in only about 0.1% of exposed females up to the age of 24 years. As of 2008, 757 cases of clear cell adenocarcinoma of the cervix or vagina had been accessioned worldwide to the Registry for Research on Hormonal Transplacental Carcinogenesis. Consequent to the removal of DES from the market for the treatment of high-risk pregnancy in 1971, the exposed population has aged, and between 2003 and 2008, only 35 cases of clear cell carcinomas were reported to the Registry (personal communication). Our understanding of DESmediated carcinogenesis remains incomplete. A high frequency of microsatellite instability and overexpression of wild-type p53 has been observed [306, 307]. Currently, many of the cases of clear cell adenocarcinoma of the vagina are diagnosed in older, non-DES-exposed women.

Clinical Features

Larger tumors almost always cause symptoms such as vaginal bleeding or discharge, while many small tumors are asymptomatic. Approximately 60% of lesions have been confined to the vagina. The remainder have been limited to the cervix or involved both the cervix and vagina.

Gross Findings

The tumor may involve any portion of the vagina and/or cervix. Most of the larger cancers are polypoid and nodular, but some are flat or ulcerated, having a granular or indurated surface. Small tumors may be invisible on colposcopic examination if confined to the lamina propria and covered by normal, or metaplastic squamous epithe-lium, and are detectable only by palpation (**>** *Fig. 3.46*).

Microscopic Findings

DES-associated clear cell adenocarcinoma is identical to the clear cell adenocarcinoma of the ovary and endometrium, which occur sporadically in older women. Several histologic patterns may be observed, either alone or in combination. A characteristic pattern, for which the tumor is named, consists of solid sheets of clear cells (> Fig. 3.47), the clear appearance of the cytoplasm being caused by the dissolution of glycogen when the specimen is processed for microscopic examination. A second (and the most frequent) pattern, the tubulocystic pattern (**>** Fig. 3.48), is characterized by tubules and cysts lined by hobnail cells, by flat cells, or by cells that resemble müllerian-type epithelium to varying degrees. The hobnail cell is characterized by a bulbous nucleus that protrudes into the lumen (> Fig. 3.49). Flat cells often appear cytologically bland. When only this type of epithelium is present in a small biopsy, it may be difficult to differentiate tumor from adenosis [256]. Less common patterns include a papillary and a tubular pattern resembling endometrial carcinoma. In any of these patterns, the lumen may contain mucin.

Atypical adenosis, characterized by glands with cellular stratification, nuclear pleomorphism, hyperchromasia, and prominent nucleoli, has been identified near the periphery of most clear cell carcinomas. The frequent finding of the tuboendometrial type of glandular cell and the rarity of the mucinous type of cell adjacent to the tumors suggest that the clear cell adenocarcinoma arises from the tuboendometrial cells [243, 244].

Fig. 3.46

Flat clear cell carcinoma of vagina. This tumor was detectable only by palpation since the overlying mucosa underwent complete squamous metaplasia and the underlying neoplastic glands produced a small nodule

Fig. 3.48

Tubulocystic pattern of tumor in which small tubules are lined by neoplastic hobnail, cuboidal or flattened cells

Fig. 3.49

Clear cell carcinoma. Detail of solid and hobnail cells showing high nuclear/cytoplasmic ratio and apically located nuclei protruding into the cystic spaces

Differential Diagnosis

Microglandular hyperplasia usually occurs in the cervix, but may arise in vaginal adenosis. It contains many small, closely packed glands devoid of intervening stroma (see Chap. 4, Benign Diseases of the Cervix). The presence of extensive nests of metaplastic squamous cells with pale eosinophilic cytoplasm may make the lesion difficult to distinguish from the solid pattern of clear cell carcinoma. A clue to the diagnosis is the presence of clefts lined by mucinous epithelium that course through the metaplastic squamous epithelium. The Arias-Stella reaction usually occurs in pregnant women. Although usually seen in the endometrium, the Arias-Stella reaction has been observed in the endocervix and occasionally in vaginal adenosis of the tuboendometrial type. Characteristically, hypersecretory glands are lined by cells with markedly enlarged nuclei resembling hobnail cells. However, in clear cell adenocarcinoma, the presence of sheets of clear cells or prominent papillae should enable the two lesions to be distinguished. In addition, the hobnail-like nuclei in the Arias-Stella reaction commonly contain smudged nuclear chromatin.

Clinical Behavior and Treatment

The tumor spreads locally and also metastasizes via lymphatics and blood vessels. Clear cell carcinoma extends outside the abdominal cavity more frequently than does squamous cell carcinoma of the vagina or cervix. Thirtysix percent of the initial recurrences of clear cell carcinomas are in the lung or a supraclavicular lymph node, in contrast to less than 10% for squamous cell carcinomas.

The 5-year actuarial survival rates for all patients with clear cell adenocarcinoma are high, about 93% at 5 years and 87% at 10 years when the tumor is at stage I [111]. Large size and/or deep invasion into the wall are associated with a poorer prognosis, but small or superficial tumors also may recur or metastasize. Recurrences develop most often within 3 years after primary therapy; however, recurrences as late as 19 years after treatment have been observed [28].

The prognosis for women with clear cell adenocarcinoma who have known exposure to DES in utero is significantly better than for those who have no history of DES exposure (5-year survival rates of 84% and 69%, respectively) [305]. Although some of this difference could reflect earlier detection in the intensively screened exposed population, the survival advantage persists even when the comparison is adjusted for stage of disease. Metastases to the lungs or supraclavicular lymph nodes are more frequent in the non-DES-exposed group.

Embryonal Rhabdomyosarcoma (Sarcoma Botryoides)

General Features

The most common malignant neoplasm of the vagina in infants and children is embryonal rhabdomyosarcoma, most of which is of the subtype designated sarcoma botyroides [46, 48, 197]. Nearly 90% of cases are diagnosed before 5 years of age [48, 76]. This is a rare tumor of unknown etiology and pathogenesis. Certainly the distribution of embryonal rhabdomyosarcomas does not correlate with the mass of skeletal muscle, as most of these neoplasms arise in or near the mucosa of either the head and orbit or the lower urogenital system.

Clinical Features

The mean age at diagnosis is 2 years, with a range extending from birth to 41 years [76]. Most children present with symptoms of a vaginal mass or bleeding. The tumors usually are located along the anterior wall of the vagina, and appear as papillae, small nodules, or pedunculated or sessile soft, polypoid masses with an intact overlying mucosa. Larger tumors may protrude through the introitus. The tumors usually are staged according to a modification of the Intergroup Rhabdomyosarcoma Study (IRS) classification, which is based on combined features of extent of disease, resectibility, and microscopic evaluation of margins of excision (**>** *Table 3.3*).

Gross Findings

Soft gray or tan, edematous, and nodular tumors are typical. The polypoid gross configuration is thought to result from relatively unrestricted growth into the lumen of a hollow organ (\bigcirc *Fig. 3.50*).

Microscopic Findings

The distinction of sarcoma botryoides from the spindle or nonspecialized variants of embryonal rhabdomyosarcoma is based on the presence of a cambium tumor cell layer underlying an intact epithelium in at least one microscopic field [227]. The cambium layer is defined as the condensed subepithelial layer of rhabdomyoblasts that are scattered in a loose myxoid or dense collagenous stroma (> Fig. 3.51). The term cambium was chosen as an analogy to the peripheral, actively growing layer in tree trunks and branches, which it mimics at a microscopic level. The histologic criteria are more important in establishing the diagnosis than the gross demonstration of a polypoid or "grapelike" pattern of tumor growth. The cells in the cambium layer often are polyhedral, with little discernible cytoplasm, but extensive rhabdomyoblastic differentiation, with a spindled configuration of tumor cells, may predominate in this or other portions of the tumor. The tumor cells are of round to spindle shape, with oval nuclei, an open chromatin pattern, and inconspicuous nucleoli [293].

Focal evidence of rhabdomyogenesis may be evident in any of the patterns, with eosinophilic cytoplasm

Table 3.3

IRSG surgical-pathologic grouping system

Group	Definition
-	Localized tumor, completely removed with pathologically clear margins and no regional lymph node involvement
Π	Localized tumor, grossly removed with (a) microscopically involved margins, (b) involved, grossly resected regional lymph nodes, or (c) both
111	Localized tumor, with gross residual disease after grossly incomplete removal, or biopsy only
IV	Distant metastases present at diagnosis

containing fibers in which cross-striations are present (\bigcirc *Fig.* 3.52). However, in cases that lack such features immunohistochemical staining with antibodies directed against muscle-specific actin, desmin, myoglobin, or myogenin (myf 4) may be helpful in establishing the diagnosis [12, 27, 67, 144, 227]. Although the first two antibodies are more sensitive than myoglobin, they are not specific for skeletal muscle differentiation. It is important not to be misled to the erroneous diagnosis of melanoma by the presence of immunoreactivity for S-100 protein, which has been reported in about 20% of cases of rhabdomyosarcoma [227].

Fig. 3.50 Embryonal rhabdomyosarcoma, botryoid type. Note the polypoid appearance of the tumor

Fig. 3.51

Embryonal rhabdomyosarcoma, botryoid type. The cambium layer is recognized as a condensed subepithelial layer of rhabdomyoblasts that are scattered in a loose myxoid or dense collagenous stroma The differential diagnosis includes fibroepithelial polyps, müllerian papillomas, and rhabdomyomas. The correct diagnosis can be made by considering the age at presentation and the microscopic features described above. After radiation or chemotherapy, occasionally there is difficulty in determining whether scattered mature-appearing skeletal muscle fibers represent residual tumor cells that are refractory to therapy or radiated benign muscle fibers of the pelvis. One study suggests that differentiation occurs more frequently with the botryoid variant of rhabdomyosarcoma following therapy and that it is associated with a favorable outcome [43].

Clinical Behavior and Treatment

The tumor initially grows into the vaginal wall and soft tissue of the pelvis, bladder, or rectum and subsequently metastasizes to lymph nodes, lungs, liver, and bone.

Fig. 3.52

Embryonal rhabdomyosarcoma, botryoid type. In contrast to the vaginal rhabdomyoma, the embryonal rhabdomyosarcoma contains densely cellular regions composed of small primitive cells. Interspersed strap cells confirm the skeletal muscle differentiation Historically, the prognosis after radical surgery was poor, with survival rates of less than 20% [42]. The introduction of combined multiagent chemotherapy and in some cases radiotherapy, in addition to surgery, has dramatically improved the probability of survival [42, 93, 168, 197].

Based on five consecutive clinical trials conducted by the Intergroup Rhabdomyosarcoma Study Group (IRSG) [231], a number of prognostic factors have been identified that strongly correlate with patient outcome. These include clinical group (> Table 3.3), stage of disease (> Table 3.4), patient age, and histologic subtype. Fortunately, the botryoid type, the variant of embryonal rhabdomyosarcoma found most frequently in the vagina, has a superior prognosis, with a survival rate greater than 90% [108, 184, 227]; however, even the focal presence of an alveolar histology confers a worse prognosis [227]. In addition, a recent study suggests that the presence of cellular anaplasia may be of prognostic significance in patients with embryonal rhabdomyosarcoma [226]. Two examples of relapse approximately 10 years after initial diagnosis, a few months following menarche, have been reported, and a possible causal association with estrogen has been postulated [300].

Melanoma

General Features

More than 155 cases of vaginal melanoma have been reported, representing less than 5% of the malignant

Table 3.4

IRSG staging system

Stage	Sites of primary tumor	Tumor size (cm)	Regional lymph nodes	Distant metastases
1	Orbit, non-PM head, neck; GU non-bladder/ prostate; biliary tract	Any size	N0, N1	МО
2	All other sites	\leq 5	N0	MO
3	All other sites	\leq 5	N1	MO
		\leq 5	N0 or N1	
4		Any size	N0 or N1	M1

PM, parameningeal; GU, genitourinary; NO, regional bodes not clinically involved by tumor; N1, regional nodes clinically involved by tumor; M0, no distant metastases; M1, distant metastases at diagnosis.

neoplasms of the vagina and less than 1% of all melanomas [48, 59, 90, 102, 122, 214]. These tumors can occur at any age, with a range from 22 to 90 years; however, most patients are postmenopausal with a mean age of approximately 60 years [154, 214, 228]. Presenting symptoms include vaginal bleeding, discharge, and a mass. Although the tumors may arise anywhere within the vagina, there is a predilection for the distal third [35]. The etiology and pathogenesis are unknown, but a disproportionately large number of vaginal melanomas have occurred in Japanese women, followed in frequency by Caucasian and then black women [35, 48, 154]. In one autopsy study, melanocytes were identified in the basal layer of the vagina of 3 of 100 women. It has been suggested that such a condition, referred to as benign melanosis, is the setting from which melanoma occasionally may arise [105], and we have seen localized regions of melanosis in the vagina remote from melanomas. Unfortunately, the term melanosis also has been used to designate melanophages in the stroma and lentigo malignum-like lesions in mucosal tissues, further obscuring interpretation of the scant available literature.

Gross Findings

Melanomas may appear as nodular, polypoid, or fungating gray or black soft masses that vary from 0.5 to 8 cm in diameter (\bigcirc *Fig.* 3.53) [35, 102, 264]. Frequently, there is ulceration of the overlying epithelium.

Microscopic Findings

Vaginal melanomas have no microscopic characteristics that are distinctive for this site. The diagnosis usually rests on a constellation of features. In addition to junctional activity, the presence of highly atypical melanocytes, either singly or in clusters, extending through the squamous epithelium is common (\bigcirc *Fig. 3.54*). The infiltrating neoplastic cells may be epithelioid, spindled, or mixed (\bigcirc *Fig. 3.55*). Melanin is common within both neoplastic melanocytes and benign melanophages. The lateral spread is typically of the lentiginous type, with single, spindled cells containing pleomorphic nuclei at the epithelial–stromal interface [35]. Rarely, a pagetoid junctional component consisting of epithelioid melanocytes in nests is present [35].

Because Clark's levels are not appropriate for mucosal sites of melanoma, a system based entirely on tumor thickness has been proposed by Chung et al., as follows: level I, tumor confined to the surface epithelium; level II, invasion of 1 mm or less; level III, invasion of 1–2 mm; and

Fig. 3.53 Melanoma of the vagina. Confluent nodular pigmented masses are present

Melanoma of the vagina. Junctional involvement (right side of field) is frequently identified peripheral to ulcerated or intact central region of deep stromal invasion in primary vaginal melanomas

level IV, invasion greater than 2 mm [35]. Unfortunately, most of the tumors are deeply invasive. In a group of 19 patients, only 1 was at level III; the remainder were at level IV [35].

Fig. 3.55

Melanoma of the vagina. The neoplastic cells may be of polyhedral or spindle configuration and may be confused in routinely stained sections with either squamous carcinoma or sarcoma, particularly if the overlying epithelium is ulcerated. Immunohistochemistry can help to resolve the diagnosis when melanin pigment is not apparent

Differential Diagnosis

The diagnosis usually is straightforward as most vaginal melanomas are large, with gross and microscopic pigmentation. The differential diagnosis may include melanoma metastatic from other sites, poorly differentiated squamous carcinoma, sarcoma, and blue nevus. Because primary vaginal melanoma is rare, it is important to rule out metastasis from other sites. The presence of an extensive lateral junctional component is typical in melanomas arising in the vagina but relatively uncommon in metastases. A complete history is essential, and some cases can be confirmed only by postmortem examination. When large ulcerated lesions are devoid of pigment, immunohistochemistry and ultrastructural examination may permit discrimination of melanoma from other poorly differentiated neoplasms. Positive staining of malignant cells with antibodies directed against S-100 protein is a sensitive, but not specific, marker of melanocytic or neural differentiation. HMB-45 is a less sensitive (negative in 23% of cases in one study [102]) but more specific indicator of melanoma, and staining for keratin or desmin should be absent. Ultrastructural findings include premelanosomes and melanosomes, as well as abundant rough and smooth endoplasmic reticulum [105]. A high degree of nuclear atypia and numerous mitotic figures usually permit discrimination of melanoma from the rare benign vaginal nevus.

Clinical Behavior and Treatment

The prognosis for vaginal melanoma is poor, with 5-year survival rates of less than 10–20% [35, 48, 154, 228, 310]. Undoubtedly, this reflects the inherent aggressiveness of melanoma coupled with the typically deep invasion found at the time of diagnosis [35, 48, 59, 234]. In one study, survival was inversely related to the mitotic activity [22]. Both lymphatic and hematogenous metastases are common, with the vagina and groin being the most common initial sites of spread. Primary therapy usually includes radical local excision, although pelvic exenteration has been suggested as treatment for tumors greater than 3 mm in thickness. The value of groin node dissection, radiation, and chemotherapy remains unknown [154, 209].

Yolk Sac Tumor

Although the yolk sac tumor (endodermal sinus tumor [EST]) usually arises in the gonads, about 57 cases have been reported in the vagina [39]. It is appealing to consider that these tumors originate from germ cells that have failed to complete migration normally in the embryo from the hindgut to the gonad. However, this hypothesis does not provide an obvious explanation for the absence of other malignant germ cell tumors in the vagina, or the predilection of EST for the vagina.

Most vaginal ESTs have been diagnosed in children less than 4 years of age. The presenting symptom usually is a bloody vaginal discharge. The gross and microscopic features of vaginal EST closely resemble those of ovarian origin. Polypoid or sessile, soft, and tan or white vaginal masses 1-5 cm in diameter are typical [144]. A variety of histologic patterns may be present including the microcystic, reticular, papillary, and solid types of EST. Schiller-Duval bodies, composed of papillary arrangements of columnar cells separated from central vascular channels by an acellular zone of connective tissue, are characteristic findings. Extracellular hyaline droplets also are common. Although the histologic findings usually are typical, the diagnosis may not be considered initially because of the rarity of EST in the vagina. The differential diagnosis includes clear cell adenocarcinoma from which EST may be distinguished by the younger age and positive immunohistochemical reactions for alpha-fetoprotein and alpha-1-antitrypsin [317].

EST is an extremely aggressive tumor. In the past, the median survival was 11 months, and the survival rate at 5 years was less than 25% [45, 209]. Most patients developed recurrence and died within 2 years, even after radical surgery [45, 144]. The addition of multiagent chemotherapy, usually

consisting of vincristine, actinomycin, and cyclophosphamide, since 1970 has resulted in a 95% disease-free survival at 2 years [8, 45, 317]. Preliminary data suggest that combination chemotherapy and conservative surgery may permit preservation of future sexual function and fertility as well as an excellent cure rate [209].

Leiomyosarcoma

About 65 leiomyosarcomas of the vagina have been reported [48, 52, 211]. The frequency and behavior have been difficult to establish because the pathologic criteria separating benign from malignant smooth muscle tumors have varied. Currently, it is recommended that smooth muscle tumors of greater than 3 cm diameter, with five or more mitotic figures per ten HPFs, moderate or marked cytologic atypia, and infiltrating margins be classified as leiomyosarcoma (**)** *Fig.* 3.56) [282]. The age range extends from 25 to 86 years with most patients being older than

Fig. 3.56

Vaginal leiomyosarcoma. The tumor resembles that of uterine origin, with fascicles of spindle cells having moderate or marked nuclear pleomorphism with increased mitotic activity 40 years. Vaginal bleeding is the most common presenting symptom. The gross and microscopic features resemble those of uterine leiomyosarcoma, but the spread of tumor is by local invasion and hematogenous metastasis. The 5-year survival rate is about 35%, and the stage of the disease is the most important prognostic indicator [211]. The primary therapy is surgical, and exenteration may be required to provide an adequate margin around larger tumors.

Malignant Mixed Tumor

Probably unrelated to the benign vaginal mixed tumor is the reportedly malignant mixed tumor, which resembles either synovial sarcoma or a malignant tumor arising from mesonephric rests [201, 275, 278]. Two of these rare tumors occurred in women 24 and 33 years old, who presented with a polypoid nodule in the lateral vaginal fornix. The microscopic appearance is of an intact vaginal squamous mucosa with a subjacent mixture of solid nests of polyhedral-shaped cells and flattened epithelial cells in acinar or tubular arrays, bordered peripherally by smaller bundles of spindle cells resembling fibroblasts. Ultrastructural features resembling synovial sarcoma were noted in one case [201, 275]. The presence of mitotic activity as great as eight mitoses per ten HPFs coupled with nuclear pleomorphism and moderate-sized nucleoli suggested that the process was malignant. However, the biologic potential remains uncertain in the absence of long-term follow-up.

Secondary Neoplasms

Although primary neoplasms of the vagina are quite rare, secondary spread of malignant neoplasms to the vagina by

Fig. 3.57 Metastatic endometrial adenosarcoma to the vagina. This tumor represents a recurrence of a uterine adenosarcoma initially resected 8 years earlier

direct extension or lymphatic or hematogenous metastasis is quite common (\bigcirc *Fig.* 3.57). Fu and Reagan found that only 58 (16%) of 355 invasive carcinomas involving the vagina represented primary neoplasms [81]. Spread from primary carcinoma of the cervix was most common (32%), followed by endometrium (18%), colon and rectum (9%), ovary (6%), vulva (6%), and urinary tract (4%) (\bigcirc *Fig.* 3.58). Even among the squamous carcinomas found in the vagina, only a minority prove to be primary to this site. About 75% are secondary, arising in either the cervix (79%) or vulva (14%) [81].

About 70 cases of vaginal metastases from renal cell carcinoma have been reported (**>** *Fig. 3.59*) [281, 292, 315]. Metastases from clear cell carcinoma of the kidney may be very difficult to distinguish histologically from primary clear cell carcinoma of the vagina. This difficulty is complicated by the observation that in some instances the identification of the metastatic lesion has preceded the diagnosis of the renal tumor [292]. A young age, history of

DES exposure in utero, prior or concurrent vaginal adenosis, and foci of neoplastic clear cells with a tubulocystic or papillary architecture are features that favor a vaginal primary, whereas older age and regions of granular, cytoplasm or sarcomatoid differentiation are more common in tumors that originate in the kidney. In rare cases, the histologic distinction of clear cell carcinoma of the vagina from a renal metastasis may be impossible.

Miscellaneous Malignant Neoplasms

Endometrioid adenocarcinomas, stromal sarcomas, and carcinosarcomas occasionally originate in the vagina, at times arising from a background of endometriosis (\bigcirc *Fig. 3.60*) [99, 194, 211]. In addition, there are occasional reported cases of primary vaginal adenocarcinoma in situ [38], intestinal-type adenocarcinoma [79], adenosquamous

Fig. 3.58

Metastatic endometrial adenocarcinoma. Vaginal recurrence of adenocarcinoma of the endometrium is common. There is great fidelity in most cases to the histologic appearance of the endometrial primary

Fig. 3.59 Metastatic renal cell carcinoma. Solid masses of polygonal cells with clear cytoplasm are separated from each other by delicate fibrovascular septa

Fig. 3.60

Endometrioid adenocarcinoma of the vagina. This primary endometrioid adenocarcinoma is arising in association with endometriosis (right side of illustration)

carcinoma [237, 258, 273], adenocarcinoma arising in mesonephric duct remnants, adenoid basal cell carcinoma [193], adenoid cystic carcinoma [144], carcinoid tumor [84], small cell carcinoma [126, 236], malignant schwannoma [57], fibrosarcoma [204], malignant fibrous histiocytoma [308], angiosarcoma [223, 291], alveolar soft part sarcoma [30, 147].

Gross Anatomy

The uterus is divided into the corpus, isthmus, and cervix [63]. The cervix (term taken from the Latin, meaning neck) is the most inferior portion of the uterus, protruding into the upper vagina. The transition between the endocervix and the lower portion of the uterine corpus is termed the isthmus or lower uterine segment. The latter is used for descriptive purposes during gestation and labor and is an important landmark for the pathologist when describing cancers of the uterine corpus. The muscular layer in the region of the isthmus is less well developed than in the corpus, a feature that facilitates effacement and dilation during labor. The vagina is fused circumferentially and obliquely to the distal part of the cervix and is divided into an upper, supervaginal, and lower vaginal portion. The cervix measures 2.5-3 cm in length in the adult nulligravida, and when normally positioned, is angled slightly downward and backward. The vaginal portion (portio vaginalis) of the cervix, also referred to as the exocervix, is delimited by the anterior and posterior vaginal fornices; it has a convex elliptical surface. The portio may be divided into anterior and posterior lips, of which the anterior is shorter and projects lower than the posterior lip. In the center of the exocervix is the external os. The external os is circular in the nulligravida and slitlike in the parous woman () Fig. 4.1a, b). The external os is connected to the isthmus of the cervical canal (endocervix). The canal is an elliptical cavity, measuring 8 mm in its greatest diameter and contains longitudinal mucosal ridges, the plicae palmatae.

The blood supply of the cervix is provided by the descending branches of the uterine arteries, reaching the lateral walls along the upper margin of the paracervical ligaments (cardinal ligaments of Mackenrodt) (> Fig. 4.2). These ligaments and the uterosacral ligaments, which attach the supervaginal portion of the cervix to the second through fourth sacral vertebrae, are the main sources of fixation, support, and suspension of the organ. The venous drainage parallels the arterial system, with communication between the cervical plexus and neck of the urinary bladder. The lymphatics of the cervix have a dual origin: coursing beneath the mucosa and deep in the fibrous stroma. Both systems collect into two lateral plexuses in the region of the isthmus and give origin to four efferent channels running toward the external iliac and obturator nodes, the hypogastric and common iliac nodes, the sacral nodes, and the nodes of the posterior wall of the urinary bladder (**)** Fig. 4.2). The innervation of the cervix is chiefly limited to the endocervix and peripheral deep portion of the exocervix. This distribution is responsible

Fig. 4.1
 Normal cervix uteri. (a) Nulliparous cervix (b) Parous cervix

for the relative insensitivity to pain of the inner two-thirds of the portio vaginalis. The cervical nerves are derived from the pelvic autonomic system, the superior, middle, and inferior hypogastric plexuses.

Histology and Physiology

The cervix is composed of an admixture of fibrous, muscular, and elastic tissue and is lined by columnar and squamous epithelium. Fibrous connective tissue is the predominant component. Smooth muscle comprises 15% of

• Fig. 4.2 Anatomy of the cervix. The blood supply and lymphatic drainage of the cervix are demonstrated

the substance and is located mainly in the endocervix, the portio vaginalis being nearly devoid of smooth muscle fibers. In contrast, at the isthmus, 50–60% of the supportive tissue consists of concentrically arranged smooth muscle, which acts as a sphincter.

Squamous Epithelium

Histology

The mature nonkeratinized squamous epithelium of the exocervix is similar to the vaginal epithelium but under normal circumstances lacks the rete pegs seen in the vagina. It is divided into three zones: the basal/parabasal or germinal cell layer, which is responsible for continuous epithelial renewal, the midzone or stratum spinosum, the dominant portion of the epithelium, and the superficial zone, containing the most mature cell population (\triangleright Fig. 4.3).

The basal/parabasal or germinal layer contains two types of cells. One type is the true *basal cell*, which is about 10 μ m in diameter, with scant cytoplasm and oval nuclei oriented perpendicularly to the underlying basal lamina (\bigcirc *Fig. 4.4*). The other type of cell is termed the *parabasal cell* because of its geographic placement. Parabasal cells are larger than basal cells and have more cytoplasm. Parabasal cells typically form a layer that is one-to-two-cells thick over the basal layer.

Normal squamous epithelium. The mature squamous epithelium of the portio of the cervix shows a gradual ascending maturation, vacuolization of midzone cells, and a single layer of basal cells in which the nuclei are perpendicularly oriented to the basal lamina. The stromalepithelial junction contains finger-like, fibrovascular stromal papilla penetrating the lower portion of the epithelium

Epithelial regeneration is the major function of the basal and parabasal layers. Accordingly, epidermal growth factor receptors including HER-2/neu, and receptors for estrogen and progesterone are found predominantly in the basal and parabasal cells [8, 54]. The number of growth factor receptors becomes reduced as the squamous epithelial cells differentiate into the intermediate cell layer. Basal cells appear to act as stem cells, whereas parabasal cells comprise the actively replicating compartment. Indeed, mitotic figures are usually found in parabasal but not basal cells, and other markers for actively proliferating cells such as Ki-67 antigen, PCN, and other cyclins are localized to parabasal cells (**2** *Table 4.1*) [12, 60, 80].

The midzone is occupied by cells that are undergoing maturation, characterized by a gradual increase in the volume of the cytoplasm. Nuclear size, however, remains stable up to the most superficial cell level. These cells are referred to as *intermediate cells* when they exfoliate. They do not divide. Intermediate cells have abundant periodicacid Schiff (PAS)-positive, diatase-labile intracellular glycogen, which is responsible for the clear, vacuolated appearance of their cytoplasm.

Fig. 4.4

Normal squamous epithelium. Under normal conditions the basal layer acts as a reserve cell layer, and mitoses are only identified in parabasal cells

The superficial zone forms the most differentiated compartment of the squamous epithelium. These cells are flattened and have a larger area of cytoplasm (50 μ m in diameter) and smaller pyknotic nuclei than the underlying intermediate cells. The pink, eosinophilic cytoplasm has abundant intermediate filaments, which provide rigidity membrane-bound keratinosomes by electron microscopy (\bigcirc *Fig. 4.5*).

The squamous epithelium of the portio is supported by fibrous connective tissue, devoid of endocervical glands. It has occasional finger-like extensions into the epithelium, the stromal papillae (\bigcirc *Fig.* 4.3). The penetrating vessels within the papillae supply the epithelial cells with nutrients and oxygen. Occasional free nerve endings are seen entering the stromal papilla.

In postmenopausal women, who no longer produce ovarian hormones, the squamous epithelium is atrophic with little or no intracytoplasmic glycogen (\bigcirc *Fig. 4.6*). Surface epithelial maturation and stromal papillae are absent. These cellular alterations should not be confused with cervical intraepithelial neoplasia (**)** Chap. 5, Precancerous Lesions of the Cervix). The atrophic epithelial covering does not adequately protect the subepithelial vasculature against trauma, a situation that frequently leads to bleeding and inflammation.

Effect of Estrogen and Progesterone

The epithelium of the exocervix is remodeled by proliferation, maturation, and desquamation during the reproductive period. The epithelium is completely replaced by a new population of cells every 4-5 days; the process of squamous epithelial maturation can be accelerated to 3 days by the administration of estrogenic compounds [61]. Estrogen receptors have been localized to nuclei in the basal, parabasal, and intermediate cell layers [54, 60]. Compared to the endometrium in the cervix, only a small increase of estrogen receptor levels occurs during the follicular phase as compared to the luteal phase. In atrophic and highly inflamed exocervical epithelium, the amount of estrogen receptor is reduced. No, or only low levels, of progesterone receptors are detected immunohistochemically in the exocervical epithelium during the follicular phase of the menstrual cycle, whereas during the luteal phase and during pregnancy, progesterone receptors appear in the parabasal cell layer [60]. Both estrogen and progesterone receptors can be detected in stromal fibroblasts of the exocervix throughout the menstrual cycle.

In general, estradiol- 17β stimulates epithelial proliferation, maturation, and desquamation, whereas progesterone inhibits maturation at the upper midzone level of the epithelium. Accordingly, the portio epithelium during the postnatal period is fully mature and contains large amounts of glycogen as a result of maternal estrogen stimulation. Maturation ceases and glycogen rapidly disappears as the serum hormone levels fall. The epithelium remains atrophic during childhood until menarche when, under the stimulatory effect of ovarian hormones, maturation occurs again and glycogen reappears. During pregnancy, when progesterone levels are elevated, superficial cell maturation is absent.

Columnar Epithelium

Histology

A single layer of mucin-secreting, columnar epithelium lines both the surface of the endocervical canal and the

Normal squamous epithelium. Electron microscopy of the superficial cells. These cells have pyknotic nuclei (N) and flattened cytoplasm packed with glycogen (G). The most superficial cells are rich in microfilaments and contain irregular surface membrane projections. Note the lack of desmosomal attachments between the most superficial cells, a feature facilitating desquamation. X4795. *Inset*: Higher magnification of intracytoplasmic microfilaments in the most superficial cells. X11,370

underlying glandular structures. The latter are traditionally called compound, tubular racemose, endocervical glands. Three-dimensional plastic reconstructions from serial histological sections demonstrate that the endocervical glands actually represent deep, cleft-like infoldings of the surface epithelium with numerous blind, tunnellike collaterals (**>** *Fig.* 4.7) [28]. Because of the complex architecture of these clefts, or grooves, including oblique, transverse, and longitudinal arrangements, they appear as isolated glands in histological sections. The epithelium lining the clefts is identical with that lining the surface, and consequently the endocervical mucin-producing apparatus is not considered glandular but a complex infolding mucinous membrane. True glands, in contrast, have different epithelial lining in their secretory apparatus compared to their ductal and surface epithelial portions.

The columnar epithelial cells characteristically have basally placed nuclei and tall, uniform, finely granular cytoplasm filled with mucinous droplets (\bigcirc *Fig. 4.8*). The droplets have great affinity for Alcian blue stains, reflecting their sulfated, sialic acid, mucopolysacchride content [23]. Cells lining the luminal surface have been termed *picket cells* because of their resemblance to a picket

Fig. 4.6

Atrophic squamous epithelium. The epithelium is devoid of glycogen-rich vacuolated cells. The normal cellular orientation is disrupted, but cellular cohesion is normal and cytologic atypia is absent fence. Occasionally, nonsecretory cells with cilia are observed (*Fig. 4.9*), the main function of which is to distribute and mobilize the endocervical mucus [35]. Isolated neuroendocrine, argyrophil and argentaffin cell types also are identified within the endocervical epithelium by histochemical stains [26]. The argentaffinpositive cells often contain serotonin. The physiologic purpose of these rare endocrine endocervical cells is obscure. Biochemically and immunohistochemically, the columnar cells of the endocervix have features of simple epithelia, characterized by the presence of only low molecular weight cytokeratins, including cytokeratins 7, 8, 18, and 19 [29].

Mitoses in the normal columnar epithelium are very rarely observed. It is not known whether regeneration occurs from the underlying subcolumnar reserve cells, which under normal circumstances are seldom seen even at the ultrastructural level, or from the persisting mature endocervical cells [35]. Unlike the attenuated vascular stromal papillae of the original squamous portio epithelium, the subepithelial capillary network in the endocervical mucosa is well developed.

The stroma of the endocervix is comparatively better innervated than that of the exocervix. Fibers run parallel to muscle bundles, but sensory free endings have not been clearly demonstrated. True lymphoid follicles, with or without germinal centers, are encountered in the subepithelial stroma of both the exocervix and the endocervix.

Fig. 4.7

Endocervical mucosa. There are cleft-like infoldings and tunnel-like collaterals. The neighboring gland-like structures represent tangentially sectioned cleft-tunnel complexes

■ Fig. 4.8 Endocervical mucosa. Tall columnar mucin-filled endocervical cells with basal nuclei

Effects of Estrogen and Progesterone

The cervical mucus is subject to profound cyclic changes. Under estrogenic stimulation, the endocervical secretions are profuse, watery, and alkaline, facilitating sperm penetration. During the postovulatory phase, secretions are scant, thick, and acid, containing numerous leukocytes and act as a barrier to sperm penetration. Endocervical secretory activity operates by both the apocrine and the merocrine type of expulsion of secretory products [24]. In the former, a portion of apical cytoplasm packed with secretory granules is detached whereas, in the latter, secretory products are released from apical granules through pore-like openings of the surface cytoplasmic membrane.

Langerhans Cells and Lymphoid-Derived Cells

Mucosal immunity is an important component of the host's defense mechanism against viral and bacterial pathogens. Components of the secretory (IgA antibody mediated), humoral (IgG antibody mediated) as well as the cellular immune systems are present in the cervix. A variety of lymphocyte and dendritic macrophage subsets are present in both the epithelium of the exo- and endocervix as well as the subepithelial stroma [68]. Dendritic cells include both mature and immature forms. They are primarily

Fig. 4.9

Endocervical mucosa. When endocervical cells engage in apocrine secretion, portions of atypical cytoplasm are expelled

responsible for antigen recognition and the earliest stage of cellular immune response.

Large numbers of T lymphocytes are also present in the cervix under normalConditions [47]. CD3+ T lymphocytes are concentrated in a band directly beneath both the squamous epithelium of the exocervix and the columnar epithelium of the endocervix [47, 72]. These cells are predominately cytotoxic T-lymphocytes (e.g., CD8+), although helper T lymphocytes (e.g., CD4+) are also present. Variable numbers of B lymphocytes and plasma cells are also found in the lamina propria of the cervix [47]. Because the presence of lymphocytes as well as lymphoid follicles (\bigcirc *Fig.* 4.10) is a normal finding in the cervix, the diagnosis of chronic cervicitis should be reserved for specimens showing a marked infiltration of lymphocytes.

The Transformation Zone

The squamocolumnar junction of the cervix is defined as the border between the stratified squamous epithelium and the mucin-secreting columnar epithelium of the

■ Fig. 4.10 Lymphoid follicles. Occasional lymphoid follicles can be seen in the cervical stroma in the absence of cervicitis

endocervix. Morphogenetically, there are two different squamocolumnar junctions (\bigcirc *Fig. 4.11*). One is termed the *original* squamocolumnar junction and is the site at which the native squamous epithelium of the exocervix abuts the endocervical columnar epithelium at the time of birth. At birth, most newborns have some mucinsecreting columnar endocervical epithelium present on the exocervix, which forms an *ectropion* or cervical *ectopy*. The exact location of the original squamocolumnar junction and, therefore, the amount of endocervical ectopy present at birth depends on the extent of inward migration of squamous epithelium from the lower third of the vagina.

At about the age of 1 year, the cervix begins to elongate. This results in the migration of the squamocolumnar junction toward the external os. This migration is frequently incomplete. Hormonal and other physical factors influence the size and distribution of the cervical ectopy by altering the shape and volume of the cervical lips. At the time of menarche or during pregnancy both the uterus and the cervix enlarge. Enlargement of the cervix is accompanied by alterations in its shape, which result in more of an "eversion" or rolling outward of endocervical columnar epithelium onto the portio (\bigcirc *Fig.* 4.11). As a result, in most women during the reproductive period, cervical ectopy is present, and the size of the ectopy is most

Fig. 4.11

The transformation zone. Schematic representation of original and functional squamocolumnar junctions and three basic types of portios. *Left*: Diagram of a portio completely covered with native squamous epithelium. The squamocolumnar junction is at the external os. *Middle*: Denotes cervical ectopy, with the squamocolumnar junction being located on the exocervix below the external os. *Right*: Indicates areas of cervical ectopy that have become covered with squamous epithelium. This area is the cervical transformation zone. The new, or functional, squamocolumnar junction of the transformation zone is at the external os. S, squamous epithelium; C, endocervical columnar epithelium; I, uterine isthmus extensive in women under 20 years of age and following the first pregnancy. When viewed with the naked eye, the endocervical mucosa appears as a red, velvety zone, sharply contrasting with the neighboring pink, translucent squamous portio epithelium (\triangleright *Fig. 4.12a*).

Over time, the columnar epithelium that composes the cervical ectopy is remodeled and replaced by metaplastic squamous epithelium. As this occurs, the histological squamocolumnar junction moves toward the exocervical os. This newly formed squamocolumnar junction is called the physiologic, functional, or new squamocolumnar junction. While the original squamocolumnar junction is usually quite abrupt, the junction between the columnar and squamous epithelium at the physiologic or functional squamocolumnar junction can be either abrupt or gradual (**)** Fig. 4.12b). The region between the original squamocolumnar junction and the postpubertal functional squamocolumnar junction is termed the transformation zone. The transformation zone is histologically characterized by the presence of metaplastic epithelium (see section **S**quamous Metaplasia).

The concept of the transformation zone is extremely important for understanding the pathogenesis of squamous cell carcinomas of the cervix and its precursors, since virtually all cervical squamous neoplasia begins at the new squamocolumnar junction and because the extension and limits of cervical cancer precursors coincide with the distribution of the transformation zone. It is also important to remember that during the childbearing years and during pregnancy, the transformation zone is located, in almost all instances, on the exposed portion of the cervix. Consequently, the vast majority of cervical neoplasias can be removed for histologic diagnosis by punch biopsy. Movement of the functional squamocolumnar junction continues throughout the reproductive years. Therefore, in older and postmenopausal women, the functional squamocolumnar junction is nearly always located within the external os (> Fig. 4.12c).

Pregnancy and Puerperium

The morphologic alterations that occur in the antepartum or postpartum cervix are not pathognomonic of pregnancy or parturition but are seen more commonly at these times than in the nonpregnant postpartum state. They are related to the stimulatory effects of elevated steroid hormones. The spongy enlargement of the pregnant cervix is caused by increased vascularity and edema of the stroma accompanied by acute inflammation. The massive destruction of collagen fibers and accumulation

Fig. 4.12

The transformation zone. Colpophotographs of endocervical eversion of the transformation zone. (a) Endocervical mucosa is everted on both the anterior and the posterior lip and surrounds the anatomic external os. The original squamocolumnar junction (SCJ) is on the portio of the cervix (*arrows*). (b) Squamous metaplasia is occurring and the new SCJ (*arrows*) is now internal to the original SCJ. The area between the original and new SCJ is the transformation zone. (c) The transformation zone is completely mature and the SCJ is inside the endocervical canal. Residual endocervical gland mouths are present (*arrows*)

of extracellular glycoprotein ground substance before labor result in cervical softening and effacement, facilitating dilation of the cervix to about 10 cm during labor. Gestational cervical mucus is thick, tenacious, rich in leukocytes, and forms a mucous plug that obliterates the cervical canal, sealing the endometrial cavity from the vagina and thus preventing bacterial invasion. Squamous metaplasia and lobules of tightly packed small endocervical glandular units, forming polypoid protrusions into the canal are often seen.

Pseudodecidual Reaction

Pseudodecidualization of the stroma, either patchy or diffuse, occurs in about one-third of the cervices examined
histologically and disappears by 2 months postpartum [49]. It is presumably mediated by the high levels of progesterone during pregnancy. The appearance of pseudodecidualized cervical is identical to decidualized stroma at other sites. The cells develop abundant pink cytoplasm, with well-defined cellular borders (\bigcirc *Fig. 4.13a, b*).

Arias-Stella Reaction

During pregnancy, the gestational Arias-Stella reaction can develop in both endocervical glands and in ectopic endometrial glands within the cervix. In one study of 191 gravid hysterectomy specimens, an Arias-Stella reaction of endocervical glands was seen, at least focally, in 9% of the cases [85]. The Arias-Stella reaction of the endocervix is usually focal and is more commonly present in the proximal portion of the endocervix involving superficial as opposed to deeply situated glands. Microscopically, the Arias-Stella reaction that occurs in the endocervical glands during pregnancy is identical to that which occurs in the endometrium. The cells within the affected glands are markedly enlarged with irregular, frequently hyperchromatic nuclei that can project into the glandular lumen in a hobnail pattern. The cells are pseudostratified and have hypersecretory cytoplasmic features with abundant vacuolated cytoplasm (> Fig. 4.14). Papillary processes with fibrovascular cores, lined by enlarged epithelial cells can project into the endocervical gland lumen.

The Arias-Stella reaction can occasionally be mistaken for clear cell carcinoma or adenocarcinoma in situ of the cervix. Differentiation from clear cell carcinoma is made by the lack of a mass lesion and clear-cut stromal invasion as well as by the absence of the classic tubular and papillary areas typical of clear cell carcinoma. The cells in adenocarcinoma in situ have more uniform nuclei and less cytoplasmic vacuolization. The Arias-Stella reaction lacks mitotic activity, whereas both clear cell carcinoma and adenocarcinoma in situ are mitotically active. Because of the possibility of confusing Arias-Stella reaction with clear cell carcinoma or adenocarcinoma in situ, the diagnosis of the later two entities should be made with caution in the pregnant patient.

Metaplasia

Squamous Metaplasia

Metaplasia is defined as the replacement of one type of mature tissue by another equally mature type of tissue. In

Fig. 4.13

Pseudodecidual reaction. A pseudodecidual reaction of cervical stromal cells can occur during pregnancy. (a) In this case, the pseudodecidual reaction forms a discrete nodule. (b) The decidualized stromal cells are identical with gestational decidual cells of the endometrium

the cervix, squamous metaplasia is the replacement of the mucin-producing columnar epithelium by stratified squamous epithelium and appears to occur by two different mechanisms (\bigcirc *Fig. 4.15*). One mechanism consists of direct ingrowth from the native portio epithelium

Arias-Stella reaction. The Arias-Stella reaction should not be confused with clear cell adenocarcinoma of the cervix

Fig. 4.15

Squamous metaplasia. There are two histogenic mechanisms by which the endocervical mucosa is replaced by squamous epithelium. The first is the direct ingrowth of squamous epithelium from the portio, which is referred to as squamous epithelialization (*top*). The other is through proliferation of subcolumnar reserve cells and their subsequent maturation into a squamous epithelium, which is called squamous metaplasia (*bottom*). Both result in a mature squamous epithelium overlying endocervical mucus-producing glands (*right*)

bordering the columnar epithelium, a process frequently referred to as "squamous epithelialization." The second mechanism involves a proliferation of undifferentiated subcolumnar reserve cells of the endocervical epithelium, which differentiate into squamous epithelium. This process has been termed *squamous metaplasia*.

During squamous epithelialization, tongues of native squamous epithelium of the portio grow beneath the adjacent columnar epithelium and expand between the mucinous epithelium and its basement membrane. As the squamous cells expand and mature, the endocervical cells are gradually displaced upward, degenerate, and eventually are sloughed (> Fig. 4.16). The progression of squamous transformation of the endocervical ectropion has been hypothesized to be primarily dependent on local (vaginal) environmental factors initiated by the low (acid) pH of the vagina after puberty [16]. Trauma, chronic irritation, or cervical infection also play a role in development and maturation of the transformation zone by stimulating repair and remodeling; eventually the ectocervix is covered by a protective surface of mature squamous epithelium (**>** Fig. 4.17). The process of squamous epithelialization is thought to be responsible for the obliteration of the outer two-thirds of endocervical ectopy. Rapid squamous re-epithelialization of the columnar epithelium of the transformation zone may also be produced iatrogenically by electrocautery, cryosurgery or laser surgery.

The second mechanism involved in replacement of columnar epithelium by a squamous epithelium and the function of the transformation zone is squamous metaplasia. The first stage of squamous metaplasia is the appearance of small cuboidal cells beneath the columnar mucinous epithelium, the so-called subcolumnar reserve

• Fig. 4.17 Mature transformation zone. Mature squamous epithelium covers the underlying endocervical glands that are distended with mucin

Fig. 4.18 Reserve cell hyperplasia. Reserve cells are seen under the columnar epithelium

cells (**)** Fig. 4.18). Reserve cells have large, uniformly shaped, round nuclei with faintly granular chromatin and occasional aggregates of chromatin (i.e., chromocenters of reserve cells). The cell borders are poorly defined and the cells have only scant amounts of cytoplasm. The origin of subcolumnar reserve cells is controversial. Some investigators suggest a direct derivation from columnar mucinous secretory cells, whereas others favor an origin from the basal cells of the squamous portio epithelium, embryonal rests of urogenital origin, or stromal cells as possible sources.

Progressive growth and stratification of reserve cells (subcolumnar reserve cell hyperplasia), followed by the differentiation into immature squamous metaplasia followed by an additional maturation, result in the formation of a fully mature squamous epithelium indistinguishable from the native portio epithelium (> Figs. 4.19a-c and **2** 4.20). Immature squamous metaplastic epithelium is distinguished from its mature counterpart by a lack of surface maturation and inconspicuous intracytoplasmic glycogen. It is, characteristically, sharply demarcated from the native portio epithelium by a perpendicular or oblique line to the surface. As a result, the uninitiated observer may mistake immature squamous metaplasia for a squamous intraepithelial lesion (SIL), particularly when the process also involves the underlying glands. In contrast to neoplastic epithelium, the immature squamous metaplastic

epithelium maintains cell organization and cohesion, nuclear atypia is absent and, frequently, a single row of endocervical cells overlies the squamous cells. Biochemically and immunohistochemically, immature squamous metaplasia shares features of both the mature squamous epithelium and the columnar mucinous epithelium.

Tubal Metaplasia

Tubal metaplasia refers to endocervical glands that are lined by a Mullerian-type epithelium that closely resembles that of the fallopian tube. In pure tubal metaplasia, the endocervical glands are lined by an epithelium that more closely resembles that of the fallopian tube and contains many more ciliated cells than are normally present in the endocervical epithelium as well as tubal type secretory cells and reserve or intercalary cells (**)** *Fig. 4.21a, b*) [50, 74, 96]. Tubal metaplasia can be found in up to 31% of patients and does not appear to be related to the phase of menstrual cycle, the presence of inflammatory changes, or low-grade SIL (CIN 1) [50].

Tubal metaplasia can be quite extensive and can occasionally be mistaken for endocervical glandular neoplasia. However, the bland cytological features, lack of mitotic activity, and prominent cilia seen at the apical surfaces of tubal metaplasia usually allow it to be differentiated

Squamous metaplasia. (a) Reserve cells proliferate and are stratified under the columnar epithelium. (b) Columnar differentiation is lost, resulting in a multilayered squamous epithelium composed of immature metaplastic cells. Note occasional mucinous endocervical cells at the surface. (c) The immature metaplastic epithelium begins to differentiate

from a neoplastic lesion. Other features that can aid in distinguishing between tubal metaplasia and glandular neoplasia are the location and shape of the glands and the surrounding stroma. Glands demonstrating tubal metaplasia are typically confined to the superficial third of the cervical wall (i.e., they extend less than 7 mm into the cervical stroma) and typically show only slight variation in size and shape. Moreover, the stromasurrounding glands involved by tubal metaplasia is usually normal appearing and is neither desmoplastic nor edematous appearing. Cases of tubal metaplasia demonstrating glandular architectural abnormalities or hypercellularity of the adjacent stroma can present diagnostic difficulties [76].

Atypical tubal metaplasia is a form of tubal metaplasia in which the glands are lined by ciliated and nonciliated cells that are crowded and have larger, more hyperchromatic nuclei than that observed in typical tubal metaplasia (> Fig. 4.22). The cells of atypical tubal metaplasia are frequently pseudostratified. Atypical tubal metaplasia frequently presents a diagnostic problem since it histologically can be confused with adenocarcinoma in situ. Differentiation from adenocarcinoma in situ is based on a lack of significant mitotic activity, the absence of architectural abnormalities such as cribiforming and papillary projections, and the failure of cells to stain for p16^{ink}. However, one should be cautioned that atypical tubal metaplasia can occur in association with adenocarcinoma in situ of the cervix, including both tubal and non-tubal types (> Chap. 5, Precancerous Lesions of the Cervix).

Tubo-Endometrioid Metaplasia

Tubo-endometrioid metaplasia of the cervix is a type of metaplasia that is histologically similar to the tubal metaplasia that can develop in the endometrium in patients with unopposed estrogenic stimulation. Endocervical glands demonstrating tubo-endometrioid metaplasia are lined by a pseudostratified epithelium composed of columnar cells with a high nuclear:cytoplasmic ratio (\bigcirc *Fig. 4.23*).

Fig. 4.20

Transformation zone epithelium. On the *left*, the native portio epithelium is present with full maturation. On the *right*, metaplastic squamous epithelium is present. Note the sharp boundary. Metaplasia has extended into the endocervical crypts and completely replaced the columnar epithelium Many of these cells are ciliated or have secretory features with apical snouts, but the glands lack an associated endometrial stroma. Tubo-endometrioid metaplasia occurs commonly after cervical conization and has been interpreted as a form of aberrant differentiation following cervical injury [46]. Because of the pseudostratification and high nuclear:cytoplasmic ratio, these glands can be misinterpreted as representing adenocarcinoma in situ. As with tubal metaplasia, the features that indicate a metaplastic, as opposed to a neoplastic, process are the location and shape of the glands and lack of a desmoplastic or edematous stromal response.

h

Fig. 4.21

Tubal metaplasia. (a) The columnar, mucus-producing epithelium has been replaced by a tubal type epithelium with ciliated, secretory and intercalated cells. (b) At higher magnification the resemblance to the epithelium of the fallopian tube is obvious

Atypical tubal metaplasia. The epithelium is more crowded and pseudostratified than in typical tubal metaplasia. The cells have larger, hyperchromatic nuclei. Ciliated cells are present, but mitotic figures are uncommonly seen

Transitional Cell Metaplasia

Transitional cell metaplasia refers to a controversial type of metaplasia in which the surface of the cervix and endocervical crypts is lined by an epithelium that is interpreted by some to resemble a hyperplastic urothelium [19, 20, 51, 98]. By definition, the epithelium has a "disordered" appearance that is comprised of over ten layers of cells that have oval- to spindle-shaped nuclei and are oriented vertically in the deeper layers (\bigcirc *Fig. 4.24*). The cells of the superficial layer often resemble the umbrella cells of the normal urothelium and have horizontally oriented nuclei.

The controversy surrounding transitional cell metaplasia revolves around whether it represents a unique histopathological entity that has a specific biology or whether it simply represents a biologically insignificant histological variation of other well-described histological entities. Almost all of the reported examples of transitional cell metaplasia have been identified in postmenopausal women. In the two largest series, the mean ages of women with the lesion were 60 and 67.8 years [20, 98]. Some of these women have had previous abnormal Papanicolaou smears, and it has been suggested that some of the cases may represent atrophic high-grade SIL [62]. In addition to arising in the transformation zone, transitional cell metaplasia can also be identified in the exocervix and the vagina [98]. This suggests that in some cases, transitional cell metaplasia may simply represent

Fig. 4.23

Tubo-endometrioid metaplasia. Typical endocervical epithelium on the *left*. On the *right* columnar, mucusproducing epithelium has been replaced by pseudostratified epithelium with high nuclear: cytoplasmic ratios

Transitional cell metaplasia. The squamous epithelium in this postmenopausal patient is more than ten layers thick and is disorganized. This type of change is referred to by some as "transitional cell metaplasia"

a histological variant of atrophy, either of the original squamous epithelium or of a fully mature metaplastic squamous epithelium, in which the number of cell layers is not reduced. Immunohistochemical studies using cytokeratin antibodies have shown that foci of transitional cell metaplasia express cytokeratins 13, 17, and 18, which are expressed in normal urothelium but do not express cytokeratin 20 and the asymmetric unit membrane that are related to urothelial differentiation [39].

Inflammatory Diseases

Cervicitis can be divided into two categories, based on whether the etiology of the disorder is noninfectious or infectious. Whatever the etiology, the tissue response of the cervix to injury is limited and reflects the basic mechanisms of inflammation and repair. Two types of morphologic changes, however, that are often encountered in association with a variety of inflammatory diseases deserve specific attention. These are atypia of repair and hyperkeratosis and parakeratosis.

Atypia of Repair

In cases of severe, acute, long-standing chronic inflammation or infection with epithelial injury of any kind -

true erosion, biopsy, or conization - the squamous and endocervical epithelia undergo reactive changes characterized by epithelial disorganization and nuclear atypia. These changes are often confused, histologically and cytologically, with high-grade squamous intraepithelial lesions (HSIL). In reactive squamous atypia, the cytoplasmic membrane is well defined, the nuclei are uniform in shape and size, and the chromatin is aggregated in prominent aggregates or clumps (**)** Fig. 4.25a, b). The epithelium is often infiltrated with migrating inflammatory cells. Mitotic figures are normal and are confined to the proliferative basal and parabasal cell populations. Characteristically, the cells in the upper half of the epithelium are normal, and maturation occurs in an orderly fashion.

When reparative changes affect endocervical columnar cells, the morphological alterations include nuclear enlargement and hyperchromasia with irregularity of nuclear size and shape and smudgy chromatin. There can also be cytoplasmic eosinophilia and loss of mucinous droplets (> Fig. 4.26a, b). The combination of endocervical cell

Fig. 4.25

Squamous reparative atypia. (a) When reparative changes develop in mature squamous epithelium, there is usually basal cell hyperplasia that involves the lower one-third of the epithelium. The nuclei contain prominent chromocenters but lack nuclear abnormalities associated with neoplasia. Intermediate and superficial epithelial cells continue to show maturation but often develop perinuclear halos and some degree of nuclear enlargement. However, the superficial cells lack the nuclear atypia characteristic of HPV-infected cells. (b) When reparative changes develop in immature metaplastic squamous epithelium, the epithelium exhibits intercellular edema, and acute and chronic inflammatory cells often infiltrate both the epithelium and stroma. The nuclei of the metaplastic cells become hyperchromatic and enlarged and typically have prominent chromocenters. Microabsesses are frequently seen

Endocervical reparative atypia. The endocervical epithelium develops nuclear enlargement, mitosis, microabscesses, and inconspicuous intracellular mucus. Note the diffuse distribution of nuclear chromatin, the cytoplasmic eosinophilia, and the absence of abnormal mitoses, features distinguishing endocervical atypia of inflammation from in situ adenocarcinoma of the cervix

enlargement with dense, eosinophilic, focally vacuolated cytoplasm and varying degrees of nuclear atypia has been referred to as "atypical oxyphilic metaplasia." Although this type of glandular epithelium appears atypical, the changes are focal, alternating with normal mucinous columnar cells, and are confined to areas with inflammation or mucosal injury. In addition, the deep cytoplasmic eosinophilia, when it is present, and the absence of abnormal mitoses are features that distinguish the inflammatory lesions from an in situ adenocarcinoma of the endocervix (AIS). In both squamous and endocervical cell atypia of repair, immunostaining for p16^{ink} is uniformly negative. The use of the antibody is of great help for distinguishing HSIL and AIS from their mimic, for example, epithelial atypia of repair () Chap. 5, Precancerous Lesions of the Cervix). Occasionally, when there is an endocervical inflammation, the stroma becomes filled with chronic inflammatory cells and this results in the endocervix taking on a papillary configuration (**>** *Fig. 4.27*).

Radiation-Induced Atypia

Treatment of the cervix with therapeutic levels of radiation can cause morphological changes in both the squamous

• Fig. 4.27 Papillary endocervical reparative change. The marked inflammation of the stroma results in the endocervical epithelium being raised into papillary projections

and glandular epithelium. The atypical squamous cells that develop post radiation have nuclear enlargement and can be multinucleated. The cells can have abundant amounts of vacuolated cytoplasm and are usually detected in cervical cytological preparations. Radiation-induced changes in the endocervical glandular epithelium include cellular enlargement, a loss of polarity of nuclei, dense eosinophilic, enlarged nucleoli that can be multiple [66]. The stroma in women who have received therapeutic radiation is frequently fibrotic, often with hyalinization. Blood vessels often have an intimal hyaline thickening and can be totally occluded. "Radiation fibroblasts" are usually not present [66]. These morphological changes can exist up to 17 years after the radiation therapy.

Hyperkeratosis and Parakeratosis

Hyperkeratosis and parakeratosis can be detected cytologically in up to 8% of all women undergoing routine Pap smear screening [48]. Both hyperkeratosis and parakeratosis have the gross appearance of a thickened, white epithelium and can be either focal or diffuse. When diffuse, the entire portio is covered by a thickened, white, and wrinkled epithelial membrane. When focal, a slightly raised white plaque is present. The etiology of cervical hyperkeratosis is poorly understood, but in some cases it appears to be related to chronic irritation. For example, 172

most patients with diffuse hyperkeratosis have prolapsed uteri. Focal areas of hyperkeratosis can be associated with a local chronic irritation, such as that seen in women who wear a diaphragm or pessary and in women with cervical neoplasia. However, in most cases there is no known cause.

Microscopically, the whitish plaque corresponds to the presence of a thick keratin layer (hyperkeratosis), which may or may not contain pyknotic nuclei (parakeratosis) (\bigcirc *Figs.* 4.28 and \bigcirc 4.29). The epithelium is often acanthotic and has a well-developed granular layer, prominent intercellular bridges and elongated rete pegs. Characteristically, the epithelial cells contain sparse glycogen, but cytological atypia is absent. Frequently, there is epithelial hyperplasia and chronic inflammation. Mature squamous metaplasia is often associated with parakeratosis.

Although there is neither morphological nor clinical evidence that parakeratosis represents precursor lesions to cervical neoplasia, both hyperkeratosis and parakeratosis can occur in association with HSIL and invasive cervical cancer. Because of this association, some experts have suggested that all women with otherwise negative Pap smears but demonstrating these findings need colposcopy. However, several studies have reported that less than 4% of women with hyperkeratosis or parakeratosis without nuclear atypia on an otherwise negative Pap smear had SIL

Fig. 4.28

Hyperkeratosis of the cervix. A superficial layer of anucleated, keratinized squamous cells, which is frequently accompanied by a thickened granular layer is present and that in all instances the SIL was low grade. This suggests that the routine colposcopic evaluation is unnecessary in such women [48]. It should be emphasized, however, that since hyperkeratosis may occasionally overlie HSIL and invasive carcinomas, all grossly visible white plaques on the portio vaginalis or vaginal epithelium should be biopsied.

Noninfectious Cervicitis

Noninfectious cervicitis is, for the most part, chemical or mechanical in nature, and the inflammatory response is nonspecific. Common causes include chemical irritation secondary to douching or local trauma produced by foreign bodies, including tampons, diaphragms, pessaries, and intrauterine contraceptive devices. Surgical instrumentation and therapeutic intervention are common iatrogenic causes of cervical tissue injury and inflammation. Stromal edema, vascular congestion, and neutrophilic infiltration of the stroma and epithelium characterize

Fig. 4.29

Parakeratosis of the cervix. Pyknotic nuclei are retained in the superficial cell layer. Parakeratosis is frequently accompanied by hyperkeratosis acute cervicitis. Clinically, the cervix appears swollen, erythematous and friable, and there may be an associated purulent endocervical discharge. Prolonged or severe acute inflammation eventually leads to degenerative changes in the epithelial surface, loss of endocervical secretory activity, and ulceration.

In chronic cervicitis, round cells, including lymphocytes, plasma cells, and histiocytes, predominate in the inflammatory infiltrate and are associated with varying amounts of granulation tissue and stromal fibrosis. The diagnosis of chronic cervicitis should be reserved for cases where there is definite clinical and histological evidence of a significant chronic inflammatory process. Otherwise, a histological diagnosis based on the presence of scattered lymphocytes has no clinical significance and is meaningless. Occasionally, lymphoid follicles with germinal centers are found beneath the epithelium in noninfectious cervicitis (\bigcirc *Fig. 4.30*). The presence of lymphoid follicles beneath the cervical epithelium is frequently referred to as *follicular cervicitis*. In some instances, the lymphoid inflammatory reactions may produce lymphoma-like lesions, raising the question of lymphoma (see below).

Infectious Cervicitis

◆ Table 4.2 summarizes some of the important or pathologically significant etiologic organisms of infectious cervicitis. It is apparent from this listing that infectious cervicitis is important because of its epidemic proportions and because of its central role in the pathogenesis of pelvic inflammatory disease and endometrial infections. According to the understanding of the pathogenesis of pelvic inflammatory disease, infectious cervicitis is the initial event of the pelvic inflammatory disease. It is also the primary infectious focus in related syndromes such as postpartum and postabortal endometritis. Spontaneous abortion, premature delivery, chorioamnionitis, stillbirth, and neonatal pneumonia and septicemia have been directly related to concurrent bacterial infectious cervicitis

Fig. 4.30

Chronic cervicitis. A subepithelial lymphoid follicle with a prominent germinal center is present. When lymphoid follicles are numerous, the condition is referred to as *follicular cervicitis*

Table 4.2

Microorganisms causing infectious cervicitis

Bacteria, chlamydia, mycobacteria, polymicrobial, endogenous vaginal aerobes and anaerobes
Chlamydia trachomatis
Neisseria gonorrhoeae
Mycoplasma hominis
Group B Streptococcus
Ureaplasma ureolyticum
Gardnerella vaginalis
Actinomyces israelii
Mycobacterium tuberculosis
Treponema pallidum
Viruses
Herpes simplex virus
Human papillomavirus
Fungi
Candida
Aspergillus
Protozoa and parasites
Trichomonas vaginalis
Ameba
Schistosomes

can be clinically important since it can act as a source of sexual transmission to male partners, as well as ascending infection in the female, and vertical transmission during pregnancy.

Infectious cervicitis can affect either the endocervicaltype columnar epithelium producing *endocervicitis* (mucopurulent cervicitis) or affect the stratified squamous epithelium of the exocervix producing *exocervicitis* [42]. The infectious agents that cause endo- and exocervicitis tend to differ, although some agents can cause both.

Bacterial and Chlamydial Cervicitis

Bacterial and chlamydial infections of the cervix are the most common cause of infectious cervicitis and are associated with a nonspecific inflammatory response. The columnar epithelium of the endocervix is much more susceptible to bacterial and chlamydial infections than is the surrounding squamous epithelium, and endocervicitis is characteristic. The infectious agents that most commonly cause clinically significant endocervicitis are *Chlamydia trachomatis* and *Neisseria gonorrhoea*. Infection with either of these two agents requires no predisposing factors and is primarily dependent on exposure and size of the inoculum.

Histologically, follicular cervicitis is frequently found in patients with *chlamydia trachomatis* infection, and *chlamydia trachomatis* is now presumed to be a major cause of this condition in younger women. *Chlamydia trachomatis* cervicitis has also been associated with a dense, diffuse inflammatory exudate as well as reactive squamous and endocervical atypia [17].

Actinomycosis

Actinomyces israelii is a frequent commensual organism found in the female lower genital tract. Culture and immunofluorescence studies of cervical and vaginal secretions indicate that 3–27% of asymptomatic women without obvious risk factors are infected with Actinomyces israelii [67]. Aggregates of bacteria with the morphological appearance of actinomyces have been reported to occur in approximately 0.13% of all Papanicolaou smears [78]. The organism is more commonly identified in women wearing intrauterine devices (IUDs) than in women in the general population, and detection is related to the length of time that the IUD has been in place [18, 67, 78]. Structures resembling the "sulfur granules" observed in Actinomyces israelii infections are sometimes identified in endocervical curettings of asymptomatic women. In the majority of cases these are "pseudoactinomycotic radiate granules," which are nonspecific collections of bacteria or foreign material (e.g., fragments from nylon strings of IUD), glycoproteins, and lipids rather than actual collections of *Actinomyces israelii* [9].

The identification of *Actinomyces israelii* in asymptomatic women has little clinical significance and does not warrant antibiotic therapy [67]. Rarely *Actinomyces israelii* can be associated with pelvic abscesses.

Tuberculosis

Tuberculosis of the cervix is almost invariably secondary to tuberculous salpingitis and endometritis and is typically associated with pulmonary tuberculosis (> Chap. 7, Benign Diseases of the Endometrium, O Chap. 11, Diseases of the Fallopian Tube and Paratubal Region). The prevalence of cervical tuberculosis in a population with genital tuberculosis varies between 2% and 82% [4]. Macroscopically, the cervix may appear normal, inflamed, or may simulate invasive carcinoma. Histologically, tuberculous infection of the cervix is recognized by the presence of multiple granulomas or tubercles, characterized by central caseous necrosis, epithelioid histiocytes, and multinucleated Langhans giant cells. Granulomas typically disappear after successful anti-tubercular therapy [4]. Tuberculous cervicitis may appear as a noncaseating, granulomatous lesion. Since caseating, nontuberculous granulomas due to lymphogranuloma venereum or sarcoidosis may be encountered in the cervix, the unequivocal diagnosis of tuberculous cervicitis requires demonstration of acidfast Mycobacterium tuberculosis, a straight, rod-shaped bacillus, by Ziehl-Neelsen-stained sections, or by culture [22]. Because culture yields far better results than staining of tissue sections, unfixed biopsy material should be obtained for microbiologic testing whenever tuberculosis is suspected. The most common granulomatous lesions to be distinguished from tuberculous cervicitis include foreign body giant cell granulomas secondary to sutures, crystals, or cotton, lymphogranuloma venereum, schistosomiasis, and sarcoidosis. Cervical granuloma may occasionally develop after a biopsy or operation as a reaction to local tissue necrosis [22].

Other Granulomatous Infections

Certain venereally transmitted diseases commonly encountered in the vulva may also involve the cervix

(Ohap. 1, Benign Diseases of the Vulva). These include syphilis, either as the primary chancre, secondary mucous patches, or tertiary gumma, lymphogranuloma venereum, granuloma inguinale, and chancroid. All these conditions may resemble carcinoma clinically. This is particularly a problem with granuloma inguinale that is endemic in areas of Africa that have high prevalence of invasive cervical cancer. Up to 50% of women with granuloma inguinale may be initially misdiagnosed as having carcinoma of the cervix. Many of these women are thought to have high stage tumors because of the spread of the infection to the parametrial tissue [43]. In addition to the characteristic morphologic features, specific bacteriologic and immunologic techniques are available for identifying each of these diseases.

Viral Diseases

In contrast to bacterial infections of the cervix, the most common cervical viral infections – human papillomavirus (HPV) and herpes simplex virus (HSV) – have a predilection for the squamous epithelium and produce characteristic morphologic changes. Cytomegalovirus, although often isolated from cervical secretions, is not typically associated with cervicitis, and its role in cervical infection is poorly understood.

Herpesvirus Infection (HSV)

Although the precise prevalence of cervical HSV infection (herpes genitalis) is not known, it is far greater than generally recognized. At least 50 million individuals in the USA have genital HSV infection [100]. Up to 70% of HSV-2 infections appear to be asymptomatic. Both HSV-1 and HSV-2 can cause genital herpes and in some populations, HSV-1 is more common or the cause of initial herpes infection than is HSV-2 [100]. However, HSV-2 is responsible for the majority of cases of recurrent HSV. Cervical involvement can be detected in 70-90% of women with primary genital HSV-2 infections. Occasionally, in women with cervical involvement, the ulceronecrotic process is so extensive that a fungating, necrotic mass appears on the cervical portio, which can be mistaken for carcinoma. During the vesicular phase of a cervical lesion, a biopsy may reveal the presence of suprabasal intraepidermal vesicles filled with serum, degenerated epidermal cells, and multinucleated giant cells, some containing eosinophilic, intranuclear inclusions surrounded by a clear halo (> Fig. 4.31).

Fig. 4.31

Herpetic cervicitis. Suprabasal vesicle in squamous epithelium of the portio. A multinucleated squamous cell with a ground-glass intranuclear viral inclusion is present in the *lower right*

Herpes-Like Lesions

Vesicular and bullous lesions of the cervical squamous mucous membrane, other than herpetic cervicitis, have been reported [11]. Pemphigus vulgaris of the cervix is a common finding in women with generalized disease [56]. Microscopically, there are multiple intraepithelial bullae in a suprabasal location containing the characteristic acantholytic Tzanck cells.

Human Papillomavirus (HPV)

Exophytic condyloma acuminata are one of the common manifestations of human papillomavirus type infection of the lower anogenital tract and are usually caused by HPV type 6 and less frequently type 11 [95]. When florid condylomas of the vulva are identified, multicentric disease can occur and internal vaginal or cervical exophytic condylomas can be occasionally identified. Exophytic condylomas of the cervix without vulvovaginal involvement are rare. They are commonly multifocal and may involve the mature squamous epithelium of the native cervical portio as well as the immature squamous epithelium of the transformation zone, including metaplastic squamous epithelium, replacing endocervical glands. Extension into the endocervical canal may occur. Grossly and colposcopically, condyloma accuminata appear white, and the degree of whiteness depends largely on the thickness of the associated surface hyperkeratosis (**)** Fig. 4.32). Other configurations of cervical exophytic

• Fig. 4.32 Exophytic condyloma acuminata. The lesions are multifocal and form raised white projections on both the vagina and cervix

condylomas include myriad of minute, maculopapular, only slightly raised, condylomas involving the vagina and the cervix.

Microscopically, the histological features of exophytic cervical condyloma acuminata include architectural alterations such as papillomatosis, acanthosis, parakeratosis, and hyperkeratosis as well as cytologic alterations including koilocytosis (manifested by perinuclear cytoplasmic cavitation), nuclear enlargement and atypia. Multinucleation is also frequently observed (**>** *Fig. 4.33*) (**>** Chap. 1, Benign Diseases of the Vulva, **>** Chap. 5, Precancerous Lesions of the Cervix).

The natural history of exophytic cervical condyloma accuminata is one of the spontaneous regressions, good response to conservative therapy, unpredictable recurrence, and sometimes persistence. Lesion regression or apparent cure following biopsy is fairly common. The natural history of genital condylomata in general may be modified by host factors, notably immunosuppression and steroid hormone levels.

Fungal Diseases

Cervical fungal infection by *Candida albicans* usually occurs as part of a generalized lower genital tract infection

■ Fig. 4.33 Exophytic condyloma acuminata. The classic histological features are papillomatosis with acanthosis, parakeratosis, hyperkeratosis, as well as cytological alterations including multinucleation, koilocytosis and nuclear atypia

involving the vagina and vulva. Antibiotic therapy, poorly controlled diabetes mellitus, and immunosuppression all favor fungal overgrowth [93]. Cervical candidal infections can be associated with increased numbers of polymorpholeukocytes present in the upper layers of the epithelium and fungal hyphae that can be identified by periodic acid-Schiff (PAS) stains, both at the surface of the epithelium and within the superficial layers of the epithelium.

Protozoal and Parasitic Diseases

Cervical infestation by *Trichomonas vaginalis* is quite frequent and most often associated with concurrent trichomonal vaginitis. Acute trichomonal cervicitis may provoke an intense inflammatory response with prominent reparative atypia in exfoliated squamous and endocervical cells, with corresponding gross and colposcopic abnormalities.

Rare instances of parasitic infestations such as echinococcosis or hydatid cysts, Chagas' disease, and ulceronecrotic amebiasis have been encountered in the cervix [15]. In contrast, schistosomiasis (bilharziasis) of the cervix, generally caused by *Schistosoma mansoni*, is very common in Africa (Egypt), South America, Puerto Rico, and several Asian countries [81]. A large number of cases of cervical schistosomiasis are associated with urinary schistosomiasis and sterility. Microscopically, noncaseating granulomas (pseudotubercles) with ova surrounded by multinucleated giant cells are seen and the ova are often calcified (**)** *Fig. 4.34*). *S. mansoni* has a long lateral spine, whereas *S. haematobium* has a short spine extending from one of its poles. Cervical schistosomiasis may be associated with extensive pseudoepitheliomatous hyperplasia of the cervical squamous epithelium, masquerading both clinically and histologically as carcinoma. Although it was previously thought that chronic, untreated cervical schistosomiasis plays a role in the genesis of cervical carcinoma in populations where schistosomiasis is prevalent, there is now evidence indicating no association between schistosomiasis and cervical cancer [82].

Cervicovaginitis Emphysematosa

Multiple, blue-gray, subepithelial cysts of the portio vaginalis and vagina characterize this unusual disease [33]. In rare cases, the cysts have been misdiagnosed as an invasive cervical cancer [5]. The cause of this condition is unknown, but it is often associated with trichomoniasis [33]. Gas-forming bacteria have never been identified within the cysts. The cysts are dilated connective tissue spaces without lining epithelium that contain air and carbon dioxide. Multinucleated foreign body giant cells surround some of the cysts, and often the subepithelial veins and lymphatics are dilated.

Fig. 4.34 Cervical schistosomiasis. Note calcified Schistosoma haematobiium ova

Benign Diseases of the Cervix

Cervical Vasculitis

Isolated arteritis of the cervix, histologically identical but clinically unrelated to polyarteritis nodosa, may rarely be encountered [65]. It may be asymptomatic or may be associated with bleeding and may clinically resemble cancer. Gynecologic vasculitides are encountered in 0.04% and 0.1% of surgically removed gynecologic specimens. Most are isolated, single organ disease and the cervix is the most frequently involved organ [40]. In most cases, medium-sized arteries contain non-granulomatous vasculitis and is usually an incidental finding in surgical specimens. The pathogenesis of single organ gynecologic vasculitis is unknown and if no systemic disease is identified, no further therapy is indicated.

Pseudoneoplastic Glandular Conditions (Hyperplasias) and Endometriosis

Microglandular Endocervical Hyperplasia

Microglandular endocervical hyperplasia is a benign proliferation of endocervical glands. Microglandular hyperplasia is frequently detected as an incidental finding on a cervical biopsy, cone biopsy or a hysterectomy specimen. If clinically apparent, it most often resembles a cervical polyp, measuring 1-2 cm in size. These patients may complain of postcoital bleeding or spotting. Microglandular hyperplasia is most common in women of reproductive ages and has been detected in up to 27% of cone biopsies or hysterectomy specimens [10]. Early studies reported that the microglandular hyperplasia typically occurs in patients with a history of recent progesterone exposure, either as a result of oral contraceptive use or pregnancy, and concluded that it represents a progestin-induced lesion. However, a number of cases have been reported in which there is no associated hormonal history, and a recent comprehensive study did not find a relationship between microglandular hyperplasia and progestin exposure [36]. Therefore, the role of progestin exposure in the pathogenesis of this lesion is currently unclear.

Histologically, microglandular hyperplasia may present in a single focus or be distributed in multiple foci. It may involve the surface and/or deeper portions of endocervical clefts. The most common form consists of tightly packed varying-sized glandular or tubular units, lined by flattened to cuboidal cells with eosinophilic granular cytoplasm containing small quantities of mucin (**)** *Fig. 4.35a, b*). The glands vary in size and shape from

Microglandular hyperplasia. (a) There is an adenomatous pattern with cuboidal lining cells and focal squamous metaplasia. (b) At higher magnification the cells appear uniform and form a reticular pattern. Note the extensive vacuolization of the lesion that is caused by cystic dilation of intercellular spaces. There is a paucity of intracellular mucin

round and small to large irregularly dilated cystic structures. The stroma separating the glands is usually infiltrated with acute and chronic inflammatory cells. The nuclei of the endocervical cells are uniform, with occasional pleomorphism and hyperchromasia, but mitotic activity is quite low with only 1 mitotic figure per 10 high-power fields [105]. Associated squamous metaplasia and subcolumnar reserve cell hyperplasia are seen in a large number of cases. Foci with a solid proliferation of cells, including signet ring cells, can also be present. In more florid forms of microglandular hyperplasia, the glandular elements are arranged in a reticulated or solid pattern with areas of nuclear hyperchromasia and pleomorphism. The significance of the florid forms of microglandular hyperplasia is that the irregularly arranged glands can impart an infiltrative appearance and they can be mistaken for adenocarcinoma, in particular, clear cell adenocarcinoma. Microglandular hyperplasia with solid areas, especially when the solid component predominates or when signet ring cells are present, can also be difficult to distinguish from adenocarcinomas [105]. The benign nature of these florid lesions is usually demonstrable by a lack of clear-cut stromal invasion and the low mitotic activity of microglandular hyperplasia as compared to endocervical adenocarcinoma. In addition, florid forms of microglandular hyperplasia almost always contain areas with the more typical histological features of microglandular hyperplasia.

Mesonephric Hyperplasia and Remnants

The vestigial elements of the distal ends of the mesonephric ducts are found in 1-22% of adult cervices and in up to 40% of the cervices of newborns and children [44, 92]. The wide variation in the reported prevalence of these remnants appears to be a function of how extensively the cervix is sampled and the site of sampling [25]. Mesonephric remnants are most commonly present in the lateral aspects of the cervix, a region that is usually not sampled on routine hysterectomy specimens. They consist of small tubules or cysts that are usually located deep in the lateral cervical wall. Characteristically, the tubules are arranged in small clusters or have an orderly distribution reminiscent of the ampullary portion of the fetal mesonephric duct. The tubules are lined by nonciliated, low columnar, or cuboidal epithelium. The lining cells contain no glycogen or mucin, features that distinguish mesonephric from endocervical epithelium (**>** *Fig.* 4.36). The tubular lumen, however, is often filled with pink, homogeneous, PAS-positive secretions.

Mesonephric remnants. The mesonephric tubules are lined by cuboidal epithelium with bland nuclei. Occasional tubules contain pink, homogenoeous intraluminal secretions

Mesonephric remnants may become hyperplastic, resulting in a florid, tubuloglandular proliferation with transmural involvement of the cervix (> Fig. 4.37). Based on the architecture of the glandular structures, mesonephric hyperplasia has been classified by some authors into different histological types [25, 87]. The most common type is called the lobular type and is characterized by clustered mesonephric tubules, with or without a centrally placed duct. The lobular form tends to occur at a younger age, is less extensive, and tends to arise deeper in the cervical stroma. The less common type is called the diffuse type and is characterized by a nonclustered diffuse pattern or proliferation of mesonephric tubules. The histological subdivision of mesonephric hyperplasia into different forms does not have a clinical significance.

Mesonephric hyperplasia is almost always asymptomatic and is detected on either cervical biopsy, cone biopsy or hysterectomy specimens. Histological differentiation between mesonephric hyperplasia and mesonephric remnants is quite arbitrary, and of little clinical importance. Mesonephric hyperplasia is a benign condition that is of pathological significance, because it can be misinterpreted as a minimal deviation adenocarcinoma of the endocervix (O Chap. 6, Carcinoma and Other Tumors of the Cervix). Mesonephric hyperplasia is distinguished from carcinoma by lack of a complex glandular pattern, mitosis, intracellular mucin, and periglandular stromal edema. In contrast to most cervical adenocarcinomas, carcinoembryonic antigen (i.e., CEA) is absent in mesonephric hyperplasia, and these

Fig. 4.37

Florid mesonephric hyperplasia. Extensive mesonephric tubular-ductal proliferation in the deeper portion of the cervix, resembling an invasive adenocarcinoma. Unlike the latter, the lobular architecture is maintained in hyperplasia. Note the mesonephric duct in the lower left surrounded by a proliferation of small tubules

lesions have low Ki-67 staining indices [69]. In addition, normal mesonephric remnants are usually admixed with the hyperplastic tubules.

Lobular Endocervical Glandular Hyperplasia (LEGH)

Endocervical hyperplasia can sometimes be encountered and can take several different forms. Lobular endocervical glandular hyperplasia (LEGH) is a rare form, first described by Nucci et al. [75]. Later studies have shown that it has a distinctive gastric phenotype (pyloric gland metaplasia) by demonstrating immunohistochemical positivity for H1K1083, an antibody specific for gastric pyloric mucin [71]. Most cases are incidental findings in hysterectomy specimens; some patients, however, complain of abundant mucoid or watery discharge. Microscopically, there is a proliferation of tightly packed, small-sized endocervical glands displaying a well-demarcated, multilobular pattern. Several of the lobules are centered by a larger glandular structure (> Fig. 4.38a, b). Typically, LEGH is confined to the inner one-half of the cervical wall, and the glandlining cells are devoid of "malignant" atypia, and mitoses do not exceed 2 per 10 high-power fields. LEGH may be mistaken for adenoma malignum (>>>> Chap. 6, Minimal Deviation Endocervical Adenocarcinoma). The orderly,

Lobular endocervical glandular hyperplasia (LEGH).

(a) There is a proliferation of highly packed, small-sized endocervical glands in a lobular pattern. (b) The cells lack cellular atypia and have a gastric phenotype with a large number of goblet type cells

lobular architecture of glandular units, absence of irregular, deep stromal infiltration and desmoplasia, and immunonegativity for CEA are features distinguishing the former from the latter. Occasionally, LEGH is associated with in situ and invasive adenocarcinoma, particularly adenoma malignum of endocervix, as well as benign, borderline, and invasive endocervical-type mucinous lesions of the endometrium, tubes, and ovaries [74]. The possibility of LEGH being a precursor of malignant endocervical neoplasms has been raised, however, not via the high-risk HPV-related carcinogenesis pathway, for it is uniformly HPV DNA negative by PCR and in situ hybridization [57]. Its association with malignancy may be a reflection of chromosomal inbalances common to adenoma malignum [57]. It has been suggested, furthermore, that the association may be predominantly limited to those cases in which both LEGH and cervical adenocarcinoma display gastro-pyloric glandular metaplasia [71].

Diffuse Laminar Endocervical Glandular Hyperplasia (DLEGH)

Diffuse laminar endocervical glandular hyperplasia (DLEGH) is another rare form of hyperplasia described by Jones et al. [53] in which tightly packed, small to medium-sized endocervical glands are typically confined to the upper one-third of the cervical wall (\bigcirc *Fig. 4.39a*, *b*). Unlike LEGH, its laminar counterpart is devoid of lobulation and is clearly demarcated from the underlying stroma exhibiting a straight line at its base. The lining epithelium of glandular structures is cytologically normal without mitoses, and stromal desmoplasia is not seen. These features and its superficial position distinguish DLEGH from adenoma malignum.

Occasionally, cases of endocervical hyperplasia are encountered which do not fit the published descriptions of either LEGH or DLEGH. We utilize the descriptive term *endocervical hyperplasia* – *NOS* to describe such cases. Figure 4.40a, b illustrates such as case which lacks both a lobular architecture as well as a well-demarcated laminar architecture. Follow-up studies of such lesions are not published, but most cases are diagnosed on hysterectomy specimens and appear to be incidental findings.

Endocervicosis

Endocervicosis is a very rare condition described by Zaino [106] and Young et al. [102] in which the outer aspect of the cervical wall is enlarged, rubbery and may be grossly cystic. Histologically, glands varying in shape and size, often cystically dilated, are lined by mucinous-type endocervical cells and typically occupy the outer one-third of the cervical wall with extension to the paracervical tissues (\bigcirc *Fig.* 4.41). The lining epithelium is normal to flattened with very occasional mitotic figures, and occasional glands can be surrounded by endometrial-like stroma. Overall, the lesion resembles endocervicosis of urinary bladder and its distinctive feature from adenoma malignum is that it is located in the outer wall of the cervical glands of the endocervical mucosal layer [102].

Diffuse laminar endocervical glandular hyperplasia (DLEGH). (a) There is a proliferation of highly packed, small-sized endocervical glands that is clearly demarcated from the underlying cervical stroma. (b) The cells lack cellular atypia and have a normal endocervical appearance

Endometriosis

Endometriosis refers to lesions that are composed of ectopic endometrial glands and stroma (Chap. 9, Endometrial Carcinoma), whereas *tubo-endometrioid metaplasia* refers to endocervical glands that are lined by ciliated cells or secretory-type cells with apical snouts that resemble those that can be seen in the endometrium but which lack endometrial stroma. Endometriosis of the cervix may occur on the portio or in the endocervical canal. The process is usually confined to the superficial third of the cervical wall [7]. Most areas of endometriosis of the exocervix appear as

Fig. 4.40

Endocervical glandular hyperplasia – NOS. (a) There is a proliferation of loosely packed endocervical glands. (b) The cells lack cellular atypia or mitotic activity and there is no stromal reaction to the proliferation

one or more, small, blue or red nodules, measuring a few millimeters in diameter. Occasionally, however, the lesion may be larger or cystic and may produce abnormal vaginal bleeding. Histologically, the glands and stroma resemble proliferative endometrium (\bigcirc *Fig. 4.42*). Rarely, the glands are secretory. Decidua may be seen in pregnancy or with progestin therapy.

The mechanism responsible for the development of endometriosis is unknown, but it is clear that cervical endometriosis frequently develops following cervical trauma. Cervical endometriosis is encountered in 5–43% of patients undergoing cervical cautery or cold-knife cone biopsy or loop excisional procedures [32]. This association has been interpreted by some investigators as evidence supporting the implantation theory of endometriosis. According to this theory, endometrial tissue is implanted into the cervical mucosa or submucosa, following postmenstrual cauterization or during delivery. However, the frequent occurrence of posttraumatic endometriosis could also be interpreted as supporting the view that cervical endometriosis represents a reparative/metaplastic process. Support for the concept that the cervical endometriosis develops as a metaplastic process, as opposed to direct implantation, also comes from the frequent demonstration of glands with either *tubo-endometrioid* or pure *tubal metaplasia* in posttraumatic cervices.

Benign Tumors

Endocervical Polyps

Endocervical polyps constitute the most common new growths of the uterine cervix. Cervical polyps are focal, hyperplastic protrusions of endocervical folds, including the epithelium and substantia propria. Cervical polyps are most often found during the fourth to sixth decades and in multigravidas. They may present with profuse leukorrhea due to hypersecretion of mucus from inflamed endocervical epithelium or abnormal bleeding from ulceration of the surface epithelium. Clinically, cervical polyps are rounded or elongated with a smooth or lobulated surface that is often reddened because of increased vascularity. Most polyps are single and measure from a few millimeters to 2-3 cm. In rare instances, they may reach gigantic dimensions, protruding beyond the introitus and resembling carcinoma. Various cervical lesions with a polypoid gross appearance are presented in **>** *Table 4.3.* Microscopically, cervical polyps display a variety of patterns that vary according to the preponderance of one or another of the tissue components. The most common type is the endocervical mucosal polyp. It is composed of mucinous epithelium that lines crypts, with or without cystic changes (> Fig. 4.43). Occasionally, they may be mainly fibrous, representing an overgrowth of the connective tissue stroma of the portio. In other cases, blood

G Fig. 4.41

Endocervicosis of the cervix. Cystically dilated endocervical glands extend into the outer third of the wall of the cervix (Photograph courtesy of Dr. Phillip Clement of Vancouver, Canada)

vessels predominate and the lesion is called a *vascular polyp*. Squamous metaplasia involving the surface or glandular epithelium of polyps is frequently observed. The supporting connective tissue of polyps is generally loose, with centrally placed feeding vessels and is almost always infiltrated by a chronic inflammatory infiltrate. Occasionally, such infiltration may be so extensive as to be the principal tissue constituent of the polyp. In these cases, polypoid granulation tissue devoid of surface epithelium is observed (\bigcirc *Fig. 4.44*). Polyps originating in the isthmus often have an admixture of endocervical- and endometrial-type epithelial components and are referred to as *mixed polyps*.

Table 4.3

Differential clinical diagnosis of polypoid lesions of the cervix

Polyp	Squamous papilloma
Microglandular endocervical hyperplasia	Condyloma acuminatum
	Papillary adenofibroma
Decidua	Squamous cell carcinoma
Granulation tissue	Adenocarcinoma
Leiomyoma	Sarcoma, primary
Adenomyoma	Sarcoma, secondary
Fibroadenoma	

High-grade SIL, carcinoma, either in situ or invasive (adeno- or squamous), arising in cervical polyps is extremely rare. Endocervical polyps with adenocarcinomatous changes must be differentiated from polypoid adenocarcinoma of the endocervix and from endocervical polyps that are secondarily involved by an adjacent adenocarcinoma. The most useful criterion for differentiating between the two is to determine whether or not the base of the pedicle of the polyp is involved by carcinoma. The base of a polyp that harbors a primary tumor is free of disease, and the carcinoma usually has a focal distribution within an otherwise benign polyp. In a polypoid carcinoma, the entire mass is malignant, including its base and neighboring areas. A focus of carcinoma in a cervical polyp without involvement of its base but associated with similar carcinoma in the adjacent regions should be regarded as a secondary rather than a primary focus. Adenocarcinoma confined to a polyp has an excellent prognosis [2].

Mesodermal Stromal Polyp

Mesodermal stromal polyps are benign, exophytic proliferations of stroma and epithelium that can occur in the vagina and cervix of women of reproductive ages. These lesions are seen most frequently in pregnant patients and arise more commonly from the vagina than from the cervix [73]. Histologically, these polyps are composed of an edematous stroma that is covered by a benign

Fig. 4.43

Endocervical polyp. This is the most common type of endocervical polyp. Endocervical-type, tall columnar, mucinous epithelium covers the surface and crypts

Fig. 4.44

Granulation tissue. Polypoid nodules of granulation tissue can grossly resemble an endocervical polyp. This type of lesion often leads to bleeding appearing stratified squamous epithelium (**?** *Fig. 4.45a*). The stromal component is usually comprised of bland appearing plump stromal fibroblasts. However in some cases, there can be focal areas of bizarre fibroblasts with irregular, occasionally multinucleated hyperchromatic nuclei that resemble the fibroblasts in radiation reactions

(\diamond *Fig.* 4.45*b*) [13]. Occasional multinucleated stromal giant cells can be identified in approximately 25% of cone biopsy or hysterectomy specimens when carefully searched for [38]. These cells stain negatively for cytokeratin, desmin, factor VIII, and S100 protein but stain positively for vimentin and alpha1-antichymotrypsin. When stromal polyps contain large number of these cells, they can appear quite alarming and simulate the appearance of sarcoma botryoides [21]. However, careful inspection will allow these lesions to be differentiated from sarcoma botryoides by the absence of mitotic figures, lack of rhabdomyoblasts, and lack of a cambium layer.

Placental Site Trophoblastic Nodule

Placental site trophoblastic nodules can be found in the endocervix, immediately beneath the epithelium. They are sometimes detected in endocervical curettages. These lesions are histologically identical to early implantation sites that can be detected in the endometrium of women of reproductive ages [105]. Microscopically, placental site trophoblastic nodules are well-defined lesions that have a hyalinized appearance and contain intermediate trophoblasts and inflammatory cells (**>** *Fig. 4.46*). The intermediate trophoblast cells are frequently degenerated and have an

Fig. 4.45

Mesodermal stromal polyp. (a) Spindle-shaped and stellate fibroblasts are embedded in a loose myxoid stroma that has a stratified squamous surface epithelium. (b) At higher magnification, stellate atypical fibroblasts can be seen in the stroma

Fig. 4.46

Placental site nodule. A hyalinized nodule containing intermediate trophoblast is identified in an endocervical curettage obtained several months postpartum extensive cytoplasmic vacuolization but lack significant nuclear atypia, lack mitotic activity, and have very low Ki-67 labeling indices [89]. Intermediate trophoblast stains positively with antibodies against cytokeratins, human placental lactogen, and Mel-CAM, a cell adhesion molecule of the immunoglobulin gene superfamily [89]. The lack of significant nuclear atypia and mitotic activity, as well as staining with antibodies against human placental lactogen, allow these lesions to be microscopically differentiated from invasive nonkeratinizing squamous cell carcinomas.

Leiomyoma

Cervical leiomyomas are much less common than uterine myomata. They usually occur singly and produce unilateral enlargement of the cervical portio. At times, the lesion may protrude from the canal, resembling an endocervical polyp, and in pregnancy may produce dystocia. Cervical leiomyomas are grossly similar to those observed in the myometrium; microscopically they tend to be more vascularized than those of the uterus; a variety of histological patterns may be encountered, including atypical leiomyoma, which contains cells with bizarre nuclei (> Chap. 10, Mesenchymal Tumors of the Uterus).

Adenomyoma and Papillary Adenofibroma

These neoplasms are rare and are composed of an admixture of fibroconnective tissue and smooth muscle elements, intermingling with glands lined by a predominately endocervical-type epithelium. The tumors typically measure 1.3–8 cm in diameter and usually present as asymptomatic cervical polyps [34]. The epithelial component is typically composed of irregular, large glands that may be accompanied by smaller glands in a lobular arrangement. These tumors can be distinguished from endocervical adenocarcinomas by the lack of invasion of the stromal component by the epithelial component, lack of nuclear atypia, and minimal mitotic activity. Adenomyomas can persist or recur, but there are no reported instances of extracervical spread or metastasis [34].

Papillary adenofibromas are rare benign neoplasm with histological characteristics similar to the ovarian adenofibroma. Only several cases have been reported in the literature. They consist of an admixture of fibroconnective tissue and glands lined by either endocervical-type epithelium or a tubal type epithelium. The fibroconnective tissue usually forms papillary projections (\bigcirc *Fig. 4.47*) [1, 30].

Papillary adenofibroma of the endocervix. Fibroepithelial papillae project from the cervix. The papillae are covered with an endocervical-type epithelium

Miscellaneous Tumors

Hemangiomas are rarely found in the cervix. They may be of capillary or cavernous type [37]. A single instance of cervical lymphangioma was reported by Stout and several cases of lipoma of the cervix are on record [94]. Neoplasms of neurogenic derivation arising in the cervix are extremely rare and include neurofibroma and ganglioneuroma. Benign blue nevi of the endocervix, indistinguishable from those arising in the dermis, are seen occasionally [77]. They are composed of melanincontaining fusiform cells with dendritic cytoplasmic processes, located in the stroma of the endocervix. Cervical melanosis is an uncommon finding characterized by the hyperpigmentation of the cervical basal epithelium. It is reported to occur either with or without accompanying basal melanocytes [101].

Cysts

Nabothian Cyst

Nabothian cysts are the most common type of cyst of the cervix and develop within the transformation zone secondary to squamous metaplasia, covering over and obstructing endocervical glands. Grossly, these lesions appear as yellow white cysts that are frequently multiple and can measure up to 1.5 cm in diameter. Microscopically, they are lined by a somewhat flattened, single layer of mucin-producing endocervical epithelium (\bigcirc *Fig. 4.48*). In some cases, squamous metaplasia of the lining epithelium occurs. The lining epithelium is almost always at least focally positive with mucicarimine stains, allowing these lesions to be distinguished from traumatic inclusion cysts and mesonephric duct cysts. Although nabothian cysts are usually confined to the superficial portion of the cervix, they may extend through the wall of the cervix [14].

Tunnel Clusters

Endocervical tunnel clusters are benign collections of endocervical glands that are usually located close to the surface epithelium of the cervix. Tunnel clusters are quite common and become more prevalent with increasing age. In the Fluhmann's original description of this condition,

 Fig. 4.48
Nabothian cysts. Nabothian cysts are lined by a flattened layer of mucin-producing epithelium

they were detected in 8% of all adult women and 13% of the postmenopausal women [27]. They appear to be more common in pregnant women. These lesions are asymptomatic and are detected as incidental findings in either hysterectomy specimens or cone biopsies obtained for unrelated reasons [86].

Two types of tunnel clusters were originally described. One type represents a cluster of closely packed glands that are noncystic and are lined by tall columnar epithelium. The other type is grossly cystic and lined by a cuboidal or flattened epithelium (\bigcirc *Fig.* 4.49). These collections of glands have a clustered appearance with a rounded margin and do not invade into the deep cervical stroma. The importance of tunnel clusters is that they are occasionally misinterpreted as minimal deviation adenocarcinomas of the cervix [52, 86]. However, tunnel clusters do not have nuclear atypia, mitotic activity, and most importantly do not invade into the deep cervical stroma.

Inclusion Cyst

Traumatic inclusion cysts are a form of epidermal inclusion cysts that commonly occur in the vagina at sites of surgical repair of episiotomies or vaginal intrapartum lacerations (**>** Chap. 3, Diseases of the Vagina). They are thought to develop from viable fragments of epithelium, which

Fig. 4.49

Endocervical tunnel cluster. Closely packed cystically dilated glands lined by a flattened epithelium. The condition is well demarcated and does not extend beyond the depth of the normal endocervical glands become entrapped within the stroma at the time of obstetrical trauma or subsequent surgical repair. Inclusion cysts are uncommonly found on the cervix. Grossly, they present as unilocular cystic structures measuring 1–2 cm in diameter beneath the native portio epithelium [28]. Microscopically, traumatic inclusion cysts are lined by a stratified squamous epithelium similar to that of the vaginal mucosa but usually somewhat thinner. The epithelium shows normal maturation with the basal cells, oriented away from the cyst cavity that is filled with desquamated epithelial cells. The cyst contents are identical to those of epidermal inclusion cysts at other sites and are thick, white, and cheesy.

Tumor-Like Lesions

Decidual Pseudopolyp

The gross appearance of the pseudodecidual change that can occur during pregnancy depends on the site. If the change occurs on the exocervix, it frequently presents as a raised plaque or pseudopolyp that can be mistaken for invasive carcinoma both colposcopically and microscopically. During gestation, cervical polyps may also contain focal stromal pseudodecidual changes, and rarely massive decidualization of endocervical stroma occurs, producing a polypoid protrusion from the endocervix. Clinically, decidualized polyps need to be differentiated from extruded fragments of decidua that may indicate an impeding miscarriage. Distinction is made by identifying a stalk for the decidualized polyp, whereas expulsed fragments of decidua lack a stalk. Areas of pseudodecidualization are microscopically differentiated from invasive nonkeratinizing squamous cell carcinoma by the lack of significant nuclear atypia, as well as lack of mitotic figures, a coexisting squamous intraepithelial lesion (SIL) and continuity with the surface epithelium. In difficult cases, immunohistochemistry using antibodies against cytokeratin proteins can be used to differentiate cytokeratin-negative decidual reactions from cytokeratin-positive nonkeratinizing squamous cell carcinoma.

Mullerian Papilloma

Rare instances of a benign, papillary growth of the cervix that occur primarily in children have been described [41, 64, 88]. They are composed of complex papillary projections, lined by flat cuboidal epithelium with cores

Fig. 4.50

Mullerian papilloma. (a) Papillary projections; (b) papillary projections covered with cuboidal to columnar epithelium

of loose fibrovascular tissue (\bigcirc Fig. 4.50a, b). Cytologic atypia and mitoses are absent. In the past, the lesions were thought to be of mesonephric duct origin, although they have not been encountered in association with mesonephric remnants. Although the histogenesis of these lesions remains uncertain, recent studies favor a Mullerian origin.

Postoperative Spindle Cell Nodule and Inflammatory Pseudotumor

Postoperative spindle cell nodules of the cervix are clinically and histologically identical to their more common counterparts of the vulva and vagina [58, 79]. These lesions may develop after either a cervical biopsy or some other form of trauma. They resemble nodular fasciitis and are composed of actively proliferative spindle cells with oval nuclei arranged in interlacing bundles (Chap. 3, Diseases of the Vagina). The cells may vary slightly in size and mitotic figures are often present. A characteristic feature is the presence of neutrophils and erythrocytes in the lesion, giving it the appearance of granulation tissue.

Inflammatory pseudotumor refers to a lesion closely related to postoperative spindle cell nodule that occurs in the absence of a known history of trauma [3]. Inflammatory pseudotumor is a proliferative process of an unknown etiology with a polymorphic morphology. The lesions contain two cellular components: a fibrohistiocytic component consisting of fibroblasts, myofibroblasts and histiocytes and a polymorphous inflammatory component consisting of lymphocytes and plasma cells. The lesion can be differentiated from other neoplastic processes by the lack of atypia, mitoses, and the presence of a polymorphous inflammatory infiltrate.

Lymphoma-Like Lesions

Lymphoma-like lesions (pseudolymphomas) are marked inflammatory lesions of the cervix, extensive enough to cause confusion with a lymphoproliferative lesion [105]. Lymphoma-like lesions are composed of a superficial band of large lymphoid cells admixed with mature lymphocytes and plasma cells. The lymphoid infiltrates commonly include macrophages and germinal centers, which help to distinguish them from lymphomas. Another feature, which helps to distinguish lymphoma-like lesions from lymphomas, is the superficial localization of the infiltrate. Lymphoma-like lesions rarely infiltrate deeper than 3 mm from the surface epithelium, whereas lymphomas of the cervix usually extend beyond the depth of the endocervical glands (• Chap. 6, Carcinoma and Other Tumors of the Cervix).

Heterologous Tissue

Glia

There are 15 recorded cases of neuroglial tissue in the cervix or the endometrium (**O** Chap. 7, Benign Diseases of the Endometrium) [91]. Although the term glioma is used for this condition, the high degree of differentiation of the glial tissue, the absence of mitoses, and the absence

of recurrence are against its being neoplastic. The lesion should not be confused with a pure heterologous sarcoma or a teratoma. The neural tissue is believed to represent either implantation of fetal cerebral glia at the time of instrumentation of the gravid uterus or heterotopic maldevelopment during embryogenesis. When the cervix is involved, the lesion usually appears as a polyp that bleeds readily.

Skin

Among the pathologic curiosities of the cervix are cases of true epidermidization of the cervical mucosa. In these instances, sebaceous glands, hair, sweat glands, and occasionally mantle structure are found. The presence of these ectodermal structures, which are normally appendages of the epidermis, on a mucous membrane of mesodermal derivation is difficult to explain. It is conceivable, however, that stratified squamous epithelium under certain circumstances, such as long-standing chronic inflammation or congenital misplacement, can form the appendages of its epidermal analogue [59].

Cartilage

Four cases of heterotopic mature cartilage in the cervix are on record [83]. The finding of these structures alone has no clinical significance. They should not be confused with a malignant mixed mesodermal tumor.

Precursors of Squamous Cell Carcinoma

Terminology and Historical Perspective

The histopathological classification of a disease should reflect both current concepts of its pathogenesis as well as its clinical behavior. Over the last 50 years, our understanding of the pathobiology and behavior of cervical cancer precursors has evolved considerably. As a result, the terminology used to classify preinvasive lesions of the cervix has frequently changed. Although these changes in nomenclature and the resulting lack of a uniform terminology have been an ongoing source of confusion to both gynecologists and pathologists, each change has actually reduced the number of specific pathological categories and has made clinical decision making more straightforward.

The existence of precursor lesions for invasive cervical cancer has been recognized for over a century. As early as 1886, Sir John Williams commented on the presence of noninvasive epithelial abnormalities adjacent to the invasive squamous cell carcinomas of the cervix [198]. The spatial relationships and the histological appearance of these noninvasive epithelial lesions were better described by Cullen in 1900 who recognized that these intraepithelial lesions histologically resembled the adjacent invasive cancers [44]. In the 1930s, Broders reintroduced the term carcinoma in situ that was first used by Schottlander and Kermauner to refer to these intraepithelial cervical lesions [24]. A temporal relationship between carcinoma in situ and invasive cancer was subsequently reported by Smith and Pemberton, as well as by Galvin, Jones, and Telinde who diagnosed carcinoma in situ in several patients months to years before the development of invasive cervical cancer [148]. The recognition that there were both a spatial and temporal relationship between carcinoma in situ and invasive squamous cell carcinoma led to the hypothesis that invasive squamous cell carcinoma develops from a histologically well-defined precursor lesion [24]. This hypothesis was subsequently substantiated by long-term follow-up studies, which clearly demonstrated that a significant proportion of untreated patients with carcinoma in situ subsequently develop invasive squamous cell carcinoma [102, 104].

Once it was accepted that carcinoma in situ was a precursor to invasive squamous cell carcinoma, population-based cytological screening programs were begun to detect and treat precursor lesions prior to the actual development of cancer. As large numbers of women began to be screened for cervical disease, it became apparent that many women had cervical epithelial abnormalities that were cytologically/histologically less severe than carcinoma in situ. These lesions formed a histological spectrum that ranged from lesions in which the majority of the cells had the cytological features of carcinoma in situ to those in which the degree of atypicality was much less. The term *dysplasia* was used to refer to this spectrum of cervical abnormalities with features intermediate between those of carcinoma in situ and normal cervical epithelium [157].

The key distinguishing feature of dysplasia was that the atypical cells did not extend through the full thickness of the epithelium or invade the basement membrane. In the cytological nomenclature, dysplasia was considered to be a benign to possibly malignant squamous epithelial atypia, whereas carcinoma in situ was designated as positive for malignant cells.

The separation of noninvasive cervical lesions into two groups, dysplasia and carcinoma in situ, implied that there was a biologic distinction between these two entities and that the two could be reproducibly distinguished from each other. In most centers, dysplasia was considered to be a potentially reversible process and therefore was either ignored, followed, or treated depending on a variety of clinical factors, whereas carcinoma in situ was considered to be a highly significant lesion and patients with this diagnosis were usually treated with hysterectomy. This classification of noninvasive precursor lesions into dysplastic and carcinoma in situ lesions was based solely on arbitrary histological differences that were often quite subtle [28, 103]. In the 1960s, several studies of interand intraobserver variability of histological diagnosis demonstrated that pathologists could not reproducibly distinguish between severe dysplasia and carcinoma in situ [41, 100].

A number of studies in the late 1960s suggested that the cellular changes of dysplasia and carcinoma in situ were qualitatively similar and remained constant throughout the histological spectrum. Both dysplasia and carcinoma in situ were found to be monoclonal proliferations of abnormal squamous epithelial cells with an aneuploid nuclear DNA content [65]. On the basis of these descriptive biologic studies, Richart introduced the concept that all types of precursor lesions to squamous cell carcinoma of cervix represented a single disease process that he termed *cervical intraepithelial neoplasia* (CIN) [159].

The CIN terminology divided cervical cancer precursors into three groups: CIN 1 corresponds to lesions previously diagnosed as mild dysplasia, CIN 2 corresponds to moderate dysplasia, and CIN 3 to both severe dysplasia and carcinoma in situ, since pathologists could not reproducibly distinguish between the two. At the time of its introduction, CIN was thought to define a spectrum of

histological changes that shared a common etiology, biology, and natural history. Furthermore, the diagnostic term CIN implied that such lesions, if untreated, had a significant, albeit individually unknown risk of developing into invasive carcinoma in the future. As a corollary, it was presumed that when the histological changes of CIN were diagnosed and the lesion adequately treated, the development of invasive cancer could be prevented. The CIN terminology became the most widely used histological terminology for cervical cancer precursors in the 1970s and the 1980s. However, over the last 2 decades, there has been an explosion of information about the etiology of cervical cancer and its precursor lesions. It is now widely accepted that both invasive squamous cell carcinomas and adenocarcinomas of the cervix, as well as their respective precursor lesions, are caused by specific types of high-risk human papillomavirus (HPV) that infect the anogenital tract [213, 214]. Since infection with specific high-risk types of HPV plays a critical role in the development of cervical cancer, a new model of cervical carcinogenesis has been developed (> Fig. 5.1). This model has three discrete steps: (1) initial infection with a high-risk type of HPV, (2) progression to a histologically defined precursor lesion that requires persistence of the HPV infection, and (3) invasion [167, 176, 209]. Based on this biological model, it is highly unlikely that cervical cancer develops according to a stepwise progression that envisions CIN 1, progressing to CIN 2, to

CIN 3, and on to cancer. Moreover, it now appears that the basic premise underlying the CIN terminology is incorrect; the spectrum of histological changes that are referred to as CIN do not represent a single disease process at different stages in its development but instead two distinct biological entities, one a productive viral infection and the other a true neoplastic process confined to the epithelium [202].

Productive HPV infections of the cervical squamous epithelium are self-limited in the majority of patients and commonly result in flat cervical lesions (> Fig. 5.2) and less frequently in exophytic ones (condylomata acuminata). Flat HPV-associated lesions in which productive viral infection is occurring display cytoplasmic cavitation and nuclear abnormalities. Traditionally, flat and exophytic condylomas were not classified as CIN 1 since they do not have the degree of nuclear atypia usually present in CIN. However, in the 1980s, it was found that the HPV types found in the cervical flat and exophytic condylomas are the same types that can be found in CIN 1 lesions [43]. Moreover, flat condylomas and CIN 1 lesions are similar with respect to their ploidy status [63]. Therefore, both exophytic and flat condylomatous lesions of the cervix were combined into the CIN 1 category. These lesions have been designated in the past as koilocytotic atypia, koilocytosis, or flat condyloma.

The other entity subsumed within the morphologic CIN spectrum is histologically "high grade." High-grade

lesions are frequently aneuploid and represent true intraepithelial neoplasia with a potential to progress to invasive squamous cell carcinoma if left untreated. They are composed of proliferating basal-type atypical cells with a high nuclear : cytoplasmic ratio and have been designated *moderate dysplasia, severe dysplasia, carcinoma in situ*, or *CIN 2* or *3*. There is a common misconception that low-grade lesions are "viral," whereas high-grade lesions are not. The prevalence of HPV in both low- and high-grade lesions is similar, approximately 80–90% [36, 37, 175]. However, in low-grade lesions, large numbers of viral particles are produced, whereas in high-grade lesions, viral DNA is present, but infectious viral particles are produced in comparatively lower amounts, **>** *Fig. 5.3.*

Because of our increased understanding of the pathogenesis of cervical cancer precursors, it has been suggested that the terminology used to refer to these lesions be changed to better reflect the biological processes that underlie the histological patterns. The most widely accepted modification is the terminology that has been incorporated into the Bethesda System (TBS) of cytological diagnosis. This terminology uses the term *low-grade squamous intraepithelial lesion* (LSIL) for lesions previously classified as koilocytotic atypia and CIN 1 and *high-grade squamous intraepithelial lesion* (HSIL) for lesions previously called CIN 2 and CIN 3 [116, 177]. For histopathological reporting, it has been suggested that the terms LSIL and HSIL also be used [205]. Therefore, in this chapter, we have adopted the use of the Bethesda Terminology for reporting cytopathology and the terms LSIL (CIN 1) and HSIL (CIN 2, 3) for histopathology. The rationale for adapting the two-tiered terminology for histopathology is the same as for using a twotiered terminology for cytology. First, LSIL (previously referred to as CIN 1) represents a biologically distinct group compared to HSIL (previously referred to as CIN 2 and CIN 3). HSIL are heterogeneous with respect to associated HPV types, clonality, ploidy, and loss of heterozygosity (LOH) at specific chromosomal loci, whereas HSIL are homogeneous with respect to these parameters. Moreover, the natural history of LSIL is characterized by higher rates of spontaneous regression and lower rates of progression than compared to HSIL. In our opinion, using the term "lesion" rather than "neoplasia" better reflects the natural history of these histopathological entities, since the majority of CIN are histologically low grade and represent self-limited HPV infections that will spontaneously resolve in the absence of therapy. "Intraepithelial lesion" better describes these low-grade viral infections than does the term "intraepithelial neoplasia." It must be emphasized that different terminologies are currently in use by different pathology laboratories. Although many laboratories in the USA have switched to the two-tiered or modified CIN terminology, some continue to utilize the original three-tiered CIN terminology and some even utilize the terms dysplasia and carcinoma in situ. This is expected to change over the next several years since the World Health Organization (WHO) recently switched to the CIN terminology, and in the new Armed Forces Institute of Pathology Fasicle on Tumors of the Cervix, the terms LSIL and HSIL are utilized for histopathology, as well as cytology [107, 196]. However, some clinicians find the use of LSIL and HSIL for both cytology and histology somewhat confusing since distinction between cytologically and histologically diagnosed lesions is clinically important [202]. Correlations between the different terminologies are shown in Table 5.1. It should be noted that because older studies utilized either the dysplasia/carcinoma in situ or the CIN terminology, in many places in this chapter we have used the older terminology.

General Features

Prevalence

SIL is predominantly a disease of women in their reproductive years, with a large population impact and risk

Fig. 5.3

HPV-infected cells. Electron microscopy of cells productively infected with HPV. (a) There are intranuclear aggregates of HPV in a koilocytotic, superficial cell of an HSIL. The marginated nuclear chromatin is agglutinated, and the cytoplasmic substance displays vacuolar degeneration (vd). The latter corresponds to koilocytotic ballooning on light microscopy. (b) Higher magnification of HPV particles in the nucleus

Table 5.1

Older classification	WHO ^a classification	Bethesda system terminology
Mild dysplasia	CIN 1	Low-grade squamous intraepithelial lesion (LSIL)
Moderate dysplasia	CIN 2	High-grade squamous intraepithelial lesion (HSIL)
Severe dysplasia/ Carcinoma in situ	CIN 3	HSIL

Terminologies for cervical cancer precursor lesions

^aWorld Health Organization. CIN, cervical intraepithelial lesion factors characteristic of a sexually transmitted disease (STD). The prevalence of SIL in different countries and populations within a country varies widely depending on the underlying risk factors in the population and the extent of cytological screening. Although SIL is not a reportable disease, good estimates of the prevalence of cytologic abnormalities in women undergoing screening in the USA are available from a number of sources. One of the most comprehensive surveys is the College of American Pathologists (CAP) "Q-Probes" study that compiles rates of cytological abnormalities diagnosis from over 300 U.S. cytology laboratories. According to this survey, in 2003 the mean reporting rate of LSIL was 2.6% and it was 0.7% for HSIL [47]. Age has a profound impact on both the rate of detection of cytological abnormalities as well as the histologically confirmed SIL lesions. In the Kaiser Permanente health plan, the highest rate of LSIL is in adolescents between 15 and 19 years of age [84]. Almost 4% of Papanicolaou tests (Pap tests) obtained from adolescents enrolled in the Kaiser Permanente health plan were diagnosed as LSIL. The LSIL rate drops with an increasing age and was only approximately 1% in women 25-40 years of age and was much lower in women over the age of 40 years. In contrast, the rate of HSIL increases up until 25–29 years and then decreases, > Fig. 5.4. In the recent quadrivalent HPV vaccine trial, the prevalence of LSIL on enrollment cytology in the North American participants 16-26 years of age (mean age 20 years) was 6.2% and the prevalence of HSIL was 0.5% (Barr 2008). The same impact of age as is seen with cytological abnormalities is also found for histologically diagnosed LSIL and HSIL lesions in Kaiser, > Fig. 5.5 [84]. The peak age for the diagnosis of HSIL is 25-29 years of age. Another large national program that compiles statistics of cytological abnormalities among women in the USA is the National Breast and Cervical Cancer Early Detection Program (NBCCEDP). The overall rate of cytological abnormalities in this program between 1995 and 1998 was 2.3% and 0.8% for LSIL and HSIL, respectively [12]. In this program, the rates of histologically identified LSIL and HSIL are highest in women under the age of 30 years. Rates tend to increase up until the age of 30 years and then begin to decrease, with lowest rates in women 60 years and older [12, 166]. In contrast, the rate of histologically confirmed invasive cervical cancer reported in the U.S. Surveillance Epidemiology and End Results (SEER) cancer registry increases until 40 years of age and then shows only minimal changes through 65 years of age, **>** Fig. 5.6 [192].

Fig. 5.4

Impact of age on cytological abnormalities. The data come from Kaiser Northern California (Modified from [84]) After the age of 65 years, there is a minimal decline. It is also important to note that during the 1970s–1990s that the rates of HSIL appear to have increased both in Western Europe and the USA. In Iceland, for example, the rate of detection of HSIL in women 20–24 years of age increased almost fourfold from 1979–1983 to 1994–1998 and then leveled out, \bigcirc *Fig.* 5.7 [173]. In women 25–29 years of age, it almost doubled during this time period and then appears to have begun to decrease.

Etiology

Epidemiologic studies have documented that the major risk factors for cervical cancer are infection with specific

Impact of age on histologically confirmed SIL. The data come from Kaiser Northern California (Modified from [84])

Fig. 5.6

high-risk types of HPV and a lack of cervical cancer screening, **7** *Table 5.2.* Other risk factors that have classically been associated with cervical cancer play a much less important role. Among women infected with high-risk types of HPV, other factors such as smoking, immuno-suppression, and long-term use of oral contraceptives can result in a doubling or tripling of risk for HSIL and invasive cancer [167]. The mechanisms of action of any of the risk factors other than infection with high-risk types of HPV and lack of cervical cancer screening are not understood.

Human Papillomaviruses

In the late 1970s, based on theoretical considerations, Dr. Harald zur Hausen suggested that there might be an association between HPV and cervical cancer, an achievement for which he received the Nobel Prize in Medicine in 2008 [212, 214]. A large number of epidemiological, clinicopathological, and molecular studies subsequently linked the presence of specific types of HPV to the development of anogenital cancers and their precursors and it is now accepted that high-risk HPVs play a critical role in the pathogenesis of most cervical cancers and their precursor lesions [83].

Classification of HPV and Association with Specific Types of Anogenital Lesions

Papillomaviruses are classified as members of the family Papillomaviridae [83]. They are double-standard DNA

tumor viruses that have a double-stranded DNA genome of approximately 8,000 base pairs in length, a nonenveloped virion that measures 45 to 55 nm in diameter, and an icosahedral capsid composed of 72 capsomers. They are widely distributed throughout nature. There are bovine, canine, avian, rabbit, deer, and human papillomaviruses. They are all highly species-specific viruses that infect only one species. Within a given species, many types and subtypes of papillomaviruses may exist. Unlike many other viruses in which specific viral isolates have capsid proteins with different antigenic structures, the capsid proteins of papillomavirus are highly conserved and antibodies directed against BPV capsid proteins cross-react with human papillomaviruses [90]. Therefore, DNA sequence is used to classify different viral types (genotypes). The classification of papillomaviruses is based on phylogenetic algorithms that compare either the whole viral genomic sequence or specific subgenomic segments. To date, the phylogenetic classification of papillomaviruses includes 118 distinct types, **>** Fig. 5.8 [50]. The human papillomaviruses are included in the genus alpha-papillomavirus and consists of a number of closely related groupings referred to as species or clades. The most important of these are the A9 clade that has HPV 16 as the prototypic virus and the A7 clade that includes HPV 18 and 45. The genetic sequence of papillomaviruses is quite stable and changes in molecular sequence through either mutation or recombination appears to be quite uncommon [191]. For example, there are three distinct lineages
200

Fig. 5.8

Phylogenetic classification of papillomaviruses. Based on their DNA sequence, papillomaviruses can be group in closely related clusters or clades (Used with permission from [50])

of HPV 18 variants and these appear to have diverged about the time Homo sapiens began establishing residence in difference continents [14]. Over 118 types of papillomaviruses have been molecularly cloned and sequenced and more than 120 putative novel types have been partially characterized [83]. Although the different types of HPV are quite similar structurally, they have significant specificity with regard to the anatomic location of the epithelia that they infect and the type of lesions that they produce at the site of infection. In addition to types, there also are subtypes or variants of specific types, such as HPV 16. In order to be considered a subtype or variant, a virus must differ by 2-5% from the original isolate. Different subtypes of HPV 16 have been shown to have different biological potential and specific variants appear more likely to be associated with invasive cervical cancers than others [48].

Papillomaviruses are epitheliotropic viruses that predominantly infect skin and mucous membranes and produce characteristic epithelial proliferations at the sites of infection. These benign epithelial proliferations or papillomas have the capacity to undergo malignant transformation under certain circumstances. Examples of this in animals include the papillomas induced in domestic rabbits by the cottontailed rabbit papillomavirus (CRPV) that can progress to invasive squamous cell carcinomas when treated with topical applications of methylcholanthrene and alimentary tract papillomas induced in cattle by bovine papillomavirus (BPV), which undergo malignant transformation when the animals eat radiomimetic bracken ferns. In humans, HPV infections occur on the skin and mucous membranes, on the conjunctiva, oral cavity, larynx, tracheobronchial tree, esophagus, bladder, anus, and genital tract of both sexes. HPVs appear to be

Table 5.3

Unclear oncogenic risk	26, 68, 73, 82

^aFor cervical cancer

fastidious in their growth requirements and replicate only in the nucleus of infected cells. In addition to being species specific, papillomaviruses are also relatively tissue- and site specific.

More than 40 types of HPV can infect the anogenital tract. The most commonly encountered ones are shown in **7** Table 5.3. Based on their associations with cervical and anogenital cancers, 13 anogenital HPVs have been classified by the International Agency for Research on Cancer (IARC) as oncogenic. These are HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 66 [83]. Others also consider HPV types 68 and 82 to be oncogenic [135]. HPV types 6 and 11, which are the two types most commonly found in association with condyloma acuminata, are not implicated in the development of cervical cancer, but are associated with squamous cell carcinomas of the larynx and various carcinomas of the vulva, penis, and anus [83].

More than 80% of SIL lesions are found to be associated with HPV when sensitive molecular methods are used to detect HPV DNA. LSIL can be associated with any of the anogenital types identified in women in the general population. A meta-analysis of HPV types identified in women with either cytologically identified LSIL or histologically diagnosed LSIL lesions found that HPV was detected in 80% of LSIL from North America and approximately 70% for LSIL from other regions of the world [36, 37]. This difference most likely is due to regional differences in how lesions are diagnosed. HPV 16 was the most common genotype, being found in 26% of HPV positive cases, **>** Fig. 5.9. HPV types 31, 51, and 53 were the next most commonly identified types, each being identified in approximately 10-12% of lesions. HPV 16 was less likely to be found in lesions from Africa and HPV 18 was more common in lesions from North America than in lesions from Europe or Latin America. All of the associations are complicated by the fact that multiple types of HPV are frequently found in association with low-grade lesions.

 Fig. 5.9
Prevalence of anogenital HPV types in LSIL (Modified from [36])

In contrast to LSIL, most studies have found that almost half of HSIL are associated with HPV 16. The prevalence of HPV 16 in cytologically identified HSIL and histologically diagnosed HSIL in studies from different areas of the globe range from 30% to 70% [36, 175]. A recent meta-analyses of the distribution of HPV in HSIL has concluded that HPV 16 is identified in 45.3% of the lesions, HPV 18 in 6.9% and HPV 31 in 8.6%, **2** *Fig. 5.10a* [175]. HPV 16 and 18 were found in 52% of the HSIL lesions. HPV types 31, 33, 58, and 52 are the next most common types found in HSIL. Multiple types of HPV are less commonly found in HSIL than in LSIL.

The distribution of HPV types in invasive cervical cancers shows an even stronger enrichment for HPV 16 and 18 that is observed in women with HSIL, **>** *Fig. 5.10b.* HPV 16 and 18 are found in approximately 70% of invasive cervical cancers worldwide [175]. HPV 31, 33, 35, and 45 are each found in 3–4% of cervical cancers [175]. None of the other high-risk types are found in association with more than 2.5% of cervical cancers and most are found in less than 1%. As with HSIL, multiple HPV types are rarely found in association with invasive cervical cancers.

Genomic Organization of HPV

The genomic organization of the different types of HPV appears to be similar, \bigcirc *Fig. 5.11*. The viral genome can be divided into three regions: an upstream regulatory region (also referred to as the long control region or LCR), the early region, and the late region. The LCR is a noncoding region of the viral genome that is important in regulating viral replication and transcription of downstream sequences in the early region. The early region is

Fig. 5.10 Prevalence of anogenital HPV types. (a) HSIL. (b) Invasive cervical cancer (Modified from [175])

transcribed early in the viral life cycle (hence its name) and encodes predominately for proteins that are important in viral replication, whereas the late region encodes for viral structural proteins that are produced late in the viral life cycle.

The early region open reading frames (ORFs) encode for proteins required for viral replication and maintenance of a high viral copy number in infected cells [52]. The early region also includes the transforming regions of the HPV genome: E5, E6, and E7. The E6 and E7 ORFs encode the major transforming genes of HPV [213]. The E5 ORF encodes a protein with weak transforming capacity. Both, the E6 and E7 proteins are small zinc-binding proteins that lack endogenous enzymatic activity and exert their transforming activity through binding to cell regulatory proteins. E6 can bind to p53 and results in rapid proteolytic degradation of p53 through an ubiquitin-dependent pathway, thus blocking apoptosis. E7 binds to the retinoblastoma (Rb) gene product, as well as other "Rb-like proteins." Binding of E7 to Rb blocks the cell proliferation inhibiting function of these endogenous tumor suppressors. E7 can also activate cyclins A and E as well as block the cell proliferation inhibiting functions of WAF-1 and p27, two cyclindependent kinase inhibitors. The end result of overexpression of E6 and E7 within cells is unrestricted cell proliferation and a blockage of apoptosis.

The late region of HPV is downstream of the early region and contains two ORFs termed L1 and L2 that encode capsid proteins. The L1-encoded protein is the major capsid protein and is highly conserved among papillomaviruses from all species. The L2-encoded protein is a minor capsid protein that is much more variable among viral types. Transcription from the L1 and L2 ORFs occurs

Genomic organization of HPV. HPV is a double-stranded, circular, DNA tumor virus whose genome can be divided into three regions: the upstream regulatory region (URR), the early region, and the late region

as a late event in the viral life cycle at a time when infectious virus is being produced. L1 capsid proteins produced in in vitro culture systems are capable of associating and forming viral-like particles (VLPs) that are similar to native virions, but lack the viral genome. VLPs composed of L1 capsid proteins have recently been introduced as prophylactic HPV vaccines.

Life Cycle of HPV

Although the HPV life cycle is not completely characterized, the rough outlines of the process are known, > Fig. 5.12 [167, 176]. The initial site of infection is thought to be either basal cells or primitive "basal-like" cells of the immature squamous epithelium that HPV reaches presumably through defects in the epithelium. Localization in the basal layer may be due to the presence of specific receptors for HPV on the basal cells. Once HPV enters into the basal cells, it can exist within the cells in two distinct biological states. One is as a nonproductive infection in which HPV DNA continues to reside in the basal cells, but infectious virions are not produced. In the literature, nonproductive HPV infections have frequently been referred to as latent infections. Usually in nonproductive latent infections a small number of copies of the HPV genome remain in the nucleus in a free circular form called an episome. Replication of the episomal DNA in latent

infections is tightly coupled to the replication of the epithelial cells and only occurs in concert with replication of the host cell's chromosomal DNA. Since complete viral particles are presumably not produced in latent infections, the characteristic cellular effects of a HPV infection are not present and HPV can only be identified using molecular methods. Latently infected epithelium displays no morphologic abnormality. Thus, latent infection is used to characterize HPV infections in which there is no gross or microscopic evidence of a HPV-induced epithelial lesion, and the virus is present at such low copy number in the epithelium that it cannot be detected with routine molecular detection methods.

The other form of HPV infection is *a productive viral infection*. In productive viral infections, viral DNA replication occurs independently of host chromosomal DNA synthesis. This independent viral DNA replication produces large amounts of viral DNA and results in infectious virions. Viral DNA replication takes place predominantly

Fig. 5.12

HPV life cycle (Source: Kahn JA (2009) HPV vaccination for the prevention of cervical intraepithelial neoplasia (CIN). N Engl J Med 361:273)

in the intermediate and superficial cell layers of the stratified squamous epithelium. As the virally infected epithelial cells mature and move toward the epithelial surface, cell-derived, differentiation-specific transcriptional factors produced by the epithelium stimulate the production of viral capsid proteins. This allows large amounts of intact virions to be formed and produces the characteristic virally associated effects of HPV that can be detected both cytologically and histologically, \bullet *Fig. 5.13a, b.* These viral-associated effects include acanthosis, cytoplasmic vacuolization, koilocytosis, multinucleation, and nuclear atypia.

Epidemiology of HPV Infections

Anogenital HPV infections are primarily transmitted by direct skin-to-skin or mucosa-to-mucosa contact. Based on prevalence studies among both men and women in the population, it appears that although sexual intercourse is the most common route of infection, intercourse is not required for transmission [27]. The efficiency of transmission during sexual intercourse is unknown, but clearly quite high with some estimates indicating a 40% transmission risk per act of intercourse [27]. Infection with multiple types of HPV is seen in 20–30% of infected young men and women. Condom use reduces but does not eliminate the risk of transmission to women. It also appears that male circumcision reduces transmission and carriage of HPV [199].

Most women become infected with HPV within several years of initiating sexual activity [25, 200]. Cumulative exposure is difficult to measure because most infections are transient and relatively short-lived, and serology is an insensitive indicator of exposure since many infected women do not produce measurable levels of antibody [78]. However, prospective follow-up studies of female college students report that after 5 years of follow-up 80% have been infected at some point with HPV [200]. Follow-up studies indicate that a frequent pattern of infection in sexually active young women is multiple serial infections with different types of HPV with each infectious episode being of relatively short duration [25].

The majority of HPV infections are transient and undergo clearance or become latent within 1–2 years of detection [27]. Clearance or development of latency is presumed to be mediated by cell-mediated immunity. High oncogenic risk HPV infections tend to clear more slowly than those caused by low oncogenic HPV types. After an infection has been persistent for 36 months, the

Fig. 5.13

Cytopathic effects of HPV. The cytopathic effects of HPV include nuclear enlargement, nuclear pyknosis or hyperchromaticity, anisocytosis, multinucleation, and perinuclear cytoplasmic vacuolization. (a) Histological features of a lesion is classified LSIL. (b) Cytological features of LSIL

potential for future clearance diminishes considerably [167]. Moreover, the longer an infection persists, the greater the likelihood that a high-grade precursor lesion will develop [167]. Therefore, infections caused by high

oncogenic risk HPV infections that persist for two or more years pose the greatest risk to women since these are the infections that may progress to a high-grade cervical cancer precursor or even an invasive cervical cancer. Approximately 10% of HPV infections will persist for two or more years. Long-term prospective cohort studies have demonstrated that in some women, HPV infections that have appeared to have cleared can reappear. Moreover, followup studies of HIV-infected women show a strong relationship between increasing levels of immune suppression and detection of HPV [204]. This suggests that in many instances women who appear to have cleared HPV infections actually harbor latent HPV infections in which the virus remains in the epithelium at a low copy number. The combination of multiple anogenital types of HPV, all of which appear to be highly transmissible in sexually active populations, combined with the transient nature of most infections explains the prevalence of HPV in the population. Prevalence of high-risk HPV DNA positivity is high in women with normal cytology in their late teens and 20s and drops with increasing age, **>** Fig. 5.14 [46]. Reactivity of latent infections could explain the slight increase in HPV prevalence seen in postmenopausal women [49]. Developmental status of the country of residence also appears to be important [49]. The reasons for the increased HPV prevalence in less-developed countries are unknown, but many relate to sexual practices and poor hygienic conditions, as well as an increase in burden of comorbid disease in the population.

Fig. 5.14

Prevalence of high-risk HPV DNA in women with normal cytology in the USA. This data come from a large, CDC surveillance survey (Modified from [46])

Development of Cervical Disease After HPV Infection

About one-third of the HPV DNA positive women will have a cytological abnormality [167]. The cumulative incidence of minor cytological abnormalities in HPVinfected women with initial normal cytology is 25-50% within 1-2 years. The risk of a cytological abnormality declines to baseline level in the population by 4 years [34, 131]. Risk factors for HPV persistence and the subsequent development of HSIL are not yet well characterized; however, HPV type is clearly important. HPV 16 infections are especially oncogenic and the cumulative risk for HSIL approaches 40% in women with persistent HPV infections for 3-5 years. Risk for HSIL is increased in women who are infected with multiple types of HPV, but this may simply reflect the sum of the risks for each individual type [197]. Risks of persistence and subsequent development of HSIL are also increased for HIV-infected and other immunosuppressed women [204].

In light of our current understanding of the pathogenesis of SIL, it would be expected that LSIL would be frequently multicellular in origin, since it develops within a field of latently infected cervical epithelium and frequently is associated with multiple types of HPV. In contrast, HSIL is typically associated with only a single type of HPV, is frequently aneuploid, and may contain integrated HPV DNA. Therefore, HSIL would be expected to be unicellular in origin. Studies that have utilized PCRbased detection methods to identify X-chromosome linked genetic markers have shown that SIL can be either monoclonal or polyclonal. Park et al. analyzed clonality by evaluating inactivation of the human androgen receptor gene that is located in the X-chromosome [144]. They found that LSIL associated with low-risk HPV types are typically polyclonal, whereas LSIL associated with high-risk HPV types are typically monoclonal, as are almost all HSIL. This indicates that LSIL associated with low risk or novel types of HPV are biologically different at their inception from lesions that are histologically low grade, but associated with high-risk HPV types. This conclusion is supported by studies that have determined the rates of regression, persistence, and progression of CIN 1 and CIN 2 lesions have found that 83% of monoclonal lesions progress or persist, whereas 64% of polyclonal lesions regress [189]. Other studies that have looked at LOH at specific chromosomal loci have found that a relatively small proportion of LSIL have LOH, but frequent LOH in HSIL [35, 108].

There is no unanimous opinion on the cellular origin of SIL. Three cellular sites of origin have been proposed: basal cells of the squamous epithelium of the portio, basal cells of the transformation zone epithelium, and reserve cells of the endocervix [91]. Most SIL begins at the squamocolumnar junction of the transformation zone, with one edge of the lesion bordering the endocervical columnar epithelium. Only about 10% of SIL will involve the endocervical canal without involving the squamocolumnar junction [1]. In general, the portion of SIL on the exocervical portio surface is low grade, whereas the portion of SIL that extends into the endocervical canal is high grade, \bigcirc *Fig. 5.15*. From these observations, it is now thought that most SIL arises in the basal cells of the transformation zone epithelium that is formed by the coalescence of squamous metaplastic epithelium with native squamous epithelium.

The subsequent development of invasive cervical cancer in persistently infected women appears to take a decade or more since the peak prevalence of HPV infection in the population is in the late teens/early 20s, whereas cervical cancer incidence in the unscreened populations plateaus from around 35–55 years of age. High-grade cervical cancer precursors are consistently more common than are invasive cervical cancers in the unscreened populations, suggesting that only a minority of high-grade precursors develop the capacity to become invasive cancers [80]. Long-term follow-up studies of untreated or partially treated HSIL have found that 30–50% progress to invasive cancer over a 30-year follow-up period [125].

Fig. 5.15

Distribution of SIL on the cervix. When both HSIL and LSIL are present on the cervix, the HSIL generally develops internally to the LSIL. It is much more likely that HSIL will extend into the endocervical canal

Other Risk Factors

It should be stressed that although infection with specific high-risk types of HPV is necessary for the development of invasive cervical cancer, it is not sufficient for the development of cervical cancer. The long latency between the initial exposure to HPV and the development of cervical cancer, as well as the fact that only a small fraction of women exposed to HPV develop cervical disease suggest that additional steps and perhaps other cofactors are necessary in the pathogenesis of cervical neoplasia.

Smoking, Diet, Oral Contraceptives

Cigarette smoking has also been associated with the development of cervical cancer [22]. In a comprehensive review of the literature, Szarewski concluded that a positive association between cigarette smoking and the development of cervical cancer had been reported by the majority of studies designed to address this question [182]. There are a number of possible mechanisms that could account for an association between cervical cancer and cigarette smoking. One is the secretion of cigarette smoke byproducts, including nicotine and cotinine, in cervical mucous of tobacco users and women passively exposed to cigarette smoke [122]. Another possible mechanism that could account for the association is the effect of cervical smoke by-products on the number and distribution immune effector and regulatory cells such as Langerhan's cells in the cervix [183].

The use of combined oral contraceptives is now recognized as a significant risk factor for the development of both cervical cancer precursors and invasive cervical cancers. A meta-analysis of 28 studies evaluating the risk of cervical cancer in women on oral contraceptives demonstrated that the relative risk of invasive cervical cancer increased with increasing duration of contraceptive use. After 10 years of use, the summary relative risks for were 2.2 (95% CI. 1.9-2.2) for all women and 2.5 (95% CI. 1.6-3.9) for HPV positive women [174]. A recent reanalysis of epidemiological studies involving over 50,000 women has confirmed that oral contraceptive use increases the risk of cervical cancer [6]. The impact of exogenous hormone use and cervical disease could be explained by a number of mechanisms including direct interactions between the hormones and the HPV genome, as well as by indirect effects such as a reduction in blood folate levels that is occasionally observed in women on oral contraceptives. It is unclear whether there is an association between endogenous hormone levels and invasive cervical cancer. No association has been found between age at menarche or age of menopause and cervical squamous cell carcinoma.

Only a few studies have focused on relationships between cervical cancer and diet, but some studies of the association between micronutrients and cervical neoplasia have shown a probable protective effect for folate, retinol, and vitamin E and possibly for vegetable and several other micronutrients [67, 180]. However, there has been no confirmation of the role of any micronutrients in supplementation trials. A review of the cervical disease and antioxidant nutrients concluded that there are only six studies that have properly controlled for HPV [31]. In these six well-controlled studies, an inverse relationship was observed between serum carotene and cervical carcinogenesis. Other studies have found an inverse association between cervical neoplasia and serum lycopene and beta-carotene [31]. Folate deficiency may also be a risk factor and a case-control study recently reported that higher folate levels are associated with significantly lower risk of SIL [29, 151]. Other factors that may be important include coinfection with Chlamydia trachomatis and low socioeconomic status (even after accounting for screening) [167].

Immunosuppression

Although cellular immune response against HPV are rather poorly characterized, they clearly play an important role in determining whether HPV infections are ultimately cleared or whether they persist and can develop into cervical neoplasia [179]. The human leukocyte antigen DRB1*1301 appears to confirm a protective effect in epidemiological studies from diverse populations [194]. Immunosuppression is a well-established risk factor for the development of both SIL and cervical cancer. Renal transplant recipients have a relative risk of 13.6 for the development of cervical carcinoma in situ compared to women in the general population [204]. There is also an association between cervical disease and infection with the human immunodeficiency virus (HIV) [204]. HPV infections are more prevalent, and tend to be more persistent in HIV-infected women. Numerous studies have documented a higher prevalence of cervical neoplasia among HIV-infected women compared to various control groups of HIV-uninfected women [204]. There also appears to be an increase in invasive cervical cancer, and cervical cancer is classified as an AIDS-defining condition. Among women in New York City, the standardized incidence ratio for cervical cancer is 9.2 times higher in HIV infected compared to noninfected women [59]. It is clear

that the invasive cervical cancers that do develop in HIVinfected women act aggressively and respond poorly to standard forms of therapy [117].

Clinical Features

SIL appears to be somewhat more frequently detected on the posterior lip of the cervix compared to the anterior lip of the cervix and is rarely seen at the lateral cervical angles [73, 153]. SIL may expand horizontally and involve the entire transformation zone, but it usually does not extend onto the native portio epithelium. The endocervical extension of SIL is not restricted and extension along the entire endocervical canal and into the uterus can rarely occur. The size and endocervical distribution of SIL tend to vary directly with increasing severity of lesion grade. HSIL usually has the largest surface area and more frequently involves the endocervical canal.

Pathologic Findings

SIL is characterized by abnormal cellular proliferation, abnormal maturation, and cytologic atypia. The cytologic abnormalities include hyperchromatic nuclei, abnormal chromatin distribution, nuclear pleomorphism, and increased nuclear : cytoplasmic ratio. Nuclear atypia is the hallmark of SIL. The nuclear borders are irregular, and the chromatin is coarse, granular (salt and pepper), or filamentous throughout the nuclear mass [134, 149].

Ultrastructurally, both the nuclear and cytoplasmic alterations of SIL are consistent with a progressive lack of normal differentiation [172]. There is a decrease in glycogen, tonofilaments, desmosomes, and specialized junctional units with increasing histologic dedifferentiation. These alterations are correlated with a progressive decrease in cellular adhesion, basal pseudopodia, and cell contact inhibition demonstrated by time-lapse cinematography in cells grown in vitro [161]. The surface ultrastructure of SIL also differs from the normal architecture. The most outstanding feature is the absence of surface microridges and the presence of abundant microvilli.

The traditional grading of SIL was based on the proportion of the epithelium occupied by basaloid, undifferentiated cells, reflecting a progressive loss of epithelial maturation, and decreasing glycogenization with increasing lesion severity. The spectrum of epithelial alterations that comprises SIL was therefore semiquantitatively classified into three categories: CIN grade 1 – neoplastic, basaloid cells occupying the lower third of the epithelium; CIN grade 2 – basaloid cells occupying the lower third to two-thirds of the epithelium; and CIN grade 3 – basaloid cells occupying two-thirds to full thickness of the epithelium, \bigcirc *Fig. 5.16*. Adoption of TBS nomenclature to histologic classification results in a two-tier rather than a three-tier grading system.

LSIL

HPV-induced cytologic and histologic changes are considered the most characteristic features of LSIL (CIN 1). The most important of these changes is significant nuclear atypia. Nuclear atypia is characterized by variation in nuclear size with nuclear enlargement, hyperchromasia, and irregularity, and wrinkling of the nuclear membrane. Nuclei often vary up to threefold in size and have quite variable staining patterns, \bigcirc *Fig. 5.17*. However, in LSIL there is usually minimal nuclear atypia in the epithelial cells residing in the lower third of the epithelium, \bigcirc *Fig. 5.18*. Cells in the superficial layers of the epithelium may have nuclei that are somewhat smaller and pyknotic. Squamous cells with productive HPV infections

also frequently show perinuclear cytoplasmic cavitation or halos that are accompanied by thickening of the cytoplasmic membrane, **>** Fig. 5.19a. These halos are best appreciated in cytology specimens, **>** Fig. 5.19b. They develop because productive HPV infections induce cytoskeletal abnormalities that may lead to cytoplasmic cavitation. The combination of significant nuclear atypia and cytoplasmic halos has been termed koilocytosis or koilocytotic atypia and is pathognomonic of a productive HPV infected. Mitotic spindle abnormalities also occur in productive HPV infections and these appear to interfere with mitosis and cytokinesis. This leads to the polyploidy and bi- or multinucleated cells that are usually present in productive HPV infections, **>** *Figs.* 5.13 and **>** 5.19 [62]. Polyploid cells are cytologically atypical and are readily recognized as being "abnormal" on either cytology or histology. Taken together, the histological and cytological features of koilocytosis, nuclear atypia, architectural abnormalities, and multinucleation are pathognomonic of an HPV-infected epithelium at any site in the lower genital tract and are especially prominent in LSIL.

Fig. 5.16

Cervical squamous carcinoma precursors. Schematic representation of cervical cancer precursors and the different terminologies that have been used to refer to them. The risk of developing microinvasion from different states of SIL is arbitrarily represented and is not necessarily proportional to that illustrated in this scheme

The architectural abnormalities associated with low-grade SIL are due to a proliferation of basal and parabasal cells in the infected epithelium. The architectural abnormalities associated with LSIL causes the lesional tissue to appear quite different from the adjacent epithelium. Therefore, LSIL can usually be identified at lower magnifications based on the increased thickness of

Fig. 5.17

Nuclear atypia in LSIL. The most significant feature of LSIL is nuclear atypia. This is characterized by nuclear enlargement, hyperchromasia, nuclear irregularity, and variation in nuclear size

Fig. 5.18

LSIL with minimal cytological atypia in lower third of the epithelium. Typically, the cells in lower third of the epithelium show minimal atypia in LSIL the epithelium accompanied by cells with prominent hyperchromatic nuclei in the upper levels of the epithelium, **•** *Fig. 5.20.* HPV-induced hyperplasia can be highly variable and takes many forms, but is most commonly characterized by papillomatosis and acanthosis, **•** *Fig. 5.21.* One of the more common patterns of the acanthosis is that of moderate epithelial thickening and an undulating, slightly raised surface. In the older literature, cervical lesions with HPV-associated cytopathic effects and only a moderate degree of epithelial thickening were referred to as *condyloma planum* or *flat condyloma.* Other types of epithelial hyperplasia that can occur in productive HPV infection are multiple papillary fronds containing fibrovascular cores and pointed epithelial spikes, **•** *Fig. 5.22.* Colposcopically, these can present as an

Fig. 5.19

Koilocytosis in LSIL. The cytological features of a productive HPV infection include multinucleation and perinuclear cytoplasmic cavitation or halos. The combination of nuclear atypia and cytoplasmic halos is referred to as *koilocytosis*. (a) Koilocytosis on histology, (b) Koilocytosis on cytology exophytic condyloma acuminatum similar to those that occur on the vulva or vagina or as a less-exophytic lesion with prominent, fine surface spikes. The latter are frequently referred to in the colposcopic literature as *spiked*

Fig. 5.20

LSIL recognized at low magnification. LSIL can usually be recognized at relatively low magnification based on the increased thickness of the epithelium accompanied by prominent hyperchromatic nuclei in upper level of the epithelium

Fig. 5.21

LSIL. Papillomatosis, acanthosis, parakeratosis, and hyperkeratosis are frequently present

condyloma. A third type of papillary low-grade CIN is referred to as immature condyloma (e.g., papillary immature metaplasia). These represent infections of the transformation zone epithelium by HPV 6 or 11. These lesions typically have a filiform papillary architecture, *Fig. 5.23a*. Immature condylomas can be viewed as part of a histologic spectrum that ranges from squamous papillomas at the benign end to papillary carcinomas at the malignant end. Because HPV 6- and 11-infected transformation zone epithelial cells do not mature, koilocytotic features are minimized and these lesions retain an immature condylomas demonstrate only a mild degree of nuclear atypia and typically have a relatively low mitotic index.

The surface of LSIL frequently has a layer of parakeratosis and somewhat less commonly hyperkeratosis with an associated granular layer, \bigcirc *Fig. 5.24*. When gland involvement by the HPV-infected epithelium and acanthosis predominate, the histological pattern appears endophytic and superficially resembles that of an inverted nasal papilloma.

Fig. 5.22

LSIL of type referred to as *spiked condyloma*. This lesion shows exaggerated epithelial thickening with multiple papillary fronds, each of which contains a fibrovascular core. The individual cells in these lesions are similar to the cells seen in flat lesions. Such lesions are referred to as "spiked condyloma" on colposcopy

Differential Diagnosis

Studies measuring interobserver variability of histological diagnosis of cervical lesions demonstrate that although agreement between pathologists is excellent for invasive lesions, and moderately good for HSIL, it is poor for LSIL [87, 163, 171, 181]. In the NCI-sponsored ALTS (ASCUS-LSIL Traige Study) multicenter study, 2,237 colposcopically directed biopsies that had been initially diagnosed at the clinical performance sites were reviewed by a quality control panel of pathologists. Only 43% of the biopsies initially diagnosed as LSIL were classified as LSIL after review, **7** *Table 5.4.* Most of the discrepancies were due to the inability of the pathologists to distinguish LSIL from reactive squamous proliferations. This suggests that

Fig. 5.23

LSIL of type referred to as *immature condyloma*. These lesions occur in the transformation zone and are associated with HPV 6 or 11. (a) They typically form thin, papillary projections. (b) Typically, the cells have a metaplastic phenotype with minimal koilocytosis the morphologic criteria routinely used to distinguish these two lesions have serious shortcomings.

Prospective follow-up studies indicate that the majority of LSIL lesions spontaneously regress over a several year period of time [126]. Therefore, it is not surprising that lesions are frequently encountered that have some, but not all of the features of LSIL. Such lesions may represent regressing LSIL and are classified as borderline condyloma by some authors [64]. Such lesions as described as having mild acanthosis and mild cellular proliferation in the parabasal layers remain quite organized. They show rare, mildly atypical squamous cells in the intermediate and superficial layers that are characterized by minor nuclear enlargement, hyperchromasia, and sometimes binucleation, **S** *Fig. 5.25a, b.* It is important to recognize that there are no good molecular : histopathological correlation studies of these lesions and therefore the clinical significance of borderline condylomas is unknown and we do not recommend the use of this term.

Two biomarkers, $p16^{ink}$ and Ki-67, appear to be useful for differentiating SIL from other conditions. $p16^{ink}$ is a cyclin-dependent protein kinase inhibitor that is overexpressed in almost all HSIL and invasive cervical cancers [96, 101, 188]. $p16^{ink}$ is particularly attractive as a biomarker for HPV-associated SIL since overexpression within cervical neoplasia has been directly linked to the continued expression of the HPV oncogene E7. Moreover, $p16^{ink}$ overexpression appears to be independent of

 Fig. 5.24
LSIL with both hyperkeratosis and parakeratosis. Both hyperkeratosis and parakeratosis are frequently associated with LSIL

Table 5.4

212

Variability in histopathological diagnoses in ALTS

	Quality control panel review diagnosis				
lnitial Dx	WNL (%)	ASCUS (%)	LSIL (%)	HSIL (%)	Total
WNL	91	22	4	3	685
ASCUS	77	10	9	4	184
LSIL	44	4	43	13	887
HSIL	7	2	14	77	481

Modified from [181].

Fig. 5.25

LSIL of the type referred to as *borderline condyloma*.

(a) Lesions of this type have less nuclear atypia and acanthosis than usually seen in LSIL. This lesion contains considerable numbers of multinucleated cells. (b) It stains positively with p16^{ink} and we would classify it as LSIL

Fig. 5.26

Junction between HSIL and normal squamous epithelium. (a) This section shows the junction between a HSIL and normal squamous epithelium. Both (b) p16^{ink} and (c) Ki-67 staining demonstrates how sharp the demarcation usually is between lesional and non-lesional tissue the particular type of high-risk HPV-associated with the lesion. Studies have uniformly shown p16^{ink} staining to be absent in normal squamous epithelium and benign inflammatory/reparative conditions, **>** Fig. 5.26b [155, 188, 193, 211]. Therefore, it has been suggested that p16^{ink} immunostaining could improve the ability of pathologists to differentiate between immature squamous metaplasia or reaction/reparative conditions and SIL associated with high-risk types of HPV. Since approximately two-thirds of LSIL is associated with a high-risk type of HPV, it is not surprising that approximately one-third to half of LSIL will show strong diffuse staining of the basal layer with p16^{ink}, **)** Fig. 5.27a, b, and another one-third show focal p16^{ink} staining [75, 193, 211]. Therefore, although absence of p16^{ink} staining does not mean that a lesion is not LSIL, the presence of strong diffuse staining of the lower half of the epithelium is a fairly good indicator that a lesion is a SIL. Ki-67 is a marker of cellular proliferation that is also useful for the identification of SIL that show staining in the upper two-thirds of the epithelium whereas normal squamous epithelium typically shows only limited staining in the parabasal cell layer, ♦ Figs. 5.26c and ♦ 5.27c [86, 154]. However, unlike p16^{ink}, Ki-67 staining may be positive in HPV-negative squamous metaplasia and reactive/reparative conditions that reduces its usefulness in differentiating these conditions from SIL.

Overdiagnosis of LSIL can be reduced if it is remembered that significant nuclear atypia is the hallmark of SIL. Correlation of HPV DNA with specific cytologic/histologic findings has uniformly found that perinuclear halos in the absence of significant nuclear atypia are nonspecific features [60, 130, 195]. Therefore, the diagnosis of LSIL should be made only when significant nuclear atypia accompanies perinuclear halos and the indiscriminate use of the term "koilocytosis" whenever the cervical squamous epithelium demonstrates the slightest hint of "cytoplasmic vacuolization" should be discouraged. Cytoplasmic vacuolization in the absence of nuclear atypia is a nonspecific change that may occur as a reflection of atrophy-related vacuolar degeneration or with prominent glycogen vacuolization of the normal squamous epithelium, **>** Fig. 5.28a, b. Although LSIL does occur in postmenopausal women, it is uncommon. "Pseudokoilocytes" can also be seen in non-HPV-related infections, such as trichomoniasis, Gardnerella vaginalis, and candidiasis, **>** Fig. 5.29. In contrast to the focal distribution of koilocytes in LSIL, cells of normal squamous epithelium that have perinuclear clearing are not sharply demarcated, the nuclei are not enlarged or atypical, and multinucleated cells are infrequent. In addition to the

Fig. 5.27

p16^{ink} and Ki-67 staining of LSIL. Approximately one-third of LSIL will show strong diffuse staining of the lower portion of the epithelium with p16^{ink}. Most LSIL will have an increased Ki-67 labeling index. (a) H&E, (b) p16^{ink}, and (c) Ki-67 staining absence of nuclear atypia, normal stratification and maturation are maintained in such conditions, whereas in HPV-associated lesions, there is some degree of cellular disorganization, particularly near the surface, and there is disturbance in the normal pattern of maturation.

Misdiagnosis of LSIL as HSIL can be avoided by recognizing that LSIL generally does not have a high mitotic index, loss of cell polarity, and abnormal mitotic figures (AMFs). Although a diagnosis of LSIL requires significant atypia, the atypia does not usually involve the basal or parabasal cell layers. The classification of lesions that have the characteristic histologic features of LSIL, but also have

Fig. 5.28

Atrophy-related perinuclear halos. (a) Biopsy from a postmenopausal patient. The squamous epithelial cells show prominent perinuclear halos, but do not have significant nuclear atypia. (b) This lesion does not stain for p16^{ink}

Fig. 5.29

Pseudokoilocytosis secondary to infection. (a) Infectionrelated perinuclear halos are frequently observed in women with non-HPV-related infections. Generally in infection considerable numbers of inflammatory cells are present. (b) At higher magnification, the nuclei are not as enlarged or atypical as usually seen in LSIL and multinucleated cells are infrequent AMFs is controversial. AMFs generally indicate that a lesion is aneuploid, **>** Fig. 5.30. Therefore, an argument could be made that lesions with AMFs should be classified as HSIL, although in the absence of significant basal or parabasal atypia many pathologists would classify lowgrade-appearing lesions with only one or two AMFs as LSIL. It is also important to note that many HSIL have significant koilocytotic change in the upper layers of the epithelium, so simply having koilocytosis and differentiation in the upper half of the epithelium should not result in a lesion being classified as LSIL if it has significant basal-parabasal nuclear atypia, **>** Fig. 5.31. **>** Figure 5.32 is a lesion that might be classified as LSIL by some pathologists. However, the lesion has significant basal and parabasal nuclear atypia, as well as a mitosis in the midportion of the epithelium and an AMF. Therefore, we would classify this lesion as a HSIL.

■ Fig. 5.30 Abnormal mitotic figures (AMFs) in SIL. AMFs indicate that a lesion is aneuploid and are typically found in HSIL

HSIL

In HSIL (CIN 2, 3), atypia should be present in all layers of the squamous epithelium, but to an extent and degree that exceeds what is seen in LSIL. There is significant basalparabasal nuclear atypia and AMFs. Immature basal-type cells typically occupy more than the lower third of the

Fig. 5.31

HSIL mimicking an LSIL. This lesion has marked koilocytosis in the upper half of the epithelium, but has significant atypia of the basal, parabasal layers and abnormal mitotic figures (AMFs). Because of the atypia in the basal and parabasal layers, this should be classified as HSIL

Fig. 5.32

LSIL versus HSIL. Sometimes it is difficult to differentiate between LSIL and HSIL. This lesion has many features of LSIL, but also has a mitosis in the middle of the epithelium and an abnormal mitotic figure (AMF) and based on this it should be classified as HSIL

epithelium, **>** Fig. 5.33. In addition, there is nuclear crowding, pleomorphism, and loss of the normal cell polarity. The nuclei of the immature basal-type cells are enlarged when compared to the nuclei of cells at comparable levels of the normal epithelium. This nuclear enlargement is frequently most pronounced in the lower half of the epithelium although in all cases the superficial cells demonstrate some degree of nuclear enlargement. As in LSIL, the nuclei are hyperchromatic and the chromatin is finely to coarsely granular, **>** Fig. 5.34. Prominent nuclei or chromocenters are uncommon. Normal and abnormal mitotic figures are present and mitoses are usually present in the upper half of the epithelium. Cytoplasm is usually scant resulting in an increase in the nuclear : cytoplasmic ratio. Cell borders between the primitive cells are usually indistinct. The cells overlying the basal-type cells also have atypical nuclei but have more cytoplasm and therefore lower nuclear : cytoplasmic ratios, more distinct cell boundaries, and can have prominent HPV cytopathic effects, including perinuclear halos and bi- or multinucleation. In the superficial layers of the epithelium, individual dyskeratotic cells may be seen, **>** Fig. 5.35. These cells are small with pyknotic hyperchromatic nuclei and dense acidophilic cytoplasm. Another characteristic feature of HSIL is the variability in nuclear size (anisonucleosis), **>** Fig. 5.36. It should be stressed, however, that this is a variable histological feature. In some HSIL lesions, particularly those that were previously termed carcinoma in situ, the nuclei at first glance appear relatively uniform in size, although careful scrutiny will reveal some variation in nuclear size and shape, **Fig.** 5.37. Many HSIL lesions also have koilocytotic features in the upper layers of the epithelium similar to what is seen in LSIL, **Fig.** 5.38. However, these koilocytotic features are often associated with bizarre nuclei and abnormal keratinization. These lesions were previously classified as CIN 2.

The original CIN terminology subdivides HSIL into two categories: CIN 2 and CIN 3. This distinction is made based on the proportion of the epithelial thickness occupied by undifferentiated neoplastic cells. In CIN 2, the immature basaloid-type cells occupy up to two-thirds of the epithelial thickness, but do not extend into the upper third of the epithelium, \bigcirc *Fig. 5.38*. Similarly, mitoses are found in the lower two-thirds of the epithelium, but not in the upper third. In CIN 3 lesions, immature basaloid-type cells occupy the upper third of the epithelium and mitoses can be present at any level, \bigcirc *Fig. 5.39*. Studies of the reproducibility of the histopathological diagnosis of different grades of cervical cancer precursors have shown that diagnosis of CIN 2 is not reproducible [33, 87, 163]. The lack of reproducibility of the diagnosis of CIN 2 is due to

Fig. 5.33

HSIL. Undifferentiated neoplastic cells replace 50–70% of the epithelium. The nuclear : cytoplasmic ratio is high, and the cytoplasmic membranes and the basal layer are indistinct

Fig. 5.34

HSIL. This is a typical HSIL with numerous mitoses in the middle portion of the epithelium and immature basaloid cells extending almost to the surface

Fig. 5.35

HSIL with dyskeratotic cells. This HSIL shows both parakeratosis and dyskeratotic cells (small dark cells with pyknotic nuclei and eosinophilic cytoplasm) in the upper half of the epithelium

the subjective criteria used to separate the different grades of CIN and the fact that the thickness of the epithelium occupied by immature basaloid-type cells varies considerably, even in cervical biopsy specimens.

In most tissues, aneuploidy is a marker of malignant potential and multiple studies have shown that the majority of HSIL lesions are aneuploid [17, 19, 20]. A number of studies have compared histologic features with ploidy levels and found that cervical lesions with diploid or polyploid DNA contents generally retain polarity of the basal cell layer and lack AMFs, whereas aneuploid lesions have more marked nuclear atypia and more cellular disorganization. The best histologic correlate of aneuploid is AMFs [13, 63]. Therefore, some authors have suggested that AMFs other than multipolar and dispersed metaphases are an accurate histologic surrogate of aneuploidy and can be used as a histological determinate for discriminating between LSIL and HSIL [160]. Although AMFs are commonly seen in HSIL, > Fig. 5.39, they should not be used as the sole criterion for discriminating between LSIL

Fig. 5.36
HSIL with marked variability in nuclear size (anisonucleosis).
Anisonucleosis is a variable feature of HSIL

and HSIL for several reasons: (1) they can be difficult to distinguish from karyorrhexis, (2) detection of AMFs is influenced by variables that are independent of ploidy level, including size of biopsy, quality of fixation, quality of the microscopic section, and number of levels examined, and (3) some HSIL lesions, and even some invasive cancers, lack AMFs and are not aneuploid [74, 134]. Therefore, although a lesion showing the above features with unequivocal AMFs should be classified as HSIL, the converse is not true. Lesions with the other histological features of a HSIL should be classified as such even in the absence of AMFs. It is also important to point out that using these criteria, some high-grade lesions will have cells with prominent HPV cytopathic effects similar to those seen in LSIL, **>** *Figs. 5.31* and **>** *5.32*. The presence of such cells should not be taken as evidence that the lesion is low grade if other features of a high-grade lesion are present. Therefore, the criteria that are used for distinguishing LSIL from HSIL include other features such as the distribution of immature, basal-type cells, the level at which mitotic figures in the epithelium are identified, the extent

Fig. 5.37

HSIL. The full thickness of the epithelium is composed of small, undifferentiated neoplastic cells. This is the classic *small cell carcinoma in situ*. Note numerous mitotic figures, loss of cellular maturation and organization, and lack of koilocytes

Fig. 5.38

HSIL with marked koilocytosis. In addition to having immature basaloid cells extending to the middle of the epithelium, this lesion has considerable koilocytotic features. Lesions with this histology were previously classified as CIN 2

of abnormalities of differentiation and polarity, and the degree of nuclear atypia, **2** *Table 5.5.*

It is important to recognize that HSIL has quite a variable histological presentation, especially with respect to size of the cells, extent of koilocytosis, degree of atypia, and degree of keratinization. The most common different presentations include a mature or koilocytotic form that is characterized by prominent HPV features (i.e., koilocytosis) accompanied by atypia of the basal and parabasal cell layers together with mitotic figures, including abnormal forms, in the upper two-thirds of the epithelium. Another commonly encountered presentation is keratinizing HSIL that has quite prominent superficial keratinization accompanied by cells with the typical histological and cytological features of HSIL, **>** Fig. 5.40. Other HSILs show less keratinization but have a prominent layer of parakeratotic cells, > Fig. 5.41. Perhaps the most difficult forms of HSIL to recognize are those that have an immature metaplastic phenotype. These lesions resemble immature squamous metaplasia and are sometimes encountered underneath an intact columnar epithelium, **>** Fig. 5.42. Compared to immature squamous metaplasia, HSIL with an immature metaplastic phenotype shows a greater degree of hyperchromasia and anisonucleosis. Nuclear density does not decrease in the superficial cell layers and a syncytium of nuclei can

Fig. 5.39

HSIL. This form of HSIL has immature basaloid cells and mitoses extending almost to the surface. Lesions with this histology were previously classified as CIN 3

Table 5.5

Distinguishing features of LSIL and HSIL

Feature	LSIL	HSIL
HPV types	Any anogenital HPV	High-risk types ^a
Koilocytosis	Frequently present	Occasionally present
Ploidy	Mostly diploid or polyploid	Usually aneuploid
Abnormal mitotic figures (AMFs)	Absent	Frequent
Location of undifferentiated cells and mitotic figures	Lower third	Upper two- thirds

^aHigh risk types of HPV include 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66.

Fig. 5.41

HSIL with prominent abnormal parakeratosis. This HSIL has a superficial layer of compacted parakeratotic cells that appear abnormally keratinized

Fig. 5.40

HSIL with hyperkeratosis and parakeratosis. Prominent keratinization is frequently seen in HSIL. This HSIL has a thick plaque of keratin on the surface that can often be seen at the time of a gynecological examination. Clinicians call plaques of keratin on the surface of the cervix leukoplakia. Parakeratosis is also present

sometimes be seen in the superficial layers. $p16^{Ink}$ is very useful in diagnosing these lesions, **>** *Fig. 5.43a, b.* In addition, some HSIL have both squamous and mucinous differentiation, **>** *Fig. 5.44a.* This reflects the multipotential nature of the cells in the transformation zone. These

lesions with both squamous and mucinous differentiation have been referred to as *stratified mucin-producing intraepithelial lesion* (SMILE) and contain cells with prominent mucin droplets [145]. SMILE usually shows a high Ki-67 labeling index and strong diffuse staining with p16^{Ink}, **○** *Fig. 5.44b, c.* These lesions are often found in association with both HSIL and adenocarcinoma in situ (AIS) [145].

220

In the past, some investigators have proposed formally subtyping high-grade precursors into small cell anaplastic, large cell keratinizing, and large cell nonkeratinizing dysplasia [147, 157]. Because accurate studies concerning the invasive potential of each of these subtypes are lacking, prediction of the likelihood of progression to invasive carcinoma should not be based on the above subclassification.

Differential Diagnosis

Immature metaplasia, reactive/reparative processes, and atrophy are the most common lesions mistaken for HSIL. This is because cells of these lesions can show immaturity of the squamous epithelium, nuclear atypia, and inflammatory cellular changes. In immature

Fig. 5.43

HSIL with metaplastic features. (a) This lesion is relatively bland appearing, but has considerable numbers of mitotic figures. (b) P16^{ink} staining demonstrates strong diffuse positivity

Fig. 5.44

C

Stratified mucin-producing intraepithelial lesion (SMILE). (a) These HSIL show both mucinous and squamous differentiation. (b) It has a high Ki-67 labeling index and (c) stains positively for p16^{ink}

• Fig. 5.45 Immature squamous metaplasia. Metaplastic squamous cells are regularly oriented with uniformly disposed nuclear chromatin and cellular borders. Intracellular bridges are present

metaplasia, the full thickness of the epithelium is composed of immature parabasal cells with a high nuclear : cytoplasmic ratio, **>** Fig. 5.45. The cells usually are vertical and the nuclei are only slightly hyperchromatic. The most helpful feature in distinguishing HSIL with an immature metaplastic phenotype from immature metaplasia is the absence of nuclear pleomorphism in the latter. The chromatin in metaplastic squamous epithelium is finer and more evenly distributed than in HSIL. In addition, cellular polarity is retained, cell membranes are clearly defined, and cellular crowding is not marked. Immature metaplasia typically shows a regularity of nuclear spacing and the lesions lack significant variation in nuclear size and staining pattern. Atypical cells are rarely seen in the superficial layers of the epithelium and the superficial layers of the epithelium often appear more normal than the lower half. Mucinous epithelium is often present on the surface of immature metaplastic squamous epithelium but only occasionally overlies HSIL, > Fig. 5.46. Immature metaplasia may have mitotic activity, but AMFs are not present. When significant numbers of mitoses are present it is more likely that the lesion represents a HSIL, **>** Fig. 5.47. Sometimes, there may be more pronounced nuclear atypia within immature metaplasia, **>** Fig. 5.48a, b. Such lesions are designated by some as atypical immature metaplasia (AIM) [42]. Histologically, AIM lesions have a monomorphic population of squamous cells that retain

Immature squamous metaplasia. This lesion has a relatively uniform metaplastic appearance, but the nuclei are hyperchromatic and irregular. Some mitoses are present. However, the lesion is found underlying columnar epithelium and the degree of nuclear atypia is insufficient to warrant a diagnosis of HSIL

Fig. 5.47

HSIL. This lesion has a relatively uniform metaplastic appearance, but has considerable numbers of mitoses and exhibits loss of polarity. It is somewhat similar to the lesion shown in **Fig. 5.46**. However, this lesion showed strong diffuse p16^{ink} staining throughout its full thickness (not shown) and was associated with classic HSIL in other sections. Immunohistochemical staining for p16^{ink} is helpful in classifying lesions of this type their cellular polarity. They are more cellular than the usual immature squamous metaplasia but show a low mitotic activity, usually less than one mitoses per ten high-powered fields and very few cells are Ki-67 positive [64]. The use of the term AIM is not generally recommended unless clarified with a note because it is not widely accepted and may be confusing to clinicians. Moreover, an AIM diagnosis is poorly reproducible and many of the lesions diagnosed as AIM will be accompanied by a concurrent or subsequent diagnosis of HSIL [143]. In one study, 80% of high-risk HPV positive patients with AIM lesions had a follow-up or concurrent diagnosis of HSIL [70] suggesting that the lesions classified as AIM were very likely subtle forms of HSIL.

Fig. 5.48

Atypical immature metaplasia (AIM). (a) This immature squamous metaplastic lesion has more pronounced nuclear atypia than usually seen in metaplasia. Lesions with this histology are referred to by some as AIM lesions. (b) This particular lesion has negative/patchy p16^{ink} staining Reparative processes are also sometimes very difficult to differentiate from HSIL, \bigcirc *Fig. 5.49*. In reparative processes atypical basal cells occupy the lower half of the epithelium but the cells have a regular nuclear outline, prominent nucleoli, and usually have distinct cell membranes. In addition, dense acute and chronic inflammatory infiltrates are usually present. In reactive/reparative processes there is usually intracellular edema which leads to spongiosis of the epithelium. Multinucleated cells are generally not observed and the superficial epithelial cells lack the marked variability in nuclear size, shape, and density that characterize HSIL.

Atrophy can have a variety of histological appearances and is occasionally difficult to distinguish from HSIL because it is composed of basal and parabasal cells showing no differentiation. In most instances the atrophic cells are immature but they are quite bland appearing. Although there is a high nuclear : cytoplasmic ratio, atrophic epithelium is thin and shows no nuclear pleomorphism, mitotic activity, atypia, or lack of polarity.

Fig. 5.49

Reparative process mimicking HSIL. This reparative process shows more nuclear variability than usually seen in repair. However, there is considerable inflammation present These cases rarely are mistaken for HSIL, provided the patient's age is known. However, in other instances atrophy results in disturbances in cellular maturation with pseudokoilocytotic cells and cells with nuclear enlargement and nuclear hyperchromasia, \bigcirc *Fig.* 5.50. Finally, HSIL, particularly with extensive gland involvement, may be confused with microinvasive carcinoma (see \bigcirc Chap. 6, Carcinoma and Other Tumors of the Cervix), \bigcirc *Fig.* 5.51.

In our experience it is sometimes simply impossible to distinguish immature metaplasia, AIM, reactive/reparative changes, or atrophy from HSIL based on histopathology alone. In these cases, immunohistochemical staining is essential in differentiating HSIL from the other conditions. P16^{ink} is overexpressed in almost all HSIL and invasive cervical cancers and almost all HSILs show strong, diffuse staining of the epithelium, **>** *Fig.* 5.52 [96, 101, 188]. Both reparative/metaplastic processes and atrophic epithelium do not stain with p16^{ink}, **>** *Figs.* 5.48b and **>** 5.50c. Atrophic epithelium shows either absent or

Fig. 5.50

Atrophy mimicking HSIL. (a) In severe atrophy, there can be considerable variation in nuclear size and irregularly oriented cells mimicing HSIL. (b) Atrophy has a very low Ki-67 staining index and (c) does not stain with p16^{ink}

Fig. 5.52 p16^{ink} immunostaining of HSIL. HSIL typically shows strong, diffuse staining with p16^{ink}

minimal staining with Ki-67, whereas HSIL shows considerable numbers of labeled cells in all layers of the epithelium.

Behavior of SIL

Before discussing the behavior of SIL, it is important to emphasize that most natural history studies were conducted in the 1970s and 1980s prior to our enhanced understanding of the role of HPV in the pathogenesis of cervical cancer and the realization that LSIL is simply a cytological and histological marker for a productive HPV infection. Moreover, over the last decade, we have come to realize that not only is the interpretation of cervical biopsies and cytology subjective and prone to considerable error, but also that colposcopy is much less accurate than previously thought [66, 120, 181]. Nevertheless, the older natural history studies remain important because they provide insight into both the likelihood that a woman with SIL will spontaneously clear her lesion and the likelihood that she will develop an invasive cervical cancer. Since these studies used the dysplasia/CIS or CIN terminology, in this section those terms will be retained in order to accurately describe the findings from these studies. Two approaches have been used to determine the natural history of SIL. These are prospective, clinical follow-up studies of individual women with cervical lesions and epidemiological studies linking cytology records with cancer registries. Prospective clinical followup studies of the "natural history" or behavior of SIL have provided widely varying estimates of the rate of progression and regression in the different lesions. This is not surprising since various studies have used different entry criteria, different diagnostic criteria for categorizing lesions as SIL, and different study designs. For example, some studies have used punch biopsy and endocervical curettage (ECC) to establish the diagnosis. These diagnostic methods may remove (treat) lesions and therefore may interfere with long-term analysis by increasing the frequency of spontaneous regression and decreasing the frequency of progression [137].

● *Table 5.6* provides a summary of a meta-analysis of clinical follow-up studies of biopsy-confirmed CIN published through the mid-1990s [129]. The higher the grade of a lesion, the more likely it is to persist and the less likely it is to regress. Overall, it appears that approximately 57% of CIN 1 lesions spontaneously regress in the absence of therapy, and 11% progress to carcinoma in situ. The rates of persistence and progression are greater for high-grade CIN. Forty-three percent of CIN 2 lesions regress

Table 5.6

Natural history of CIN is dependent of lesional grade

	% Regression	% Persist	Progress to CIS
CIN 1	57	32	11
CIN 2	43	35	22
CIN 3	32	56	12

From [129]

and 22% progress to carcinoma in situ. The equivalent rates for CIN 3 lesions were 32% regression and 12% progression to carcinoma in situ. Overall, the progression of all grades of CIN to invasive cancer in the published observational studies is 1.7%. More recently, Castle et al. published estimates of the rate of spontaneous regression of biopsy-confirmed CIN 2 and found that after 24 months of follow-up 43% of the lesions had regressed, which is almost identical to what was found by the meta-analysis of older studies [32].

In 1998, Melnikow et al. performed a meta-analysis of studies in which women with a cytologic result of SIL were followed [126]. The analysis included 13,226 women with a cytologic result of LSIL who were followed for at least 6 months and had a median-weighted follow-up of 29 months. There were 10,026 women with HSIL who had a median-weighted follow-up of 25 months. The pooled estimates for regression to normal were 47% for LSIL and 35% for HSIL, **>** Fig. 5.53. No evidence of a relationship between the proportion of subjects regressing to normal and the length of follow-up was observed. Rates of progression of LSIL were 7% at 6 months and 21% at 24 months. For HSIL, the 6- and 24-month pooled progression rates were 7 and 24%. The pooled progression rates for invasive cancer at 6 and 24 months for LSIL were 0.04 and 0.15%, respectively. For HSIL, they were 0.15% at 6 months and 1.44% at 24 months. A much higher rate of regression of cytologically diagnosed LSIL has been reported by Moscicki et al. who prospectively followed a cohort of young women with LSIL. After 12 months of follow-up, 61% had regressed and by 36 months of follow-up 91% had regressed [133].

Another very informative study evaluated the records of the largest cytology laboratory serving the Toronto (Canada) region and linked these records with the Ontario Tumor Registry for the years of 1962–1980 [80]. During this period of time, most women with dysplasia who were evaluated by this laboratory were managed conservatively and did not undergo treatment. This study provides a unique insight into the long-term natural history of

Fig. 5.53

Pooled estimates of the rates of spontaneous regression (*left panel*) of a cytologic diagnosis of LSIL and HSIL. Pooled estimates of the rates of spontaneous progression (*right panel*) of LSIL and HSIL after 6 months (*circles*) and 12 months (*squares*). Progression of HSIL is from CIN 2 to CIN 3 or carcinoma in situ. Bars represent 95% confidence intervals (Modified from reference [126])

Table 5.7

Toronto long-term follow-up of abnormal cervical cytology

Grade of lesion	2 years	10 years
Regression rates ^a		
Mild dysplasia	44%	88%
Moderate dysplasia	33%	83%
Progression rates ^b		
Mild dysplasia	0.6%	12%
Moderate dysplasia	1.5%	17%
Severe dysplasia	2.8%	21%

^aRegression to within normal limits.

^bProgression to carcinoma in situ or worse. Modified from [80].

untreated SIL, **2** *Table 5.7*. The key findings of this study were that after 10 years of follow-up only 12% of untreated mild dysplasia and 17% of untreated moderate dysplasia were diagnosed with carcinoma in situ. At 10 years, 88% of the mild dysplasia and 83% of cases of moderate dysplasia had regressed [80].

What these studies show is that the vast majority of LSIL spontaneously regress in the absence of treatment and the risk that a woman with a LSIL will be subsequently diagnosed with either carcinoma in situ or invasive cervical cancer is relatively low. They also demonstrate that the likelihood that HSIL will regress in the absence of treatment is higher than many clinicians realize and that it generally takes many years for a HSIL to progress to an invasive carcinoma.

Management

Colposcopy combined with colposcopically directed cervical biopsies are the primary modality by which women with abnormal Pap smears are evaluated. Colposcopic examination consists of viewing the cervix with a long-focal-length, dissecting-type microscope at a magnification of about 16× after a solution of dilute (4%) acetic acid has been applied to the cervix. The acetic acid solution acts to remove and dissolve the cervical mucus and causes SIL to become whiter than the surrounding epithelium (acetowhite), **>** Fig. 5.54. This coloration allows the colposcopist to identify and biopsy epithelial lesions. In addition to allowing the detection of acetowhite areas, colposcopy also allows for the detection of blood vessel patterns that can indicate HSIL and the detection of invasive cancers. Colposcopy and appropriately directed biopsy have greatly facilitated the management of patients with preinvasive lesions of the cervix because it allows the clinician to rule out invasive cancer and determine the limits of preinvasive disease. Conservative ablative treatment modalities such as cryosurgery, laser ablation, and loop electrosurgical excision procedure (LEEP) can then be used to treat preinvasive disease, with success rates similar to those obtained with cone biopsies.

Precursors of Cervical Adenocarcinoma

Terminology and Historical Perspective

The first indication that precursor lesions for invasive endocervical adenocarcinomas exist came in 1952 when

Fig. 5.54 Colposcopic appearance of SIL. An acetowhite, wellcircumscribed lesion is present at the external os

Helper described highly atypical neoplastic cells lining architecturally normal endocervical glands adjacent to frankly invasive endocervical adenocarcinomas [76]. Shortly thereafter, Friedell and McKay described two patients with atypical glandular lesions of the cervix and designated these lesions AIS because of their histological resemblance to invasive endocervical adenocarcinoma [61]. One of these patients had a coexistent invasive adenocarcinoma of the cervix and one, squamous "carcinoma in situ."

By analogy to squamous cell cervical cancer precursors, some authors have proposed parallel classification schemata for endocervical adenocarcinoma precursors that include lesions with a lesser degree of abnormality than AIS [23, 26, 69, 115]. Such low-grade putative glandular precursor lesions were originally termed endocervical dysplasia by Bousfield et al. but other terms such as *atypical hyperplasia* are also used to refer to lesions that resemble AIS, but have a somewhat lesser degree of nuclear atypia and mitotic activity [23, 81]. Gloor and associates suggested that the term cervical intraepithelial glandular neoplasia (CIGN) be used to refer to both endocervical glandular dysplasia and AIS and that endocervical glandular dysplasia be classified as either CIGN grade 1 or 2 and AIS be classified as CIGN grade 3 [71]. The World Health Organization utilizes the term glandular dysplasia to describe a "glandular lesion characterized by significant nuclear abnormalities that are more striking than those in glandular atypia, but fall short of the criteria for adenocarcinoma in situ" [186]. Because of the relative rarity of endocervical glandular dysplasia,

the subjective nature of the morphologic criteria used to distinguish it from AIS, and the infrequent coexistence of endocervical glandular dysplasia with AIS, the significance of endocervical glandular dysplasia is not known [110]. A number of studies have utilized objective biomarkers including HPV DNA positivity, proliferation markers such as Ki-67/MIB-1, p16^{INK}, and selective mucin staining to determine whether endocervical glandular dysplasia acts as a precursor to AIS or invasive endocervical adenocarcinoma [3, 10, 71, 77, 109, 111, 136, 162, 185]. Although some of these studies have shown a similar pattern of biomarker expression in both endocervical glandular dysplasia and AIS, most recent studies have not [85, 110, 162]. Investigators who advocate the use of the term "glandular dysplasia" do so under the misguided notion that there is a similar relationship of glandular precursors to HPV infection as there is for squamous precursor lesions. As previously discussed, the histologic manifestation of productive viral infection is LSIL (mild dysplasia). Productive HPV infection is tightly linked to squamous differentiation. Glandular epithelium does not support productive infection. Accordingly, there is no comparable low-grade lesion in glandular epithelium. Since the term glandular dysplasia implies a relationship to AIS and invasive carcinoma that does not exist, the use of this term should be discontinued. Instead, atypical glandular proliferations that fall short of AIS should be evaluated using biomarkers such as p16^{INK} and Ki-67 and classified as reparative changes if they are p16^{INK} negative and show a low Ki-67 labeling index. In contrast, if they express p16^{INK} strongly and diffusely and show a high Ki-67 proliferation index they are classified as AIS.

Epidemiology and Etiology

Over the last 3 decades, endocervical glandular lesions have received increasing attention. This is attributable to a variety of factors. One is a perception that the prevalence of adenocarcinomas of the cervix and its precursor lesions is increasing. There has been a documented absolute increase in the prevalence of invasive adenocarcinomas in specific groups of women in both the USA and Europe. This may be due, in part, to the increased routine use of cytobrushes in screening and the widespread adoption of excisional methods for treating SIL such as the LEEP that permit pathological examination of the entire transformation zone. In addition, there is an increased awareness of these lesions by pathologists, and an awareness by colposcopists that certain types of glandular lesions are difficult to recogniz colposcopically.

The prevalence of AIS is not known but it is considerably less common than SIL. In most series, the ratio between AIS and HSIL has ranged from 1:26 to 1:237. Estimates for the USA as a whole are available in the SEER public database that contains data from patients entered into the database between 1976 and 1995, which is the last year that in situ carcinomas were reported to the database [5, 192]. In the SEER registry, there are a total of 149,178 women with either in situ or invasive cervical cancer. Of these, 96% had squamous lesions and 4% had glandular lesions. 121,793 (82%) of all cervical lesions were classified as in situ and of these, 120,317 (99%) were squamous cell carcinoma in situ and only 1,476 (1%) were AIS. For comparison, of the 27,385 women with invasive cervical cancer, 4,369 (16%) had invasive adenocarcinoma. In 1991-1995, the age-adjusted incidence rate in the SEER database for squamous carcinoma in situ in White women was 27.93 cases per 100,000, whereas the age-adjusted incidence rate for AIS was only 1.25 per 100,000 [152, 192]. Although the overall incidence of AIS remains quite low, the incidence increased approximately sixfold from the 1970s to the 1990s [192]. Because AIS is no longer reported, we do not know if the incidence has continued to increase over the last 2 decades. AIS rates peak at age 35-44 years in both White and Black women [192].

The age relationship between AIS and invasive adenocarcinoma is similar to that of HSIL and invasive squamous cell carcinoma, suggesting that AIS is a precursor lesion [152]. However, unlike squamous lesions of the cervix in which high-grade precursors occur more frequently than invasive cancer, exactly the opposite relationship exists for AIS and invasive adenocarcinoma of the cervix. The incidence of invasive glandular lesions is higher than that of noninvasive glandular lesions in all age groups [152]. A number of reasons have been proposed for this apparent discrepancy, including the fact that AIS is more difficult to detect both cytologically and colposcopically than is SIL and, therefore, might not be detected prior to the development of invasive adenocarcinoma. The experience reported for both Finland and Australia indicates that few women with endocervical adenocarcinoma are identified through screening [128, 140]. Additional support implicating AIS as a precursor of invasive adenocarcinoma comes from several anecdotal case reports and two small series of patients who had cytological or histological evidence of AIS several years prior to the detection of invasive adenocarcinoma [18, 21, 95]. Although these studies have been interpreted as indicating that AIS is a precursor lesion, it is conceivable that an unrecognized invasive cancer was present at the time of the original Pap test or cervical biopsy.

The proportion of AIS that occurs in association with SIL ranges from 24% to 75% [4, 38, 51]. This suggests that the two types of lesions may share a common etiology. Moreover, many of the risk factors are similar between glandular and squamous lesions. These include multiple sex partners, use of oral contraceptives, early onset of sexual activity, and low socioeconomic class [190]. Both squamous and glandular lesions also appear to be associated with high-risk types of HPV. Using in situ hybridization, Tase and coworkers examined eight cases of AIS for the presence of HPV DNA and found that five of the cases contained HPV but that, unlike SIL lesions analyzed with the same method, the majority of AIS was associated with HPV 18 as opposed to HPV 16 in SIL [184]. Since this initial report, other groups have analyzed AIS for the presence of HPV DNA, and it appears clear that most AIS is associated with HPV DNA and that HPV 16 and 18 are the most commonly encountered types. Duggan analyzed a series of 37 cases of AIS using PCR with dot blot enhancement and identified HPV 18 in 43% of cases and HPV 16 in 23% [55]. HPV DNA positivity was not correlated with any clinical variable in that series. Recently, Quint et al. analyzed 31 cases of AIS using a highly sensitive PCR method and identified HPV DNA in all of the cases. HPV 18 was found in 26% and HPV 16 in 70% [156].

Clinical Features

Most women with AIS are asymptomatic and the lesions are detected either during screening or fortuitously on an ECC, cervical punch biopsy, cone or loop excisional biopsy performed during the workup for SIL. In women who are symptomatic, the most common complaint is abnormal vaginal bleeding, either postcoital, postmenopausal, or out of phase. Rarely, symptomatic patients present with an abnormal discharge.

AIS is difficult to detect both cytologically and colposcopically [57, 158]. The detection of AIS on ECC can also be difficult [4]. In one histological study of 42 women with AIS, only 45% of the women had atypical glandular cells (AGC) detected cytologically on the prediagnosis cervical cytology [51]. The other cases were detected fortuitously on biopsies taken to evaluate SIL. In another study of 36 women with AIS, glandular abnormalities were detected on the prediagnosis cytology in only one-half of the women [4]. However, a large case-control study of AIS from Australia using data from a statewide registry found that the screening histories of 307 women with AIS were similar to that of healthy,

control women which was interpreted as indicating that AIS is usually detected through screening [127].

The distribution of AIS in the cervix is important for determining the most appropriate clinical management of these patients. AIS involves both the surface and glands in almost all cases. In 65% of cases, it involves the transformation zone [4, 15] and in the vast majority of cases it is unifocal. It can extend for a distance of up to 3 cm into the endocervical canal [15, 45].

Pathologic Findings

AIS is characterized by the presence of endocervical glands lined by atypical columnar epithelial cells that cytologically resemble the cells of invasive adenocarcinoma but which occur in the absence of invasion, **>** Fig. 5.55. These cells have elongated, cigar-shaped, hyperchromatic nuclei with coarse granular chromatin, **>** Fig. 5.56. The amount of cytoplasm is greatly reduced and there is only minimal intracellular mucin. This produces an increased nuclear : cytoplasmic ratio. The cells are crowded and pseudostratified, forming two or more rows. AIS may involve glands either focally, multifocally, or diffusely. Typically, some glands show an abrupt transition between normal epithelium and AIS, > Fig. 5.57. Mitotic figures including AMFs are common and apoptotic bodies are also commonly seen in the epithelium, usually subadjacent to the nucleus, **>** Fig. 5.58. Architecturally, the glands of AIS can have numerous outpouchings and

complex papillary infoldings and may display a cribriform pattern focally, **>** *Fig. 5.57*.

Ostor et al. have described two histological types of AIS [142]. One is the typical endocervical type of AIS described above. The other has features of an intestinal, as opposed to endocervical, mucosa with goblet cells and sometimes Paneth cells, \bigcirc *Fig. 5.59.* The colonic type is uncommon and usually occurs in association with typical endocervical AIS. The goblet cells in colonic AIS contain

Fig. 5.55

Adenocarcinoma in situ (AIS). AIS is characterized by endocervical glands lined by atypical columnar cells resembling the cells of adenocarcinoma

Adenocarcinoma in situ (AIS). Frequently there is a sharp transition between the normal columnar epithelium and the neoplastic glandular epithelium

Fig. 5.59

Adenocarcinoma in situ (AIS) of the intestinal type. The intestinal type of AIS shows goblet cells and sometimes even Paneth cells

O-acetylated sialomucin, which is a marker of intestinal differentiation. Some intestinal types of AIS also contain argentaffin and Paneth cells [88, 187]. Endometrioid types of AIS and more rarely, adenosquamous, and clear cell AIS also occur [71, 89].

Invasion should be suspected if the involved glands extend beyond the glandular field or beyond the deepest uninvolved endocervical crypt. In addition, in AIS there should be no desmoplasia or stromal reaction around the involved glands. Other worrisome features that can be associated with invasion are exuberant glandular

budding, an extensive cribiform pattern, foci in which the glands become confluent or back to back and the formation of papillary projections from the endocervical surface [105, 141].

Differential Diagnosis

The differential diagnosis of AIS includes reparative/ reactive glandular atypia secondary to inflammation, radiation or viral infections, Arias-Stella reaction, microglandular hyperplasia, endometriosis, tubal metaplasia, mesonephric remnants, and invasive adenocarcinoma. Endocervical glands may display a wide range of cytological and architectural changes in response to inflammation and radiation. In reactive/reparative atypia, the nuclei become enlarged and have prominent nucleoli, but have nuclear clearing and lack hyperchromasia, **S** *Fig. 5.60.* Nuclei may be pleomorphic but the chromatin is usually smudged and degenerative in appearance. Mitotic activity is usually absent or minimal, as is pseudostratification. Care must be taken to distinguish between true pseudostratification and tangential sectioning through glands that can appear as pseudostratification. Inflamed endocervical glands with reserve cell hyperplasia can also appear as pseudostratification, > Fig. 5.61. Although intraglandular papillary projections

Fig. 5.61 Inflamed endocervical epithelium with reserve cell hyperplasia. When endocervical glands are inflamed and also have reserve cell hyperplasia, they can appear to be pseudostratified and occasionally be mistaken for AIS

should not occur in reactive/reparative processes, exaggerated endocervical papillary projections that project into the endocervical canal can occur. These stromal projections contain infiltrates of chronic inflammatory cells and are lined by a single layer of endocervical cells. Endocervical atypia secondary to repair characteristically has a dense acute and chronic inflammatory infiltrate surrounding the glands and polymorphonuclear leukocytes may infiltrate into the epithelium.

Reactive glandular atypia secondary to irradiation is characterized by nuclear enlargement and pleomorphism, but the cytoplasm is frequently vacuolated or granular. Pseudostratification and mitotic figures are absent. Atypia due to irradiation has greater cell-to-cell variation in size and shape than AIS or endocervical glandular atypia. Glands with the Arias-Stella reaction have a single layer of hyperchromatic, enlarged nuclei that frequently protrude into the gland lumen (i.e., hobnail cells). Typically, Arias-Stella reaction involves only a portion of a gland and mitotic activity is absent. Although microglandular hyperplasia, especially when inflamed, can occasionally be confused with AIS, microglandular hyperplasia lacks significant nuclear atypia, lacks pseudostratification, and has few mitotic figures, **>** *Fig. 5.62*. Moreover, microglandular

Fig. 5.62

Microglandular hyperplasia with reparative changes. When significant inflammation is present microglandular hyperplasia can become somewhat atypical and mistaken for AIS. Even when inflamed, mitotic figures are uncommon in microglandular hyperplasia and there is a lack of pseudostratification and minimal nuclear atypia

hyperplasia has a characteristic pattern of closely packed, small, uniform glands. Atypical forms of microglandular hyperplasia have been described that form solid masses of epithelium and have significant degrees of cytological atypia [210]. These lesions almost always contain areas of typical microglandular hyperplasia that allow them to be identified as atypical forms of microglandular hyperplasia (see O Chap. 6, Carcinoma and Other Tumors of the Cervix). Similarly, endometriosis of the cervix is usually readily recognizable and easily distinguished from AIS. Typical endometriosis consists of glands and endometrial-type stroma. The cells lining the glands are basally located endometrial-type cells that can be pseudostratified and mitotically inactive. Both tubal metaplasia and mesonephric remnants should not be mistaken for AIS since they have bland, non-mitotically active nuclei and typical histological features that allow them to be recognized (see • Chap. 6, Carcinoma and Other Tumors of the Cervix). However, tubal metaplasia can occasionally have more enlarged nuclei with coarse chromatin that can make it difficult to distinguish from AIS, **>** *Fig.* 5.63.

Immunohistochemical staining can be quite useful in distinguishing AIS from other glandular lesions. Most, but not all, AIS lesions demonstrate diffuse nuclear and/or cytoplasmic immunoreactivity for p16^{INK}, *Fig.* 5.64 [30, 138, 162]. Reactive/reparative lesions and microglandular hyperplasia are usually p16^{INK} negative. Tubal metaplasia is not infrequently p16^{INK} positive, but the staining pattern is different than that seen with AIS. In tubal metaplasia the staining with p16^{INK} is usually focal and weak, as opposed to diffuse and strong as seen in AIS, *Fig.* 5.65 [123]. Another useful marker is Ki-67 (MIB1). The Ki-67 proliferation index in tubal metaplasia and endometriosis is usually quite low, less than 10% of the

Fig. 5.65 [123]. Another useful marker is Ki-67 (MIB1). The Ki-67 proliferation index in tubal metaplasia and endometriosis is usually quite low, less than 10% of the cells will stain positively, whereas the Ki-67 proliferation index in AIS is much higher [30, 124, 150]. Over 30% of the cells in AIS lesions usually show nuclear staining with Ki-67 and in most instances the majority of AIS cells will stain positively, > Fig. 5.64b. Bcl-2 has also been used to help differentiate AIS from endometriosis and tubal metaplasia. Bcl-2 appears to have anti-apoptotic properties and both tubal metaplasia and endometriosis stain positively for bcl-2, whereas AIS lesions that show significant degrees of apoptosis stain either negatively or only focally positive with bcl-2 [30]. Carcinoembryonic antigen (CEA) is expressed cytoplasmically in 67% of AIS, whereas the normal columnar epithelium of the endocervix is either negative or demonstrates only luminal, as opposed to cytoplasmic staining [82, 119]. Immunohistochemical staining for vimentin typically is negative in AIS lesions but shows cytoplasmic positivity in tubal metaplasia and endometriosis [119]. Similarly, both tubal metaplasia

Fig. 5.63

Atypical tubal metaplasia. Occasionally, tubal metaplasia becomes more hyperchromatic and has enlarged nuclei with coarse chromatin. When this occurs it can be misinterpreted as AIS. However, such lesions typically lack mitotic activity and pseudostratification

Fig. 5.64

p16^{ink} staining of adenocarcinoma in situ (AIS). (a) Classic AIS showing sharp demarcation between normal and neoplastic tissue. (b) The neoplastic tissue stains strongly with p16^{ink}. (c) It has a high Ki-67 labeling index

Fig. 5.65

Typical tubal metaplasia. Tubal metaplasia shows focal weak staining with p16^{ink}, as opposed to the strong diffuse staining seen in AIS. (a) H&E, (b) p16^{ink} immunostaining

and endometriosis usually stain positively for estrogen receptors, whereas AIS does not. Some authors have recommended that a panel of antibodies be utilized when trying to identify difficult cases of AIS. This panel includes Ki-67, p16^{ink}, bcl-2, monoclonal CEA, vimentin, and estrogen receptor antibodies [123]. In our experience, a panel of p16, Ki-67, estrogen and progesterone receptors suffices.

Clinical Behavior and Treatment

Due to the relative rarity of AIS, no natural history studies have been published and therefore the evidence that these lesions are precursors for invasive endocervical adenocarcinoma remains circumstantial. Despite this, until recently the treatment of choice was simple hysterectomy. Recently, however, there have been several series of patients with AIS who have been followed after cone biopsy. These studies have generally shown relatively low rates of invasive adenocarcinoma and recurrent AIS among women treated by means of a cone biopsy, provided the endocervical margin is negative. A recent meta-analysis found that of 671 patients who had been treated by cone biopsy and followed, 26% with negative margins developed recurrent disease, and 0.1% developed invasive adenocarcinoma [165]. Women with positive endocervical margins are at significantly greater risk for having an undiagnosed invasive cervical adenocarcinoma or for developing recurrent AIS. Invasive adenocarcinoma was found in 5.2% of such patients in the above meta-analysis. Based on these studies, conservative management by cone biopsy alone is now considered to be an option in women with AIS desirous of maintaining their fertility, if the cone biopsy margins are negative.

Cervical Cytology

Strengths and Limitations of Cervical Cytology

Although it was introduced over a half century ago, cervical cytologic screening continues to be the most effective cancer prevention test available. The cytologic screening has never been tested in a prospective double-blind study; however, over the half century since it was introduced, so much epidemiological and modeling data have accumulated demonstrating the effectiveness of cytology that it has become the index by which all other cancer screening tests are compared. Cytologic screening performed only twice in a woman's lifetime can reduce her risk for invasive cervical cancer by up to 43% and yearly screening is estimated to reduce a woman's risk by over 90% [72, 146]. However, despite the effectiveness of cytologic screening, it is important to remember that no screening, diagnostic, or therapeutic technique used in medicine is perfect, and cervical cytology is no exception. Some women will develop invasive cervical cancer, despite annual cytologic screening.

Over the last decade, numerous advances have been made in cervical cytology collection techniques, how cytological preparations are evaluated, and the classification systems used for reporting cytologic diagnosis. One of the most important advances has been the recent introduction of liquid-based cytology. With liquid-based cytology, the cells collected from the cervix are transferred directly to a liquid fixation solution that is shipped to the cytology laboratory where the slide is prepared. One of the primary advantages of liquid-based cytology is that HPV DNA testing can be performed directly from liquid-based specimens when a diagnosis of ASCUS is made (i.e., "reflex" HPV DNA testing).

TBS Terminology

In 1988, TBS for reporting cervical/vaginal cytological diagnoses was developed to provide uniform guidelines for reviewing and reporting gynecological Pap tests. TBS classification was subsequently modified in 1991 and 2001 [201]. This is now the most widely used classification for cervical cytology in the USA. There are two distinct parts to the report: a statement of specimen adequacy and a general categorization, **7** *Table 5.8*. In addition, in many instances a descriptive diagnosis is provided. This is designed to assist clinicians by answering three basic questions: (1) Was the sample adequate? (2) Was the Pap test normal? (3) If the test was not completely normal, what specifically was wrong?

Cytological Appearance of Cervical Cancer Precursors

TBS classification categorizes precursors to cervical cancer as "epithelial cell abnormalities." The category "epithelial cell abnormalities" is subdivided into abnormalities of squamous cells and abnormalities involving glandular cells, either endocervical or endometrial. Cytological changes previously classified as mild squamous cytological atypia and atypical endocervical cells are also included in this category.

Squamous Cell Abnormalities

ASC The ASC category is used to designate cytological changes suggestive of a squamous intraepithelial lesion that are quantitatively or qualitatively insufficient for a definitive diagnosis of SIL. There are several points that need to be made with respect to ASC. First, a diagnosis of ASC is one of exclusion; the cells are abnormal, but they do not warrant a diagnosis of SIL. Second, a diagnosis of ASC should not be used when the underlying process is inflammatory or reactive, such slides should be classified as "negative for intraepithelial lesion or malignancy" rather than ASC. Third, although the ASC category is sometimes disparagingly referred to as a "cytological wastebasket," there are specific criteria that should be used for making this diagnosis. If these criteria are adhered to, the rate of ASC in a routine cytology laboratory should be no greater

Table 5.8

The Bethesda system (TBS) 2001 classification.

Adequacy of the specimen
Satisfactory for evaluation
Unsatisfactory for evaluation
General categorization
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormalities
Squamous Cell
Atypical squamous cells (ASC)
Atypical squamous cells – undetermined significance (ASCUS)
Atypical squamous cells – cannot exclude HSIL (ASC-H)
Low-grade squamous intraepithelial lesion (LSIL) encompassing human papillomavirus ^a and mild dysplasia/CIN 1
High-grade squamous intraepithelial lesion (HSIL) encompassing moderate and severe dysplasia, CIS/ CIN 2 and CIN 3
Squamous cell carcinoma
Glandular cell
Atypical glandular cells
Atypical glandular cells (unqualified)
Atypical endocervical cells (unqualified)
Atypical endometrial cells (unqualified)
Atypical glandular cells, favor neoplastic
Atypical endocervical cells, favor neoplastic
Adenocarcinoma in situ (AIS)
Endocervical adenocarcinoma
Endometrial adenocarcinoma
Adenocarcinoma, nonspecific
Other
Hormonal evaluation (applies to vaginal smears only)
Hormonal pattern compatible with age and history
Hormonal pattern incompatible with age and history (specify)
Hormonal evaluation not possible because of(specify)

^aCellular changes of human papillomavirus, previously termed koilocytosis koilocytotic atypia, and condylomatous atypia are included in the category of LSIL.

CIN, cervical intraepithelial neoplasia; CIS, carcinoma in situ.

than about 5% of all cytology specimens and the ASC rate should be approximately twice the SIL rate.

The 2001 Bethesda System subdivides the ASC category into two subdivisions. Atypical squamous cells of

Table 5.9

Criteria used to diagnose atypical squamous cells (ASC)

Atypical squamous cells of undetermined significance (ASCUS)
Cells resemble superficial or intermediate squamous cells in size and configuration
Nuclei are 2–3 times the size of a normal intermediate cell
Nuclei are round to oval with minimal irregularities
Nuclei are normochromatic to slightly hyperchromatic
Atypical squamous cells – cannot exclude HSIL (ASC-H)
Cells resemble parabasal or basal cells in size and configuration
Nuclei often have uneven chromatin and are
hyperchromatic
Nuclear contour is often irregular

undetermined significance (*ASCUS*) refers to samples in which the cytological changes are suggestive of LSIL, but lack sufficient cytological abnormalities to allow a definitive diagnosis. Atypical squamous cells – cannot exclude HSIL (*ASC-H*) refers to samples in which the cytological changes are suggestive of HSIL but the cytological abnormalities are insufficient to allow a definitive interpretation [170].

The specific criteria used to diagnose ASC are given in **Table 5.9.** One of the major criteria used to distinguish ASCUS from benign cellular changes is nuclear size. In ASCUS, the nuclei are typically 2-3 times the size of a normal intermediate cell. In addition, to changes in nuclear size, the nuclei in ASCUS are somewhat irregular and frequently hyperchromatic, **>** Fig. 5.66. However, the degree of nuclear changes considered sufficient to warrant a diagnosis of ASCUS is highly subjective and varies between cytologists. This introduces a degree of uncertainty with respect to a diagnosis of ASCUS, and studies have shown that a diagnosis of ASCUS is the least reproducible of all cytological diagnoses [39, 40, 68, 181]. In the recent NCI-sponsored ALTS trial, only 55% of the referral Pap tests originally classified as ASCUS were classified as ASCUS by the pathology quality control panel [181]. It should also be noted that a diagnosis of ASCUS is sometimes made when there are cells with some, but not all of the criteria necessary for a diagnosis of LSIL, **>** *Fig.* 5.67.

In the USA, the median reporting rate of ASCUS is 4.7% according to a 2003 College of American Pathology survey [47]. Approximately, 7–12% of women with a diagnosis of ASC will have HSIL when colposcopy is performed [2, 9, 113, 118, 206].

Fig. 5.66

Atypical squamous cells of undetermined significance (ASCUS). Intermediate squamous epithelial cells demonstrate nuclear enlargement and hyperchromasia. No organisms or inflammatory changes were identified on the smear

Fig. 5.67

Atypical squamous cells of undetermined significance

(ASCUS). These cells are suggestive, but not diagnostic of a LSIL since they have a considerable degree of nuclear enlargement and perinuclear halos. However, the findings are not sufficient to allow a diagnosis of LSIL and there were only a limited number of such cells present so a diagnosis of ASCUS was rendered In ASC-H, the cells resemble parabasal or basal cells in size and configuration. These cells frequently have irregular nuclear contours and uneven chromatin, **?** *Fig. 5.68.* There are varying degrees of hyperchromasia. The differential diagnosis in such cases is between atypical immature squamous metaplasia and HSIL. The median reporting rate of ASC-H in the USA in 2003 was 0.4% according to the CAP survey [47]. The majority of women with ASC-H are high-risk HPV DNA positive and HSIL (CIN 2, 3) lesions are identified at the time of colposcopy in 12–68% of women with ASC-H [11, 112, 170]. Because of the high prevalence of HSIL (CIN 2, 3) lesions in women with ASC-H, it has been suggested that ASC-H would be more appropriately referred to as "equivocal HSIL" [207].

LSILs The LSIL category in TBS includes both HPV effects and mild dysplasia (CIN 1). The cells of LSIL are of the superficial or intermediate cell type. They have enlarged nuclei that are 4–6 times the size of a normal intermediate cell nucleus (\bigcirc *Fig.* 5.69), but many vary in size and in LSIL with marked HPV cytopathic effects, the nuclei are often only two times the size of a normal intermediate cell nucleus, \bigcirc *Fig.* 5.70. In LSIL, the nuclei are

Fig. 5.69

LSIL. The cells are of the intermediate type with nuclear enlargement and prominent koilocytosis. One of the nuclei is more than 10 times the size of a normal intermediate cell

Fig. 5.68

Atypical squamous cells of undetermined significance cannot exclude HSIL (ASC-H). A cluster of atypical immature metaplastic type cells is present. The cells have an increased nuclear : cytoplasmic ratio, hyperchromasia, and slightly irregular nuclei. However, the cells have more cytoplasm than usually associated with HSIL and only a few clusters were present

Fig. 5.70
LSIL. Cells from this lesion demonstrate considerable koilocytosis with multinucleation and prominent halos
Table 5.10

Criteria used to diagnosed squamous epithelial cell abnormalities

Bethesda system	LSIL	HSIL		
CIN terminology	CIN 1	CIN 2	CIN 3	
WHO terminology	Mild dysplasia	Moderate dysplasia	Severe dysplasia	CIS
Cell type	Superficial or intermediate	Parabasal	Basal	Basal, spindle, pleomorphic
Cell arrangement	Singly or sheets	Singly or sheets	Singly or sheets	Singly or sheets or syncitia
Number abnormal cells	+	++	+++	++++
Koilocytosis	+++	+	+/-	+/-
Nuclear size	+++	++	+	+
Hyperchromasia	+	++	+++	++++
Nuclear:cytoplasmic ratio	+	++	+++	++++

usually hyperchromatic, and multinucleation is common. The chromatin is finely granular and uniformly distributed. The cells typically occur as individual cells or as sheets of cells with well-defined cell borders. With cytology methods such as liquid-based cytology and computerized imaging systems, the rate of LSIL appears to be increasing in the USA. In surveys taken in the 1990s, the median reporting rate of LSIL in U.S. laboratories was 1.6% but by 2004 this has increased to 2.4% [47, 92]. A recent report of the impact of implementing a computerized cytology imaging system in a tertiary military medical center reported that after implementation the rate of LSIL increased from 2.6% to 3.9% [54].

HSILs Because TBS combines moderate and severe dysplasia together with carcinoma in situ in the HSIL category, there is a wide variation in the cytological appearance of HSIL. As the severity of the lesion increases, the degree of differentiation and the amount of cytoplasm decreases, the nuclear : cytoplasmic ratio increases, and the degree of nuclear atypia increases, **2** Table 5.10. HSIL of the type previously classified as moderate dysplasia typically contains cells similar to those seen in LSIL, as well as atypical immature cells of the parabasal type, > Fig. 5.71. The nuclei of these cells are more hyperchromatic and irregular than typically seen in LSIL. In HSIL of the type previously classified as severe dysplasia, the overall size of the cells is reduced compared to HSIL previously classified as moderate dysplasia, but because the cells demonstrate minimal differentiation, the nuclear : cytoplasmic ratio is greatly increased, > Fig. 5.72. In these cases, there are usually greater numbers of neoplastic cells and individual dysplastic cells are frequently found. According to the CAP 2003 survey, the

Fig. 5.71

HSIL. HSIL of the type previously referred to as moderate dysplasia. Many of the cells have a considerable amount of cytoplasm, but the nuclear : cytoplasmic ratio is higher than usually seen in LSIL

mean reporting rate of HSIL in the USA is 0.7% [47]. The rate of HSIL varies with age. In one U.S. center, the rate of HSIL in women 20–29 years old was 0.6% compared with 0.2% and 0.1% in women 40–49 years old and 50–59 years old, respectively [84]. A diagnosis of HSIL connotes a high risk for significant cervical disease. Recent studies have found that HSIL (CIN 2, 3) is found in 84–97% of women evaluated using a loop electrosurgical excision [56, 121].

Fig. 5.72

HSIL. HSIL of the type previously referred to as severe dysplasia. The atypical parabasal type cells have hyperchromatic nuclei and a high nuclear : cytoplasmic ratio

HSIL that was previously classified as carcinoma in situ can be of the small cell type, of the large cell nonkeratinizing type, or of the large cell keratinizing (pleomorphic) type. Although separation of carcinoma in situ into these three different cytological types has no clinical significance, they do differ in cytological appearance. Small cell lesions consist of small basal-type cells similar to those seen in severe dysplasia but which demonstrate even less cytoplasm and higher nuclear : cytoplasmic ratios. Because of their small size, these cells can be easily overlooked during routine screening and these cases account for a disproportionate percentage of false negative Pap tests. The cells of large cell nonkeratinizing lesions typically form syncytial-like cell sheets in which individual cell membranes are difficult to identify. These cells have enlarged, hyperchromatic nuclei and minimal amounts of cytoplasm. The keratinizing large cell type of carcinoma in situ is composed of pleomorphic, highly atypical cells many of which have thick orangophilic, keratinized, cytoplasm, > Fig. 5.73. These cells are often spindled or "tadpole" shaped and have extremely dense nuclear chromatin.

Invasive Squamous Cell Carcinoma Squamous cell carcinomas of the cervix are subdivided into keratinizing and non-keratinizing types. Non-keratinizing carcinomas typically have large numbers of malignant cells that form

Fig. 5.73 High-grade SIL. High-grade SIL of the type previously referred to as keratinizing large cell type carcinoma in situ.

Many of the cells are keratinized and have quite hyperchromatic nuclei. It is often difficult to distinguish between HSIL of this type and keratinizing invasive squamous cell carcinoma

loose cell sheets and syncytial arrangements. The cells have enlarged nuclei that are 2-3 times the size of a normal intermediate cell nucleus, coarsely clumped chromatin, prominent macronucleoli, and focal chromatin clearing, > Fig. 5.74. These cells are often smaller than those seen in SIL. Using conventional cytology, squamous cell carcinomas often have a "dirty" background containing blood, cellular debris, fibrin, and necrotic material. This is often referred to as a tumor diathesis. This characteristic background is less prominent in liquid-based cytology specimens. However, in liquid-based cytology, there is often a distinctive necrotic background that is easy to recognize since it surrounds the cellular material in a "clumped" appearance and large, necrotic tissue fragments are sometimes present, > Fig. 5.75.

Pap tests from women with keratinizing carcinomas contain malignant cells, demonstrating a variety of cell shapes and sizes, **>** Fig. 5.76. Some of the cells are pleomorphic or tadpole shaped. These cells have abundant orangophilic cytoplasm. There is frequently abundant hyperkeratosis and parakeratosis. The nuclei are irregular in shape and quite hyperchromatic. Sometimes the nuclei are degenerated, appearing as opaque masses or "inkblots." Unlike nonkeratinizing squamous cell

carcinoma, keratinizing squamous cell carcinomas usually do not have "dirty" background or evidence of tumor diathesis.

Glandular Cell Abnormalities

In the 2001 Bethesda System, all types of glandular cell abnormalities, including both atypical endocervical and endometrial cells are combined together in a single entity referred to as glandular cell abnormalities. Benign appearing endometrial cells occurring in postmenopausal women are now classified as "Other." Glandular cell abnormalities are divided into three categories: AGC, either unqualified or favor neoplastic; AIS; and invasive adenocarcinoma.

AGC All AGC lacking the diagnostic features of adenocarcinoma, irrespective of whether they are of endometrial or endocervical origin, are classified by the 2001 Bethesda System as AGC with a specification as to whether they are endocervical, endometrial, or of uncertain origin. There are two categories of AGC. The first is AGC

Fig. 5.74

Invasive squamous cell carcinoma. The cells of this nonkeratinizing squamous cell carcinoma are polygonal and arranged in syncytial sheets. They are highly atypical, but smaller than the cells of many intraepithelial lesions (either endocervical, endometrial, or unclassified), not qualified and the second is AGC, favor neoplastic.

Glandular cytological abnormalities are considerably less common than squamous abnormalities and most cytologists tend to be less comfortable recognizing and diagnosing them. In addition, the criteria used to differentiate reactive endocervical changes, endocervical dysplasia, endocervical AIS, and invasive endocervical

Fig. 5.75

Tumor diathesis. This liquid-based cytology preparation from a woman with squamous cell carcinoma shows necrotic material surrounding malignant cells giving it a "clumped" appearance

Fig. 5.76

Invasive squamous cell carcinoma. The cells of this keratinizing squamous cell carcinoma are quite pleomorphic and include spindle-shaped, elongate, and caudate forms. The nuclei of some cells are extremely hyperchromatic adenocarcinoma are less well established than those used for squamous lesions. Cytologists even have difficulty in differentiating atypical endocervical cells from cases of HSIL that have extended into endocervical crypts. This accounts for the high prevalence of squamous abnormalities (approximately 30%) detected in women referred to colposcopy for AGC [97, 164].

The cytological features of atypical endocervical cells vary depending on the degree of the underlying histopathologic abnormality. Cases of the type designated by cytopathologists as atypical endocervical cells - unqualified have minor degrees of variability in nuclear size and shape, > Fig. 5.77. Endocervical cells form dense two- or three-dimensional aggregates that have minor degrees of nuclear overlapping. In some cases, the chromatin is somewhat granular and nuclear feathering can be seen at the periphery of the cellular aggregates. Atypical endocervical cells favor neoplasia includes those cases where the cytological features are suggestive of AIS, but are insufficient to allow a definitive diagnosis. These cases typically have more nuclear hyperchromasia, variability in nuclear size, and granularity of the cytoplasm than is observed in cases of atypical endocervical cells, unqualified, > Fig. 5.78.

AIS In cases of AIS, there are usually a larger number of AGC that form crowded cellular clusters. The sheets are usually three-dimensional and sometimes retain the architecture of the underlying glands, **>** *Fig. 5.79*. The cells

Fig. 5.78

Atypical glandular cells (AGC) – favor neoplasia. These endocervical cells are somewhat suggestive of adenocarcinoma in situ (AIS). The nuclei are hyperchromatic and the chromatin is coarsely clumped. There is variation in nuclear size and the cells form a three-dimensional aggregate

Fig. 5.77

Atypical glandular cells – endocervical type (AGC-EC). These endocervical cells have enlarged nuclei, prominent nucleoli, and vary somewhat in size and shape. The smear was obtained 6 weeks postpartum and follow-up examination was completely negative

Fig. 5.79

Adenocarcinoma in situ (AIS). These endocervical cells form a tight three-dimensional structure that is similar to the outline of an endocervical gland. Large numbers of these formations are often present in specimens from AIS within these sheets occasionally form rosettes and have extensive feathering of the cells at the periphery. Individual endocervical cells are highly atypical with enlarged round, oval, or elongated nuclei that vary in size from cell to cell. In most cases, the chromatin is coarsely clumped and multiple mitoses are seen, \bigcirc *Fig. 5.80*. Sometimes, it is difficult for the cytologist to determine whether the atypical cells represent AGC or HSIL cells that have extended into an endocervical crypt or "gland." In these cases, highly atypical nuclei are identified in the center of a cell aggregate and some of the cells at the periphery of the aggregate appear to be endocervical cells.

Adenocarcinoma TBS subclassifies invasive adenocarcinomas into "adenocarcinoma-endocervical type," "adenocarcinoma-endometrial type," and "adenocarcinoma-not otherwise specified." The cytological diagnosis of invasive adenocarcinoma is relatively straightforward. Adenocarcinoma cells from either an endocervical or an endometrial primary have enlarged nuclei, high nuclear : cytoplasmic ratios, coarsely clumped chromatin, and prominent nucleoli, **?** *Fig. 5.81*. They can occur singly or in clusters. Cytologists should try to distinguish between

Fig. 5.80

Adenocarcinoma in situ (AIS). The individual atypical endocervical cells are hyperchromatic with coarsely clumped chromatin. They show the characteristic feathering of the nuclei at the edge of the cluster that is typical of AIS endometrial and endocervical primary adenocarcinomas whenever possible. Key features that allow discrimination between endometrial and endocervical origin in cytology include number of abnormal cells, size of the cells, retention of columnar configuration, appearance of cytoplasm, and unclear structure [139]. Typically, adenocarcinoma of the cervix shows considerably larger numbers of cells than does endometrial adenocarcinoma. Cells derived from endocervical adenocarcinoma typically retain a columnar configuration that is lost in most endometrial carcinomas. The cytoplasm of cells exfoliated from endocervical adenocarcinoma is typically eosinophilic and glandular, whereas the cytoplasm from cells of endometrial adenocarcinoma is typically finely vacuolated cytoplasm and cyanophilic. The nuclei of cells of endometrial adenocarcinoma have less glandular chromatin, are less hyperchromatic, are smaller, and less frequently have multiple nucleoli than do the nuclei of cells of endocervical adenocarcinoma.

Management of Cytologic Abnormalities and Cervical Cancer Precursors

In 2006, the American Society for Colposcopy and Cervical Pathology sponsored a consensus workshop to update the 2001 Consensus Guidelines for the Management of

G Fig. 5.81

Endocervical adenocarcinoma. These endocervical cells have the features of frank adenocarcinoma. The nuclei are quite enlarged, the chromatin is coarsely clumped and marginated, and there are prominent nucleoli. The background shows inflammation and necrosis indicating tumor diathesis is present Women with Cytological Abnormalities and Cervical Cancer Precursors [206, 208]. These guidelines are widely used in the USA and are evidence based with each recommendation accompanied by a grading of both the strength of the recommendation and the strength of the data supporting the recommendation. What follows is a brief synopsis of the guidelines. The complete recommendations and management algorithms are available at www.asccp.org.

ASC

The prevalence of biopsy-confirmed HSIL among women undergoing colposcopy for an ASC cytology varies from 5% to 17% [206]. The prevalence of HSIL in women with ASC depends on the number of factors including the patient's age, history, and the subclassification of the result. Overall, it appears that approximately half of women with histologically confirmed HSIL have ASC as their initial abnormal cervical cytology result [99, 114]. However, it should be noted that the risk that a woman with ASC has invasive cervical cancer is quite low (about one per thousand).

Atypical Squamous Cells of Undetermined Significance (ASCUS)

Three methods are considered acceptable for managing women in the general population with ASC; immediate colposcopy, high-risk HPV DNA testing, and repeating the cervical cytology twice at 6-month intervals, Fig. 5.82. HPV DNA testing identifies more cases of HSIL than does a single repeat cervical cytology, but refers approximately equivalent numbers of women for colpos-copy [7]. Moreover, cost-effectiveness modeling has demonstrated that HPV DNA testing for women with ASCUS is highly attractive when the initial ASCUS cytology was obtained from a liquid-based sample [98, 106]. Thus,

high-risk HPV DNA testing is the preferred approach to managing women with ASCUS whenever liquid-based cytology is used for screening [206]. Women found to be high-risk HPV DNA positive should be referred to colposcopy, whereas HPV DNA negative women should be rescreened in 12 months.

Since the prevalence of HPV DNA positivity is much higher in young women with ASCUS than in older women and is extremely high in adolescents with ASCUS, HPV DNA testing is not recommended for adolescents with ASCUS [16, 169, 206]. Instead, adolescents should be managed using annual repeat cytological examinations and only referred to colposcopy if the repeat Pap tests are diagnosed as HSIL or are persistently abnormal for a period of 2 years, **?** *Fig.* 5.83 [206]. Management options for pregnant patients with ASCUS are identical to those for nonpregnant patients with the exception that it is acceptable to defer the colposcopic examination until the patient is 6–8 weeks postpartum [206].

ASC-H

ASC-H is a much more concerning cytology result than ASCUS since biopsy-confirmed HSIL is identified in 24–94% of women with ASC-H [203]. Thus, for the purposes of management, ASC-H should be considered to be an equivocal HSIL result and all women with ASC-H should be referred for a colposcopic evaluation [206]. If SIL is not identified, followed-up utilizing either repeat cytology at 6 and 12 months or high-risk HPV DNA testing at 12 months is acceptable.

LSIL

Biopsy-confirmed HSIL is found in 15-30% of women with LSIL on cervical cytology [8, 94, 114]. Therefore, all women in the general population with a cytological result of LSIL should be referred to colposcopy, **>** Fig. 5.84 [206]. A diagnostic excisional procedure is not necessary when a woman with LSIL cytology is found to have an unsatisfactory colposcopic examination. Since invasive cervical cancer is very uncommon in adolescents and prospective studies have shown that over 90% of LSIL will spontaneously clear in adolescents, adolescents with LSIL should not be referred to colposcopy, but should be followed using yearly Pap tests for a period of 2 years [131, 132, 206]. Another "special population" is postmenopausal women with LSIL. Both the prevalence of HPV DNA and the prevalence of HSIL are lower in postmenopausal women than in women in the general population with LSIL. Therefore, postmenopausal women with LSIL can be managed in the same manner as women with

Management of adolescent women with either atypical squamous cells of undetermined significance (ASC-US) or low-grade squamous intraepithelial lesion (LSIL)

Management of women with low-grade squamous intraepithelial lesions (LSIL)*

Fig. 5.84 ASCCP Consensus Conference algorithm for managing women with LSIL

ASCUS. This includes using reflex HPV DNA testing to determine who should undergo colposcopy [58, 169].

HSIL

Histologically confirmed HSIL is identified in 53–97% of women with a cytological result of HSIL and invasive cervical cancer is found in approximately 2% [47, 92, 93, 206]. Therefore, women with a cytological result of HSIL should be referred for either a colposcopic evaluation or an immediate LEEP, **>** *Fig.* 5.85 [206]. If histologically confirmed HSIL is not identified after colposcopy and the colposcopic examination is satisfactory and endocervical sampling is negative, either a diagnostic excisional procedure or follow-up using colposcopy and cytology at 6-month intervals is acceptable for 1 year. Nonpregnant women with HSIL who have an unsatisfactory colposcopic examination require a diagnostic excisional procedure.

AGC

AGC is a relatively uncommon cytological diagnosis with a mean reporting rate of 0.4% in the USA in 2003 according to a survey of the CAP [47]. Most clinicians consider a diagnosis of AGC to much more concerning than a diagnosis of ASCUS. This is because women with AGC are much more likely to have a significant underlying condition of the cervix or endometrium. Either HSIL, AIS, or invasive cancer is found in 9-38% of women with AGC and invasive cancer of either the cervix or endometrium is found in 3-17% [206]. Therefore, the initial work-up of women with AGC generally includes both evaluation of the cervix using colposcopy and endocervical curettage to exclude HSIL, AIS, and cervical cancer, as well as endometrial sampling to rule out endometrial hyperplasia and cancer, **>** *Fig.* 5.86. Endometrial sampling is not necessary in women under the age of 35 years who do not have other risk factors for endometrial disease such as abnormal bleeding or polycystic ovarian syndrome since these women are at low risk for having endometrial pathology. Similarly, colposcopy can be deferred until after the results of endometrial and endocervical sampling are available in women who have atypical endometrial cells since these women are much more likely to have endometrial as opposed to cervical disease. Subsequent management of women with AGC depends not only on the findings at the time of colposcopy and endometrial sampling, but also on the patient's HPV DNA status and on the subclassification of the referral AGC cytology result, > Fig. 5.87. If the referral cytology was classified as atypical endocervical,

Management of women with high-grade squamous intraepithelial lesions (HSIL)*

Initial workup of women with atypical glandular cells (AGC)

Fig. 5.86 ASCCP Consensus Conference algorithm for the initial management of women with AGC cytology results

Subsequent management of women with atypical glandular cells (AGC)

Fig. 5.87 ASCCP Consensus Conference algorithm for the subsequent management of women with AGC cytology results

endometrial, or glandular cells not otherwise specified (NOS) and significant disease is not identified during initial workup, the patient can be followed up with repeat cytologic testing combined with HPV DNA testing. However, if the referral AGC cytology was atypical glandular cells "favor neoplasia" or AIS, the patient should undergo a diagnostic excisional procedure which can be either a cold-knife or loop excisional conization [206].

Histologically confirmed LSIL

There is a considerable degree of overdiagnosis of reactive reparative conditions as LSIL and the majority of histologically confirmed LSIL will spontaneously regress in the absence of therapy. Therefore, it is recommended that histologically confirmed LSIL preceded by ASCUS, ASC-H, or LSIL cytology undergo conservative follow-up consisting of either HPV DNA testing every 12 months or repeat cervical cytology every 6–12 months, **•** *Fig. 5.88.* If histologically confirmed LSIL persists for at least 2 years, either continued follow-up or treatment is acceptable. Since the risk of an undetected HSIL or glandular lesion

is expected to be higher in women referred for the evaluation of a HSIL or AGC on cytology, women with histologically confirmed LSIL preceded by HSIL or AGC cervical cytology can undergo either a diagnostic excisional procedure or be followed using both colposcopy and cytology at 6-month intervals for 1 year, provided the colposcopic examination is satisfactory and endocervical sampling is negative [208].

Histologically confirmed HSIL

Women with histologically confirmed HSIL are at significantly high risk of progressing to invasive cervical cancer and therefore treatment is recommended. Provided the colposcopic examination is satisfactory and there is no suggestion of invasive disease (e.g., either by colposcopy, cytology, or histology), both ablative and excisional treatment modalities are considered acceptable forms of treatment [208]. A diagnostic excisional procedure is recommended for all women with histologically confirmed HSIL and an unsatisfactory colposcopic examination or with recurrent disease.

Management of women with biopsy-confirmed cervical intraepithelial neoplasiagrade 1 (CIN 1) preceded by ASC-US, ASC-H or LSIL

Fig. 5.88 ASCCP Consensus Conference algorithm for managing women with histologically confirmed LSIL

ECC

ECC is performed to evaluate lesion distribution and morphology within the endocervical canal and to exclude the presence of invasive carcinoma, and unsuspected cervical AIS and invasive adenocarcinoma. Recently, the utility of ECC has become the subject of considerable debate [53]. In ALTS, the ECC provided only a minimal 2.2% increase in the detection of HSIL when performed in women under the age of 40 years, but provided a 13% increased detection of high-grade CIN when performed in women 40 years and older [178]. Nevertheless, many clinicians perform an ECC during colposcopic evaluation of the cervix.

The ECC specimen consists of endocervical tissue fragments, blood, mucus, and, when positive, strips of atypical epithelium, \bigcirc *Fig.* 5.89. To avoid the loss of tiny tissue fragments during processing, the clinician should collect and concentrate the sample, including mucus and blood, on a small square of lens paper or using a cytobrush and immediately place it in the fixative [79]. By this method, even the smallest tissue fragments can be recovered easily in the laboratory, embedded, and sectioned entirely.

Fig. 5.89HSIL present in an endocervical curetting

In most instances, when atypical epithelium is detected in the ECC it lacks underlying stroma and orientation is not possible. As a result, the pathologist can neither rule out underlying invasion nor grade an

- Cameron RI, Maxwell P, Jenkins D et al (2002) Immunohistochemical staining with MIB1, bcl2 and p16 assists in the distinction of

intraepithelial lesion. In other cases, where the atypical epithelium is well oriented, the pathologist is able to grade the lesion and can, if desired. It is also helpful if the pathologist conveys an estimate of the amount of atypical epithelium that is present in the ECC. If only a few small fragments of atypical epithelium are present in the ECC, these may represent "pickups" from a lesion that is actually confined to the portio and does not extend into the endocervical canal. In such cases, it may be preferable to reexamine the patient with the colposcope rather than proceeding directly with a diagnostic excisional procedure. Frequently the second carefully performed curettage yields no atypical epithelium and the patient may be managed on a conservative, outpatient basis. Conversely, the pathologist should be careful not to discount or overlook a few or even a single fragment of atypical epithelium in an ECC. In a review of 21 women who developed invasive cancer after cryotherapy, 7 out of 18 ECCs taken before cryotherapy were found on review to contain SIL that had been missed at the time of original diagnosis [168].

Invasive Carcinoma

The World Health Organization (WHO) recognizes three general categories of invasive carcinoma of the cervix: squamous cell carcinoma, adenocarcinoma, and "other epithelial tumors" (**>** *Table 6.1*) [278]. The "other epithelial tumors" include adenosquamous carcinoma, adenoid basal cell carcinoma, adenoid cystic carcinomas, as well as neuroendocrine tumors and undifferentiated carcinoma (**>** *Table 6.1*) [278]. The relative frequency of these different tumor types varies between studies; in general, squamous cell carcinoma is the most common histologic subtype accounting for 70–80% of invasive carcinomas. Adenocarcinoma and adenosquamous carcinoma comprise 10–15% of all cases, and all others 10–15% [45, 245, 271].

The most widely accepted staging system for tumors of the cervix is the four-stage system of the International Federation of Gynecologists and Obstetricians (FIGO) (Table 6.2) [205]. Stage I includes all tumors confined to the cervix and is divided into two subcategories: those that invade 5 mm or less into the stroma and are macroscopically not visible, and those that either invade more than 5 mm or are macroscopically visible. As such, staging of cervical cancer is based on clinical, not surgical, examination of the cervix. Stage II tumors extend beyond the cervix, but not to the pelvic sidewall, and do not invade the lower third of the vagina. Stage III tumors include those that extend to the pelvic sidewall, cause hydronephrosis, or invade the lower third of the vagina. Stage IV tumors extend beyond the true pelvis or clinically involve the mucosa of the bladder or rectum.

Squamous Cell Carcinoma

Microinvasive Squamous Cell Carcinoma

The concept of prognostically favorable, microinvasive carcinoma (MICA) of the cervix was first introduced in 1847 by Mestwerdt. Microinvasive carcinoma is considered a preclinical stage in the spectrum of squamous intraepithelial lesions (SIL), and frank clinical invasive carcinoma of the cervix. Most patients who die of disseminated squamous cell carcinoma have either lymphatic involvement, tumors that invade beyond 5 mm into the cervical stroma, or tumors more than 2.5 cm³ in volume. Therefore, microscopic tumors that invade <5 mm beyond the base of the epithelium, either surface or glandular, and with horizontal spread not exceeding 7 mm (stage IA) are defined by FIGO as MICA (see **?** *Table 6.2*).

Table 6.1

Modified World Health Organization histological classification of invasive carcinomas of the uterine cervix

Squamous cell carcinoma

Adenoid cystic carcinoma
Adenoid basal carcinoma
Neuroendocrine tumors
Carcinoid
Atypical carcinoid
Small cell carcinoma
Large cell neuroendocrine carcinoma
Undifferentiated carcinoma

Tumors that qualify as stage IA are further subdivided into those that invade no more than 3 mm (stage IA1) and those that invade more than 3 mm, but <5 mm, into the cervical stroma (stage IA2). The presence of lymphvascular invasion does not exclude a tumor from FIGO Stage IA. Proponents who believe that classification systems should guide clinical treatment consider only FIGO stage IA1 as MICA.

The Society of Gynecological Oncologists (SGO) in the United States has proposed a more restricted definition for MICA. According to that definition, histologically detected lesions with <3 mm stromal invasion and no vascular invasion are considered MICA [52]. Lesions that 2009 modification of FIGO staging of carcinoma of the cervix uteri [205]

Stage	Definition
-	Cervical carcinoma confined to uterus (extension to the corpus should be disregarded)
IA	Invasive carcinoma diagnosed only by microscopy; all macroscopically visible lesions, even with superficial invasion, are stage IB
IA1	Stromal invasion no greater than 3.0 mm in depth and 7.0 mm or less in horizontal spread
IA2	Stromal invasion more than 3.0 mm and not more than 5.0 mm with a horizontal spread of 7.0 mm or less
IB	Clinically visible lesion confined to the cervix or microscopic lesion greater than IA2 ^a
IB1	Clinically visible lesion 4.0 cm or less in greatest dimension
IB2	Clinically visible lesion more than 4.0 cm in greatest dimension
II	Tumor invades beyond the uterus but not to pelvic wall or to lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion \leq 4.0 cm in greatest dimension
IIA2	Clinically visible lesion >4 cm in greatest dimension
IIB	With parametrial invasion
111	Tumor extends to the pelvic wall and/or involves lower third of vagina and/or causes hydronephrosis or nonfunctioning kidney ^b
IIIA	Tumor involves lower third of vagina with no extension to pelvic wall
IIIB	Tumor extends to pelvic wall and/or causes hydronephrosis or nonfunctioning kidney
IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

^aThe depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. The depth of invasion is defined as the measurement of the tumor from the epithelial–stromal junction of the adjacent most superficial epithelial papilla to the deepest point of invasion. Vascular space involvement, venous or lymphatic, does not affect classification.

^bOn rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or non-functioning kidney are included, unless they are known to be due to another cause.

fulfill the SGO definition of MICA have virtually no potential for metastases or recurrence. Therefore, this definition appears to be the most appropriate one for guiding clinical management. Patients with MICA by SGO criteria are sometimes treated conservatively, usually with conization, while those that have tumors measuring >3 mm in depth or with lymphatic invasion are often considered for more radical therapy [55]. It is important to stress that because the lesion cannot be visualized on gross inspection, the diagnosis of MICA is always based on histologic examination of a cone biopsy specimen that includes the entire lesion.

General Features

The majority of MICA occurs in women 35-46 years of age. In screened populations, MICA accounts for approximately 20% of all cervical cancers [36, 177]. The reported frequency of MICA in patients with a squamous intraepithelial lesion (SIL) varies from <1% to >50%. This wide variation in prevalence reflects differences in the definition of MICA, methods of sampling of cervical specimens, and the criteria used for diagnosing invasion. A 4% prevalence of MICA has been demonstrated in serial step sections of specimens with a squamous intraepithelial lesion (SIL) [28, 136]. However, it should be noted that such studies typically identify only microscopic foci of a few epithelial cells invading the stroma. Estimates of the prevalence of MICA in the general population can be obtained from population-based cervical cancer registries. A population-based registry from British Columbia, Canada, estimates the prevalence of MICA to be 4.8 per 100,000 women screened, whereas the prevalence of carcinoma in situ is 316 per 100,000 women screened [23]. With the widespread adoption of shallow laser excisional conization and loop electrosurgical excision procedure (LEEP) as diagnostic and therapeutic methods for SIL, better estimates for the prevalence of MICA in patients with all grades of SIL have been obtained. Larger studies of specimens obtained by LEEP have reported colposcopically undetected MICA in 0.4-3% of all patients with biopsy-confirmed SIL [251]. In an audit of the National Health Service (NHS) Cervical Cancer Screening Program in the United Kingdom During the 1991-1993 period, the incidence of MICA was 3.6 per 100,00 total female population [100]. In assessing the probability of MICA developing in women with SIL, the size as well as grade of the lesion is important. Microinvasive squamous cell carcinoma appears to be most commonly associated with extensive high-grade

SIL involving the endocervical crypts [8]. Two additional histologic features predicting microinvasion include presence of luminal necrosis and intraepithelial squamous maturation [8].

Clinical Features

Most patients with MICA are asymptomatic with a grossly normal cervix or nonspecific findings such as chronic cervicitis or erosion. Cytologic studies do not accurately predict the presence of microinvasion [200]. In a study of 536 women undergoing laser conization, cytology predicted the presence of invasion in only 27.3% of women with MICA [10]. In another study, cytology predicted invasion only in 12.5% of women with MICA [36]. A definitive diagnosis of microinvasion is made by histologic evaluation of cervical tissue removed by conization or at hysterectomy. Colposcopically, areas of MICA usually show acetowhitening consistent with highgrade SIL, and may contain one or more foci of bizarre surface branching vessels [159]. However, microinvasion frequently cannot be accurately detected using colposcopy. In a study that correlated colposcopic appearances with histologic findings from a large number of LEEP specimens, Murdoch et al. demonstrated that accurate colposcopic detection of MICA requires invasion of more than 1 mm into the cervical stroma [187]. Because it is difficult to colposcopically identify MICA, most colposcopists routinely treat all large biopsy-confirmed, high-grade SIL using excisional methods such as LEEP.

Pathologic Features

The diagnosis of MICA is based on the presence of one or more tongues of malignant cells penetrating the basement membrane of the squamous epithelium (> Figs. 6.1-6.4). The squamous epithelium invariably demonstrates varying grades of SIL, and in most instances the underlying endocervical glands are extensively replaced by the intraepithelial disease. Within the microinvasion foci, the cells are better differentiated with abundant eosinophilic cytoplasm and prominent nucleoli as compared to the associated SIL. Occasionally, small foci of keratinization are seen within the microinvasive foci. Because of focal disruption of the basement membrane, the margin of the invading nests is ragged, flanked by intact basement membrane on either side. This irregular contour is probably the most reliable criterion for the diagnosis of MICA. It is easily distinguished from the smooth and regular contour

Fig. 6.1

Microinvasive squamous carcinoma. Irregular islands of squamous cell carcinoma invade superficial cervical stroma but do not exceed 5 mm in depth or 7 mm in horizontal extent

Fig. 6.2

Microinvasive squamous carcinoma. Some small nests of squamous cell carcinoma are isolated in superficial stroma, whereas one larger island remains attached to the overlying high-grade squamous intraepithelial lesion

of endocervical gland involved by high-grade SIL. There is often a conspicuous lymphoplasmacytic infiltrate surrounding the tips of the invasive epithelial tongues, and frequently there is a desmoplastic response in the adjacent stroma. Two additional histologic features that are reported to be helpful for diagnosing MICA, particularly when there is a marked inflammatory infiltrate, are apparent duplication or folding of the neoplastic epithelium

Fig. 6.3

Microinvasive squamous cell carcinoma. Small foci of squamous cell carcinoma present in superficial stroma not exceeding 5 mm in depth from the basement membrane of the overlying high-grade squamous intraepithelial lesion and not exceeding 7 mm in horizontal extent

Fig. 6.4

Microinvasive squamous cell carcinoma. Small

detached nests and one attached elongated tongue of squamous cell carcinoma are present in superficial stroma beneath the overlying high-grade squamous intraepithelial lesion

and scalloping of the margins of the epithelium at the dermal-epidermal interface [57].

After establishing a diagnosis of MICA, the pathologist evaluates the surgical margins, depth of stromal invasion,

Fig. 6.5

Methods of measuring depth of invasion of microinvasive squamous cell carcinoma of the cervix. The pattern of stromal invasion determines the stromal depth measurement that is most appropriate. (a) Origin of invasion at surface HSIL: depth of stromal invasion is measured from point of origin of invasion downward to the last cell of the invasive focus. (b) Origin of invasion at HSIL with gland involvement: depth of stromal invasion is measured from site of origin downward to the last cell of the invasive focus. (c) Origin of invasion not seen: depth of stromal invasion is measured from basal lamina of surface HSIL downward to the last cell of the invasive focus

greatest lateral extent of the lesion, and whether lymphyascular invasion is present. For consistency in the measurement of the depth of stromal invasion, the following guidelines are recommended. The depth of neoplastic projections should be measured from the initial site of invasion, either from the basal lamina of the surface epithelium or from endocervical glands replaced by intraepithelial neoplasia (> Fig. 6.5). There are cases, however, in which direct continuity between invasive foci and SIL cannot be demonstrated, even in deeper cuts of the paraffin block. In such instances, it is assumed that the invasion originated from basal cells of the overlying SIL. Therefore, the depth of invasion is arbitrarily measured from the basal lamina of the surface SIL. The most accurate method to measure the depth of stromal penetration is with a calibrated slide or ocular micrometer. A more convenient, but perhaps less accurate, method of establishing the size and depth of penetrating foci consists of direct microscopic visualization with a transparent metric ruler. The depth of invasion also depends on the angle at which sections are prepared, and therefore efforts should be made to secure vertically sectioned tissue samples. The lateral extent of MICA is measured as described for the depth of stromal invasion. Measurements are made between the two farthest lateral points where invasion is identified.

At the site of initial stromal invasion, disruption of the basement membrane has been historically identified using electron microscopy. Therefore, a number of studies have attempted to use immunohistochemistry and antibodies directed against basement membrane constituents such as laminin or type IV collagen as a way of enhancing the recognition of early stromal invasion in cervical lesions. However, small basement membrane disruptions (as defined by laminin and type IV collagen staining) frequently occur both in the normal cervical epithelium and in squamous intraepithelial lesions that lack microinvasion, especially in areas with severe stromal inflammatory infiltrates [159, 187]. In addition, foci of basement membrane staining frequently occur in areas of invasion, and the amount of staining tends to increase as the degree of differentiation of the invading tumor advances [66]. Furthermore, metastatic foci of squamous cell carcinoma in the lymph nodes were found to be surrounded by basement membrane [96]. Therefore, immunohistochemistry appears to be of limited value in assessing questionable early stromal invasion.

Differential Diagnosis

The detection of microscopic foci of invasion in SIL can be difficult by light microscopy. The problem is often compounded by the presence of dense, obscuring inflammatory infiltrates, the small size of the biopsy specimens, and artifacts associated with shallow cervical excisions. Therefore, MICA is frequently misdiagnosed. Of 265 purported cases of MICA submitted to a group of reference pathologists of the Gynecologic Oncology Group (GOG), 132 cases (approximately 50%) were rejected [232]. Another study from the United Kingdom that reviewed 286 cases initially diagnosed as MICA found that 41% were incorrectly diagnosed [180]. Special attention should be paid to the interpretation of recently biopsied conization specimens as these may harbor nests of neoplastic epithelium buried within the cervical stroma at the site of a previous punch biopsy. Both SIL and immature squamous metaplasia with extensive gland involvement should also be distinguished from MICA. A prominent stromal desmoplastic response, abundant eosinophilic cytoplasm, and an irregular margin or scalloping of the epithelial nest are associated with invasive foci.

Risk Factors

Factors that have been reported to increase an individual's risk for nodal metastases, recurrence, and death are (1) depth of stromal invasion, (2) presence of lymphvascular invasion, (3) tumor volume, and (4) involvement of the resection margin. However, the lack of a uniform definition of MICA and methodology for measuring the depth of invasion together with different follow-up time and treatment methods make interpretation of the published data difficult. For example, the maximal depth of stromal invasion in studies of MICA varies from 1 to 5 mm. Some studies characterize microinvasion by the absence of confluency of invasive foci or the absence of lymphvascular invasion, whereas in others these features do not exclude the diagnosis of MICA. As a result, the frequency of pelvic node metastasis associated with MICA in the published literature varies from 0% to 9% [56, 232].

Depth and Pattern of Invasion

Depth of stromal invasion is a major factor in determining the outcome of patients with MICA. Early studies reported that no residual carcinoma was detected in the subsequent hysterectomy specimen when MICA invaded 1 mm or less in the cone biopsy. In contrast, residual carcinoma was detected in a significant proportion of cases when MICA in the cone biopsy invaded 3 mm or more. Histologic analysis of lymph nodes removed at the time of radical surgery has shown a clear relationship between the depth of stromal invasion and the presence of lymph node metastases (**)** *Table 6.3*). Lymph node metastases are very uncommon in patients with stromal invasion of 3 mm or less. In contrast, the prevalence of lymph node metastases is 7.6% in women with 3.1–5 mm of invasion [17, 51, 56, 61, 98, 152, 163, 232, 234, 242, 263, 267].

The development of recurrent disease or death from cervical cancer in women with <1 mm of stromal invasion who have been managed with either a cone biopsy or a simple hysterectomy is infrequent [53, 56, 142, 190]. In three long-term follow-up studies involving 403 women, not a single patient with <1 mm of stromal invasion treated with a cone biopsy or simple hysterectomy died of their tumor (**>** *Table* 6.4) [34, 53, 142].

Similarly, recurrent disease occurs in approximately 0.4% of patients when tumors invade <3 mm (**>** *Table* 6.5) [56, 66, 96, 180, 233, 285]. Recurrence occurs in approximately 5% of patients when there is 3.1-5 mm of invasion (**>** *Table* 6.5).

Confluency of neoplastic epithelium in MICA has not been associated with pelvic node metastases, vaginal recurrence, or cancer death in most series [142, 263]. A reproducible definition of what constitutes a confluent pattern of invasion has been difficult to achieve, particularly for smaller lesions [22]. Therefore, clinical outcome is strongly influenced by the depth but not the pattern of invasion.

Lymphvascular Space Invasion (LVSI)

Roche and Norris defined lymphatic space invasion as endothelial-lined (capillary-like) spaces containing tumor cells that are contiguous with the stroma [219]. In view of the difficulties in distinguishing small blood

vessels and capillaries from small lymphatic channels, the term lymphvascular space(s) invasion (LVSI) is used in this chapter. Identification of early LVSI, particularly in the cervical stroma adjacent to the overlying epithelium, may be difficult and is often hampered by technical processing artifacts. A recently developed monoclonal antibody D2-40, specific for lymphatic endothelium, is helpful in distinguishing between true LVSI and processing artifacts [88]. The relationship between LVSI and clinical outcome in women with early invasive squamous cell carcinoma is less clear-cut than the relationship between the depth of invasion and lymph node metastases. LVSI is reported to occur in 0–10% of MICA that invade <1 mm and in 3–30% of MICA invading 1–3 mm (\bigcirc Table 6.6) [27, 66, 98, 180, 217, 242, 267, 271].

The large variation between the different reports results from several factors, including the number of pathologic sections evaluated and interobserver variability in determining LVSI. Shrinkage of stroma surrounding invasive nests can result in the formation of artifactual spaces that can be erroneously interpreted as LVSI. One study of early invasive squamous cell carcinoma reported that the frequency of LVSI detection increased from 30% to 57% when step sections were cut through the site of invasion [219]. Despite the problems with recognizing LVSI, most studies have found a relationship between the increasing depth of invasion and the increased frequency of LVSI (Table 6.6). Most studies indicate that the presence of LVSI is an adverse prognostic factor [34, 51, 56, 163, 232, 267]. Three of 96 patients (3.1%) with <3 mm invasion and LVSI developed recurrence compared to 3 of 486 patients (0.6%) who did not have LVSI. In patients with 3-5 mm invasion and LVSI, 8 of 51 (15.7%) had recurrent disease. This was in contrast to only 2 of 115 patients (1.7%) who developed recurrence with similar depth of invasion but absence of LVSI. LVSI also appears to be a predictor of the presence of invasive carcinoma in subsequent hysterectomy specimens and lymph node metastasis [22, 61]. Therefore, although FIGO does not take LVSI into account in staging, the prevailing opinion in the United States is that LVSI should be assessed in women with early invasive squamous cell carcinoma; its presence excludes a diagnosis of MICA.

Tumor Volume and Horizontal Extent

Burghardt and Holzer have introduced the concept of tumor volume as applied to MICA and have reported no pelvic node metastases in patients with 420 mm³ of cancer or less, with the exception of one case in which vascular invasion was noted [35]. In recent years, the concept of MICA tumor volume has been emphasized by some authors. However, MICA tumor volume estimation by serially sectioning cone specimens is both cumbersome and time-consuming, and is unlikely to become a routine laboratory method. Other investigators and FIGO have used lateral extent of spread as a surrogate for measuring tumor volume. The lateral extent of spread of early invasive squamous cell carcinoma has been correlated with the frequency of residual neoplasia in postcone hysterectomy specimens (> Table 6.7) [232]. In a study of 402 patients with stromal invasion of 5 mm or less, Takeshima et al. found that 18% had >7 mm of horizontal spread [253]. As the depth of invasion increased, there was an increase in horizontal spread. Only 6.3% of lesions with

3 mm of invasion or less had >7 mm horizontal spread, whereas 61% of those with 3–5 mm of invasion had more than 7 mm lateral spread [253].

Surgical Margins

Perhaps one of the most important contributions of the pathologist to the appropriate management of early invasive squamous cell carcinoma is evaluating surgical margins of conization specimens [56, 94, 119, 152, 232]. In fact, the status of cone margins may well be the most important single parameter in deciding the therapeutic approach to patients with early invasive squamous cell carcinoma. In most studies, women with cone margins positive for either SIL or invasive disease are much more likely to have residual invasive disease in the hysterectomy specimens than are women with a negative margin. Furthermore, the residual invasion may actually be deeper than that found in the cone biopsy specimen (\bigcirc *Table 6.8*).

Treatment

The therapy for IA1 MICA is more conservative than that for stage IA2, and treatment is often individualized based on (1) the definition of the lesion (FIGO vs. SGO), (2) lateral extent, and (3) involvement of cone margins. The data on risk factors for nodal metastases, recurrence, and death suggest that lesions with 3 mm or less stromal invasion without LVSI have virtually no potential for metastasis or recurrence. Those invading 3 mm or less but with LVSI may potentially metastasize, Relationship between status of cone biopsy margin in patients with early invasive squamous cell carcinoma of the cervix and residual disease in the postcone hysterectomy specimen

although the risk is small, about 3.5%. Therefore, most authorities believe that women with <3 mm of stromal invasion who lack LVSI can be managed with procedures less radical than those required for higher-stage invasive squamous cell carcinomas [24, 151, 181]. Patients who are managed with less radical procedures should have had a diagnostic conization that removed the entire lesion with negative resection margins and a negative endocervical curettage obtained at the time of conization.

At most centers the recommended therapy for MICA, by the SGO definition, is a simple hysterectomy. Most authorities now agree that women with MICA who desire to remain fertile can be managed safely with conization, provided they clearly understand that there is a low risk of developing pelvic lymph node metastases or recurrent disease. Such patients have to return for regular followup examinations including cytology, colposcopy, and HPV testing [25, 151, 181]. In one series with medium follow up of 45 months, 10% of patients developed cervical intraepithelial neoplasis 3 [81]. At present, radical hysterectomy with pelvic lymphadenectomy is considered the most appropriate therapeutic approach for most stage IA2 early squamous cell carcinomas of the cervix and stage IA1 tumors with LVSI. In women desiring to preserve fertility, radical trachelectomy (amputation of cervix) and laparoscopic bilateral pelvic lymphadenectomy can be performed [63].

Invasive Squamous Cell Carcinoma

General Features

Worldwide, cervical cancer is second only to breast cancer in incidence and is the third leading cause of cancer mortality (after lung and breast cancers) [77]. Over the past 3 decades the incidence of cervical carcinoma in the United States has declined by almost one third, mostly due to a decrease in squamous cell carcinoma (SCC) [270]. In 2008, there were 11,270 new cases and 4,070 deaths due to cervical cancer [116]. Despite the decrease in incidence, cervical cancer is the second leading cause of mortality in women aged 21-39 in the United States [116]. Regardless of the advances in detection and management in developed countries, cervical cancer continues to be a significant health problem worldwide. Cervical cancer is the most frequent type of cancer in women in some developing countries, whereas it is the seventh most frequent type in much of the developed world [211]. The regions of the world where the incidence is greatest include eastern and southern Africa, Central and South America, and south-central Asia. The highest incidence rate is in eastern Africa, where there is an age-standardized rate of 42.7. The lowest reported incidence rates are from China and western Asia, with age-standardized incidence rates of 6.8 and 5.8, respectively [203]; however, cervical cancer incidence has been increasing in China among women under age 50 [286].

The majority of women with invasive SCC are diagnosed in their mid-40s or 50; however, cervical carcinoma can occur at almost any age between 17 and 90 years [209]. Patients with invasive SCC are 15–23 years older than patients with high-grade SIL and 8 years older than patients with microinvasive carcinoma. In recent years there has been increased recognition that cervical cancer can occur in women under 35 years. Women under 35 years account for 22.1% of all patients with invasive cervical cancer in the United States [192].

There is little doubt that cytologic screening plays a major role in reducing both the incidence and mortality of invasive cervical cancer. According to the American Cancer Society, in 1961 only 30% of all US women had ever had a Pap smear, but this number increased to 87% by 1987 [214]. In 1940, the incidence of invasive cervical cancer in the United States was 32.6 per 100,000 women, which is similar to that currently seen in the developing world, whereas by 2008 the incidence was 8.3 per 100,000 women [192]. The reduction in incidence was paralleled by a reduction in mortality. Despite the low incidence of invasive cervical cancer in the United States, cervical cancer continues to be a problem among selected groups of women. The incidence among African-American women is almost 50% higher than the incidence of white women in the United States, and the incidence among Hispanic women is twice that of Caucasian women. The incidence of cervical cancer deaths is highest for black women (5.3 per 100,000), followed by Hispanic women (3.5 per 100,000), and Caucasian women (2.5 per 100,000) [115]. A significant proportion of the remaining cases of invasive cervical carcinoma in the United States could be prevented if all women at risk underwent routine cytologic screening and colposcopic evaluation of significant cytologic abnormalities. In the United States, 56% of the women who developed invasive cervical cancer had not had a Pap smear in the preceding 3 years [286].

Pathogenesis and Etiology

Molecular, clinical, and epidemiological studies have implicated HPV infection in the pathogenesis of cervical carcinoma. More than 90% of cervical carcinoma contains DNA sequences of specific HPV types, especially HPV 16 and HPV 18 [48]. The distribution of HPV types in invasive cervical cancers shows only minor geographic variations. Globally, HPV 16 is most frequently detected in invasive cervical cancer, followed by HPV 18. HPV types 31, 33, 35, 45, 52, and 58 are the next most common types found in cancers globally with minor variations seen in their relative importance by region [185]. The failure to detect HPV DNA in a small subset of invasive squamous cell carcinomas appears to be caused by a number of factors including failure to adequately sample the lesion, presence of a HPV type other than those assayed for, and loss of, part of the HPV genome from the malignant cells. A study that investigated supposedly HPV DNA-negative tumors using multiple molecular techniques detected HPV DNA in most of the cases and concluded that the worldwide prevalence of HPV in cervical carcinomas is 99.7% [272]. In patients with metastatic cervical carcinoma, HPV DNA can also be identified in distant metastases, with viral DNA hybridization patterns frequently matching those of the primary cervical tumor [298]. Based on the strength of the molecular and epidemiologic evidence linking HPV to invasive squamous cell carcinoma of the cervix, 13 high-risk types of HPV (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 66) have been classified as carcinogenic to humans by the WHO.

There is a considerable body of evidence indicating that invasive squamous cell carcinoma develops from SIL and women with invasive squamous cell carcinoma have similar epidemiologic characteristics to those with preinvasive precursor lesions (see **O** Chap. 5, Precancerous Lesions of the Cervix). Like women with SIL, the majority of women with invasive cancer of the cervix are from lower socioeconomic groups, began heterosexual activity early in life, married early, are multiparous, and have many sexual partners or have partners who have been sexually promiscuous even if they have not been [113, 201, 228].

There is also considerable epidemiologic evidence indicating that factors other than HPV are important in the development of invasive squamous cell carcinoma of the cervix. Two studies found that even after controlling for HPV, there continued to be a significant associations between cervical cancer and number of sexual partners, smoking, and histories of venereal disease [15, 42]. In women infected with high-risk carcinogenic HPV, longterm use of oral contraceptive can significantly increase the risk of developing high-grade SIL and carcinoma [243]. Genetic and immunologic host factors and viral factors such as viral load and viral integration are probably important but their precise roles have not yet been clarified [186].

It has been estimated that approximately 1–5% of untreated low-grade SIL eventually progress to invasive cancer [280]. In the Ontario Cancer Registry study of more than 17,000 women with a history of abnormal Pap smears, the actual rate of untreated low-grade SIL progressing to carcinoma in situ or invasive cervical cancer was 2.8% for women followed more than 10 years [105]. The percentage of carcinoma in situ that progressed to invasive squamous cell carcinoma has been between 6% and 74% in various follow-up series (see **>** Chap. 5, Precancerous Lesions of the Cervix).

The presenting symptoms of patients with invasive carcinoma of the cervix of all histologic types appear to be dependent on the size and stage of the lesion [214]. Early series from the 1950s through the 1970s were composed predominantly of patients with bulky, late-stage disease. Nearly all these patients had clinically visible cancers and nearly all complained of abnormal vaginal bleeding. The most significant and common feature was bleeding following intercourse or douching. Intermittent spotting, serosanguinous discharge, and frank hemorrhage were also frequently encountered. Around 10-20% of the patients complained of bloody malodorous discharge and pain, often radiating to the sacral region. Weakness, pallor, weight loss, edema of the lower extremities, rectal pain, and hematuria are symptoms and signs of either locally advanced or metastatic disease.

More recent studies include a much higher percentage of patients with stage I disease. Patients with stage I disease

are frequently asymptomatic, particularly those with endophytic cancers. In these cases, cytology is often negative, i.e., contains no abnormal cells. About two thirds of exophytic lesions are detected on the basis of an abnormal Pap smear [100, 214]. Primary presentation correlates well with disease severity and survival. Patients who present with an abnormal Pap smear have a disease free survival of 96% as compared to 51% for those with vaginal bleeding and 21% for those presenting with pain [214]. Accurate detection and diagnosis of frank invasive carcinoma is based on cytology, colposcopy, and colposcopically directed punch biopsy [24]. Cervical cancers are clinically staged based on biopsy, physical examination, and chest x-ray results. If the stage is >IB1, CT or MRI of the abdomen and pelvis is typically done to identify metastases, estimate tumor volume, and determine parametrial involvement. If MRI and CT are not available, cystoscopy, sigmoidoscopy, and IV urography, when clinically indicated, may be used, but are not required, for staging [24, 205].

Invasive carcinoma of either the squamous or glandular type can develop in the cervical stump that remains following subtotal hysterectomy in 0.1–3% of patients [235, 283]. In a study of 173 women with carcinoma of the cervical stump, Wolff et al. divided patients into those that developed carcinoma less than and more than 2 years from the operation [283]. The 5-year survival of patients in the first group was worse (30%) than those in the second group (49%) or those with cancer of the cervix in general. Based on these observations, it has been suggested that cervical stump cancers occurring within the first 2 years following surgery represent residual malignancy, whereas those discovered after 2 years are "new" cancers arising from the cervical stump.

Cervical cancer is the most common gynecologic cancer in pregnancy, but the incidence is low (1.5–12 per 100,000 pregnancies) [109, 120]. Routine cervical cytology is a part of the initial prenatal examination. The mean age of pregnant women with invasive cervical cancer is 32 years, which is considerably lower than that of women in the general population with invasive cervical cancer. Women who are pregnant usually present with early-stage tumors; in one series 83% were stage I [120]. The treatment of pregnant patients with invasive cervical cancer depends on the clinical stage and gestational age. In general, prognosis is not altered by pregnancy.

Gross Findings

The gross appearance of invasive squamous cell carcinoma varies widely. Early lesions may be focally indurated,

ulcerated, or present as a slightly elevated, granular area that bleeds readily. Colposcopic examination usually reveals atypical, tortuous vessels varying widely in size and configuration. Approximately 98% of early carcinomas are localized within the transformation zone, with variable degrees of encroachment onto the neighboring native portio. Most advanced tumors are endophytic or exophytic. Endophytic carcinomas are ulcerated or nodular; they tend to develop within the endocervical canal and frequently invade deeply into the cervical stroma to produce an enlarged, hard, barrel-shaped cervix. In some patients with endophytic carcinomas, the cervix appears grossly normal. The exophytic varieties of cervical carcinoma have a polypoid or papillary appearance.

Microscopic Findings

Microscopically, invasive squamous cell carcinoma is characterized by anastomosing tongues or cords of neoplastic epithelium infiltrating the stroma (**>** *Fig.* 6.6). Characteristically, the contour of the infiltrating nests and clusters is irregular and ragged. In other cases, the tumor invades either as individual cells or almost completely replaces the stroma with large masses of neoplastic squamous cells. Cells in the center of the invading nests frequently become necrotic or undergo extensive keratinization. Individual

Fig. 6.6

Invasive squamous carcinoma. Well to moderately differentiated carcinoma is composed of islands and nests of neoplastic squamous epithelium with keratinization invading stroma cells are generally polygonal or oval with eosinophilic cytoplasm and prominent cellular membranes. Intracellular bridges may or may not be visible. In some cases, the nuclei are relatively uniform, whereas in others they are quite pleomorphic. In most cases, the chromatin is coarse and clumped, and mitotic figures, including abnormal forms, commonly are encountered.

Histological Typing

One of the earliest approaches to classifying cervical squamous cell carcinomas was based on the predominant cell type. The classification separated squamous cell carcinomas into large cell keratinizing, large cell nonkeratinizing, and small cell nonkeratinizing. In the experience of Wentz and Reagan, the best 5-year survival rate after radiation therapy was associated with large cell nonkeratinizing carcinomas (68.3%), followed by the large cell keratinizing type (41.7%), and small cell carcinomas (20%) [279]. Because there has been frequent confusion between the small cell nonkeratinizing squamous cell carcinomas described by Wentz and Reagan and small cell carcinomas with neuroendocrine features similar to those described in the lung, the current WHO classification of invasive cervical cancers places small cell undifferentiated carcinoma with neuroendocrine features in a separate category and divides invasive squamous cell carcinomas into two groups, keratinizing and nonkeratinizing [278].

Keratinizing carcinomas are characterized by the presence of well-differentiated squamous cells that are arranged in nests or cords that vary greatly in size and configuration. The defining feature of keratinizing carcinomas is the presence of keratin pearls within the epithelium, and the presence of a single keratin pearl is sufficient to classify a tumor as a keratinizing carcinoma. Keratin pearls are composed of clusters of squamous cells that have undergone keratinization and are arranged in a concentric nest. The neoplastic squamous cells not forming keratin pearls frequently have abundant eosinophilic cytoplasm and prominent intracellular bridges. The nuclei are often enlarged, but mitotic figures are not numerous.

Nonkeratinizing squamous cell carcinoma is characterized by nests of neoplastic squamous cells that frequently undergo individual cell keratinization but, by definition, do not form keratin pearls. The cells have relatively indistinct cell borders. The nuclei tend to be round to oval with coarsely clumped chromatin. Mitotic figures are numerous. In some cases SCC is composed of solid sheets of cells with clear cytoplasm (**)** *Fig. 6.7*). Other nonkeratinizing squamous cell carcinomas are composed of masses and nests of small basaloid cells with scant cytoplasm and hyperchromatic uniform nuclei with numerous mitotic figures (\bigcirc *Fig. 6.8*). These tumors are similar to the basaloid carcinomas of the vulva and vagina.

Fig. 6.7

Squamous cell carcinoma. Solid sheets of carcinoma contain cells with clear cytoplasm; this variant lacks the characteristic cytologic and architectural features of clear cell carcinoma and should not be misclassified as such

Fig. 6.8

Squamous cell carcinoma. Basaloid variant resembles highgrade squamous intraepithelial lesion within endocervical glands but nests within desmoplastic cervical stroma are indicative of invasive tumor Some investigators have reported that this classification has prognostic significance in patients treated with radiotherapy [279]. Others authors have reported no significant difference in prognosis between patients with large cell nonkeratinizing and large cell keratinizing squamous carcinomas when treated with radical surgery [297].

Microscopic Grading

The most commonly used grading system for squamous cell carcinoma is a modification of the original system proposed by Broders in 1920 [32]. This method was based on the proportion of the tumor undergoing keratinization with the formation of squamous pearls and a number of mitoses. Currently histologic grading divides squamous cell carcinomas into three groups, well differentiated (grade 1), moderately differentiated (grade 2), and poorly differentiated (grade 3). Most squamous cell carcinomas are moderately differentiated (grade 2), followed by poorly differentiated (grade 3) and well differentiated (grade 1).

In well-differentiated (grade 1) tumors, the most striking feature is abundant keratin, which is deposited as keratin pearls in the center of neoplastic epithelial nests. The cells appear mature, with abundant eosinophilic cytoplasm. Individual cell keratinization (dyskeratosis) characterized by intense cytoplasmic eosinophilia may also be present. The cells are tightly packed and have welldeveloped intercellular bridges. The nuclei are large, irregular, and hyperchromatic. Mitotic figures are present most notably at the periphery of the advancing epithelial nests. The stroma is often infiltrated by chronic inflammatory cells, and occasionally a foreign body giant cell reaction is observed.

In moderately differentiated (grade 2) squamous cell carcinomas, the neoplastic cells are more pleomorphic than in grade 1 tumors, have large irregular nuclei, and have less abundant cytoplasm. The cellular borders and intercellular bridge appear indistinct. Keratin pearl formation is rare, but individual cell keratinization is seen in the center of nests of tumor cells. Mitotic figures are more numerous than in grade 1 carcinomas (see \bigcirc Fig. 6.6).

Poorly differentiated (grade 3) squamous cell carcinomas are generally composed of cells with hyperchromatic oval nuclei and scant indistinct cytoplasm, resembling the malignant cells of high-grade SIL (**)** *Fig. 6.9*). Clear-cut squamous differentiation manifested by keratinization may be difficult to find. Mitoses and areas of necrosis are abundant. Poorly differentiated lesions are occasionally composed of large, pleomorphic cells with giant, bizarre

Fig. 6.9

Squamous cell carcinoma. Poorly differentiated carcinoma is composed of sheets of atypical cells

Fig. 6.10 Squamous cell carcinoma. Poorly differentiated carcinoma has some cells with spindled morphology

nuclei and abnormal mitotic figures. In rare instances, the neoplastic cells assume a spindle-shaped configuration resembling a sarcoma (\bigcirc *Fig.* 6.10). Immunohistochemical staining for epithelial membrane antigen and cytokeratins demonstrates the epithelial nature of the spindle cells in these cases. Although in some studies tumor grade was associated with patients survival [18], most studies have failed to confirm that histopathologic grade influences clinical outcome [103, 252]. A study from the Gynecologic Oncology Group (GOG) evaluated a number of different tumor-grading systems including

those proposed by Warren, Reagan, and Broder in surgically treated stage IB cervical cancers. Although there was good reproducibility between observers (76-92%), none of the grading systems had prognostic significance. Nuclear grade, degree of keratinization, mitotic activity, pattern of infiltration, and degree of lymphoid response all lacked prognostic significance [297]. Because histopathologic grade has failed to predict clinical outcome in many studies, systems taking into account growth pattern at the invasive tumor front have been developed. Three patterns of invasion have been described: pushing, finger-like, and spray-like [106]. The pushing pattern of invasion is characterized by a well-delinated tumor border. The finger-like pattern of invasion shows a trabecular tumor growth in solid cords. The spray-like pattern is defined by the presence of small groups and/or single cells at the invasive tumor front. In several studies spray-like growth pattern has been associated with a reduced 5-year survival in cervical cancer patients with primary surgical treatment [106, 239], but this finding was not confirmed by other authors [225, 297].

Prognostic Biomarkers

Several studies have investigated the immunohistochemical detection of prognostic biomarkers in squamous cell carcinomas of the cervix. In a study of 129 women with squamous cell carcinoma, a high number of CD4 positive tumor infiltrating lymphocytes were associated with good prognosis, while a high Ki-67 index among the tumor cells predicted poor prognosis in patients with late-stage cervical cancer. In the same study, expression of the transmembrane protein, leucine-rich repeats, and immunoglobulin-like domains 1 (LRIG1) were associated with a favorable prognosis in early-stage cervical cancer [99]. LRIG1 has been shown to restrict growth factor signaling by enhancing ubiquitylation and degradation of epidermal growth factor receptor (EGFR) and inhibiting the function of cellular oncogenes Met and Ret [95, 149, 236]. High cyclooxygenase 2 (COX-2) expression in cervical cancer cells has been associated with poor survival in several studies [70, 158]. COX-2 is the key enzyme in the conversion of arachidonic acid to prostaglandins and its overexpression increases metastatic potential and angiogenesis, while decreasing host immune response and apoptosis. In addition, a recent study has demonstrated that COX-2 transcription is regulated by HPV 16 oncoproteins E6 and E7 through EGFR signaling [248]. Synchronous co-expression of EGFR and COX-2 has been reported in 32% of cervical cancers and also correlates with poor outcome [137]. Ferrandina et al. have reported that in celecoxib-treated patients, tumor biopsies showed decreased expression of COX-2, Ki-67 (a cellular proliferation marker), and CD31 (an angiogenesis marker), as well as a decrease in microvessel density [71]. These data were used as the background for two clinical trials of celecoxib in advanced cervical cancer. Despite biologic promise, two phase II trials testing specific COX-2 inhibitors as radio-sensitizers in locally advanced cervical cancer demonstrated increased toxicity with no change in therapeutic effect [83, 101].

The presence of EGFR and human EGFR 2 (HER2) has been associated with accelerated tumor progression and therapeutic resistance in several malignancies including cervical cancer. Previous studies have shown that EGFR is expressed in up to 76% of cervical cancers and correlates with poor prognosis [134]. EGFR inhibitors are currently undergoing testing in clinical trials. In a recent phase II trial, EGFR expression levels, evaluated by immunohistochemistry, did not correlate with tumor response and disease control in patients treated with gefitinib (EGFR inhibitor) [89]. Using the standardized HercepTest scoring criteria, HER2 expression is considered a rare event in cervical cancer [138].

High peritumoral lymphatic vessel density evaluated by counting D2-40-positive (a selective marker for lymphatic endothelium) vessels has shown significant correlation with higher tumor stage, lymph node metastases, and poor survival in 111 cervical squamous cell carcinomas FIGO stage 1A–IIA [88]. Another recent study using an antibody against lymphatic vessel endothelial hyaluronan receptor-1 has also shown that increased lymphatic vessel density was associated with lymph node metastasis and lymphatic vessel invasion in early-stage cervical carcinoma [300].

The dependence of tumor growth and metastasis on blood vessels makes angiogenesis one of the fundamental hallmarks of cancer and a target for therapy. One of the major pathways involved in angiogenesis is the vascular endothelial growth factor (VEGF) family of proteins and receptors. Overexpression of VEGF has been associated with tumor progression and poor prognosis in several tumors, including cervical cancer. Intratumoral protein levels of VEGF are increased in cervical cancer compared to normal cervical tissue and higher VEGF levels correlate with higher stage and increased risk of lymph nodes metastasis [41]. It has also been demonstrated that higher VEGF expression and increased tumor vascularization are independent predictors of shorter disease-free interval and overall poor survival [160]. There is also data suggesting that HPV may directly stimulate VEGF production through upregulation of the E6 oncoprotein [260]. In phase II clinical trials, bevacizumab (a recombinant humanized anti-VEGF monoclonal antibody) was well tolerated and active as second- and third-line treatment of patients with recurrent cervical cancer [178].

P53 and RAS mutations are rare in cervical squamous cell carcinoma and in recent studies have not been associated with tumor stage, tumor grade, or survival [199, 256]. Amplification and overexpression of cellular oncogene c-myc have been demonstrated in approximately 20% of cervical squamous cell carcinomas and shown to be associated with the presence of HPV16. Overexpression of c-myc has also been associated with worse prognosis in some studies [14, 99].

Differential Diagnosis

Histologically, the lesions most commonly confused with invasive squamous cell carcinomas are squamous metaplasia, high-grade SIL with extensive endocervical gland involvement, gestational decidual reaction with degenerative features, trophoblastic lesions such as placental site nodules and epithelioid trophobastic tumors, condylomata acuminata, and reparative changes associated with chronic granulomatous diseases such as lymphogranuloma venereum and granuloma inguinale. Both squamous metaplasia and high-grade SIL are frequently extensive and extend into endocervical glands. Even though a low level of mitotic activity can be present in squamous metaplasia, careful evaluation of the cytologic appearance of the metaplastic cells reveals their benign nature because the cells are relatively uniform in size and shape and lack significant nuclear atypia. Moreover, the borders of endocervical glands involved with either squamous metaplasia or high-grade SIL are rounded and distinct and lack the irregular margins, scalloping, and desmoplasia in the stroma adjacent to the glands. A decidual reaction with degenerative features lacks mitotic activity and in difficult cases can be differentiated from invasive squamous cell carcinomas by the use of immunohistochemical staining because decidual cells do not contain cytokeratin. Placental site nodules appear as well-circumscribed nodules or plaques containing intermediate trophoblastic cells. These cells lack mitotic activity and are arranged in nests surrounded by hyaline material. Epithelioid trophoblastic tumors in contrast to squamous lesions have a more nested appearance and typically display a characteristic pattern of geographic necrosis. In difficult cases immunohistochemistry can be used to discriminate cervical neoplastic lesions from trophoblastic lesions as the latter

express inhibin and CK 18 but are negative for p16, while the converse expression patterns occur in cervical neoplasia.

It can also be difficult to distinguish between poorly differentiated squamous cell carcinomas composed of small, basaloid cells and small (oat) cell carcinomas of the neuroendocrine type, lymphoma, and malignant melanoma. Small cell carcinomas of the neuroendocrine type typically invade the stroma diffusely as individual cells or as small discohesive nests and show extensive crush artifact; they frequently form rosettes or trabeculae and the cells characteristically have smudged, intensely hyperchromatic nuclei and lack nucleoli. In contrast, poorly differentiated squamous cell carcinomas invade as cohesive nests, and the cells have oval nuclei with granular chromatin. In difficult cases immunohistochemical stain for p63 can be used to confirm squamous differentiation. In a study of 250 invasive carcinomas, a strong, diffuse p63 expression was present in 97% of squamous cell carcinomas, including 91% of small cell nonkeratinizing squamous cell carcinomas. All neuroendocrine carcinomas did not show p63 staining or only focal expression (<30% of tumor cells) [274]. Malignant melanoma and lymphoma are p63 and cytokeratin negative.

Squamous cell carcinomas that contain large amounts of cytoplasmic glycogen can sometimes be confused with clear cell carcinomas (*Fig. 6.7*). Like clear cell carcinomas, cells in these tumors have clear cytoplasm and distinct cell membranes. However, squamous cell carcinoma with clear cytoplasm lacks the characteristic hobnail cells and the papillary or tubulocystic areas that are typical of clear cell carcinomas. In squamous cell carcinoma, a careful search of multiple sections will usually detect areas with unambiguous squamous differentiation. Expression of p63 confirms squamous differentiation.

In rare cases, primitive neuroendocrine tumors occur in the cervix [164]. Membranous staining for CD99, nuclear staining for FLI-1, and negative p63 staining help to differentiate these tumors from poorly differentiated squamous cell carcinomas [76]. In addition, primitive neuroendocrine tumors have t(11;12)(q24;q12) chromosomal translocation, which can be demonstrated by reverse transcription polymerase chain reaction and fluorescence in situ hybridization.

Although diffuse p16 expression is a surrogate marker for the presence of high-risk HPV in cervical neoplasia, it is important to remember that positive immohistochemical p16 staining may occur in non-HPV-related neoplasms (\bigcirc *Fig. 6.11*) [139]. Therefore, molecular testing for HPV using sensitive methods such as PCR or HPV in situ hybridization can be used to determine origin of

Fig. 6.11

Squamous cell carcinoma. Tumor exhibits characteristic diffuse/strong p16 expression of a high-risk HPV-related carcinoma

Squamous cell carcinoma. In situ hybridization demonstrates punctate nuclear signals in tumor nuclei indicating the presence of HPV 16 DNA

metastatic squamous cell carcinoma when cervical origin is suspected (**)** *Fig.* 6.12). However, when paraffinembedded material is utilized for testing many of the broad spectrum primer sets used for PCR-based HPV testing have a relatively low sensitivity for HPV and therefore absence of HPV DNA does not definitively rule out a cervical primary.

Histopathologic Prognostic Features

Stage is the most important prognostic factor in cervical carcinoma. Histologic typing and grading have little direct influence on survival within any stage (see "Microscopic grading"). The most significant pathologic prognostic factors in women with surgically treated stage IB and IIA squamous cell carcinoma are tumor size, depth of invasion, parametrial involvement, and nodal status [62, 144, 297]. A study of 188 women undergoing radical hysterectomy with bilateral pelvic lymphadenectomy for stage IB squamous cell carcinoma found that patients with tumors measuring <2 cm in diameter or larger tumors that only invaded <10 mm into the cervical stroma had a 5-year disease-free survival of 95%. In contrast, all other patients had a 5-year disease-free survival of 52% [61]. In the GOG series of patients with stage IB squamous cell carcinoma treated surgically, women whose tumors invaded the inner third of the cervical stroma had a 98% 5-year progressionfree survival, whereas for those whose tumors invaded the outer third progression-free survival was only 63% [297]. In the same GOG series, the 5-year progression-free interval was 70% in tumors with lymphvascular invasion (LVSI) compared to 83% in cases without LVSI [297]. In most series of surgically treated stage IB cancers, LVSI has proven to be somewhat less important than tumor size and depth of invasion. Accordingly, in reporting squamous cell carcinomas, the depth of invasion (in millimeters or the proportion of the wall invaded), the presence or absence of LVSI, and the size of the tumor (greatest tumor dimension) should be reported.

Among stage IB patients, presence of LVSI has been associated with four to five times increased risk of pelvic lymph node metastases. In a GOG study of 732 IB patients, Delgado et al. reported 3-year disease-free survival of 74% and 86% for those with and without lymph node metastases [62]. In a series of 978 Stage IB–IIA patients, the median survival was 5.3 years for those with negative nodes and decreased to 3.2 and 1.3 years for those with positive pelvic and paraaortic lymph nodes, respectively [18].

Parametrial extension correlates with LVSI, lymph node metastases, tumor recurrence, and poor survival [61]. In 69 radical hysterectomy specimens performed for stage IB and IIA carcinomas, evaluation of the entire parametria by a giant section technique revealed parametrial involvement in 31% of IB tumors, 63% of IB2, and 58% of IIA tumors. Survival was significantly higher for the patients with negative parametrial findings compared with those with positive parametrial findings (100% vs. 78%) [25]. Another factor that may influence prognosis is patient age. In 1952, Lindell, and subsequently others, demonstrated that survival was improved for older women [157]. However, other large studies, including one that analyzed more than 10,000 women with invasive cervical cancer, reported that younger women had a better prognosis than older women [172]. When stratified by stage it appears that there is little difference in prognosis between younger and older women with early-stage disease, however, with high-stage disease younger women have poorer survival [222].

HPV DNA Status

Several studies have assessed the effect of HPV type on prognosis and most show a significant correlation between HPV 18 and poor prognosis. In a study of 296 Stage IB-IV cancers, detection of HPV 18 DNA was associated with an approximately threefold increase in the risk of death in stage IB disease. This association was independent of established cervical carcinoma prognostic factors, such as FIGO stage and tumor size [231]. A recent study evaluated prognostic significance of HPV type in 1,067 patients with Stage IA-IIA disease. HPV 18 was detected in 16.5% of the samples, a typical prevalence for this genotype in most series. In a multivariant analysis of FIGO stage II tumors, deep stromal invasion, parametrial extension, and HPV 18 positivity were significant predictors for death [147]. Recent studies have suggested that patients infected with multiple HPV types had a significantly shorter cancer-specific survival and do not respond as well to radiation treatment as patients with a single HPV type [19, 184].

Spread and Metastases

Squamous cell carcinoma of the cervix spreads principally by direct local invasion of adjacent tissues and lymphatics and less commonly through blood vessels. Initially, the tumor grows by extending along tissue planes, such as the perineural and perivascular tissues, into the para-cervical and parametrial areas, and into the cardinal and uterosacral ligaments. Ultimately, lateral spread may reach the bony pelvis, encompassing and obstructing one or both ureters. Direct extension may also involve the uterine cavity and vagina, with extension into the urinary bladder and rectum, resulting in vesicovaginal and rectovaginal fistulas.

The spread of cervical cancer via lymphatics occurs relatively early and is present in 25-50% of patients with stage IB and II carcinomas. The most common sites of lymph node metastases are the internal iliac, obturator, external iliac, and common iliac lymph nodes. Later in the course of the disease, extension to the lateral sacral, paraaortic, and inguinal nodes can occur. Isolated invasion of the sacral, external iliac, and hypogastric nodes is occasionally observed. Distant lymph node metastases above the diaphragm including the supraclavicular lymph nodes are uncommon and are a feature of widespread disease. In these cases, cancer cells are transported from the paraaortic nodes into the mediastinum and then into the thoracic duct. Hematogenous dissemination is the least common metastatic pathway of cervical carcinoma. Blood-borne metastases to the lung, liver, bone, heart, skin, and brain are generally seen in stage IV tumors or when the local growth has previously been irradiated.

Ureteral obstruction caused by tumor invasion of the ureteral wall or by compression due to tumor periureteral lymphatics leads to hydroureter, in hydronephrosis, hydronephrotic renal atrophy, pyelonephritis, and loss of renal function. Obstruction of both ureters results in uremia and is a leading cause of death. Although the frequency of ureteral involvement was unchanged between 1930 and 1960, advances in radiation therapy during the 1970s reduced the number of patients dying of ureteral obstruction and uremia from 28% to 6.7% [131]. Peritonitis caused by obstruction and bowel perforation, respiratory failure associated with pulmonary metastasis, massive edema, hemorrhage, cardiac failure, massive venous thrombosis, pulmonary embolism, and complications of radiation therapy represent the major causes of death in order of frequency.

Behavior and Treatment

The three basic therapeutic modalities for squamous cell carcinoma are surgery, radiation, and combinations of radiation and surgery or radiation with concurrent chemotherapy. Recently targeted therapies have shown some promise. In stage IB and early stage II patients, virtually identical results are seen with radical hysterectomy with bilateral pelvic lymphadenectomy and radiation therapy. In young women with Stage IA1/2 and IB1 lesions, particularly those measuring <2 cm in diameter and desire to preserve their fertility, radical trachelectomy combined with laparoscopic pelvic lymphadenectomy has been widely accepted [63]. The 5-year disease-free survival in these women has been 96%. The pregnancy rate ranges between 41% and 79%, and 44% to 64% of pregnancies resulted in live births. A large randomized GOG trial

compared radiation therapy followed by adjunctive extrafascial hysterectomy for bulky-stage IB cervical cancers with radiation therapy combined with concurrent cisplatin chemotherapy and adjunctive extrafascial hysterectomy. The concurrent use of cisplatin and radiation significantly improved survival [135]. Other recent trials that have incorporated combinations of combined external and intracavitary radiotherapy with concurrent platinum-based chemotherapy for stage II and stage III cancers have also shown significant improvements in survival with the addition of chemotherapy compared to radiation alone [179]. A recent Cochrane Review of the treatment of early-stage cervical cancer concluded that the addition of platinum-based chemotherapy to radiotherapy may offer clinical benefit in early-stage cervical cancer with risk factors for recurrence [221].

Morphologic changes in cervical squamous carcinoma cells that are considered evidence of response to ionizing radiation are cellular differentiation with keratinization, cell degeneration with cytoplasmic vacuolization, pyknosis, and nucleomegaly. Radiation-induced changes in adenocarcinoma of cervix include nuclear shrinkage and pyknosis, cytoplasmic vacuolization, and decrease in mucin synthesis.

Chemotherapy using a variety of regimens, most of which use cisplatin either alone or in combination with other drugs, has been recommended by the National Cancer Institute and GOG for concurrent therapy in women with stage IB2 and locally advanced (stage II-IVA) cervical cancer undergoing radiation therapy. A subsequent metaanalysis of 19 randomized controlled trials totaling 4,580 patients verified that the addition of chemotherapy to radiation therapy improved progression-free and overall survival [145]. Although 40-70% of such patients being treated for the first time will respond to cisplatincontaining regimens, the proportion of patients with prolonged responses is considerably less [161]. In addition, chemotherapy is used for patients with metastatic or recurrent cancer previously treated with surgery or radiation therapy. Response rates for cisplatin-based therapy in these recurrent or late-stage patients ranges 20-30% and overall survival is less than 10 months. Since effective treatment options are limited for advanced cervical cancer, therapies targeting cervical cancer signaling pathways are currently being investigated.

The 5-year survival for treated stage I patients is 90-95%, for stage II 50-70%, for stage III 30%, and <20% for patients with stage IV disease [24]. The survival rates are reduced even in patients with low-stage disease when metastases to lymph nodes are present; survival rates appear to correlate with the number of positive

nodes [111]. Metastatic node involvement occurs in 8–25% of stage I, 21–38% of stage II, and 32–46% of stage III lesions [194]. Typically, the majority of recurrences appear within 2 years after initial therapy.

Verrucous Carcinoma

Verrucous carcinoma is a rare variant of squamous cell carcinoma. In the female genital tract, the region most commonly involved is the vulva, but well-documented cases have been described in the cervix [129, 299]. In the past, this tumor has been reported as giant condyloma acuminatum of Buschke and Lowenstein, but the implication that this tumor is a type of condyloma is erroneous and the term is no longer used. More recently some studies have implicated HPV as an etiologic agent since low- and high-risk HPV types were identified in verrucous carcinoma [37, 78].

Clinically, verrucous carcinoma appears as a large, sessile tumor that grossly resembles a condyloma. Verrucous carcinoma is a slow-growing, locally invasive malignant tumor. Because it is frequently diagnosed incorrectly, it may become quite advanced and lead to death. Five of eight patients in one series died shortly after the diagnosis was made [162]. Histologically, cervical verrucous carcinomas are identical to the more common vulvar tumors and are predominately exophytic and characterized by frondlike papillae with or without surface keratinization (\triangleright *Fig. 6.13*). The epithelium lacks significant cytologic

Fig. 6.13

Verrucous carcinoma. Broad, bulbous nests of very welldifferentiated neoplastic squamous epithelium invade superficial stroma with a pushing border atypia and mitotic activity, although in some cases mitoses may be found in the deep layers. The base of the tumor is composed of invasive nests of epithelium that are broad and expansile with a well-circumscribed pushing margin. There is a conspicuous inflammatory reaction at the epithelial stromal junction. For accurate diagnosis the biopsy should be large to include the rete ridge pattern at the base of the tumor as well as more superficial areas. If only superficial keratotic areas are examined the correct diagnosis is impossible.

Verrucous carcinoma should be distinguished from warty carcinoma (see section **9** Warty (Condylomatous) Carcinoma) and condylomata acuminatum. Unlike condyloma acuminatum, verrucous carcinoma lacks the central fibroconnective tissue cores in the epithelial papillae that are characteristic of condylomata. Typically, these tumors recur locally but do not metastasize unless they are inadequately radiated, in which case accelerated growth and metastasis may occur [129]. The most appropriate therapy is wide local excision if possible. However, these lesions can frequently be deeply invasive, even extending into the endometrium or adjacent pelvic tissue [162, 250]. Regional lymph nodes are rarely involved, and distant metastases are exceedingly rare [162].

Warty (Condylomatous) Carcinoma

Warty (condylomatous) carcinoma is a variant of squamous cell carcinoma of the cervix that has marked condylomatous changes. Unlike verrucous carcinoma, warty carcinomas demonstrate features of a typical squamous cell carcinoma at the deep margin. In addition, many of the malignant cells have cytoplasmic vacuolization and nuclear changes closely resembling koilocytotic atypia. Although clinical experience with these tumors is very limited, they appear to behave less aggressively than typical well-differentiated squamous cell carcinomas of the cervix. In one study, multiple types of HPV including low-risk types were identified in two thirds of these tumors [43].

Papillary Squamous Cell (Transitional) Carcinoma

Papillary squamous cell carcinoma is a rare variant of squamous cell carcinoma of the cervix. These tumors were initially described by Randall et al., who reported that they had a histologic resemblance to transitional cell carcinoma of the bladder [215]. A comprehensive study from the Armed Forces Institute of Pathology of 32 cases of papillary cervical carcinomas reported that these papillary tumors of the cervix can be subdivided into three groups based on their histologic appearance: predominately squamous, predominantly transitional, and mixed squamous and transitional [141]. However, all three histologic subdivisions demonstrated similar immunohistochemical staining patterns for cytokeratin 7 and 20. The tumors were typically positive for cytokeratin 7 and negative for cytokeratin 20, which is a pattern more typical of cervical squamous lesions than of transitional cell tumors of the urinary tract. Follow-up was available for 12 patients, and 3 were reported to have died of their disease [141]. However, no apparent differences were observed in the clinical behavior of the three subtypes. Therefore, it appears that papillary squamous cell carcinomas of the cervix present a spectrum of histologic appearances with some tumors appearing more squamous and others more transitional. Because they demonstrate a spectrum of histologic appearances, these tumors have been referred to as papillary squamotransitional carcinomas. HPV 16 has been identified in three cases of papillary squamous cell carcinoma of the cervix [31].

Histologically, papillary squamous cell carcinomas are composed of papillary projections that are covered by several layers of atypical epithelial cells (\bigcirc *Fig. 6.14*). In cases that appear more transitional, the cells are oval with their long axis oriented perpendicular to the surface and there is minimal flattening of the cells as they reach the surface. In cases with more squamous differentiation, the

Fig. 6.14 Papillary squamous cell carcinoma. Papillary fronds are lined by atypical squamous epithelium

Fig. 6.15

Papillary squamous cell carcinoma. Atypical squamous epithelium displaying loss of maturation and nuclear hyperchromasia with pleomorphism

cells are more basaloid and resemble those of a high-grade SIL (**)** *Fig. 6.15*). The cells have hyperchromatic, oval nuclei, and minimal amounts of cytoplasm. Mitoses are frequent. Focally, there are usually areas of squamous differentiation. Typical invasive squamous cell carcinoma can often be identified at the base of the tumor, appearing as well-circumscribed nests of epithelium in continuity with papillae that extend deeply into the stroma. Focal invasion of the papillae themselves also sometimes occurs. The behavior of papillary squamous cell carcinoma is similar to that of invasive squamous cell carcinoma with the exception that late recurrences have been reported in the larger series [215].

Papillary squamous cell carcinoma can be mistaken for a papillary squamous cell carcinoma in situ on a superficial biopsy. Because papillary squamous cell carcinoma is capable of acting aggressively and metastasizing, it is important that a cone biopsy performed to rule out invasion whenever a papillary squamous cell carcinoma in situ is diagnosed. These tumors can also be mistakenly diagnosed as verrucous carcinoma or as condyloma accuminatum with atypia. Papillary squamous cell carcinomas lack the condylomatous changes and degree of cytoplasmic differentiation present in the other lesions.

Lymphoepithelioma-like Carcinoma

Lymphoepithelioma-like carcinomas (LELC) are a distinctive subset of squamous cell carcinomas of the cervix that are typically well circumscribed and composed of

Fig. 6.16

Lymphoepithelioma-like carcinoma. Large, atypical, discohesive cells simulating lymphoma are intimately associated with a mixed chronic inflammatory cell infiltrate

undifferentiated cells surrounded by a dense stromal inflammatory infiltrate [167]. These tumors are reported to have a better prognosis than typical squamous cell carcinoma. LELC represent only 0.7% of all primary cervical malignancies in Western countries but up to 5.5% of cervical cancers in some series from Asia [262]. The pathogenesis of cervical LELC is still unclear. The Epstein-Barr virus (EBV) has been suggested as a potential causative agent and has been detected in 75% of cervical LELC cases in Asian women [166, 262]. In contrast, a role for EBV in LELC pathogenesis in women in Western countries seems less likely since EBV has not been detected in cervical LELC in Caucasian women so far. A possible role for the human papillomavirus (HPV) in the pathogenesis of cervical LELC has also been suggested [20, 193]. The cells composing LELC are relatively undifferentiated but have abundant cytoplasm and uniform vesicular nuclei $(\bigcirc$ Fig. 6.16). The cell borders tend to be indistinct and form what has been described as a syncytium. The nests of undifferentiated cells are surrounded by a marked chronic inflammatory infiltrate composed of lymphocytes, plasma cells, and eosinophils.

LELC can be mistaken for either glassy cell carcinoma or true lymphoproliferative disorders. Glassy cell carcinomas have a very poor prognosis and are characterized by prominent cell borders, ground glass cytoplasm, and prominent nucleoli. Lymphoproliferative disorders can be easily differentiated from LELC by immunohistochemical staining with antibodies against leukocyte common antigen, cytokeratin, and epithelial membrane antigen.

Adenocarcinoma

Adenocarcinomas of the cervix comprise a heterogeneous group of neoplasms that displays a variety of histologic patterns (see **7** *Table 6.1*). Because these cell types and patterns are frequently admixed, the histologic classification of these tumors is based on the predominant cell type. If additional histologic components comprise at least 10% of the tumor, some authors recommend classifying the tumor according to the predominant pattern and listing the individual components as part of the diagnosis.

The most common cervical adenocarcinoma type is the usual type, also referred to as "mucinous type," followed by endometroid adenocarcinoma [6, 290]. Although some studies have found endometrioid adenocarcinomas to be more prevalent than usual type adenocarcinomas, in most series endometrioid adenocarcinomas account for 7–30% of cervical adenocarcinomas [223, 277, 290].

Prevalence

The relative proportion and absolute incidence of squamous cell carcinoma and adenocarcinoma of the cervix has been changing in the United States and Western Europe since the introduction of widespread cytologic screening programs. The incidence of all invasive cervical cancer and of cervical squamous cell carcinoma has been decreasing, however the incidence of cervical adenocarcinoma (i.e., adenosquamous carcinoma and adenocarcinoma) among young women has increased in developed countries, even those with widespread screening programs and histology-specific cancer registration [33, 271]. In the 1950s and 1960s, approximately 95% of all invasive cervical carcinomas were classified as squamous cell carcinomas and only 5% as adenocarcinomas [175]. However, invasive cervical cancer series published since the early 1970s have found that squamous cell carcinomas account for 75-80% of the cases, while the remaining 20-25% include various types of adenocarcinomas, adenosquamous carcinomas, and other epithelial tumors [33, 271]. Between 1973 and 1996, the overall age-adjusted incidence of invasive cervical cancer in the United States decreased by 36.9%. At the same time, the age-adjusted incidence of adenocarcinoma increased by 29.1% and the proportion of adenocarcinoma relative to squamous cell carcinoma increased by 95% [245]. In contrast to squamous cell carcinoma, rates of adenocarcinoma were significantly lower among African-American women than in Caucasian women. Rates of adenocarcinoma were significantly higher in Hispanic women than among

non-Hispanics [226]. Most studies have noted increasing rates of adenocarcinoma among younger women, particularly under the age of 40 [245, 275, 301]. An international study monitoring trends in adenocarcinoma incidence from 1973 to 1991 reported increasing risk in cohorts born after 1935 in England, Scotland, Denmark, Sweden, Slovenia, and Slovakia [271]. A recent review from 13 European countries confirmed this report, and with data spanning the 1990s also showed increased adenocarcinoma incidence in Estonia, Spain, Finland, and Italy, countries previously reported to have either stable or decreasing trends [30].

Pathogenesis and Risk Factors

The cell of origin for invasive cervical adenocarcinoma is thought to be the pluripotential subcolumnar reserve cell of the columnar endocervical epithelium, and adenocarcinoma in situ is regarded as the immediate precursor to invasive endocervical adenocarcinoma. Many of the epidemiologic risk factors for the development of adenocarcinoma of the cervix are similar to those described for invasive squamous cell carcinomas [39]. Both are frequently associated with SIL, multiple sexual partners (more than 10 partners has a relative risk of 10.9 and 2.9 for adenocarcinoma and squamous cell carcinoma, respectively), and young age at first intercourse (intercourse before the age of 15 has a relative risk of 2.0 for both adenocarcinoma and squamous cell carcinoma) [140]. Tobacco smoking is associated with increased risk of squamous cell but not adenocarcinoma of the cervix [113]. Epidemiologic studies have shown a strong association between HPV and cervical adenocarcinoma, suggesting a causal relationship, as is the case for the squamous cell carcinoma. HPV 16 and 18 are the most common types of HPV found in association with both squamous cell carcinomas and adenocarcinomas of the cervix. However, HPV 18 is more commonly found in association with adenocarcinomas than with squamous cell carcinomas [11, 39, 210]. Use of oral contraceptives for more than 10 years, particularly those with a large progestational component, has been shown to be a risk factor for invasive cervical adenocarcinoma [39, 277]. Some studies comparing the risk factors for invasive adenocarcinomas with those of squamous cell carcinomas have revealed no significant differences in oral contraceptive usage between the two groups of women after controlling for HPV and sexual factors [93, 113]. It should also be noted that one study has reported a significant association between the use of hormone replacement

therapy in older women and invasive adenocarcinomas of the cervix [146].

A genetic predisposition to invasive cervical adenocarcinoma has been documented in women with Peutz–Jeghers syndrome in whom minimal deviation adenocarcinoma of the cervix occurs more frequently than in the general population [50]. It also appears that a generalized predisposition to the development of adenocarcinoma of the ovary and cervix can occur because dual primary cervical and ovarian adenocarcinomas develop in some women [174, 291]. Mucinous tumors of the ovary appear to be particularly prevalent in women with minimal deviation mucinous adenocarcinomas of the cervix [291].

Clinical Features

The most common presenting symptom is abnormal vaginal bleeding, occurring in about 75% of patients [153]. Occasionally women present with vaginal discharge or with pelvic pain. The majority of invasive cervical adenocarcinomas arise in the transformation zone, and on gross examination 50% of patients have a fungating, polypoid, or papillary mass [110]. In approximately 15% of patients, the cervix is either diffusely enlarged or nodular. In another 15%, no gross lesions are visible. Although the majority of patients with grossly inapparent tumors have early-stage tumors, some have deep invasion because the carcinoma arose deep within the endocervical canal [223]. Adenocarcinoma of the cervix is confined to the cervix (stage I) or the parametrium/vagina (stage II) in 80% of women at the time of diagnosis. The diagnostic accuracy of cytopathology in the detection of cervical adenocarcinoma varies according to the expertise of the pathologist and the sampling techniques used. In most large series the majority of patients with cervical adenocarcinomas have cytologic abnormalities [183, 195].

Microinvasive Adenocarcinoma

Definition

The current definition FIGO definition for microinvasive (stage IA) cervical cancer applies to both squamous cell carcinoma and adenocarcinoma. However it is important to emphasize that recognizing microinvasive adenocarcinoma is often problematic and less is known about behavior of microinvasive adenocarcinoma compared to microinvasive squamous cell carcinoma [195, 295]. The

irregular distribution and architecture of the normal endocervical crypts in the cervical stroma makes it difficult to differentiate between early stromal invasion and adenocarcinoma in situ [195]. In cases with admixed adenocarcinoma in situ and superficially invasive adenocarcinoma the actual depth of the invasion may be very difficult to measure (see below).

Microscopic Findings

Several growth patterns can be present in microinvasive carcinoma. Presence of a finger-like extension of epithelium with abundant pink cytoplasm into the stroma from a gland demonstrating the histologic features of adenocarcinoma in situ is often the first histologic sign of invasion [195]. More advanced areas of invasion show glands that lack the lobular architecture of crypts involved by adenocarcinoma in situ (> Fig. 6.17). These glands are often separated by stroma and may be within the zone of normal endocervical mucosa. There may or may not be a stromal response with edema, inflammation, and desmoplasia. However, in some cases of early invasive adenocarcinoma these features are not present and invasion is indicated by the gland pattern and haphazard distribution on low power examinations. Confluent glandular pattern and complex gland architecture are more

Fig. 6.17

Superficially invasive endocervical adenocarcinoma associated with adenocarcinoma in situ. A region of confluent glandular growth within extensive adenocarcinoma in situ indicates superficial stromal invasion

subtle patterns of invasion [195]. Smooth-contoured, dilated glands with complex intraglandular cribriform or papillary growth patterns also indicate invasion as well as presence of glands below the deep margin of normal endocervical glands [150]. Finally, if the distance between neoplastic glands and thick-walled blood vessels is less than the thickness of the vessel wall, invasion should be strongly suspected [281]. Most patients have coexisting adenocarcinoma in situ and some also have HSIL. After establishing invasion, the depth of invasion and horizontal extent of the invasive component should be measured. Measurements with a calibrated optic are recommended. The depth of invasion is measured from the surface (when the in situ component is not present on a section with the deepest invasion) or from overlying the in situ carcinoma. Similar to microinvasive SCC a definitive diagnosis of microinvasive adenocarcinoma requires examination of the entire lesion in a cold knife cone biopsy or hysterectomy specimen.

Clinical Behavior and Treatment

Microinvasive adenocarcinoma accounts for 12% of adenocarcinomas [195]. The average age at presentation is 39 years, approximately 7 years younger than the peak age for frankly invasive adenocarcinoma. The natural history of microinvasive cervical adenocarcinoma is not well understood since a cone biopsy is necessary to confirm the diagnosis and is often curative. There are rare documented cases of in situ adenocarcinoma progressing to invasive carcinoma after conservative treatment with cone excision [104, 132]. In a recent review of microinvasive adenocarcinomas 2 of 228 (0.8%) stage IA1 and 3 of 179 (1.6%) stage IA2 had lymph node metastasis [212]. In a literature review of 26 reports of microinvasive adenocarcinomas, totaling 436 cases of invasive adenocarcinoma defined as 5 mm or less of invasion, only 5 (2%) of 219 patients undergoing lymphadenectomy had metastases [195]. Review of 531 cases from the SEER (Surveillance, Epidemiology, and End Results) database confirmed low incidence (1.28%) of lymph node metastasis in Stage IA1 and IA2 tumors [244]. Data on lymphvascular space involvement are difficult to extract since most series do not comment on the presence or absence of this feature.

Kaspar et al. analyzed 25 cases with stage IA adenocarcinoma and found tumor volume to be a better predictor of lymph node metastasis and recurrence. None of the patients with tumor volume $<500 \text{ mm}^3$ had lymph node metastases or recurrence whereas two of two patients with tumor volume more than 500 mm³ had recurrence and one of two developed lymph node metastases [130]. Other studies confirmed this observation [54, 124]. There is also very little information on margin status at conization and residual disease in a subsequent hysterectomy specimen. In two studies, patients who underwent conization with negative margins did not have residual disease in the subsequent hysterectomy specimen. Half of the patients with positive margins had tumor in the uterus [195, 212]. The overall prognosis for microinvasive adenocarcinoma (stage IA1 and IA2) is excellent. Based on SEER data the risk for stage IA1 versus IA2 for lymph node metastases (1.45 vs. 1.73%), recurrence (1.54 vs. 1.96%), and death (0.85% vs. 1.12%) was not statistically different [244]. In the same study there was no difference in recurrence and death of disease between patients treated conservatively (with conization or simply hysterectomy) and those undergoing radical hysterectomy. However, 10% of the patients in the study received adjuvant radiotherapy or underwent a pelvic lymphadenectomy. Therefore, a conization alone for patients with stage IA1 adenocarcinoma was not recommended. In a recent report none of four patients with stage IA1 adenocarcinoma treated with conization developed recurrence after 2-13 years of follow-up [284]. All the patients had a term delivery. No residual invasive adenocarcinoma was present in three of four patients who underwent radical hysterectomy with pelvic lymph node dissection. Prospective, long-term follow-up studies for patients with microinvasive adenocarcinoma treated with conization are lacking.

Endocervical Adenocarcinoma

Cervical adenocarcinoma displays a wide variety of morphologic patterns but over 75% of the tumors display a relatively similar pattern. The WHO classification adopted the traditional approach of referring to these tumors as "mucinous carcinomas" but since they have little, if any, intracytoplasmic mucin evident on H&E and mucin stains, we prefer the designation "endocervical adenocarcinoma of usual type" [6]. True endometrioid-type endocervical adenocarcinoma is relatively uncommon, accounting for approximately 10% of cervical adenocarcinomas. The remainder of cervical adenocarcinomas comprises a diverse group that includes mucinous adenocarcinoma, of which there are three variants (endocervical type, intestinal type, and signet ring type), minimal deviation adenocarcinoma, villoglandular adenocarcinoma, clear cell carcinoma, serous carcinoma, mesonephric carcinoma, and a number of uncommon variants.

Adenocarcinoma, Usual Type

Gross Findings

Most adenocarcinomas are papillary or polypoid, whereas some are nodular and may ulcerate the cervix. Some are high in the endocervical canal and are therefore very difficult to visualize on clinical examination. Others diffusely infiltrate and enlarge the cervix resulting in a "barrel" configuration.

Microscopic Findings

This is far and away the most common histologic type of cervical adenocarcinoma and although it has a somewhat similar appearance to endometrioid carcinoma, the glands exhibit a hybrid of endocervical and endometrioid differentiation (\bigcirc *Figs. 6.18–6.21*). The cells are columnar with elongated, hyperchromatic nuclei that may show marked atypia with nuclear pleomorphism and coarse chromatin. The cells are often stratified and contain amphophilic or eosinophilic apical cytoplasm. Mitotic figures, which typically appear to be "floating" in the cytoplasm, are frequent as are apoptotic bodies. The glands may be widely spaced or densely arranged in a complex racemose pattern. A cribriform pattern is very common and papillae commonly project into gland lumens.

The usual-type adenocarcinomas of the cervix are graded on the basis of architectural features, in a manner similar to that used for endometrial adenocarcinomas.

Fig. 6.18 Endocervical adenocarcinoma, usual type. Crowded glands within desmoplastic stroma exhibit a hybrid of endometrioid and mucinous features

Well-differentiated tumors are defined as those in which <10% of the tumor volume is composed of solid sheets of cells, the remainder of the tumor being glandular; in moderately differentiated tumors, 11-50% of the tumor is composed of solid sheets of cells; and in poorly differentiated tumors, >50% of the tumor is solid.

Measurement of the depth of invasion is more difficult than for squamous cell carcinomas because of the difficulty in determining the point of origin. Measurement

Fig. 6.19

can be expressed either in millimeters or centimeters or as the percentage of involvement of the wall. Measurements with a calibrated eyepiece or microscopic fields are recommended. The presence of vascular invasion should be noted.

Immunohistochemical Findings

Distinction of endometrial endometrioid carcinomas from endocervical adenocarcinomas is important because surgical management of these tumors often differs. The vast majority of endocervical adenocarcinomas (~90%) are HPV-related and exhibit diffuse/moderate-strong p16 expression due to complex molecular mechanisms by which high-risk HPV-transforming proteins (E6, E7) interact with cell cycle regulatory proteins (p53, pRb) to generate a futile feedback loop resulting in p16 overexpression (> Fig. 6.22). Interestingly, these HPVrelated endocervical adenocarcinomas also often lack hormone receptor expression (estrogen [ER] and progesterone [PR] receptors) [171, 220, 247, 288] (> Fig. 6.23). In contrast, endometrial endometrioid carcinomas are considered etiologically unrelated to HPV. They have been shown to exhibit generally patchy p16 expression of variable intensity, with mean/median extent of expression in 30-40% of tumor cells across all FIGO grades, and only rare tumors exhibiting diffuse/strong expression [289]. This patchy pattern is distinct from the diffuse/strong

■ Fig. 6.22 Endocervical adenocarcinoma, usual type. Tumor exhibits diffuse/strong p16 expression

Fig. 6.23

Endocervical adenocarcinoma, usual type. Tumor has loss of progesterone receptor expression (estrogen receptor expression is usually also lost). Positive intervening stromal cells serve as an internal control

expression characteristic of HPV-related endocervical adenocarcinomas. In addition, most endometrial endometrioid carcinomas, particularly FIGO grade 1 and 2 tumors but also many FIGO grade 3 tumors, express hormone receptors [148, 171, 247]. Thus, a panel of immunohistochemical markers comprised of ER, PR, and p16 has been shown to be useful for distinguishing endometrial endometrioid carcinomas from endocervical adenocarcinomas [12, 170, 176, 247, 288]. Typical endometrial endometrioid carcinomas are p16 focal+/ER+/PR+,

whereas typical endocervical adenocarcinomas are p16 diffuse+/ER-/PR-, with some of the latter retaining focal/limited expression of hormone receptors. We specifically recommend the use of PR in conjunction with ER based on our published [220, 247, 288] and unpublished experiences indicating that the subset of endocervical carcinomas that retains some expression of hormone receptors most often retains ER expression to some degree (often focal/weak-moderate) but entirely loses PR expression; thus, PR is the more discriminatory marker of the two when trying to distinguish endocervical adenocarcinomas from endometrial endometrioid carcinomas.

A number of studies have suggested that using a combination of inhibin, ER, and CEA staining can distinguish between endocervical and endometrial adenocarcinomas [59, 171, 296]. However others have found that this combination of stains is influenced not only by the site of origin of the adenocarcinoma, but also by the pattern of differentiation of the tumor [128]. The state of differentiation of the tumor (mucinous vs. endometriod) had a strong impact on whether or not a tumor stained positively with either vimentin or CEA. Furthermore, in our experience with numerous consultation cases, immunostains for CEA and vimentin are often difficult to interpret due to problems in discerning the localization of staining in tumor epithelium versus intimately associated stroma (for vimentin) or apical/luminal secretions (for CEA), and not infrequently, focality of staining for both markers can be observed in tumors of both sites. For these reasons, a panel comprised of p16, ER, and PR is recommended as most useful because differential expression patterns are based on biologic differences between endocervical and endometrial adenocarcinomas. Expression of p16 is also useful for identifying metastatic endocervical adenocarcinoma in the ovary. These ovarian metastases have a propensity to simulate primary ovarian endometrioid and mucinous tumors (atypical proliferative (borderline) tumors and carcinomas). Ovarian endometrioid and mucinous tumors, with few exceptions, are characterized by generally patchy p16 expression (or lack of expression) whereas metastatic HPV-related endocervical adenocarcinomas are diffusely/strongly positive [220, 268]. In the absence of a known primary endocervical adenocarcinoma, demonstrating high-risk HPV by in situ hybridization can be used for arriving at a definitive diagnosis [220] (> Fig. 6.24). Although it should be recognized that in most laboratories in situ hybridization has a relatively low sensitivity for detecting HPV in carcinomas, it should also be noted that p16 has no utility for identifying minimal-deviation-type endocervical adenocarcinomas since these tumors are

unrelated to high-risk HPV and thus do not exhibit diffuse/strong p16 expression.

A recent study reviewed expression of CDX2 in cervical adenocarcinomas [249]. CDX2 is a member of the caudal-related homeobox gene family that is expressed during the normal development of the intestinal tract. CDX2 is highly sensitive for the identification of colorectal adenocarcinomas; however its expression has been described in other tumors showing intestinal-type differentiation. Sullivan at al. have demonstrated that nuclear CDX2 expression in cervical adenocarcinomas is not restricted to intestinal type tumors but may be seen in 30% of the more common subtypes (endocervical and endometrioid) [249]. Therefore, CDX2 has limited value in determining origin of metastatic carcinoma when colorectal, pancreaticobiliary, mucinous ovarian, and endocervical adenocarcinomas are possible primary sites.

Differential Diagnosis

Invasive adenocarcinoma must be distinguished from adenocarcinoma in situ (AIS), primary endometrial adenocarcinoma with extension into the endocervical canal, and metastatic adenocarcinoma. Features favoring a benign glandular process include lack of an infiltrative pattern, lobular arrangement of glands, superficial location and a well-demarcated margin as well as lack of a desmoplastic stromal response and cytologic atypia. It is important to note that occasionally normal cervical

glands may extend deep into the cervical wall. Absence of cytologic atypia, stromal reaction, and usually a widely scattered distribution allow exclusion of a malignant process [60]. It is important to make sure that the stromal reaction elicited by an infiltrating adenocarcinoma does not represent reaction to extravasated mucin from a ruptured benign gland. Cytologic atypia can be seen in the Arias-Stella reaction, atypical oxyphilic metaplasia, radiation changes, and rarely, viral infection. An Arias-Stella reaction involving endocervical glands is detected in 10-50% of gravid uteri [229]. Occasionally glandular changes similar to the Arias-Stella occur in nonpregnant women, usually in patients taking exogenous hormones. Whereas the distinctive cyto- and nucleomegaly raises concern for malignancy, lack of mitoses and partial gland involvement help to establish the correct diagnosis. The degenerative nature of atypia with enlarged, hyperchromatic nuclei containing smudged chromatin, cytoplasmic vacuolation, and preservation of the nuclear to cytoplasmic ratio are features of atypical oxyphilic metaplasia and radiation induced atypia [122, 156]. Distinctive cytopathic features associated with cytomegalovirus (CMV) and herpes simplex virus (HSV) infections and immunohistochemistry for detection of the specific pathogen assist in diagnosis.

One of the common benign mimics, tunnel clusters, has to be distinguished from cervical adenocarcinoma with a microcystic pattern [254]. Tambouret et al. described a small series of microcystic endocervical adenocarcinomas resembling type B tunnel clusters. In addition to architecture simulating a benign process, some of the cases had largely denuded atypical epithelium. High power examination of the lesion is recommended to look for the presence of cytologic atypia, which indicates that the lesion is microcystic endocervical adenocarcinoma. Other benign lesions that must be distinguished from invasive adenocarcinoma of the cervix are microglandular hyperplasia and hyperplastic mesonephric remnants. Microglandular hyperplasia tends to occur in young women and is frequently polypoid. Like endocervical adenocarcinoma, microglandular hyperplasia is CEA positive. In contrast to cervical adenocarcinoma, microglandular hyperplasia is composed of relatively uniform, small glands lined by a single layer of bland epithelium with few mitoses. Mesonephric remnants are tubular, retain a clustered arrangement associated with a mesonephric duct, and are usually deep in the cervical stroma. The epithelium lining the tubules is usually cuboidal and not stratified. Cytologic atypia is minimal [74].

Adenocarcinoma in situ of the cervix is distinguished from invasive cervical adenocarcinoma by the lack of

extension beyond the depth to which normal endocervical glands extend, lack of desmoplasia surrounding the glands, and lack of foci of closely packed glands. The normal endocervical glandular architecture is maintained in adenocarcinoma in situ. Morphologically, endocervical adenocarcinoma can be distinguished from endometrial adenocarcinoma extending to the cervix by the presence of squamous metaplasia and foamy histiocytes in the latter. Immunohistochemical stains (as discussed earlier) may be useful in difficult cases. Metastatic adenocarcinoma of the cervix usually occurs in the setting of a patient with a known, widely metastatic primary lesion and is histologically characterized by a lack of surface involvement and widespread lymphvascular involvement. In assessing whether a carcinoma is of primary endocervical origin or is metastatic in the cervix, the pathologist should evaluate the following morphologic features: (1) neoplastic growth pattern, (2) coexistent in situ changes, (3) cell type, and (4) immunohistochemical characteristics. Transition between in situ and invasive carcinoma provides the strongest evidence for a primary origin and is found in approximately 50% of primary cervical adenocarcinomas.

Risk Factors

Major prognostic indicators for cervical adenocarcinoma include tumor size, depth of invasion, involvement of lymphvascular spaces, parametrial involvement, stage, age, and presence or absence of lymph node metastases [16, 26, 68]. Poor prognostic features include size >3 cm, uterine enlargement and high histologic grade. Women with poorly differentiated stage I tumors have a 5-year survival of 41–62% compared to 80–90% for those with well-differentiated adenocarcinomas [68]. Young age at presentation has been associated with a good prognosis in several series [16, 238]. Infection with HPV 18 has been associated with poor survival [191].

Clinical Behavior and Treatment

Adenocarcinoma of the cervix spreads in a fashion similar to squamous cell carcinoma and, in general, both squamous and adenocarcinomas are treated similarly. The most commonly used therapeutic modalities for stage I and II adenocarcinoma are radiation alone, radiation with concurrent chemotherapy, radiation followed by simple hysterectomy, or radical surgery [208]. Only a few studies have directly compared the therapeutic results achieved with invasive squamous cell and adenocarcinomas over the same time period and from the same institution, and these studies have produced conflicting data. Some studies have found that the overall 5-year survival rates are lower for adenocarcinoma (48-65%) than for squamous cell carcinoma patients (68%) [26, 68]. In a study of 1,538 stage IB squamous cell carcinomas of the cervix and 229 adenocarcinomas initially treated with radiation therapy, Eifel et al. observed a worse outcome in women with adenocarcinoma [68]. A large retrospective analysis of 3,678 cases of cervical cancer from Taiwan found that the difference in survival between adenocarcinomas and squamous cell carcinomas appeared to be predominantly the result of a poorer outcome in early-stage lesions [40]. In data from the United States, reported survival is lower for adenocarcinoma versus squamous cell carcinoma for stage II disease but not for stage I or stage III or IV disease [238, 245]. Other comparison studies, as well as several population-based studies, have failed to confirm that prognosis, and survival are affected by histologic type [13, 114, 153]. Therefore, the prognosis of cervical adenocarcinoma relative to squamous carcinoma remains a controversial issue.

Mucinous Adenocarcinoma

Endocervical-Type Mucinous Carcinoma

Endocervical-type adenocarcinomas are composed of cells that have basal nuclei and abundant pale granular cytoplasm, which stains positively with mucicarmine stains. The cells resemble those in the normal endocervical glands but nuclear atypia is significant and mitotic figures are present. The majority of the endocervical-type adenocarcinomas are well-to-moderately differentiated, and the glandular elements are arranged in a pattern simulating the cleft-tunnel configuration of the normal endocervical mucosa (**)** Fig. 6.25). In less-differentiated tumors, the cells contain less cytoplasm but usually still form recognizable glandular structures. Cells are typically stratified, and there may be considerable nuclear atypia with variation in nuclear size, coarsely clumped chromatin, and prominent nucleoli. Mitoses are usually numerous. Large amounts of mucin may be found in the stroma, forming mucin lakes or pools.

Intestinal-Type Mucinous Carcinoma

The intestinal-type mucinous carcinoma is composed of cells similar to those present in adenocarcinomas of the

■ Fig. 6.25 Endocervical adenocarcinoma, mucinous type. Invasive glands have prominent apical mucinous cytoplasm

large intestine. These tumors frequently contain goblet cells and more rarely argentaffin cells and Paneth cells. In the intestinal type, the tumor cells tend to be pseudostratified, and contain only small amounts of intracellular mucin. They can either form glands with papillae or infiltrate throughout the stroma in a pattern similar to that of colonic adenocarcinoma.

Signet-Ring Cell-Type Mucinous Carcinoma

Signet-ring cell carcinomas rarely occur in a pure form and are usually admixed with intestinal or endocervical adenocarcinomas.

Minimal Deviation Adenocarcinoma

Minimal deviation adenocarcinoma is an extremely welldifferentiated variant of cervical adenocarcinoma in which most of the cells lack the cytologic features of malignancy. These tumors were originally referred to as adenoma malignum. Because of their close cytologic resemblance to normal endocervical glands, in 1975 Silverberg and Hurt introduced the term "minimal deviation adenocarcinoma" (MDA) for these lesions [241]. Although all the tumors in the original description were extremely welldifferentiated mucin-producing adenocarcinomas, MDA has been expanded to include endometrioid and clear cell variants [257, 293].

Minimal deviation adenocarcinomas are uncommon tumors and account for only 1-3% of all cervical adenocarcinomas [102, 127]. In a study of 389 primary adenocarcinomas of the cervix on file at the Armed Forces Institute of Pathology, only 1.3 % of cases represented MDA [127]. Patients with MDA range in age from 25 to 72 years (average 42 years). When sensitive PCR techniques are utilized, MDA are usually found to be negative for HPV [210]. MDA is more likely to either precede or develop coincidentally with an ovarian carcinoma than other types of cervical adenocarcinomas. The ovarian neoplasms with which MDA is most likely to be associated include mucinous adenocarcinomas and sex cord tumors with annular tubules. Both MDA of the cervix and ovarian sex cord tumors with annular tubules have been strongly associated with Peutz-Jeghers syndrome [294]. In one series, 4 of 27 women with Peutz-Jeghers syndrome developed MDA [294]. Therefore, close surveillance of women with Peutz-Jeghers syndrome is recommended, including careful endocervical cytologic examination and periodic endocervical curettage.

The characteristic microscopic features of MDA are the presence of cytologically low-grade but architecturally atypical glands that vary in size, shape, and location (\bigcirc *Figs.* 6.26–6.28). In the mucin-producing forms, the glands are lined by a single layer of tall columnar epithelium that usually has minimal, if any, nuclear atypia but careful scrutiny will almost always disclose cells with clearcut atypia. The nuclei are bland, may have conspicuous nucleoli, and are located at the base of the epithelium (\bigcirc *Figs.* 6.29–6.30). In the endometrioid type, the cells lining the glands resemble either normal proliferative or hyperplastic endometrium. Although the glands may exhibit a branching arrangement similar to that of the normal endocervical glands, characteristically glands with bizarre angular outpouchings, which vary greatly in size, are present [86]. Desmoplasia is frequently present surrounding the angular outpouchings of MDA or in the deep portion of the tumor. Large areas of invasive tumor may be devoid of any stromal reaction. In such areas, the presence of glands adjacent to thick-walled blood vessels is a helpful finding in determining that stromal invasion is present. The most reliable criterion to assess the malignant

Fig. 6.27

Minimal deviation adenocarcinoma. Smaller invasive welldifferentiated mucinous glands within desmoplastic stroma are present adjacent to a larger hyperplastic gland

Fig. 6.26

Minimal deviation adenocarcinoma. Highly differentiated mucinous glands in fibrous stroma are present along with irregular infiltrative glands in deeper edematous stroma

Fig. 6.28

Minimal deviation adenocarcinoma. Smaller invasive welldifferentiated mucinous glands within desmoplastic stroma are present adjacent to a larger hyperplastic gland

Fig. 6.29

Minimal deviation adenocarcinoma. Very welldifferentiated mucinous gland has vesicular nuclei with conspicuous nucleoli, the characteristic cytologic features of this adenocarcinoma

Fig. 6.30

Minimal deviation adenocarcinoma. Invasive glands have atypical vesicular nuclei with nucleoli whereas hyperplastic gland has small uniformly hyperchromatic basally situated nuclei

nature of MDA is the haphazard arrangement of glands that extend beyond the level of normal endocervical glands and the presence of occasional mitoses in glandular cells. Mitoses are quite uncommon in the normal, nonneoplastic, endocervical epithelium, and the presence of mitoses should alert the pathologist to the possible presence of MDA. However, occasional mitotic figures in otherwise normal-appearing glands should not be taken as sufficient for a diagnosis of MDA. Minimal deviation

adenocarcinoma often involves more than two thirds of the thickness of the cervical stroma and should be regarded as invasive because the normal endocervical crypts and tunnels do not extend beyond 7 mm [86, 127]. Because the depth of penetration of the glands is an essential histologic feature of MDA, in most cases, the diagnosis cannot be made on a superficial cervical biopsy, but instead requires either a cone biopsy or hysterectomy specimen. Immunohistochemical studies using CEA have found highly variable staining of MDA with only focal areas of positivity, and CA 125 staining is significantly reduced compared to normal endocervical glands [86, 259]. Immunohistochemical staining for estrogen and progesterone receptors is uniformly negative in MDA, and this criterion can be used to help differentiate these tumors from variants of normal endocervical glands [259]. Stains for p16 are negative or only focally positive since MDA is not associated with high-risk HPV infection and Ki-67 proliferation index is often low. Immunoreactivity for a monoclonal antibody to gastric gland mucous cell mucin (HIK1083) has been reported; however it is also positive in gastric metaplasia associated with lobular endocervical glandular hyperplasia [173]. Some authors believe that MDA can be derived from lobular endocervical glandular hyperplasia and morphologically usual-type AIS showing gastric phenotype [173].

The differential diagnosis of MDA includes several conditions in which nonneoplastic glands extend beyond 7 mm from the surface. These conditions include endocervical tunnel clusters, deeply situated nabothian cysts, endocervicosis of the cervical wall, and mesonephric hyperplasia [290]. The glands of endocervical tunnel clusters, mesonephric hyperplasia, and deep nabothian cysts are usually much more uniform in size than are the glands of MDA and lack the bizarre branching and irregular outpouchings that are characteristic of the glands of MDA. The benign processes also lack a desmoplastic response.

Villoglandular Adenocarcinoma

Villoglandular adenocarcinoma is a well-differentiated form of cervical adenocarcinoma that occurs predominantly in young women and has an excellent prognosis [121, 292]. The characteristic features of this tumor are a surface component that is composed of papillae lined by epithelium that has only mild cytologic atypia (\bigcirc *Fig.* 6.31). The epithelial cells lining the papillae can display endocervical, endometrioid, or intestinal features (\bigcirc *Figs.* 6.32–6.34). Because of the large number of surface

Fig. 6.31

Endocervical adenocarcinoma, villoglandular type. Tumor is composed of papillary structures with central fibrous cores

Fig. 6.33 Endocervical adenocarcinoma, villoglandular type. Elongated villous papillary structures have an endometrioid appearance at lower magnification

Fig. 6.32
Endocervical adenocarcinoma, villoglandular type.
Epithelium lining papillae exhibits mucinous differentiation

■ Fig. 6.34 Endocervical adenocarcinoma, villoglandular type. Villous structures have thin fibrovascular cores and are lined by epithelium with a hybrid of endometrioid and mucinous features ("usual type" differentiation)

papillae, these tumors frequently form an exophytic, friable tumor mass. Most of the papillae have central cores containing spindle-shaped stromal cells resembling those of the normal cervical stroma and a variable number of inflammatory cells. The papillae can be either long and thin or thick and short. Small papillary tufts composed entirely of epithelial cells of the type characteristic of serous carcinomas of the ovary are absent. Beneath the papillary surface, the infiltrating portion of the tumor is

composed of irregular branching glands that are typically surrounded by only a minimal desmoplastic response.

The differential diagnosis of these tumors includes papillary endocervicitis, papillary adenofibromas of the cervix, and müllerian papillomas. All three of these lesions lack the degree of cellular atypia that is present in villoglandular adenocarcinomas. The müllerian papilloma is a lesion of children, whereas the age of patients with villoglandular adenocarcinomas ranges from 27 to 54 years, with a mean of 37 in one series [121]. In contrast to villoglandular adenocarcinoma, adenofibroma of the cervix and müllerian papilloma have a more prominent stromal component. Villoglandular adenocarcinoma must also be distinguished from serous papillary carcinomas of the cervix. Serous papillary carcinomas have more irregular papillae that are lined by cells with marked nuclear atypia and high mitotic counts, which frequently form cellular tufts.

Villoglandular adenocarcinomas have been associated with the use of oral contraceptives and are frequently associated with high-risk types of HPV [117]. In the majority of cases, the tumor is superficially invasive, although deep invasion with extension into the uterine corpus may occur. In most of the cases published to date, the clinical outcome of patients with villoglandular adenocarcinomas has been excellent. In the two largest series, all patients, including those who were treated by simple excisional biopsy or cone biopsy, were alive and well with no evidence of recurrent disease after 7-77 months of follow-up [121]. There are also reports of villoglandular adenocarcinomas treated successfully with conization in young patients who wished to preserve fertility [143]. Conservative treatment should be considered only if the tumor is superficial, does not involve lymphyascular spaces, and there is no residual disease in the cone margins. In a series of seven cases from Japan the presence of lymphvascular space involvement was associated with lymph node metastases in two cases and resulted in death in one patient [125]. Rarely, villoglandular carcinomas may be mixed with other types of carcinomas. The authors are aware of two such cases in which lymph node metastasis has occurred (unpublished observations).

Endometrioid Adenocarcinoma

Endometrioid adenocarcinomas of the cervix are defined as tumors composed of cells that resemble those of primary adenocarcinomas of the uterine corpus. In different series endometrioid carcinomas accounted for 7–50% of endocervical adenocarcinomas [230, 296]. This wide range is due to the fact that at times it can be difficult to differentiate endometrioid adenocarcinoma from the more common, usual type of cervical adenocarcinoma as the latter frequently has endometrioid features. Many tumors classified as endometrioid adenocarcinomas may actually represent poorly differentiated mucinous tumors that have lost their capacity to produce mucin [290].

Fig. 6.35 Endocervical adenocarcinoma, endometrioid type. Crowded glands have columnar cells with elongated nuclei and little apical cytoplasm, analogous to primary endometrial endometrioid carcinoma

The cells of endometrioid adenocarcinomas tend to be stratified and have oval nuclei that are arranged with their long axis perpendicular to the basement membrane of the gland (**)** Fig. 6.35). The cells do not contain mucin and have less cytoplasm than the cells of the usual type of endocervical adenocarcinomas. Endometrioid adenocarcinomas frequently contain small foci of squamous epithelium. It can also be difficult to differentiate between an endometrioid carcinoma primary in the cervix and a primary endometrial adenocarcinoma extending to cervix. Primary uterine corpus tumors are usually bulky tumors that have invaded the myometrium by the time they extend to the cervix and therefore cause uterine enlargement. In contrast, primary cervical adenocarcinomas often cause cervical enlargement in the absence of uterine enlargement. Even with large, destructive primary cervical adenocarcinomas, differentiation from primary endometrial adenocarcinomas can be made if normal endometrium is present either on a fractional dilation and curettage or on an endometrial biopsy. Contamination, however, of the endometrial sample can occur while passing the curette or biopsy instrument through the involved endocervical canal. In these cases, a careful search through multiple sections may reveal atypical endometrial hyperplasia in primary endometrial tumors and either AIS, SIL, or foci with features of a typical endocervical carcinoma in primary endocervical tumors. Immunohistochemistry can also assist (see above).

Clear Cell Adenocarcinoma

Clear cell carcinomas account for approximately 4% of adenocarcinomas of the cervix. Most of the cases of clear cell adenocarcinoma diagnosed during the 1970s, 1980s, and 1990s have been linked to prenatal exposure to diethylstilbestrol (DES) [218]. Cases diagnosed more recently have developed in the absence of exposure to DES [169]. Tumors that develop in the absence of DES exposure occur more commonly in postmenopausal women, whereas those in women exposed to DES occur in younger women [97]. The sporadically developing tumors arise in either the exocervix or endocervix, whereas the tumors developing in DES-exposed women develop predominately on the exocervix. The microscopic features of clear cell carcinoma, developing in women with or without DES exposure, are the same. There are three basic microscopic patterns: solid, tubulocystic, and papillary. The cells comprising the tumor have abundant clear cytoplasm due to the accumulation of glycogen or granular eosinophilic cytoplasm, with prominent nuclei that can be quite hyperchromatic and pleomorphic and project into the lumen of the cysts and tubules to form "hobnail cells" (> Fig. 6.36). The papillae often have hyalinized cores.

The differential diagnosis of clear cell carcinomas includes other types of cervical adenocarcinomas as well as benign processes such as the Arias-Stella reaction and microglandular and mesonephric remnant hyperplasia. Distinguishing between these entities can be difficult, especially on small biopsy samples. Microglandular hyperplasia usually lacks the degree of nuclear atypica of clear cell carcinoma and it usually contains mucin.

■ Fig. 6.36 Clear cell carcinoma of the cervix. Glands are lined by markedly atypical cells with clear cytoplasm

Microglandular hyperplasia develops in women of reproductive age, whereas most clear cell carcinomas currently occur in older women. The Arias-Stella reaction can be differentiated on the basis of lack of mitotic activity, lack of the classic patterns of clear cell carcinoma, and the clinical history of pregnancy. Rarely on low-power magnification, mesonephric remnant hyperplasia can mimic the tubulocystic pattern of clear cell carcinomas; however, examination at high power does not reveal clear or hobnail cells.

The prognosis of surgically treated patients with stage IB–IIB clear cell carcinomas without exposure to DES is similar to patients with non-clear cell adenocarcinomas [216]. The overall survival of DES exposed women with clear cell adenocarcinoma has been higher than non-DES exposed women likely due to early detection [126].

Serous Adenocarcinoma

Serous adenocarcinoma of the cervix is an uncommon form of cervical adenocarcinoma that histologically is identical to serous adenocarcinomas arising in the endometrium. The diagnosis of primary serous cervical adenocarcinoma should be made only if spread from other gynecologic sites has been excluded. These tumors are composed of papillary tufts and complex papillae lined by cells with pleomorphic, high-grade nuclei [302]. In the largest reported series this histological variant has been associated with a poor prognosis when diagnosed at an advanced stage, but the outcome for patients with stage I tumors is similar to that of patients with cervical adenocarcinomas of the usual type [302].

Mesonephric Carcinoma

Mesonephric duct remnants are detected in up to 20% of cervices removed during routine hysterectomy, and adenocarcinomas can rarely develop in these remnants [108]. Mesonephric carcinomas are very rare, and in the past were confused with clear cell carcinomas of the cervix. Patients range in age from 34 to 72 years and most present with abnormal vaginal bleeding [46, 74, 240]. In most cases, gross inspection of the cervix reveals a mass that can be exophytic or endophytic. In contrast to the superficial location of cervical clear cell adenocarcinomas, true mesonephric adenocarcinomas develop deep in the lateral wall of the cervix, in a site corresponding to the location of mesonephric duct remnants. Therefore, they often extend into the outer third of the cervical wall. The tumors can be either pure adenocarcinomas or adenocarcinomas that are mixed with a spindle cell component. In one series, 50% of the mesonephric carcinomas contained a spindle cell component [46]. The most common appearance has been termed the ductal pattern and consists of tubular glands that vary in size and are lined by one to several layers of columnar cells (\bigcirc *Figs. 6.37* and \bigcirc *6.38*). Some of the gland lumens contain PAS-positive, diastase-resistant eosinophilic secretions. Other patterns that have been described include a retiform pattern, a tubular pattern, and a sex cord pattern [46]. Mesonephric hyperplasia,

Fig. 6.37

Mesonephric carcinoma. Tubular glands with eosinophilic secretions invade deep cervical stroma in a haphazard fashion

Fig. 6.38

Mesonephric carcinoma. Densely packed small tubular glands are lined by atypical cells and contain eosinophilic secretions

often with atypical architectural and nuclear features, is often found at the periphery of the tumor or admixed with it. The immunohistochemical profile of mesonephric carcinomas is similar to that of normal mesonephric duct remnants. Epithelial markers (including CK7 and EMA) are positive and vimentin expression is present in 70% of cases. Calretinin is found in 88%, and androgen receptor in 33% cases, whereas monoclonal CEA, estrogen receptor protein, progesterone receptor protein, and CK20 are absent [240].

Distinguishing mesonephric carcinoma from florid mesonephric hyperplasia can be difficult because the majority of carcinomas develop in the setting of diffuse mesonephric hyperplasia [74]. In contrast to mesonephric hyperplasia, the carcinoma does not have a lobular architecture and the nuclei appear cytologically malignant. Mesonephric carcinomas with a prominent spindle cell component have to be distinguished from cervical carcinosarcoma. The carcinomatous component in the latter entity is often squamous or basaloid in contrast to tubules and glands present in mesonephric carcinomas with a prominent spindle cell component. Since there are morphologic similarities between mesonephric carcinoma and clear cell carcinoma, a diagnosis of mesonephric carcinoma should only be made if the tumor is located deep in the wall of the cervix, the endocervical mucosa is uninvolved, and there is no evidence that the patient was exposed to DES.

Stage I mesonephric carcinomas seem to have a more indolent behavior than other types of cervical adenocarcinoma [46]. However, several high-stage tumors have had an aggressive course and several tumors with a sarcomatoid component have metastasized [240].

Other Epithelial Tumors

Adenosquamous Carcinoma

Adenosquamous carcinomas are defined as tumors that contain an admixture of histologically malignant squamous and glandular cells. Adenosquamous carcinomas account for between 3.6% and 25% of all cervical cancers [69, 238, 269, 287]. They occur in both young and old women and can occur during pregnancy. The squamous component generally includes areas that are well differentiated and contain either keratin "pearls" or sheets of cells with individual cell keratinization. To make the diagnosis of adenosquamous carcinoma, there must be sufficient differentiation of the adenocarcinomatous component so that glands are histologically recognizable (**>** *Fig. 6.39*).

Although the well-differentiated forms are usually easily recognized, when the adenocarcinomatous component is less well differentiated and is present in relatively small amounts, it can easily be overlooked. The term adenosquamous carcinoma is not used for adenocarcinomas that have bland (nonmalignant)-appearing squamous differentiation. Instead, such tumors are classified as endometrioid adenocarcinomas of the cervix with squamous metaplasia. Lesions with mixed patterns of epithelial differentiation are thought to arise from the pluripotential subcolumnar reserve cells of the endocervical mucous epithelium and represent biphasic differentiation. In a recent study, squamous and glandular components were shown to be monoclonal in origin and had identical types of HPV supporting origin from a common precursor cell [264]. The prevalence of adenosquamous carcinomas may be increased in young women, and these tumors metastasize to pelvic lymph nodes twice as frequently as squamous cell carcinomas or adenocarcinomas [223, 269]. Despite the increase in pelvic lymph node metastases, the prognosis in patients with adenosquamous carcinomas has not been significantly worse than that of patients with squamous cell carcinomas in some studies, although other series have reported a poorer prognosis associated with these tumors [69, 238, 269, 287].

Glassy Cell Carcinoma

Glassy cell carcinoma is a poorly differentiated adenosquamous carcinoma with distinct microscopic

Fig. 6.40

Glassy cell carcinoma. This poorly differentiated variant of adenosquamous carcinoma is characterized by notably atypical cells with abundant eosinophilic to amphophilic, "ground glass" cytoplasm, distinct cell membranes, and a prominent inflammatory infiltrate

features. It comprises <1% of cervical cancers. On gross examination glassy cell carcinomas are generally large and produce a barrel-shaped cervix (> Fig. 6.40). The distinctive microscopic features include: (1) uniform large polygonal cells with finely granular ground glass-type cytoplasm (hence the name glassy cell), (2) distinct cell membranes, and (3) prominent nucleoli (Fig. 6.43). The glassy cell appearance is due to abundant filaments and dilated rough endocytoplasmic reticulum [266]. In addition, the cells lack intercellular bridges, dyskeratosis, and intracellular glycogen. Mitotic figures are abundant. Lymphoplasmacytic and eosinophilic inflammatory cells characteristically heavily infiltrate the stroma. Occasionally, areas of keratin pearl and abortive lumen formation are seen together with signet-ring cells and intracellular mucin. Glassy cell carcinoma has to be distinguished from adenosquamous carcinoma treated with neoadjuvant chemoradiation therapy.

Glassy cell carcinoma has an extremely aggressive clinical course, with a poor response to radiation and surgery [197, 255]. More recently patients treated with neoadjuvant chemotherapy have been reported to have longer survival [189].

Clear Cell Adenosquamous Carcinoma

Adenosquamous carcinoma in which at least 70% of tumor cells have vacuolated, clear cytoplasm containing

large amounts of glycogen has been referred to as clear cell adenosquamous carcinoma [80]. The cohesive sheets of tumor cells are frequently subdivided by connective tissue septa, which can have a prominent lymphocytic infiltrate that produces a lobulated appearance. The tumors demonstrate focal gland formation and stain positively with a mucin stain such as mucicarmine. In some clear cell adenosquamous carcinomas there are spindle-shaped cells suggesting squamous differentiation. Clear cell adenosquamous carcinomas need to be distinguished from clear cell carcinomas and glassy cell carcinoma of the cervix. Unlike clear cell carcinomas, clear cell adenosquamous carcinomas lack papillary or tubulocystic areas and hobnail cells. Clear cell adenosquamous carcinoma is associated with HPV 18 and has an aggressive clinical course. In one series, 7 of the 11 patients died of their disease, including 3 of 5 patients with stage IB disease [80].

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma (MEC) is not recognized as separate entity in the recent WHO classification of cervical tumors but is included within the category of adenosquamous carcinoma. Rearrangements of CRTC1 and MAML2 genes (translocation involving these two genes is common in minor salivary gland MEC) have been recently described [155]. None of the analyzed cervical adenosquamous carcinomas harbored rearrangements of either locus suggesting that cervical MEC is distinct from conventional cervical adenosquamous carcinoma. Morphologic criteria for diagnosing cervical MEC are identical to those of salivary gland MEC and include the presence of three cell types (epidermoid, intermediate, and mucin-producing) and lack of recognizable glands [64, 258]. In mucoepidermoid carcinoma, the squamous component is usually large cell nonkeratinizing or focally keratinizing, and the mucin-producing cells are frequently localized in the center of nests of squamous cell carcinoma. The mucinous component includes goblet or signet-ring-type cells that contain mucinocarminophilic, periodic acid-Schiff (PAS)-positive, diastase-resistant mucopolysaccharides. The mucin from these cells is extruded into the intercellular spaces or fibrous stroma, where it may collect in small or large lakes.

In some studies, MEC is more common in younger patients and has been associated with an increased risk of lymph node metastases [224, 258]. This association has led some authors to propose that MEC has a distinctive clinical presentation and contributes to a subset of highly aggressive cervical cancers occurring in young women. However, most studies have failed to detect a significant clinical difference between patients with MEC and those with pure squamous cell carcinomas of the cervix [224, 269].

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma of the cervix is a relatively uncommon tumor accounting for <1% of all cervical adenocarcinomas. The tumor is most often seen in patients between the sixth and seventh decades (mean age of 71 years in the largest series) and is more common in blacks than whites [91].

Clinically, these tumors generally present as hard palpable masses that can be ulcerated or friable. The histologic features are similar to those seen in salivary gland adenoid cystic carcinomas. The tumor is characterized by nests of small basaloid cells of varying size with high nuclear-to-cytoplasmic ratios that have a cribriform appearance due to cylindrical hyaline bodies or small acini or cysts [91, 188]. In cross section, the hyaline cylinders appear round or ovoid, giving the neoplasm a sievelike appearance (\bigcirc *Fig.* 6.41). These tumors frequently display peripheral palisading of the cells. The nuclei of the cells are small, only mildly pleomorphic, and there are occasional mitotic figures. Focal squamous differentiation and necrosis may be present. Lymphvascular invasion is common. At the electron microscopic level, the hyaline

 Fig. 6.41
Adenoid cystic carcinoma. Glands demonstrate focal cribriform growth and contain central eosinophilic material

material is partly composed of coalesced masses of basal lamina produced by the epithelial tumor cells and partly of fine precollagen and collagen fibers of fibroblastic origin. This material stains positively on immunohistochemistry for laminin and type IV collagen [91]. Unlike adenoid cystic carcinomas of other sites, cervical adenoid cystic carcinomas contain few myoepithelial cells as detected by electron microscopy or S-100 and actin immunohistochemical stains. The basaloid cells stain positively on immunohistochemistry with MNF 116 and CAM 5.2 (low molecular weight cytokeratin) [91]. A predominance of solid foci is seen in up to 20% of cases (so-called solid variant of adenoid cystic carcinoma) [5].

Integration of high-risk HPV DNA, including 16, has been implicated in the pathogenesis of adenoid cystic carcinoma [204]. Grayson has proposed the "reserve cell origin" for the tumor claiming that adenoid cystic carcinoma and the basaloid cystic carcinoma of the cervix derive from a common progenitor cell [91].

Adenoid cystic carcinoma behaves aggressively with frequent local recurrences or metastatic spread. In a review of 43 cases, overall survival for patients with stage I disease was 56% at 3–5 years [213]. While some studies have reported a higher survival rate, it appears to be considerably lower than other types of stage I cervical cancer. Adenoid cystic carcinoma of the cervix should be differentiated from adenoid basal carcinoma of the cervix.

Adenoid Basal Carcinoma

Adenoid basal carcinoma shares histologic features with adenoid cystic carcinoma and the two entities are often confused. Adenoid basal carcinomas are uncommon neoplasms that account for less than 1% of cervical adenocarcinomas and usually are found in postmenopausal, especially black, women [29, 73]. The mean age of patients with adenoid basal carcinoma is approximately 64 years.

Patients with adenoid basal carcinoma are usually asymptomatic without grossly detectable masses. Adenoid basal carcinomas are usually detected as unexpected findings in patients undergoing hysterectomy or cone biopsy for a coexistent SIL or another reason. Tumors are composed of small, uniform basaloid cells resembling basal cell carcinomas of the skin. The cells are arranged in small nests and cords with a rounded or lobulated appearance (\diamond *Figs. 6.42* and \diamond *6.43*). At the periphery of the nests palisading of the nuclei is seen, and some of the nests have central cystic spaces that can be filled with necrotic debris. In the center of the nests there also can be squamous or glandular differentiation. Adenoid basal carcinoma shares

Fig. 6.42

Adenoid basal carcinoma. Nests and islands of carcinoma deep in cervical stroma exhibit basaloid features with central glandular differentiation

Fig. 6.43 Adenoid basal carcinoma. Island of carcinoma demonstrates both basaloid and central glandular differentiation; nuclei are hyperchromatic and several mitotic figures are evident

some histologic features with adenoid cystic carcinoma and the two entities are often confused. Adenoid basal carcinomas can usually be distinguished from adenoid cystic carcinomas by the lack of the characteristic intraluminal hyaline material frequently present in adenoid cystic carcinomas; the presence of smaller, less pleomorphic nuclei; and less mitotic activity than is characteristic of adenoid cystic carcinomas [29]. Both adenoid basal and adenoid cystic carcinomas are frequently associated with SIL. Therefore, these features should not be used to distinguish between the two types of tumors. It should be noted that adenoid basal carcinomas can be found in association with adenoid cystic carcinomas, adenosquamous cell carcinomas, and squamous cell carcinomas of the cervix and are associated with high-risk types of HPV [72, 204].

Adenoid basal carcinomas of the type reported in the older literature (which is dominated by tumors having features of "adenoid basal epithelioma" – see below) almost uniformly pursue a benign clinical course. Although tumors can penetrate into the wall of the cervix and almost half the reported cases are classified as stage IB, tumors with typical histologic features of adenoid basal carcinoma do not metastasize or show any evidence of aggressive clinical behavior. There are rare reported cases that acted aggressively. Aggressive tumors typically have irregularly shaped nests of basaloid cells that infiltrate into the stroma and elicit a stromal reaction analogous to morpheaform basal cell carcinoma of the skin [72, 91].

Recently, in view of overwhelmingly benign behavior of tumors traditionally referred to as adenoid basal carcinomas, it has been proposed that adenoid basal tumors be divided into benign and malignant types based on morphologic features. The term "adenoid basal epithelioma" has been suggested for the low-grade variety; these tumors resemble basal cell carcinoma of the skin with squamous differentiation [29] (\bigcirc *Figs. 6.44* and \bigcirc *6.45*). The highgrade variety, which is often associated with adenoid basal epithelioma, has an infiltrative component with architectural and cytologic features of carcinoma and is classified as "adenoid basal carcinoma." Additional diagnostic terms can be applied to describe any other accompanying specific components of carcinoma, which can include basaloid, squamous, and adenoid cystic carcinoma components [29, 204].

Neuroendocrine Tumors

Neuroendocrine tumors of the cervix are relatively rare. The terminology that has been used to describe these tumors has varied over the last 25 years resulting in difficulties in interpreting clinicopathologic studies. Because the morphologic features of cervical neuroendocrine tumors are similar to those in the lung, the current WHO classification for cervical tumors is the same as the one used for the lung. The four categories of neuroendocrine tumors of the cervix include: (1) typical carcinoid tumor, (2) atypical carcinoid tumor, (3) large cell neuroendocrine carcinoma, and (4) small cell carcinoma.

The exact cellular origin of neuroendocrine tumors of the cervix is unknown. Small numbers of argyrophil cells, a potential precursor for neuroendocrine tumors, are present in the exocervical epithelium of \sim 40% of women and in the endocervical epithelium in about 20% of women [75]. However argyrophil cells are also detected in about 60% of minimal deviation adenocarcinomas of the cervix

Fig. 6.44

Adenoid basal epithelioma. Small nests of bland tumor with basaloid, squamous, and focal central glandular differentiation are situated within cervical stroma

Fig. 6.45

Adenoid basal epithelioma associated with invasive squamous cell carcinoma. Larger islands of squamous cell carcinoma invade cervical stroma, with smaller adjacent nests of adenoid basal epithelioma and in 14% of other types of cervical adenocarcinomas or adenosquamous carcinomas [67].

Typical and Atypical Carcinoid Tumor

Tumors that have been categorized as well-differentiated carcinoid tumors of the cervix were originally described by Albores-Saavedra et al., and were classified as carcinoid tumors because they contained neuroendocrine granules and were histologically similar to intestinal carcinoid tumors [4]. Microscopically these well-differentiated tumors grow in trabecular, nodular, or cord-like patterns. Rosette-like structures are common, but follicles with eosinophilic material are uncommon. The neoplastic cells have round to oval spindle-shaped nuclei and finely granular cytoplasm. Mitoses are rare. Atypical carcinoids share the same architectural patterns of growth as typical carcinoids, but are much more cellular than typical carcinoids and have increased mitotic activity (5-10 mitoses/10 high-power fields), moderate cytologic atypia, and focal areas of necrosis (> Table 6.9) [3]. These tumors stain positively for synaptophysin, chromogranin A, and neuron-specific enolase. Neurosecretory granules can be identified in these tumors by electron microscopy.

Typical and atypical carcinoid tumors are uncommon [282]. Some of the tumors that have been previously described as well-differentiated cervical carcinoid tumors appear to be adenocarcinomas of the cervix that focally resemble carcinoid tumors of the intestinal tract and have neuroendocrine differentiation. It should be noted that neurosecretory granules can be identified in many carcinomas of the cervix if a diligent search is made. Although early reports suggested that these tumors had a relatively good prognosis, more recent reports demonstrate that these tumors can act in a malignant fashion with local and distant metastasis. To date, none of the published cases has been associated with the carcinoid syndrome.

Large Cell Neuroendocrine Carcinoma

Large cell neuroendocrine carcinomas are poorly differentiated tumors that typically grow in organoid, trabecular, or cord-like patterns, although some cases only grow in sheets (\triangleright *Fig. 6.46*). Peripheral palisading of the cells and

Fig. 6.46

Neuroendocrine carcinoma. Solid islands of carcinoma exhibit some cords and palisading typical of neuroendocrine differentiation; nuclei are atypical and numerous mitotic figures are evident

Table 6.9

Histologic features used for distinguishing neuroendocrine tumors of the cervix

Tumor	Patterns	Mitoses	Nuclear atypia	Neurosecretory granules ^a	Necrosis
Typical carcinoid tumor	Trabecular, insular, sheetlike	Rare	No	Yes	No
Atypical carcinoid tumor	Trabecular, insular, sheetlike	5–10/10 HPF	Moderate	Yes	Focal
Large cell neuroendocrine carcinoma	Sheets, organoid trabecular, cordlike	10/10 HPF	Marked	Yes	Moderate
Small cell carcinoma	Sheets, nests, trabecular, cordlike	10/10 HPF	Moderate	Sometimes	Extensive

^aBy electron microscopy or immunohistochemistry.

HPF, high-power fields.

Adapted from [3, 87]

geographic patterns of necrosis are frequently present. The cells of large cell neuroendocrine carcinomas are large with abundant eosinophilic cytoplasm, and small eosinophilic cytoplasmic granules can sometimes be identified on hematoxylin- and eosin-stained sections. The cells have vesicular high-grade nuclei with prominent nucleoli. Mitotic figures are numerous (>10 mitoses/10 high-power fields). The tumor cells usually stain for neuron-specific enolase, chromogranin A, and synaptophysin. Cytokeratin stains are often positive and CEA is expressed in 70% of cases [87]. Large cell neuroendocrine carcinomas are often associated with glandular lesions. In the series of Gilks et al., 66% of large cell neuroendocrine carcinomas had a coexisting adenocarcinoma [87].

Atypical carcinoids and large cell neuroendocrine carcinomas can be distinguished based on mitotic activity, nuclear atypia, and degree of necrosis (> Table 6.9) [3]. It is more difficult to differentiate between large cell neuroendocrine carcinoma and poorly differentiated cervical adenocarcinomas or squamous cell carcinomas. It is important that trabecular and insular growth patterns be looked for in poorly differentiated cervical tumors and that stains for neuroendocrine markers be used whenever there is an indication of neuroendocrine differentiation. It should be cautioned, however, that occasional typical cervical adenocarcinomas and adenosquamous carcinomas can stain focally with neuroendocrine markers or contain occasional argyrophilic cells [227]. In contrast, large cell neuroendocrine carcinoma have evidence of neuroendocrine differentiation by routine light microscopy and show more diffuse expression of neuroendocrine markers. Finally large cell neuroendocrine carcinoma has to be distinguished from malignant melanoma. Presence of melanin pigment and immunoreactivity for S-100 and HMB-45 facilitate the distinction between these tumors.

Several studies have explored the role of HPV in large cell neuroendocrine carcinomas. In the largest series, HPV 16 was detected by in situ hybridization or polymerase chain reaction in 58% and HPV 18 in 16% cases [90]. Large cell neuroendocrine carcinomas are highly aggressive neoplasms. In the review of 31 published cases, 65% patients died of disease within 3 years of diagnosis [87].

Small Cell Carcinoma

Small cell carcinomas of the cervix are histologically identical to their counterparts at other sites such as the lung. In most series these tumors account for 1-2% (range 0.5–5%) of all cervical tumors [1, 85]. The age of the patients ranges from 21 to 87 years with mean and median ages in the fifth decade in most series [1, 85]. In a study comparing small cell carcinoma to nonkeratinizing squamous carcinoma composed of small cells, the mean age of women with small cell carcinoma was 36 years compared to 50 years for squamous carcinoma [9]. Most patients present with abnormal vaginal bleeding and have an obvious mass on pelvic examination. In rare cases, patients present with abdominal symptoms related to ovarian metastases [293]. The number of patients presenting with abnormal cytologic examination is smaller than in patients with squamous cell carcinoma. This results from lack of an in situ component and rapid growth of the tumor [273].

Pathologic Findings

Grossly, small cell carcinomas range in size from small, clinically inapparent lesions to large ulcerated lesions measuring more than 6 cm in greatest dimension [85]. Microscopically tumors are composed of sheets and cords of closely packed, small, scant cells with inconspicuous cytoplasm, closely resembling the cells of "oat cell" carcinoma of the lung. The cells have hyperchromatic nuclei with finely stippled chromatin, inconspicuous nucleoli, and high nuclear to cytoplasmic ratios. Mitotic rate is high with three or more mitoses present in most high-power fields (\bigcirc *Fig. 6.47*). The nuclear shape varies from

Fig. 6.47

Small cell carcinoma. Tumor is composed of cells with enlarged, atypical hyperchromatic nuclei, numerous mitotic figures, scanty cytoplasm. Cellular molding also is present round to spindled, and nuclear molding is a characteristic feature. Smudging of the nucleus and extensive crush artifact frequently obscures nuclear detail and nucleoli. Small areas of either squamous or glandular differentiation can be present but should account for less than 5% of the total tumor volume [85].

Immunohistochemical and Molecular Genetic Findings

Neuroendocrine dense-core granules can be detected using Grimelius stains or electron microscopy in most cases. Although small cell carcinomas have been associated with ectopic ACTH, insulin, and gastrin production, clinical symptoms related to ectopic hormone production are uncommon [85, 293]. This suggests that hormones are produced in an inactive form, in insufficient amount, or are rapidly inactivated. By immunohistochemistry, neuroendocrine markers such as neuron-specific enolase, chromogranin, or synaptophysin are present in many cases; however, staining might be very focal [85]. Small cell carcinomas show variable expression of cytokeratins, epithelial membrane antigen, as well as variety of hormones and polypeptides including ACTH, calcitonin, serotonin, gastrin, substance P, VIP and somatostatin [1, 9, 112, 265].

In recent studies virtually all cervical small cell carcinomas have been associated with high-risk HPV types 18 and 16, with type 18 being the most prevalent, detected in 82% of the cases [107, 275]. Data on *TP53* mutation in small cell carcinomas are conflicting. Wistuba et al. has reported *TP53* gene mutations and loss of heterozygosity at the 17p/p53 locus in six of eight cervical small cell carcinomas, among which four cases were positive for HPV 18 or 16 [282]. However, no mutations or loss of heterozygosity at the 17p/p53 locus were found in other studies [165, 198, 276].

Differential Diagnosis

Differentiation between small cell carcinoma and nonkeratinizing squamous carcinoma with small cells can be difficult. The diagnosis of small cell carcinoma should be reserved for tumors composed of small cells in which squamous or glandular differentiation is absent or minor. Women with small cell carcinoma tend to be younger than women with nonkeratinizing squamous carcinoma with small cells. Histologically, cells of nonkeratinizing squamous carcinoma with small cells resemble those of high-grade SIL and lack the nuclear molding and extensive crush artifact present in most small cell carcinomas. Small cell carcinomas invade the stroma diffusely in trabeculae and poorly defined nests. In contrast, nonkeratinizing squamous carcinomas with small cells invade the stroma in discrete nests. In an individual case, immunohistochemistry for neuroendocrine markers may not be helpful because 40% of nonkeratinizing squamous carcinomas with small cells are positive for neuroendocrine markers and 40% of small cell carcinomas are positive for cytokeratins [9]. Nuclear staining for p63 confirms squamous differentiation in nonkeratinizing small cell carcinomas, while neuroendocrine type small cell carcinomas are negative for this marker [274]. Due to the presence of high-risk HPV in nonkeratinizing small cell carcinomas, they are positive for p16. Expression of thyroid transcription factor 1 (TTF1) has been reported in cervical small cell carcinomas and can cause diagnostic problems in tumors that metastasize to the lungs [2]. Immunohistochemical staining with antibodies against leukocyte common antigen and neuroendocrine markers can be useful for differentiating between small cell carcinoma from lymphoproliferative disorders.

Clinical Behavior and Treatment

Small cell carcinoma of the cervix is a highly aggressive tumor [1, 303]. Lymphvascular invasion is present in 90% of cases and is often extensive [1]. The prognosis of small cell carcinoma of the cervix is worse than that of stagecomparable, poorly differentiated squamous carcinoma [9]. Most patients have advanced disease at the time of hysterectomy even if they present clinically with stage I disease. In one study, 57% of clinical stage IB or IIA patients had lymph node metastases [237]. In another series, 9 of 12 patients died as a direct result of their tumor, and the median duration of survival of those dying of disease was only 12.5 months [273]. Similarly, in the series of Gersell et al., 10 of 15 patients died as a direct result of their tumor [85].

Combined modality treatments with chemotherapy and radiotherapy are currently used in management of small cell carcinoma. In a recent series, patients with early stage disease treated with platinum-based chemotherapy in addition to radiation had significantly better overall and disease-free survival when compared to patients who did not receive chemotherapy as part of their initial treatment [303].

Mixed Epithelial and Mesenchymal Tumors

Malignant mesenchymal tumors that can arise in the cervix include leiomyosarcoma, endocervical stromal sarcoma, embryonal rhabdomyosarcoma (botryoid type), alveolar soft part sarcoma, malignant schwannomas, and osteosarcomas (see **2** Chap. 10, Mesenchymal Tumors of the Uterus) (**2** *Figs. 6.48* and **2** *6.49*). Primary cervical sarcomas are rare, of which the most common is leiomyosarcoma.

Primary cervical mixed epithelial and mesenchymal tumors include müllerian adenosarcomas and malignant müllerian mixed tumors (MMMT) of the cervix. Cervical MMMT are less common than their much more common uterine counterparts [47]. Both usually occur in postmenopausal women and both typically form polypoid or pedunculated masses. The mean age of patients was 65 years in the largest published series [47]. However, cervical MMMTs differ in their histologic appearance from MMMTs arising in the uterus. The carcinomatous component in cervical MMMT is in the form of cervical carcinoma type rather than endometrial carcinoma as seen in uterine MMMT. The most common carcinomatous pattern in cervical tumors is a basaloid pattern that consists of anastomosing densely cellular trabeculae composed of small cells with scant cytoplasm and peripheral palisading. Other epithelial patterns include typical squamous cell carcinoma and endometrioid adenocarcinoma. Adenoid basal and adenoid cystic components have also been reported in several cases [168]. The sarcomatous element is typically homologous and frequently has the appearance of a fibrosarcoma or endometrial stromal sarcoma. The sarcomatous element is frequently high grade and may have myxoid change.

Extension of uterine MMMT to the cervix is in the differential diagnosis of cervical MMMT. The correct diagnosis is based on the dominant location of the tumor, the appearance of the carcinomatous component and detection of HPV. In a study of eight patients with cervical MMMT, HPV-DNA was detected by polymerase chain reaction in all cases. Interestingly, using in-situ hybridization HPV-16 DNA was detected in both epithe-lial and sarcomatous components in three cases [92]. Although the number of reported cases is small, cervical MMMTs may have a better prognosis than their uterine counterparts.

Only a small number of müllerian adenosarcomas of the cervix have been reported. They may occur more frequently than reported because they are frequently misdiagnosed [84, 118, 133]. Adenosarcomas occur in women between the ages of 14 and 67 years, with a mean age of 38 years [118, 133]. Women typically present with vaginal bleeding or recurrent cervical polyps. Microscopically, tumors usually demonstrate thick papillae covered with a typical endocervical-type endothelium. The appearance of the sarcomatous component can vary considerably. In some tumors, it consists of mitotically active, plump spindle cells that form periglandular cuffs and

Fig. 6.48

Embryonal rhabdomyosarcoma. Polypoid tumor has a cambium layer of hypercellular stroma immediately beneath the benign endocervical epithelium

Fig. 6.49

Embryonal rhabdomyosarcoma. Hypercellular foci within background edematous hypocellular stroma are composed of immature atypical cells with scant cytoplasm; mitotic figures and apoptotic bodies are usually evident a cambium layer under the surface epithelium. At least two mitotic figures per 10 high power fields are required to make a diagnosis of adenosarcoma, but in most cases the mitotic index exceeds 4 per 10 high power fields. In other tumors, the stromal component contains foci that are more embryonic in appearance, with small, undifferentiated round cells that are mitotically active. Heterologous sarcomatous elements including strap cells, lipoblasts, cartilage, and osteoid can be present.

The differential diagnosis includes adenofibroma, atypical endocervical polyp, adenomyoma of the cervix, and MMMT. Adenofibroma is also a biphasic lesion, but both the epithelium and stroma are benign. Atypical endocervical polyps show increased stromal cellularity and reactive nuclear atypia but these changes are often focal and mitotic activity is absent. Adenomyomas can be distinguished from adenosarcoma by the presence of welldefined myomatous component. The prognosis of cervical adenosarcoma is usually good after surgical therapy, although several patients have died of disease or developed recurrent tumor [84, 118, 133].

Miscellaneous Tumors

Primary malignant melanoma is among the least common of the malignant tumors that arise in the cervix; 27 patients have been reported [38, 44]. Common presenting signs include vaginal bleeding, frequently of short duration. In most instances, the lesion is pigmented and dark brown. The diagnosis of primary melanoma of the cervix is based on the histologic demonstration of junctional changes in the squamous epithelium and the absence of similar lesions elsewhere in the body. Morphologically, it is identical to melanoma arising in the skin and extragenital mucous membranes; it frequently contains intracytoplasmic melanin pigment granules. Some tumors are amelanotic and have to be distinguished from undifferentiated carcinoma. Rarely cervical malignant melanoma can be composed of clear cells. Immunohistochemical staining for HMB 45, Melan-A (MART-1), S-100 protein and absence of epithelial markers are helpful to rule out clear cell carcinoma. Spindle cell malignant melanoma has to be distinguished from leiomyosarcoma or malignant peripheral nerve sheet tumor. In contrast to malignant melanoma, leiomyocarcoma expresses smooth muscle markers and is negative for melanocytic markers. The cell pigmentation, nesting, and the presence of an atypical epidermal or junctional component, together with diffuse, strong reactivity for S100 protein and positivity for other melanocytic markers help to differentiate

melanoma from malignant peripheral nerve sheet tumor [58]. The prognosis of primary malignant melanoma is poor, with only 25% survival rate for patients with stage I disease [44].

Primary choriocarcinoma and epithelioid trophoblastic tumors in the cervix are rare [123]. The gross and microscopic appearance, as well as the clinical course, is identical with those found in the uterine corpus.

Primary cervical germ cell tumors have been described: these include both the mature teratomas and yolk sac tumors [21, 52]. There are also case reports of primitive neuroectodermal tumors (PNET) of the cervix [246]. These tumors appear to be identical to PNETs occurring at other sites, and in some cases have stained positive on immunohistochemistry for the restricted surface antigen MIC-2 and contained the EWS/FLI-1 chimeric mRNA transcript characteristic of PNET/Ewing's sarcoma family.

Secondary Tumors

Direct extension from a pelvic tumor is the most common source of cervical involvement by secondary carcinoma, often originating in the endometrium, rectum, or bladder. Intrapelvic and intragenital, lymphatic, or vascular metastases to the cervix occur less frequently. These lesions are usually associated with ovarian carcinoma, endometrial adenocarcinoma, and less commonly with transitional cell carcinoma of the bladder [154, 182]. Another lesion that has a relatively high rate of cervical metastasis is choriocarcinoma. Sarcomas of the uterine corpus may also involve the cervix. Metastases to the cervix from distant primary sites are rare, the most common being the gastrointestinal tract (colon and stomach), ovary, and breast. Instances of metastatic carcinoma from the kidney, gallbladder, pancreas, lung, thyroid, and malignant melanoma have also been described. On occasion, metastases may occur primarily as cervical involvement and pose a differential diagnostic problem. Unusual gross appearance or histologic patterns, e.g., signet-ring cell carcinoma or clear cell carcinoma, provide a clue to the possibility of origin from a distant primary site.

Endometrial Autolysis

The endometrium and the myometrium are of mesodermal origin and are formed secondary to fusion of the müllerian (paramesonephric) ducts between the 8th and 9th postovulatory weeks. The cervix is generally considered to be of müllerian origin, although it has been claimed that its mucous membrane is derived from the urogenital sinus; however, the exact contribution of müllerian and sinus tissue to the cervix remains uncertain [47]. Until the 20th week of gestation, the endometrium consists of a single layer of columnar epithelium supported by a thick layer of fibroblastic stroma. After the 20th gestational week, the surface epithelium invaginates into the underlying stroma, forming glandular structures that extend toward the underlying myometrium. At birth, the uterus, which is made up of the uterine corpus and uterine cervix, measures approximately 4 cm in length, the majority of which is made up of the cervix. The endometrium measures less than 0.5 mm in thickness, and the surface and glands are lined by a low columnar to cuboidal epithelium devoid of either proliferative or secretory activity, which resembles the inactive endometrium of postmenopausal women.

During the prepubertal years, the endometrium remains inactive, and the cervix continues to comprise the major part of the uterus. In the reproductive years, the dimensions and weight of a normal uterus varies widely according to parity. In nulliparous women, the uterus measures approximately 8 cm in length, 5 cm in width at the level of the fundus, and 2.5 cm in thickness; most weigh between 40 and 100 g. Multigravid uteri are larger with increasing length and weight with increasing parity. The internal os, a fibromuscular junction, separates the muscular uterine corpus from the fibrous uterine cervix. The uterine corpus is divided into the fundus, body, and isthmus. The fundus is that part of the uterus above the orifices of the fallopian tubes, and the isthmus represents the lower uterine segment. The uterus is located between the rectum (posteriorly) and the urinary bladder (anteriorly); it is supported by the round ligaments and the utero-ovarian ligaments and covered by the pelvic peritoneum. The endometrium during the reproductive period undergoes cyclical morphologic changes (described in detail below), which are particularly evident in the superficial two thirds, the so-called functionalis layer. Morphologic alterations are minimal in the deeper one third, the so-called basalis layer. In postmenopausal women, the endometrial morphology is similar to that in the prepubertal years (see section **>** Postmenopausal Endometrium).

Vascular Anatomy

The endometrium has an abundant vascular supply that originates from the radial arteries of the underlying myometrium. These arteries penetrate the endometrium at regular intervals and give rise to the basal arteries, which in turn divide into horizontal and vertical branches, the former providing the blood supply to the endometrial basalis and the latter to the overlying functionalis layer. The endometrial vessels in the functionalis layer are referred to as spiral arteries. Their development and arborization near the endometrial surface and their connections with the subsurface epithelial precapillary system, as well as extreme coiling during the menstrual cycle, are influenced by ovarian steroid hormones and prostaglandins.

A differentiating feature between the endometrial and myometrial arteries is the absence of subendothelial elastic tissue in the endometrial arteries, except for those in the basal layer, and its presence in the myometrial arteries. Veins and lymphatics are closely associated with the endometrial arteries and glands, respectively. Uterine lymphatics drain from subserosal uterine plexuses to the pelvic and para-aortic lymph nodes.

Congenital Defects

Congenital abnormalities of the uterus are uncommon. They may be secondary to the effects of exogenous hormones, such as diethylstilbestrol (DES), in utero [70], or imbalances in endogenous hormones associated with abnormal gonads and chromosomal defects. In utero exposure to DES is, of course, nowadays rare. Genotypically normal females with normal gonads may also have müllerian duct abnormalities. These developmental aberrations, such as defects in the fusion of the müllerian ducts, are caused by errors in embryogenesis. The etiology of these developmental errors is mostly unknown, but hormonal imbalances or genetic abnormalities may be implicated. These disorders are frequently associated with malformations in the urinary system and the distal gastrointestinal tract. For practical purposes, müllerian duct abnormalities can be divided into two categories, namely abnormalities of fusion and abnormalities caused by atresia.

Fusion Defects of the Müllerian Ducts

Normally, the upper one third of the vagina and the uterus are formed by fusion of the paired müllerian ducts.
After fusion, the intervening wall degenerates, forming the endometrial cavity and the upper vaginal canal. Nonfusion of the müllerian ducts results in a bicornuate uterus. If the ducts fuse but the wall between the two lumens persists, an abnormal septate uterus results. Occasionally a carcinoma develops in one cavity, and only the other normal cavity is sampled during the investigation of abnormal uterine bleeding. If the defect is minor or confined to the fundus, the uterus is referred to as arcuatus. If the full length of the uterus and the upper vagina is divided by a septum, the condition results in uterus didelphys with a partially double vagina. These congenital anomalies may result in infertility or spontaneous abortion and in some cases require surgical correction.

Atresia of the Müllerian Ducts and Vagina

Atresia of the müllerian ducts and the vagina may be partial or complete. The etiology of these conditions is obscure, although a genetic cause is suggested in families with multiple affected siblings. The pattern of inheritance may be autosomal recessive or dominant. If only one of the müllerian ducts is involved, only the tubal fimbria and a small muscular mass at the pelvic sidewall will form. With bilateral atresia, the upper genital tract may consist of bilateral noncanalized muscular tissue located on the lateral pelvic walls. In Rokitansky-Kuster-Hauser syndrome, a severe defect characterized by müllerian and vaginal aplasia, patients may have urinary tract anomalies such as a pelvic kidney or anephria. Vertebral and other skeletal abnormalities may also be present, suggesting a more generalized morphogenetic abnormality. Patients with these conditions are endocrinologically normal with normal gonads. It has been postulated that activating mutations affecting the gene coding for antimüllerian hormone or its receptor may be related to the development of these syndromes [78]. If the anomaly is associated with obstruction of the vagina and functional endometrial tissue is present, hydrocolpos may be present at birth, or patients may present with primary amenorrhea. A uterus bicornis unicollis may develop in women with one affected müllerian duct, resulting in a pelvic mass and cyclic pelvic pain associated with menses. A number of multiple malformation syndromes have been associated with müllerian or vaginal agenesis. Winter syndrome, a genetically inherited autosomal recessive disorder, is characterized by vaginal agenesis, renal agenesis, and middle ear anomalies [156]. Management of patients with complete vaginal atresia requires surgery to create a neovagina. If the anomaly is isolated vaginal atresia, as most commonly occurs, the patient will usually be fertile if a normal uterus and fallopian tubes are present.

Normal Cyclical Endometrium

In the reproductive years, the endometrium is characterized by cyclical growth, shedding, and regrowth in response to estrogen and progesterone secretion by the ovaries. Endometrial morphology, as a consequence, is continually altering depending on the levels of estrogen and progesterone [33, 107]. During the proliferative phase of the menstrual cycle, the endometrium has a relatively constant morphology, which does not differ significantly from day to day; as such, accurate dating is not possible in the proliferative phase. Following ovulation, the morphological appearances in the secretory phase have been considered relatively specific from day to day such that it is possible to accurately date secretory phase endometrium to within 1 or 2 days. However, this view has been challenged with one study finding that traditional endometrial histologic dating criteria are much less temporally distinct and discriminating than originally described [102]. Nowadays, most endometrial biopsies are performed during the investigation of abnormal uterine bleeding, and it is relatively uncommon to be asked to date the endometrium, although formerly this was often requested in the investigation of infertility. The typical endometrial cycle is 28 days, although the length varies between women and even in the same woman. In general, the differences in cycle length are due to variation in the duration of the proliferative phase, the secretory phase usually being constant and lasting 14 days from the time of ovulation to the onset of menstruation. In the reproductive years, the endometrium is divided into two regions, namely the superficial functionalis (stratum spongiosum) and the basalis (stratum basale). The former exhibits the greatest degree of hormonal responsiveness, while the latter is much more unresponsive, the morphology not varying greatly during the menstrual cycle; as such, a biopsy consisting entirely of basalis is not adequate for dating of the menstrual cycle. Usually, the endometrial glands are regularly spaced and have a perpendicular arrangement from the basalis to the surface. The basalis abuts the myometrium and regenerates the functionalis following its shedding during menstruation. The basalis is composed of inactive appearing glands, cellular stroma, and spiral arteries that have thicker muscular walls than those in the functionalis. Accurate typing of the endometrium is, in general, not possible when polyps, endometritis, or other pathological lesions are present.

Proliferative Phase

The onset of menstruation is the first day of the menstrual cycle. Following menstruation, the uterus is lined by shallow basal endometrium and the deeper part of the functionalis. The endometrium begins to proliferate on the third or fourth day of the cycle, and during the proliferative phase, it increases in thickness up to 4 or 5 mm. Between the 5th and 14th days of a typical 28-day cycle, there is glandular, stromal, and vascular growth, the endometrium progressively increasing in depth until ovulation. The endometrial glands are uniform, widely and regularly spaced, and on cross section are tubular (> Fig. 7.1). An occasional mildly dilated gland is a normal feature and of no significance. Mitotic figures are easily identified within the glands, and the presence of mitotic activity should be confirmed before labeling an endometrium as proliferative in type. The glandular epithelium is composed of pseudostratified cuboidal or low columnar cells with a moderate amount of basophilic cytoplasm. The nuclei are oval or rounded and may contain small nucleoli; they remain orientated to the basement membrane. Proliferative activity is maximal between the 8th and 10th days of the cycle, and, at this stage, the glandular epithelium becomes more stratified and mitoses more frequently seen. In the late-proliferative phase, the glands become progressively more convoluted and tortuous and appear more variable in size and shape. Occasional subnuclear vacuoles may be seen. During the proliferative phase, the endometrial stroma is usually densely cellular, and the stromal cells are small and oval with hyperchromatic

Fig. 7.1 Proliferative endometrium. Widely spaced tubular glands exhibit mitotic activity

nuclei and indistinct cytoplasm and cell borders. Mitotic figures are present within the stroma, although less numerous than within the glands. Scanty thin-walled stromal blood vessels are present. The degree of mitotic activity within both the glands and stroma decreases in the lateproliferative phase, and early stromal edema develops. Estrogenic activity during the proliferative phase often results in focal ciliation of the surface epithelial cells; thus, surface ciliated cells are a feature of normal proliferative endometrium, and this does not indicate ciliated or tubal metaplasia (discussed below).

Secretory Phase

Secretory endometrium is characterized by glandular secretion, stromal maturation, and vascular differentiation occurring in response to progesterone produced by the postovulatory corpus luteum. The endometrium increases in thickness up to 7 or 8 mm. The secretory phase may be divided into three stages, namely the early secretory phase (from the 2nd to 4th postovulatory day; days 16–18 of a normal 28-day cycle), the mid-secretory phase (from the 5th to 9th postovulatory day; days 19–23 of a normal 28-day cycle), and the late-secretory phase (from the 10th to 14th postovulatory day; days 24–28 of a normal 28-day cycle). These phases are continuous and not sharply demarcated, and some areas of endometrium may appear at a slightly more advanced stage than others.

There is an interval of 36 to 48 h between ovulation and the first morphologically recognizable signs of early secretory activity. In the early secretory phase, the endometrial glands still have a tubular appearance and mitotic activity may be identified. The initial morphological feature of ovulation is the appearance within the glandular epithelium of subnuclear vacuoles. These typically appear on the 16th day of the typical 28-day cycle, that is, the 2nd postovulatory day. Initially, subnuclear vacuoles are identified only within occasional cells and are irregularly distributed but usually most obvious in the mid-zone of the functionalis. There is a progressive increase in the number of and distribution of subnuclear vacuoles until they involve almost all cells within most glands in the functionalis (**)** Fig. 7.2). Subnuclear vacuoles are maximal between the 17th and 18th day of the cycle (3rd and 4th postovulatory days). As stated, some areas of endometrium may appear at a slightly more advanced stage than others, and in the early secretory phase, there may be an admixture of glands exhibiting proliferative and secretory activity; in fact, an individual gland may exhibit both mitotic activity and subnuclear vacuolation. It is generally

Fig. 7.2 Early secretory phase endometrium. Tubular glands exhibit subnuclear vacuolation

Mid-secretory endometrium. The glands contain supranuclear vacuoles with secretions within glandular lumina

assumed that ovulation has occurred when there are subnuclear vacuoles in at least 50% of the cells in at least 50% of the glands; scattered subnuclear vacuoles are not reliable evidence of ovulation and, as stated, may be seen in late-proliferative endometrium. In the early secretory phase, the stroma is indistinguishable from that of lateproliferative endometrium.

Between the 19th and 23rd day of a typical 28-day cycle (the mid-secretory phase), the degree of glandular secretion increases. Cytoplasmic vacuoles become supranuclear and secretions are seen within glandular lumina (> Fig. 7.3); it is important to realize that secretory material within glandular lumina is not specific to secretory endometrium but may also be seen in proliferative, hyperplastic, and malignant endometria. Mid-secretory glands are usually angular in shape, and mitotic activity is no longer apparent. The glands in the superficial layers of the functionalis tend to exhibit less secretory activity, and, as a result, superficial biopsies may produce a false impression of poorly developed secretory activity. Stromal edema progressively increases, is most obvious in days 22 and 23, and is most prominent in the mid-zone (> Fig. 7.4). Spiral arteries become apparent. At this stage, the stromal cells have more conspicuous eosinophilic cytoplasm; these cells are referred to as predecidual cells.

In the late-secretory phase (days 24 to 28 of a typical 28-day cycle or 10th to 14th postovulatory days), there is typically diminution of glandular secretory activity (secretory exhaustion), and the glands become serrated. Predecidual stromal change increases, initially being most apparent in the cells surrounding the spiral arteries

Fig. 7.4 Mid-secretory endometrium. There is marked stromal edema

(**)** *Fig.* 7.5). The predecidual change results in formation of the so-called compact layer (stratum compactum) beneath the surface epithelium, the deeper layers of stroma exhibiting less predecidual change. Sometimes, the predecidual cells may have a spindle cell or even signetring morphology and may not be readily appreciated as predecidual cells. Occasional mitoses may reappear in the predecidual stromal cells on day 26 or 27. A stromal infiltrate of granulated lymphocytes (described in detail later) is now obvious, and occasional neutrophils may appear in the premenstrual phase; the presence of granulated

Late-secretory endometrium. There is predecidual change surrounding the spiral arteries

Fig. 7.6

Late-secretory endometrium. The glands may be closely packed superficially resembling a hyperplastic endometrium

lymphocytes and neutrophils should not be misinterpreted as evidence of an endometritis. In late-secretory endometrium, the glands may be closely packed (this impression can be exacerbated by tangential sectioning), and this can superficially resemble hyperplastic endometrium (\bigcirc *Fig.* 7.6); however, other features of a hyperplastic endometrium, such as mitotic activity, are absent. In some late-secretory endometria, the glands have a "hypersecretory" appearance, resembling Arias-Stella effect endometrium (\bigcirc *Fig.* 7.7); this should not, in itself, be interpreted as evidence of early pregnancy. In the immediate premenstrual days, apoptotic activity is seen within glands, fibrin thrombi appear in small blood

Late-secretory endometrium. The glands exhibit the Arias-Stella reaction

vessels, and there is extravasation of red blood cells into the stroma.

Menstrual Phase

Menstruation occurs after the 28th day of the normal cycle (the onset of menstruation is the first day of the menstrual cycle) and is characterized by glandular and stromal breakdown. Menstruation usually lasts for about 4 days. The endometrial glands are serrated and collapsed. Some of the glands remain vacuolated and of secretory appearance. The stroma is condensed and collapsed, and the stromal cells aggregate into tightly packed balls (stromal blue balls) and separate from the glands (> Fig. 7.8); the presence of tightly aggregated balls of stromal cells with hyperchromatic nuclei may be worrisome to the unwary. The predecidual appearance of the stromal cells is lost. Other features include the presence of necrotic debris, neutrophil infiltration, interstitial hemorrhage, and fibrin deposition. Apoptotic bodies are identified within both the glands and the stroma (**)** Fig. 7.9). When menstrual activity is well developed, little or no stromal tissue may remain, and the glands become closely packed, sometimes with a back to back appearance; to the unwary, this may result in consideration of a hyperplasia or carcinoma. Following breakdown, the endometrial glands assume a surface micropapillary architecture (**)** Fig. 7.10). The term papillary syncytial metaplasia (discussed later) is used for this appearance, but this is an inaccurate term since this is not strictly speaking a metaplasia but rather a regenerative or degenerative process secondary to tissue

Menstrual phase endometrium. The stromal cells aggregate into "blue balls"

Fig 7.10

Papillary syncytial metaplasia. Following breakdown, the endometrial glands regenerate with a surface micropapillary architecture

Fig. 7.9 Menstrual phase endometrium. Apoptotic bodies are present within endometrial glands and stroma

breakdown. Mitotic figures may be present within the papillary proliferations. Papillary syncytial metaplasia is also seen following surface breakdown associated with nonmenstrual conditions. On occasions, the micropapillary architecture is particularly striking, and, if associated with mitotic activity, this raises the possibility of a serous carcinoma; appreciation of the accompanying features of breakdown and immunohistochemical staining with p53 may be of value. Most serous carcinomas exhibit diffuse intense nuclear immunoreactivity with p53, while papillary syncytial metaplasia is negative, or there may be a pattern of staining, which has been described as weak and heterogeneous [123].

Lower Uterine Segment Endometrium

Lower uterine segment or isthmic endometrium is poorly responsive to steroid hormones, and the morphology does not alter significantly during the menstrual cycle; as is the case with the endometrial basalis, lower uterine segment endometrium is not useful for dating the menstrual cycle. Lower uterine segment endometrium is composed of inactive poorly developed glands that are often ciliated (**)** Fig. 7.11). They are irregularly distributed, and some may be dilated. The stroma typically has a fibrous appearance, and the stromal cells are more elongate and "fibroblast-like" than in the corpus. Given these features, lower uterine segment endometrium may be mistaken for a polyp in a biopsy specimen. In the inferior part of the lower uterine segment, the glands merge with mucinous type glands from the upper endocervix, and the stroma becomes even more fibrous.

Steroid Hormone, Steroid Hormone Receptor, and Immunopeptide Interactions in the Endometrial Cycle

As detailed, the menstrual cycle in postmenarchal, premenopausal women follows a regular series of morphological and physiological events characterized by proliferation, secretory differentiation, shedding, and regeneration of the uterine lining. These alterations are controlled by the cyclical release of the steroid sex hormones estradiol (E2) and progesterone (P) from the

Lower uterine segment endometrium. This is composed of a mixture of ciliated and mucinous glands within a fibrous stroma

ovaries; the endometrium is thus a highly sensitive indicator of the hypothalamic–pituitary–ovarian axis. Steroid hormone control of endometrial epithelial and stromal cells is mediated by estrogen receptors (ER) and progesterone receptors (PR). These steroid receptors are proteins concentrated in the nuclei of endometrial epithelial and stromal cells that have high affinity to bind E2 and P. Because they are sex steroid hormone (ligand) specific, a particular receptor may display high affinity for a closely related class of hormones, and these classes may compete for available binding sites. For example, ER effectively binds not only E2 but also estrone (E1), as well as synthetic estrogens, such as diethylstilbestrol (DES).

Although E2 plays a crucial role in the proliferation of endometrial cells in vivo, E2 alone is not able to induce proliferation of endometrial cells in primary culture. It has been suggested that the mitogenic action of E2 is mediated indirectly via a paracrine effect by the polypeptide growth factor, epidermal growth factor (EGF). EGF promotes the transition of cells from the G_0 to G_1 phase of the cell cycle [144]. Human endometrial cells possess EGF receptors and mRNA for EGF. EGF-like immunoreactivity is seen in both the endometrial epithelial and stromal cells, with higher concentrations in the epithelium than the stroma, and parallels the fluctuation of cyclic sex steroid hormones during the menstrual cycle. It appears that the regulation of EGF receptor content is regulated by ovarian E2 and P secretion (autocrine control). Indeed, EGF alone fails to influence cell proliferation, but in combination with E2, it increases the mean glandular but not stromal cell counts by more than 50% in vitro. The immunolocalization of

EGF in normal human endometrium and the stimulation of epithelial cell proliferation in culture by EGF and E2 provide support for a role of EGF in endometrial growth.

The continuous dynamic remodeling of the endometrium results from a delicate balance of cellular proliferation and programmed cell death within specific subpopulations of stromal and epithelial cells, a process that is modulated by steroid hormones. A ladder pattern of DNA cleavage characteristic of apoptosis is seen in the late-secretory, menstrual, and early-proliferative phases. Localization of apoptotic subpopulations using in situ assays for DNA breakage has shown that the majority of apoptotic cells represent glandular cells within the basalis and these cells increase in number throughout the secretory phase and peak during menses [141]. The apoptotic effects of steroid hormones are likely mediated through a complex network of inhibitors and initiators. Progestins have been shown to decrease endometrial secretion of the apoptosis inhibitor bcl-2 [51], a process that is reversed upon administration of antiprogestogenic agents [32]. Progestins may also positively promote apoptosis by increasing levels of the apoptosis inducer gene BAK. The concentrations of ER and PR in the normal endometrium vary during the normal menstrual cycle according to fluctuating plasma levels of E2 and P. The highest values of ER (approximately 400 fmol/mg protein) and PR (approximately 1,000 fmol/mg protein) occur during the mid-proliferative phase (8th-10th day of the cycle) and correspond to rising plasma levels of E2. E2 promotes the synthesis of both ER and PR, whereas P inhibits the synthesis of ER. Monoclonal antibodies to ER allow the precise intracellular localization of ER by means of immunohistochemistry. Most ER is localized in the nuclei rather than the cytoplasm of endometrial epithelial and stromal cells. Endothelial cells fail to stain with ER antibodies. The concept of the mechanisms of sex steroid hormonereceptor action in target cells includes the following major steps: (1) circulating and unbound steroid hormone molecules are taken up from the cytoplasmic membrane, presumably by cytoplasmic receptors; (2) the hormone molecules enter the nucleus, which contains most (90-95%) of the cellular receptors; (3) the intranuclear hormone molecules induce conversion of the inactive (nonfunctional) 4S form of receptor to the active (functional) 5S form of the receptor; (4) the hormonally activated 5S receptor binds to acceptor genes in the nucleus and influences gene expression by stimulating RNA polymerase and thus mRNA transcription; and (5) the newly formed mRNA is transported to the cytoplasm, where it is translated into proteins, including anabolic and catabolic enzymes, as well as new receptors (receptor replenishment). According

to this concept, the most significant effect of sex hormones is intranuclear activation of receptors that in turn initiate a sequence of events, which results in alterations in the physiologic functions of target cells.

Immunohistochemistry of Normal Endometrium

The normal endometrial glands and stroma are estrogen receptor (ER) and progesterone receptor (PR) positive (> Fig. 7.12). Endometrial glands are diffusely positive with the anti-apoptotic protein bcl-2 during the proliferative phase of the menstrual cycle. There is marked diminution in staining during the early and mid-secretory phases with reappearance during the late-secretory phase [13, 51, 101]. A minor population of endometrial epithelial cells exhibit nuclear immunoreactivity with p63; it has been speculated that these are reserve cells or basal cells and the origin of metaplastic endometrial epithelial cells [111]. Endometrial glands are cytokeratin 7 positive and cytokeratin 20 negative. The normal endometrial stroma is CD10 (> Fig. 7.13) and bcl-2 positive [86] and CD34 negative, in contrast to cervical stroma, which is largely CD10 and bcl-2 negative and CD34 positive [9], although there may be immunoreactivity with CD10 of stromal cells surrounding endocervical glands [89]. This differing immunophenotype may be useful in assessing whether the stroma accompanying a neoplasm is endometrial or cervical in type and in assessing tumor origin when this is problematic. The immunophenotype of lower uterine segment stroma overlaps with that of the endometrial and the cervical stroma. Normal endometrial stroma may be smooth muscle actin positive but is desmin negative. The immunohistochemistry of endometrial hematopoietic cells is discussed in the next section.

Hematopoietic Cells Within the Endometrium

The normal endometrium contains a variety of hematopoietic cells, the composition of which varies depending on the stage of the menstrual cycle and the menopausal status. Lymphocytes, including lymphoid aggregates and occasionally lymphoid follicles with germinal centers, are found at all stages of the menstrual cycle and in the postmenopausal endometrium. In the normal menstrual cycle, lymphoid aggregates are most common in the proliferative phase. They are more commonly seen postmenopausally within the basal endometrium; it is not clear whether this is due to lymphoid aggregates being more numerous postmenopausally or whether they are more obvious secondary to the glandular atrophy. Immunohistochemical studies have demonstrated that B lymphoid cells (CD20 and CD79a positive) constitute approximately 1% of the normal lymphoid population of the endometrium and are present mainly in aggregates in the basalis and rarely as individual cells in the functionalis. T lymphocytes (CD3 positive) are more common and are present throughout the endometrial stroma, usually as individual cells [37]. The distribution of B and T lymphoid cells is altered in endometritis; this is discussed below. Granulated lymphocytes (CD56 positive)

• Fig. 7.12 Estrogen receptor in endometrium. The normal endometrial glands and stroma are positive with estrogen receptor

Fig. 7.13
CD10 in endometrium. The normal endometrial stroma is
CD10 positive

are present in large numbers in predecidualized endometrial stroma in the mid- and late-secretory phases [16, 17] (**)** *Fig.* 7.14); these were formerly designated endometrial stromal granulocytes and have a mononuclear or bilobed nucleus and abundant eosinophilic cytoplasm containing a variable number of granules. The function of granulated lymphocytes is not entirely clear but they have the characteristics of natural killer cells and, as well as being positive with CD56, are immunoreactive with T cell markers. Neutrophils are present in small numbers throughout the menstrual cycle but only become morphologically evident in large numbers in association with the tissue breakdown and necrosis associated with menses. In contrast to lymphocytes and neutrophils, plasma cells are not considered to be a component of the normal endometrium, although the presence of an occasional plasma cell is allowable in an otherwise morphologically normal endometrium. Plasma cells are, of course, a feature of endometritis (discussed below). Rare mast cells, demonstrable with toluidine blue or Giemsa staining, may be found in the endometrium, primarily within the basalis. Mast cells are also found normally in the myometrium, in endometrial polyps and in leiomyomas, often in large numbers in the latter. The number of mast cells in the endometrium and myometrium tends to decrease with advancing age. Histiocytes are also seen in the normal endometrium (discussed later - section Ocontaminants and Other Elements in Endometrial Biopsies). Eosinophils are not a component of the normal endometrium. Rarely, foci of extramedullary hematopoiesis

G Fig. 7.14

CD56 in endometrium. CD56 positive granulated lymphocytes are present in large numbers in predecidualized endometrial stroma in the mid-and late-secretory phases are present in the endometrium, usually in association with an underlying hematopoietic disorder or occasionally representing remnants of fetal tissue [31].

Gestational Endometrium

Pregnancy is characterized by morphological changes involving the endometrial glands and stroma. The trophoblastic populations in an intrauterine gestation are covered in **O** Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions. Early in pregnancy, the endometrium displays hypertrophic and hypersecretory features that have been referred to as "gestational hyperplasia." The endometrium is characterized by (1) glandular ferning with epithelial and intraluminal secretions, (2) stromal edema and vascular congestion, and (3) decidual reaction of the stromal cells. The changes are similar to but quantitatively exaggerated compared to those of nongestational endometrium at days 22 to 26 of the menstrual cycle. In the normal cycle, each of these alterations is prominent on a given day of the secretory phase, whereas during early pregnancy they occur simultaneously. The features described are not pathognomonic of early pregnancy but may occasionally be seen in other situations (see section Arias-Stella Reaction).

Immediately after implantation of the blastocyst on the endometrial surface, changes begin to occur in the endometrial glands and the stroma, although the overall morphology of late-secretory endometrium is maintained for several days. The early changes include glandular serration and distension, increase in glandular secretions, stromal edema, and a stromal predecidual reaction. The morphological features during the first 2 weeks of gestation are subtle, but after approximately 15 days, they become more characteristic with the formation of decidual cells. Compared to predecidual cells, decidual cells are larger with prominent cell membranes and more abundant eosinophilic cytoplasm that may contain small vacuoles (**)** Fig. 7.15). The nuclei of decidual cells are round to ovoid with finely dispersed chromatin and indistinct nucleoli. Stromal granulated lymphocytes are present during early pregnancy and spiral arteries become more apparent; they have thicker walls than in nongestational secretory endometrium. Some of the spiral arteries display acute atherosis with concentric intimal proliferation of myofibroblasts and accumulation of foamy cells. As the pregnancy progresses, decidual cells become widespread with better defined cell borders and develop an epithelioid appearance. Small numbers of granulated lymphocytes remain throughout the gestation. Some of the glands

become atrophic while others have a hypersecretory appearance. Four to eight weeks after implantation, the glands often exhibit, at least focally, the Arias-Stella reaction, which is a response to the presence of trophoblastic tissue in the uterus or at an ectopic site. Histologically, the Arias-Stella reaction is characterized by cellular stratification, secretory activity, vacuolated cytoplasm, and enlargement of the epithelial cell nuclei and cytoplasm (\bigcirc *Fig. 7.16*). The nuclei may be enlarged up to three

Fig. 7.15

Gestational endometrium. The stroma is expanded and composed of decidualized cells with abundant eosinophilic cytoplasm

times normal and can exhibit considerable atypia and a hobnail appearance with bulging into the glandular lumina. Mitotic figures may be present, although these are rarely prominent and there is a low MIB1 proliferation index. Atypical mitoses have rarely been described [3]. The Arias-Stella reaction may be extensive, involving many glands, or focal with involvement of only a few glands or even part of a gland. The changes persist for at least 8 weeks following delivery. Several histological variants have been described, namely atypical, early secretory pattern, hypersecretory pattern, regenerative pattern, and monstrous cell pattern [4]. However, there is considerable overlap between these patterns, and there is no value in attempting to subclassify Arias-Stella effect endometrium. The Arias-Stella reaction may also be seen in the glandular epithelium of the cervix and fallopian tube and involving endometriosis or vaginal adenosis [109].

Apart from the Arias-Stella reaction, the endometrial glands may undergo other changes in the presence of trophoblastic tissue. These include abundant clear glyco-gen-rich cytoplasm; this overlaps with the Arias-Stella reaction, but the nuclear enlargement of the latter is not present. Another pregnancy-related change is the presence of optically clear nuclei within the endometrial epithelium [98] (\bigcirc *Fig. 7.17*). This may occur in association with the Arias-Stella reaction or independently. This appearance is due to the intranuclear accumulation of biotin and may simulate the ground glass nuclei of herpes simplex virus infection [157]. However, the nuclei lack the Cowdry type A eosinophilic intranuclear inclusions and nuclear

■ Fig. 7.16 Arias-Stella reaction in pregnancy. There is cellular stratification, vacuolated cytoplasm, and enlargement of the epithelial cell nuclei

• Fig. 7.17 Optically clear nuclei in pregnancy. Endometrial glands in pregnancy may contain cells with optically clear nuclei

been described during pregnancy, usually in first trimester gestations of women in their 4th or 5th decades. These rare focal lesions are characterized by glandular expansion, nuclear stratification, a cribriform architecture, and intraluminal calcifications [49] (\bigcirc *Fig.* 7.18). There is mitotic activity, but the cytology is bland. These appear to be benign lesions based on uneventful follow-up and an unusual response to pregnancy.

In early pregnancy, endometrial glands become strongly S100 positive [106]. This immunoreactivity disappears after the 12th week of gestation. The reason for this S100 positivity is not clear.

It is emphasized that the endometrial morphological changes of pregnancy described may be seen with both an intrauterine gestation and an ectopic pregnancy. Confirmation of an intrauterine gestation requires the presence of trophoblast, either in the form of chorionic villi or a placental site reaction (described in) Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions). In the placental site, intermediate trophoblast infiltrates the decidua. On occasions, it may be difficult to distinguish between decidual cells and implantation site intermediate trophoblast, although intermediate trophoblastic cells are larger and more variable in size and shape, ranging from polygonal to spindle shaped. The nuclei are lobated and hyperchromatic and binucleate or multinucleate cells may be present. There may be prominent nucleoli and sharply defined cytoplasmic vacuoles. In contrast, the nuclei of decidualized stromal cells are uniform and round to oval

Fig. 7.18

Endometrial glandular proliferation of pregnancy. In rare cases, the endometrial glands in pregnancy exhibit proliferation with papillary and cribriform arrangements

with finely dispersed chromatin and inconspicuous nucleoli. In problematic cases, immunohistochemical staining may assist in distinguishing between intermediate trophoblastic cells at the placental site and decidualized stromal cells. Markers of value are discussed in **>** Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions but trophoblastic cells are immunoreactive with broad-spectrum cytokeratins, cytokeratin 7, human placental lactogen, HLA-G, inhibin and mel-CAM (CD146), while decidua is negative [75, 82, 112].

Endometrium Associated with Ectopic Pregnancy

The morphology of gestational endometrium is discussed in the previous section. Endometrial changes also occur with an ectopic pregnancy. The features are variable but by day 22 to 28 of the ectopic gestation, the endometrial glands usually exhibit secretory or hypersecretory features, sometimes with Arias-Stella reaction, at least focally. Occasionally, the endometrial glands are atrophic. If the ectopic trophoblast regresses, the endometrial glands have a variable appearance, ranging from proliferative to secretory to a picture identical to that seen in disordered proliferation or progestogen effect. The endometrial stroma in association with an ectopic gestation is usually decidualized and devoid of inflammation. Thick-walled spiral arteries are present. Trophoblastic tissue, in the form of chorionic villi or a placental site reaction, is absent.

Postmenopausal Endometrium

The age of the menopause with cessation of ovulation and resultant diminution of hormone production by the ovaries is variable but is usually around age 50. Postmenopausally, the endometrium becomes thin and atrophic, unless there is continuing estrogenic drive, either in the form of endogenous production or exogenous hormone use. When there is no estrogenic drive, the functionalis is absent and the endometrium is composed only of a basalis, similar to the basalis of the reproductive years and of the premenarchal endometrium.

The histological appearance of the postmenopausal endometrium is variable. The endometrium is usually thin and this is appreciated in hysterectomy or endometrial resection specimens. The glands do not exhibit proliferative activity and vary from consisting entirely of small widely spaced atrophic tubules (\bigcirc *Fig.* 7.19) to cystically dilated glands throughout (so-called cystic atrophy or senile cystic atrophy) (\bigcirc *Fig.* 7.20); a mixture of small

Atrophic endometrium. There are widely spaced small atrophic tubules

 Fig. 7.20
Cystic atrophy. Cystically dilated glands are present within a fibrous stroma

tubules and cystically dilated glands may occur. The cystic glands seen in atrophic endometria in hysterectomy or resection specimens may not be observed in endometrial biopsies because tissue fragmentation during the procedure disrupts the glands. Usually, tubular glands are more prominent in the years immediately following the menopause while cystic atrophy is more common in older women but this is variable. The glandular cells have small dark regular nuclei that may be round, ovoid, or low columnar; in cystic glands, the nuclei are often compressed and attenuated. Sometimes, there is a degree of nuclear pseudostratification, which may result in a false impression of proliferative activity. The cytoplasm is

■ Fig. 7.21 Lymphoid aggregates in endometrium. Lymphoid aggregates are a normal phenomenon within the endometrial stroma

usually scanty. High-power examination is required to confirm an absence of mitotic activity, and this is especially so in the distinction between proliferative endometrium and atrophy with small tubular glands and between cystic forms of atrophy and simple hyperplasia. The stroma in postmenopausal endometria may be densely cellular and composed of ovoid to spindle-shaped cells with scant cytoplasm or have a more fibrous appearance than in the premenopausal endometrium; the stroma tends to become more hypocellular and fibrous with advancing age. This may be the direct cause of the cystic change because of blockage of the glands. Lymphoid aggregates are often prominent (> Fig. 7.21), more so than in premenopausal endometria; it is not clear whether this is due to an actual increase in the number of aggregates or due to them being more obvious because of the glandular atrophy. Sometimes, occasional mitotic figures are seen in the glands of postmenopausal endometria with no proven source of estrogenic stimulation. This may occur in women in whom the menopause appears gradually and also with uterine prolapse. The postmenopausal endometrium is hormone receptor positive, like that of premenopausal endometria, and retains the capacity to respond to estrogenic stimulation.

The morphological features of postmenopausal endometria are similar to those of atrophic endometrium due to other causes, for example, exogenous hormones, although there is often also stromal decidualization in those patients taking progestogen-only compounds or combined preparations containing a progestogen. Atrophic endometrium may also occur in young patients with premature ovarian failure, either idiopathic or due to surgical removal, chemotherapy, or radiotherapy.

Endometrial Sampling

Most endometrial samples are taken during the investigation of abnormal uterine bleeding in pre-, peri-, or postmenopausal women. Traditionally, most endometrial samples were obtained by cervical dilatation and curettage (D and C). It was believed that this had a therapeutic effect in some cases of abnormal uterine bleeding, as well as producing a sample for histological examination. Nowadays, most endometrial samples are outpatient biopsies performed by pipelle or other methods of endometrial sampling. In contrast to the traditional D and C sample, pipelle biopsies do not require an anesthetic and are often performed in conjunction with ultrasound examination and/or hysteroscopy, both of which may identify focal lesions that could be missed by pipelle biopsy. The disadvantages of a pipelle biopsy are that often only very scant tissue is obtained, especially in a postmenopausal woman with an atrophic endometrium, and focal lesions may be missed. Issues relating to adequacy of endometrial samples are discussed below. On occasions, a pipelle biopsy is followed by a D and C, for example, when there is a suspicion of malignancy and pipelle biopsy produces only a scant amount of tissue, which is nondiagnostic or when there are worrying features on the pipelle sample that are not diagnostic of malignancy. As stated earlier, endometrial sampling is nowadays not widely undertaken in the investigation of infertility, but when this is the case, the timing of the biopsy is important; ideally, the biopsy should be taken in the mid-secretory phase between the 7th and 11th postovulatory days. Endometrial polypectomy may be undertaken, and in such instances, sampling of the non-polypoid endometrium should also be undertaken. Transcervical resection of the endometrium (TCRE) may be performed under a variety of circumstances, such as in the management of menorrhagia or multiple polyps or occasionally when conservative nonsurgical management of an endometrial hyperplasia or a low-grade endometrioid adenocarcinoma is undertaken. This procedure produces a specimen consisting of multiple chippings, similar to prostatic chips. Chips should be weighed (this should also be done when biopsy or D and C yields a significant amount of tissue but may be impractical with very scant specimens). All endometrial specimens should be submitted in their entirety for histological examination. The exception is large endometrial polyps where representative sampling may be undertaken; it should be remembered that endometrial polyps may be involved by small carcinomas or by serous endometrial intraepithelial carcinoma (serous EIC), and, as a rule of thumb, at least one block per cm should be taken of large endometrial polyps. Endometrial chips should be orientated if possible since poorly orientated specimens, especially if tangentially sectioned, may result in a histological suspicion of adenomyosis; it is doubtful whether adenomyosis can be reliably diagnosed on a TCRE sample, although this can be suspected on wellorientated specimens, especially when there is smooth muscle hypertrophy surrounding the islands of endometrial tissue within the myometrium. A related, although uncommon, problem with endometrial resection specimens is the potential for overdiagnosis of myometrial invasion in cases of endometrial hyperplasia or adenocarcinoma; again, this is due to poor orientation and tangential sectioning.

In evaluating any endometrial specimen, an adequate clinical history is important, including the age of the patient and the reason for biopsy. Knowledge of the menopausal status as well as the date of onset of the last menstrual period (LMP) and the length of the menstrual cycle in premenopausal women should be provided. In some cases of "postmenopausal bleeding," the patient is not actually postmenopausal but rather perimenopausal with a prolonged interval between periods, resulting in the clinician and the patient assuming that the woman is postmenopausal. Many women with abnormal uterine bleeding have been prescribed exogenous hormones, especially progestins, before biopsy to control the bleeding and this information is not always conveyed to the pathologist. Other women may be taking hormone replacement therapy (HRT) or contraceptive agents. These hormonal compounds may alter the morphological appearance of the endometrium and a knowledge that these, and relevant medications such as tamoxifen, are being taken is paramount to the pathologist.

Criteria for Adequacy of Endometrial Sample

With the increasing trend to perform outpatient endometrial pipelle biopsies rather than formal curettage, pathologists are dealing with increasing numbers of endometrial specimens in which there is scant, or even no, endometrial tissue, especially when the endometrium is atrophic. These specimens may consist entirely of superficial strips or wisps of atrophic glands (\bigcirc *Fig. 7.22*), with little or no stroma, admixed with cervical mucus, ectocervical or endocervical tissue, and tissue from the

Scanty endometrial biopsy. Endometrial pipelle biopsy in postmenopausal woman where the specimen consists entirely of superficial strips of atrophic endometrial glands without accompanying endometrial stroma

lower uterine segment. Paradoxically, it often takes the pathologist longer to examine such specimens since no underlying architecture is present, and the tissue must be examined carefully under high power to look for mitotic activity, which is abnormal in a postmenopausal endometrium. In specimens such as this, it is controversial as to what constitutes an adequate or inadequate specimen. Designation of a biopsy as inadequate may be of importance since this can have management and medicolegal implications. For example, some clinicians routinely perform a repeat biopsy when an earlier sample has been reported as inadequate while others do not. A biopsy reported as inadequate may suggest to some that the clinician is at fault or has not undertaken the biopsy procedure correctly. While this may be the case in some instances, in most it is not. In published studies, inadequate rates of outpatient endometrial biopsies range from 4.8 to 33% [1, 2, 22, 52, 94], but in most of these studies, the criteria for adequacy are not clear. It is also worth noting that studies have shown that with an atrophic endometrium and no focal lesion, minimal tissue is the norm with a pipelle biopsy, and there is little chance of missing significant pathology [7]. Although it is difficult to recommend precise criteria for adequacy, caution should be exercised before categorizing an endometrial biopsy as inadequate or insufficient. In the majority of cases, the presence of only scant tissue in an endometrial specimen is not a reason for a repeat biopsy, provided the endometrial cavity has been entered, and at least some endometrial tissue is present in the biopsy specimen to confirm this,

Fig. 7.23 Telescoping (glands within glands). This is a common artifact in endometrial biopsy specimens

although theoretically endometrial type glands with or without stroma could be derived from tuboendometrial metaplasia or endometriosis within the cervix.

It has been suggested that with an endometrial biopsy containing scant tissue that cannot be typed, the term unassessable is more appropriate than inadequate or insufficient [120]. In such cases, the gynecologist should correlate the biopsy results with the ultrasonic and/or hysteroscopic findings. If there is a clinical suspicion of hyperplasia or malignancy, for example, if there is recurrent postmenopausal bleeding, or if the ultrasonic and/or hysteroscopic findings are worrying, then D and C should be performed. If the above investigations suggest an atrophic endometrium, rebiopsy is probably unnecessary.

Artifacts in Endometrial Biopsy Specimens

There are several common artifacts in endometrial biopsy specimens that have received scant attention in the literature [91]. Occasionally, these may be misinterpreted as an endometrial hyperplasia or even a carcinoma if not appreciated to be artifactual. Telescoping is common and refers to the presence of glands within glands (\bigcirc *Fig. 7.23*). This artifact seems to be a result of mechanical disruption and "snap back" of the glands during biopsy, resulting in a form of intussusception. Artifactual crowding and compression of glands are also common and may result in consideration of a complex endometrial hyperplasia. With this artifact, the glands often become "molded" together, and there is commonly tearing of the tissue around the

glands, which is a clue to the artifactual nature (\bigcirc *Fig.* 7.24). An artifact that is especially common with, but not exclusive to, outpatient biopsies is the presence of superficial strips of endometrial epithelium, sometimes accompanied by a little stroma, with a pseudopapillary architecture (\bigcirc *Fig.* 7.25). This may result in consideration of a wide range of papillary lesions, benign and malignant, which occur in the endometrium. Such superficial strips of

Fig. 7.24

Glandular molding. A common artifact in endometrial biopsies is glandular "molding." There is tearing of the tissue around the glands, which is a clue to the artifactual nature pseudopapillary epithelium, which are generally atrophic, should be examined carefully under high power to look for proliferative activity and nuclear atypia. Crushed endometrial glands and stroma may be extremely cellular and can cause concern. Extensive crush artifact is more likely to occur in biopsies from atrophic endometrium in postmenopausal patients. As with the examination of other tissues, crushed elements should not be viewed in isolation. Problems associated with poorly orientated endometrial resection specimens have already been described. Another artifact that may be seen in endometrial resection specimens and which is secondary to cautery is vacuolation of the endometrial stromal cells, resulting in a signet-ring appearance (> Fig. 7.26); this is a similar phenomenon to the vacuolation of cervical stromal cells, which may occur secondary to cautery [93].

Contaminants and Other Elements in Endometrial Biopsies

Not uncommonly, fragments of tissue other than from the endometrium are present in endometrial biopsy or curettage specimens. Superficial myometrium is commonly seen, especially in vigorous curettage specimens and in postmenopausal women with an atrophic endometrial lining. It is very common to see cervical mucus, often admixed with neutrophils, histiocytes and giant cells (\bigcirc *Fig. 7.27*), and cervical tissue in endometrial biopsy specimens. The cervical tissue usually takes the form of strips of

• Fig. 7.25 Pseudopapillary endometrium. Endometrial biopsy composed of superficial strips of endometrial epithelium with a pseudopapillary architecture

Fig. 7.26 Vacuolation of endometrial stromal cells. Vacuolation, resulting in a signet-ring appearance, may occur secondary to thermal artifact

endocervical glandular or squamous epithelium, sometimes with accompanying stroma. The squamous epithelium may be immature metaplastic in type. Usually the cervical origin is obvious but occasionally this is not the case and diagnostic confusion may ensue. For example, if cervical glandular elements exhibiting microglandular hyperplasia are identified within an endometrial biopsy specimen, this may result in consideration of an endometrial hyperplasia or carcinoma. The confusion may be

Fig. 7.27

Cervical mucus in endometrial biopsy specimen. In many endometrial biopsies, mucus derived from the cervix is present, often admixed with neutrophils, histiocytes, and giant cells heightened by artifactual apposition such that it can appear that the endometrial and cervical tissue is in continuity; assessment of whether the accompanying stroma is endometrial or cervical in type may assist in interpretation. Sometimes, dysplastic cervical squamous or glandular epithelium or tissue derived from a cervical neoplasm is present in an endometrial biopsy specimen. Fragments of fallopian tube epithelium may also be seen occasionally.

On occasions, aggregates or sheets of histiocytes may be seen in an endometrial biopsy specimen, either free floating or within the endometrial stroma. Small numbers of histiocytes are not uncommon and are usually inconspicuous but when present in large aggregates this may result in consideration of an epithelial or stromal neoplasm () Fig. 7.28). Recognition of the characteristic lobated, reniform, or coffee-bean nucleus of histiocytes assists and immunohistochemical staining for histiocytic markers, such as CD68 or lysozyme, may be of value. The histiocytes are probably a reaction to debris within the endometrial cavity and, when present in large numbers, this has been referred to as nodular histiocytic hyperplasia [74]. Occasionally, mitotic figures may be identified within the aggregates of histiocytes, and there may be prominent cell membranes. Rarely, the histiocytes have intracytoplasmic vacuoles and a signet-ring appearance [66] (> Fig. 7.29) raising the possibility of a signet-ring carcinoma; staining for epithelial and histiocytic markers facilitates the diagnosis. Decidualized and predecidualized endometrial stromal cells may also contain intracytoplasmic vacuoles and simulate signet-ring cell

■ Fig. 7.28 Histiocytes in endometrial biopsy. Aggregate of histiocytes in an endometrial biopsy composed of cells with a coffeebean nucleus and abundant eosinophilic cytoplasm

Extrauterine Tissues in Endometrial Biopsy Specimens

Rarely, extrauterine tissues are present in an endometrial biopsy specimen and this raises the possibility that uterine perforation has occurred during the current biopsy procedure or some time previously and that a fistulous tract is present. The most common extrauterine tissue is adipose tissue. Although this may potentially be derived from a uterine lipoleiomyoma, lipoma, hamartomatous lesion [83], other pathological lesion containing adipose tissue or represent metaplastic adipose tissue within the endometrial stroma, in most instances the adipose tissue is derived from the pelvic soft tissues or omentum and indicates perforation. Occasionally, the adipose tissue is accompanied by fibrinous material and mesothelial cells; this is a reflection of underlying pelvic pathology with resultant mesothelial proliferation, which results in fixation of the uterus within the pelvis and makes perforation more likely. In some cases, the patient comes to no harm because of the perforation, presumably due to contraction of myometrial smooth muscle sealing off the defect, but in other instances, a pelvic and/or abdominal inflammatory process ensues and the patient becomes symptomatic. For this reason, the identification of adipose tissue in an endometrial biopsy specimen should prompt a phone call to the clinician. Rarely, other extrauterine tissues, such as intestinal mucosa, may be present in an endometrial biopsy specimen secondary to perforation.

Endometritis

Endometritis is a histological diagnosis based upon the identification within the endometrium of an abnormal pattern of inflammatory infiltrate; as such, it must be distinguished from the normal hematopoietic component of the endometrium (see above). Most cases of endometritis occur in the reproductive years but sometimes postmenopausal women are affected. Presentation is typically with abnormal vaginal bleeding, most commonly intermenstrual bleeding or menorrhagia. Endometritis may have both an infective and noninfective etiology. The endometrium is relatively resistant to ascending infection from the lower female genital tract because of the barrier created by the cervix and the cervical mucus. However, on occasions, an endometritis occurs secondary to ascending infection, and this is often a component of pelvic inflammatory disease with inflammation elsewhere in the genital tract. Predisposing factors to endometritis include a recent pregnancy, the presence of an intrauterine device (IUD), cervical stenosis, and prior instrumentation. Endometritis may also accompany a pathological lesion within the uterus, such as an endometrial polyp, hyperplasia, carcinoma, or a leiomyoma. Usually, the morphological appearances are nonspecific, and, in the absence of an associated pathological lesion, an underlying cause cannot be determined, although occasionally the histological features suggest a particular etiology. Specific forms of endometritis are discussed later. Endometritis has traditionally been divided into acute and chronic forms, but these constitute a continuum, and often there is an admixture of acute and chronic inflammatory cells.

Endometritis may be focal or diffuse and can range from a subtle finding to a pronounced inflammatory reaction. Usually, the endometrial glands exhibit proliferative activity, and there may be mild glandular architectural distortion, in the form of occasional dilated glands. There is often associated surface breakdown with features identical to those seen in menstrual breakdown and breakdown due to non-menstrual causes. In some cases, an initial low-power clue to the diagnosis of endometritis is spindle cell alteration of the stroma (\bigcirc *Fig. 7.30*), although this feature is not specific and is not always present. In other cases, the stroma may be edematous. In acute endometritis, the predominant inflammatory cells are neutrophils and collections of these may be seen within glandular

■ Fig. 7.30 Endometritis. In some cases of endometritis, the endometrial stroma has a spindle cell appearance

lumina, forming microabscesses (\bigcirc *Fig. 7.31*), or surrounding glands; neutrophils are often most easily seen just deep to the surface endometrium. In some cases, there is surface erosion with fibrinous debris and numerous acute inflammatory cells. By tradition, an unequivocal diagnosis of endometritis requires the presence of plasma cells (\bigcirc *Fig. 7.32*) since neutrophils are found normally in the endometrium just prior to and in association with menstruation and lymphocytes, including lymphoid aggregates, are a normal component of the endometrial

Fig. 7.31

Acute endometritis. In acute endometritis, neutrophils are present, sometimes forming microabscesses within glandular lumina stroma. However, in acute forms of endometritis, plasma cells may be absent or few in number. Plasma cells are usually most numerous surrounding endometrial glands and just deep to the surface epithelium. A form of endometritis without plasma cells has been described and termed focal necrotizing endometritis [12]. The histological features of this are of focal, patchy inflammation comprising lymphocytes and neutrophils and centered on individual glands. Due to the focal nature, this form of endometritis can be easily overlooked.

Besides plasma cells, there are also increased numbers of lymphocytes in chronic endometritis, sometimes with prominent and unusually large lymphoid aggregates and occasionally with the formation of lymphoid follicles. Other inflammatory cells, which may be a component of endometritis, include eosinophils and histiocytes. Usually, histiocytes are inconspicuous since they are admixed with other inflammatory cells but occasionally large numbers of histiocytes, sometimes with abundant foamy cytoplasm, are present. When these are abundant, this is referred to as xanthogranulomatous endometritis may occur in association with an endometrial hyperplasia or carcinoma and secondary to cervical stenosis and obstruction.

In endometritis, reactive and metaplastic changes may involve the endometrial surface and glandular epithelium. Squamous, ciliated, eosinophilic, and other forms of epithelial metaplasia can occur, and there may be mild nuclear atypia with nuclear enlargement and prominent

• Fig. 7.32 Chronic endometritis. In cases of chronic endometritis, plasma cells are present within the endometrial stroma

Fig. 7.33 Xanthogranulomatous endometritis. Large numbers of foamy histiocytes are present within the endometrial stroma

Syndecan immunohistochemical stain in endometritis. Syndecan (CD138) immunohistochemical staining may be useful in identifying plasma cells. The endometrial glands are also positive

nucleoli. As stated, sometimes there are mild architectural changes with occasional dilated glands, but significant glandular crowding is not a feature of endometritis.

As stated, there may be problems in identifying plasma cells when they are few in number, especially in suboptimally stained sections. Endometrial stromal cells may have a plasmacytoid appearance, especially predecidualized cells in the mid-and late-secretory phase, and unequivocal plasma cells with eccentric nuclei and a perinuclear hof should be present. Occasional plasma cells may be seen in an otherwise normal endometrium and, in the absence of at least some of the other features of endometritis described, a rigorous search for plasma cells is not justified. Plasma cells may be present in the stroma of an endometrial polyp and this is not classified as an endometritis unless these are also seen in the non-polypoid endometrium. In problematic cases, histochemical or immunohistochemical stains may be of value in identifying plasma cells. Histochemical stains include methyl green pyronin and immunohistochemistry may be performed using plasma cell markers such as VS38 or syndecan (CD138) [10, 11, 77]. However, endometrial glandular epithelium commonly reacts with both VS38 and syndecan (> Fig. 7.34) and endometrial stromal cells may be VS38 positive; therefore, syndecan is more useful than VS38, in that although endometrial glandular epithelium is commonly positive, stromal cells are negative. Immunohistochemistry or in situ hybridization for kappa and lambda immunoglobulin light chains may also help demonstrate plasma cells but this is not routinely performed [41].

Fig. 7.35

CD20 in chronic endometritis. Chronic endometritis in which increased numbers of B lymphoid cells (CD20 positive) are present within the endometrial stroma

Immunohistochemical staining with B lymphoid markers (CD20 and CD79a) may also assist in distinguishing between the physiological endometrial lymphocytic infiltrate and the inflammatory infiltrate of endometritis. Normally, the vast majority of lymphoid cells within the endometrial stroma are T cells (CD3 positive) with B lymphocytes accounting for about 1% of all endometrial leucocytes [96]. B lymphoid cells are largely confined to lymphoid aggregates within the endometrial basalis with occasional individual cells in the functionalis. In most cases of chronic endometritis, there are increased numbers of B lymphoid cells, and these also have an abnormal location being found outside lymphoid aggregates within the stroma and sometimes intraepithelially and within glandular lumina (> Fig. 7.35) [37]. The number of T lymphocytes, histiocytes, and granulated lymphocytes in endometritis does not differ significantly from controls. It is emphasized that plasma cells do not usually stain with CD20 but are positive with CD79a.

Specific Forms of Endometritis

Chlamydia Trachomatis

Chlamydia trachomatis has been isolated from cases of both acute and chronic endometritis. However, it is unclear whether the organism is causative in such cases or an accompanying pathogen. Chlamydia trachomatis is a relatively common infection in both the upper and lower

female genital tract and may be associated with pelvic inflammatory disease and infertility. Endometritis secondary to Chlamydia trachomatis has no specific histological features, although the inflammatory infiltrate may be intense and lymphoid follicles and large numbers of blasts may be seen [115]. Stromal necrosis and reactive atypia of the endometrial epithelium may be present. Definitive diagnosis in most cases requires culture. However, Chlamydia trachomatis inclusion bodies have been identified within endometrial epithelial cells; these are extremely difficult to detect on hematoxylin-and eosin-stained sections but can occasionally be recognized on Giemsa stain. Immunohistochemical staining may also be of value [155], positivity being localized to the epithelial cells in the form of stippling within supranuclear intracytoplasmic vacuoles. Molecular investigations may also be of value in demonstrating Chlamydia trachomatis infection.

Cytomegalovirus

Cytomegalovirus (CMV) endometritis is rare. It is most common in immunosuppressed patients but occasionally occurs in women with no underlying immune disorder. Typical intranuclear and cytoplasmic CMV inclusions are seen, mainly in epithelial cells but occasionally in stromal or endothelial cells. The other histological features are nonspecific; granulomas have been described in occasional cases [48].

Herpes Simplex Virus

Herpes simplex virus type II rarely results in an endometritis, usually secondary to ascending infection from the cervix and sometimes in women who are immunosuppressed. Typical herpes simplex virus inclusions are present within the glandular epithelium and there are multinucleate cells with molded ground glass nuclei. The other histological features are nonspecific, but patchy necrosis of the endometrial glands and stroma with an associated inflammatory infiltrate may occur [38]. Optically clear nuclei, due to the accumulation of biotin, associated with the presence of trophoblast may superficially resemble herpes simplex virus inclusions; immunohistochemical staining may be of value in such instances.

Mycoplasma

Rarely mycoplasma organisms, usually ureaplasma urealyticum, result in an endometritis. The inflammatory

infiltrate is typically focal and has been termed "subacute focal endometritis" [73]. The inflammatory cells comprise mainly lymphocytes and histiocytes with few neutrophils and plasma cells and they tend to be concentrated beneath the surface epithelium, adjacent to glands, or around spiral arteries. Granulomas have rarely been described.

Actinomyces

The gram-positive anaerobic bacterium actinomyces may result in an endometritis, often in association with a longterm IUD. The bacterial colonies form the so-called actinomycotic granules (AMGs), referred to as sulfur granules because of their tan to yellow color on gross examination. It is important to recognize actinomyces since the organism may result in ascending infection with resultant tubo-ovarian abscess formation and pelvic inflammatory disease. Histologically, AMGs are usually seen on the endometrial surface or within the superficial stroma as nonrefractile granules with thin basophilic radiating filaments and sometimes a dense more eosinophilic granular core (> Fig. 7.36). They are Gram positive on Brown and Brenn stain and are highlighted with Gomori methenamine silver stain [122]. Although the diagnosis can be strongly suspected on morphological examination, culture is recommended for confirmation since other grampositive filamentous bacteria may be found in the gynecological tract. Because of the potential complications, actinomyces must be distinguished from pseudoactinomycotic radiate granules (pseudo-sulfur granules).

Fig. 7.36

Actinomycotic granules. Actinomycotic granules (AMGs) composed of thin basophilic radiating filaments with a dense more eosinophilic granular core

Pseudoactinomycotic radiate granules. Pseudoactinomycotic radiate granules with thick irregular club-like peripheral projections without a central dense core

These are noninfectious lesions, most commonly seen in association with an IUD, but sometimes in non-IUD users. They consist of thick irregular club-like peripheral projections without a dense central core (> Fig. 7.37). An associated inflammatory response may be present. With Brown and Brenn stains, there is diffuse, intense nonspecific staining, while silver stains are negative. Pseudoactinomycotic radiate granules are probably more common than actinomyces [110] and occasionally the two coexist. The former may also be seen in association with pelvic inflammatory disease. The noninfectious nature of pseudoactinomycotic radiate granules is supported by microbiological and histochemical studies and ultrastructural analysis. Their exact composition and nature is unknown but they may represent an unusual response to foreign bodies (Splendore-Hoeppli phenomenon). Their main significance is that they may be mistaken for AMGs.

Fungi and Parasites

Fungi and parasites may rarely result in an endometritis, more commonly in underdeveloped countries. Blastomycosis (*Blastomyces dermatitidis*) and coccidioidomycosis (*Coccidioides immitis*) may result in an endometritis as part of a disseminated infection. Granulomas may be a component of the inflammatory infiltrate. There have been occasional reports of candidal and cryptococcal endometritis. Gomori methenamine silver and periodic acid-Schiff (PAS) stains are helpful in identifying these organisms.

Schistosoma, Enterobius vermicularis, and Echinococcus granulosus are rare causes of endometritis in developed countries but schistosomiasis is endemic in some parts of the world. Schistosomal endometritis may be mild or severe and is characterized by granulomatous inflammation with lymphocytes, plasma cells, eosinophils, and histiocytes, sometimes closely simulating a tubercle. The endometrial surface may be ulcerated and replaced by granulation tissue. Diagnosis is made by identifying the ova in tissue sections or in smears of vaginal secretions. Toxoplasmosis (*Toxoplasma gondii*) evokes a nonspecific inflammatory reaction in the endometrium. The microorganism can be identified by immunofluorescence.

Malakoplakia

Malakoplakia may involve several organs, most commonly the urinary bladder, and is characterized by the presence of sheets of foamy histiocytes (von Hansemann's histiocytes) containing Michaelis-Gutmann bodies. These are small, round, laminated calcospherites, which are present in the cytoplasm of the histiocytes and in an extracellular location. They contain calcium and can be demonstrated by von Kossa stain. The histiocytes are often admixed with other inflammatory cells, including plasma cells and neutrophils. Occasional examples have been reported in the endometrium [145]. Malakoplakia is a result of an abnormal immune response to bacteria, most commonly Escherichia coli, which are retained within the phagolysosomes of the histiocytes but are not digested; the Michaelis-Gutmann bodies are the result of mineral encrustation of incompletely digested bacteria.

Lymphoma-like Lesion

The so-called lymphoma-like lesions are more common within the cervix but have rarely been described in the endometrium [158] (see ◆ Chap. 21, Hematologic Neoplasms and Selected Tumor-Like Lesions Involving the Female Reproductive Organs). Histologically, they are characterized by dense aggregates of lymphoid cells, often with large numbers of blasts and a starry-sky appearance, forming a superficial band-like infiltrate, this only being appreciated on a hysterectomy or endometrial resection specimen. Lymphoid follicles with germinal centers, which may be large and ill defined, are typically present. Along with germinal centers and large numbers of blasts, a mixed inflammatory infiltrate is present with small lymphocytes, plasma cells, neutrophils, and histiocytes. Lymphoma-like lesions represent an exaggerated form of chronic endometritis. The polymorphic nature of the infiltrate together with the presence of germinal centers and the superficial location of the inflammation (as stated, only appreciated on hysterectomy or endometrial resection specimens) help to distinguish lymphoma-like lesion from malignant lymphoma, as does the absence of a mass lesion grossly. Immunohistochemistry for kappa and lambda light chains or molecular investigations to demonstrate a polyclonal population may also be of value. Occasional cervical cases have been associated with Epstein–Barr virus infection [158].

Endometrial Granulomas

Granulomas within the endometrium are rare. Worldwide, the most common cause is tuberculosis and, although rare in developed countries, granulomatous endometritis should be considered as tuberculous in origin until proven otherwise. Tuberculosis of the endometrium usually occurs in premenopausal women and is rare after the menopause. Caseous necrosis is characteristic of tuberculous granulomas but due to the constant shedding associated with menstruation, endometrial granulomas in patients with tuberculosis are often noncaseating. Tubercle bacilli are seldom identified on Ziehl-Neelson stained sections, and culture should be undertaken in all cases in which histological examination raises the possibility of tuberculosis. Other infectious causes of granulomatous endometritis include various fungi, schistosomiasis, Enterobius vermicularis, and Toxoplasma gondii (see section > Fungi and Parasites). As already discussed, granulomas are occasionally a feature of cytomegalovirus and mycoplasma endometritis.

Endometrial granulomas, especially when well circumscribed, also raise the possibility of sarcoidosis and there have been rare reports of sarcoidosis involving the endometrium [117]. A granulomatous reaction to keratin may be seen in association with an endometrioid adenocarcinoma or atypical polypoid adenomyoma exhibiting squamous differentiation. Occasionally, such keratin granulomas may also be found on the surface of the ovaries, the fallopian tubes, or on the omentum or peritoneum; this is secondary to spread of keratin through the fallopian tubes and in the absence of associated neoplastic cells does not represent tumor spread. Foreign body granulomas in the endometrium may be secondary to talc or other substances and in association with an IUD. A palisading granuloma with fibrinoid

 Fig. 7.38
Granulomatous endometritis. A single granuloma is present within the endometrial stroma

material and a surrounding histiocytic and giant cell reaction, the features resembling a rheumatoid nodule, may occur secondary to endometrial ablation; usually, the entire endometrium or much of the endometrium is affected, and well-circumscribed granulomas are not generally found. A similar picture may be seen secondary to endometrial resection. In rare instances, there is no obvious cause for endometrial granulomatous inflammation, so-called idiopathic granulomatous endometritis (\triangleright *Fig. 7.38*).

Ligneous (Pseudomembranous) Endometritis

Ligneous (pseudomembranous) endometritis is discussed here, although the term endometritis is not strictly appropriate since there is often little or no inflammatory infiltrate. Ligneous disease is an inherited autosomal recessive condition. The histological features in the endometrium are identical to those when other sites are affected, most commonly the conjunctiva. Ligneous disease is rare in the female genital tract and most commonly affects the cervix, vulva, or vagina. Rare endometrial cases have been described [129]. When the endometrium is affected, this may result in dysmenorrhea and infertility. Histology shows amorphous eosinophilic material, somewhat similar to amyloid, but Congo red negative, which represents fibrin. There may be associated mild inflammation, including occasional multinucleate giant cells. The inflammatory infiltrate may be more severe if there is surface ulceration. The underlying etiology is due to absent or low plasminogen levels, which results in accumulation of fibrin.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding (DUB) is abnormal uterine bleeding in a premenopausal woman resulting from alterations in the normal cyclical changes of the endometrium and without an underlying specific pathological cause such as endometritis, polyps, exogenous hormones, hyperplasia, or carcinoma. In many cases, DUB is probably secondary to endogenous hormone imbalance. There are several morphological alterations of the endometrium that are characteristic of DUB, the most common being those associated with anovulatory cycles or luteal phase defects. These can be regarded as estrogen-related and progesterone-related, respectively, and are discussed in the next sections. Often DUB is managed by hormonal therapy and a biopsy only performed when symptoms persist; the hormone therapy may result in modification of the morphology. It is stressed that DUB is not a pathological diagnosis but rather a clinical term. A common, but not invariable, feature of biopsies from patients with DUB is the presence of glandular and stromal breakdown. The features associated with this are not unique to DUB and are seen in menstrual endometrium and in bleeding associated with a variety of organic disorders. It is important to recognize the features of breakdown and to distinguish them from other pathological lesions. It is also important to realize that glandular and stromal breakdown is a nonspecific feature and that the intact endometrium must be assessed to evaluate the underlying abnormality. Glandular and stromal breakdown may also occur in an atrophic endometrium. The changes associated with glandular and stromal breakdown are described in the next paragraphs. In menstrual endometrium, the features of breakdown are diffuse and occur on a background of secretory endometrium. In contrast, in DUB, the background endometrium is typically nonsecretory in type and breakdown is usually a focal phenomenon, resulting in a heterogeneous pattern with intact fragments of endometrium admixed with fragments exhibiting the features of breakdown. Furthermore, in menstrual endometrium the changes are acute and there are no features of chronic bleeding, such as hemosiderin deposition and accumulation of foam cells.

The morphological features associated with glandular and stromal breakdown are summarized in \bigcirc *Table 7.1*. An early feature is the accumulation of nuclear (apoptotic) debris in the basal cytoplasm of the glandular cells (\bigcirc *Fig. 7.39*) [139]. The stromal cells collapse and aggregate into tight clusters, which are separated by lakes of blood. These clusters of stromal cells, sometime called "stromal blue balls," may form small polypoid extrusions or become detached from the surrounding tissue (\bigcirc *Fig. 7.40*). They are characterized by tightly packed cells with hyperchromatic nuclei and scanty cytoplasm admixed with apoptotic debris. They can exhibit nuclear molding and to the unwary may raise the possibility of small cell carcinoma. However, they are often covered by an epithelial lining, which may be flat or may exhibit the features of papillary syncytial metaplasia (see below) and are associated with other features of breakdown. Because of the stromal collapse, the endometrial glands become disrupted and crowded (\bigcirc *Fig. 7.41*). This glandular crowding may mimic hyperplasia or even

Table 7.1

Foam cell accumulation
Fibrosis and hyalinization

Fig. 7.39

Glandular and stromal breakdown. An early feature is the accumulation of apoptotic debris in the cytoplasm of the glandular epithelial cells

adenocarcinoma but recognition of the other features of breakdown facilitates the diagnosis. Fibrin thrombi are usually seen in small blood vessels, either in the spiral arteries or in superficial ectatic stromal vessels (\bigcirc *Fig.* 7.42). Another consistent feature of breakdown is papillary syncytial metaplasia (\bigcirc *Fig.* 7.10). Synonymous terms include eosinophilic syncytial change and surface syncytial change. The term papillary syncytial metaplasia is a misnomer since this is not a true metaplasia but has rather been variously considered a regenerative reaction to surface breakdown or a degenerative or regressive process [131]. Papillary syncytial metaplasia is characterized histologically by syncytial sheets of epithelial cells with indistinct cell borders that form micropapillary structures, sometimes with small glandular lumina. The syncytia are devoid of stromal support, lacking fibrovascular stromal cores. The cells usually have eosinophilic cytoplasm and there is often a neutrophilic infiltrate. There may be mild nuclear atypia and sometimes mitoses are identified.

Other features of breakdown, which are not present in all cases, include hemosiderin deposition, free either within the stroma or within histiocytes (\bigcirc *Fig. 7.43*) and

■ Fig. 7.40 Breaking down endometrium. With breakdown, the stromal cells aggregate into stromal "blue balls"

■ Fig. 7.42 Breaking down endometrium. With breakdown, fibrin thrombi are typically seen within blood vessels

• Fig. 7.41 Breaking down endometrium. With breakdown, the endometrial glands become disrupted and crowded because of stromal collapse

• Fig. 7.43 Chronic breakdown. With chronic breakdown, hemosiderin pigment may accumulate within histiocytes within the endometrial stroma

accumulation of foam cells, neither of which occurs in normal cyclical endometrium during the reproductive years. These features usually indicate chronic bleeding. The foam cells were initially thought to represent histiocytes, but it has been suggested that they may represent endometrial stromal cells, which become distended with lipid following erythrocyte breakdown [42]. Chronic bleeding may also occasionally result in focal stromal fibrosis and hyalinization.

Estrogen Related Dysfunctional Uterine Bleeding, Including Endometrium Associated with Anovulatory Cycles

This endometrial morphology is most common in the perimenopausal years where it is usually secondary to anovulatory cycles with resultant absence of development of the corpus luteum and decrease in progesterone secretion; in fact, this is sometimes referred to as anovulatory endometrium. The term persistent proliferative endometrium has also been used. The underlying causes are complex but many cases may be a result of hypothalamic dysfunction. The developing follicles persist for a variable period of time and produce estradiol before undergoing atresia at which time estrogen withdrawal bleeding occurs. In other cases, estrogen breakthrough bleeding occurs when the persisting follicles produce estradiol resulting in the proliferating endometrium becoming thicker and outgrowing its blood supply. The usual presentation is with perimenopausal bleeding, but younger women may also be affected, for example, perimenarchal adolescents in whom regular ovulatory cycles are not established, those with polycystic ovarian syndrome (Stein-Leventhal syndrome), or older women taking unopposed estrogens or with an increase in endogenous estrogens, for example, secondary to obesity. Anovulatory cycles may also occur sporadically throughout the reproductive years. The histological features involve the entire endometrial compartment and are those of proliferative endometrium but with superimposed breakdown, as described above [103]. The extent of breakdown is highly variable and ranges from minute focal changes to a widespread phenomenon involving most of the specimen. There are often foci of ciliated (tubal) or other types of epithelial metaplasia that are randomly dispersed.

With chronic anovulatory cycles, there is abundant proliferative endometrium and mild degrees of disorganization with dilated glands may occur. This results in a picture, which is neither normal proliferative nor hyperplastic and which is referred to as disordered proliferative Benign Diseases of the Endometrium

endometrium (**)** Fig. 7.44). Occasional dilated glands within an otherwise normal proliferative endometrium does not warrant a diagnosis of disordered proliferation; in other words, there should be significant numbers of dilated glands and these should have a widespread distribution, although they are admixed with normal proliferative glands. In disordered proliferative endometrium, the normal gland to stroma ratio is largely maintained although there may be focal mild glandular crowding and branching. In cases with significant numbers of dilated glands, the morphological appearances merge with and overlap with those of simple hyperplasia; in fact, disordered proliferative endometrium and simple hyperplasia almost certainly constitute a continuum, and it is likely that both represent a response to unopposed estrogens and not a true premalignant lesion, although there is a small increased risk of the development of an endometrioid adenocarcinoma. In simple hyperplasia, there is usually more glandular dilatation, with a paucity of normal proliferative glands, and the glands exhibit more budding and branching. However, there is significant interobserver variability in the distinction between disordered proliferative endometrium and simple hyperplasia, and, as stated, these form part of a continuum without sharply defined borders. Disordered proliferative endometrium may occasionally be confused with a polyp because of the glandular architectural distortion and dilatation; however, the fibrous stroma and thick-walled stromal blood vessels characteristic of a polyp are absent and disordered proliferation involves the entire endometrium.

 Fig. 7.44
Disordered proliferative endometrium. Occasional cystically dilated glands are present within an otherwise typical proliferative endometrium

Cystic atrophy may also enter into the differential diagnosis but in this there is an absence of mitotic activity and the cells lining the glands are attenuated. Menstrual shedding following ovulation often results in disordered proliferative endometrium reverting to normal.

Progesterone-Related Dysfunctional Uterine Bleeding-Luteal Phase Defects

Luteal phase defects (also known as inadequate luteal phase, secretory insufficiency, or inadequate secretory phase) are a relatively common cause of DUB and also of ovulatory infertility. Although ovulation occurs, there is a relative or absolute insufficiency of progesterone secretion by the corpus luteum, which may either regress prematurely or fail to produce an adequate amount of progesterone. As a consequence, the luteal (secretory) phase does not develop appropriately, the secretory features in the endometrium being poorly developed. The underlying cause is unknown but is thought to be a result of hypothalamic or pituitary dysfunction, which results in decreased levels of follicle stimulating hormone (FSH) and abnormal luteinizing hormone (LH) secretion. Because of inadequate progesterone secretion, there may be a lag in the histological date of the endometrium of at least two days compared to the actual postovulatory date. Other morphological features in some cases include discordance in development of the glands and stroma and different areas of the endometrium exhibiting marked variation in development; for example, some areas may exhibit early secretory activity while others show predecidual change. Alternatively, the glands may exhibit hypersecretory features while the stroma lacks predecidual change. Although the endometrium exhibits a secretory pattern, often this cannot be assigned to any day of the normal cycle. In addition to the features described, there is surface breakdown. The diagnosis can be made by a combination of repeated biopsies over several cycles and serial hormone measurements. In other cases, irregular shedding may be a result of a persistent corpus luteum with prolonged progesterone production. This is a poorly understood form of DUB and, as such, the histological features are not well described.

Effects of Exogenous Hormonal Agents and Drugs

There are a plethora of exogenous hormonal agents in widespread use for a variety of indications including

contraception, alleviation of menopausal symptoms, management of organic lesions or DUB, treatment of infertility, management of endometrial hyperplasia or carcinoma, and endometrial prophylaxis in patients with hyperestrogenic states or taking medications such as tamoxifen. The effects of the various hormonal agents on the endometrium is varied, although in many instances predictable, and depends on a number of factors, including the menopausal status of the patient, the exact composition of the hormonal preparation, and the dose and duration of administration. Not uncommonly, the endometrium is biopsied in patients taking exogenous hormones, for example, when abnormal bleeding occurs, when hormones do not correct suspected DUB, or when the effect of hormonal agents on the endometrium is assessed. Hysterectomy or endometrial resection may also be performed in patients taking exogenous hormones. Some nonhormonal agents may also result in endometrial morphological changes, although much less commonly than with hormonal compounds. In the following sections, the effects on the endometrium of the most common hormonal agents and of some nonhormonal medications are described. Full details regarding the preparations being taken are obviously of paramount importance to the pathologist in assessing the endometrium but often the details are incomplete or not relayed to the pathologist at all. As such, the pathologist should always suspect the possibility of exogenous hormone use, especially when the endometrial morphology does not correspond to a normal cyclical or postmenopausal appearance.

Estrogen-Only Hormone Replacement Therapy (HRT)

There are various synthetic preparations of estrogens that are largely given to perimenopausal or postmenopausal women to treat menopausal symptoms. In women with a uterus, estrogen-only HRT (unopposed estrogen) is contraindicated due to the risk of endometrial proliferative lesions, including hyperplasia and endometrioid adenocarcinoma, and, as such, the use of estrogen-only preparations is unusual in a woman with a uterus. The morphological features in the endometrium vary, but there may be proliferative activity, a picture identical to disordered proliferation, any type of endometrial hyperplasia, or an endometrioid adenocarcinoma [40]. There may be associated surface breakdown and epithelial cytoplasmic change, including squamous and ciliated metaplasia. The risk of malignancy increases with the dose and duration of therapy; those adenocarcinomas that develop are usually, but not always, low grade and early stage. Unopposed estrogens result in endometrial hyperplasia in approximately 20% of women following 1 year of treatment. The "postmenopausal estrogen/progestin intervention (PEPI) trial " concluded that women taking estrogens alone had a high incidence of simple (27.7%), complex (22.7%), and atypical (11.7%) hyperplasia; this was significantly higher than in those taking placebos. The reported risk ratio for endometrial carcinoma in women taking unopposed estrogens has ranged from 2.3 to 10 [53, 116]; the risk persists for many years after estrogen treatment is discontinued [15, 132]. Estrogen-only preparations may also result in proliferative changes and the development of premalignant and malignant lesions in endometriosis; as such, caution should be exercised before prescribing unopposed estrogens following hysterectomy in a woman with known endometriosis.

Combined Estrogen and Progestin Hormone Replacement Therapy

Because of the potential adverse effects of unopposed estrogens, in most women with a uterus an estrogen is combined with a progestin for HRT. Estrogen and progestin combinations may be given sequentially or continuously. Sequential (cyclic) regimes are variable but usually employ daily estrogens for the first 21 to 25 days or the whole of the month with daily progestins added for the last 10 to 13 days; these regimes result in a withdrawal bleed. Continuous combined regimes use both estrogen and progestin daily. With continuous regimes, breakthrough bleeding may occur during the first 6 months, but this bleeding then usually stops. Patients receiving sequential or continuous regimes may undergo biopsy as part of routine surveillance or when unexpected bleeding occurs; there is no correlation between bleeding patterns and endometrial histology. With sequential regimes, the endometrium may exhibit atrophy, secretory, or weak proliferative activity, the latter especially if the biopsy is taken during the period of estrogen therapy. If the endometrium is biopsied during the period of progestin therapy, there may be poorly developed secretory activity in the glands with cytoplasmic vacuoles and scant luminal secretions. Focal glandular and stromal breakdown may also be seen. Sequential regimes do not completely eliminate the risk of carcinoma associated with unopposed estrogen therapy; the prevalence of endometrial hyperplasia associated with sequential HRT is 5.4% and that of atypical hyperplasia 0.7% [140]. It should be remembered that HRT is most commonly taken by postmenopausal women, and in this

age group, there is a background incidence of endometrial hyperplasia and carcinoma. With the continuous combined regimes, the endometrium is usually atrophic or exhibits weak secretory activity (**)** *Fig. 7.45*) and, in many instances, biopsies yield scanty material. There is no increased risk of endometrial proliferative lesions with continuous combined HRT [105], and, in fact, these regimes may protect against the development of endometrial hyperplasia and carcinoma and normalize endometria that have exhibited complex hyperplasia [40, 43, 136]. This suggests that continuous combined HRT is suitable for long-term use in perimenopausal and postmenopausal women. Endometrial polyps are relatively common in women taking combined HRT and appear more common with sequential than continuous regimes [43].

Progestin-Only Compounds

Various forms of synthetic analogues of progesterone, termed progestins, are in widespread use, either alone or in combination with an estrogen. Progestin-only hormonal compounds, taken either orally or systemically, are usually prescribed for abnormal uterine bleeding and result in suppression of ovulation and inhibition of endometrial growth. Progestins may also be given for the management of conditions such as endometriosis, for contraception, or for endometrial protection in patients taking tamoxifen. The effects of progestins on the endometrium are variable and depend on the degree of estrogen priming as well as the type of progestin and the dose

and duration of therapy. They typically result in atrophy of the endometrial glands with predecidual change or decidualization (sometimes termed pseudodecidualization) of the stroma. The endometrial glands are most commonly small tubular and atrophic and lined by cuboidal cells with small round nuclei and scant cytoplasm but sometimes exhibit poorly developed secretory activity. The stroma is usually expanded and composed of predecidualized or decidualized cells with abundant eosinophilic cytoplasm (> Fig. 7.46) with infiltration by granulated lymphocytes; this may mimic endometritis, but plasma cells are absent. Marked decidualization is most common with high-dose progestins and may result in copious polypoid fragments of tissue being obtained at biopsy. These often exhibit superficial breakdown with associated neutrophil infiltration; again this may be mistaken for an endometritis. On occasions, some of the polypoid tissue fragments are totally necrotic, probably due to the stromal expansion with outgrowth of the blood supply. The decidualized stroma may, on occasions, contain cells exhibiting variation in nuclear size and shape with nuclear hyperchromasia; this may result in an alarming appearance, which may be exacerbated by stromal myxoid change (> Fig. 7.47) and cytoplasmic vacuolation, resulting in a signet-ring appearance and mimicry of signet-ring carcinoma. When the progestin dose is low, the stromal cells may not exhibit predecidual or decidual change. The morphological effects associated with the Mirena coil, a progestin containing intrauterine device, are described below.

Decidualized endometrial stroma. Occasionally decidualized stroma contains cells with enlarged nuclei with cytoplasmic vacuolation and stromal myxoid change

Progestin-like Effect Without Exogenous Hormone Use

Occasionally the endometrium exhibits identical changes to those occurring with progestins, namely atrophic glands and stromal decidualization, in a patient not taking exogenous hormones. This may occur in both premenopausal and postmenopausal women and the etiology is, in most cases, poorly understood. In very rare cases, the changes will be secondary to a progesterone secreting neoplasm in an ovary or elsewhere. Most other cases are probably secondary to a persistent functioning corpus luteum or a luteinized unruptured follicle where a follicle develops without ovulation and persists with luteinization of the granulosa and theca cells that produce progesterone. There have also been occasional reports of changes identical to those of progestin effect in postmenopausal women not taking exogenous hormones [24]. The changes may be a result of local mechanical factors rather than a response to progesterone-like hormones. Mechanical stimulation, including biopsy or the presence of an intrauterine device, may rarely result in predecidual or decidual change in the endometrium.

Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone agonists (GnRH agonists), including buserelin acetate, goserelin acetate, and leuprolide acetate, are commonly used in the management of uterine leiomyomas and endometriosis. After initial stimulation of the pituitary gland with increased production of luteinizing hormone (LH) and follicle stimulating hormone (FSH), further administration results in desensitization of the pituitary to GnRH and a subsequent decreased production of LH and FSH. This results in decreased estrogen production by the ovaries and a hypo-estrogenic state. As a consequence, there is shrinkage of uterine leiomyomas, thus alleviating symptoms and potentially allowing myomectomy rather than hysterectomy or vaginal hysterectomy rather than abdominal hysterectomy. The endometrium in patients taking GnRH agonists is typically atrophic with small tubular glands or sometimes the glands exhibit weak proliferative activity. When GnRH agonists are used in conjunction with a progestogen, the endometrium may exhibit decidualization of the stroma.

Androgens

Several androgens are in widespread use, for example, danazol and livial. The main indications for these preparations are the treatment of endometriosis but androgens may also be used in the management of menorrhagia or endometrial hyperplasia or as HRT. In the early stages of androgen therapy, the glands may exhibit weak secretory activity, but with prolonged therapy, the endometrium becomes atrophic [95].

Progesterone Receptor Modulators

Progesterone receptor modulators (PRMs) are synthetic compounds that interact with the progesterone receptor to inhibit or stimulate a downstream hormonal response. Compounds with progesterone receptor antagonist activity are used in contraception and in the management of uterine leiomyomata or endometriosis. The endometrial effects of PRMs have been described [104]. While in some cases, the endometrium is inactive or has a normal cyclical appearance, in a subset of cases, there is asymmetry of stromal and epithelial growth, resulting in prominent cystically dilated glands with admixed estrogenic (mitotic) and progestogenic (secretory) activity. Vascular changes described include a chicken wire vasculature and the presence of thick-walled and ectatic vessels. These novel changes are termed PRM-associated endometrial changes.

Tamoxifen

Tamoxifen is a nonsteroidal triphenylethyl compound that is widely used as adjuvant therapy in the treatment of breast cancer. It is a selective estrogen receptor modulator (SERM) and prolongs overall and disease-free survival in breast cancer, reduces the likelihood of disease in the contralateral breast, and may reduce the risk of development of breast cancer in asymptomatic women with a strong family history. Results from the National Surgical Adjuvant Breast and Bowel Project Breast Cancer Prevention study demonstrated that 5 years of tamoxifen use at a dose of 20 mg/day reduced breast cancer risk in high-risk women by 49% [45]. The efficacy of tamoxifen in breast cancer is due to its antiestrogenic properties that are mediated by competitive binding to the estrogen receptor. However, tamoxifen may also exert a weak estrogenic effect and act on the human endometrium [68, 69, 130]. Transvaginal ultrasonography has shown that the endometrium of tamoxifen-treated postmenopausal patients is significantly thicker than that of age-matched controls of women not taking tamoxifen [19]. Benign postmenopausal endometria of patients treated with tamoxifen exhibit a higher Ki-67 proliferation index than controls of patients not taking tamoxifen [54]. Tamoxifen therapy may result in a spectrum of endometrial proliferative lesions, including polyps, simple, complex, and atypical hyperplasia, and adenocarcinomas. Various other malignancies have also been described in association with tamoxifen. Since the majority of women taking tamoxifen are postmenopausal, most of the information regarding the endometrial side effects is related to this age group. The effects of tamoxifen on the endometrium appear to depend on the menopausal status, as well as on the dose and duration of tamoxifen usage.

Non-neoplastic endometrium in postmenopausal patients taking tamoxifen is most commonly atrophic while in other cases there is proliferative activity. The stroma is often fibrous and, as a result, endometrial biopsies in patients taking tamoxifen are often very scanty. There may be glandular dilatation secondary to obstruction of the glands by stromal fibrosis. Stromal decidualization is usually secondary to simultaneous progestin administration [28]. One of the most characteristic and common endometrial lesions in women taking tamoxifen is polyps, which may be single or multiple and may occur on a background of hyperplasia, such that there is merging of polypoid and non-polypoid endometrium. There are no pathognomonic features of tamoxifen-associated endometrial polyps but they tend to be larger than sporadic polyps. Periglandular stromal condensation, staghorn-shaped glands polarized along the long axis of the polyp, stromal edema and myxoid change, and epithelial metaplasias are all more common in tamoxifen-associated than sporadic polyps [72, 127], although all these features may be seen in sporadic polyps. Polyp cancers may develop in tamoxifen-associated polyps and can be of endometrioid or serous type. The presumed precursor lesion of serous carcinoma, serous endometrial intraepithelial carcinoma (serous EIC), may also involve tamoxifen-associated polyps [90, 134]. Rarely, a metastatic breast carcinoma, usually of lobular type, is identified within a tamoxifen-associated endometrial polyp [60].

As stated earlier, endometrial carcinomas may develop in association with tamoxifen. It is generally accepted that the risk of developing endometrial carcinoma in patients taking tamoxifen is two to three times higher than in an age-matched population of women not taking tamoxifen. It is probable that it is women who have been taking tamoxifen for a prolonged period of time and with a high cumulative dose who are at greatest risk. Most carcinomas are endometrioid in type but type 2 endometrial carcinomas, especially serous, are possibly proportionally more common than in the general population, although it is impossible to draw firm conclusions. Since most endometrial cancers that develop in association with estrogenic stimulation are low-grade endometrioid in type, it might be expected that carcinomas associated with tamoxifen would have a similar profile. However, although some studies support this [147], it has also been suggested that high-grade endometrial cancers, including serous carcinomas and carcinosarcomas (in reality metaplastic carcinomas or carcinomas with sarcomatous metaplasia) [87], are more common in patients taking tamoxifen and that the development of these cancers is not secondary to estrogenic stimulation but due to other mechanisms such as the formation of DNA adducts [84, 133]. Occasional uterine leiomvosarcomas, endometrial stromal sarcomas, adenofibromas, and adenosarcomas have been described in patients taking tamoxifen [27, 63, 81]; it is possible that these complications arise simply by chance since tamoxifen is widely used. Adenomyosis has been shown to be more common in postmenopausal patients taking tamoxifen [29], and this may exhibit unusual morphological features, such as stromal fibrosis, glandular dilatation, and epithelial metaplasias [85]. A rapid increase in size of uterine leiomyomas has been observed with tamoxifen therapy.

Other SERMs, such as raloxifene, have a similar efficacy to tamoxifen in the management of breast cancer. In contrast to tamoxifen, these seem to be pure estrogen antagonists, lacking the weak estrogen agonist effects of tamoxifen and do not result in endometrial proliferative lesions [35].

Taxanes

Taxanes, such as paclitaxel, are commonly used chemotherapeutic agents as first-line treatment in ovarian, breast, and lung cancer. Taxanes act by the simultaneous promotion of tubulin assembly into microtubules and inhibition of microtubule disassembly. The morphological features in the endometrium have been rarely reported but numerous mitoses in metaphase arrest with the formation of ring mitoses have been described [67]. Similar morphological changes are seen in other organs, such as the gastrointestinal tract, in association with taxanes.

Endometrial Epithelial Metaplasia (Epithelial Cytoplasmic Change)

Endometrial epithelial metaplasias are non-neoplastic alterations (metaplasias may coexist with endometrial hyperplasia or carcinoma but, in themselves, are nonneoplastic) in which the normal endometrial epithelium is replaced, focally or diffusely, by another type of differentiated epithelium. The variety of epithelial metaplasias encountered within the endometrium reflects the capacity of epithelium derived from the müllerian ducts to undergo differentiation into any other form of epithelium found in the müllerian system. The various epithelial metaplasias commonly coexist. It has been suggested that metaplasia is an inappropriate term for some of the alterations as strictly speaking the term metaplasia refers to the replacement of one type of epithelium by another that is not normally found in that organ [57]. For this reason, some authors use the term "epithelial cytoplasmic change" rather than metaplasia.

Metaplasia usually involves nonsecretory endometrium and is often associated with hyperestrogenism. Metaplasias are common within endometrial polyps. Other associations include exogenous hormone therapy, especially but not exclusively unopposed estrogens, the presence of an intrauterine device, chronic endometritis, and pyometra; the latter two conditions are particularly associated with squamous metaplasia. In some cases, there is no obvious underlying cause. It has been suggested that progestin therapy given for endometrial hyperplasia or endometrioid adenocarcinoma may result in various epithelial metaplasias within the malignant or premalignant lesion [154]. Metaplasia by itself is not associated with clinical symptoms but if there is an associated endometrial hyperplasia or carcinoma, there may be abnormal bleed-ing related to this [88].

A particular problem with epithelial metaplasias is their tendency to be associated with endometrial hyperplasias [18] or endometrioid adenocarcinoma. Squamous metaplasia and mucinous metaplasia are particularly common in endometrioid adenocarcinomas. In such instances, it may be difficult, at the lower end of the spectrum, to distinguish between a metaplasia with mild glandular complexity and a hyperplasia with coexistent metaplasia. It is important to make this distinction, since metaplasia by itself has no premalignant potential, and it is recommended that similar criteria are employed to those that are used in the diagnosis of endometrial hyperplasia without metaplasia (> Chap. 8, Precursor Lesions of Endometrial Carcinoma).

With some epithelial metaplasias, such as clear cell metaplasia and papillary syncytial metaplasia, the differential diagnosis may be between a metaplasia and a type 2 endometrial cancer or serous endometrial intraepithelial carcinoma (serous EIC). In such instances, immunohistochemistry may be of value in that serous EIC and type 2 cancers often exhibit diffuse intense nuclear p53 immunoreactivity while ER is generally negative or weakly positive. In contrast, most epithelial metaplasias are ER positive and exhibit a pattern of p53 immunoreactivity, which has been described as weak and heterogenous [123]. A minor population of endometrial epithelial cells exhibit nuclear immunoreactivity with p63; it has been speculated that these are reserve cells or basal cells and the origin of the various epithelial metaplasias [111].

Squamous Metaplasia

Squamous metaplasia is one of the commonest forms of endometrial epithelial metaplasia. Although usually a focal finding, on occasions there may be widespread squamous metaplasia with obliteration of the glandular lumina such that it is difficult to assess the underlying glandular component. This is especially common when the squamous metaplasia is of morular type (see below). Squamous metaplasia is common in endometrioid adenocarcinoma and in endometrial hyperplasias; these should be excluded by careful examination of the glandular elements. Squamous metaplasia may also be seen in endometrial polyps. There are two types of squamous metaplasia, namely typical squamous metaplasia and morular metaplasia, although these sometimes coexist. Typical squamous elements are characterized by sheets of cells exhibiting obvious squamous differentiation in the form of intercellular bridges, prominent cell membranes, or keratinization (> Fig. 7.48). Sometimes there is a histiocytic and giant cell reaction to keratin. Typical squamous metaplasia rarely involves much of or the entire endometrial surface such that the endometrial cavity is extensively lined by squamous epithelium, the condition known as ichthyosis uteri. This condition most commonly develops secondary to longstanding cervical obstruction or chronic inflammation. Usually, in ichthyosis uteri, the squamous epithelium is of normal appearance, but rarely, it may have the features of a condyloma acuminatum [137] or intraepithelial neoplasia [121]. It may rarely extend to involve the fallopian tubes and ovaries. Rarely an invasive squamous carcinoma develops in this manner.

Squamous morules are morphologically distinct structures, which were named so because of their threedimensional resemblance to mulberries [39]. They are composed of rounded aggregates or syncytial sheets of cells that often fill glandular lumina (\bigcirc *Fig.* 7.49). The constituent cells have central bland round, ovoid, or spindle shaped, evenly spaced nuclei, sometimes with small nucleoli. Some of these nuclei may contain optically clear biotin-rich inclusions. The cell borders are indistinct. Mitoses are rare or absent. There may be central necrosis. It is controversial whether morules actually exhibit squamous differentiation. Morphological features of overt squamous differentiation, such as keratinization, intercellular bridges, and prominent cell membranes, are typically absent in morules. Immunohistochemically,

Fig. 7.48

Squamous morules in endometrium. Squamous morules are composed of rounded aggregates or syncytial sheets of cells filling glandular lumina

Fig. 7.50

Beta-catenin immunohistochemistry in squamous morules. Morules exhibit nuclear and cytoplasmic immunoreactivity with beta-catenin

morules exhibit a somewhat different immunophenotype to that of typical squamous elements. Morules exhibit nuclear and cytoplasmic positivity with beta-catenin (**?** *Fig.* 7.50) [14, 124] while in typical squamous elements the "normal" membranous pattern of immunoreactivity is maintained [62]. Endometrial proliferative lesions with morules often exhibit beta-catenin gene mutation, and this results in the cytoplasmic and nuclear immunoreactivity. Morules are usually estrogen receptor (ER) and p63 negative [21], diffusely positive with CD10 [20], and exhibit nuclear immunoreactivity with the intestinal transcription factor CDX2 (**)** *Fig.* 7.51) [62, 152]; it has been suggested that this is secondary to beta-catenin gene mutation. In contrast, typical squamous elements are usually positive with ER, p63, and CD10, and negative with CDX2. On the basis of the immunophenotype, it has been concluded that morules exhibit no firm immunohistochemical evidence of squamous differentiation, although immature squamous features cannot be excluded [62]. It has been suggested that the term morular metaplasia is used instead of squamous morules.

Mucinous Metaplasia

Mucinous metaplasia is a relatively uncommon form of endometrial epithelial metaplasia and is most commonly seen in association with a premalignant or malignant lesion. It may also be seen in endometrial polyps. A diagnosis of mucinous metaplasia should be reserved for cases in which the endometrial epithelial cells are replaced by cells with abundant intracytoplasmic mucin, the cells resembling endocervical cells (> Fig. 7.52). Normal endometrial epithelial cells contain a little intracytoplasmic mucin, especially with a luminal distribution, and so abundant intracytoplasmic mucin is required to diagnose mucinous metaplasia. Rarely, intestinal metaplasia has been described in the endometrium where the mucinous epithelium contains goblet cells [153]. Enteric type mucins may be demonstrable with mucin stains in cases without morphological evidence of

intestinal metaplasia [80]. In mucinous metaplasia without an associated premalignant or malignant glandular proliferation, there are often small micropapillary projections. The nuclei are small and uniform and mitoses are rare or absent. An important point with a florid mucinous proliferation of the endometrium is that mucinous adenocarcinomas, even those exhibiting myometrial invasion, can be cytologically bland with little in the way of mitotic activity. As such, complex mucinous proliferations of the endometrium present a particular diagnostic problem, especially, but not exclusively, in biopsy material [150]. Mucinous proliferations of the endometrium have been divided into three categories depending on the degree of architectural complexity and association with underlying adenocarcinoma [108]. With any architecturally complex mucinous proliferation in an endometrial biopsy, a diagnosis of well-differentiated mucinous adenocarcinoma should be considered, and the term "complex endometrial mucinous proliferation" may be applied with a comment that there is a significant risk of a welldifferentiated mucinous adenocarcinoma in the uterus. Rarely, mucinous metaplasia in the endometrium is accompanied by mucinous lesions elsewhere in the female genital tract, for example in the cervix and the ovary, perhaps as a manifestation of a field-change effect [6].

Ciliated (Tubal) Metaplasia

Ciliated epithelial cells are normal on the endometrial surface, especially in the proliferative phase of the menstrual cycle. A diagnosis of ciliated metaplasia should be

Ciliated metaplasia in endometrium. The endometrial glands are lined by ciliated cells with abundant eosinophilic cytoplasm

made only when one or more endometrial glands contain ciliated cells, which may be interspersed among nonciliated cells or be extensive and line most of the gland (\bigcirc *Fig.* 7.53). The nuclei may be rounded, mildly stratified, and contain small nucleoli but are cytologically bland. Ciliated cells often have abundant eosinophilic cytoplasm. Ciliated metaplasia is particularly associated with estrogenic stimulation. As with other types of epithelial metaplasia, ciliated cells may be found in nonneoplastic, hyperplastic, and malignant endometria. The presence or absence of hyperplasia or adenocarcinoma is evaluated by the usual parameters.

Clear Cell Metaplasia

Clear cell metaplasia is rare and is characterized by replacement of endometrial epithelial cells by cells with abundant clear cytoplasm (\bigcirc *Fig. 7.54*). This may be a feature of pregnancy when the features overlap with Arias-Stella reaction. Clear cell metaplasia may be misdiagnosed as clear cell carcinoma, especially on a biopsy specimen. Distinction is based on the bland nuclear features and the fact that in clear cell metaplasia the endometrial glands maintain a normal architecture and distribution. Other features favoring clear cell metaplasia over clear cell carcinoma include the focal nature of the lesion, absence of a grossly visible tumor, absence of stromal invasion, and strong estrogen receptor positivity. Some, but not all, endometrial clear cell carcinomas are estrogen receptor negative.

Hobnail Cell Metaplasia

Hobnail cell metaplasia or change is rare and is characterized by the presence of cells with rounded apical blebs, which may involve the endometrial surface or protrude into glandular lumina (\bigcirc *Fig.* 7.55). Hobnail cell metaplasia may be a reparative phenomenon following endometrial curettage or may be seen on the surface of a polyp. It may also occur in pregnancy. Hobnail cells are also

Fig. 7.54 Clear cell metaplasia in endometrium. The endometrial glands are replaced by cells with abundant clear cytoplasm

a feature of some clear cell carcinomas and this may enter into the differential diagnosis. Criteria useful in the distinction of hobnail cell metaplasia from clear cell carcinoma are similar to those used in distinction of the latter from clear cell metaplasia.

Eosinophilic (Oxyphilic, Oncocytic) Metaplasia

Eosinophilic or oxyphilic metaplasia is relatively common and is characterized by the presence of epithelial cells with abundant eosinophilic cytoplasm (> Fig. 7.56). The cytoplasm may be granular, in which case the term oncocytic metaplasia has been used. Ultrastructurally, abundant cytoplasmic mitochondria may be present, as is characteristic of oncocytes in other organs. The term pink cell metaplasia has also been used. Ciliated metaplasia is often characterized by abundant eosinophilic cytoplasm and overlaps with eosinophilic metaplasia. The epithelial cells in eosinophilic metaplasia can exhibit a significant degree of nuclear atypia (**)** Fig. 7.57); this is analogous to the degenerative nuclear atypia that is common in oncocytic cells in other organs. The main differential diagnosis is the eosinophilic or oxyphilic variant of endometrioid adenocarcinoma. Distinction from adenocarcinoma is based on the absence of a grossly visible lesion and maintenance of the normal glandular architecture.

• Fig. 7.55 Hobnail cell metaplasia in endometrium. Hobnail cells are present on the surface of an endometrial polyp

Fig. 7.56 Eosinophilic metaplasia in endometrium. The epithelial cells contain abundant eosinophilic cytoplasm

Papillary Syncytial Metaplasia

The term papillary syncytial metaplasia is a misnomer since this does not actually represent a metaplasia but rather a degenerative or reparative phenomenon associated with surface breakdown, either menstrual or nonmenstrual in type. However, since the term papillary syncytial metaplasia is in widespread use, it is discussed here. Synonymous terms include eosinophilic syncytial change and surface syncytial change. It has been suggested that papillary syncytial metaplasia is a degenerative or regressive phenomenon based on a low proliferation and mitotic index [131]. Papillary syncytial metaplasia is common and is characterized by small syncytia or micropapillary proliferations of endometrial epithelial cells, which may contain small glandular lumina and which are devoid of stromal support, lacking fibrovascular stromal cores (> Fig. 7.10). The cells usually have eosinophilic cytoplasm and there is often a neutrophilic infiltrate. There may be mild nuclear atypia and in a minority of cases, mitoses are present. The distinction between papillary syncytial metaplasia and serous adenocarcinoma or serous EIC has been discussed earlier. Another important consideration is that foci similar to papillary syncytial metaplasia may occur on the surface of some endometrioid adenocarcinomas. The distinction between papillary syncytial metaplasia and papillary adenocarcinomas of endometrioid or serous type is facilitated by recognition that papillary syncytial metaplasia is limited to the endometrial surface and is associated with other morphological features of breakdown such as apoptotic debris, neutrophils, and adjacent glandular and stromal breakdown.

Arias-Stella Reaction

Arias-Stella reaction (Arias-Stella effect or change) has been discussed earlier and is almost always associated with pregnancy, either intrauterine or ectopic, or with trophoblastic disease. It rarely occurs secondary to hormone therapy, especially progestins; occasionally there is no obvious cause [64]. The most important differential diagnosis is clear cell carcinoma, but the diagnosis of Arias-Stella reaction is usually straightforward if the patient is known to be pregnant and if other morphological features of pregnancy are present, such as decidualization of the stroma. Arias-Stella reaction involves preexisting endometrial glands without evidence of stromal infiltration and there is no mass lesion. Although there is nuclear enlargement and atypia, a low nuclear to cytoplasmic ratio is maintained.

Papillary Proliferation of Endometrium

The term hyperplastic papillary proliferation of the endometrium has been used for a lesion, usually occurring in postmenopausal women, characterized by the presence of papillae with fibrovascular stromal cores and variable degrees of branching and cellular tufting (\bigcirc *Fig.* 7.58). The papillae are lined by epithelial cells with bland nuclei [76]. Although not strictly a metaplasia, the lesion is discussed here since epithelial metaplasias, most commonly mucinous, eosinophilic, or ciliated, are often also

 Fig. 7.58
Papillary proliferation of endometrium. Papillary projections lined by bland epithelial cells on the surface of an endometrial polyp

present. Sometimes the papillae are entirely intracystic (projecting into cystically dilated endometrial glands) while in other instances they involve the endometrial surface. Papillary proliferation is most commonly seen on the surface of an endometrial polyp and, in some instances, the features are florid. There may be an association with hormonal preparations. A misdiagnosis of an adenocarcinoma of endometrioid or serous type is possible, especially if an underlying polyp is not present or not obvious. Awareness of this phenomenon and the realization that it often occurs in a polyp are clues to the diagnosis, although both endometrioid and serous adenocarcinomas may arise in and be confined to a polyp. An absence of nuclear atypia helps to exclude an adenocarcinoma. It has been considered that these papillary proliferations are a form of hyperplasia that is closely associated with epithelial metaplasia. However, given the uneventful outcome in those cases with follow-up, the term hyperplasia may not be appropriate.

Endometrial Mesenchymal Metaplasia

Various forms of mesenchymal metaplasia, all of which are rare, may involve the endometrial stroma. There are two theories regarding the pathogenesis of the various mesenchymal metaplasias. They may result from metaplasia of the endometrial stroma or represent remnants of fetal tissue following abortion or instrumentation. They should be distinguished from heterologous mesenchymal components within a carcinosarcoma or another uterine neoplasm.

Smooth Muscle Metaplasia

This is the most common mesenchymal metaplasia in the endometrium. Given the common embryonic origin of endometrial stromal and smooth muscle cells, it is thought that a multipotential cell exists in the uterus, which has the capacity to differentiate into endometrial stroma and smooth muscle. This is in keeping with the observation that hybrid endometrial stromal and smooth muscle neoplasms exist. It is not uncommon to find small foci of smooth muscle within the endometrial stroma, and these foci have sometimes been referred to as intraendometrial leiomyomas. It is probable that some intraendometrial smooth muscle nodules are a result of the irregular nature of the normal endometrial– myometrial junction, but others reflect the capacity of endometrial stroma to differentiate into smooth muscle.

Cartilaginous and Osseous Metaplasia

Rarely, foci of benign cartilage or bone are found within endometrial biopsies, either within the endometrial stroma or free floating [5]. In most cases, it is likely that this is of fetal origin, and this is especially likely if these tissues are found in the endometrium of a young woman with a past history of abortion. In other cases, the cartilage or bone is truly metaplastic. These tissues may also rarely be found within the stroma of an endometrial carcinoma. Benign cartilaginous or osseous metaplasia in an endometrial carcinoma should not be mistaken for the heterologous sarcomatous component of a carcinosarcoma. Rarely, endometrial ossification is associated with Asherman's syndrome.

Glial Metaplasia

The presence of glial tissue in the endometrium is extremely rare. In most cases, glial tissue (confirmed if necessary by positive immunohistochemical staining with glial fibrillary acidic protein (GFAP)) is a consequence of a previous abortion. Support for this may come from the identification of other elements such as cartilage or bone.

Adipose Metaplasia

Metaplastic adipose tissue is rarely found within endometrial stroma or within the stroma of an endometrial polyp. If identified in an endometrial biopsy or curettage specimen, the possibility of uterine perforation must be raised. Other explanations for the presence of adipose tissue in an endometrial biopsy specimen include derivation from a lipoma, a lipoleiomyoma, a uterine hamartomatous-like lesion containing adipose tissue [83], or a carcinosarcoma.

Extramedullary Hematopoiesis

Rarely, foci of extramedullary hematopoiesis are present in the endometrium, usually in association with an underlying hematopoietic disorder or occasionally representing remnants of fetal tissue [31].

Endometrial Polyps

Endometrial polyps are common and have been identified in between 2 and 23% of patients undergoing endometrial biopsy because of abnormal uterine bleeding [126]. Polyps occur in pre- and postmenopausal women and are thought to be related in some way to hyperestrogenism, possibly originating as a localized hyperplasia of the endometrial basalis secondary to hormonal influences. There is an increased incidence of endometrial polyps with HRT usage, either estrogen-only HRT or combined preparations. Tamoxifen is also associated with an increased risk of the development of endometrial polyps. Molecular studies have demonstrated that many endometrial polyps represent monoclonal endometrial stromal overgrowths with secondary induction of polyclonal benign glands through undefined stromal–epithelial interactions [46]. They may contain abnormalities of chromosome 6 [34].

Polyps may be single or multiple, sessile or broad based, pedunculated or attached to the endometrium by a slender stalk. They usually have a smooth surface and small cysts may be seen on sectioning. They can arise anywhere in the endometrium, including the lower uterine segment, but are most common in the fundus. When large, they may fill the endometrial cavity and extend into the endocervical canal.

The pathological diagnosis is generally straightforward if the gynecologist is aware of the presence of a polyp, has conveyed this information to the pathologist, and has removed the polyp intact. On occasions, the gynecologist believes that a polyp is present but histological examination shows a cyclical endometrium, often secretory in type, reflecting the fact that an abundant secretory endometrium may have a polypoid appearance. In many cases, the gynecologist is not aware of the presence of a polyp, which is removed piecemeal with the result that in biopsy material, fragments derived from the polyp are admixed with fragments of non-polypoid endometrium, making the diagnosis difficult. In biopsies performed because of abnormal uterine bleeding, the pathologist should always consider the possibility of a polyp. Under low-power examination, the initial clue to the diagnosis is often the admixture of fragments of normal cyclical or atrophic endometrium and fragments that are morphologically different. The histological features of a polyp, not all of which are present in every case, include the following:

- 1 Polypoid pieces of tissue lined by epithelium on three sides,
- 2 Glands set in a stroma that is qualitatively different than the endometrial stroma in the non-polypoid fragments. The stroma is often, but not always, more fibrous than that in the non-polypoid fragments and is sometimes markedly hyalinized (\triangleright *Fig. 7.59*),
- Glandular architectural abnormality with dilated glands and sometimes mild glandular crowding (>>> Fig. 7.60),

Fig. 7.60

Endometrial polyp. There may be a mild degree of glandular crowding within some endometrial polyps

- 4 Glands that appear different to those in the surrounding endometrium; for example, the glands of the nonpolypoid endometrium may be secretory in type while the glands within the polyp are atrophic or exhibit poorly developed secretory or proliferative activity,
- 5 Collections of thick-walled stromal blood vessels (> Fig. 7.61).

The glands within a polyp are usually endometrioid in type but not uncommonly exhibit metaplastic change, including ciliated, eosinophilic, mucinous, and squamous metaplasia. The epithelium may be atrophic but often exhibits proliferative activity, even when the patient is
postmenopausal and the surrounding endometrium is atrophic. The presence of proliferative activity in a polyp in a postmenopausal woman is of no clinical importance, although it is useful to comment in the pathology report on whether non-polypoid endometrium is also present and whether this exhibits proliferative activity. The stroma of a polyp is often more fibrous than that of the non-polypoid endometrium but this is not invariable and, in some polyps, the stroma is dense and cellular and resembles that of normal proliferative endometrium. As stated, collections of thick-walled stromal blood vessels are a characteristic feature of endometrial polyps, and ectatic thin-walled vessels are also sometimes seen. Some authors have divided endometrial polyps into different types, such as proliferative/hyperplastic (proliferative, sometimes crowded, glands), atrophic (atrophic glands), and functional (glands resembling those in the surrounding cyclical endometrium). However, these patterns often overlap and assignment to a specific type may be difficult; moreover, there is no clinical significance attached to the different types. Some polyps originate at the junction of the upper endocervix and lower uterine segment and contain both endocervical and ciliated lower uterine segment type glands.

A variety of morphological appearances affecting the epithelium or stroma may be seen in endometrial polyps and can result in diagnostic difficulty. Papillary proliferations with fibrovascular cores (see section **?** Papillary Proliferation of Endometrium) occasionally occur on the surface of an endometrial polyp or within cystically dilated glands. The epithelium on the surface of a polyp may exhibit a degree of atypia, often with degenerate

appearing nuclei (**)** *Fig.* 7.62), and sometimes hobnail cell change. There may be focal surface glandular and stromal breakdown and, on occasions, polyps are extensively necrotic secondary to torsion or if they outgrow their blood supply; vascular thrombosis may be seen in such cases. In some instances, this may result in the formation of a necrotic polypoid mass with only the surface epithelium or the ghost outlines of glands remaining (**)** *Fig.* 7.63). Variable amounts of stromal edema and occasionally myxoid change may be present as well as

Endometrial polyp. The epithelium on the surface of a polyp may exhibit a degree of nuclear atypia with a degenerate appearance

 Fig. 7.61
Endometrial polyp. Collections of thick-walled stromal blood vessels are a characteristic feature of endometrial polyps

Fig. 7.63 Necrotic endometrial polyp. Necrosis has occurred secondary to torsion

hemosiderin pigment and foamy histiocytes. Sex cord-like areas have rarely been described in the stroma of an endometrial polyp [36]. Some endometrial polyps contain bundles of smooth muscle within the stroma, often in close proximity to thick-walled blood vessels. This is usually a minor feature and of no significance. However, when the smooth muscle is prominent, the term adenomyomatous polyp has been used (see section Adenomyomatous Polyp). Stromal inflammatory cells, including plasma cells, may be present in endometrial polyps; this should not be interpreted as an endometritis unless plasma cells are also present in the non-polypoid endometrium. Stromal decidualization or pseudodecidualization may occur secondary to progestational compounds but the degree of decidualization is typically less than in the surrounding endometrium.

As discussed previously, there is an increased frequency of endometrial polyps in patients taking tamoxifen. The polyps may be single or multiple and may be large. There are no pathognomonic histological features of tamoxifen-associated endometrial polyps, but an increased incidence of epithelial metaplasias, periglandular stromal condensation, stromal edema, and myxoid change and staghorn-shaped glands polarized along the long axis of the polyp have been reported [72].

As stated, diagnosing an endometrial polyp is generally straightforward when the polyp is large and removed intact. However, when small and fragmented, the diagnosis is more difficult. Lower uterine segment endometrium may be mistaken for a polyp because of the irregular glandular architecture and fibrous stroma. The spindle cell alteration of the stroma seen in some cases of endometritis may resemble the fibrous stroma of a polyp. However, other morphological features of a polyp are absent and there is a plasma cell infiltrate within the stroma; it should be remembered, however, that plasma cells may occur within the stroma of an endometrial polyp. Especially in large polyps with a degree of stromal condensation and increased cellularity around the glands, the differential diagnosis may include an adenosarcoma. Adenosarcoma typically has a leaf-like or club-like architecture, with broad papillae lined by surface epithelium, and intraglandular stromal projections, the overall architecture resembling a phyllodes tumor of the breast. In contrast, endometrial polyps usually have a smooth outline. The stroma in adenosarcoma is usually more cellular than in a benign polyp with increased mitotic activity and a degree of nuclear atypia, especially immediately surrounding the glands. With multiple recurrent endometrial polyps, a diagnosis of adenosarcoma should be suspected since the morphological features may be subtle.

Adenofibroma may also be considered but this is rare and exhibits a similar low-power architecture to adenosarcoma. In polyps with a stromal smooth muscle component, an atypical polypoid adenomyoma may be considered. However, the stroma of atypical polypoid adenomyoma exhibits more extensive smooth muscle differentiation, the glandular architecture is more complicated, and there is often extensive squamous morule formation. Polyps in which the glands are mildly crowded and exhibit proliferative activity may be confused with an endometrial hyperplasia. In such cases, the identification of normal background endometrium facilitates the diagnosis since hyperplasia is usually a diffuse process.

Endometrial Polyp with Atypical Stromal Cells

Rare endometrial polyps contain stromal cells with markedly atypical symplastic-like nuclei (**>** *Fig. 7.64*), resembling those seen in polypoid lesions elsewhere in the female genital tract, such as in fibroepithelial stromal polyps of the vulva and vagina [143]. These atypical stromal cells are of no significance.

Adenomyomatous Polyp

As discussed, some endometrial polyps contain a minor component of stromal smooth muscle bundles, often in close proximity to thick-walled blood vessels. When the

Fig. 7.65

Adenomyomatous polyp (adenomyoma). Endometrioid type glands are surrounded by endometrial type stroma, which is in turn surrounded by smooth muscle

smooth muscle is prominent, the term adenomyomatous polyp has been used. This term and the term adenomyoma have also been used for a lesion in which endometrioid type glands, sometimes with minor foci of ciliated, mucinous, or squamous metaplasia, are surrounded by endometrial stroma, which is in turn surrounded by smooth muscle [50, 142] (\bigcirc *Fig. 7.65*). These lesions, which may also be non-polypoid and located entirely within the myometrium can be associated with underlying adenomyosis. They should not be confused with atypical polypoid adenomyoma. In adenomyomas, the glands are usually surrounded by endometrioid type stroma, which is in turn surrounded by smooth muscle [50, 142].

Hyperplasia and Carcinoma Arising in Endometrial Polyp

Occasionally a hyperplasia or carcinoma arises within or involves a benign endometrial polyp [18]. A diagnosis of simple hyperplasia should not be made in a polyp since proliferative activity with glandular dilatation is a feature of many endometrial polyps. Complex and atypical hyperplasia is diagnosed in the same way as in non-polypoid endometrium. The hyperplasia may be confined to the polyp but also involves the non-polypoid endometrium in approximately 50% of cases [71, 100]. Both endometrioid and serous carcinomas (and occasionally other morphological types of malignancy) may arise within or involve an endometrial polyp and sometimes be confined to this. Serous carcinomas have a particular tendency to arise in or involve endometrial polyps as does

G Fig. 7.66

Endometrial polyp with serous endometrial intraepithelial carcinoma (serous EIC). Serous endometrial intraepithelial carcinoma rarely arises on the surface of an endometrial polyp

Fig. 7.67

p53 immunohistochemistry in serous endometrial intraepithelial carcinoma. Diffuse intense nuclear p53 immunoreactivity of serous endometrial intraepithelial carcinoma on surface of an endometrial polyp

the presumed precursor lesion serous endometrial intraepithelial carcinoma (serous EIC) [65, 134]. When serous EIC involves an endometrial polyp, there is partial replacement of the surface epithelium or sometimes the epithelium of the glands by cells with markedly atypical hyperchromatic nuclei, sometimes with prominent nucleoli, and prominent mitotic activity (\bigcirc *Fig.* 7.66). Immunohistochemical staining may assist in highlighting the

serous proliferation since the cells of EIC typically exhibit diffuse intense nuclear immunoreactivity with p53 (\bigcirc *Fig.* 7.67) and there is a high MIB1 proliferation index. ER is usually negative. In contrast, the benign epithelium within the polyp exhibits a low MIB1 proliferation index, is ER positive and is negative or only scattered nuclei are positive with p53. p53 staining may reveal that the EIC is more extensive than is appreciated on initial morphological examination. Rarely a carcinosarcoma arises in and is confined to an endometrial polyp. Occasional cases of metastatic carcinoma, especially breast lobular carcinoma, have been reported in endometrial polyps [60].

Atypical Polypoid Adenomyoma

Atypical polypoid adenomyoma is a biphasic polypoid lesion composed of endometrioid type glands in a myomatous or fibromyomatous stroma [97, 159]. Since the stroma may be fibromyomatous rather than overtly myomatous, some prefer the designation atypical polypoid adenomyofibroma [79]. Most patients are premenopausal or perimenopausal (average age 40 years) and present with abnormal uterine bleeding, usually in the form of menorrhagia. In some cases, the diagnosis is made during investigations for infertility. Occasional cases occur in postmenopausal women, and rare examples have been described in patients with Turner's syndrome who have been prescribed unopposed estrogens [23]. A single study has investigated molecular events in atypical polypoid adenomyoma and found MLH-1 promotor hypermethylation in some cases, a molecular alteration characteristic of some atypical hyperplasias and endometrioid adenocarcinomas [114].

Atypical polypoid adenomyoma is most commonly located in the lower uterine segment, although some cases involve the fundus, uterine body, or endocervix. In most cases, the lesion has an obvious polypoid gross appearance, in the form of either a sessile or broad-based polyp, but sometimes the polypoid nature is not grossly obvious, especially in smaller lesions.

The diagnosis may be made on endometrial biopsy, or polypectomy, or at hysterectomy. Histology shows architecturally irregular endometrioid type glands that may be widely separated and haphazardly arranged or somewhat crowded and arranged in groups, sometimes with a vaguely lobular pattern (\bigcirc *Fig. 7.68*). The endometrioid epithelium varies in appearance from cuboidal to low columnar to pseudostratified. The nuclei are usually round, sometimes with prominent nucleoli, and exhibit

Atypical polypoid adenomyoma. Endometrioid type glands are embedded within a myomatous stroma

Fig. 7.69 Atypical polypoid adenomyoma. There is abundant squamous morule formation

mild or, at the most, moderate cytological atypia. Occasional foci of ciliated or mucinous epithelium may be present. A characteristic histological feature that is present in most, but not all, cases is abundant squamous morule formation (\bigcirc *Fig. 7.69*); sometimes, the morules exhibit central necrosis. The glands are set in an abundant stroma, which varies from obviously smooth muscle in nature to fibromyomatous. Endometrial stroma is not present. The stromal cells are often arranged in short interlacing fascicles. Occasional mitotic figures may be identified within the stroma. The margin between the lesion and the underlying myometrium is usually rounded and well delineated but occasionally there is merging with underlying adenomyosis.

In some cases, there is significant glandular crowding with a back-to-back architecture and stromal exclusion, such that there are foci, which are virtually indistinguishable from, and which are best regarded as, grade I endometrioid adenocarcinoma. The term atypical polypoid adenomyoma of low malignant potential has been used for lesions with marked architectural complexity [79], but this term is not recommended. Very rarely, there is underlying myometrial invasion, and/or an endometrioid adenocarcinoma is present in the surrounding endometrium.

Atypical polypoid adenomyoma is generally a benign lesion, but there is a risk of recurrence if curettage or polypectomy is undertaken. In one series, 45% of cases treated by curettage or polypectomy recurred [79]. Given this risk of recurrence and the small, but definite, risk of transition to endometrioid adenocarcinoma, which was estimated at 8.8% in one meta-analysis [55], hysterectomy is the treatment of choice if the diagnosis is made on biopsy or polypectomy. In a woman who wishes to retain her uterus and in whom a confident diagnosis of atypical polypoid adenomyoma has been made on biopsy or polypectomy, complete removal by curettage or polypectomy may be undertaken with close follow-up and imaging. Successful pregnancies have ensued in patients managed in this way. It has been suggested that recurrence is more likely in cases with marked architectural complexity.

The most important differential diagnosis is an endometrioid adenocarcinoma exhibiting myometrial invasion or with a prominent desmoplastic stroma, an obviously important distinction since most atypical polypoid adenomyomas exhibit a benign behavior with a potential for conservative management. Recognition of the polypoid nature of the lesion assists in establishing the diagnosis. Marked cytological atypia favors a myoinvasive adenocarcinoma since in atypical polypoid adenomyoma, there is usually no more than mild to moderate cytological atypia. The stromal component of atypical polypoid adenomyoma grows in short interlacing fascicles, in contrast to the elongated fibers of the normal myometrium. In curettings or biopsy from an atypical polypoid adenomyoma, there are usually also fragments of normal background endometrium, and with an endometrioid adenocarcinoma, it would be unusual on biopsy to obtain only myoinvasive neoplasm without free tumor fragments. Immunohistochemistry is of little value in distinguishing between atypical polypoid adenomyoma

and a myoinvasive endometrioid adenocarcinoma since the stromal component of atypical polypoid adenomyoma and myometrium infiltrated by carcinoma are both desmin and smooth muscle actin positive [135]. It has been suggested that CD10 may be of value since this is negative in the stromal component of atypical polypoid adenomvoma while the myoinvasive glands of endometrioid adenocarcinoma are typically surrounded by CD10 positive stromal cells [113]. The differential diagnosis can also include a benign endometrial polyp in which there may be a minor component of smooth muscle within the stroma. So-called typical adenomyomatous polyps or adenomyomas also occur (discussed earlier) and are composed of benign endometrioid type glands in a myomatous stroma [50, 142]. Often, endometrioid stroma surrounds the glands and this in turn is surrounded by smooth muscle. Rarely a carcinosarcoma enters into the differential diagnosis because of the admixture of epithelial and stromal elements. However, both the mesenchymal components epithelial and of a carcinosarcoma are obviously malignant and typically high grade.

Adenofibroma

Adenofibroma is a mixed tumor of the endometrium (and rarely also of the cervix) consisting of a benign epithelial and a benign mesenchymal component, both of which are integral components of the neoplasm. Adenofibromas most commonly occur in postmenopausal women but the age range is wide. The most common presenting symptom is abnormal vaginal bleeding. Occasional cases have arisen in patients taking tamoxifen [63]. Adenofibroma is rare and must be distinguished from the more common adenosarcoma with a subtle malignant stromal component [160] (discussed in O Chap. 10, Mesenchymal Tumors of the Uterus). Grossly, adenofibroma occupies the uterine cavity, typically arising as a broadbased polypoid mass. The cut surface may be spongy or overtly cystic. Bland epithelium that is usually of endometrioid type but which may be mucinous, ciliated, or even squamous covers broad or fine papillary stromal fronds (> Fig. 7.70). Cells of fibroblastic type and more rarely endometrial stroma or smooth muscle make up the mesenchymal element. The stroma may be cellular or fibrous and the constituent cells are cytologically bland without nuclear pleomorphism. Mitotic figures are usually absent and should not exceed 1 per 10 high power fields; greater mitotic activity than this warrants a diagnosis of adenosarcoma, which is more common. Periglandular cuffing by stromal cells should also result in consideration of adenosarcoma. Occasionally, an adenocarcinoma arises within an adenofibroma but this is probably a coincidental association [151].

While the adenofibroma is benign, hysterectomy is the most appropriate treatment. This is because adenosarcoma cannot be excluded in curettings or biopsy and also because recurrence of an adenofibroma treated by curettage or local excision may occur. It is for these reasons that some consider that adenofibroma does not exist, but rather is a well-differentiated form of adenosarcoma. At the heart of the controversy whether or not adenofibroma exists as an entity is the ability to distinguish it from adenosarcoma. The important features are the degree of mitotic activity in the stroma, the morphology of the stromal cells, and the presence of periglandular cuffing by stromal cells. A mitotic count greater than 1 per 10 high power fields warrants a diagnosis of adenosarcoma, a diagnosis that should also be made if there is more than mild nuclear atypia or significant periglandular stromal cuffing. It is difficult to make a confident diagnosis of adenofibroma on curetted or avulsed material because theoretically adenosarcoma cannot be excluded unless the whole tumor is available for examination. Thus, a hysterectomy is required to ensure that the tissue examined was not just the most benign area of an adenosarcoma. Using these strict criteria, the diagnosis of adenofibroma is made only rarely. Cases have been reported in which repeated curettages have been carried out because the lesion was wrongly thought to be benign before a diagnosis of adenosarcoma has eventually been

made [26]. It is also important to differentiate between adenofibroma and a benign endometrial polyp since the latter does not require further treatment. While the distinction can be difficult, adenofibroma should be considered if the lesion has a papillary surface and a stroma that is cellular. The stroma of endometrial polyps tends to be more hyaline than that of adenofibroma, although there is considerable overlap.

Effects of Intrauterine Device (IUD)

Intrauterine devices (IUDs) are in widespread use, mainly for contraceptive purposes. Older devices were usually composed entirely of plastic while more modern devices are often composed of plastic with a copper coating. The effects of the Mirena coil, a progestin containing IUD, are discussed in the next section. The histological features in the endometrium in association with an IUD are largely due to local mechanical effects. The surface endometrium may take on the configuration of the IUD due to a direct pressure effect. There may be surface micropapillary formations and focal reactive changes with nuclear enlargement, mild nuclear atypia, small nucleoli, and cytoplasmic vacuolation (> Fig. 7.71). When micropapillary fragments of epithelium exhibiting these features are present in an endometrial biopsy, this may result in diagnostic difficulty. The glandular epithelium may also exhibit epithelial cytoplasmic change, including squamous metaplasia, and there may be surface ulceration. The endometrial glands at the site of contact, and immediately surrounding this, may

Fig. 7.70 Adenofibroma of endometrium. Adenofibroma containing benign glands with underlying bland fibrous stroma

Fig. 7.71 Reaction to intrauterine device (IUD). Micropapillary formations are present, in keeping with a reaction to an intrauterine device

exhibit a different pattern of maturation from the rest of the endometrium. With long-term usage, the endometrium adjacent to the IUD may on occasions be fibrosed or simplified and composed of a monolayer. Rarely there is stromal microcalcification. Although the features may be subtle, a focal inflammatory infiltrate is commonly present consisting of polymorphs, lymphocytes, histiocytes, and plasma cells. Foreign body type giant cells and granulomas may be a component of the inflammatory infiltrate, the severity of which may be related to the type of IUD and the duration of use. In most cases, the inflammation is superficial and largely confined to the site of contact but in other instances it is more widespread. When confined to the IUD site, the inflammation is probably a consequence of irritation rather than infection but when more widespread it may be secondary to infection; in such cases, the inflammatory infiltrate, as well as being more widespread, is typically more intense. Infection appears more common with plastic devices than with copper-coated devices. Usually, a mixture of organisms is present. Long-term IUD use is associated with infection by the gram-positive anaerobic bacterium actinomyces (discussed earlier).

A rare but serious complication of IUD use is uterine perforation or laceration, most commonly occurring at the time of insertion. The risk of perforation is greatest in the postpartum period when the tissues are soft and expanded. Displacement of the IUD into the pelvis with an associated inflammatory reaction may ensue secondary to perforation and spontaneous expulsion may also occur.

Effects of Mirena Coil

The Mirena coil is a levonorgestrel (a progestin)-releasing IUD that is in widespread use as a highly effective contraceptive. The Mirena coil is also licensed for the management of idiopathic menorrhagia and has been used to deliver progestin for endometrial protection in postmenopausal hormone replacement regimes. It has also been suggested that the Mirena coil can be used to prevent endometrial hyperplastic changes in patients taking tamoxifen or estrogen-only HRT.

The histological features of the endometrium in association with the Mirena coil include a low-power polypoid architecture (\bigcirc *Fig. 7.72*), probably secondary to a direct mechanical effect. Ulceration, surface micropapillary proliferations, and reactive atypia of the surface endometrium may also be present. The endometrial glands are usually small tubular and atrophic but occasionally exhibit weak secretory activity. There is stromal expansion and

decidualization or pseudodecidualization with infiltration by granulated lymphocytes (**>** *Fig.* 7.73) [119]. Other histological features found in some cases include stromal myxoid or mucinous change, hemosiderin pigment and glandular metaplastic changes. Stromal necrosis, infarction, and microcalcifications are found in a small percentage of cases. In some cases, plasma cells are present within the stroma, indicating a coexistent chronic endometritis, secondary to the presence of the IUD. Stromal hyaline

Fig. 7.74

Mirena coil-associated endometrium. Stromal hyaline nodules may be seen in Mirena coil-associated endometrium

Fig. 7.75 Radiation effect endometrium. Glands are lined by cells with enlarged atypical nuclei

nodules have also been described (**>** *Fig. 7.74*) [56]. There may be associated progestational effects in the cervix, including microglandular hyperplasia and stromal decidualization.

Radiation Effects on the Endometrium

The endometrial morphology can be altered by the effects of radiation, which may have been administered many years earlier. Radiation effect endometrium is characterized by surface endometrium or glands lined by cells with enlarged atypical, sometimes bizarre, hyperchromatic nuclei () Fig. 7.75). The nuclear chromatin may be smudged and indistinct or there may be prominent nucleoli. Hobnail cells may be present. There is usually abundant cytoplasm that can be eosinophilic, clear, or vacuolated. The normal glandular architecture is typically maintained or there may be glandular loss. The stroma can be fibrotic with associated vascular changes characteristic of radiation. The presence of cells with enlarged atypical nuclei can raise the possibility of serous EIC. Knowledge of the history of prior radiation is obviously paramount in establishing the diagnosis; a lack of mitotic activity and a low nuclear to cytoplasmic ratio are other diagnostic clues. p53 immunohistochemistry may assist since serous EIC usually exhibits diffuse intense nuclear immunoreactivity while in radiation effect the nuclei are negative or exhibit weak heterogeneous staining. Prior radiation is associated with an increased risk of the subsequent

development of uterine malignancies. These may be of any morphological type but carcinosarcomas are proportionally overrepresented.

Effects of Endometrial Ablation or Resection

Endometrial ablation is commonly undertaken as a nonsurgical procedure in the management of abnormal uterine bleeding, especially in premenopausal women where the suspicion of malignancy is low and preservation of fertility is not an issue. The object of endometrial ablation is destruction of the entire endometrium and superficial myometrium using thermal coagulation (electrosurgical rollerball), laser vaporization, or resection. Most patients become amenorrheic or hypomenorrheic following the ablation but some have continuous bleeding and/or pain and repeat endometrial biopsy or sometimes hysterectomy is undertaken either soon after the procedure or some time later. The histological features depend on the time interval between the ablation and the subsequent biopsy or hysterectomy. In the early stages (up to 3 months), there may be complete or almost complete necrosis of the endometrium and superficial myometrium with replacement of this by a coagulum of necrotic fibrinoid material with a surrounding histiocytic and giant cell reaction (> Fig. 7.76), the morphological features resembling that of a rheumatoid nodule or a necrotizing granulomatous process [30, 44]. Spicules of thermally damaged tissue may be identified and there is a variable

Fig. 7.76

Reaction to previous endometrial ablation. Endometrium is replaced by fibrinoid material with a surrounding histiocytic and giant cell reaction

degree of inflammation. Later, necrotic tissue is no longer present but a giant cell and granulomatous reaction may persist, sometimes with pigment within giant cells. There is usually striking fibrosis and there may be regeneration of the endometrium with the formation of a monolayer of simple cuboidal epithelium directly abutting the myometrium. In other cases, the endometrium is histologically relatively normal. Scarring may result in obstruction and the subsequent development of hematometra or pyometra. The histological features following endometrial resection are similar [92].

Usually, an endometrial biopsy is taken just prior to ablation being performed. Rarely this contains an unsuspected carcinoma and hysterectomy is performed soon after the ablation. In such instances, the endometrial carcinoma may have undergone total or extensive necrosis, secondary to the ablation procedure.

Effects of Curettage

Morphological changes may be seen in the endometrium secondary to recent curettage, especially if this has been vigorous. The changes are transient and will only be seen if repeat endometrial sampling or hysterectomy is undertaken a short time after curettage. There may be focal surface erosion with an associated mixed inflammatory infiltrate; in some cases, eosinophils are conspicuous [99]. Following this, there is usually epithelial regeneration, sometimes with a micropapillary architecture, hobnail cell change, and mild reactive nuclear atypia. Usually, the changes are minor, result in no particular diagnostic difficulties, and return to normal within 10 to 14 days. A similar phenomenon has been described in the endocervix secondary to recent endometrial sampling and termed atypical reactive proliferation of the endocervix ([128].)

Asherman's Syndrome

Asherman's syndrome is characterized by focal or diffuse endometrial fibrosis and loss of distinction between the functionalis and basalis. The endometrium may be composed of a monolayer of epithelium with underlying fibrous tissue and adhesions may form across the cavity. The endometrial stroma is fibrosed, may be calcified and, on rare occasions, even ossified. The endometrial glands are typically sparse, inactive, and may be cystically dilated. Asherman's syndrome can result in infertility, amenorrhea, or hypomenorrhea. Pregnancies may be complicated by premature labor, placenta previa, or placenta accreta. In some, but not all, cases, there is a known cause for the Asherman's syndrome, which may be secondary to previous surgery, curettage or ablation, infection, miscarriage, or retained products of conception. Hysteroscopic lysis of adhesions can result in successful pregnancies.

Postoperative Spindle Cell Nodule

Postoperative spindle cell nodule represents an exaggerated reparative response at the site of previous surgery or biopsy and, in the female genital tract, is most common in the vagina. It has rarely been described in the endometrium [25]. Postoperative spindle cell nodule occurs within weeks or months of the inciting procedure and consists of a cellular proliferation of spindle-shaped cells with admixed vascular channels and inflammatory cells. There may be abundant mitotic activity, raising the possibility of a sarcoma, usually a leiomyosarcoma. However, the high mitotic activity contrasts with the bland nuclear features and lack of cytological atypia. The history of a recent procedure is obviously paramount in establishing the diagnosis. The constituent cells may be positive with smooth muscle actin, desmin and, on rare occasions, cytokeratins.

Psammoma Bodies in the Endometrium

Calcified psammoma bodies may be seen in the endometrium in association with benign and malignant lesions and rarely in normal endometrium. They are present in up

to one third of uterine serous carcinomas, a lower frequency than in ovarian serous carcinomas [58]. More uncommonly, they are seen in other morphological types of endometrial malignancy, such as endometrioid carcinoma. Psammoma bodies are occasionally seen in normal endometria (usually atrophic or proliferative in type), sometimes in association with hormonal preparations, and in benign lesions, most commonly endometrial polyps [59, 146]. They are often located within glandular lumina () Fig. 7.77), in which case it is likely that they represent calcification of inspissated secretions. In other cases, they are situated within the stroma where they may be secondary to prior inflammation or the presence of an IUD. In the absence of a malignant lesion, the occurrence of psammoma bodies within glandular lumina or endometrial stroma is not an indication for evaluation of the upper female genital tract to exclude malignancy. However, free-floating psammoma bodies without attachment to tissue may be an indication of an extrauterine serous carcinoma.

Emphysematous Endometritis

There have been occasional reports of emphysematous (pneumopolycystic) endometritis characterized by the presence of gas-filled cysts in the endometrial stroma [118, 149]. There may be simultaneous involvement of the cervix or the condition may be confined to the endometrium. Histology shows empty cystic spaces of variable size and contour within the endometrial stroma lined by

flattened stromal cells with occasional histiocytes and/or giant cells. Spontaneous resolution usually occurs. Emphysematous endometritis should be distinguished from sectioning artifact, dilated vascular spaces, and gas gangrene of the uterus, which is life threatening and associated with tissue necrosis.

Benign Endometrial Stromal Proliferations

Endometrial stromal neoplasms are discussed in \bigcirc Chap. 10, Mesenchymal Tumors of the Uterus, as is the differential diagnosis of fragments of tissue composed entirely of endometrial stroma in an endometrial biopsy. Occasional cases of multifocal microscopic benign endometrial stromal proliferations confined to the endometrium without invasive growth have been reported [138]. These have been termed focal endometrial stromal hyperplasia and may mimic an endometrial stromal nodule or endometrial stromal sarcoma in biopsy samples. Rarely, markedly atypical stromal cells with a symplastic appearance are present within an otherwise normal endometrium [148] (\bigcirc *Fig. 7.78*).

Benign Trophoblastic Lesions

Benign lesions of intermediate trophoblast, namely placental site nodule or plaque (PSNP) and exaggerated placental site, are discussed in **O** Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions.

 Fig. 7.77
Psammoma bodies in endometrium. Psammoma bodies within glandular lumina within an endometrial polyp

Fig. 7.78 Atypical endometrial stromal cells. Rarely endometrial stromal cells with atypical symplastic-like nuclei are present in the normal endometrium

Fig. 7.79 Placental site nodule or plaque. A well-circumscribed lesion is composed of epithelioid cells with abundant cytoplasm

An endometrial PSNP may be identified in a biopsy, resection, or hysterectomy specimen many years following a pregnancy or abortion and rarely even in a postmenopausal woman. PSNP is characterized histologically by a well-circumscribed lesion composed of cells with large degenerate, often atypical nuclei and abundant eosinophilic cytoplasm (\bigcirc *Fig.* 7.79). The immunophenotype is discussed in detail later in \bigcirc Chap. 20, Gestational Trophoblastic Tumors and Related Tumor-Like Lesions.

Intravascular Endometrium

Occasionally in a hysterectomy specimen, menstrual endometrium is present within myometrial vascular channels (\bigcirc *Fig. 7.80*) [8]. Rarely there is extensive vascular involvement and even invasion of parametrial vessels. Intravascular menstrual endometrium is of no significance other than that it may be mistaken for neoplastic involvement of vascular channels. It should also be distinguished from intravascular foci of adenomyosis [125].

Endometrial Autolysis

Hysterectomies are performed for a wide variety of benign and malignant conditions. Especially with large uteri, the formalin does not penetrate into the endometrial cavity and, as a consequence, fixation is often not adequate and the endometrium may be markedly autolyzed. This not uncommonly results in problems in morphological assessment of the endometrium, which in some cases is so autolyzed that interpretation is impossible. This is

important in all uteri but particularly so with endometrial neoplasms where autolysis may result in problems in assessing tumor type and grade. Bisection of the uterus soon after surgery may improve fixation, but this often results in distortion of the specimen making assessment of parameters such as the depth of myometrial invasion by tumor problematic. Packing the cavity with absorbable tissue paper following bisection and ensuring that the two halves of the uterus remain apposed minimizes the distortion. Uteri may also be injected with formalin using a needle and syringe directed alongside a probe, which is inserted through the external cervical os into the endometrial cavity [61]. This initiation results in significantly less endometrial autolysis.

Endometrial hyperplasia often precedes the development of endometrioid carcinoma, the most common type of endometrial carcinoma. More recently, studies have found that the risk of endometrial hyperplasia is associated with increasing body mass index and nulliparity [24]. In addition, obesity, anovulatory cycles, and exogenous hormones are associated with both endometrioid carcinoma and hyperplasia. All of these factors are thought to result in unopposed estrogen stimulation of the endometrium. The role of unopposed estrogen stimulation in the development of endometrial hyperplasia and carcinoma is further supported by studies demonstrating elevated serum estrogen levels in patients with endometrioid carcinoma [14, 72]. However, other histologic types of endometrial carcinoma appear to be unrelated to hormonal factors and hyperplasia [81]. Serous carcinoma is the prototypic endometrial carcinoma that is not related to estrogenic stimulation or hyperplasia. It usually arises in atrophic endometrium through a precursor lesion called endometrial intraepithelial carcinoma (EIC). Over the past 3 decades, clinicopathologic, immunohistochemical, and molecular genetic studies have provided data to support the development of a dualistic model of endometrial carcinogenesis. In this model, two types of precursor lesions precede the two most common types of endometrial carcinoma. Atypical hyperplasia (AH) is recognized as the precursor for endometrioid carcinoma and endometrial intraepithelial carcinoma (EIC) is recognized as the precursor for serous carcinoma. The following discussion summarizes current knowledge about these precursor lesions including their differential diagnosis, treatment, and relationship to endometrial carcinoma.

Endometrial Hyperplasia

Definition and Classification

In the past, the terms "adenomatous hyperplasia" and "atypical hyperplasia" were used to denote proliferative lesions of the endometrium with varying degrees of architectural complexity and cytologic atypia [15, 32, 37, 70, 93]. In addition, the term "carcinoma in situ" was proposed to describe small lesions, with or without glandular crowding, having the cytologic features of carcinoma but lacking invasion [37, 89, 93]. Carcinoma in situ was never clearly defined and therefore the term was abandoned. In retrospect, many of these lesions would be classified today as hyperplasia with eosinophilic change. Recently, the term has been applied to an entirely different lesion (see below), adding further confusion [64]. In this chapter, we will utilize the World Health Organization

(WHO) classification [77], which does not recognize carcinoma in situ as a diagnostic term.

In summary, pathologists have recognized for decades that endometrial cancer precursors are morphologically and biologically heterogeneous. However, early studies designed to clarify the significance of these lesions were limited by the lack of standardized diagnostic criteria, failure to consider cytologic and architectural features separately, and inclusion of irradiated patients, which may have altered the natural history of the lesions studied [12, 17, 32, 37, 93]. Many of these limitations have been addressed in more recent studies (see "Behavior of Hyperplasia"). However, as will be discussed below, there remain significant issues in diagnostic reproducibility.

Endometrial hyperplasia is defined as a proliferation of glands of irregular size and shape with an associated increase in the gland/stroma ratio compared with proliferative endometrium. Although the process is often diffuse, it may also be focal. The World Health Organization (WHO) classification, presently the most widely used, is a four-tier classification system that takes into account both cytologic and architectural abnormalities [77]. Over the years, studies have raised doubts about the clinical significance of the architectural categories in this classification system and have suggested that endometrial hyperplasia could be simply subdivided into two broad categories: hyperplasia without cytologic atypia and hyperplasia with cytologic atypia (atypical hyperplasia) (**>** *Table 8.1*). The rationale for this classification is based on the natural history of the disease as shown in long-term follow-up studies [8, 26, 49]. In one natural history study, fewer than 2% of hyperplasias without cytologic atypia progressed to carcinoma, whereas 23% of hyperplasias with cytologic atypia (atypical hyperplasia) progressed to carcinoma. In addition, a more recent epidemiologic study added further support for this simplified classification by showing that the only lesion that significantly increased the relative risk of carcinoma was atypical hyperplasia [53]. In that study, non-atypical hyperplasia (both

Table 8.1

Classification of endometrial hyperplasia

Hyperplasia without atypia
Simple hyperplasia without atypia
Complex hyperplasia without atypia
Atypical hyperplasia
Atypical hyperplasia Simple atypical hyperplasia (very rare)

simple and complex) had a 10% chance of progression whereas atypical hyperplasia (both simple and complex) had a 40% chance of progression to carcinoma. Thus, the presence of cytologic atypia appears to be the main characteristic of hyperplasia that determines the risk of progression. Although increasing degrees of glandular complexity and crowding (architectural abnormalities) show a trend in increasing the likelihood of progression to carcinoma, these features are not statistically significant. Thus for practical purposes, it is reasonable to classify noninvasive proliferative lesions of the endometrium as either hyperplasia without atypia or atypical hyperplasia.

Clinical Features

Patients with endometrial hyperplasia typically have abnormal bleeding. Occasionally, the lesion is detected fortuitously by endometrial biopsy performed during the course of an infertility workup or before the start of hormone replacement therapy in postmenopausal women. Hyperplasia develops as a result of unopposed estrogenic stimulation, and consequently most patients with hyperplasia have a history of either persistent anovulation or exogenous unopposed estrogen usage. Although anovulation occurs at menarche and in perimenopausal women, hyperplasia is not usually encountered in young women. This may be because bleeding in menarchial women is seldom evaluated by an endometrial biopsy, although hyperplasia has been reported in a patient at 16 years of age [55]. During the reproductive years, hyperplasia is relatively uncommon, typically occurring in women with polycystic ovarian disease (Stein-Leventhal syndrome). In the original description of this syndrome, these women were reported to be anovulatory, obese, infertile, and exhibit hirsutism, but many women with this disorder lack these features. Conversely, women who are obese but who do not have polycystic ovarian disease may have hyperplasia, presumably as a result of peripheral conversion of androstenedione to estrogen in adipose tissue.

Diabetes mellitus and hypertension may occur in women with hyperplasia, but often these disorders are not present. Although hyperplasia or carcinoma should always be suspected in a postmenopausal woman with abnormal uterine bleeding, atrophy is the most common cause of bleeding in this age group. In one study of postmenopausal women with bleeding, 7% had endometrial cancer, 15% had various types of hyperplasia, and 56% had atrophy [58]. Typically, women with hyperplasia or carcinoma have moderate or heavy vaginal bleeding compared with women with atrophic endometria who present with spotting.

Pathologic Findings

Hyperplastic endometrium is not distinctive grossly. In hysterectomy specimens, hyperplasia may have a velvety, knobby surface of pale, spongy tissue with vague borders. Although diffuse thickening of the endometrium is common, hyperplasia can be focal and may simulate a polyp. The volume of tissue obtained in curettings is usually increased, but it may be quite variable and less than that obtained during the secretory phase of the normal cycle. A diagnosis of hyperplasia, therefore, depends on the histologic pattern and not on the volume of tissue.

Hyperplasia Without Cytologic Atypia

Hyperplasia is characterized by an increased gland/stroma ratio and a variety of abnormal architectural patterns. Glands typically vary in size and shape. Dilatation and outpouching of glandular epithelium characterize the lesser degrees of architectural abnormalities. In simple hyperplasia, the glands are cystically dilated, with occasional outpouchings surrounded by abundant cellular stroma (\triangleright *Fig.* 8.1). In other instances, the glands are only minimally dilated but focally crowded (\triangleright *Fig.* 8.2). Admixtures of the various patterns frequently occur (\triangleright *Fig.* 8.3). The cells lining the glands are stratified and

Fig. 8.1 Simple hyperplasia (without atypia). Glands are only minimally crowded but are dilated and have outpouchings

Fig. 8.2

Simple hyperplasia (without atypia). Glands are mildly crowded and some are cystically dilated

Fig. 8.4

Complex atypical hyperplasia (AH). Glands with complex profiles and papillary infoldings are crowded in a back-toback fashion, compressing intervening normal endometrial stroma

■ Fig. 8.3 Simple hyperplasia (without atypia). Glands are mildly crowded and dilated, with some exhibiting outpouchings and simple branching

columnar with amphophilic cytoplasm. Mitotic activity is variable. With increasing degrees of architectural abnormality, glands become complex and branched with irregular outlines and papillary infoldings into the lumens. In addition, with increased proliferation glands become crowded, compressing the intervening stroma, resulting in "back-to-back" glandular crowding. Thus, complex hyperplasia is composed of crowded glands with little intervening stroma [49] (Figs. 8.4–8.7).

Complex hyperplasia (without atypia). Branching and tubular glands are sufficiently crowded for classification as complex hyperplasia, despite the presence of some glands with simple tubular profiles

Usually the glandular outlines are highly complex (\bigcirc *Fig.* 8.4) but at times are tubular, with or without dilatation (\bigcirc *Figs.* 8.6 and \bigcirc 8.7). Epithelial stratification can range from two to four layers, but some glands may exhibit little or no stratification. Mitotic activity is variable and is usually less than five mitotic figures per 10 high-power fields. Even in highly complex hyperplasia with marked stratification, mitotic figures may be

Fig. 8.6

Complex hyperplasia (without atypia). Glands are sufficiently crowded for classification as complex hyperplasia, despite the presence of glands having only simple tubular profiles

Fig. 8.8

Simple hyperplasia (without atypia). Nuclei are elongated, oriented perpendicular to the basement membrane, and have even chromatin

Fig. 8.7

Complex hyperplasia (without atypia). Dilated glands resemble those seen in simple hyperplasia but are sufficiently crowded for classification as complex hyperplasia

inconspicuous. In hyperplasia lacking atypia the epithelial cells contain oval, basally oriented bland nuclei with smooth, uniform contours resembling those in normal proliferative glands (**•** *Figs. 8.8–8.11*). In simple hyperplasia, the stromal cells are more densely packed than in proliferative endometrium. The cells retain their spindle shape but are plump, with enlarged nuclei and indistinct cytoplasm. Mitotic activity in endometrial stromal cells is variable but may be increased. In complex hyperplasia, the

Fig. 8.9 Complex hyperplasia (without atypia). Nuclei are elongated, oriented perpendicular to the basement membrane, and have even chromatin

stromal cells are spindle shaped and compressed by the glandular proliferation. In addition to densely packed stromal cells, clusters of foamy, lipid-laden cells may be present in the stroma of simple and complex hyperplasias, atypical hyperplasias, and well-differentiated adenocarcinomas [19, 83]. Foam cells have small pyknotic nuclei and cytoplasm that contain lipid droplets but no mucin. The foam cells have been shown to be histiocytes by immuno-histochemistry [83]. These histiocytic cells may also be

observed in atrophic and nonneoplastic endometria. The isolated finding of histiocytes in cervicovaginal smears of asymptomatic postmenopausal women has not been associated with an increased likelihood of detecting endometrial hyperplasia or carcinoma [33]. The presence of histiocytes alone in cervicovaginal smears from postmenopausal women with abnormal uterine bleeding also has not been shown to predict the presence of either endometrial hyperplasia or carcinoma. However, the finding of histiocytes containing phagocytosed acute inflammatory

Fig. 8.10

Complex hyperplasia (without atypia). Nuclei are elongated, oriented perpendicular to the basement membrane, and are evenly hyperchromatic

Fig. 8.11 Complex hyperplasia (without atypia). Nuclei are elongated, oriented perpendicular to the basement membrane, and are evenly hyperchromatic

cells or normal endometrial cells in postmenopausal women with abnormal uterine bleeding has been associated with a three- to fourfold greater likelihood of coexistent endometrial carcinoma or hyperplasia [68].

Atypical Hyperplasia

The most important feature in the evaluation of endometrial hyperplasia is the presence or absence of nuclear atypia. Cells with nuclear atypia are stratified and show loss of polarity and an increase in the nuclear/cytoplasmic ratio (> Figs. 8.12-8.16). The nuclei are enlarged, irregular in size and shape, with coarse chromatin clumping, a thickened irregular nuclear membrane, and prominent nucleoli. Nuclei tend to be round as compared with the oval nuclei of proliferative endometrium and hyperplasia without atypia. As a result, the nuclei often have a cleared or vesicular appearance with condensation of the chromatin around the nuclear membrane. Nuclear atypia is variable, both qualitatively and quantitatively. Not all glands contain atypical cells, and in an individual gland some cells are atypical and others are not. Rare atypical cells should be ignored, but if cellular atypia is evident without a diligent search, the diagnosis of atypical hyperplasia should be made. One of the main issues facing diagnostic surgical pathologists is the intra- and interobserver variability in the identification of atypia. Thus, grading atypia as mild, moderate, or severe is not recommended, as it is subjective and not reproducible. Furthermore, assessment of atypia is often problematic

■ Fig. 8.12 Complex atypical hyperplasia. Nuclei are rounded and have vesicular chromatin

Fig. 8.13

Complex atypical hyperplasia. Nuclei are rounded, have vesicular chromatin, and display stratification and loss of polarity

Fig. 8.15

Complex atypical hyperplasia. Nuclei vary from ovoid to rounded, have even chromatin with evident nucleoli and mitotic figures, and display some stratification and loss of polarity

Fig. 8.14

in the setting of metaplasias (see below). The nuclear enlargement, rounding and vesicular change seen in tubal metaplasia, for example, can suggest cytologic atypia, but this metaplastic change is not interpreted as true atypia as it has not been shown to affect clinical outcome [35]. Moreover, metaplasia and atypia can occur together in the same glands, so if the nuclear changes are present in cells that are not metaplastic a diagnosis of atypical hyperplasia can be made even in the setting of metaplasia (\bigcirc *Fig. 8.17*).

Fig. 8.16

Complex atypical hyperplasia. Nuclei are enlarged and rounded, have vesicular chromatin with fine granularity and evident nucleoli, and display stratification and loss of polarity

The architectural features of simple atypical and complex atypical hyperplasia are similar to their counterparts without cytologic atypia. The glandular outlines in simple atypical hyperplasia may show minimal complexity or they may be more irregular with intraglandular tufting. The glands are separated by abundant stroma; back-toback crowding is absent. In complex atypical hyperplasia, the glands almost invariably demonstrate marked structural complexity with irregular outlines and back-to-back

Fig. 8.17

Complex hyperplasia with tubal metaplasia and atypia.

Nuclei vary from ovoid to rounded, have finely granular chromatin, and display some stratification and loss of polarity. Ciliated cells are present, indicating tubal metaplasia. Some nuclear changes are related to the tubal metaplasia but the loss of polarity and stratification are beyond those attributable to metaplasia (compare with **Figs. 8.39** and **8.40**)

crowding (**>** *Fig.* 8.4). Epithelial stratification and mitotic activity are variable. Papillary infoldings also are seen. Some atypical hyperplasias have little stratification, and mitotic activity may be inconspicuous. Since simple atypical hyperplasia is exceedingly rare, recent studies have included it in the category with complex atypical hyperplasia.

Differential Diagnosis

Simple and complex hyperplasia should be distinguished from disordered proliferative phase, polyps, ciliated cell change (tubal metaplasia), cystic atrophy, and endometrial glandular and stromal breakdown. Disordered proliferative phase is similar qualitatively to simple hyperplasia but is a focal lesion characterized by irregularly shaped and enlarged glands that are interspersed among normal proliferative glands (\bigcirc *Fig.* 8.18). The latter may be focally crowded. The key feature that distinguishes disordered proliferative phase from simple hyperplasia is the focal nature of the glandular abnormality in disordered proliferative phase. The fragments of endometrium containing the disordered glands should not have the appearance of a polyp. Hyperplastic endometrial polyps often contain areas of simple and complex hyperplasia

Fig. 8.18

Disordered proliferative endometrium. Cystically dilated glands with outpouchings are admixed with small tubular proliferative glands

that are confined to one or just a few fragments of polypoid tissue. The polyp usually stands out as a large rounded tissue fragment in sharp contrast to the remainder of the uninvolved endometrium. Polyps typically have dense fibrous stroma and contain clusters of thick-walled blood vessels near the center of the fragment. The fragments usually are covered on three sides by surface endometrium (see **2** Chap. 7, Benign Diseases of the Endometrium).

Endometrial glands with ciliated cell change are often found in association with simple and complex hyperplasia. When found with hyperplasia, the presence of ciliated cell change does not need to be specified. Ciliated glands are usually slightly dilated. When a few isolated glands show ciliated cell change in the absence of hyperplasia, a diagnosis of ciliated cell change (tubal metaplasia) is justified (see following). Ciliated cell change often contains scattered vesicular nuclei with occasional nucleoli that should not be mistaken as cytologic atypia when found in association with hyperplasia.

Distinction of cystic atrophy from simple hyperplasia is seldom a problem in curettings because atrophic glands collapse as a result of the procedure. In hysterectomy specimens, glands are dilated and lined by a single layer of cells that are often flattened. Mitotic activity is not present. In contrast, in simple hyperplasia there is pseudo-stratification of columnar epithelial cells. Mitotic activity is variable but present.

In endometrial glandular and stromal breakdown caused by estrogen withdrawal, proliferative-type glands appear back-to-back because of loss of intervening endometrial stroma. Glands are often fragmented, and apoptotic bodies are present. Clusters of stromal cells and fragmented glands surrounded by blood are consistent features (see \bigcirc Chap. 7, Benign Diseases of the Endometrium). In contrast, in complex hyperplasia the glandular outlines are more irregular and complex than the tubular, proliferative-type glands in breakdown. Furthermore, glandular fragmentation, apoptotic bodies, and rounded clusters of stromal cells, so-called stromal blue balls, are usually absent in hyperplasia. In addition, the tissue fragmentation and artifactual apposition of segments of surface epithelium encountered in biopsy and curettage specimens can complicate interpretation and should be considered prior to rendering a diagnosis of hyperplasia (\bigcirc *Fig.* 8.19).

Atypical hyperplasia must be distinguished from an atypical polypoid adenomyoma and from well-differentiated adenocarcinoma. The atypical polypoid adenomyoma is composed of glands that show variable architectural complexity and some cytologic atypia (\bigcirc *Fig. 8.20*). Squamous differentiation in the form of squamous morules is an almost constant feature of the atypical polypoid adenomyoma. Characteristically, the glands in the atypical polypoid adenomyoma are surrounded by smooth muscle, in contrast with the dense proliferative stroma found in hyperplasia and the altered or desmoplastic stroma found in association with well-differentiated carcinoma.

Most endometrial carcinomas are readily identified. However, several recent studies highlight the difficulty in distinguishing some cases of well-differentiated carcinoma from atypical hyperplasia on preoperative endometrial sampling by either biopsy or curettage. Specific histologic features can often be used to separate hyperplasia from well-differentiated carcinoma that reduce the subjectivity of the evaluation. In the presence of invasion the endometrial stroma interacts directly with malignant cells, and the morphologic changes it undergoes can serve as a means of identifying carcinoma. The stromal and epithelial alterations associated with invasive carcinoma are referred to collectively as endometrial stromal invasion. There are three useful criteria, any of which identifies stromal invasion: (1) an irregular infiltration of glands associated with an altered fibroblastic stroma (desmoplastic response); (2) a confluent glandular pattern in which individual glands, uninterrupted by stroma merge, at times creating a cribriform pattern; and (3) an extensive papillary pattern. It should be noted that on occasion complex hyperplasias can display a papillary architecture, including the presence of fibrovascular cores, but in contrast to the papillary pattern of carcinoma, complex hyperplasia is characterized by bland cytology, absence of epithelial stratification, and a low level of mitotic activity [56]. It has been reported that a process manifesting the features of invasion must be sufficiently extensive to involve half (2.1 mm) of a low-power field 4.2 mm in diameter to have value in predicting the

Fig. 8.19

Artifactual glandular crowding. Apposition of surface epithelium of fragments of proliferative endometrium simulates the cystically dilated glands of simple hyperplasia but is an artifact

presence of a biologically significant carcinoma in the uterus [50, 69]. This criterion, however, should not be applied too rigidly in view of the potential of missing a carcinoma in small samples. If unequivocal evidence of stromal invasion is present in an area measuring less than one half of a low-power field, a diagnosis of well-differentiated carcinoma should be made (\bigcirc *Figs. 8.21* and \bigcirc *8.22*). The quantification criterion does not apply to moderately or poorly differentiated carcinomas. The three criteria for the identification of stromal invasion are described in greater detail below.

1. The altered stroma that reflects invasion contains parallel, densely arranged fibroblasts with more fibrosis than normal endometrial stroma, that disrupts the usual glandular pattern (> Fig. 8.23). The stromal cells are more spindle shaped than are the stromal cells of proliferative endometrium, with more elongated nuclei. Collagen compresses the stromal cells so that they have an eosinophilic and wavy appearance (> Fig. 8.24), compared with the basophilic nakednucleus appearance of stromal cells found in proliferative endometrium and hyperplasia. In specimens containing fragments of polyps with fibrous stroma, or specimens from the lower uterine segment, these features cannot be applied. The distinction of hyperplasia from carcinoma in these cases is based on the identification of a confluent pattern (see below).

Atypical polypoid adenomyomas (see **○** Chap. 7, Benign Diseases of the Endometrium) contain smooth muscle and may simulate myometrial invasion (see **○** *Fig. 8.20*) [62]. In contrast with the atypical polypoid adenomyoma, smooth muscle is rarely identified in curettings of well-differentiated carcinoma even

Fig. 8.21

Complex atypical hyperplasia with foci of welldifferentiated endometrioid carcinoma. Small aggregates of fused glands consistent with early endometrioid carcinoma are architecturally distinct from the individual larger glands of associated complex atypical hyperplasia

Fig. 8.23

Well-differentiated endometrioid carcinoma. Crowded atypical glands with early glandular confluence are surrounded by eosinophilic spindled stromal cells, which constitute a desmoplastic stromal reaction, indicating stromal invasion by carcinoma

Fig. 8.24

Well-differentiated endometrioid carcinoma. Stromal desmoplasia, a manifestation of endometrial stromal invasion by endometrioid carcinoma, is characterized by spindled cells with a fibroblastic appearance

Fig. 8.26

Well-differentiated endometrioid carcinoma. Complex branching glands creating a confluent glandular/ labyrinthine pattern and altered (desmoplastic) stroma indicate endometrial stromal invasion by carcinoma

Fig. 8.25

Well-differentiated endometrioid carcinoma. Glands are fused and interconnected in a confluent glandular pattern, without intervening stroma, indicating endometrial stromal invasion by carcinoma

when there is deep myometrial invasion because only the exophytic portion of the tumor is removed in biopsies and curettings.

2. Confluent glandular aggregates without intervening stroma reflect stromal invasion (> *Figs. 8.25* and > 8.26). Confluent patterns are characterized by glandular configurations in which individual glands are not surrounded by stroma. Instead, glands appear to merge into one another to form a complex labyrinth.

Fig. 8.27

Well-differentiated endometrioid carcinoma. Fused glands creating a cribriform pattern indicate endometrial stromal invasion by carcinoma

Some proliferations are cribriform, resulting from proliferation and bridging of epithelium (**>** *Fig. 8.27*).

3. Complex papillary patterns represent stromal invasion if multiple, branching, fibrous processes lined by epithelium are present (> *Figs. 8.28* and > 8.29). Often, these papillary structures create a villoglandular pattern. Intraglandular epithelial papillations lacking a fibrovascular core do not qualify as a feature of invasion; such proliferation is often encountered in eosinophilic metaplasia within complex hyperplasia

Fig. 8.28

Well-differentiated endometrioid carcinoma. A papillary/ villoglandular proliferation indicates carcinoma when the papillary/villous structures have an exophytic growth pattern and are not merely intraglandular epithelial papillae

Fig. 8.30

Complex papillary hyperplasia. Intraglandular papillae reflect a papillary variant of hyperplasia rather than carcinoma (compare with **)** *Fig. 8.28*)

Fig. 8.29

Well-differentiated endometrioid carcinoma. A papillary/ villoglandular pattern indicates carcinoma when the papillary/villous structures are lined by atypical endometrioid epithelium along the external aspect and have a central fibrovascular core

(see below). Delicate papillary structures (with or without fibrovascular cores), often accompanied by metaplastic changes (mucinous, eosinophilic cell) and often occurring in polyps, are a feature of simple and complex papillary hyperplasias (\bigcirc *Figs. 8.30* and \bigcirc *8.31*) [56]. In these lesions, the cytology is bland and

Fig. 8.31

Complex papillary hyperplasia. Papillae can lack or contain fibrovascular cores; their intraglandular location and absence of atypia indicates a hyperplasia rather than a papillary pattern of carcinoma

the epithelium overlying the fibrovascular cores is not stratified. The mitotic index and the Ki-67 proliferation index are very low.

In the past, the presence of masses of squamous epithelium replacing the endometrial stroma was considered a feature of invasion [50]. Masses of squamous epithelium with minimal nuclear atypia that extensively replace the

endometrium (over a 2-mm² area) reflect stromal invasion only if they are associated with a desmoplastic response or a confluent glandular pattern.

Increasing degrees of nuclear atypia, mitotic activity, and stratification of cells in curettings are associated with a higher frequency of carcinoma in the uterus but are of limited value because even a mild degree of these changes is associated with carcinoma in nearly one third of cases [56]. Even with mild atypia, low mitotic activity, and lesser degrees of stratification in curettings, 20% of residual carcinomas in the resected uterus are moderately or poorly differentiated, and 10% deeply invade the myometrium. These other features in curettings, although useful, therefore are not sufficiently accurate to predict whether a biologically significant lesion is present in the uterus. Unfortunately, assessing varying degrees of nuclear atypia in this borderline group of lesions is subjective and not easily reproduced. In contrast, when stromal invasion is absent in curettings, carcinoma is found in the uterus in only 17% of cases, and the carcinomas are well differentiated and either confined to the endometrium or only superficially invasive (> Table 8.2).

If stromal invasion is present in curettings, residual carcinoma is found in the uterus in half; more than one third of the carcinomas are moderately or poorly differentiated, and a fourth of them invade deeply into the myometrium (**2** *Table 8.3*). A small proportion (7%) of patients with invasion in curettings will have extrauterine metastases at hysterectomy, and half with metastasis will

die of tumor [50]. Thus, the absence of stromal invasion provides the basis for distinguishing atypical hyperplasia from a biologically significant, well-differentiated carcinoma [46, 50]. A number of more recent studies have found higher frequencies of endometrial carcinoma in hysterectomy specimens following (43 - 52%)a diagnosis of atypical hyperplasia [39, 92, 96]. Of the carcinomas detected in two of these studies, 43% were stage IC or greater. In the most recent study, only 10.6% were stage IC while 30.9% were stage IB and the remaining were stage IA. These studies included patients who had been diagnosed by either curettage or biopsy, but there were no significant differences in the frequencies with which carcinoma was detected at hysterectomy in those patients who received a curettage compared to those who had been biopsied. However, in one of these studies, the biopsy and curettage specimens were not reviewed to confirm the absence of features of stromal invasion in these specimens [39]. More recently, additional studies have demonstrated that clinically significant endometrial proliferations, that is, those that have a high likelihood of myometrial invasion, can be recognized when either sufficient architectural complexity or nuclear atypia, including prominence of nucleoli, is present [60, 63]. In addition, the strong association of a desmoplastic stromal response with a myoinvasive lesion was confirmed.

The identification of stromal invasion is important because it is semiquantitative, therefore less subjective than other criteria, and it delineates a biologically significant lesion that has a much greater likelihood of metastasis than one in which invasion is absent. Experimental studies of neoplasms from the breast, colon, pancreas, and lung lend support to the division of endometrial proliferations into noninvasive and invasive forms based on the histologic alterations observed in the endometrial stroma. These studies demonstrate profound molecular and structural alterations in the stroma adjacent to invasive as compared with noninvasive tumors. Invasive tumors can induce a conversion of stromal fibroblasts into myofibroblasts, which elaborate extracellular matrix components, such as type V collagen and proteoglycans, which are increased in desmoplasia and are readily observed by light microscopy using the criteria for stromal invasion as outlined. It has been shown that tumor cells produce growth factors such as platelet-derived growth factor, epidermal-derived growth factor, and insulin-like growth factor, which may play a role in stimulating the growth of stromal cells surrounding tumors.

Reproducibility Studies and Adjunctive Techniques in the Classification of Endometrial Hyperplasias

A number of studies have addressed the reproducibility of the diagnosis of endometrial hyperplasia and its distinction from well-differentiated carcinoma [11, 44, 97]. One study of 100 endometrial biopsy and curettage specimens ranging from proliferative endometrium to welldifferentiated carcinoma found substantial interobserver agreement for diagnoses of hyperplasia without atypia and well-differentiated carcinoma but only moderate agreement for the diagnosis of atypical hyperplasia [44]. Several histologic features, including nuclear enlargement, vesicular change, nuclear pleomorphism, chromatic irregularities, loss of polarity, nuclear rounding, and presence of nucleoli, were associated with a diagnosis of atypical hyperplasia by univariable logistic regression analysis. However, of the histologic features evaluated, the only feature that was associated with the distinction of atypical hyperplasia from hyperplasia without atypia in multivariable logistic regression analysis was the presence of nucleoli.

The features that were associated with the distinction of carcinoma from atypical hyperplasia in both univariable and multivariable analysis included stromal alteration (stromal desmoplasia) and glandular confluence. A more recent study found similar values for intraobserver agreement and slightly lower values for interobserver agreement [11]. In addition, the study confirmed that the category of atypical hyperplasia has the lowest diagnostic reproducibility of the various categories. Similar histologic features were found to be useful for distinguishing the various diagnostic categories, although the utility of the presence of nucleoli for diagnosing well-differentiated carcinoma alteration for diagnosing well-differentiated carcinoma were somewhat less, as evidenced by lower mean interobserver agreement values for these features. Thus, interobserver agreement is lowest for the diagnostic category of atypical hyperplasia, indicating that further refinement of the histologic criteria, enhanced endometrial sampling techniques, and novel objective analyses are required to improve the reproducibility of the diagnosis of atypical hyperplasia.

Some investigators have attempted to use computerized morphometric analyses of endometrial hyperplasias to predict coexistent carcinoma in hysterectomy specimens [2, 4, 6, 7, 22]. Nuclear morphometry alone has been shown to be insufficiently sensitive and specific to properly distinguish hyperplasias that are associated with carcinoma from those that are not [2, 4]. Although, the combination of architectural and nuclear morphometric features has been shown to be useful for predicting risk of endometrial carcinoma in patients with hyperplasia it has not become widely used because it is labor intensive and too costly to be practical for most laboratories [5–8, 22].

More recently, investigators have proposed that endometrial proliferations be broadly divided into two categories based on the molecular genetic analysis of clonality [65–67]. Proliferations that are polyclonal are regarded as a response to an abnormal hormonal environment - either unopposed estrogenic stimulation associated with anovulatory cycles or exogenous estrogenic stimulation - and are designated "hyperplasia." Monoclonal lesions, on the other hand, are associated with an increased risk of progression to carcinoma and are designated "endometrial intraepithelial neoplasia" (EIN). The rationale cited for this approach is that therapy for hyperplasia should be aimed at treating the suspected cause and symptoms, whereas EIN should be removed or ablated. Since progestin treatment can frequently suppress atypical hyperplasia and well-differentiated endometrioid carcinoma this is not a good reason for adopting the EIN classification. Because clonality cannot routinely be performed on diagnostic specimens in most laboratories, it has been proposed that the diagnosis of EIN be made when glandular crowding results in a volume percentage of stroma less than 55%. Ideally, this parameter would be assessed by morphometric analysis, which has been shown to separate hyperplasias, particularly those classified as non-atypical by light microscopic assessment, into monoclonal and polyclonal lesions [67]. For practicality, routine light microscopic assessment aided by an ocular graticule and

a web-based tutorial that correlates patterns of endometrial proliferations with clonality data has been proposed as an alternative to morphometry. However, in a recent nested case-control study the risk of progression to carcinoma was similar after either a diagnosis of EIN or atypical hyperplasia [54]. In addition, the diagnostic reproducibility of the light microscopic assessment of volume percentage stroma has not been adequately determined. Finally, cytologic atypia that allegedly differs from atypia as shown in the WHO classification is required for the diagnosis of EIN and is defined as cytology that differs from normal endometrial glands present in the same sample. Thus, when compared to a simplified version of the WHO classification system that collapses the four categories into two (hyperplasia and atypical hyperplasia) there are no apparent advantages to the use of the EIN system. In the future, molecular genetic data will undoubtedly play a role in the classification of these lesions, but at present since the WHO system is well understood and in widespread use, the proposed hyperplasia-EIN classification system is not recommended for clinical practice.

Molecular Genetics and Immunohistochemistry

Molecular genetic studies are mentioned only briefly here with a more detailed discussion in the chapter on "Endometrial Carcinoma" (see O Chap. 9, Endometrial Carcinoma). There have been a number of molecular genetic alterations identified in atypical endometrial hyperplasia, including microsatellite instability and mutations in the PTEN tumor suppressor gene and the KRAS oncogene [57]. Of note, these are the most common molecular genetic alterations in endometrioid carcinoma. These findings support clinicopathologic and epidemiologic data indicating that atypical endometrial hyperplasia is the immediate precursor for endometrioid carcinoma. PTEN mutations are found at approximately the same frequency in complex atypical hyperplasia and carcinoma and have rarely been described in hyperplasia without atypia [34]. In addition, KRAS mutations and microsatellite instability have been reported in complex atypical hyperplasia [23, 25, 57]. Only a relatively small number of hyperplasias without atypia have been analyzed for mutations in PTEN, KRAS, and for microsatellite instability. Studies suggest that all of these alterations occur before the development of invasion but it is not clear when in the progression of the disease they occur.

Currently, immunohistochemistry does not play a role in the diagnosis of endometrial hyperplasia. Although a number of studies have been done with a wide variety of antibodies, none have been found to have diagnostic utility.

Behavior

Many of the past studies designed to determine the outcome of women with endometrial hyperplasia did not consider cytologic and architectural features separately. This issue was addressed in a retrospective analysis of 170 patients with endometrial hyperplasia on curettings with a mean follow-up of 13.4 years in which hysterectomy was not performed before 1 year after the initial diagnosis. Various histologic features were evaluated, and cytologic and architectural abnormalities were analyzed independently in an effort to delineate the histologic features associated with an increased risk of progression to carcinoma. A third of the patients with both non-atypical and atypical hyperplasia were asymptomatic after the diagnostic curettage and required no further treatment. Only 2 (2%) of 122 patients with hyperplasia lacking cytologic atypia, one with simple and one with complex hyperplasia, progressed to carcinoma. The two cases of simple hyperplasia that progressed to carcinoma first developed atypical hyperplasia. In contrast, 11 (23%) of the 48 women with atypical hyperplasia progressed to carcinoma (**2** Table 8.4); 8% of patients with simple atypical hyperplasia and 29% of patients with complex atypical hyperplasia progressed to carcinoma (**)** Table 8.5). The presence of glandular complexity and crowding superimposed on atypia, therefore, appears to place the patient at greater risk than does cytologic atypia alone. The differences in progression to carcinoma among the four subgroups, however, were not statistically significant. Similar findings were subsequently reported by other

investigators [8, 26]. More recently a nested case-control study of 138 cases diagnosed with endometrial hyperplasia followed by carcinoma at least 1 year later with 241 controls (matched for age, date and follow-up duration, and counter-matched for endometrial hyperplasia diagnosis) showed that women with both simple and complex endometrial hyperplasia without atypia, had a 10% probability of developing carcinoma in contrast to a 40% probability for women with atypical hyperplasia, both simple and complex [53]. These studies show that cytologic atypia is the most useful feature in identifying a lesion that might progress to carcinoma.

The carcinomas that develop in patients with hyperplasia are relatively innocuous [32, 49]. In one study,

Adapted with permission from [49].

the mean duration of progression of hyperplasia without atypia to carcinoma is nearly 10 years, and it takes a mean of 4 years to progress from atypical hyperplasia to clinically evident carcinoma [49]. In another study the median interval from atypical hyperplasia to carcinoma was 6.7 years. A comparison of the clinicopathologic features and behavior of the carcinomas developing after a diagnosis of atypical hyperplasia in women at the age of 40 years or younger compared with women over the age of 40 years is shown in **?** Table 8.6. Although all but one of the carcinomas that developed from atypical hyperplasia were well differentiated and minimally invasive, one welldifferentiated tumor that extended into the endocervix metastasized to the pelvic peritoneum and a paraaortic lymph node. After abdominal radiation the patient was disease free 19 years later. These findings and others suggest [10] that carcinomas associated with hyperplasia are relatively innocuous compared with carcinomas without associated hyperplasia.

It has been shown that 17–43% of women with atypical hyperplasia in curettings will have a well-differentiated carcinoma in the uterus if a hysterectomy is performed within 1 month of the curettage [46, 89]. Increasing degrees of nuclear atypia, mitotic activity, and stratification of cells in curettings are associated with a higher frequency of carcinoma in the uterus. With long-term follow-up, however, only 11–40% of women with atypical hyperplasia develop carcinoma if a hysterectomy is not done [32, 49]. Thus, the lesion designated as welldifferentiated carcinoma usually remains stable for a long period of time. Reasons that may account for the relatively low rate of progression to carcinoma in untreated patients with atypical hyperplasia include a general tendency for the highest grade of atypical hyperplasia to be selected for hysterectomy, leaving the lesser degree of atypia for conservative management, and atypical hyperplasia may not be the precursor of all forms of endometrial cancer, but only of a type that is slowly progressive.

A more recent study of the behavior of endometrial hyperplasia found that most cases of endometrial hyperplasia without atypia regressed spontaneously whereas those with complex atypical hyperplasia were much more likely to persist [90]. Another recent study confirmed the significance of cytologic atypia in predicting increased risk of associated endometrial carcinoma in hysterectomy specimens [38]. Because most atypical hyperplasias have complex architecture, it is complex atypical hyperplasia that is associated with a significant risk of persistence and progression to carcinoma. Hence, this lesion is regarded as a direct precursor of well-differentiated endometrioid carcinoma of the endometrium. However, hyperplasia is identified in a prior endometrial specimen or in the hysterectomy specimen in only 35-75% of women with endometrial carcinoma [3, 10, 13, 20, 31, 42]. In those reports that specified the number of hyperplasias that were classified as atypical, 14-36% of women with endometrial carcinoma had associated atypical hyperplasia [31, 42]. It is unclear whether failure to identify an associated atypical hyperplasia in all cases of endometrioid carcinoma reflects overgrowth of a preexisting hyperplasia

by carcinoma or the development of carcinoma through a different pathway.

Management

Management of patients with endometrial hyperplasia is based on clinical factors, which include the desire to preserve fertility in young women and associated medical conditions that render older women at high risk for a surgical procedure, and microscopic findings [47].

Premenopausal Women (Less Than 40 Years of Age)

Most premenopausal women who present with abnormal bleeding have nonspecific hormonal disorders that are self-limited. These women are at low risk of having carcinoma (**7** Table 8.7). In a study of 460 women 40 years of age and younger, 6 (1.3%) had "mild" hyperplasia (simple hyperplasia) but none had atypical hyperplasia or carcinoma [43]. Therefore, most women in this age group with abnormal bleeding do not require an endometrial biopsy. Women with risk factors for endometrial cancer, such as polycystic ovarian disease or obesity, and women with persistent bleeding should have an endometrial biopsy performed. Traditionally, evaluation of such patients has been by curettage in the operating room but it

has been shown by some studies that office-based endometrial sampling devices such as the Pipelle device are comparable and are substantially less expensive, with 96% agreement between the biopsy and hysterectomy findings [30, 82, 87].

If a diagnosis of simple or complex hyperplasia is made, the patient can be treated conservatively because these lesions have an extremely low risk (1-2%) of progression to carcinoma. Because the transit time to carcinoma is approximately 10 years and hyperplasia without cytologic atypia first progresses through atypical hyperplasia before becoming carcinoma, follow-up and periodic endometrial biopsies suffice [49]. Conservative management of young women with simple hyperplasia and complex hyperplasia resulted in subsequent pregnancies in 29% and 20% of these women, respectively, in one study (\bigcirc *Table 8.8*) [49].

Women with atypical hyperplasia on an endometrial biopsy who wish to preserve their fertility should be treated with progestin suppression. In view of the very similar accuracy of endometrial biopsy and curettage and the low risk of an associated endometrial carcinoma in women younger than 40 years of age, a curettage need not be performed to exclude carcinoma but close follow-up and periodic endometrial biopsies are necessary. A conservative plan of management is justified because the risk of progression to carcinoma in young women is low and the carcinomas that do develop tend to be innocuous (**7** *Table 8.9*); 20% of those women less than 40 years of age can subsequently become pregnant and have normal deliveries [74]. A recent study of complex hyperplasia with and without atypia found that progestin therapy

Table 8.8

Subsequent pregnancies in "untreated" women with hyperplasia and atypical hyperplasia

resulted in regression of complex atypical hyperplasia (**)** *Table 8.10*) but that the majority of complex hyperplasias without atypia regressed with or without progestin therapy [75]. This study also found that higher doses and longer duration of progestin therapy increase the likelihood of regression of complex atypical hyperplasia (**)** *Table 8.11*).

Conservative management also can be considered for women diagnosed with well-differentiated carcinoma. One study of progestin treatment of atypical hyperplasia and well-differentiated carcinoma in women under age 40 found that 75% of women with carcinoma and 95% with atypical hyperplasia had regression of their lesions [74]. In addition, all patients were alive without evidence of progressive disease during the follow-up period. The median duration of progestin treatment necessary to effect regression was 9 months. In another study, 62% of women under the age of 40 years treated with progestins alone for endometrial carcinoma responded to the hormonal therapy, although 23% of these later developed recurrent disease [45]. Ninety percent of the patients were alive without evidence of disease during the follow-up period. The lower frequency of responders in this study may have been a result of the relatively short duration of the hormonal therapy. Thus, in premenopausal women, atypical hyperplasia and well-differentiated carcinoma can be

regarded as a single clinicopathologic entity for management purposes. Nonetheless, pathologists should distinguish atypical hyperplasia from well-differentiated carcinoma since atypical hyperplasia is more likely to respond to progestin treatment. If conservative management is elected, magnetic resonance imaging (MRI) must be performed to exclude deep myometrial invasion or the presence of a coexisting ovarian neoplasm.

Perimenopausal Women (40 to 55 Years of Age)

Abnormal bleeding in the perimenopausal age group can be managed in a similar fashion as in younger women because perimenopausal women also are at low risk of having carcinoma (see **7** *Table 8.7*). Most simple and complex hyperplasias in the 40- to 55-year-old age group are related to anovulation and are self-limited. Nonetheless, a biopsy is usually performed to exclude carcinoma. Patients with a diagnosis of atypical hyperplasia can be treated with progestins or a hysterectomy.

Nearly 60% of atypical hyperplasias regress, but the likelihood of residual carcinoma in the uterus after a curettage increases with age. For patients in the 40- to 55-year age range, treatment should be individualized. Regression occurs frequently, and the risk of residual carcinoma is lower than in older women. Therefore, observation or suppression with progestins monitored by endometrial biopsies every 3 months suffices. If the lesion persists, a hysterectomy may have to be performed.

Postmenopausal Women (Over 55 Years of Age)

Women in the postmenopausal age group who have abnormal bleeding have a significant risk of having either carcinoma or atypical hyperplasia (see) Table 8.7). Accordingly, abnormal bleeding requires immediate evaluation with an endometrial biopsy. A diagnosis of hyperplasia or atypical hyperplasia should be evaluated with a fractional curettage. If the curettings demonstrate hyperplasia without atypia, conservative management is an option because these types of hyperplasia are related to unopposed estrogenic stimulation, either from exogenous hormone treatment or because of peripheral conversion of androgens to estrogen in adipose tissue. Most (80%) hyperplasias treated with cyclic medroxyprogesterone acetate at 10 mg/day for 14 days regress; none progressed to carcinoma in a prospective study of 65 postmenopausal women [26]. Conservative management, which makes use of either observation only or treatment with medroxyprogesterone to produce a medical curettage, therefore, is adequate. Repeated episodes of irregular bleeding that are not responsive to hormone treatment require a hysterectomy. Hysterectomy is the treatment of choice for a diagnosis of atypical hyperplasia based on a curettage. In postmenopausal women with surgical risk factors that preclude a hysterectomy, continuous treatment with 20-40 mg/day megestrol acetate can be used effectively to avoid surgery. In a study of 70 women treated with complex hyperplasia (38 women) and atypical hyperplasia (32 women), surgery was avoided in 93% of patients. The hyperplasias (atypical and non-atypical) completely regressed in 85% after a mean follow-up of more than 5 years. None of the lesions progressed to carcinoma [28].

For postmenopausal women with hyperplasia or atypical hyperplasia who are receiving exogenous estrogen, termination of the estrogen usually suffices even for atypical hyperplasia, because these proliferations regress after the stimulus for their growth has been removed. Alternatively, the addition of cyclically or continuous administered medroxyprogesterone in women being treated with estrogen can be considered because the use of even low doses of progestins substantially reduces the risk of development of endometrial hyperplasia and carcinoma [91]. Using a 7- to 14-day regimen of orally administered 10 mg medroxy-progesterone to postmenopausal women receiving estrogen, 5 endometrial carcinomas were detected in 5,402 woman-years of continuous estrogen therapy [29]. This incidence is not greater than that of untreated postmenopausal women, in whom the expected incidence of endometrial cancer is 1-2 per 1,000 woman-years, that is, 5.4-9.8 cases. The addition of continuous low doses of norethindrone acetate to estradiol therapy also reduces the incidence of endometrial hyperplasia in postmenopausal women. Hyperplasia developed in 15% of women receiving unopposed estradiol therapy compared to less than 1% of those receiving continuous low doses of norethindrone combined with estradiol [52].

Morphologic Changes Associated with Progestin Treatment

Treatment with progestins for women with complex atypical hyperplasia and well-differentiated carcinoma has become an accepted alternative to hysterectomy. Correct interpretation of the morphologic changes that result from the treatment is required for the appropriate management of women who chose this therapeutic approach. Unfortunately, there have been few studies to describe these changes. One recent study, described a number of histologic changes including decreased gland-to-stroma ratio, decreased glandular cellularity, reduced to absent mitotic activity, loss of cytologic atypia, and a variety of metaplastic changes (> Figs. 8.32 and > 8.33) [94]. In addition, cribriform and papillary architectural changes may be induced by treatment and confused with disease progression. Importantly, the persistence of architectural abnormalities and/or cytologic atypia after 6 months of treatment were the only histologic features found to be associated with treatment failure. Based on these findings,

Fig. 8.32

Complex hyperplasia with treatment (progestin) effect. Individual glands with complex profiles are interspersed with inactive glands within endometrial stroma (a). The confluent glandular pattern of the prior endometrioid carcinoma is absent. Glands exhibit mucinous change (b)

a classification of progestin-treated lesions was proposed (**>** *Table 8.12*). It is important that the pretreatment specimen be available for review in order for the pathologist to evaluate the response to progestin treatment, and therefore provide information to the gynecologist that will assist in modifying or discontinuing therapy.

Endometrial Cellular Changes: Metaplasia, Cellular Differentiation

In contrast to hyperplasia, which is a proliferative response to estrogenic stimulation, metaplasia represents cytoplasmic differentiation. The cytoplasmic alterations (metaplasia) are manifested by eosinophilic, ciliated cell (tubal), squamous, secretory/clear, and mucinous differentiation. Metaplasias develop most commonly in response to estrogenic and progestational stimulation, although these changes may develop in response to various other stimuli as well. Thus, the morphologic response of the endometrium to hormonal stimulation is complex and is reflected by a combination of architectural, nuclear, and cytoplasmic alterations. Although classifications separate hyperplasia and the various metaplasias, both are usually intimately associated and cannot always be separately classified.

Fig. 8.33

Complex hyperplasia with treatment (progestin) effect.

Complex glands exhibit prominent metaplastic changes (eosinophilic, mucinous, tubal), which are commonly seen, along with reduction of nuclear atypia, as a result of progestin therapy

Table 8.12

Classification of progestin-treated lesions of the endometrium

Diagnosis	Histologic features
Progestin-treated complex hyperplasia	No cytologic atypia with crowded, back-to-back glands and/or a confluent glandular pattern (cribriform and/or papillary)
Progestin-treated CAH	Cytologic atypia with crowded, back-to-back glands that lack a confluent glandular pattern
Progestin-treated well- differentiated carcinoma	Cytologic atypia with confluent glandular pattern (cribriform and/or papillary pattern)

Adapted with permission from [94].

Definitions and Classification

Metaplasia is defined as replacement of one type of adult tissue by another type that is not normally found in that location. In the endometrium, most of the changes that are designated as metaplasia represent a variety of cytoplasmic alterations or forms of differentiation that are not encountered in normal proliferative endometrium but do not qualify as true metaplasia. Accordingly, it has been suggested that a more appropriate term is change [84]. Use of the term change also has the advantage of providing a descriptive designation without employing a specific mechanism of development. In this chapter, the terms metaplasia, change, and differentiation are used interchangeably. The various forms of cellular differentiation are typically focal when unaccompanied by hyperplasia but can be diffuse when hyperplasia is present. The WHO classification subdivides endometrial metaplasia as follows: squamous, mucinous, ciliary, hobnail, clear cell, eosinophilic, surface syncytial, papillary proliferation, and Arias-Stella effect [77]. This classification combines both cytologic and architectural alterations, some of which have different etiologies. As previously noted, the endometrial epithelium can undergo a variety of cytoplasmic changes in response to different stimuli that can be observed in both benign and malignant conditions. A simplified classification of these cytoplasmic changes is shown in **2** Table 8.13. It is important to recognize the various cytoplasmic changes because they are benign and can be confused with hyperplasia. When hyperplasia and the cytoplasmic alterations coexist, as they often do, the hyperplasia should be classified, but it is not necessary to describe the cytoplasmic changes because they do not influence prognosis (see section **>** Behavior).

Clinical Features

The frequent association of the various endometrial cytoplasmic changes with hyperplasia probably results from a hyperestrogenic state. More than 70% of perimenopausal

Table 8.13

Mucinous	
and postmenopausal women with metaplasia had received exogenous estrogen in one study [35]. In addition, most young women with metaplasia have clinical manifestations of persistent anovulation and primary infertility, features of polycystic ovarian disease [18, 35]. Metaplasia also may occur in various benign conditions, including polyps, endometritis, trauma, and vitamin A deficiency [18, 27, 35, 36].

Pathologic Findings

The various types of endometrial cytoplasmic changes have no distinctive gross features.

Eosinophilic Change

Eosinophilic change is the most common cytoplasmic alteration (\bigcirc *Figs.* 8.34 and \bigcirc 8.35). Several types of eosinophilic cytoplasmic transformation occur, all of them innocuous. Ciliated cells, squamous cells, oncocytes, and papillary and surface syncytial change all may have eosinophilic cytoplasm. However, eosinophilic cells also occur in association with hyperplasia, particularly atypical

hyperplasia. Glands may be partially or completely lined by eosinophilic cells. Eosinophilic cells that line glands can show considerable variation in shape. They may be columnar when associated with atypical hyperplasia, rounded when associated with ciliated cells, or polygonal, forming pavement-like aggregates, when they merge with cells that show squamous differentiation. In hyperplastic lesions, aggregates of eosinophilic cells often form intraglandular papillary tufts and bridges, thus simulating carcinoma. Eosinophilic cells contain variable amounts of cytoplasm that at times can be partially vacuolated. The nuclei tend to be round and somewhat stratified. In most instances, the nuclei are smaller, more uniform, and lack the irregular nuclear membrane, coarse chromatin, and nucleoli that characterize cells with true cytologic atypia. Occasionally, the nuclei can be enlarged and contain a single prominent nucleolus. Mitotic figures are rarely present. On the endometrial surface, cells with eosinophilic cytoplasm typically merge into a syncytium that either can be flat or more commonly form papillary processes [76]. Typically, the papillary processes lack connective tissue support and contain small cystic spaces filled with polymorphonuclear leukocytes. This lesion has been referred to as surface syncytial change, papillary syncytial change, or papillary metaplasia [36, 84]. We prefer the term eosinophilic

Fig. 8.34

Complex hyperplasia (without atypia) with eosinophilic metaplasia. Intraglandular epithelial tufts composed of bland cells with abundant eosinophilic cytoplasm are present within a non-atypical hyperplasia

Fig. 8.35

Complex atypical hyperplasia with eosinophilic metaplasia. Intraglandular epithelial clusters composed of rounded cells with abundant eosinophilic cytoplasm are present within an atypical hyperplasia; assessment of atypia is based on the appearance of the glandular epithelium, which displays vesicular nuclei with prominent nucleoli and loss of polarity syncytial change because the lesion is characteristically composed of eosinophilic cells forming a syncytium and can involve glands as well as the surface. Eosinophilic syncytial change is commonly associated with endometrial stromal breakdown or inflammation, suggesting that it is a degenerative or a reparative process [98]. A recent study using immunohistochemical stains for proliferation further support the regressive nature of this type of epithelial change [78]. The nuclei within the syncytium are arranged haphazardly and piled up; they generally are small and bland but at times may be round and vesicular and display alterations in shape and chromatin texture. Mitotic figures are rare. Hyperchromatic nuclei with smudged chromatin and irregular nuclear membranes appear degenerated whereas enlarged, vesicular nuclei with a prominent nucleolus and smooth nuclear membranes appear reactive. These degenerative and reparative changes should not be interpreted as nuclear atypia. Eosinophilic change can be seen in combination with hobnail secretory change on occasion. In fact, typically the various types of metaplasia occur concomitantly.

Squamous Differentiation (Squamous Metaplasia)

Squamous differentiation may occur in all forms of hyperplasia (**○** *Figs. 8.36–8.38*) as well as in carcinoma. It is especially common in the more atypical endometrial proliferations and is rare in normally cycling endometrium or in simple and complex hyperplasias. The squamous cells are usually cytologically bland. The degree of nuclear atypia, when present, generally parallels that of the glandular cells. Typically, the squamous cells have a moderate amount of eosinophilic cytoplasm and are surrounded by a well-defined cell membrane. Often they merge with eosinophilic cells that qualify as eosinophilic change. The squamous cells tend to be rounded or polygonal but may be spindle shaped, forming a circumscribed nest (squamous morule) within the gland lumen (> Fig. 8.37). Morules reflect immature or incomplete squamous differentiation. The cells are smaller and the cytoplasm is less prominent than in more completely differentiated squamous cells. Central keratinization and necrosis rarely occur. Eventually, proliferation results in protrusion of the squamous cells into the lumen, leading to replacement of the lumen by nests of squamous cells and coalescence with neighboring glands undergoing the same process. Mitotic activity is rare. A recent study found that squamous morules in hyperplastic proliferations lack expression of the estrogen and progesterone receptors and demonstrate rare to undetectable Ki-67 proliferative activity when compared to the associated hyperplastic epithelium. However, the glandular and squamous components had identical PTEN mutations indicating that the squamous component is clonally related to the glandular

Fig. 8.36

Complex hyperplasia (without atypia) with squamous metaplasia. Islands of squamous metaplastic epithelium are intimately admixed with non-atypical hyperplastic glands

Fig. 8.37 Complex hyperplasia (without atypia) with squamous metaplasia. Squamous morules are intimately admixed with non-atypical hyperplastic glands exhibiting tubal metaplasia as well

Complex hyperplasia (without atypia) with squamous

metaplasia. Squamous metaplastic epithelium with central necrosis forms a confluent mass intimately admixed with non-atypical hyperplastic glands but should not be interpreted as an indicator of stromal invasion when the glandular component does not manifest confluence or induce desmoplasia

component. The authors concluded that the squamous morules are inert elements of the proliferative lesions. Importantly, since they are often associated with complex atypical hyperplasia and endometrioid carcinoma their presence on endometrial sampling, in the absence of an identifiable proliferative process, should result in close follow-up of the patient for the possibility of an under sampled or occult glandular lesion [59].

Ciliated Cell Change (Tubal Metaplasia)

Cilia are not usually evident microscopically in proliferative endometrial glandular cells, although they may be observed on the endometrial surface [61]. Ciliated cells occasionally are observed in isolated glands in atrophic or inactive endometria or in polyps in the absence of hyperplasia. The presence of a significant number of ciliated glandular cells is referred to as ciliated cell change or tubal metaplasia because of the resemblance to the epithelium of the fallopian tube. The ciliated cells are often round and slightly enlarged, but the nuclear membranes are smooth and uniform and the chromatin is fine and evenly dispersed. There is no nuclear atypia. The ciliated cells may be interspersed singly or in small groups among nonciliated cells, or they may line a larger segment of a gland. Mitotic activity is limited to the adjacent non-ciliated

Fig. 8.39

Complex hyperplasia (without atypia) with tubal metaplasia. Crowded glands have multiple cell types, including ciliated cells and those with rounded nuclei and cytoplasmic clearing (halos), similar to those seen in fallopian tube epithelium

cells. Ciliated cell change may occur in glands in the absence of hyperplasia. Dilated venous sinusoids are also frequently present. All these changes reflect a mild degree of estrogenic stimulation. Ciliated cell change frequently accompanies simple, complex, or atypical hyperplasia (**)** *Figs. 8.39–8.41*).

Secretory and Hobnail Change

Secretory change is characterized by columnar cells with sub- or supranuclear vacuoles containing clear glycogenated cytoplasm resembling the glandular cells of early secretory endometrium. These cells also can be observed in nonneoplastic proliferative endometria but are seen more often in association with hyperplasia or carcinoma (**)** *Fig.* 8.42) [48, 51]. Rarely, the cells in secretory change can display hobnail morphology reminiscent of the Arias-Stella reaction (> Fig. 8.43); such hobnail change, with or without the cytoplasmic vacuolization of secretory change (**)** Fig. 8.44), should not be misinterpreted as endometrial intraepithelial carcinoma (see below). At times secretory change can result from progestational stimulation, but often there is no such association. Columnar cells with secretory change may merge with polygonal-shaped clear cells and with squamous cells containing clear glycogenated cytoplasm. The accumulation of glycogen can occur in the cytoplasm of a variety of cell types.

Complex hyperplasia (without atypia) with tubal metaplasia. Crowded glands have some ciliated cells and cells with nuclear rounding and cytoplasmic clearing

Fig. 8.42 Complex hyperplasia (without atypia) with secretory change. Crowded glands have elongated nuclei and discrete sub- and supranuclear vacuoles, reminiscent of day 18 secretory endometrium

Fig. 8.41

Complex atypical hyperplasia with tubal metaplasia.

Markedly crowded glands have some cells with rounded nuclei and cytoplasmic clearing indicating underlying tubal metaplasia but the nuclear enlargement and loss of polarity are beyond that attributable to metaplasia and indicate atypia

Mucinous Change

Mucinous change is characterized by mucinous epithelium resembling that of the endocervix cytologically, histochemically, and ultrastructurally [21]. Although it is one of the least commonly encountered cytoplasmic alterations, it occurs more frequently than generally

described. The mucinous epithelium tends to be distributed focally and is composed of tall columnar cells with bland, basally oriented nuclei and clear, slightly granular cytoplasm (**)** *Figs. 8.45* and **)** *8.46*). At times mucinous change is accompanied by a papillary proliferation. The papillary processes contain normal but compressed stromal cells and are lined by nonstratified

Complex hyperplasia (without atypia) with hobnail change.

Crowded glands are partially lined by epithelial tufts containing cells with hyperchromatic rounded nuclei that bulge into the gland lumen. These tufts also share features with eosinophilic cell change

Fig. 8.45 Complex hyperplasia (without atypia) with mucinous change. Crowded glands have abundant pale mucinous cytoplasm and basally situated small nuclei

columnar epithelium, which may have mucinous areas. Mitotic figures are rare. The cytoplasm is clear in hematoxylin and eosin (H&E) stains because it contains mucin, which is periodic acid–Schiff (PAS) positive and diastase resistant and stains with mucicarmine, toluidine blue, and alcian blue. In contrast to mucinous epithelium, the vacuolated cytoplasm of secretory endometrium contains glycogen. On rare occasion, the mucinous epithelium may

Fig. 8.46

Complex hyperplasia (without atypia) with mucinous change. Crowded glands are lined by cells with pale mucinous cytoplasm and small round nuclei, with some forming papillary tufts

contain goblet cells and is referred to as intestinal metaplasia.

Mucinous differentiation can be seen in a spectrum of epithelial proliferations ranging from benign to malignant. In one study, the likelihood of finding carcinoma associated with mucinous proliferations of the endometrium varies according to the degrees of architectural complexity and cytologic atypia of the lesions [71]. Architecturally simple lesions with papillary projections into luminal spaces and no cytologic atypia were found to have carcinoma on follow-up only when the initial specimen also contained atypical hyperplasia; otherwise, none of these simple mucinous proliferations were associated with carcinoma on follow-up. More complex proliferations with microglandular or cribriform patterns and minimal cytologic atypia, often presenting as endometrial surface lesions without coexistent atypical hyperplasia, were found to have well-differentiated noninvasive or minimally invasive carcinoma on followup in 65% of cases. Highly complex proliferations with glandular budding, cribriform growth, and branching of villous structures that also displayed moderate to severe cytologic atypia were invariably associated with carcinoma on follow-up (> Fig. 8.47). Importantly, 80% of the study patients were over age 50. Thus, in perimenopausal and postmenopausal women with complex mucinous proliferations, including those with and without cytologic atypia, the risk of finding coexistent carcinoma is high.

Complex atypical mucinous proliferation. This term is used for limited specimens in which crowded, fused, or cribriform glands with mucinous cytoplasmic change and atypical nuclei are concerning for at least complex atypical hyperplasia but there is little or no associated stroma to diagnose stromal invasion. Such lesions are often associated with FIGO gradel endometrioid carcinoma on follow-up, as occurred in this case

Mixed Cellular Changes

Mixtures of different types of cellular changes are common. Most are closely related and represent different morphologic responses to a variety of stimuli, including estrogenic stimulation [35]. For example, eosinophilic change, especially eosinophilic syncytial change, may resemble squamous epithelium and often is associated with squamous metaplasia. Likewise, eosinophilic and ciliated cell change share many morphologic features and commonly occur together.

Differential Diagnosis

The most important aspect of the evaluation of the various metaplasias and cellular changes is not to confuse them with hyperplasia or carcinoma, which is best accomplished by evaluating the glandular architecture and cytological features. In hyperplasia, the glandular outlines are irregular and complex and there is stratification of the epithelium reflecting a proliferative process. In contrast, in the various cytoplasmic changes the glandular outlines are regular and have a tubular configuration, although cystic dilatation and slight glandular irregularity occasionally can occur.

Although the various cellular changes may be accompanied by slight nuclear enlargement, the cells lack the abnormal chromatin patterns that characterize the nuclei in atypical hyperplasia. At times the various cellular changes may look ominous and suggest carcinoma, but evidence of stromal invasion is lacking and therefore a diagnosis of carcinoma is not justified. For example, extensive squamous metaplasia may suggest a diagnosis of carcinoma but without a desmoplastic response or a confluent glandular pattern, a diagnosis of carcinoma should not be made. Squamous and eosinophilic change associated with hyperplasia can fill and bridge gland lumens but lack a true confluent or cribriform pattern. Mucinous change at times can form complex papillary processes, but the stroma of the papillae is composed of normal endometrial stroma and the epithelium lacks cytologic atypia.

Behavior

Cytoplasmic changes, other than eosinophilic syncytial change, rarely occur in the absence of hyperplasia or carcinoma [41]. In the absence of hyperplasia, these changes (metaplasia) had no clinical significance in one study of 89 patients [35]. In a long-term followup study of endometrial hyperplasia, 5 of 11 patients with atypical hyperplasia and associated squamous metaplasia eventually developed carcinoma, indicating that atypical hyperplasia with squamous metaplasia has malignant potential [49]. Inasmuch as the cytoplasmic changes by themselves have no prognostic significance, the importance of recognizing them lies in not confusing these benign processes with hyperplasia or carcinoma.

Management

The management of endometrial cytoplasmic changes depends entirely on the nature of the associated proliferative process. If hyperplasia is present it should be managed accordingly. Endometrial cytoplasmic changes without hyperplasia do not require treatment.

Endometrial Intraepithelial Carcinoma

Definition and Pathologic Findings

Serous carcinoma is the prototypic endometrial carcinoma that is not related to estrogenic stimulation and typically occurs in the setting of endometrial atrophy. Serous carcinoma is frequently associated with a putative precursor lesion, termed "endometrial intraepithelial carcinoma" (EIC). The lesion also has been referred to as "carcinoma in situ" [86] and "uterine surface carcinoma" [100], but we prefer the term EIC to CIS because EIC can be associated with metastatic disease (see following), whereas the term CIS implies a lesion that does not have metastatic potential. In view of the association of EIC with serous as

Fig. 8.48

Endometrial intraepithelial carcinoma (EIC) involving a polyp. The surface epithelium of the polyp (best seen in blunt papillary structures along upper left and middle surface) is lined by markedly atypical cells of EIC (see **)** *Fig. 8.49*) opposed to endometrioid carcinoma it is reasonable to use the term serous EIC as has been proposed in the WHO classification. EIC is characterized by markedly atypical nuclei, identical to those of invasive serous carcinomas, lining the surfaces, and glands of the atrophic endometrium The lesion can be very small and focal and is often present on the surface of a polyp (\bigcirc *Figs.* 8.48–8.54) [1, 80]. EIC often has

Fig. 8.50

Endometrial intraepithelial carcinoma (EIC). Markedly atypical cells containing enlarged vesicular nuclei with prominent nucleoli, hobnail cells, and apoptotic bodies are lining the surface epithelium and partially involving an underlying gland

Endometrial intraepithelial carcinoma (EIC). Markedly atypical cells lining endometrial surface and underlying glands (*upper*, *middle*, and *lower left*) have enlarged vesicular nuclei with prominent nucleoli, distinct from the elongated nuclei in the normal glands (*lower middle* and *middle right*)

a slightly papillary contour and some cells display hobnail morphology and smudged, hyperchromatic nuclei. The nuclei are enlarged, and frequently display enlarged eosinophilic nucleoli. Numerous mitotic figures, including atypical ones, are present. On occasion, the abnormal proliferation involves only a portion of an endometrial

Fig. 8.54

Endometrial intraepithelial carcinoma (EIC). Markedly atypical cells lining endometrial glands have enlarged vesicular nuclei with prominent red nucleoli

gland (**)** *Fig. 8.50*). More recently a lesion has been described, termed endometrial glandular dysplasia, which also exhibits cytologic atypia with serous features but lacks the marked atypia associated with EIC [101]. It has been proposed that this lesion represents the precursor of EIC and serous carcinoma.

Molecular Biology and Immunohistochemistry

Molecular genetic evidence supports the concept that EIC is a precursor lesion of serous carcinoma. Studies have demonstrated immunohistochemical overexpression of p53 protein, loss of heterozygosity of chromosome 17p, and corresponding p53 gene mutations in a high proportion of serous carcinomas and EIC (> Fig. 8.55) [79, 88]. The finding of diffuse, intense staining for p53 is highly correlated with identification of p53 mutation in these cases. Lack of immunoreactivity for p53, however, does not exclude the presence of a mutation in p53 because mutations have been detected in a small number of serous carcinomas that were nonreactive for p53 due to the formation of a truncated or unstable protein [88]. Identical p53 gene mutations have been found in the EIC and adjacent serous carcinoma in several cases. Examples of pure EIC unassociated with serous carcinoma also have been shown to contain p53 mutations. In addition, a case of pure EIC has been shown to contain p53 mutation in the absence of loss of heterozygosity of chromosome 17p, suggesting that p53 mutation occurs early in the evolution

of serous carcinoma [88]. The finding of EIC unassociated with invasive carcinoma and the presence of identical p53 mutations in both lesions support the view that EIC is the precursor lesion of serous carcinoma. As mentioned above, endometrial glandular dysplasia has been suggested as a precursor to EIC, in part based on a study that has shown that these lesions show intense staining for p53, as

Fig. 8.55

Endometrial intraepithelial carcinoma (EIC). Surface epithelium and underlying glands involved by EIC are highlighted by diffuse/strong nuclear expression of p53; normal glands are negative well as p53 mutations. Additional preliminary studies have suggested that endometrial glandular dysplasia is preceded by histologically normal lesions that demonstrate increased expression of p53 and p53 mutations. These histologically normal appearing glands have been called "p53 signatures" because of the expression of p53 [40, 99]. Presently, their relationship to serous carcinoma has not been definitely determined, but future studies will likely be done to further our understanding of their biologic significance in the pathogenesis of serous carcinoma.

Differential Diagnosis

The distinction of extensive EIC from early serous carcinoma has not been well defined. Crowded glands involved by EIC within a polyp or within the endometrium should be classified as extensive EIC when the proliferation lacks a confluent glandular pattern, demonstrates no evidence of stromal desmoplasia (stromal invasion), and is less than 1 cm in greatest dimension. When either glandular confluence or stromal invasion is present and the proliferation exceeds 1 cm in greatest dimension, the lesion qualifies as serous carcinoma. Lesions with glandular confluence or stromal invasion but measuring less than 1 cm can be subclassified as minimal uterine serous carcinoma (\triangleright *Figs.* 8.56 and \triangleright 8.57; see following). It is important to note, however, that metastatic serous carcinoma can be

Fig. 8.56

Extensive endometrial intraepithelial carcinoma (EIC)/ minimal uterine serous carcinoma. An endometrial polyp involved by EIC on its surface, as well as in the adjacent endometrium (*left*), contains crowded glands measuring less than 1 cm but verging on being confluent, suggesting early stromal invasion

 Fig. 8.57
 Extensive endometrial intraepithelial carcinoma (EIC)/ minimal uterine serous carcinoma. Immunohistochemical stain for p53 highlights the extent of the lesion in
 Fig. 8.56

found in other sites in the genital tract and in the abdomen in the absence of demonstrable invasion in uteri with EIC, indicating that EIC is capable of metastasizing without first invading the stroma of the endometrium [9, 85].

EIC must be distinguished from benign metaplastic endometrial lesions that can mimic the nuclear changes seen in EIC, which include eosinophilic cell change, hobnail change, and tubal metaplasia. At times, eosinophilic cell change and hobnail change can display enlarged, smudged, hyperchromatic nuclei, but these nuclei usually have a degenerative appearance and typically lack the prominent nucleoli seen in EIC. On occasion, however, the nuclei can appear more overtly atypical, with prominent nucleoli, suggesting EIC (see) Figs. 8.43 and ≥ 8.44). Tubal metaplasia typically displays enlarged, hyperchromatic nuclei, but these are admixed with other cell types, including ciliated cells and intercalated cells, and nucleoli are usually not prominent. Immunohistochemistry for Ki-67, a proliferation marker, is very useful for distinguishing EIC from eosinophilic cell change and tubal metaplasia in that EIC typically displays a very high proliferation index (virtually all the nuclei express Ki-67), whereas the metaplasias have very low proliferation indices. In addition, EIC is usually diffusely and strongly positive for p53, whereas eosinophilic metaplasia is typically negative or occasionally displays weak or scattered moderate nuclear staining. Preliminary data based on a small number of cases indicate that tubal metaplasia and eosinophilic metaplasia do not strongly overexpress p53 [73]. Thus, the combination of Ki67 and p53 immunohistochemical stains is useful to distinguish EIC from metaplasia when the distinction is difficult by morphologic assessment alone.

Behavior and Treatment

There are limited data on the behavior of pure EIC. A recent study found that patients with pure EIC, and those with minimal uterine serous carcinoma (less than 1 cm of carcinoma in the endometrium) lacking myometrial or vascular invasion and no evidence of extrauterine disease, had an overall survival of 100% after a mean follow-up of 27 months [95]. The majority of these patients received no treatment after hysterectomy. In addition, the few patients with involvement of endocervical glands by EIC (stage IIA disease) were also alive without evidence of disease at intervals ranging from 12 to 54 months. Similarly, in another study of stage IA serous carcinoma, 11 of 13 patients were alive without evidence of disease after a median follow-up of 38 months [16]. In contrast, patients with either EIC or minimal serous carcinoma and evidence of extrauterine disease (even microscopic disease) all died of disease despite intensive chemotherapy [95]. Accordingly, patients with a diagnosis of EIC in an endometrial biopsy or curettage specimen should undergo careful surgical staging at the time of hysterectomy.

Epidemiology

Endometrial carcinoma is the most common invasive neoplasm of the female genital tract and the fourth most frequently diagnosed cancer in women in the USA. In 2008, it is estimated there will have been 40,100 new cases and 7,470 deaths resulting from this neoplasm. These figures represent an estimated 6% of the new cancer cases and 3% of the cancer deaths in women [377]. Worldwide, approximately 150,000 cases are diagnosed each year, making endometrial carcinoma the fifth most common cancer in women [304, 305]. The incidence of endometrial cancer varies widely throughout the world. The highest rates occur in North America and Europe, whereas rates in developing countries and Japan are four to five times lower. The incidence is also about twice as high in whites compared to blacks. However, the proportion of endometrial cancer related deaths is higher in blacks due to a relative increase in the incidence of high-risk endometrial carcinoma in the black population. The reason for this is not well understood but access to and quality of health care as well as genetics are considered possible factors [17].

Classification

Based on clinicopathologic and molecular genetic features, endometrial carcinoma can be broadly divided into two major categories, referred to as type I and type II. As discussed, factors associated with unopposed estrogenic stimulation, such as obesity and exogenous hormone use, as well as the presence of endometrial hyperplasia, are related to the development of the most common form of endometrial carcinoma, the endometrioid subtype, which is the prototype of type I carcinoma [44]. More recent studies have confirmed this association by demonstrating elevated serum estrogen levels in patients with endometrioid carcinoma [50, 323]. It also has been recognized that some forms of endometrial carcinoma appear to be unrelated to hormonal factors and hyperplasia [363]. Serous carcinoma is the most common form of endometrial carcinoma that is not related to estrogenic stimulation and represents type II carcinoma. Molecular genetic studies, as discussed below, have provided further support for the dualistic categorization by identifying significant molecular genetic differences between the two types (> Table 9.1). Most of the other histologic subtypes of endometrial carcinoma can be classified as variants of either type I or II on the basis of

Table 9.1

Pathogenetic forms of endometrial carcinoma

Feature	Туре І	Type II
Unopposed estrogen	Present	Absent
Menopausal status	Pre- and perimenopausal	Postmenopausal
Precursor lesion	Atypical hyperplasia	Endometrial intraepithelial carcinoma
Tumor grade	Low	High
Myometrial invasion	Variable, often minimal	Variable, often deep
Histologic subtypes	Endometrioid	Serous and clear cell
Behavior	Indolent	Aggressive
Genetic alterations	PTEN mutation	P53 mutation
	Microsatellite instability	
	K-ras mutation	

clinicopathologic, immunohistochemical, and molecular features. Thus, other low-grade carcinomas, which are associated with endometrial hyperplasia and estrogenic stimulation, such as mucinous or low-grade endometrioid with squamous differentiation, are type I carcinomas. In contrast, some clear cell carcinomas share features with serous carcinoma and are considered a type II carcinoma. However, recent data suggests that clear cell carcinomas are a heterogenous group of tumors and that some may fit in the type I category (see below in Oclear Cell Carcinoma).

A modified version of the recent World Health Organization (WHO) and International Society of Gynecological Pathologists (ISGYP) classification of endometrial carcinoma is shown in **2** Table 9.2 [356]. This classification has certain limitations. The WHO classification uses the term papillary in the designation of serous carcinoma. Although uterine serous carcinomas often demonstrate papillary growth, a papillary pattern can be seen in other carcinomas, including villoglandular, mucinous, and clear cell carcinomas. Thus, papillary growth is not specifically associated with serous differentiation. Hence, its use in designating subtypes of endometrial carcinoma should be avoided. Malignant Mesodermal (Müllerian) mixed tumors (MMMTs, carcinosarcomas) are classified as mixed epithelial and nonepithelial tumors in the WHO classification of uterine tumors but as epithelial tumors in

the ovarian tumor classification. This inconsistency reflects the confusion over the histogenesis and classification of carcinosarcomas in different anatomic sites. Recent molecular genetic data support the concept that both components in these biphasic tumors are clonally derived from a transformed epithelial cell. Accordingly, many investigators now consider these neoplasms as poorly differentiated carcinomas that display sarcomatous differentiation (see the following).

Etiology

Hormonal Stimulation

The strong association between replacement estrogen therapy and the development of endometrial cancer was demonstrated in a number of case-control studies in the late 1970s [155, 157, 253, 264, 360, 376, 449]. More recent reviews summarize the data generated by numerous studies of hormonal therapy and risk of endometrial cancer and confirm the increased risk of unopposed estrogen therapy [39, 315]. A study of endogenous hormones and endometrial cancer demonstrated that the risk associated with elevated levels of unopposed estrogen varies according to menopausal status [323]. In particular, high estrone and albumin-bound estradiol levels were associated with increased risk in postmenopausal women, but high levels of total, free, and albumin-bound estradiol were unrelated to increased risk in premenopausal women. In addition, 395

high circulating levels of androstenedione were identified as a risk factor in both pre- and postmenopausal women. In both age groups, the risk associated with obesity was not affected by adjustment for hormones. Factors that lower the exposure of the endometrium to unopposed estrogen reduce the risk of endometrial cancer; these include the addition of progestin to hormone replacement regimens, the use of oral contraceptives, and smoking [1, 32, 39, 131, 139, 156, 211, 243, 306, 315, 422]. It has been shown that women using unopposed estrogen for more than 2 years have a two- to threefold increase in the risk of endometrial cancer, whereas women receiving progestins in conjunction with estrogen have no increased risk [309]. One large case-control study demonstrated that the use of oral contraceptives for at least 1 year reduces the risk of endometrial carcinoma by 50% and that protection persists at least 15 years after discontinuation [1]. The risk of endometrial carcinoma may also be effected by polymorphisms in the estrogen receptor genes; however, the mechanism responsible is not currently understood [31].

The data on the risk of endometrial cancer in patients on tamoxifen are conflicting [358]. Tamoxifen is a nonsteroidal compound that acts by competing with estrogen for estrogen receptors. In reproductive age women it therefore has an antiestrogenic effect, but in postmenopausal (hypoestrogenic) women it has weak estrogenic effects. Some large studies have reported that there is a significantly increased risk of endometrial cancer, apparently related to dose and duration of use, whereas others have not shown a significant risk [25, 42, 86, 127, 128, 130, 210, 330, 338, 339, 390, 411]. In addition, some studies have reported a higher proportion of high-risk types of carcinomas in tamoxifen-treated women whereas others have found predominantly low-grade carcinomas [36, 128, 255, 370]. Thus, some investigators are convinced that tamoxifen confers an increased risk of endometrial cancer while others believe the evidence is inconclusive [90, 185, 189, 199, 223, 254].

Constitutional Factors

Obesity, like estrogen replacement therapy, is a well-defined risk factor for endometrial cancer [415], with reported relative risks ranging from 2 to 10 [304, 305]. The risk can be explained by the increased availability of peripheral estrogens as a result of aromatization of androgens to estrogens in adipose tissue and lower concentrations of sex hormone-binding globulins in obese women [114].

Diabetes has been repeatedly associated with an increased risk of endometrial cancer, ranging from 1.2 to 2.1, and this risk appears to be independent of other frequently associated variables such as obesity [50, 304, 305]. Other factors that have been associated with an increased risk of endometrial cancer include early age of menarche, later age of menopause, and nulliparity. The association with nulliparity appears to be primarily on the basis of infertility due to chronic anovulation in which unopposed estrogenic stimulation occurs [50, 305]. The protective effect of pregnancy appears to be related and restricted to the first fullterm pregnancy because abortions and increasing numbers of births do not influence the risk.

Diet

Endometrial cancer risk is correlated with total caloric intake, total protein intake, and frequency of consumption of meat, eggs, milk, fats, and oils. These dietary factors, as well as decreased energy expenditure and physical exercise associated with a sedentary lifestyle, are major determinants of obesity, which is an established risk factor. The independent contribution of specific dietary factors to endometrial cancer risk has not been clearly established [245, 305]. A recent study suggests that activity decreases the risk of endometrial cancer independent of body weight [415].

Molecular Genetics

Since the initial proposal that endometrial carcinoma could be divided into two broad disease entities, it has been recognized by pathologists that there is a general correlation of the clinical type with the morphologic features of the endometrial tumor. For the most part, type I tumors are associated with endometrioid features and arise in the setting of hyperplasia, whereas type II tumors are often of serous histology and present in a background of endometrial atrophy. Although somewhat oversimplified given the diversity of histologic subtypes of endometrial carcinoma, this histologic distinction is important to the understanding of endometrial carcinoma at the molecular level. For conceptual and practical reasons, this section does not attempt to provide an exhaustive list of the cancer-causing genes that have been studied but rather is intended to provide the reader with an overview of the current understanding of the molecular genetics of endometrial carcinoma. For this reason, the two tumor types are discussed separately, recognizing that many of the early molecular studies did not clearly classify the tumors by morphologic type.

Endometrioid Carcinoma

Over the past 3 decades, a number of cancer-causing genes have been analyzed in endometrial carcinoma. Recently, a number of studies have shown that the most frequently altered gene in endometrioid carcinoma is the PTEN tumor suppressor gene, which is mutated in 30-54% of cases [333, 395]. PTEN is located on chromosome 10q23.3 and encodes a dual-specificity phosphatase [247]. The primary target is the lipid molecule phosphatidylinositol-3,4,5-triphosphate (PIP3) that is involved in a signal transduction pathway that regulates cell growth and apoptosis. The dephosphorylation of PIP3 counteracts the activity of a protein complex called PI3K (phosphoinositol 3 kinase) that leads to the conversion of PIP2 (phosphatidylinositol-4,5-diphosphate) to PIP3. Consequently, the inactivating mutations in PTEN result in increased levels of PIP3, which activates downstream molecules including phosphorylation of AKT. AKT is a central regulator of numerous pathways involved in cell proliferation, cell growth, and apoptosis that are altered in cancer development. Although the specific consequences of PTEN mutation have not been completely elucidated in endometrial carcinoma development it has been noted that the frequency of PTEN mutation is similar in all three grades of endometrioid carcinoma. In addition, it is mutated in approximately 20-48% of atypical and nonatypical hyperplasias [246, 259]. These findings suggest that inactivation of this gene is important early in the pathogenesis of endometrioid carcinoma. Genetic mouse models with germline heterozygous deletion of PTEN spontaneously develop endometrial hyperplasia in 100% of female mice with 20% of female mice showing progression to carcinoma supporting an early role of Pten in endometrial tumorigenesis [320]. Furthermore, a recent epidemiologic study found that the presence of PTEN mutations in complex atypical hyperplasia did not predict progression to carcinoma [230]. In sum, these findings suggest that PTEN mutations may be central to the development of hyperplasia, but may not play a role in the transition to carcinoma.

Of further interest, recent publications have identified mutations in the *PIK3CA* oncogene, the catalytic subunit of PI3K, in endometrioid carcinoma [170, 301]. The mutations are found in endometrioid carcinoma with and without *PTEN* mutations but are more common in tumors with *PTEN* mutations. An additional study showed that while *PTEN* mutations occur in a similar frequency in complex atypical hyperplasia and carcinoma, *PIK3CA* mutations are rare in complex atypical hyperplasia and are

present in all three tumor grades [170]. These studies suggest that the inactivation of *PTEN* and the activation of *PIK3CA* have different roles in the development of endometrioid carcinoma. While *PTEN* is important in the development of hyperplasia, mutations in *PIK3CA* may play a role in the transition of complex atypical hyperplasia to carcinoma. Although the biologic basis of this has not yet been elucidated, understanding *PTEN* and *PIK3CA* mutations and their roles in the development of endometrial hyperplasia and carcinoma may provide targets for therapeutic intervention before the development of malignant disease.

The *p*53 tumor suppressor gene has been extensively studied in endometrial cancer, as in other tumors. *p*53 encodes a DNA-binding phosphoprotein that is involved in cell cycle control and apoptosis. Mutations in *p*53 are found in approximately 10% of all endometrioid carcinomas, with most occurring in grade 3, and occasionally in grade 2, tumors. Overall, *p*53 mutations occur in approximately 50% of grade 3 tumors, and they have not been identified in grade 1 tumors or endometrial hyperplasia [234]. This finding is consistent with a role for p53 in the progression, but not the initiation, of endometrioid carcinoma.

Another molecular alteration in endometrioid carcinomas that has received substantial attention is the molecular phenotype called microsatellite instability. Microsatellite instability is defined as alterations in the length of short, repetitive DNA sequences, called microsatellites, in tumors when compared to DNA prepared from the same patient's normal tissue. This molecular phenotype is detected in tumors that lack an intact DNA mismatch repair system, a fundamental cellular mechanism for preventing DNA alterations that are created largely during DNA replication. In tumors that display microsatellite instability, the DNA mismatch repair system has been inactivated either through mutation or "silencing" by promoter hypermethylation of one of the DNA mismatch repair genes [118]. The consequence of inactivating the DNA mismatch repair system is an increase in the rate at which mutations occur, a factor that clearly contributes to tumorigenesis. Microsatellite instability is found in tumors from patients affected by hereditary nonpolyposis colorectal carcinoma (HNPCC), a syndrome in which endometrial carcinoma is the most common noncolorectal malignancy [115]. Microsatellite instability also is present in approximately 20% of sporadic endometrial cancers and can be found in complex atypical hyperplasias that are associated with cancers that demonstrate instability [107, 246, 280]. Recent reports have suggested that like colorectal carcinoma, endometrial

carcinomas with microsatellite instability may demonstrate specific histologic features (see below in discussion of Hereditary Nonpolyposis Colorectal Carcinoma) [52]. Unlike the familial cases, which are due to germline mutations in one of the DNA mismatch repair genes (MSH2, MLH1, MSH6, or PMS2), microsatellite instability in the sporadic cases is most commonly due to inactivation of the MLH1 gene by promoter hypermethylation. This epigenetic alteration results in lack of expression of MLH1, which can be detected by immunohistochemistry. Interestingly, the hypermethylation of MLH1 can be found in complex atypical hyperplasia that does not demonstrate microsatellite instability [116]. Thus, it remains unclear exactly when in the development of endometrial neoplasia the DNA mismatch repair system becomes inactivated. Further studies of endometrial hyperplasia are warranted to address this important biologic and potentially clinically relevant question.

A number of oncogenes have been studied in endometrial carcinomas, but only a few are altered in a significant number of cases. Mutations in the KRAS proto-oncogene have been identified consistently in 10-30% of endometrial cancers in several studies [48, 113, 234]. The mutations have been found in all grades of endometrioid carcinoma and have been reported in complex atypical hyperplasia, suggesting a relatively early role for KRAS mutations in this tumor type. KRAS encodes a guanine nucleotide-binding protein of 21 kDa that plays a role in the regulation of cell growth and differentiation by transducing signals from activated transmembrane receptors. In the mutant form, KRAS is constitutively "on" even in the absence of an activated receptor. Recently, mutations in FGFR2 (fibroblast growth factor receptor 2) have been identified in 16% of endometrioid carcinomas and that KRAS and FGFR2 mutations are mutually exclusive [55, 321]. In addition, mutations in the CTNNB1 gene, which encodes the β-catenin protein, have been found in approximately 15-20% of endometrioid carcinomas, occurring primarily in tumors with squamous differentiation [133, 220, 353]. Other oncogenes that have been found to be overexpressed or amplified are EGFR, CMYC, HER-2/neu, BCL2, and CFMS [47, 177, 242, 397]. Additional studies on these genes are needed to more definitively determine their role in endometrial cancer.

Serous Carcinoma

Compared to endometrioid carcinoma, relatively little is known about serous carcinoma at the molecular level,

partly because of its relative infrequency and because this tumor type is not analyzed separately in many molecular studies. Although a number of candidate cancer genes have been analyzed in serous carcinoma, only the p53 tumor suppressor gene has been shown to be altered in a significant number, with mutations identified in almost 90% of cases [273, 396]. In fact, there are few other solid tumors that demonstrate a mutation frequency in a single gene as high as that of p53 in serous endometrial carcinoma. Furthermore, approximately 75% of endometrial intraepithelial carcinomas, the putative precursor of serous carcinoma, have mutations in p53 [396]. In this setting, it has been shown that intense, diffuse immunohistochemical staining for p53 correlates well with p53 mutation. These findings suggest that in serous carcinoma p53 mutations occur relatively early and are central to the development of this tumor type; this is in contrast to endometrioid carcinoma, in which p53 mutations are relatively uncommon and, when they do occur, they are largely confined to grade 3 tumors. Thus, it is possible that the mutation of p53 early in the pathogenesis of serous carcinoma is an important factor that accounts for its aggressive behavior. In addition, the fact that p53 mutations occur most commonly in grade 3 endometrioid and serous carcinomas most likely explains the finding that it is an indicator of tumors that behave aggressively [16].

In contrast to endometrioid carcinoma, mutations in KRAS and PTEN appear to be very uncommon in serous carcinoma, and microsatellite instability has not definitively been detected in this tumor type [234]. A recent study has described mutations in PIK3CA in 15% of serous carcinoma suggesting that the PI3K/PTEN/AKT pathway may be involved in the pathogenesis of a subset of this tumor type [169]. The same study found that 56% of serous carcinoma demonstrated staining for EGFR although they lacked intragenic mutations in the commonly mutated exons and failed to show significant amplification by flourescent in situ hybridization (FISH) analysis. Studies have suggested that there is amplification and overexpression of CMYC and HER-2/neu; however, it is not clear from the literature what percentage of serous carcinomas demonstrates these alterations.

As is apparent from this discussion, relatively little is known about the molecular pathogenesis of the two major types of endometrial carcinoma and almost nothing is known about the more uncommon histologic types of endometrial carcinoma. However, it is evident from the studies just described that endometrioid and serous carcinoma of the endometrium are distinct biologic entities. As in other tumor systems, the molecular studies of endometrial cancer support the notion that epithelial-derived tumors often develop from preinvasive precursors that accumulate a combination of genetic alterations, thus providing the cell with the attributes necessary for unregulated growth. In endometrioid carcinoma it appears that *PTEN* alterations may be central to the initiation of proliferative lesions that then acquire mutations in other cancer-causing genes (e.g., *PIK3CA*, DNA mismatch repair genes, *KRAS*, and *p53*) in the progression to malignancy. On the other hand, *p53* mutations appear to be important in the conversion of relatively quiescent, atrophic endometrium to an intraepithelial form of serous carcinoma that then sets the stage for the accumulation of alterations in yet unidentified cancer-causing genes.

The genes that have been described to play a role in endometrial cancer to date have been genes discovered in other tumor systems that have subsequently been found to have alterations in endometrial cancer. It is likely, with the technologic advances occurring in human genetics and the information being provided by the human genome project, novel genes that are involved in endometrial carcinogenesis will be identified.

Hereditary Syndromes

Hereditary Nonpolyposis Colorectal Carcinoma (Lynch Syndrome)

Lynch syndrome is the most common cause of familial endometrial carcinoma. It is due to germline transmission of defective DNA mismatch repair genes (*MSH2*, *MLH1*, *MSH6*, and *PMS2*) resulting in an autosomal-dominant inheritance pattern. As described above, mutations in DNA mismatch repair genes result in the molecular phenotype of microsatellite instability (MSI), which is thought to result in an increased rate of mutations in cancer-causing genes, thus predisposing affected individuals to the development of various cancers. Endometrial carcinoma is an integral part of HNPCC and women with early onset endometrial carcinoma may be probands for affected families (discussed below).

Up to one-third of endometrioid carcinomas demonstrate abnormal DNA MMR protein expression [101, 272, 308, 414]. This results from *MLH1* promoter hypermethylation in most cases or mutation of *MLH1*, *MSH2*, *MSH6*, or *PMS2* in the rest. Mutation, but not loss of expression alone, of one of these genes indicates that the affected patient may be part of HNPCC kindred. Therefore, DNA MMR protein immunohistochemistry serves as a screen for HNPCC; it is not a diagnostic test. For practical purposes, loss of expression of MSH2 and/or ated with an epigenetic etiology unassociated with HNPCC. In an effort to define a target endometrial cancer population in which the DNA MMR stains might be informative, several institutions have now begun testing for DNA MMR abnormalities in endometrial carcinomas that occur in women younger than 50 years and in older women whose tumors exhibit morphologic features that have been reported to covary with high levels of microsatellite instability (MSI-H). Such morphologic features, although not specific and currently considered of debatable significance, include dense peritumoral lymphocytes and [140] tumor infiltrating lymphocytes (greater than 40 TILs per ten high power fields), and tumors with undifferentiated components [365]. Most HNPCC tumors are endometrioid, but a proportion of clear cell and undifferentiated carcinomas, and perhaps even serous carcinomas and MMMTs, may also belong to this group [52]. It is increasingly recognized that clear cell carcinoma of the endometrium might represent a manifestation of HNPCC [60]; as such, there are rare clear cell carcinomas with loss of MSH2 and MSH6, related to mutations in the corresponding genes. The preliminary data from a study investigating the feasibility and utility of testing such patients' tumors for DNA MMR expression indicate disproportionate representation of tumors lacking MSH2 and MSH6 expression, indirectly indicating mutation in either of the corresponding genes and possible membership in an HNPCC kindred [140]. Any patient with an abnormal immunohistochemical result should be referred for a comprehensive genetics evaluation that might include MSI testing and, when indicated, methylation and mutational analysis of the candidate genes.

Loss of expression tends to occur in couplets (MLH1 with PMS2 and MSH2 with MSH6), although examples of isolated PMS2 loss (without MLH1) or MSH6 loss (without MSH2) are certainly on record. Only complete expression loss in the setting of a valid positive internal control is considered interpretable. Valid internal controls include nonneoplastic endometrial stroma and glands with reproducibly stained nuclei see below in **>** Endometrioid Carcinoma Immunohistochemical Findings. Care should be taken to ensure that the lesion being assessed is carcinoma, not hyperplasia. It is also extremely important that the immunohistochemical methodology and interpretation of stains be performed with the strictest guidelines in mind, as performing and interpreting the MLH1 stain, in particular, can be very problematic. Interpreting an MLH1 stain as negative in the absence of a valid positive internal

control is a rather common occurrence. Common pitfalls interpreting these stains are discussed in a recent review [364]. In one series, IHC with *MLH1* and *MSH2* antibodies had a sensitivity of 69% and a specificity of 100% in detecting MSI-H [272]. The addition of *PMS2* and *MSH6* antibodies improved the sensitivity to 91%, but decreased the specificity to 83%. The decreased specificity was primarily due to loss of *MSH6*, likely due to mutation of *MSH6*, which has been found in endometrial carcinomas that are MSI-low or MS-stable [166]. It has been proposed that a simple immunohistochemical panel including only *MSH6* and *PMS2* could allow recognition of all colorectal carcinoma mutation carriers but this has not yet been tested in endometrial carcinoma patients [366].

Cowden Syndrome

Cowden syndrome is an autosomal-dominant disorder caused by mutations in the PTEN tumor suppressor gene and is defined by a number of benign conditions and an increase in the risk of malignancies of the breast, thyroid, and endometrium. The risk of endometrial carcinoma in women with Cowden syndrome is estimated to be between 5% and 10% lifetime risk versus a 2.6% in the general population. The syndrome is recognized in approximately one in 200,000 individuals and the histologic type of endometrial carcinoma has not been described [283]. As discussed above, given the increase in lifetime risk, it is currently recommended that women with Cowden syndrome be screened for endometrial carcinoma with blind biopsies annually starting at 35-40 years of age or 5 years prior to the earliest diagnosis of endometrial carcinoma in the family and with annual endometrial ultrasound in postmenopausal women.

Clinical and Pathologic Features of Specific Types of Carcinomas

Endometrioid Carcinoma

Endometrioid carcinoma is the most common form of endometrial carcinoma, accounting for more than threefourths of all cases. These tumors are referred to as endometrioid because they resemble proliferative-phase endometrium and to maintain consistency with the terminology used for describing tumors with the same histologic appearance in the cervix, ovary, or fallopian tube. The tumors in this category, by definition, do not contain areas showing more than 10% of serous, mucinous, or clear cell differentiation. Such foci are common in endometrioid carcinoma and are designated as mixed (see **O** Mixed Types of Carcinoma).

Clinical Features

Patients with endometrioid carcinoma range in age from the second to the eighth decade, with a mean age of 59 years. Most women are postmenopausal, as the disease is relatively uncommon in young women. Only 1-8% of endometrial carcinomas occur in women under 40 years [96, 105, 151, 312, 336]. A small number of cases have been reported in women under the age of 30 years, the youngest being 15 years [121, 239]. In young women, the tumor is generally low grade and minimally invasive. In most series, the majority of patients have had clinical evidence of polycystic ovary disease (irregular menses, infertility, obesity, or hirsutism) but in some reports the patients lacked these features. Rarely, endometrioid carcinoma occurs during pregnancy [179]. In pregnant women, endometrial carcinomas are nearly always low grade, superficially invasive or noninvasive, and have an excellent prognosis.

The initial manifestation of endometrial carcinoma usually is abnormal vaginal bleeding, although rarely the patient is asymptomatic and the diagnosis is made fortuitously. In one study, 24 asymptomatic women with unsuspected endometrial carcinoma were detected among 8,998 women dying of unrelated causes who were autopsied at the Yale–New Haven and Massachusetts General Hospitals [183]. The estimated rates of undetected endometrial carcinoma were 22 and 31 per 10,000, respectively. These rates were four to five times higher than the diagnosis of endometrial carcinoma recorded by the Connecticut State Tumor Registry, indicating that a number of endometrial carcinomas may be asymptomatic and are undetected during life.

A number of studies have evaluated cytologic screening of endometrial cancer. Both direct endometrial sampling and examination of cervical cytologic smears for the presence of endometrial carcinoma have been performed. In a study of 2,586 asymptomatic women the prevalence of occult carcinoma using endometrial cytological sampling was 6.96 per 1,000; however, four cases were missed [226]. In addition, the investigators emphasized that endometrial smears were difficult to interpret and that the detection methods were only moderately reliable. About a third of the cases would have been detected using a vaginal pool specimen. In a population-based study from Australia, it was found that when a cervical smear was reported as showing endometrial carcinoma, the lesion was confirmed histologically in only 64% of cases [270]. Conversely, among women with endometrial carcinoma a cervical

smear performed in the 2 years preceding the diagnosis predicted the presence of endometrial carcinoma in only 28% of cases. Because the sensitivity and specificity of cytologic examination for the detection of endometrial carcinoma is low in asymptomatic women, it is not a cost-effective screening tool for endometrial cancer. In an attempt to use cytologic screening in specific high-risk populations, it was reported that among 597 asymptomatic women over the age of 45 with diabetes and/or hypertension the diabetic women had a significantly higher rate of atypical hyperplasia compared with women with hypertension, suggesting that screening might be useful in diabetic patients [160]. In another study of endometrial cytology in 541 women, all 16 carcinomas were detected by cytologic examination; however, because all but one patient were symptomatic, the ability to detect cancers in asymptomatic women could not be assessed [405]. Similarly, endometrial brush sampling detected all but one of 13 cancers in 1,042 symptomatic patients in another study [219]. Cytologic detection methods in symptomatic women are thus of little value as women with abnormal vaginal bleeding are evaluated by either endometrial biopsy or curettage, which yields a more easily interpreted specimen.

Gross Findings

The gross appearance of endometrioid carcinoma is similar to the various other types of endometrial carcinoma with the possible exception of serous carcinoma or malignant mesodermal mixed tumors (see Serous Carcinoma and Nalignant Mesodermal Mixed Tumors). The endometrial surface is shaggy, glistening, and tan and may be focally hemorrhagic. Endometrioid carcinoma is almost uniformly exophytic even when deeply invasive. The neoplasm may be focal or diffuse. At times the tumor may appear to be composed of separate polypoid masses. Necrosis usually is not evident macroscopically in welldifferentiated carcinomas but may be seen in poorly differentiated tumors, sometimes in association with ulcerated or firm areas. Myometrial invasion by carcinoma may result in the enlargement of the uterus, but a small atrophic uterus may harbor carcinoma diffusely invading the myometrium. Myometrial invasion usually appears as well-demarcated, firm, gray-white tissue with linear extensions beneath an exophytic mass or as multiple, white nodules with yellow areas of necrosis within the uterine wall. However, uncommon cases of well-differentiated carcinoma may show extensive myometrial invasion in the absence of a grossly identifiable invasive component. Extension into the lower uterine segment is common, whereas the involvement of the cervix occurs in approximately 20% of cases.

Microscopic Findings: Grading

The grade of endometrioid carcinoma is determined by the microscopic appearance of the tumor. It is based on the architectural pattern, nuclear features, or both (> Figs. 9.1–9.16). The architectural grade is determined by the extent to which the tumor is composed of solid masses of cells as compared with well-defined glands (**)** Table 9.3) (**)** Figs. 9.1, **)** 9.3−9.7, **)** 9.10, **)** 9.12, 29.13, 29.15). In endometrioid carcinomas with squamous differentiation, it is important to exclude masses of squamous epithelium in determining the amount of solid growth (see the following). The nuclear grade is determined by the variation in nuclear size and shape, chromatin distribution, and size of the nucleoli. Grade 1 nuclei are oval, mildly enlarged, and have evenly dispersed chromatin (**)** Figs. 9.2 and **)** 9.8). Grade 3 nuclei are markedly enlarged and pleomorphic, with irregular coarse chromatin, and prominent eosinophilic nucleoli (> Fig. 9.14). Grade 2 nuclei have features intermediate to grades 1 and 3 (> Figs. 9.9 and > 9.16). Mitotic activity is an independent histologic variable, but it is generally increased with increasing nuclear grade, as are abnormal mitotic figures.

Fig. 9.1

Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Well-differentiated glands display a confluent glandular pattern with surrounding desmoplastic stroma; these features indicate endometrial stromal invasion by carcinoma (Courtesy of EC Pirog and K Loukeris) The most recent revision of the FIGO (International Federation of Gynecology and Obstetrics) Staging System (**2** *Table 9.4*) and the WHO Histopathologic Classification of uterine carcinoma recommend that tumors be graded using both architectural and nuclear criteria [89, 356]. The grade of tumors that are architecturally grade 1 or 2 should be increased by one grade in the presence of "notable" nuclear atypia, defined as grade 3 nuclei [438]. For example, a tumor that is grade 2 by

Fig. 9.2 Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Well-formed glands have small, round to oval nuclei with uniform chromatin

■ Fig. 9.3 Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Glandular epithelium displays a confluent pattern indicating endometrial stromal invasion by carcinoma

Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Well-differentiated glands are back-to-back with foci of fusion. The latter is indicative of carcinoma

Fig. 9.6

Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Fused glands are consistent with carcinoma

Fig. 9.5

Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 2). Well-differentiated glands exhibit cribriform growth, a pattern indicating endometrial stromal invasion by carcinoma

architecture but in which there is marked nuclear atypia (nuclear grade 3) should be upgraded to grade 3. Thus, tumors are graded primarily by their architecture, with the overall grade modified by the nuclear grade when there is discordance. Marked discordance between nuclear and architectural grade is unusual in endometrioid carcinoma and should raise suspicion that the tumor is a serous carcinoma (see Serous Carcinoma). For a further discussion of grading, see S Histologic Grade.

■ Fig. 9.7 Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Back-to-back and fused well-differentiated glands have mucinous features

Marked differences in architectural grade can be seen within a tumor. It is not unusual to see well-formed glandular elements immediately adjacent to solid masses of cells. When a tumor displays this type of heterogeneity, the architectural grade should be based on the overall appearance. The heterogeneity in differentiation accounts for the differences in grade that can be observed between the endometrial curettings and the hysterectomy specimen. Discordance between the curettage and hysterectomy specimens occurs in 15–25% of cases [99, 232, 299].

Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 1). Nuclei are round to oval with uniform chromatin

Fig. 9.10

Endometrioid carcinoma, FIGO grade 2 (architectural grade 2, nuclear grade 1). Well-formed glands are admixed with solid nonsquamous nests of tumor, with the latter comprising more than 5% but less than 50% of the overall tumor

Fig. 9.9

Endometrioid carcinoma, FIGO grade 1 (architectural grade 1, nuclear grade 2). Nuclei are somewhat enlarged, rounded, and have granular to vesicular chromatin with occasional small nucleoli

Myoinvasion

Endometrial carcinoma may manifest different forms of myometrial invasion (\bigcirc *Figs.* 9.17 and \bigcirc 9.18). It can invade along a broad pushing front or it can infiltrate the myometrium diffusely as masses, cords, or clusters of cells, and individual glands. When it invades along a broad front it may be difficult to determine whether invasion is in fact present unless it can be compared to the adjacent

■ Fig. 9.11 Endometrioid carcinoma, FIGO grade 2 (architectural grade 2, nuclear grade 1). Glandular and solid areas have generally uniform small, round to oval nuclei with granular chromatin

uninvolved endomyometrium. When the tumor diffusely invades the myometrium the neoplastic glands usually elicit a reactive stromal response characterized by loose fibrous tissue accompanied by a chronic inflammatory infiltrate that surrounds the glands. Occasionally, welldifferentiated carcinomas may be deeply invasive with glands directly in contact with surrounding myometrium in the absence of a stromal response (diffusely infiltrative or adenoma malignum pattern of invasion) [250, 256].

Endometrioid carcinoma, FIGO grade 2 (architectural grade 2, nuclear grade 2). Tumor is composed of intimately admixed glandular and solid nonsquamous epithelium within an edematous and inflamed altered stroma

Fig. 9.14

Endometrioid carcinoma, FIGO grade 3 (architectural grade 3, nuclear grade 3). Solid nonsquamous tumor with foci of necrosis and rare residual glandular lumens displays notable nuclear atypia characterized by nuclear enlargement and pleomorphism with vesicular chromatin and prominent nucleoli

■ Fig. 9.13 Endometrioid carcinoma, FIGO grade 3 (architectural grade 3, nuclear grade 3). A few residual glandular structures are present within an otherwise solid nonsquamous (>50%) tumor with areas of necrosis

In these cases, when myometrial invasion is superficial the presence of invasion can be identified if a haphazard glandular arrangement is present. Usually this pattern of invasion is found in deeply invasive tumors, however, and therefore recognizing myometrial invasion is not a problem. Endometrioid carcinomas with the diffusely infiltrative pattern of invasion share the same prognostic

Fig. 9.15 Endometrioid carcinoma, FIGO grade 3 (architectural grade 3, nuclear grade 2). Tumor is composed of solid nonsquamous epithelium with areas of necrosis

indicators of clinically aggressive disease as those having the more conventional pattern of myometrial invasion [250]. An unusual form of myoinvasion has been described that consists of outpouching of neoplastic glands that become detached and may be lined by flattened epithelium sometimes appearing as microcysts, which is associated with a fibromyxoid stromal reaction (\bigcirc *Fig.* 9.18). This type of invasion has been termed MELF,

Endometrioid carcinoma, FIGO grade 3 (architectural grade 3, nuclear grade 2). Nuclei are only modestly pleomorphic, with vesicular chromatin and numerous mitotic figures. Spaces consistent with residual gland lumens favor endometrioid rather than undifferentiated carcinoma and clear cytoplasmic change in the absence of any other characteristic features of clear cell carcinoma is insufficient to diagnose the latter

Table 9.3

Architectural grading of endometrial carcinoma

Grade 1	No more than 5% of the tumor is composed of solid masses
Grade 2	6–50% of the tumor is composed of solid masses
Grade 3	More than 50% of the tumor is composed of solid masses

which stands for microcystic, elongated, and fragmented [279]. In the study cited, MELF invasion was associated with lymphovascular invasion, but not with poor prognosis in a multivariate analysis.

It may be difficult to distinguish myometrial invasion from the extension of the carcinoma into adenomyosis (\bigcirc *Fig. 9.19*). The distinction, however, is important because the presence of carcinoma in adenomyosis deeper than the maximum depth of true tumor invasion does not worsen the prognosis [164, 176, 195, 271]. When the carcinoma is surrounded by endometrial stroma and residual benign glands are present in these foci, the diagnosis of carcinoma extending into adenomyosis is straightforward. At times, however, the distinction from myometrial invasion may be extremely difficult, particularly in older women in whom adenomyosis may

IVB	G123	Distant metastases including intraabdominal and/or inguinal lymph nodes

G1, 5% or less of a nonsquamous or nonmorular solid growth pattern; G2, 6–50% of a nonsquamous or nonmorular solid growth pattern; G3, more than 50% of a nonsquamous or nonmorular solid growth pattern. Rules on staging:

1. Corpus cancer is now surgically staged. Those patients who do not undergo a surgical procedure should be staged according to the 1971 FIGO clinical staging.

2. Ideally, the thickness of the myometrium should be measured along with the depth of tumor invasion.

Notes on grading:

1. Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 or grade 2 tumor by one grade.

2. In serous adenocarcinomas, clear cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence.

3. Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

^aEndocervical gland involvement should be considered stage I.

^bPositive peritoneal fluid cytology should be reported separately, but does not affect the stage.

Endometrioid carcinoma, FIGO grade 1, myoinvasive.

Myometrial invasion by carcinoma is characterized by islands of well-differentiated glands surrounded by smooth muscle

Endometrioid carcinoma involving adenomyosis. FIGO grade 1 carcinoma is present within an island of adenomyosis, identified by the residual benign endometrial glands and stroma along the periphery of the island

Fig. 9.18

Endometrioid carcinoma, FIGO grade 1, myoinvasive. Some endometrioid carcinomas lose their characteristic columnar endometrioid features and invade myometrium insidiously as attenuated and dilated glands, often intimately associated with an inflammatory reaction

have very minimal stroma as a result of fibrosis and atrophy. In these cases, it is necessary to evaluate additional features such as the presence of desmoplasia, surrounding edema and inflammation, and the shape of the glands [195]. In contrast to carcinoma involving adenomyosis, true myometrial invasion is usually characterized by desmoplasia or loosening of the myometrium surrounding the glands. Often there is accompanying chronic inflammation and the glandular outline is jagged and irregular, as compared to carcinoma involving adenomyosis in which the glands have a smooth, rounded outline, and desmoplasia, and inflammation are lacking (> Fig. 9.19). Since CD10 is normally expressed by endometrial stromal cells but not smooth muscle of the myometrium, it would seem that the presence of CD10 in the cells around an adenocarcinoma in the myometrium would indicate its presence in adenomyosis. Unfortunately, CD10 is also often (52% of cases) expressed focally in the cells surrounding clusters of tumor in the myometrium of women in whom adenomyosis is absent, thus eliminating its utility [281, 387]. A diagnosis of carcinoma involving adenomyosis should be made only when there is evidence of adenomyosis uninvolved by carcinoma or residual adenomyosis within foci involved by carcinoma in the uterus because some endometrioid carcinomas invade the myometrium without eliciting a stromal response (see foregoing). A recent study noted that adenocarcinoma involving adenomyosis frequently is associated with preceding estrogen use, low tumor grade, and an excellent prognosis [271].

The diagnosis of superficial myometrial invasion is often problematic due to irregularity of the normal endomyometrial junction, particularly in uteri from older women. The presence of residual nonneoplastic endometrial glands and stroma along the deep or peripheral aspect of rounded nests of carcinoma situated at the

Endometrioid carcinoma, FIGO grade 1, noninvasive.

Nests of carcinoma along an irregular endomyometrial junction suggest superficial myometrial invasion but preserved benign endometrial glands at the periphery of two nests indicate the tumor is still confined to the endometrium

irregular endomyometrial junction is evidence that these nests are still within the endometrium proper and have not invaded superficial myometrium (\bigcirc *Fig. 9.20*).

Differential Diagnosis

The main problem in the differential diagnosis of lowgrade endometrioid carcinoma is the distinction from atypical hyperplasia, atypical polypoid adenomyoma, hyperplasia with various types of cytoplasmic alterations (metaplasias), Arias-Stella reaction, and menstrual endometrium. The distinction from the first three conditions is discussed in O Chap. 8, Precursor Lesions of Endometrial Carcinoma. At times an extremely atypical Arias-Stella reaction may simulate adenocarcinoma. In the reproductive age group, Arias-Stella reaction is much more likely than carcinoma, especially if the clinical history indicates a recent pregnancy. Nonetheless, carcinoma can occur in young women and also in pregnancy. In contrast to a carcinoma, the Arias-Stella reaction tends to be multifocal and is admixed with secretory glands and decidua. The glands in the Arias-Stella reaction may be complex and tortuous but lack confluent or papillary patterns. The stroma does not show a desmoplastic response. The nuclei in the glandular epithelium of the Arias-Stella reaction may be markedly enlarged, but the chromatin appears degenerated and smudged and mitotic figures are very unusual.

Menstrual endometrium can be confused with adenocarcinoma because of the extensive tissue breakdown characterized by tissue fragmentation and hemorrhage. The pattern of stromal breakdown results in fragmented glands of varying size and compact clusters of stromal cells haphazardly mixed with blood, which can appear ominous. The glandular epithelium, however, is bland and shows evidence of secretory activity. Adjacent intact fragments of endometrium with associated predecidual change usually can be identified and assist in the differential diagnosis.

Another problem in differential diagnosis is the distinction of primary endometrial carcinoma from endocervical adenocarcinoma. This is problematic because these carcinomas share morphologic features (endometrioid and mucinous differentiation). Distinction can be difficult even in hysterectomy specimens when the tumor involves both the lower uterine segment and endocervix and precursor lesions are lacking or obscured by carcinoma. The distinction is important because surgical management of these tumors often differs. See Immunohistochemical Findings for further discussion of markers that assist in this distinction.

A related problem is the distinction of a primary endometrial carcinoma from a metastasis from an extrauterine site, discussed in **?** Tumors Metastatic to the Endometrium. A high-grade endometrioid carcinoma at times may be difficult to distinguish from a Malignant Mesodermal (Müllerian) mixed tumor (MMMT) (discussed in the section).

Immunohistochemical Findings

Endometrioid carcinoma expresses pan-cytokeratins, epithelial membrane antigen (EMA), and the glycoprotein associated markers CA125, Ber EP4, and B72.3, among others. The expression of carcinoembryonic antigen (CEA), which is uncommon, is almost always limited to apical membranes, although tumors showing extensive mucinous differentiation may express this antigen more diffusely. Nearly all endometrioid carcinomas are cytokeratin 7 positive and cytokeratin 20 negative [62, 418]. Occasional mucinous varieties express CDX2 [307, 419]. Unlike many other adenocarcinomas, endometrioid tumors frequently display strong staining for vimentin.

Studies of the molecular pathogenesis of endometrioid carcinoma have led to a better understanding of its immunophenotype. The preponderance of FIGO grades 1 and 2 endometrioid carcinomas express ER and PR and

approximately one half of FIGO grade 3 endometrioid carcinomas without serous, clear cell or undifferentiated features are ER/PR positive [100, 225, 237, 328, 382, 413]. p53 overexpression resulting from p53 mutation and accumulation of mutant p53 protein is not encountered in FIGO grade 1 adenocarcinomas and only in a minority of FIGO grade 2 adenocarcinomas, but is present in a significant number of FIGO grade 3 adenocarcinomas. However, when p53 staining is prominent, serous, clear cell, or undifferentiated tumors should be considered [100, 235-237, 362, 381, 395, 448]. Overexpression is defined as diffuse and strong expression in more than 50-75% of tumor cell nuclei. This should be distinguished from low-level expression of p53 in less than 50% of tumor cell nuclei, which is commonly found in endometrioid adenocarcinomas. β-catenin expression in tumor cell nuclei and cytoplasm (as opposed to cell membranes alone), as a consequence of CTNNB1 mutation, is found in approximately one-third of FIGO grades 1 and 2 adenocarcinomas, especially those showing squamous or morular metaplasia [100, 352]. PTEN is frequently mutated in endometrioid carcinomas [54, 100, 298, 333, 373, 395, 435] and expression of this gene is sometimes silenced via hypermethylation of its promoter. Detecting these abnormalities with immunohistochemistry, however, is challenging [100, 303]. DNA MMR proteins are found to be lacking in tumor cell nuclei using immunohistochemistry in one-fifth to one-third of endometrioid carcinomas [101, 272, 308, 414]. In sporadic cases this most often results from MLH1 promoter hypermethylation. Those that arise in the setting of HNPCC are due to mutations of MSH6, MSH2, MLH1, or PMS2, listed in descending order of prevalence. Interpreting DNA MMR protein immunohistochemistry relies on complete loss of expression in the setting of a valid positive internal control. Valid internal controls include nonneoplastic endometrial stroma and glands with reproducibly stained nuclei. Expression loss, when present, usually occurs in couplets (MLH1 with PMS2 and MSH2 with MSH6) due to the fact that these form protein-protein complexes and loss of one of the proteins leads to the destabilization of the other protein in the complex.

A panel of immunohistochemical markers comprised of ER, PR, and p16 has been shown to be useful for distinguishing endometrial endometrioid carcinomas from endocervical adenocarcinomas [26, 262, 269, 388, 434]. The vast majority of endocervical adenocarcinomas (~90%) are human papillomavirus (HPV)-related and exhibit diffuse/moderate to strong p16 expression due to complex molecular mechanisms by which high-risk HPV transforming proteins (E6, E7) interact with cell cycle

regulatory proteins (p53, pRb) to generate a futile feedback loop resulting in p16 over-expression (see O Chap. 6, Carcinoma and Other Tumors of the Cervix). Interestingly, these HPV-related endocervical adenocarcinomas also often lack hormone receptor expression (estrogen [ER] and progesterone [PR] receptors) [263, 335, 388, 434]. In contrast, endometrial endometrioid carcinomas are considered etiologically unrelated to HPV. They have been shown to exhibit generally patchy p16 expression of variable intensity, with mean/median extent of expression in 30-40% of tumor cells across all FIGO grades and only rare endometrioid tumors exhibiting diffuse/strong expression (> Fig. 9.21) [433]. This patchy pattern is distinct from the diffuse/strong expression characteristic of HPV-related endocervical adenocarcinomas. In addition, most endometrial endometrioid carcinomas, particularly FIGO grades 1 and 2 tumors but also many FIGO grade 3 tumors, express hormone receptors [236, 263, 388]. Typical endometrial endometrioid carcinomas are p16 focal+/ER+/PR+, whereas typical endocervical adenocarcinomas are p16 diffuse+/ER-/PR-, with some of the latter retaining focal/limited expression of hormone receptors. We specifically recommend the use of PR in conjunction with ER based on our published [335, 388, 434] and unpublished experiences indicating that the subset of endocervical carcinomas that retains some expression of hormone receptors most often retains ER expression to some degree (often focal/weak to moderate) but entirely loses PR expression; thus, PR is the more discriminatory marker of the two when trying to distinguish endocervical adenocarcinomas from endometrial endometrioid carcinomas.

Fig. 9.21 Endometrioid carcinoma, FIGO grade 1. Tumor exhibits patchy expression of p16

Behavior and Treatment

Endometrioid adenocarcinoma spreads by lymphatic and vascular dissemination, direct extension to contiguous organs, and transperitoneal and transtubal seeding. Lymphatic metastasis is more common than hematogenous spread, but the involvement of the lungs without metastasis to mediastinal lymph nodes suggests that hematogenous spread may occur early in the course of disease. Endometrial carcinoma tends to spread to the pelvic lymph nodes before involving paraaortic lymph nodes. The relative frequency of metastasis to lymph node groups and various organs is shown in **?** *Tables 9.5* and **?** *9.6*, respectively.

The standard treatment for endometrial carcinoma is hysterectomy and bilateral salpingo-oophorectomy. Over the years, preoperative or postoperative radiotherapy and chemotherapy have been used in addition to hysterectomy. The current approach is to treat all patients when feasible by hysterectomy supplemented by surgical staging and to administer postoperative radiation to patients with poor prognostic factors that put them at high risk of recurrence. Postoperative estrogen replacement therapy has been advocated for patients with early-stage disease and no significant poor prognostic factors [93]. One study showed that survival is not compromised in patients with low tumor grade (grades 1 and 2), less than 50% myometrial invasion, and no metastases to lymph nodes or other organs [241]. Given the prognostic significance of pelvic and paraaortic lymph node status, these nodes should be sampled or dissected in patients when any of the following is present: greater than 50% myometrial invasion, grade 3 tumor, cervical involvement,

Table 9.5

extrauterine spread, serous, clear cell, or undifferentiated carcinoma, or palpably enlarged lymph nodes. In a GOG study only a quarter of patients had these findings, but they accounted for the majority of patients with positive aortic lymph nodes [277]. Several studies have shown that the depth of myometrial invasion can be assessed by gross inspection and intraoperative frozen section [106, 296, 367]. However, other studies have suggested that intraoperative assessments are not reproducible with discrepancies of up to 25% with the final diagnosis.

Postoperatively, patients are classified as low, intermediate, or high risk based on surgical pathologic staging. Patients with grade 1 or 2 tumors that are confined to the endometrium or are minimally invasive are defined as low risk and require no further therapy. Patients with pelvic or paraaortic lymph node metastases or involvement of the adnexa or intraperitoneal sites are high risk and receive postoperative radiation (vaginal cuff, pelvis, paraaortic area, or whole abdominal). Radiation appears to be of benefit because the 5-year survival rate for women with positive aortic lymph nodes who were treated with

postoperative radiation is nearly 40% [277]. Despite treatment with surgery and radiotherapy, 50% of stage III tumors recur. Half of these patients die with distant metastasis, although local control also is a major problem. About 4% of patients with endometrial carcinoma have stage IV disease. Spread to the lungs occurs in 36% of patients. Patients who do not qualify as low or high risk are intermediate in risk. A decision as to whether or not these patients should receive postoperative radiation should be individualized because there are no conclusive data demonstrating a survival benefit for these patients treated with postoperative radiotherapy. Studies evaluating the use of adjuvant hormonal or cytotoxic chemotherapy have shown no improvement in survival over surgery and radiation, and consequently these methods currently are not recommended as standard treatment. In contrast, radiation, hormone, and cytotoxic chemotherapy are used for management of patients with recurrent tumor; 50% of patients with isolated vaginal vault recurrence treated by irradiation are alive at 3 years [319].

Histologic Effects of Treatment

Radiation

The histologic changes in neoplastic tissues after intracavitary radiation are nonspecific and variable, showing minor to major alterations from their pre-irradiated state. Similarly, nonneoplastic endometrial or endocervical glands may be affected only minimally or show nuclear and cytoplasmic changes that are indistinguishable from those found in neoplastic cells. Because the cytologic changes in both neoplastic and nonneoplastic tissue are similar, the identification of carcinoma depends largely on the recognition of histologic patterns and signs of invasion. Irradiated carcinoma generally retains a haphazard glandular pattern, but nonirradiated, nonneoplastic glands tend to maintain their normal architectural arrangement despite radiation effects in the endometrial stroma and myometrium. When radiation effect is evident, nuclei tend to be enlarged, highly pleomorphic, and hyperchromatic, with coarsely clumped chromatin. The cytoplasm often is granular and swollen. Vacuolation can be present in both the nucleus and the cytoplasm. The nuclear changes result from the replication of DNA without cell division.

Cytoplasmic vacuolation results from the dilatation of various organelles and possible lysis caused by damaged lysosomal membranes. In some instances, radiation may enhance cellular differentiation. Occasionally, poorly differentiated carcinomas without squamous differentiation in the curettings may have nests of squamous epithelium in the resected uterus after radiation. It is in mitosis and the S phase of the cell cycle that a cell is most susceptible to radiation injury. Thus, the difference in radiosensitivity of tumor cells and benign cells is due largely to the increased mitotic activity of the neoplastic cells and the better reparative capacity of nonneoplastic cells. In view of the variable morphologic response to irradiation, it is often difficult to determine whether irradiated tumor cells are viable. On a practical basis, if tumor cells are evident after irradiation, it should be assumed that some retain the capacity to persist however abnormal they appear.

Radiation changes in the endometrial stroma and myometrium are greatest in the vicinity of the radiation source. The stromal cells are first converted to giant fibroblasts. Early vascular effects include damage to endothelial cells, resulting in thrombosis. The stroma undergoes progressive hyalinization, resulting in a collagenous scar. Elastic tissue often is fragmented and frayed, and blood vessels are thickened and sclerotic. Occasionally, changes similar to those found in atherosclerosis may be present in the intima of blood vessels. Foam cells occur in the intima, and myometrial cells may appear granular and swollen, especially in areas close to the radium source. Scarring, atrophy, and sclerosis of vessels characterize long-standing radiation effects. The endometrium is thin and easily traumatized, and small blood vessels in the stroma are thin walled and ectatic. Some blood vessels form plaques of lipid-filled clear cells in the media.

Progestins

Progestin-induced changes include secretory differentiation of glandular cells, mitotic arrest, conversion of spindle-shaped stromal cells to decidual cells, decrease in estrogen-related cellular changes such as ciliogenesis, and development or enlargement of squamous areas [331, 342]. The earliest evidence of progestin effect is subnuclear vacuolization, observed within 2-3 days of treatment. The vacuoles are a manifestation of glycoprotein synthesis, which is followed by an apocrine-type secretion in which the apical portion of the cytoplasm of the cell is discharged into the gland lumen, with reduction in the size of the cell. Longer term therapy aimed at eliminating the disease, at least until patients can become pregnant, results in a number of morphologic changes that can predict response to therapy. These include decreased glandularto-stroma ratio, decreased to absent mitotic activity, decreased glandular cellularity, loss of cytologic atypia, and a variety of cytoplasmic changes including mucinous, secretory, squamous, and eosinophilic metaplasia. Persistent architectural abnormalities and/or cytologic atypia were predictive of treatment failure. Some architectural changes (cribriform and papillary patterns) induced by progestin treatment, are noteworthy as they may be confused with progression [424]. Importantly, biopsies taken after the initiation of treatment require a comparison to the pretreatment sample for correct interpretation and determination of treatment response (see) Chap. 8, Precursor Lesions of Endometrial Carcinoma). It has been shown that patients with complex atypical hyperplasia and well differentiated carcinoma who were successfully treated with progestins had higher numbers of NK cells and lower numbers of regulatory T cells in post treatment specimens. These alterations in subpopulations of lymphocytes suggest that the effect of progestins goes beyond their direct growth regulatory effects on endometrial tissue [426].

Villoglandular Carcinoma

Villoglandular carcinoma is a variant of endometrioid carcinoma that displays a papillary architecture in which the papillary fronds are composed of a delicate fibrovascular core covered by columnar cells that generally contain bland nuclei [69, 174]. The median age is 61 years, similar to that of women with typical endometrioid carcinoma. In all other respects, women with these tumors are similar to patients with low-grade endometrioid carcinoma.

The microscopic appearance of villoglandular carcinoma is characterized by thin, delicate fronds covered by stratified columnar epithelial cells with oval nuclei that generally display mild to moderate (grade 1 or 2) atypia (\bigcirc *Figs.* 9.22 and \bigcirc 9.23). Occasionally, more atypical (grade 3) nuclei may be observed. Mitotic activity is variable, and abnormal mitotic figures are rare [69, 174]. Myometrial invasion usually is superficial.

Differential Diagnosis

The main consideration in the differential diagnosis is serous carcinoma because both villoglandular and serous carcinomas have a prominent papillary pattern. In contrast to serous carcinomas, villoglandular carcinomas have long delicate papillary fronds and are covered by columnar cells with only mild to moderate nuclear atypia. The cells look distinctly endometrioid with a smooth, luminal border. To have significance as a distinctive entity, the diagnosis is reserved for tumors in which most of the neoplasm has a villoglandular appearance. In contrast to villoglandular carcinomas, serous carcinomas tend to have shorter, thick, densely fibrotic papillary fronds. The most

Fig. 9.22

Endometrioid carcinoma, villoglandular type. Tumor has papillary architecture, which might lead to misclassification as serous carcinoma, but columnar epithelium with lowgrade cytologic features (see **Fig. 9.23**) is consistent with endometrioid carcinoma

Endometrioid carcinoma, villoglandular type. Endometrioid differentiation is confirmed by the presence of columnar epithelium and low-grade cytologic features (elongated uniform nuclei)

important distinguishing feature is the cytologic appearance. The cells of serous carcinoma tend to be rounder, forming small papillary clusters that are detached from the papillary fronds, a finding that is often referred to as papillary tufts. As a consequence, the luminal border has a scalloped appearance. The nuclei of serous carcinomas are highly pleomorphic and atypical (grade 3). Cherry red macronucleoli typically are present and the cells have a hobnail appearance, often with smudged, hyperchromatic nuclei. It should be noted that considerable nuclear heterogeneity can be observed.

Villoglandular carcinomas are generally better differentiated than typical endometrioid carcinomas but are not significantly different with respect to depth of invasion or frequency of nodal metastases [442]. In addition, villoglandular carcinomas are frequently admixed with typical endometrioid carcinoma. In view of the frequent admixture of the two patterns and similar prognosis, villoglandular carcinoma is considered a variant of endometrioid carcinoma. Treatment is the same as for endometrioid carcinoma of comparable stage, grade, and depth of invasion.

Secretory Carcinoma

Secretory carcinoma is a variant of typical endometrial carcinoma in which the majority of cells exhibit subnuclear or supranuclear cytoplasmic vacuoles resembling early secretory endometrium. An unusual pattern, it represents only 1–2% of endometrial carcinomas [229, 402]. The age range is from 35 to 79 years, with a mean age of 55–58 [75, 402]. Most patients are postmenopausal and experience abnormal bleeding. This histologic subtype also may be seen after progestin treatment of an endometrioid carcinoma. In all other respects, including the association of obesity, hypertension, diabetes mellitus, and exogenous estrogen administration, patients with secretory carcinoma are similar to women with endometrioid carcinoma.

Microscopically, secretory carcinoma displays a welldifferentiated glandular pattern and is composed of columnar cells, often unstratified, with subnuclear or supranuclear vacuolization closely resembling day 17-22 secretory endometrium (> Figs. 9.24-9.26) [229, 402]. Usually the nuclei are grade 1. The secretory pattern may be focal or diffuse, and it is frequently admixed with endometrioid adenocarcinoma. The endometrium adjacent to secretory carcinoma in young women typically shows a secretory pattern that is more advanced than 17 days, and a corpus luteum is found in most premenopausal patients when a hysterectomy and bilateral salpingooophorectomy are performed. Nonetheless, a relationship to progesterone stimulation is not always demonstrable. In fact, secretory carcinoma may occur spontaneously in postmenopausal women without exogenous or abnormal levels of progesterone. The secretory activity in the tumor may be transient because it has been observed in curettings but not in the later hysterectomy specimen [75].

Differential Diagnosis

It is important to distinguish secretory carcinoma from clear cell carcinoma in view of the excellent prognosis of the former and unfavorable prognosis of the latter. Although both tumors are composed of cells with clear, glycogen-rich cytoplasm, the histologic features are distinctive. At times a secretory carcinoma that has a predominantly glandular

Endometrioid carcinoma, secretory type, FIGO grade 2.

Endometrioid-type glands and solid nonsquamous epithelium exhibit diffuse secretory differentiation manifested as clear cytoplasmic change. Tumor has uniform low-grade cytologic features and lacks any of the characteristic architectural patterns of clear cell carcinoma, supporting a diagnosis of secretory type endometrioid carcinoma

pattern can become solid and simulate clear cell carcinoma. The tumors are distinguished by their architectural and cytologic appearance. Secretory carcinoma displays a glandular architecture like endometrioid carcinoma, is rarely papillary or cystic, and usually is not solid. The cells of secretory carcinoma are columnar, similar to those in endometrioid carcinoma, except that they have supranuclear or subnuclear vacuoles. In contrast, clear cell carcinoma often exhibits tubulocystic and/or papillary architecture but can be glandular. The cells usually have marked nuclear atypia (grade 3), with rounded cells having a variety of characteristic features including hobnail morphology, smudgy hyperchromasia, and prominent nucleoli. Cells with clear cytoplasm also may be seen in the squamous component of an endometrioid adenocarcinoma with squamous differentiation. The clear appearance of these cells is also due to the presence of glycogen. Clear squamous cells tend to be polygonal and usually merge with more typical squamous cells with abundant eosinophilic cytoplasm. The distinction of secretory carcinoma from atypical hyperplasia with secretory effect can be difficult and is based on the presence of stromal invasion in the carcinoma (see O Chap. 8, Precursor Lesions of Endometrial Carcinoma). Treatment is the same as that for endometrioid carcinoma of the same stage and grade. Secretory carcinoma usually is low grade with a good prognosis [402]. Death from recurrent disease occurs rarely [75].

Ciliated Carcinoma

Ciliated carcinoma is a rare form of differentiation in lowgrade endometrioid carcinoma [175]. It does not need to be classified separately from endometrioid carcinoma; its only importance is to remind the pathologist that endometrial proliferations with cilia may still be carcinomas. Estrogen induces cilia formation in the normal endometrium. Despite the prevalence of estrogen use, ciliated carcinoma is an extremely rare carcinoma, and most endometrial proliferations in which cilia are observed represent hyperplasias associated with eosinophilic or ciliated change. Patients range in age from 42 to 79 years, are often postmenopausal, and present with bleeding. Ciliated carcinoma has an association with exogenous estrogen treatment. Microscopically, ciliated carcinoma is almost always well differentiated and often displays a cribriform pattern. The gland lumens in the cribriform areas are lined by cells with prominent eosinophilic cytoplasm and cilia. The nuclei of ciliated cells generally have an irregular nuclear membrane and display coarse nuclear chromatin with prominent nucleoli. In most cases, ciliated carcinoma is admixed with nonciliated endometrioid carcinoma and occasionally areas of mucinous carcinoma. Although some ciliated carcinomas are moderately differentiated and invade to the middle third of the myometrium, none of the patients has developed recurrence or died of disease. Thus, the presence of cilia in a bona fide carcinoma identifies a low-grade neoplasm.

Endometrioid Carcinoma with Squamous Differentiation

Many endometrioid adenocarcinomas contain squamous epithelium, but the amount of squamous epithelium can vary widely. In a well-sampled neoplasm, the squamous element should constitute at least 10% of a tumor to qualify as an adenocarcinoma with squamous differentiation. Adenocarcinomas with squamous elements were formerly divided into those with benign-appearing squamous elements and favorable prognosis, designated adenoacanthoma (AA), and those with malignantappearing squamous epithelium, and a worse prognosis, termed adenosquamous carcinoma (AS) [11, 284]. Recent studies indicate that the difference in behavior between AA and AS mainly reflects the difference in the grade of these respective neoplasms [4, 440, 441]. Thus, the categorization of carcinomas with squamous epithelium according to the depth of myometrial invasion and the grade of the glandular component provides more useful

Endometrioid carcinoma with squamous differentiation, FIGO grade 1. Well-differentiated glands are intimately admixed with solid nests of low-grade squamous epithelium. Grading is based on the features of the glandular component alone

prognostic information than the division into AA or AS because the grade of the glandular component generally parallels that of the squamous element [440]. This understanding had led to the view that AA and AS reflect a continuum in the degree of differentiation of the squamous epithelium that parallels the differentiation of the glandular component. Accordingly, it is recommended that endometrioid carcinomas with squamous epithelium be classified simply as endometrioid carcinoma with squamous differentiation and graded, on the basis of the glandular component, as well, moderately, or poorly differentiated (grade 1, 2, or 3, respectively).

There are no differences in the clinical features of adenocarcinoma containing squamous epithelium and endometrioid adenocarcinoma. Thus, there are no differences in the frequency of obesity, hypertension, diabetes, and nulliparity among the large series in which this has been analyzed [11, 84].

Gross and Microscopic Findings

These tumors have no distinctive gross findings. Lowgrade tumors (grade 1) are composed of glandular and squamous elements but generally the glandular component predominates; the nests of squamous epithelium are confined to gland lumens. The squamous epithelium resembles metaplastic squamous cells of the cervical transformation zone. Frequently, nests of cells with

Fig. 9.28

Endometrioid carcinoma with focal squamous differentiation, FIGO grade 3. Carcinoma has areas of squamous differentiation and is classified as high-grade endometrioid based on the solid nonsquamous epithelium (>50%) with focal residual glandular differentiation

a prominent oval to spindle cell appearance, referred to as morules, are observed (\bigcirc *Fig. 9.27*). Intercellular bridges can be identified within the squamous epithelium, and keratin formation is common. The nuclei of the squamous cells are bland, uniform, and lack prominent nucleoli. Mitotic figures are rare. In higher-grade tumors, the squamous element is cytologically more atypical and is not confined to gland lumens but often extends out from the glands (\bigcirc *Fig. 9.28*). At times the squamous cells have a spindle appearance simulating a sarcoma. They may not be in direct continuity with the glandular epithelium, appearing in isolated nests within the myometrium or in vascular spaces. Keratinization and pearl formation occur to varying degrees.

Generally, the glandular component predominates, but masses of undifferentiated cells that may represent poorly differentiated glandular or squamous cells lie between glands. This undifferentiated epithelium should be considered glandular unless intercellular bridges are demonstrated or the cells have prominent eosinophilic cytoplasm, well-defined cytoplasmic borders, and a sheetlike proliferation without evidence of gland formation. Both the glandular and squamous components display grade 2 or 3 nuclear atypia, an increased nuclear cytoplasmic ratio, and increased mitotic activity. The glandular architecture usually is poorly differentiated. Tumors of intermediate differentiation are common. These neoplasms contain glandular and solid areas in which the squamous cells display a moderate degree of nuclear atypia, defying separation into a "benign" and "malignant" category.

A rare finding in patients with adenocarcinoma with squamous differentiation is the presence of keratin granulomas that may involve a wide variety of sites in the peritoneal cavity including the ovaries, tubes, omentum, and serosa of the uterus and bowel [70, 218]. Microscopically, these lesions consist of a central mass of keratin and necrotic squamous cells surrounded by a foreign body granulomatous reaction. A proliferation of mesothelial cells also may be present. The granulomas probably result from the exfoliation of necrotic cells from the tumor, followed by transtubal spread and implantation on peritoneal surfaces. It is important to distinguish pure keratin granulomas from lesions with both viable-appearing tumor cells and keratin accompanied by a foreign bodytype giant cell reaction because the former lesions have not been associated with an unfavorable prognosis.

Differential Diagnosis

The most common problem in the differential diagnosis of the low-grade tumors is with atypical hyperplasia showing squamous metaplasia. To distinguish between the two, the criteria for identifying endometrial stromal invasion should be employed (see O Chap. 8, Precursor Lesions of Endometrial Carcinoma). At times, a lowgrade tumor may be confused with a high-grade carcinoma because the masses of squamous epithelium are misconstrued as a solid proliferation of neoplastic cells. The nuclear grade is high in poorly differentiated carcinoma, however. Occasionally, squamous morules may be confused with granulomas, but the presence of foreign body giant cells and an inflammatory infiltrate helps to identify the latter. For high-grade adenocarcinomas with squamous epithelium, the major problem in differential diagnosis in curettings is distinguishing a primary carcinoma of the endometrium from an adenosquamous carcinoma arising in the endocervix. In the cervix, the squamous component usually predominates, whereas in the endometrium the glandular component predominates. A profusion of cell types, especially mucinous or signet ring cells, is more characteristic of an endocervical neoplasm.

Behavior and Treatment

As already described, when stratified according to stage, grade, and depth of myometrial invasion, there are few differences in the behavior of carcinomas with squamous epithelium compared with endometrioid carcinomas without squamous epithelium [4, 440, 441]. As occurs with endometrioid carcinomas, the low-grade carcinomas with squamous epithelium tend to be only superficially invasive and seldom invade vascular channels. In contrast, high-grade tumors have a high frequency of deep myometrial invasion, vascular space involvement, and pelvic and paraaortic lymph node metastases. Metastasis of high-grade tumors occurs widely throughout the pelvis and abdomen, involving bowel, mesentery, liver, kidney, spleen, and lymph nodes. Distant metastasis may involve the lungs, heart, skin, and bones. Nearly two-thirds of metastases contain both glandular and squamous elements, but pure adenocarcinoma or squamous carcinoma is encountered in 20% and 8%, respectively [284]. Often it is the squamous component that is identified in vascular channels. Accordingly, the treatment for carcinomas with squamous epithelium is the same as that for endometrioid carcinomas of comparable stage.

Mucinous Carcinoma

This uncommon type of endometrial carcinoma has an appearance similar to mucinous carcinoma of the endocervix [98, 401]. Mucinous carcinoma represents the dominant cellular population in only 1–9% of endometrial carcinomas [267, 336]. To qualify as a mucinous carcinoma, more than one-half the cell population of the tumor must contain periodic acid–Schiff- (PAS-) positive, diastase-resistant intracytoplasmic mucin.

Judging from the few published cases, the clinical features of patients with mucinous carcinoma of the endometrium do not differ from those with endometrioid carcinoma. Patients range in age from 47 to 89 years and typically present with vaginal bleeding. In one study, more than 40% had a history of receiving exogenous estrogens [267]. Most patients present with stage I disease.

These tumors do not have distinctive gross features. The most frequent architectural pattern is glandular, often in a villoglandular configuration (\bigcirc *Figs. 9.29* and \bigcirc *9.30*). The epithelial cells lining the glands and papillary processes tend to be uniform columnar cells with minimal stratification. Cribriform areas are unusual; cystically dilated glands filled with mucin and papillary fronds surrounded by extracellular lakes of mucin, containing neutrophils, are typical. Curiously, mucinous differentiation sometimes is associated with squamous differentiation. Nuclear atypia is mild to moderate, and mitotic activity is not prominent. Hyperplasia and mucinous metaplasia sometimes are present in the adjacent endometrium. One study reported that the carcinoma

Mucinous carcinoma, FIGO grade 1. Confluent glands have abundant mucinous cytoplasm and small, basally situated nuclei

Fig. 9.30

Mucinous carcinoma, FIGO grade 1. Tumor has extensive mucinous differentiation and confluent glandular and papillary growth; these architectural patterns allow for establishing a diagnosis of carcinoma

was present in a polyp in 27% of the cases [267]. The presence of intracytoplasmic mucin can be identified on hematoxylin and eosin (H&E) stains by its distinctive granular, foamy, or bubbly appearance and can be confirmed by PAS, mucicarmine, or alcian blue stains. The intracytoplasmic mucin is variable in both the distribution of mucinous cells in the tumor and in the location of the mucin within individual cells. Mucin may be diffusely present in the cytoplasm, confined to the apical area, or show a combination of both patterns. Tumors dominated

by typical endometrioid carcinoma with less than 50% of a mucinous component can be designated as endometrioid carcinomas with mucinous differentiation (**>** *Fig. 9.31*).

Differential Diagnosis

Endocervical epithelium merges with the endometrium in the lower uterine segment, so it is not surprising that the distinction of primary endocervical from endometrial mucinous carcinoma in curettings can be difficult. There is no histochemical difference in the mucin at either site [336]. The distinction of endocervical from endometrial adenocarcinomas has been discussed earlier (see section Differential Diagnosis for endometrioid carcinoma).

The distinction of mucinous carcinoma of the endometrium from clear cell or secretory carcinoma is made on the basis of morphology and PAS and mucin stains. The cells in secretory carcinoma are clear (not granular or foamy) because of the presence of glycogen, which is PAS positive and is removed by diastase treatment. Mucin in these tumors is focal at most. Clear cell carcinoma is almost always papillary or solid in contrast to the glandular pattern of mucinous carcinoma. The cells in clear cell carcinoma tend to be polygonal rather than columnar and hobnail cells are almost invariably present, a cytologic feature that is absent in mucinous carcinoma.

Rarely, a mucinous carcinoma or a mixed mucinous and endometrioid carcinoma may contain areas that simulate microglandular hyperplasia of the cervix [436, 445]. Such foci are characterized by cells showing mucinous and eosinophilic change with microcystic spaces containing acute inflammatory cells. The patients are in their 50s and 60s, in contrast to women with microglandular hyperplasia, who are young. The complexity of the glandular pattern and the degree of cytologic atypia distinguish this type of carcinoma from microglandular hyperplasia.

Behavior and Treatment

When stratified by stage, grade, and depth of myometrial invasion, mucinous tumors behave as do endometrioid carcinomas [336]. Mucinous carcinomas, however, tend to be low grade and minimally invasive and therefore as a group have an excellent prognosis. The treatment is the same as for endometrioid carcinoma. Because most of the tumors are stage I, low grade, and minimally invasive, total abdominal hysterectomy and bilateral salpingooophorectomy usually suffice.

Serous Carcinoma

The existence of papillary patterns within endometrial carcinoma has been recognized since the turn of the century. In the past 2 decades, reports have described the morphologic similarity of serous carcinomas of the endometrium, which frequently display papillary architecture, to ovarian serous carcinomas and identified them as a highly aggressive type of endometrial carcinoma [75, 174, 233, 417]. Although papillary architecture is a common finding in serous carcinoma, most other types of endometrial carcinoma can display papillary architecture but are usually not highly aggressive tumors. What distinguishes serous carcinoma from these other types is the uniformly marked cytologic atypia. Thus, the designation "serous carcinoma," rather than "papillary serous carcinoma," is preferred so that cell type rather than architecture is emphasized.

Clinical Features

The prevalence of serous carcinomas reported from referral centers usually is about 10%; however, in a populationbased study from Norway it was only 1% [5]. Patients with serous carcinoma range in age from 39 to 93 years but typically are postmenopausal and, in contrast to women with endometrioid carcinoma, are older (reported median and mean ages are in the late 60s). In addition, they are less likely to have received estrogen replacement therapy and are more likely to have abnormal cervical cytology. There are some data to suggest that women with this neoplasm are less likely to be obese and that a higher proportion of women are black [108]. In other respects, they appear similar.

Gross Findings

On gross examination, uteri containing these tumors often are small and atrophic. Generally the tumor is exophytic and has a papillary appearance. The depth of invasion is difficult to assess on macroscopic examination. It is not unusual to find a benign-appearing polyp containing the carcinoma in the hysterectomy specimen after a diagnosis of serous carcinoma or endometrial intraepithelial carcinoma has been made on a curetting because these tumors frequently develop within a polyp (see O Chap. 8, Precursor Lesions of Endometrial Carcinoma) [58, 61, 361, 369, 380, 423].

Microscopic Findings

As experience with serous carcinoma has increased, it has become apparent that this neoplasm demonstrates considerable diversity in its architectural features (**)** *Figs.* 9.32–9.42). Although a papillary pattern typically predominates, glandular and solid patterns also occur [100, 174, 238, 361]. Serous carcinoma originally was described as having thick, short papillae, but subsequent studies have shown that thin papillae may be present in more than half of them. The cytologic features of these tumors also are quite varied. Polygonal cells

Fig. 9.32

Serous carcinoma. Papillary tumor is lined by markedly atypical epithelium composed of cells with scalloped luminal borders, including hobnail type cells

Serous carcinoma. Papillary structures and detached epithelial clusters have markedly atypical cells, including hobnail type cells

Fig. 9.34 Serous carcinoma. Papillary structure is lined by markedly atypical hobnail type cells

with eosinophilic and clear cytoplasm often are seen, but hobnail cells are among the most frequently observed cells. Marked nuclear atypia is always present and is required for a tumor to qualify as serous carcinoma (\triangleright *Figs.* 9.33, \triangleright 9.35, \diamond 9.37, \diamond 9.40). Thus, serous carcinoma is defined by the discordance between its architecture, which appears well differentiated (papillary or glandular pattern), and its nuclear morphology, which is high grade (grade 3 nuclei) [104]. Areas containing clear cells do not preclude the diagnosis of serous carcinoma.

Microscopically, the exophytic component of a serous carcinoma typically has a complex papillary architecture. The papillary fronds may be either short and densely

Fig. 9.35

Serous carcinoma. Most nuclei are vesicular with prominent red nucleoli but some detached atypical cells have smudged hyperchromatic nuclei

Fig. 9.36 Serous carcinoma. Tumor is composed of papillae lined by epithelium having prominent scalloped luminal borders

fibrotic or thin and delicate. The cells covering the papillae and lining the glands form small papillary tufts, many of which are detached and float freely in spaces between the papillae and in gland lumens. The cells are cuboidal or hobnail shaped and contain abundant granular eosinophilic or clear cytoplasm. The cells tend to be loosely cohesive. There may be considerable cytologic variability throughout the tumor, as many cells tend to show marked cytologic atypia manifested by nuclear pleomorphism, hyperchromasia, and macronucleoli whereas others are small and not so ominous in appearance. Multinucleated cells, giant nuclei, and bizarre forms occur in half the tumors. Lobulated nuclei with smudged chromatin also

Serous carcinoma. Papillae are lined by cells with enlarged, vesicular nuclei with evident nucleoli. Several mitotic figures are present

Fig. 9.38

Serous carcinoma. Glands with prominent intraglandular papillary architecture infiltrate myometrium

are frequently encountered. Mitotic activity usually is high and abnormal mitotic figures are easily identified. Psammoma bodies are encountered in a third of cases. The invasive component of the neoplasm can show contiguous downgrowth; of papillary processes, or solid masses or glands, the latter often have a gaping appearance. Nests of cells within vascular spaces are commonly found (\bigcirc *Fig. 9.42*).

The adjacent endometrium in hysterectomy specimens with serous carcinoma is atrophic in almost all cases. Hyperplasia, generally without atypia, is present in less than 10% of cases [58, 361, 384]. In nearly 90% of

Fig. 9.40

Serous carcinoma. Some glandular epithelium has smooth luminal borders but papillary epithelial tufts and marked nuclear atypia, with numerous mitotic figures, are characteristic of serous carcinoma

cases, the surface endometrium adjacent to the carcinoma or at other sites away from the neoplasm is replaced by one or several layers of highly atypical cells that overlie atrophic endometrium and extend into normal glands. These cells are identical to those of the invasive carcinoma and at times form micropapillary processes. This lesion, which has been designated serous endometrial intraepithelial carcinoma (EIC; **)** *Fig. 9.41*), is discussed in detail in **)** Chap. 8, Precursor Lesions of Endometrial Carcinoma [23, 384]. The intraepithelial carcinoma can

Serous carcinoma. An area of endometrial intraepithelial carcinoma (serous intraepithelial carcinoma) is present within a background of atrophic endometrium. Markedly atypical epithelium replaces preexisting endometrial glands

■ Fig. 9.42 Serous carcinoma. Detached papillary epithelial cell clusters are present within lymphatic spaces of endometrium

extensively replace the surface endometrium and underlying glands without stromal invasion. The clinicopathologic features and distinction of extensive EIC from early invasive serous carcinoma have been reported recently [423]. It has been proposed that EIC and serous carcinoma measuring 1 cm or less should be designated minimal uterine serous carcinoma because these lesions are difficult to distinguish and they behave in a similar fashion when confirmed as stage IA by meticulous surgical staging. It is important to recognize that patients whose uteri demonstrate only EIC, without evidence of invasive serous carcinoma in the completely sampled endometrium, can have metastatic serous carcinoma in the ovary, peritoneum, or omentum, presumably as a result of exfoliation and implantation of the loosely cohesive tumor cells [380, 423].

Differential Diagnosis

Serous carcinoma must be distinguished from villoglandular carcinoma, which also has papillary architecture. Unlike serous carcinoma, villoglandular carcinoma is characterized by the predominance of long, delicate papillary fronds that do not display papillary tufting. In addition, the cells are columnar, resembling cells in endometrioid carcinoma and lack high-grade nuclear atypia (see **Villoglandular** Carcinoma). A serous carcinoma with a prominent glandular pattern that lacks prominent papillary features may be confused with an endometrioid carcinoma. In this case, it is predominantly the nuclear morphology that aids in the distinction. The glands in an endometrioid carcinoma have a smooth luminal border and are lined by columnar cells with nuclei that are grade 1 or 2. Endometrioid carcinomas with grade 3 nuclei are almost always solid, not glandular. In contrast, the glands in a serous carcinoma are lined by cells with high-grade nuclei, some of which are hobnail shaped, thus imparting a scalloped luminal border to the glands. In addition, in most cases papillary tufts project or lie detached in the gland lumens. Immunohistochemical analysis can aid in the distinction of glandular serous carcinoma from endometrioid carcinoma. Several studies have demonstrated a very high frequency of strong, diffuse positivity for p53 in serous carcinomas, and this pattern of staining is correlated with the presence of mutations in the p53 gene (see section **S** Molecular Genetics) [227, 234, 273, 362, 396]. In addition, most serous carcinomas demonstrate a relative lack of expression of estrogen and progesterone receptors and very high proliferation indices as measured by immunohistochemical expression of Ki-67 compared to endometrioid carcinoma [59, 236]. In contrast, endometrioid carcinomas (particularly grades 1 and 2 tumors) frequently express hormone receptors and have lower proliferation indices [59, 236, 237]. In addition, strong, diffuse immunohistochemical expression of p53 is confined to a subset of grade 3 endometrioid carcinomas and is not encountered in lower-grade endometrioid carcinomas [236, 237]. Hence, glandular carcinomas with high-grade cytology for which the differential diagnosis includes grade 2 endometrioid carcinoma and serous carcinoma can be distinguished by

immunohistochemistry for p53, Ki-67, and hormone receptors. The distinction of serous carcinoma from clear cell carcinoma is discussed later (see **O** Clear Cell Carcinoma).

At times papillary syncytial eosinophilic change, particularly in a small curettage specimen in an older patient, may be difficult to distinguish from serous carcinoma. The papillary processes in eosinophilic change lack fibrovascular support and the cells that form these processes are small and lack significant nuclear atypia or mitotic activity. Typically, small microcystic spaces containing neutrophils are present in the syncytial masses (see) Chap. 8, Precursor Lesions of Endometrial Carcinoma). At times it may not be clear if a serous carcinoma involving the endometrium is primary or metastatic from the ovary. More often than not the uterus is the primary site, even when invasion cannot be demonstrated in the hysterectomy specimen [420]. In these cases the ovarian involvement is typically bilateral and characterized by small foci of tumor on the ovarian surface or nodules of tumor in the parenchyma with clusters of tumor cells in hilar vascular spaces.

Immunohistochemical Findings

Approximately 75% of endometrial serous carcinoma show p53 overexpression (intense expression in greater than 50–75% of tumor cell nuclei; > Fig. 9.43) as a result of p53 mutation and the consequent accumulation of mutant protein [234, 362, 381, 396, 448]. Some of the remaining tumors, which show absolutely no p53 expression, have p53 mutations that result in a truncated p53 protein or a protein with conformational changes that cannot be detected using commercially available antibodies [396]. The Ki-67 labeling index is extremely high (i.e., greater than 50-75% of tumor cell nuclei) [236]. The typical serous carcinoma lacks diffuse ER and PR expression [59, 65, 100, 237, 380], although many carcinomas with hybrid endometrioid/serous features and admixtures of endometrioid and serous components express considerable amounts of ER [15]. PR is less frequently expressed, compared to ER. Diffuse/strong p16 is characteristic of serous carcinomas () Fig. 9.44) [73, 328, 433]. In contrast to most endocervical carcinomas, this does not imply HPV infection; rather, it may reflect disturbances in the cell cycle that favor hyperproliferative activity. In contrast to endometrioid adenocarcinomas, nuclear β-catenin expression and loss of PTEN, MLH1, MSH2, MSH6, and PMS2 are almost never encountered.

Despite important immunophenotypic differences that distinguish between clear-cut examples of serous,

Fig. 9.43

Serous carcinoma. Tumor exhibits diffuse/strong nuclear expression of p53 which correlates with a p53 mutation

Fig. 9.44 Serous carcinoma. Tumor exhibits diffuse/strong expression of p16

and endometrioid carcinomas of the endometrium, these tumors share some notable features. Like endometrioid carcinomas, endometrial serous carcinomas commonly express pan-cytokeratins, EMA, CA125, Ber EP4, B72.3, CK7, and vimentin, while they are usually negative for CK20 and lack diffuse, strong cytoplasmic expression of CEA.

Finally, there are some important differences between the immunophenotype of endometrial and ovarian, tubal and peritoneal serous carcinomas as a group. The most important is infrequent WT1 expression in endometrial serous carcinomas (seen in at most 20–30% of such cases) and the very common diffuse nuclear expression of WT1 in ovarian, tubal, and primary peritoneal examples (at least 70–80% of such cases) [9, 109, 152].

Behavior and Treatment

Serous carcinoma has a propensity for myometrial and lymphatic invasion. The hysterectomy specimen often discloses tumor in lymphatics extensively within the myometrium, cervix, broad ligament, fallopian tube, and ovarian hilus. In addition, intraepithelial carcinoma similar to that involving the endometrium has been reported on the surfaces of the ovaries, peritoneum, and mucosa of the endocervix and fallopian tube in the absence of gross disease in these sites [361, 423]. The involvement of peritoneal surfaces in the pelvis and abdomen, as in ovarian serous carcinoma, occurs early in the course of disease. Not surprisingly, most studies report that uterine serous carcinoma is clinically understaged in approximately 40% of cases [58, 108]. In addition to intraperitoneal spread, serous carcinoma can metastasize to the liver, brain, and skin.

The 5- and 10-year actuarial survival rates for all stages were 36% and 18%, respectively, in a study from Norway [5]; 5-year survival for pathologic stage I serous carcinoma was 40% in one study [58]. One study of stage I and II serous and clear cell carcinomas demonstrated a 5-year survival rate of 57% for patients with stage IA tumors, which was similar to that for patients with stage IB and IC tumors (53%) [81]. A recent retrospective study of stage I serous carcinoma evaluated outcomes in patients treated with different modalities. Patients who received chemotherapy, with our without radiation therapy, experienced more favorable outcomes when compared to patients treated with radiation or observation alone. Only 11.2% of patients treated with chemotherapy and radiation experienced recurrence, compared to 30.3% without therapy, and 25% when radiation was the sole treatment modality. The only subgroup that did not appear to benefit from chemotherapy included patients with stage IA serous carcinoma; only two of 27 such patients experienced recurrence [119].

In addition, prognostic factors for shorter survival included age greater than 60 years, vascular invasion, and greater than 50% myometrial invasion. Nearly half the serous carcinomas and 40% of the clear cell carcinomas in this study population that were thought to be early stage (clinical stage I and II) were upstaged to surgical stage III or IV despite the finding that the majority of these tumors had invaded only the inner third of the myometrium [80]. In addition, 13% of the serous carcinomas that were confined to the endometrium had paraaortic lymph node metastases. Patients with mixed endometrial carcinomas containing a component of serous carcinoma that accounted for at least 25% of the tumor have the same survival as patients with pure serous carcinoma, underscoring the importance of identifying areas of serous carcinoma in uterine carcinomas [361].

The current approach to treatment is hysterectomy bilateral salpingo-oophorectomy along with and omentectomy and careful surgical staging, including peritoneal cytology and pelvic and paraaortic lymph node sampling. In view of the highly aggressive behavior, adjuvant therapy should be considered for all tumors except those that qualify as minimal uterine serous carcinoma. In a study of 21 cases with pure EIC or minimal uterine serous carcinoma (less than 1 cm of carcinoma in the endometrium), all 14 patients whose tumors lacked myometrial or vascular invasion and who had no evidence of extrauterine disease at staging had an overall survival of 100% after a mean follow-up of 27 months [423]. The majority of these patients received no treatment after hysterectomy. Included among these cases were a few patients with the involvement of endocervical glands by EIC (stage IIA disease) who were also alive without evidence of disease at intervals ranging from 12 to 54 months. In contrast, the patients with either EIC or minimal serous carcinoma and evidence of extrauterine disease (even microscopic disease) all died of disease despite intensive chemotherapy. In another study of stage IA serous carcinoma, 11 of 13 patients were alive without evidence of disease after a median follow-up of 38 months [61]. Another study of 16 noninvasive serous carcinomas of the endometrium found that six tumors were stage IA and the remaining ten had metastases identified at staging [204]. Two of the six patients with stage IA disease experienced a recurrence but none died of disease during the follow-up period, which ranged from 2 to 73 months. Three patients with stage IIA disease also were alive without evidence of disease at intervals ranging from 37 to 61 months [119].

The finding of advanced-stage disease in the absence of myometrial invasion in ten patients emphasizes the need for complete staging of all patients with serous carcinoma. Another study of eight patients with serous or clear cell carcinoma confined to endometrial curettings without evidence of residual high-grade carcinoma (serous, clear cell, or FIGO grade 3 endometrioid) or vascular invasion in the hysterectomy specimen were without evidence of recurrence after a median follow-up of 3 years [27]. In a study evaluating cisplatin, doxorubicin (Adriamycin), and cyclophosphamide (PAC) chemotherapy, which has a 70% response rate in previously untreated ovarian serous carcinoma, the response rate for uterine serous carcinoma was only 20%, suggesting that there are inherent differences in uterine and ovarian serous carcinomas [244]. Another study of platinum-based chemotherapy found that eight of the 12 treated women were alive without evidence of disease, including four patients with advanced-stage disease and mean follow-up of 23 months, suggesting a possible role for chemotherapy [150]. More recent studies suggest that systemic platinum base therapies with or without taxane may be effective in the treatment of high stage serous carcinoma of the endometrium [212, 213]. These tumors are unresponsive to hormonal treatment because they almost always lack diffuse expression of hormone receptors.

In summary, it is very important for patients with serous carcinoma to be carefully staged as there may be extrauterine disease even if there is no or minimal myoinvasion. If there is no evidence of extrauterine disease after thorough staging the prognosis is favorable.

Clear Cell Carcinoma

In the past, clear cell carcinoma was regarded as mesonephric in origin because of its resemblance to renal carcinoma, but the occurrence of clear cell carcinoma in the endometrium, a Müllerian derivative, is evidence of its Müllerian origin [229]. The prevalence of clear cell carcinoma ranges from 1% to 6% in most series. Almost all studies report that women with clear cell carcinoma are older than women with endometrioid carcinoma (mean age in late 60s) [2, 75, 208, 314, 379, 421]. Some studies have reported a higher likelihood of abnormal cytology, a lower frequency of some of the associated constitutional symptoms, such as obesity and diabetes mellitus, and a lack of association of estrogen replacement therapy compared with endometrioid carcinomas, but this has not been confirmed by other studies.

These tumors do not have distinctive gross features. Clear cell carcinoma may exhibit solid, papillary, tubular, and cystic patterns (**)** *Figs.* 9.45–9.52). The solid pattern is composed of masses of clear cells intermixed with eosinophilic cells, whereas papillary, tubular, and cystic patterns are composed predominantly of hobnail-shaped cells with interspersed clear and eosinophilic cells. Cystic spaces frequently are lined by flattened cells. Psammoma bodies can be found in association with papillary areas within the tumor. The cells typically are large, with clear or lightly

Fig. 9.45

Clear cell carcinoma. Glands are lined by markedly atypical hobnail type cells with clear cytoplasm. This appearance is reminiscent of the Arias–Stella reaction in gestational endometrium

Fig. 9.46 Clear cell carcinoma. Glands are lined by pleomorphic cells, some attenuated and others with prominent hobnail morphology

stained eosinophilic cytoplasm. The clear cytoplasm results from the presence of glycogen, demonstrated with a PAS stain and diastase digestion. Cells that have discharged their glycogen and lost most of their cytoplasm are characterized by a naked nucleus, the hobnail cell. Nuclear atypia within a given tumor can be variable, ranging from mild to marked (\bigcirc *Figs.* 9.50–9.52). Almost always areas of marked atypia will be found, however. The atypia is manifested by pleomorphic, often large, multiple nuclei with prominent nucleoli. Mitotic activity is high, and

Clear cell carcinoma. Solid tumor is composed of cells with prominent clear cytoplasm and characteristic nuclei with vesicular chromatin and nucleoli

Fig. 9.48

Clear cell carcinoma. Papillary tumor exhibits characteristic features, including hyalinized stroma and cells with clear to granular eosinophilic cytoplasm and hobnail morphology

abnormal mitoses are readily seen. PAS-positive, diastaseresistant intracellular, and extracellular hyaline bodies, similar to those in endodermal sinus tumors, can be found in nearly two-thirds of clear cell carcinomas.

Differential Diagnosis

The differential diagnosis of clear cell carcinoma includes secretory carcinoma, serous carcinoma, and yolk sac

• Fig. 9.50 Clear cell carcinoma. Hobnail type cells protrude prominently into the gland lumen and are pleomorphic with hyperchromatic nuclei

tumor. The differential diagnosis of the first tumor has been discussed (see Secretory Carcinoma). Clear cell carcinoma can be distinguished from serous carcinoma by architectural and cytoplasmic rather than nuclear features because both tumors display similar high-grade nuclear features, including vesicular nuclei with prominent nucleoli, hobnail cells, and cells with hyperchromatic, smudged nuclei. Serous carcinomas do not display the tubulocystic or solid growth patterns, clear cytoplasm, and hyalinized stroma that are characteristic of clear cell

Clear cell carcinoma. Hobnail type cells have hyperchromatic nuclei and vacuolated clear cytoplasm

Fig. 9.52

Clear cell carcinoma. Hyalinized papillae are lined by cells with clear to eosinophilic cytoplasm and pleomorphic nuclei

carcinomas. In some cases, mixtures of both types are found. Yolk sac tumors occur rarely in the endometrium but the patients are young, in contrast to women with clear cell carcinoma, who are almost always postmenopausal. Microscopically, yolk sac tumors often have a microcystic pattern that can resemble the tubulocystic pattern of clear cell carcinoma. Characteristically, the yolk sac tumor contains Schiller–Duval bodies, which are lacking in clear cell carcinoma. Yolk sac tumors are associated with elevated serum alphafetoprotein (AFP) levels, and AFP can be identified in the tumor by immunohistochemistry.

Clear cell carcinoma tends to be high grade, deeply invasive, and to present in an advanced stage. Similar to serous carcinoma, clear cell carcinomas are more frequently associated with deep myometrial invasion, high nuclear grade, lymphovascular space invasion, and pelvic lymph node metastasis compared to low-grade endometrioid carcinomas [346]. Occasionally they are confined to a polyp [208]. The reported survival of patients with clear cell carcinoma differs considerably as reported in various series, ranging from 21% to 75% [2, 75, 229, 314, 421]. In one series, none of the patients with tumor beyond stage I survived for 5 years, and even in stage I the 5-year survival was only 44% [421]. Another report of low-stage tumors demonstrated better survival, with an estimated survival rate of 71% [258]. In a series of nearly 97 patients the 5-year crude survival was 42% and the 10-year survival, 31% [2]. One study reported 5- and 10-year actuarial disease-free survival rates of 43% and 39% [7], and in another study median survival for CC was 29 months and 5-year survival was 50% [379]. The wide range in survival reported in these different series suggests that different investigators may be applying different criteria for the diagnosis of clear cell carcinoma, resulting in a heterogeneous group of cases being studied. Treatment is variable and in some institutions chemotherapy is used irrespective of stage. The role of adjuvant radiation or chemotherapy is not established at present. In view of the poor prognosis and because these tumors often have high nuclear grade and invade the myometrium deeply, adjuvant therapy often is administered.

Immunohistochemical Findings

Like endometrioid and serous carcinomas, clear cell carcinomas usually express pan-cytokeratins, EMA, CA125, BerEP4, B72.3, CK7, and vimentin, while they are usually negative for CK20 and WT1 and lack diffuse, strong cytoplasmic expression of CEA.

Clear cell carcinomas are typically ER/PR negative and show p53, p16, and Ki-67 expression that are intermediate between endometrioid and serous carcinomas [237, 328, 413]. Notably, p53 overexpression and proliferation indices that mimic serous carcinomas are generally not seen in clear cell carcinoma. Although some clear cell carcinomas show abnormalities in *CTNNB1* (β -catenin) and *PTEN* pathways [24, 63], insufficient numbers of well-characterized cases have been studied. Clear cell carcinoma of the endometrium might represent a manifestation of HNPCC [60]; as such, there are rare clear cell carcinomas with loss of MSH2 and MSH6 expression, related to mutations in the corresponding genes.

Mixed Types of Carcinoma

An endometrial carcinoma may show combinations of two or more of the pure types. By convention, a mixed carcinoma has at least one other component comprising at least 10% of the tumor. For example, an endometrioid carcinoma containing a clear cell carcinoma that constitutes 10% of the tumor is classified as an endometrioid carcinoma with areas of clear cell carcinoma. Except for a few studies evaluating the significance of foci of serous carcinoma admixed with endometrioid carcinoma, there are no data that can be used as a basis for making valid recommendations concerning what proportion of an additional component justifies being separately classified. Mixed serous and endometrioid carcinomas containing at least 25% of a serous component behave as pure serous carcinomas [361]. Except for serous and possibly clear cell components, it is likely that the combination of other tumor types has little, if any, clinical significance.

Malignant Mesodermal (Müllerian) Mixed Tumor (Carcinosarcoma)

Malignant Mesodermal (Müllerian) mixed tumors (MMMTs) represent less than 5% of malignant neoplasms of the uterine corpus [372]. By definition, they are composed of malignant epithelial and mesenchymal components as recognized by light microscopy. Because of the biphasic appearance of carcinosarcomas (MMMTs), there has been considerable controversy about their histopathogenesis. Recent clinicopathologic, immunohistochemical, and molecular genetic studies have provided substantial evidence that most MMMTs likely represent carcinomas with a mesenchymal component as a consequence of metaplasia and/or tumor progression [132, 261]. Some MMMTs might also arise via progression from an adenosarcoma. This is supported by the recognition that as many as one-third of MMMTs contain zones that closely resemble adenosarcoma [357] and by studies that report metastases from adenosarcomas that resemble MMMT [82]. It is also possible that these tumors arise by a process of bidirectional differentiation from a single multipotent stem cell.

The risk factors for MMMT have been difficult to determine as robust epidemiologic studies have not been done due to the low prevalence of the disease. One small study suggested that MMMTs may share risk factors (body weight, exogenous estrogen use, and nulliparity) with endometrial carcinoma [446]. Tamoxifen therapy has also been noted as a possible contributor to the development of MMMTs [97, 332, 393]. The risk apparently persists and might even increase after cessation of treatment [124]. MMMTs, along with high-grade endometrial carcinomas, have been reported to arise in patients previously treated with pelvic irradiation for rectal or cervical carcinomas [163, 322]. Endometrial carcinomas and MMMTs also demonstrate similar genetic abnormalities including defective DNA mismatch repair and *p53* and *PTEN* gene mutation [20, 398, 399].

Endometrial carcinomas and MMMTs share many clinical features. Like carcinomas, MMMTs metastasize to pelvic and paraaortic lymph nodes, pelvic soft tissues, vagina, peritoneal surfaces, and lungs [78, 129, 294]. The histologic appearance of metastases is variable. Three studies on metastatic MMMT have demonstrated that invasive foci in lymphatic or vascular spaces are essentially always pure carcinoma and metastatic lesions are most commonly purely carcinoma; occasionally, mixtures of carcinoma and sarcoma are found and only rarely is pure sarcoma encountered [41, 372, 386]. Studies have also suggested that staging surgery usually performed for carcinomas, with omentectomy, peritoneal biopsies, and lymph node dissection, is better suited to detecting occult metastatic MMMT than are staging procedures commonly performed for sarcomas [125, 429]. Both carcinomas and MMMTs respond well to cisplatin-based chemotherapy [392, 412].

Clinical Features

The mean age of patients with MMMTs is in the seventh decade, but the age range spans from the fourth through tenth decades. The disease tends to present like other endometrial cancers, with vaginal bleeding being common. Another typical presentation of carcinosarcoma is a polypoid mass that protrudes through the cervical os.

Gross Findings

MMMTs are frequently polypoid and usually fill the entire endometrial cavity. Many invade the myometrium but some are confined to polyps. The tumors often protrude through the cervical os, simulating a cervical neoplasm. The protruding tip of the mass can be necrotic, making diagnosis based on biopsy of this portion of the tumor difficult. In approximately a quarter of the cases the uterine tumor extends into the endocervix. The tumors are variably soft to firm and tan with areas of necrosis and hemorrhage.

Microscopic Findings

MMMTs are composed of an admixture of histologically malignant epithelial and mesenchymal components but the epithelial component of MMMT is frequently difficult to subclassify (> Figs. 9.53–9.59). In the most recent clinicopathologic review of MMMT, the authors reported that serous carcinomas and high-grade carcinomas, not otherwise specified, were the most frequent carcinoma components in MMMT [125]. Older studies have reported endometrioid carcinomas to be more common. Clear cell, mucinous, squamous, and mesonephric carcinoma also can be found as the epithelial component, but this is less common [41, 231, 294, 295, 372]. Approximately half the cases demonstrate a homologous stromal component, which is high-grade spindle cell (like fibrosarcoma) or pleomorphic (like malignant fibrous histiocytoma) in most cases. The homologous stromal component only rarely resembles leiomyosarcoma or low-grade endometrial stromal sarcoma [123, 372]. When heterologous elements are present, rhabdomyosarcoma and chondrosarcoma are the most common types encountered [37, 125, 372] (> Figs. 9.55-9.59). Heterologous elements can usually be recognized easily by light microscopy.

Immunohistochemical stains to establish the presence of such elements are not recommended unless such confirmation is needed after the review of hematoxylin- and eosin-stained slides. Rhabdomyosarcoma can often be identified by finding round or elongated cells with fibrillar eosinophilic cytoplasm. Striated rhabdomyoblasts are apparent on occasion. Some MMMTs are composed of cells that contain cytoplasmic eosinophilic globules that should not be misinterpreted as evidence of

rhabdomyoblastic differentiation. Importantly, MMMTs as a group, are enriched for highly aggressive, biphasic, malignant mixed epithelial and mesenchymal neoplasms.

Differential Diagnosis

Monophasic tumors should not be diagnosed as a MMMT, although it is acknowledged that either the mesenchymal or epithelial components of MMMT might predominate in small samples such as biopsies and scant curettage specimens. Finding fragments of highly

Rhabdomyosarcoma is characterized by globoid
pleomorphic cells with abundant eosinophilic cytoplasm

pleomorphic sarcoma, a high-grade carcinoma that is difficult to subclassify or heterologous elements in a small biopsy is usually sufficient to suggest that the biopsy might represent an incompletely sampled MMMT, but immunohistochemical results showing coexpression of epithelial and mesenchymal-associated markers are, by themselves, insufficient for a MMMT diagnosis.

The recently described dedifferentiated endometrial carcinoma is an example of a biphasic tumor containing differentiated and undifferentiated components [368].

However, unlike MMMTs the differentiated carcinoma is usually well-differentiated endometrioid and the undifferentiated component is composed of small, round cells of uniform size instead of spindle shaped or obviously pleomorphic cells (as discussed below with > Undifferentiated Carcinomas). Endometrioid adenocarcinoma with spindle cell elements is another biphasic endometrial neoplasm that mimics MMMT; however, these tumors are composed of histologically low-grade elements and are less aggressive than typical MMMT and high-grade carcinoma [278]. In this tumor, the endometrioid elements, frequently showing squamous metaplasia, fuse imperceptibly with spindle cell elements that are never histologically high grade. In most cases, the endometrioid component is no more than FIGO grade 2 and the spindle cell component is cellular and sometimes mitotically active, but not markedly atypical. MMMT contains easily separable, high-grade epithelial, and mesenchymal elements whereas this type of endometrioid adenocarcinoma shows seamless fusion of the two. If there is confusion between this entity and MMMT, the tumor grade and the presence or absence of element fusion can be used to inform the decision. Endometrioid adenocarcinomas can contain chondroid and osteoid elements. Heterologous elements by themselves do not signify MMMT, although finding rhabdomyosarcoma along with adenocarcinoma almost always signifies MMMT.

Behavior and Treatment

Since MMMTs have been historically regarded as sarcomas, many studies have included patients with only clinical staging or incomplete surgical staging. Many older studies have also likely included histologic mimics of MMMT, particularly dedifferentiated carcinoma and endometrioid adenocarcinoma with spindle cell elements. Despite this, studies of comprehensively staged patients and others comprised of clinically staged patients agree that the behavior of MMMTs is significantly worse than FIGO grade 3 endometrial carcinomas, serous carcinomas, and clear cell carcinomas [19, 125, 148, 409]. Surgical stage is likely the most important prognostic factor.

Pathologically determined prognostic features in clinically staged MMMT patients are generally the same as for patients with suboptimally staged endometrial carcinoma. Extrauterine extension and/or deep myometrial invasion along with lymphovascular invasion are reported to be independent predictors of survival in numerous analyses [30, 37, 43, 136, 187, 289, 292, 337, 349, 429]. The presence of serous or clear cell carcinoma also is reported to have a significant tendency to be associated with metastatic disease, but the histologic appearance of the sarcomatous component does not appear to have any prognostic significance in many studies of clinically staged patients [136, 231, 292, 372, 383]. Advanced age may also be associated with poor outcome [187, 292]. The 5-year survival for patients with advanced-stage disease is only 15–30% [148, 289, 383].

A recent study looked at the clinical and pathologic features of comprehensively staged patients with FIGO stage I MMMT. This confirmed that stage I MMMT is a more aggressive disease when compared to a control group of comprehensively staged patients with FIGO stage I, FIGO grade 3 endometrioid, serous or clear cell carcinoma [125]. The 3-year disease-free survival was 87% for women with high-grade carcinoma compared with 42% for women with MMMT. Unlike studies of clinically staged patients, epithelial tumor type, lymphovascular invasion, depth of myometrial invasion, and predominance of carcinoma relative to sarcoma had no relationship to overall survival. The grade of the epithelial and mesenchymal components had no bearing on overall survival either, but they were almost always high-grade. The only clinical or pathologic factor found to have statistical significance with respect to clinical outcome was the presence of heterologous sarcomatous differentiation (principally rhabdomyoblastic), as assessed on the review of hematoxylin- and eosin-stained slides only. Heterologous sarcomatous elements were associated with very poor survivals [125]. When outcomes were stratified based on the presence of heterologous sarcomatous elements, the survival of patients with homologous MMMT was found to be indistinguishable from that of patients with highgrade endometrial carcinoma. Patients with heterologous MMMT had survivals that were significantly worse. The 3-year overall survival for surgical stage I MMMT was only 45% for heterologous tumors, compared with 93% for homologous tumors. This study evaluated the significance of heterologous sarcomatous elements in comprehensively staged FIGO stage I MMMT patients only, so it remains to be determined whether heterologous elements drive prognosis in patients with high stage disease. The clinical significance of heterologous elements had been noted previously [257], but studies of other clinically staged patients failed to support this view [136, 231, 252, 372, 425].

MMMTs metastasize to pelvic and paraaortic lymph nodes, pelvic soft tissues, vagina, peritoneal surfaces, and lungs [78, 129, 294]. MMMTs are treated by total hysterectomy and bilateral salpingo-oophorectomy with pelvic and paraaortic lymph node dissection, pelvic washings, and tumor debulking, if indicated. Older studies reported a decrease in local recurrences with external beam radiation therapy to the pelvis [182]. This was confirmed in a more recent retrospective study, but a convincing effect on overall survival was not appreciated [57]. In an analysis of recurrence patterns, this study also reported a 38% overall local recurrence rate and a 57% frequency of distant recurrences, most of which were peritoneal [57]. A Gynecologic Oncology Group (GOG) study of ifosfamide with or without cisplatin for the treatment of advanced, persistent, or recurrent MMMT demonstrated that the addition of cisplatin provided a small improvement in progression-free survival but no significant survival benefit [392]. Recently, the GOG published results that favored the use of combination chemotherapy (three cycles of cisplatin, ifosfamide, and mesna) over whole abdominal radiotherapy [427]. Although the estimated probability of recurrence in each arm of the study did not differ significantly, the recurrence rate was lower in the chemotherapy arm, when adjusted for stage and age, and the estimated death rate was lower in the chemotherapy group. In practice, many patients are offered combination therapy with carboplatin and taxol. Studies that address which, if any, MMMT patients are good candidates for targeted therapies are ongoing [79, 249, 326, 327, 351].

Undifferentiated Carcinoma

The World Health Organization (WHO) defines undifferentiated endometrial carcinoma as a tumor lacking any evidence of differentiation. The most common entity considered in the differential diagnosis of an undifferentiated tumor is FIGO grade 3 endometrioid adenocarcinoma, which should only be diagnosed when the tumor is obviously endometrioid in character. Confirmatory endometrioid features in this context include even focal glandular architecture, squamous metaplasia, or trabecular and nested growth patterns. Most FIGO grade 3 endometrioid carcinomas either contain focal glandular architecture and/or resemble non-keratinizing, poorly differentiated squamous cell carcinoma.

Different types of undifferentiated carcinomas can now be recognized, which means that tumors lacking differentiation on review of hematoxylin and eosinstained slides probably represent a very heterogeneous group. Small cell carcinoma of neuroendocrine is one tumor that should be separated from the rest, as these tumors demonstrate a unique combination of immunohistochemical, ultrastructural, clinical, and biologic features. Another unique tumor is the undifferentiated carcinoma described recently [18].

Microscopic Findings

The recently described undifferentiated carcinoma [18] is a tumor composed predominately of a monotonous proliferation of small to intermediate-sized, discohesive cells arranged in sheets without an obvious nested or trabecular architecture or gland formation (\bigcirc *Figs.* 9.60 and \bigcirc 9.61).

Fig. 9.60

Undifferentiated carcinoma. Solid tumor lacking any differentiating features is present adjacent to, but not admixed with, FIGO grade 1 endometrioid carcinoma

Fig. 9.61

Undifferentiated carcinoma. Dyscohesive atypical cells lacking any differentiating features suggest a differential diagnosis of undifferentiated carcinoma versus lymphoma However, rare foci of abrupt keratinization are allowed. The low power appearance is reminiscent of endometrial stromal sarcoma, although the tongue-like pattern of myometrial infiltration and characteristic vasculature are lacking. The nuclear features, which often include vesicular chromatin with small chromocenters or nucleoli, along with the very high mitotic rate, are also incompatible with endometrial stroma sarcoma. In many cases, the cytologic appearance of this type of undifferentiated carcinoma recalls large cell lymphoma when the cytoplasm is scant and plasmacytoma when the cytoplasm is more abundant and rhabdoid. Although the tumor stroma is generally inapparent, some tumors display a myxoid matrix. Many examples also contain numerous tumor-infiltrating lymphocytes. When this feature is prominent, the tumor may resemble a lymphoepithelial-like carcinoma of the cervix or nasopharynx. Small cell carcinoma of neuroendocrine type is also a diagnostic consideration, but undifferentiated carcinoma does not typically demonstrate salt-and-pepper chromatin, nuclear molding, or neuroendocrine marker (chromogranin and synaptophysin) expression in greater than 10% of cells. Many endometrial carcinomas containing undifferentiated components also contain foci of well- or moderately differentiated endometrioid adenocarcinoma (> Fig. 9.60). These tumors have been called "de-differentiated endometrial carcinoma" [368]. In these tumors, the gland forming, or differentiated, components are superficial, adjacent to the endometrial cavity, whereas the undifferentiated areas are deeper in the endometrium and myometrium and sharply delimited from the differentiated areas. This accounts for the occasional scenario in which the well-differentiated endometrioid component is diagnosed on endometrial curettage, followed by recognition of the presence of a more deeply placed undifferentiated component on hysterectomy.

Immunohistochemical Findings

Immunohistochemically, the undifferentiated cells in general fail to express markers that would support a diagnosis of lymphoma, plasmacytoma, rhabdomyosarcoma, or a neuroendocrine tumor. Exceptions to this rule include CD138 expression in some examples and low-level expression of synaptophysin and chromogranin in others. The undifferentiated component characteristically shows only focal or weak keratin expression, but nearly every case exhibits intense EMA and cytokeratin 18 expression in a small minority of cells [18]. ER and PR staining is negative. Perhaps as many as one-half demonstrate abnormal DNA mismatch repair protein expression.

Clinical Features

Patients with undifferentiated and dedifferentiated carcinomas span a wide age range, from the third to eighth decade. Endometrial primaries are more common than ovarian primaries. Some patients have synchronous endometrial and ovarian endometrioid carcinomas, with the presence of the undifferentiated component recognizable in only one site. The most common presentation is vaginal bleeding. In many cases, patients are suspected of having lymphoma because of extensive, systemic lymph node involvement coupled with high serum LDH levels. Approximately one-half of patients have extrauterine disease at surgery. These are described as highly aggressive tumors and are almost always fatal. In some cases, a diagnosis of well-differentiated endometrioid adenocarcinoma may be followed by the emergence of undifferentiated carcinoma in a metastatic site. Recent data suggest that undifferentiated carcinomas frequently demonstrate an abnormal DNA mismatch repair gene expression profile that places some of them within the spectrum of tumors encountered among patients with Lynch syndrome/hereditary nonpolyposis colorectal carcinoma syndrome.

Prognostic Factors of Endometrial Carcinoma

Based largely on a series of Gynecologic Oncology Group (GOG) studies, it has been shown that the risk factors for the recurrence of endometrial carcinoma can be divided into uterine and extrauterine factors [46, 94, 277]. Uterine factors include (1) histologic type, (2) grade, (3) depth of myometrial invasion, (4) cervical involvement, (5) vascular invasion, (6) presence of atypical endometrial hyperplasia, (7) hormone receptor status, and (8) DNA ploidy and S-phase fraction. Extrauterine factors include (1) adnexal involvement, (2) intraperitoneal metastasis, (3) positive peritoneal cytology, and (4) pelvic and paraaortic lymph node metastasis. Patients with no evidence of extrauterine disease, no cervical involvement, and no evidence of vascular invasion are at a low overall risk of recurrence. For these patients the grade and depth of invasion are important prognostic factors. In contrast to this low-risk group of patients, women with evidence of extrauterine disease, cervical involvement, or vascular invasion constitute a high-risk group. If one of these three factors is positive, the frequency of recurrence is 20%, increasing to 43% for two positive factors, and 63% for three factors [277].

Clinical Factors

Age, race, and socioeconomic status are prognostic factors in endometrial cancer. Some studies have shown that age is the most important prognostic factor followed by FIGO stage, tumor grade, race, and socioeconomic status [142]. Younger women tend to have lower-grade and less invasive tumors, but age remains an important independent risk factor. It has also been demonstrated that women aged 45 or less have a better prognosis than women over age 45 because of a significantly higher proportion of early-stage disease and less myometrial invasion [431]. Another study also demonstrated that age is a significant prognostic factor, with decreased survival for women over age 50 unrelated to surgical stage or grade of carcinoma [122]. Although there is a lower prevalence of endometrial cancer in African-American women as compared with white women, white women have a significant survival advantage as compared with African-American women even after controlling for other clinicopathologic and socioeconomic factors [38, 83, 178]. Some studies have shown that African-American women have a higher proportion of high-grade tumors and less favorable histologic subtypes and tend to present with higher-stage tumors compared to white women [83, 178]. In addition, they are treated less often at every stage of disease. Another study showed that the incidence of high-risk tumors is the same in African-American and white women, whereas the incidence of low-risk tumors is significantly lower in African-American women [318]. Although an elevated body mass index (BMI) is associated with a lower stage and other better prognostic factors, when adjusted for these factors, survival was lower in overweight patients [143].

Histologic Grade

Numerous studies have confirmed the value of grading [6, 75, 111, 224, 240, 440, 444]. For example, FIGO data collected from almost 5,000 surgically staged patients indicate that the 5-year overall survival rates for women with surgical stage I endometrial carcinoma dropped from 92.1% for those with grade 1 tumors, to 87.5% for those with grade 2 tumors, to 74.5% for those with grade 3 tumors [95]. The survival difference is not limited to early-stage disease, and a 30% difference in survival was also found in the comparison of women with grade 1, stage III tumors (69.7%) to those with grade 3, stage III tumors (39.6%). In a study of more than 600 women with clinical stage I or occult stage II endometrioid adenocarcinoma, the 5-year relative survival was as follows: grade 1,

94%; grade 2, 84%; and grade 3, 72% [440]. According to a population-based study from the Norwegian Radium Hospital involving nearly 2,000 patients, the 5- and 10-year survival rates for patients with grade 1 tumors were 88% and 80%, respectively; with grade 2 tumors, 77% and 62%; and with grade 3 tumors, 60% and 49% [6].

A study of the reproducibility of the FIGO grading method found that interobserver reproducibility was acceptable for the architectural grade but unacceptably low for the assessment of notable nuclear atypia [288]. A more recent study comparing FIGO grading to pure nuclear grading of endometrioid carcinoma demonstrated fair interobserver reproducibility for FIGO grading but only poor interobserver reproducibility for nuclear grading [235]. Using a database of 715 patients with low clinical stage endometrial carcinomas (excluding serous and clear cell types), the utility of the FIGO grading system using arbitrary definitions for three nuclear grades was examined [444]. Patients with architectural grade 1 or 2 adenocarcinomas but with predominantly grade 3 nuclei were moved up one grade. This change resulted in upgrading 44 patients for whom the risk of recurrence and death from tumor was similar to that of the other patients in the grade into which they were reassigned. This study provided support for the FIGO modification of architectural grade based on inappropriate nuclear atypia and reinforced the need for a uniform definition of nuclear grade.

Histologic grade is highly correlated with other prognostic factors such as age, stage, and depth of myometrial invasion, so its prognostic utility must also be examined in multivariate analyses. In such studies, the significance of histologic grade in the prediction of survival or recurrence is diminished after adjustment for the other factors, suggesting that grade primarily provides information about the probability of local or disseminated spread of tumor [6, 443]. Nevertheless, even for patients with metastatic (stage III) tumor, the histologic grade is significant in predicting outcome after multivariate analysis [158].

Alternative methods of assignment of histologic grade have been proposed, including a two-tiered system for assessing uterine tumor grade, based on a study of 85 patients with stage I and II endometrial cancer [400]. Separation of tumors into two groups based on the amount of solid growth identified those that recurred as having greater than 20% solid growth. The two-tier grading system yielded a higher degree of interobserver agreement than the three-tier FIGO system. A binary architectural grading system based on the presence of greater than 50% solid growth, a diffusely infiltrative rather than pushing pattern of invasion, and tumor cell

necrosis has been described [235]. Tumors displaying at least two of these three features were classified as high grade whereas those displaying one of those features was classified as low grade. The binary system stratified patients into three distinct prognostic groups (This study was done using the 1988 FIGO staging). Patients with stage I low-grade tumors with invasion confined to the inner half of the myometrium (stages IA and IB) had a 100% 5-year survival rate. Patients with low-grade tumors that invaded into the outer half of the myometrium or beyond (stages IC-IV) had a 5-year survival rate of 67%. Similarly, those with high-grade tumors with invasion confined to the myometrium (stages IA-IC) had a 5-year survival rate of 76%. Patients with advancedstage (stages II-IV) high-grade tumors had a 26% 5-year survival rate. In addition, greater intra- and interobserver reproducibility were demonstrated for the binary system in comparison with the FIGO system and pure nuclear grading. There are several advantages of the binary system over the FIGO system. The assessment of solid growth does not require distinction of squamous from nonsquamous growth, small amounts of solid growth (around 5%) need not be recognized, and nuclear grading is not necessary. Five studies have subsequently compared the utility of this system to the current FIGO grading method [10, 103, 209, 344, 354]. In general, both methods provide for significant stratification of risk by univariate and multivariate analysis. The two grade system tended to result in a slightly reduced difference in survival between low and high grade as compared to grades 1 and 3 in the FIGO system, but it did eliminate the intermediate grade category. Interobserver and intraobserver reproducibility was often, but not always, found to be greater for the two grade system. Based on the relatively small difference in outcome between those patients with FIGO grade 1 and FIGO grade 2 tumors, some have suggested simply collapsing FIGO grades 1 and 2 into a single category. An additional binary grading scheme has been proposed and can be applied to any type of endometrial carcinoma present in biopsy, curettage, or hysterectomy specimens. This prognostically relevant scheme categorizes a tumor as high-grade when any two of the following three features are present: predominant papillary or solid architecture; high nuclear grade; and more than five mitotic figures per ten high power fields. This grading scheme can be used in practice when an endometrial carcinoma cannot be assigned a specific subtype. The group also tested the prognostic relevance of a revised FIGO grading scheme for endometrioid carcinomas specifically; this supported grouping together FIGO grades 1 and 2 endometrioid carcinomas as low-grade and FIGO grade 3 carcinoma as high-grade. This practice was found to be reproducible and prognostically relevant [14]. It is not clear whether any of the alternative systems would significantly improve upon the reproducibility, ease, or prognostic utility of the current method, and the three grade method continues to be used in the 2009 revised FIGO staging system.

Surgical–Pathological Staging (FIGO Staging)

The stage reflects the extent of disease at the time of diagnosis. It is useful to determine prognosis and plan treatment as well as to provide a standardized method of reporting data among different investigators. Complete staging requires hysterectomy and bilateral salpingooophorectomy, as well as assessment of the pelvic and paraaortic lymph nodes. At present, there is debate regarding the necessity for complete surgical staging of all women with endometrial adenocarcinoma, with some favoring restriction of lymphadenectomy to those at intermediate or high risk of nodal spread [67]. Others have argued that lymphadenectomy itself is a therapeutic procedure, based on retrospective survival data [8]. A new FIGO staging system has been adopted in 2009, with input from the International Society of Gynecological Pathologists [437], representing a refinement to the system last revised in 1988 (> Table 9.4). Major changes from the staging system of 1988 include the inclusion of tumors with no myometrial invasion and those with inner half myometrial invasion in stage IA, elimination of cervical gland involvement from stage II, elimination of positive peritoneal fluid cytology from stage IIIA, and separation of pelvic from paraaortic lymph node metastases within stage IIIC. Pathologic analysis includes evaluation of the grade of the tumor, depth of myometrial invasion, and determination of endocervical stromal involvement; therefore, it is essential that all this information be communicated clearly in the surgical pathology report. The prognostic utility of surgical-pathologic stage has been confirmed in multiple studies of large numbers of patients using both univariate and multivariate analysis [6, 46, 94, 137, 180, 224, 428, 438, 443, 444].

Myometrial Invasion

Effective in 2009, FIGO staging of endometrial carcinoma limited to the uterine corpus (stage I) is divided into those that are confined to the endometrium or involve the inner half of the myometrium, which are stage IA, and those involving more than half the uterine wall thickness, which are stage IB. The combination of tumors that lack any myoinvasion from those with inner half myometrial invasion is based on two pragmatic observations: first, there is diagnostic difficulty and low reproducibility in distinguishing true superficial myometrial invasion from those tumors involving the basal endometrium as it interdigitates normally with the myometrium [13, 371]; second, there is almost no difference in survival between those patients with carcinoma confined to the endometrium and those with superficial myometrial invasion (91% versus 90%) [95]. In addition, we recommend measuring the maximum depth of invasion in millimeters and expressing this as a percentage of the myometrial thickness. For example, 2 mm of myometrial invasion in a uterus measuring 1 cm thick would be 20% invasion. Tumor in vascular spaces beyond the deepest point of invasion should not be used for the measurement of the depth of invasion. The distance of the tumor from the serosa also has prognostic significance [355].

Myometrial invasion, independent of tumor grade, is an important predictor of prognosis. In fact, it is probably the single most important predictor of behavior in stages I and II disease and has been shown to be an independent predictor of outcome for women with early-stage endometrial carcinoma [5, 22, 46, 77, 112, 240, 277, 443]. For example, in the GOG experience, recurrence developed in only one of 99 (1%) patients with no myometrial invasion compared with 15 of 196 (7.7%) with inner-third, eight of 55 (14.5%) with middle-third, and six of 40 (15%) with outer-third invasion when grade was not corrected [277]. In another GOG study it was shown that the 5-year relative survival for endometrioid carcinoma confined to the endometrium was 94%; involving the inner third, 91%; involving the middle third, 84%; and involving the outer third, 59% [440]. The frequency of lymph node metastasis also is related to the depth of myometrial invasion. In clinical stage I endometrial carcinoma, inner-third myometrial invasion is associated with lymph node metastasis in 5% of cases, middle-third invasion with metastasis in 23%, and outer-third invasion with metastasis in 33%. When grade and myometrial invasion are analyzed together, grade 1 tumors invading the inner third of the myometrium do not have pelvic node metastasis, but with outer-third invasion, pelvic node metastasis occurs in 25%. A similar trend occurs with higher-grade tumors.

Cervical Involvement

According to the new FIGO staging system, tumors that are confined to the uterus but involving the cervical stroma are stage II. In contrast, neoplasms that are confined to the surface epithelium or glands of the endocervix are now considered to represent only stage I disease. Cervical stromal involvement is characterized by carcinoma that is not confined to the surface epithelium or preexisting endocervical glands and typically elicits a stromal reaction. However, not all tumors evoke a stromal desmoplastic response and it then may be difficult to distinguish whether the neoplastic glands represent preexisting or newly formed glands [394]. Cervical involvement is associated with a somewhat elevated risk of recurrence, with an overall relapse rate of 16% in the absence of extrauterine disease [266]. Since cervical involvement is often associated with increasing grade, depth of invasion, and tumor volume, the higher recurrence rate is not surprising. There is limited and conflicting data on the prognostic significance of cervical invasion by endometrial adenocarcinoma, after adjustment for other risk factors [33, 91, 120, 198, 325].

Peritoneal Cytology

Tumor cells in a peritoneal cytology specimen are often found in association with adnexal, nodal, or omental spread, but are rarely the only manifestation of extrauterine spread of endometrial adenocarcinoma. Previously, a positive peritoneal cytology was a basis for classification of the tumor as stage IIIA, however, it is no longer used in the staging of endometrial adenocarcinoma. The significance of a positive peritoneal cytology has been the subject of several studies [92, 159, 168, 201, 214, 384, 407, 432, 443]. Some studies have reported the significance of positive peritoneal cytology, including one in which almost 40% of clinical stage I patients with positive peritoneal cytology suffered tumor recurrence compared with 10% of those with negative washings [92, 168, 407]. Other studies, however, have reported a lack of significance of peritoneal cytology in predicting the probability of recurrence or death from endometrial adenocarcinoma [159, 432]. Positive peritoneal cytology has been associated with other risk factors for recurrence, such as high grade, deep myometrial invasion, or extrauterine spread [159, 168, 214]. One study, however, found that positive peritoneal cytology did not correlate with histologic subtype, FIGO grade, depth of myometrial invasion, or vascular invasion and was only significantly associated with stage III and IV disease [161]. Nonetheless, in a study of 567 patients with clinical stage I and II disease, a statistically significant difference in survival between patients with and without positive peritoneal cytology was found that persisted when the data were subjected to multivariate analysis [407]. Only 7% of patients with negative cytology recurred, while 32% of those with positive peritoneal cytology suffered a recurrence. Another study also found a threefold increase in the risk of death from tumor for a similar population using a multivariate analysis that adjusted for other risk factors [443]. In a review that included a total of 3,800 patients in 17 studies, in three of five studies in which multivariate analysis was performed, malignant cytology was associated with a significant, independent decrease in survival or an increase in the recurrence rate [268]. The weight of evidence supports the interpretation that the presence of malignant cells in peritoneal washings is a significant indicator of a worsened prognosis.

Vascular Invasion and Lymph Node Metastases

Venous or lymphatic invasion is defined by the presence of neoplastic cells within endothelial-lined channels. Although artifactual retraction of stroma around aggregates of neoplastic cells may simulate vascular invasion, vascular invasion can usually be reliably assessed in the myometrium peripheral to the bulk of the tumor mass. Occasionally, a subtle pattern of lymphatic space involvement by neoplasm may mimic intravascular histiocytes [265]. Also, the presence of perivascular lymphocytic infiltrates in the myometrium, but not lymphocytic infiltrate at the tumor-myometrial junction, is frequently associated with vascular invasion and hence is a useful marker of vascular invasion [10]. Vascular invasion is relatively uncommonly seen in endometrioid adenocarcinoma of the uterus (about 10-20% of cases) [291], but the frequency increases with deeper myometrial invasion, aggressive cell types, and decreasing histologic differentiation [3, 167, 375]. Nonetheless, some studies have revealed a significant correlation between vascular invasion and tumor recurrence independent of differentiation and depth of myometrial invasion. In one investigation of FIGO stage I endometrial adenocarcinomas, nine of 15 patients with lymphatic invasion died of tumor, while none of the 78 without identified vascular invasion died of cancer [138]. In a similar study of stage I cases, it was found that lymphatic invasion represented a strong predictor of tumor recurrence and extrapelvic metastasis, which was independent of depth of invasion or histologic differentiation [167].

In an analysis of stage I, grade 1 endometrioid adenocarcinomas with a poor outcome, vascular invasion in addition to myometrial invasion, mitotic index, and absence of progesterone receptor were significant factors that predicted aggressive behavior [403]. In another study aimed at comparing the significance of various pathologic risk factors in stage I endometrioid carcinoma, univariate analysis showed that vascular invasion was more important than grade and depth of myometrial invasion in predicting prognosis [21]. In a series of 513 consecutive cases of carcinoma limited to the uterus, multivariate analysis revealed lymphatic vascular invasion as the only predictor of distant recurrence [291]. Another study examined specimens with probable lymphatic invasion using immunoperoxidase with an antibody directed against factor VIII [240]. A greatly increased risk of recurrence was present in those with definite vascular invasion but not in those in whom the lining of the spaces failed to stain. Immunohistochemistry with antibody directed against CD31 increased the identification of vascular space invasion from 19% of cases (identified by H&E stains) to 50% of cases. Interestingly, recurrence was statistically related to the detection of vascular space invasion on H&E stained but not immunohistochemically stained sections [12]. Another study found that vascular invasion was a statistically significant indicator of death from tumor in early clinical stage tumors, but not for surgical stage I and II endometrial adenocarcinoma [443]. This finding suggests that lymphatic invasion may help to identify patients likely to have spread to lymph nodes or distant sites, but that its importance is diminished for those in whom thorough sampling of nodes has failed to identify metastases. Others have also found that vascular invasion was a significant prognosticator by univariate analysis but less important after adjusting for other variables [3]. Nevertheless, one study found that among women with lymph node metastases the presence or absence of vascular invasion in the primary tumor was associated with different survival rates [186].

About 10% of women with endometrioid endometrial adenocarcinoma have metastasis to pelvic lymph nodes [71]. Nearly a third of patients with pelvic lymph node spread also have positive paraaortic lymph nodes. Among the extrauterine risk factors, the presence of positive paraaortic lymph nodes is most important in predicting prognosis [277]. Only 36% of patients with positive paraaortic nodes were free of tumor at 5 years compared with 85% with negative paraaortic nodes. The highest correlation of positive paraaortic lymph nodes is with pelvic lymph nodes. Other features that correlate with positive aortic nodes are vascular invasion (19%), deep myometrial invasion (17%), positive peritoneal cytology (16%), cervical involvement (12%), and grade 3 tumors (8%). An increasing absolute number of lymph nodes containing metastatic carcinoma has also been associated with a decreasing survival [66]. Pelvic and paraaortic sentinel node identification has been attempted, successfully, in a pilot study, but it is currently not employed as a routine procedure for endometrial carcinoma [126].

Endometrial Hyperplasia and Metaplasia

Among nontumor risk factors, the presence of atypical endometrial hyperplasia and various metaplasias, especially ciliated cell and eosinophilic change, are important in identifying patients with a favorable prognosis. The presence of atypical hyperplasia and metaplasia correlates with low tumor grade and lack of myometrial invasion [38, 204]. In contrast, high-grade tumors are associated more often with an atrophic endometrium [74].

Ploidy

About two-thirds of endometrial adenocarcinomas are composed of cells that are diploid at the level of flow or static cytometry. This statement is qualified, as the sensitivity of the technique is limited and the addition or deletion of DNA equivalent to one average chromosome would not alter the assessment of a cell as diploid. Similar to many of the other prognostic factors, diploid tumors tend to be more frequently associated with less aggressive cell type, superficial invasion, and better histologic differentiation [51, 144, 193, 378, 389, 410]. Survival has generally been higher for women with diploid tumors [51, 193, 410]. One study of stage I patients demonstrated 94% progression-free survival for those with diploid tumors versus 64% for those with aneuploid cancers, but these results have not been universally reproducible [161, 162, 164, 167]. However, in more recent larger studies employing multivariate analysis, ploidy has almost always remained a strong predictor of outcome [165, 251, 293, 313, 315, 391, 404, 439]. Thus, DNA content can be considered a prognostic indicator of demonstrated utility for endometrial adenocarcinoma.

Steroid Receptors

The studies that have employed immunohistochemical methods to assess intranuclear receptor content in formalin-fixed paraffin-embedded tumor tissues have demonstrated that endometrioid carcinomas frequently express ER and PR whereas serous and clear cell carcinomas are usually negative [202, 236, 237, 328]. In most studies, the presence and quantity of steroid receptors have been correlated with histologic differentiation, FIGO stage, and survival [65, 102, 144, 145, 202, 260].

Several studies have reported variable results regarding the correlation of hormone receptor expression and prognosis. One study found that the presence of ER, but not PR, was predictive of survival [310]. Another study found that the presence of PR was a favorable prognosticator [403]. Yet another study found that both ER and PR were predictive of survival, but also strongly related to the clinical stage, histologic grade, and the absence of vascular invasion [144]. In contrast, another study reported that recurrence was related to the absence of ER or PR, and that response to progestin therapy was more common in PR-positive tumors, but noted that survival for patients with surgical stage I or II disease was not related to ER or PR [110]. Others have found that ER and PR were not independently predictive of lymph node metastasis [276]. However, PR persisted as a significant prognosticator of survival in two studies using multivariate analyses [134, 297]. Given the disparity in results and the relationship with other strong risk factors, hormone receptor expression is best considered a prognostic indicator of potential utility.

Our understanding of steroid receptor structure and function continues to grow, with the recognition of two isoforms for estrogen receptor (alpha and beta) and for progesterone receptor (A and B) [135], with various mRNA splice variants [88]. Each of the isoforms appears to induce different and sometimes opposing effects [49, 53, 64, 85, 149, 181, 194], and the expression of isoform specific antibodies is actively being investigated in endometrial cancer [29, 345].

BCL-2 and Markers of Apoptosis

BCL-2 is a proto-oncogene that inhibits programmed cell death, which is manifest morphologically as apoptosis. In the endometrium, BCL-2 expression assessed by immunohistochemistry varies during the menstrual cycle and is highly expressed in the proliferative phase, with downregulation during the secretory phase [153]. Given this cyclic regulation of endometrial growth, differentiation, and shedding, it is not surprising that during the past few years there has been significant interest in apoptosis-related events, with more than a dozen immunohistochemical studies of BCL-2 in abnormal endometrium. In general, the observations support the concept that BCL-2 protein expression persists at high levels in simple hyperplasia but progressively diminishes in atypical

hyperplasia and with decreasing differentiation in invasive endometrial adenocarcinoma [68, 72, 146, 173, 188, 290, 347, 397, 430]. Apoptotic cells and apoptotic bodies are also increased in poorly differentiated endometrioid carcinomas, clear cell carcinomas, and serous carcinomas compared with well-differentiated endometrioid adenocarcinomas [171, 172]. Loss of BCL-2 expression has also been associated with other features of poor prognosis including increasing depth of invasion, negative PR status, increasing FIGO stage, and aggressive cell types [146, 276, 341, 397, 447]. In two studies that used multivariate analysis to adjust for other prognostic factors, loss of BCL-2 expression was significantly related to the probability of lymph node metastasis or tumor recurrence [146, 347].

Markers of Proliferation

Various aspects of proliferation within tissues can now be assessed directly or indirectly by a multitude of modalities in tissue sections and cell suspensions. These methods include the determination of mitotic indices; S-phase fraction; proliferating cell nuclear antigen (PCNA); and Ki-67-, Ki-S5-, or MIB-1-positive cell populations by immunohistochemistry. Each assessment provides slightly different information about the number and type of cells in different parts of the cell cycle. Standardized methods for detection, enumeration, and determination of levels of significance do not exist for most of these parameters, however, and need to be established before the assays can be considered clinically useful.

Antibodies (Ki-67, Ki-S5, and MIB-1) directed against the DNA-binding nuclear protein, Ki-67 antigen, identify cells in most of G1 and all of S, G2, and M phases of the cell cycle, but not in the G₀, or quiescent, phase. In one study, MIB-1 staining correlated with grade and mitotic activity but did not predict short-term outcome [287]. Ki-S5 staining has been shown to be a significant predictor of survival by univariate but not multivariate analysis [45]. However, in a prospective study of 115 women with endometrial adenocarcinoma, immunohistochemical staining with Ki-67 was related to FIGO stage, cell type, histologic subtype, and probability of survival by univariate analysis; and, in addition, using multivariate analysis, only Ki-67 expression and stage remained as significant independent prognosticators [348]. Thus, Ki-67 could be considered a prognosticator of potential utility, but further corroboration is needed.

Proliferating cell nuclear antigen (PCNA) is a nuclear protein that is expressed in the late G_1 phase, peaks in the S phase, and persists in the G_2M phases of the cycle. A high PCNA index has failed to discriminate outcome in several

studies but has been predictive of decreased survival by univariate analysis in other studies, although not by multivariate analysis [141, 165, 207, 215].

Flow cytometry can be used to distinguish populations of cells in the S phase or G_2 and M phases of the cycle. The prognostic value of flow cytometry to identify endometrial cancers composed of increased percentages (either 10% or 20%) of cells in the S phase of the cell cycle also has been variable. One study demonstrated a nonsignificant trend toward decreased survival whereas others have shown either significance by univariate analysis alone or significance by multivariate analysis [205, 313, 316, 348].

Tumor Suppressor Genes and Oncogenes

As noted above in the section **Nolecular Genetics** of endometrial carcinoma, an inactivating mutation of the tumor suppressor gene *PTEN* is the most frequent genetic alteration observed in endometrioid adenocarcinoma [333, 395]. It is common in low-grade endometrioid carcinomas (about 50% of cases) but not in serous carcinoma, and consequently it is associated with a generally good survival. Immunohistochemical detection is highly dependent on the specific antibody employed, and it is currently not considered a prognosticator in endometrioid adenocarcinoma.

The p53 gene is also classified as a tumor suppressor gene, the product of which is a protein involved in the regulation of the cell cycle at the G1 checkpoint. Mutations of the p53 gene often result in a protein with a longer halflife that accumulates in the cell. Upregulation of wild type (i.e., nonmutated) p53 may occur after DNA damage and also result in overexpression detected by immunohistochemistry. Mutations or overexpression of p53 in endometrial carcinoma has been examined in more than two dozen studies. Overexpression of p53 protein has been generally related to higher FIGO stage, aggressive cell types (particularly serous carcinoma), increased histologic grade, and depth of myometrial invasion [16, 87, 147, 165, 197, 215, 217, 222, 236, 251, 286, 293, 396, 397, 430]. There is a surprisingly high degree of concordance in the observation that p53 overaccumulation is associated with a decreased probability of survival by univariate analysis, and this is true even by multivariate analysis in at least eight studies [34, 147, 165, 190, 192, 197, 217, 221, 222, 251, 285, 286, 316, 430]. These results support the classification of p53 expression as a prognostic indicator of proven utility.

HER-2/neu is a proto-oncogene, the product of which is a transmembrane growth factor receptor, p185erb-2,

which shares some homology with the epidermal growth factor receptor. It is normally expressed at low levels in the cycling endometrium. Gene amplification or overexpression occurs in about 20-40% of endometrial carcinomas. Overexpression of HER-2/neu protein has been associated with advanced stage, decreased differentiation, aggressive cell types, particularly including clear cell type, and increased depth of myometrial invasion [40, 215, 329, 334]. Reports of its utility as a predictor of survival have been mixed, with no apparent association of overexpression to outcome identified in several studies, but a statistically significant relationship was shown in most others [35, 165, 177, 251, 282, 285, 286, 316, 329, 334, 343]. In several investigations, the significance of HER-2/neu amplification or overexpression as a prognosticator has remained after adjusting for other known risk factors [165, 282, 334]. At present, HER-2/neu overexpression is a prognostic factor of potential utility.

The activation of *RAS* proto-oncogenes through either point mutations or gene amplification has been identified in various malignant tumors. Mutations in codon 12 of *KRAS* appear to occur in only 10–15% of endometrial carcinomas, and in most studies they have not been related to stage, grade, depth of invasion, or survival, although one study found mutations predictive of recurrence and death by univariate analysis [56, 117, 191, 197, 359]. *KRAS* mutations currently represent a prognostic marker of unlikely utility.

Low-level ribosomal DNA (rDNA) methylation has been associated with a diminished disease-free survival in women with early-stage endometrial carcinoma [324].

Angiogenesis and Vascular Endothelial Growth Factor

Angiogenesis in the form of proliferation of new capillaries from preexisting vessels is necessary to permit tumor growth. This neovascularization potentially could result from stimulation by a variety of factors released from neoplastic cells, host cells responding to the neoplasm, or supporting matrix. In the endometrium, it appears that stromal vascularity is greater in the secretory phase than proliferative phase, but it is greater in the stroma of carcinoma than in cycling endometrium [275]. This difference may reflect stimulation by vascular endothelial growth factor (VEGF) RNA and its protein product, which have been found in high concentration in neoplastic cells but not in benign atrophic endometrial glandular cells [162]. Although tumor vascularity has been associated with increased stage, decreased differentiation, and lymphatic invasion, high microvessel counts have been a statistically significant predictor of decreased survival independent of other common risk factors in several, but not all, studies [203, 300, 302, 416]. Microvessel density thus represents a prognostic marker of potential utility.

Models for Predicting Prognosis

Recent studies reveal that the behavior of a tumor is based on a complex interaction of a number of different factors. Accordingly, models have been developed that assess several factors and permit more accurate prognostication than simply considering one factor alone. For example, by multivariate analysis, the depth of invasion and presence of vascular invasion-associated changes were found to provide a highly reliable model for predicting outcome (see **7** *Table 9.7*) [21]. The model was better able to define patients who were at low and high risk of recurrence as compared with the traditional risk factors using grade and depth of invasion. Inclusion of ploidy in the model permitted even better discrimination of high- and low-risk patients. In a subset of pathologic stage I endometrioid carcinoma in whom ploidy analysis was performed, multivariate analysis showed that only the depth of invasion, DNA ploidy, and vascular invasion-associated changes were significant risk factors [22]. A statistical model based on these features permitted stratification of patients into four risk groups with 93%, 67%, 38%, and 10% survival, respectively (> Table 9.8).

In an analysis of 819 women with clinical stage I and occult stage II adenocarcinoma of the endometrium entered on a GOG protocol, multivariate analysis demonstrated that age, cell type, architectural grade, depth of myometrial invasion, vascular space involvement, and peritoneal cytology

Table 9.7

Statistical model of survival predicted by myometrial invasion and vascular invasion-associated changes (Reprinted with permission from Ambros RA and Kurman RJ [10])

		Survival	
Score	No. of cases	No.	%
1	20	19	95
1–2	45	39	87
2–2.6	17	12	70
2.6	20	7	35

Table 9.8

Statistical model of survival predicted by depth of myometrial invasion, vascular invasion-associated changes, and tumor ploidy (Reprinted with permission from Ambros RA and Kurman RJ [9])

		Survival	
Score	No. of cases	No.	%
<2.2	27	25	93
2.2–2.3	12	8	67
2.4-4.0	8	3	38
>4	10	1	10

were independent risk factors for recurrence and death from tumor [443]. From these data it appears possible to create a model for assignment of the relative risk of death from tumor for individual patients based solely on information gathered by pathologic examination of the hysterectomy specimen. For example, a woman with grade 1 endometrioid carcinoma, with tumor confined to the endometrium and no vascular invasion, is arbitrarily assigned a risk of 1. Relative to this baseline risk, a woman with a grade 2 endometrioid carcinoma that invades superficial myometrium and lacks vascular space involvement has a relative risk of 2.6. Similarly, a woman with a grade 3 endometrioid carcinoma, with middle-third myometrial invasion, and positive vascular space involvement, has a relative risk of 10. The probability of disease-free survival at 5 years for these three women would be approximately 95%, 90%, and 65%, respectively. Knowledge of the specific risk for each patient would allow better prognostication and, potentially, individually tailored therapy.

Miscellaneous Epithelial Tumors

A number of rare examples of unusual neoplasms arising in the endometrium have been reported, but the data consist largely of case reports precluding a detailed clinicopathologic analysis. Some of these are discussed next.

Squamous Cell Carcinoma

Squamous carcinoma develops in the endometrium, but it is extremely rare. In a population-based study from Norway the prevalence was 0.1% [6]. To qualify as primary squamous carcinoma of the endometrium, three criteria must be met: (1) adenocarcinoma is not present in the endometrium, (2) the squamous carcinoma in the endometrium does not have any connection with the squamous epithelium of the cervix, and (3) squamous carcinoma is not present in the cervix. By these criteria, only 56 cases of primary squamous carcinoma of the endometrium have been reported [154]. The mean age of patients is 67 years. There is a strong association with cervical stenosis, pyometra, chronic inflammation, and nulliparity. The tumor may arise from ichthyosis uteri, a condition in which the endometrium is replaced by keratinized squamous epithelium. In the past, this condition was considered a sequela of the use of steam as treatment for endometritis. With the abandonment of this procedure, ichthyosis uteri have become quite rare.

Microscopically, squamous carcinomas of the endometrium resemble those in the cervix; however, at times they can be extremely well-differentiated and therefore difficult to diagnose with certainty in curettings. Sometimes the diagnosis is not established until a hysterectomy is performed.

In addition to typical squamous cell carcinoma, verrucous carcinoma may arise as a primary tumor in the endometrium (> *Fig.* 9.55) [340]. The prognosis of squamous cell carcinoma is related to stage at diagnosis. In a review of the reported cases, 80% of stage I patients survived whereas survival for patients with stage III disease was only 20% [154].

Glassy Cell Carcinoma

Glassy cell carcinoma is regarded as a variant of a mixed adenosquamous carcinoma and rarely occurs in the endometrium [28, 76]. First described in the cervix, glassy cell carcinoma is a poorly differentiated neoplasm with little or no glandular or squamous differentiation and is composed of masses and nests of characteristic polygonal cells separated by a fibrous stroma that often contains an abundance of inflammatory cells. The cells have well-defined borders and granular eosinophilic or amphophilic cytoplasm, giving a ground glass appearance. The nuclei are enlarged and round, with centrally placed, prominent, eosinophilic nucleoli. Mitotic activity, including the presence of abnormal mitotic figures, is high. The behavior, based on a small series of cases, is highly aggressive.

Yolk Sac Tumor

Four cases of primary yolk sac tumor of the endometrium have been reported [200]. Three of the patients have been

in their 20s, and one was 42 years of age. Light microscopic, immunohistochemical, and ultrastructural studies have shown features similar to yolk sac tumor of the ovary. AFP is elevated in the serum preoperatively and is localized within the cytoplasm of tumor cells. It is thought that these tumors arise in the uterus as a result of aberrant migration of primordial germ cells. All four patients were treated with hysterectomy followed by adjuvant multiagent chemotherapy. Two patients are long-term survivors, and two died of disease.

Giant Cell Carcinoma

Rare primary endometrial carcinomas may contain multinucleated giant cells resembling giant cell carcinomas in other sites such as the lung, thyroid, pancreas, and gallbladder. In a report of six cases, the giant cells accounted for a substantial part of the tumor [196]. The remainder of the neoplasm contained undifferentiated carcinoma and areas of more differentiated endometrioid carcinoma. Immunohistochemical studies demonstrated positive immunoreactivity for cytokeratin and epithelial membrane antigen in the giant cell component. Vimentin, desmin, and smooth muscle actin were negative. Four of the six patients in whom the tumor invaded more than superficially developed recurrent tumor, and three patients died of disease within 3 years. Tumors with cells resembling osteoclast-like giant cells also have been observed in the endometrium.

Choriocarcinoma

Rarely, primary choriocarcinoma of the endometrium may develop in a postmenopausal woman, representing a form of differentiation of a carcinoma derived from somatic cells rather than germ cells or trophoblasts. Six patients ranging in age from 48 to 78 years have been reported [206, 311, 350, 406]. Most patients had elevated serum human chorionic gonadotropin (hCG) levels and/or hCG detected in the syncytiotrophoblastic element in the tumor. A case of choriocarcinoma associated with a carcinosarcoma (malignant mesodermal mixed tumor) has been reported, and we have observed one such case as well [216]. These tumors appear to behave in an aggressive fashion.

Transitional Cell Carcinoma

Ten cases of transitional cell carcinoma of the endometrium have been reported [248, 385]. Patients have ranged in age from 41 to 83 years, with a mean of 62. The tumors are typically polypoid and present with uterine bleeding. Transitional cell carcinomas often are papillary and resemble transitional cell carcinomas of other organs. They are invariably admixed with other patterns of endometrial carcinoma, including endometrioid, squamous, and serous components. The overall prognosis does not appear to be worse than expected for the stage of disease, but the transitional cell component seems to be the more aggressive subtype among the patterns with which it is admixed [248].

Other Rare Variants

Other rare types of carcinomas of the endometrium that have been reported include an oxyphilic variant of endometrioid carcinoma, a primary signet-ring cell carcinoma, and an alpha-fetoprotein-secreting hepatoid adenocarcinoma associated with endometrioid carcinoma [184, 274, 317]. In addition, an endometrioid carcinoma associated with Ewing sarcoma/peripheral primitive neuroectodermal tumor has been reported [374].

Tumors Metastatic to the Endometrium

Ovarian Carcinoma

Simultaneous cancers involving the endometrium and the ovary may represent (1) metastasis from the endometrium to the ovary, (2) metastasis from the ovary to the endometrium, or (3) independent primary tumors. The distinction is important because the prognosis and treatment differ. It has been suggested that when the endometrial carcinoma is small and minimally invasive, the two neoplasms should be considered independent. One study found that if the two carcinomas have an endometrioid pattern, the prognosis is good, and therefore the two neoplasms probably are independent [111]. When serous or clear cell carcinoma is found, the prognosis is poor and a primary tumor with metastasis is likely. The primary neoplasm is identified by its larger size or more advanced stage.

Another study proposed that tumors be classified as primary in the endometrium with metastasis to the ovaries when there is multinodular ovarian involvement or at least two of the following criteria are met: (1) small (5 cm) ovaries, (2) bilateral ovarian involvement, (3) deep myometrial invasion, (4) vascular invasion, or (5) fallopian tube involvement [408]. When these criteria are used, there is a significant difference in the frequency of distant metastasis in the group classified as metastatic versus the group classified as an independent primary. Metastasis from the endometrium to the ovary occurs more often than the reverse. About a third of the cases are independent tumors involving both sites simultaneously. Independent tumors display either welldifferentiated endometrioid or nonendometrioid patterns, whereas grade 3 endometrioid carcinoma and MMMTs generally are primary in one organ and metastatic to the other when detected.

Carcinomas from Extragenital Sites

When an extragenital tumor metastasizes to the uterus, it usually is a manifestation of obvious dissemination. The diagnosis in curettings may, on rare occasion, be the first clue of an occult primary tumor. The mean age of patients is 60 years. Metastatic breast cancer is the most frequent extragenital tumor that metastasizes to the uterus (47%) (\bigcirc *Fig.* 9.62), followed by stomach (29%), cutaneous melanoma (5%), lung (4%), colon (3%), pancreas (3%), and kidney (3%) [228]. Metastatic neoplasms to the endometrium frequently infiltrate the endometrium diffusely, sparing the glands. Most neoplasms metastatic to the endometrium are poorly differentiated and lack squamous differentiation, unlike primary endometrial carcinoma. The myometrium can contain metastatic nodules as well.

Fig. 9.62

Metastatic breast carcinoma. Monotonous cells with uniform nuclei and pale eosinophilic cytoplasm replacing the stroma and surrounding residual inactive endometrial glands are consistent with metastatic lobular breast carcinoma

This chapter deals with neoplasms of the uterus in which there is mesenchymal differentiation. Purely mesenchymal tumors, such as those derived from smooth muscle and endometrial stroma, are considered, as are some benign and malignant neoplasms in which there are mixtures of epithelium and connective tissues. We use a slightly modified version of the comprehensive classification of mesenchymal neoplasms of the uterus, developed by the World Health Organization (WHO; [409]) which is shown in **?** *Table 10.1*.

Proper pathologic study of a mesenchymal tumor of the uterus is predicated on careful gross examination and adequate sectioning. The tumor should be examined thoroughly, and one block of tissue should be taken for each centimeter of tumor diameter, except from grossly typical leiomyomas; even the latter may have to be examined extensively if the microscopic appearance is unusual. Three major goals of the pathologic examination of potentially malignant mesenchymal tumors are to determine the type of tumor margin (expansile or infiltrating), to evaluate the depth of myometrial invasion, and to determine whether the tumor involves the serosa or extends beyond the uterus. Tissue samples should be taken with these requirements in mind.

Leiomyomas are common uterine tumors, but other types of benign and malignant mesenchymal tumors are uncommon. Malignant mesenchymal tumors comprise less than 3% of uterine malignancies. The tumor stage is the single most important prognostic factor. In the past, uterine sarcomas were staged using a staging system developed for endometrial carcinoma. This has not proven entirely satisfactory, and a new staging system has been developed for uterine sarcomas (Table 10.2; [131]). The new staging system has two compartments, one for leiomyosarcoma and one for endometrial stromal sarcoma (ESS) and adenosarcoma. Carcinosarcoma, or malignant mixed Müllerian tumor (MMMT), which is discussed in O Chap. 9, Endometrial Carcinoma, is a mixed epithelial-mesenchymal neoplasm in which both elements are malignant; it has much in common with endometrial carcinoma and is staged using the endometrial carcinoma staging system. The staging system for uterine tumors is a surgicalpathologic one, so pathologists must be familiar with the criteria for staging and make certain to provide all information necessary for staging in their surgical pathology reports. We complete a synoptic comment for every case that includes all information necessary for staging as well as the actual stage.

Smooth Muscle Tumors

Smooth muscle neoplasms of the uterus are extremely common, and most are leiomyomas. These tumors may

Table 10.2

Staging for uterine sarcomas (leiomyosarcomas, endometrial stromal sarcomas, adenosarcomas, and carcinosarcomas)

(1) Leiomyosarcoma			
Stage	Definition		
1	Tumor limited to uterus		
IA	<5 cm		
IB	>5 cm		
11	Tumor extends to the pelvis		
IIA	Adnexal involvement		
IIB	Tumor extends to extrauterine pelvic tissue		
III	Tumor invades abdominal tissues (not just		
	protruding into the abdomen)		
IIIA	One site		
IIIB	>One site		
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes		
IV			
IVA	Tumor invades bladder and/or rectum		
IVB	Distant metastasis		
(2) Endometrial stromal sarcomas (ESS) and			
adenosa	rcomaª		
Stage	Definition		
1	Tumor limited to uterus		
IA	Tumor limited to endometrium/endocervix with		
	no myometrial invasion		
IB	Less than or equal to half myometrial invasion		
IC	More than half myometrial invasion		
П	Tumor extends to the pelvis		
IIA	Adnexal involvement		
IIB	Tumor extends to extrauterine pelvic tissue		
III	Tumor invades abdominal tissues (not just		
	protruding into the abdomen)		
IIIA	One site		
IIIB	>One site		
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes		
IV			
IVA	Tumor invades bladder and/or rectum		
IVB	Distant metastasis		
(3) Carcinosarcomas			
Carcinosarcomas should be staged as carcinomas of the			
endometrium			

^aSimultaneous tumors of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors.

be incidental in uteri removed for other reasons, but they are also frequently responsible for a variety of common gynecologic and obstetric difficulties. Histologically, all but a small minority of leiomyomas is easily identified as having a smooth muscle phenotype and being benign. A small percentage of uterine smooth muscle neoplasms are leiomyosarcomas, which, using modern diagnostic criteria, are highly malignant neoplasms. Most leiomyosarcomas are easily recognized both as showing smooth muscle differentiation and as malignant. A small number of uterine smooth muscle proliferations pose difficult diagnostic challenges for a variety of reasons involving either problems of phenotype or anticipated clinical behavior (benign or malignant or something in between).

Our discussion of smooth muscle neoplasms first presents a general approach to the evaluation of uterine smooth muscle neoplasms, detailing the individual features that need to be assessed: the type of differentiation, the degree of cellularity, the mitotic index, the presence and degree of cytologic atypia, and the presence of necrosis and its pattern. Second, we gather the facts of epidemiology, pathology, molecular biology, cytogenetics, natural history, and treatment around a discussion of each of the named smooth muscle entities.

Evaluation of Smooth Muscle Neoplasms

The most effective way of distinguishing clinically benign from clinically malignant uterine smooth muscle neoplasms is through the use of multivariate criteria; that is, criteria that involve considering several microscopic features as an ensemble [32, 254]. These features include differentiated cell type within the smooth muscle group, the presence and type of tumor necrosis, the degree of cytologic atypia, the mitotic index, and the relationship of the process to surrounding normal structures, including extrauterine sites.

Differentiated Cell Type

The term usual smooth muscle differentiation denotes a pattern of differentiation recapitulating that of the constituent cells of the normal myometrium. Usual smooth muscle cells are elongated, possess distinct cell membranes, and have readily apparent eosinophilic, sometimes fibrillar cytoplasm. These cells grow in a fascicular arrangement.

Epithelioid smooth muscle cells are round or polygonal and have eosinophilic to colorless cytoplasm. They may have perinuclear cytoplasmic vacuoles or there may be a perinuclear rim of eosinophilic cytoplasm, although the rest of the cytoplasm is clear. When the cytoplasm is completely clear, the label "clear cell" is used. It is useful to do HMB45 stains when epithelioid tumors are encountered in the myometrium since some of these may fall into the category of PEComa (see section **PEComa**). Other considerations include metastatic (or locally invasive) carcinoma (cytokeratin positivity) and metastatic melanoma (S-100 positive). Some endometrial stromal neoplasms may have an epithelioid appearance. Recently, the use of histone deacetylase 8 (HDAC8) has been advocated as a specific marker for smooth muscle in this setting [100].

Myxoid smooth muscle proliferations feature widely spaced stellate cells with inapparent cytoplasm embedded in a myxoid matrix. Malignant myxoid smooth muscle neoplasms exhibit varying degrees of cytologic atypia and often have an appearance reminiscent of myxofibrosarcoma (myxoid malignant fibrous histiocytoma or myxofibrosarcoma) of the soft tissues.

Less common types of differentiation, such as fat and skeletal muscle, are discussed later (see **2** Leiomyomas with Other Elements).

Fig. 10.1

Coagulative tumor cell necrosis. Viable cells are present only around the blood vessel. Ghostlike outlines of necrotic atypical tumor cells can still be discerned in the surrounding tissue

Patterns of Necrosis

The presence or absence and type of necrosis are powerful predictors of clinical behavior [32]. Two patterns of necrosis in uterine smooth muscle tumors are diagnostically important: coagulative tumor cell necrosis and hyalinizing (or "infarction-type") necrosis [32].

In coagulative tumor cell necrosis, there is an abrupt transition between necrotic and preserved cells (> Fig. 10.1). The hematoxyphilia of the nuclei is often retained in the necrotic cells, and usually there is no associated inflammation. The characteristic low-power microscopic pattern is one of blood vessels cuffed by viable cells surrounded by a sea of necrotic tumor [32, 69]. Coagulative tumor cell necrosis is commonly present in clinically malignant smooth muscle neoplasms. In contrast, hyalinizing necrosis has a distinctly zonal pattern with central necrosis, a more peripheral zone of granulation tissue, and, at the periphery, a variable amount of hyaline eosinophilic collagen interposed between the central degenerated region and peripheral preserved smooth muscle cells (> Fig. 10.2). This pattern is highly reminiscent of an infarction at various stages of evolution. When shadow cells or nuclei are discernible in the necrosis, there is little hyperchromasia or nuclear pleomorphism. Acute infarction produces a necrosis pattern indistinguishable from coagulative tumor cell necrosis; that is, the juxtaposition of preserved tumor adjacent to necrotic tumor. Strategies useful in distinguishing acute ischemic necrosis

Fig. 10.2

Bland necrosis. An area of bland necrosis (N) is separated from viable spindle-shaped tumor cells (V) by a zone of hyalinized collagen (H)

from diagnostically useful tumor cell necrosis involve noting (1) the presence or absence of hyperchromasia and nuclear pleomorphism in the "shadow cells" of the necrotic tumor; and (2) (in the absence of these nuclear features) discerning a pattern of ongoing ischemia elsewhere in the problematic smooth muscle neoplasm. Trichrome preparations are useful in detecting patchy foci of healed ischemic damage of all stages beyond the acute phase of ischemia; the trichrome stain highlights a band of collagen between zones of necrotic and viable tumor. P16 immunostaining has been recommended for distinguishing between leiomyosarcoma and leiomyoma when the pattern of necrosis is ambiguous [23, 60].

Another pattern of necrosis that may be seen in ulcerated submucous leiomyomas features ulceration, acute inflammatory cells, and an associated zonal reparative process.

Cytologic Atypia

Several studies have demonstrated a relationship between cytologic atypia and clinical behavior in uterine smooth muscle neoplasms [32]. The problem, as always, is defining "significant atypia" in a way that is reproducible and can be communicated to others. Bell et al. found that a two-tiered scheme of absent to mild atypia and moderate to severe atypia is reasonably reproducible [32]. They defined moderate to severe atypia as follows: nuclear hyperchromatism and pleomorphism that is obvious at scanning power (> Fig. 10.3). Enlarged and sometimes abnormal mitotic figures (MF) are a frequent finding. Most commonly, moderate to severe atypia is diffusely present throughout the neoplasm, but it can, occasionally, be present only focally. In contrast, absent or mild atypia features uniform cells with no more than mild nuclear pleomorphism () Fig. 10.4). The chromatin of the constituent cells is typically fine to granular. The nuclei may be enlarged in comparison to those of the cells comprising the surrounding myometrium, but the enlargement is uniform throughout the tumor. More than one or two enlarged abnormal MF place the tumor in the moderate to severe atypia group. The pattern of atypia described

above is analogous to that found in malignant fibrous histiocytomas of the soft tissue (also known as pleomorphic undifferentiated sarcoma). A more difficult type of diffuse severe atypia to recognize features uniformly enlarged, hyperchromatic cells (\bigcirc *Fig. 10.5*); this pattern is analogous to that seen, for example, in monophasic synovial sarcoma of the soft tissues. Recognition of this pattern involves a comparison of the constituent cells of the tumor to the surrounding normal myocytes and appreciating the nucleomegaly and hyperchromasia of the neoplastic cells relative to the surrounding normal myocytes. A helpful feature in diagnosing the uncommon neoplasms with this type of uniform severe atypia is the associated finding of diffuse, massive infiltration of the

Fig. 10.4 Diffuse mild atypia. Uniform mild atypia characterizes this infiltrating smooth muscle neoplasm

Fig. 10.3 Severe pleomorphic atypia. Nuclear pleomorphism against a background of diffuse severe atypia of spindled cells

Fig. 10.5

Severe uniform atypia. Relatively uniform malignant cells exhibiting nuclear hyperchromasia and a high mitotic index

surrounding myometrium that leaves islands of normal myometrium in its wake.

Mitotic Index

The mitotic index is expressed in terms of the number of definite MF per 10 high-power fields (HPF; [180, 418]).

Compulsive mitosis counting, fortunately, is not always necessary; the required level of compulsiveness depends on associated features such as whether there is significant cytological atypia or whether there is tumor cell necrosis. In the absence of these two features, the precise mitotic index is of little managerial importance below 20 MF/10 HPF. The mitotic index is determined by first finding the area with the highest density of MF and then counting them in that area. The slide is searched at low magnification for the most mitotically active area. Then, mitotic counts are performed at high magnification in four sets of ten randomly chosen contiguous fields. The mitotic index is expressed as the average number of MF per 10 HPF. Care must be taken not to count lymphocytes, karyorrhectic debris, precipitated hematoxylin, or mast cells as MF. Most reliable are MF in metaphase, anaphase, or telophase. A critical review of mitotic counting has been presented [312]. Often the issue is not the statistical strategy used to count MF, but what exactly should be regarded as an MF.

Relationship to Surrounding Normal Structures and the Anatomic Distribution of the Process

It is important to note the relationship of the smooth muscle neoplasm to the surrounding myometrium and uterine vessels and to determine whether there is any extrauterine extension. Infiltrative margins, intravascular growth, and extrauterine spread, although commonly encountered in uterine malignancies, are not, when seen as isolated findings, diagnostic of sarcoma. It is important to be aware of some relatively rare smooth muscle proliferations that are either benign or clinically low-grade processes that mimic leiomyosarcoma by virtue of their relationship to normal uterine structures or their extrauterine extension.

Leiomyoma

Leiomyomas are the most common uterine neoplasms [330, 427]. They are noted clinically in 20–30% of

women over 30 years of age, and are found in as many as 75% of uteri when a systematic search is conducted [86, 96, 330]. Most leiomyomas are detected in middleaged women. They are uncommon in women less than 30 years of age; however, the youngest patient on record was 13 years old. Some leiomyomas apparently shrink after the menopause, but their frequency does not decrease. Leiomyomas are more common in African-American women than in white women [217].

The growth of leiomyomas is affected by the hormonal milieu [16, 261, 345, 391]. Leiomyomas contain estrogen and progesterone receptors, which can be demonstrated biochemically and immunohistochemically [426]. Leiomyomas may increase in size during estrogen therapy, and most decrease in size when the patient is treated with a gonadotropin-releasing hormone (GnRH) agonist [4, 349, 377, 396, 417]. Progestins, progesterone, hormone replacement therapy, clomiphene use, and pregnancy occasionally are associated with a rapid increase in the size of leiomyomas and sometimes produce hemorrhagic degeneration [376].

Clinical Features

The clinical presentation of leiomyomas depends on their size and location [51]. Leiomyomas cause many signs and symptoms, the most common of which are pain, a sensation of pressure, and abnormal uterine bleeding. Even small leiomyomas, when submucosal, can cause bleeding due to compression of the overlying endometrium and compromise of its vascular supply. In some instances, infertility is attributed to the presence of leiomyomas. Large tumors can be detected during pelvic examination because they produce uterine enlargement or an irregular uterine contour. Some leiomyomas are pedunculated and protrude through the cervical os. On rare occasions, subserosal pedunculated leiomyomas undergo torsion, infarction, and separation from the uterus. Secondary infection of leiomyomas can result in fever, leukocytosis, and an elevated sedimentation rate. Among the complications of pregnancy ascribed to leiomyomas are spontaneous abortion, premature rupture of membranes, dystocia, inversion of the uterus, and postpartum hemorrhage.

Gross Findings

Despite the variety of histologic subtypes of leiomyoma, all are grossly similar. Multiple leiomyomas are present

in two thirds of women with these neoplasms [86]. Leiomyomas are spherical and firm; they bulge above the surrounding myometrium from which they are easily shelled out. The cut surfaces are white to tan, with a whorled trabecular pattern (> Fig. 10.6). Leiomyomas can be located anywhere in the myometrium. Submucosal leiomyomas compress the overlying endometrium. As they enlarge, they bulge into the endometrial cavity. Rare examples become pedunculated and prolapse through the cervix. Intramural leiomyomas are the most common. Subserosal leiomyomas can become pedunculated and, if there is torsion and necrosis of the pedicle, the leiomyoma can lose its connection with the uterus. Very rarely, some become attached to another pelvic structure (parasitic leiomyoma). The appearance of a leiomyoma is commonly altered by degenerative changes. Submucosal leiomyomas are frequently ulcerated and hemorrhagic. Hemorrhage and necrosis can be observed in leiomyomas, particularly if they are large or occur in women who are pregnant or undergoing high-dose progestin therapy. Dark red areas represent hemorrhage, and sharply demarcated yellow areas reflect necrosis. The damaged smooth muscle is replaced eventually by firm white or translucent

Fig. 10.6

Enlarged uterus containing multiple leiomyomas. The leiomyomas have a whorled white-tan cut surface that bulges above the surrounding myometrium collagenous tissue. Cystic degeneration also occurs, and some leiomyomas become extensively calcified. The imaging features of leiomyomas have been extensively studied [112, 425].

Microscopic Findings

Typical leiomyomas are composed of whorled, anastomosing fascicles of uniform fusiform smooth muscle cells. The spindle-shaped cells have indistinct borders and abundant fibrillar eosinophilic cytoplasm (> Fig. 10.7). Nuclei are elongated with blunt or tapered ends, and have finely dispersed chromatin and small nucleoli. MF usually are infrequent. Most leiomyomas are more cellular than the surrounding myometrium; those that are not are identified by their nodular circumscription and by the disorderly arrangement of the smooth muscle fascicles within them, which are out of alignment with the surrounding myometrium. Degenerative changes are common in leiomyomas. Hyaline fibrosis is present in more than 60%, particularly in postmenopausal women [85]. Edema is present in about 50% of leiomyomas and, on occasion, marked hydropic change can mimic the appearance of a myxoid smooth muscle tumor or produce a pattern that can be confused with intravenous leiomyomatosis (IVL) [78, 79]. There are significant areas of hemorrhage, which tend to be zonal and sharply demarcated in

Fig. 10.7

Leiomyoma. The spindle-shaped tumor cells have cytologically bland relatively uniform nuclei with fine chromatin and small nucleoli. The cytoplasm is abundant, eosinophilic, and fibrillar about 10% of leiomyomas, and cystic degeneration and microcalcification each occur in about 4%. Hemorrhage, edema, myxoid change, hypercellular foci, and cellular hypertrophy occur in leiomyomas in women who are pregnant or taking progestins (see section **>** Hemorrhagic Cellular Leiomyoma and Hormone-Induced Changes). Progestational agents are associated with a slight increase in mitotic activity, but not to the level observed in a leiomyosarcoma.

The margins of most leiomyomas are microscopically circumscribed, but some benign tumors interdigitate with the surrounding myometrium, occasionally extensively (see section **Dissecting Leiomyoma**). Submucous leiomyomas, particularly if they protrude into the endometrial cavity, may display extensive necrosis, often with acute inflammatory cells. Not infrequently, there is increased mitotic activity in the tumor cells near areas of necrosis. On the other hand, the coagulative tumor cell necrosis common in leiomyosarcoma is not often associated with acute inflammation. In addition, the outlines of cells are prominent in the latter whereas they are inconspicuous or absent in submucous necrosis. Also, the MF seen in conjunction with inflammatory necrosis have normal morphology.

Immunohistochemistry

Smooth muscle cells in the myometrium and within smooth muscle tumors react with antibodies to musclespecific actin, alpha-smooth muscle actin, desmin, and caldesmon [120]. There is immunoreactivity with vimentin, but the intensity of staining and the proportion of cells that stain are less than with the muscle-specific antibodies. Cytokeratin immunoreactivity is frequently observed in the myometrium and in smooth muscle tumors, the extent and intensity of reactivity depending on the antibodies used and the fixation of the specimen [49, 120, 163]. Epithelial membrane antigen (EMA) is usually negative in smooth muscle tumors.

Cytogenetics

Nonrandom inactivation of the X chromosome, demonstrated by glucose-6-phosphate dehydrogenase isoform expression and other techniques, indicates that leiomyomas are a proliferation of a single clone of smooth muscle cells. Each one of the multiple leiomyomas in a particular uterus appears to be a distinct clone [173, 253, 267, 342]. Cytogenetic studies provide further evidence of the clonal nature of the smooth muscle cell proliferation in many leiomyomas [342].

A large literature has appeared in recent years concerning the cytogenetic abnormalities in leiomyomas. Approximately 40% of uterine leiomyomas have chromosomal abnormalities detectable by conventional cytogenetic analysis, including t(12;14)(q15;q23-24), rearrangements involving the short arm of chromosome 6, and interstitial deletions of the long arm of chromosome 7 [253, 342, 389]. This growing body of literature may in time shed some light on the development of this extremely common neoplasm but to date has little diagnostic relevance. Of more general interest is the observation that the ordinary leiomyoma is almost certainly more than one neoplasm; in other words, the conventional light microscopic leiomyoma phenotype can be realized in a multitude of genotypic ways.

Clinical Behavior and Treatment

Most leiomyomas are asymptomatic, and only a minority requires treatment. Therapy is indicated only if leiomyomas are symptomatic, interfere with fertility, enlarge rapidly, or pose diagnostic problems [51, 325, 431]. Sometimes they can be excised (myomectomy), but if they are large or multiple, a hysterectomy may be required. Treatment with leuprolide acetate or another gonadotropinreleasing hormone agonist (GnRHa) results in shrinkage of leiomyomas, a decrease in uterine volume, and alleviation of the patient's symptoms [261, 345, 377]. The maximum effect is noted after 8 to 12 weeks. The leiomyomas increase in size again with cessation of the GnRH agonist therapy. Such therapy can be used before surgery to decrease uterine size (facilitating myomectomy or permitting treatment by vaginal rather than abdominal hysterectomy) and to reduce the risk of hemorrhage during surgery. Gonadotropin-releasing hormone antagonists may become available for this type of treatment in the future. Evidence suggests that they are effective and act rapidly without causing an initial flare in steroid levels, as is caused by GNRHa [134]. Finally, leiomyomas can be treated by uterine artery embolization, which leads to ischemia and involution of the leiomyomas [263, 385, 392]. This method of treatment is of potential interest to pathologists, because (1) if a hysterectomy is subsequently necessary there may be areas of ischemic necrosis in a leiomyoma that must be differentiated from the type of tumor cell necrosis seen in leiomyosarcoma, and (2) the embolic particles can be seen in microscopic sections and may cause confusion, unless the pathologist

knows what they are [113, 274, 434].

Specific Subtypes of Leiomyoma

Most subtypes of leiomyoma are chiefly of interest in that they mimic malignancy in one or more respects. These subtypes are mitotically active leiomyoma, cellular leiomyoma, hemorrhagic cellular leiomyoma, leiomyoma with bizarre nuclei, epithelioid leiomyoma, and myxoid leiomyoma. Other leiomyoma variants – vascular leiomyoma, leiomyoma with other elements, and leiomyomas with hematopoietic elements are more curiosities than diagnostic problems.

Mitotically Active Leiomyoma

Occasionally, a typical-appearing leiomyoma in a premenopausal woman will have ≥5 MF/10 HPF (\triangleright Figs. 10.8a, b); these are designated as mitotically active leiomyomas [32, 105, 311, 333, 341]. The number is usually 5-9 MF/10 HPF, but occasional mitotically active leiomyomas with 10-20 MF/10 HPF have been reported. The clinical evolution is benign, even if the neoplasm is treated by myomectomy. It is imperative that this diagnosis not be used for neoplasms that exhibit moderate to severe nuclear atypia, for those that contain abnormal MF, or for those that demonstrate zones of tumor cell necrosis. Leiomyomas removed during the secretory phase of the menstrual cycle have a significantly increased mitotic index compared to those removed during menses or during the proliferative phase [211]. Also, leiomyomas removed from women who are taking progestins have a higher mitotic rate than that observed in women who are taking a combination of estrogen and progestin or who are not taking any exogenous hormones [413]. The patient's hormonal status may play a role in the increased number of MF seen in mitotically active leiomyomas [341]. No studies of GnRHa have demonstrated a difference in mitotic index between treated and untreated patients, although an increase may be seen several weeks after cessation of treatment. In one study comparing leiomyomas removed from treated patients with tumors from untreated controls, cellular proliferation (Ki-67 and proliferating cell nuclear antigen [PCNA] labeling indices), estrogen receptors, and progesterone receptors were decreased in tumors from treated

Fig. 10.8

Mitotically active leiomyoma. (a) The tumor is not hypercellular and there is no nuclear atypia, but two mitotic figures are present (*center*). (b) High magnification view of the central portion of **Fig. 10.8a**, showing two mitotic figures but bland tumor cell morphology and absence of necrosis

patients, but a statistically significant decrease in the mitotic index was not observed [428].

Cellular Leiomyoma

A cellular leiomyoma is one in which the cellularity is "significantly" greater than the surrounding myometrium; "significantly" translates, operationally, into a use of the modifier "cellular" in less than 5% of leiomyomas. The isolated finding of hypercellularity may suggest a diagnosis of leiomyosarcoma, but cellular leiomyoma lacks tumor cell necrosis, has few MF, and lacks the moderate to severe cytologic atypia seen in leiomyosarcoma. Palisading of nuclei, reminiscent of that seen in the Verocay bodies of a neurilemoma, is present in some cellular leiomyomas [154]. The ultrastructural appearance of these tumors,

however, is that of an ordinary leiomyoma [154]. Prolapse of submucosal leiomyomas may result in accentuated cellularity [271]. A cellular leiomyoma composed of small cells with scanty cytoplasm can be confused with an endometrial stromal tumor. This problem becomes particularly difficult with what has been termed a "highly cellular leiomyoma" (**>** *Fig. 10.9*; [321]).

Features that help distinguish a cellular leiomyoma from a stromal tumor are the spindled shape of the cells, the fusiform shape of the nuclei, the reticulin pattern, and the absence of a plexiform vasculature. Reticulin fibers tend to parallel the fascicles of cells in a leiomyoma, but the reticulin network surrounds individual tumor cells in an endometrial stromal tumor. Additionally, Oliva et al. emphasized the presence of large thick-walled muscular vessels as features that serve to distinguish a highly cellular leiomyoma from a stromal proliferation [321]. Although some authors have reported that smooth muscle cells and stromal cells have immunophenotypic similarities, marked diffuse staining with muscle markers, particularly desmin (**>** Fig. 10.10), is more suggestive of a smooth muscle tumor than of a stromal neoplasm [321]. In a hysterectomy specimen, the relationship of the proliferation to the surrounding normal structures can be appreciated. In the absence of myoinvasion or vascular invasion, the differential lies between two benign conditions: highly cellular leiomyoma and stromal nodule. When there is intravascular tumor, the distinction between endometrial stromal and smooth muscle differentiation becomes clinically relevant as the differential diagnosis lies between stromal sarcoma (a clinically low-grade malignancy) and IVL (clinically benign unless there are cardiac complications).

Care must be taken to consider benign alternatives to stromal sarcoma when a cellular mesenchymal proliferation is recovered in an endometrial sampling. Thus, three issues need to be considered in this setting: (1) what differentiation does the proliferation exhibit (smooth muscle or endometrial stromal); (2) are the criteria of malignancy evaluable; and, finally, (3) are the criteria of malignancy met? In a "low penalty" hysterectomy setting (an older woman or a young woman who has no interest in having children), the issue is usually resolved by what amounts to a diagnostic hysterectomy. In the "high penalty" hysterectomy setting (young woman wishing to retain her fertility or older woman who is a poor surgical candidate), diagnostic modalities that might clarify the situation without the need of hysterectomy (e.g., hysteroscopy, imaging studies, repeat sampling) should be considered. Again, the important point is that not all cellular, spindle cell proliferations recovered in a curettage are stromal sarcoma; the clinically innocuous cellular leiomyoma is a highly probable alternative. Rarely, some uterine neoplasms appear to be composed of a mixture of stromal and smooth muscle cells [32, 317, 318].

Hemorrhagic Cellular Leiomyoma and Hormone-Induced Changes

Hemorrhagic cellular leiomyoma, or "apoplectic" leiomyoma, is a form of cellular leiomyoma that is found in women who are taking oral contraceptives or who are

either pregnant or postpartum [294, 306]. Multifocal stellate hemorrhages are present grossly (**)** *Fig. 10.11*). Microscopically, the leiomyoma is cellular and contains patchy areas of hemorrhage and edema. Necrosis generally is not present. MF, which may be slightly increased in number, are detected mainly within a narrow zone resembling granulation tissue around areas of hemorrhage. In contrast to leiomyosarcoma, neither atypical MF nor significant cytologic atypia are present, and the neoplasm has a circumscribed, compressive margin.

With the advent of GnRHa therapy to shrink leiomyomata, a substantial body of literature has accumulated concerning the mechanism of shrinkage and the histologic correlates of this process. Some workers have found no differences between GnRHa-treated and untreated leiomyomas [167, 393], whereas others have been able to detect changes in tumor vasculature, pattern of necrosis, proliferation index, and cellularity [81, 83, 88, 103, 205, 361, 428]. None of these differences are sufficiently striking to be of practical importance in distinguishing leiomyoma from leiomyosarcoma. On rare occasions, leiomyosarcomas have been discovered in patients undergoing GnRHa therapy [278].

Leiomyoma with Bizarre Nuclei (Atypical Leiomyoma)

As an isolated finding, cytologic atypia, even when severe, is an unreliable criterion for the diagnosis of clinically malignant uterine smooth muscle tumors because it can be seen in clinically benign, otherwise banal smooth

muscle neoplasms [32, 110]. A leiomyoma that exhibits moderate to severe cytologic atypia is designated an atypical leiomyoma. The atypical cells may be distributed throughout the leiomyoma or they may be focal; they have enlarged hyperchromatic nuclei with prominent chromatin clumping and, often, smudging (**>** *Fig. 10.12*). Large cytoplasmic pseudonuclear inclusions are often present. Multinucleated tumor giant cells can be numerous and prompt the name "bizarre" or "symplastic" leiomyoma. These changes have been noted in leiomyomas excised from women taking progestins [124, 339]. By definition, MF cannot be present in numbers in excess of 10 MF/10 HPF in an atypical leiomyoma, and tumor cell necrosis must be absent. Most atypical leiomyomas have 0-4 MF/10 HPF. While tumors with 5-9 MF/10 HPF fall into the atypical leiomyoma category, it is prudent to view such tumors as smooth muscle tumors of uncertain malignant potential (STUMP), particularly if the mitotic count is at the upper end of the range or there are atypical MF. A mitotic index higher than 10 MF/10 HPF in a tumor with diffuse moderate to severe nuclear atypia is diagnostic of malignancy (> Table 10.4; [32]). A smooth muscle tumor featuring diffuse moderate to severe atypia and coagulative tumor cell necrosis should be considered a leiomyosarcoma regardless of the mitotic index.

It is worth noting that leiomyosarcomas can vary greatly in appearance and may contain areas that lack the typical features of hypercellularity, cytologic atypia, and increased mitotic activity. Thus, extensive sampling is important to rule out leiomyosarcoma; atypical leiomyoma is a diagnosis of exclusion. The age of the patient must also be considered,

• Fig. 10.11 Hemorrhagic cellular leiomyoma. Multiple foci of hemorrhage are visible on the cut surfaces of a myomectomy specimen

■ Fig. 10.12 Atypical leiomyoma. Tumor cells have single or multiple pleomorphic nuclei with coarse, smudged chromatin

as atypical leiomyoma is less common in postmenopausal women. A careful search for other features of leiomyosarcoma is indicated when a smooth muscle tumor containing atypical cells is detected in an older woman.

The natural history of smooth muscle neoplasms featuring mitotic indices of <10 MF/10 HPF that lack tumor cell necrosis, and that exhibit diffuse moderate to severe atypia remains controversial. Downes and Hart reported a benign clinical course in their series of 24 cases of atypical leiomyoma [110]. On the other hand, Bell et al. found 1 clinically malignant tumor in 43 cases (2%), all of which had at least 2 years follow-up [32]. The patient who failed did so over several years, a clinical course unlike that of the usual leiomyosarcoma. These workers considered the entire group of neoplasms with moderate to severe atypia, a mitotic index <10 MF/10 HPF, and without tumor cell necrosis as "atypical leiomyomas with a low risk of recurrence." A recent Mayo Clinic study of uterine leiomyosarcoma and leiomyoma variants reported similar findings: 3 of 18 patients with leiomyoma variants died of disease, but between 6 and 11 years after diagnosis [156]. Peters et al. reported a series of 15 STUMP and confirmed both the low failure rate in this category and the slow tempo of disease when recurrence did occur [334]. Although necrosis was not recorded, at least some of the tumors in their group would qualify as atypical leiomyomas using the Bell et al. criteria. Ip et al. reported similar findings in an analysis of 16 STUMPs [194]. Two of 16 tumors recurred at 15 and 51 months; both patients were alive at 40 and 74 months. Both tumors that recurred were atypical leiomyomas with multifocal moderate to severe nuclear atypia, 4-5 MF/10 HPF, and no tumor necrosis. The two tumors that recurred were the only ones that showed diffuse positive immunostaining for p16 and p53. The differences in reported experience are probably related to differences in patient sample size in studies of a neoplastic process with a very low clinical failure rate.

Epithelioid Leiomyoma

This category includes tumors formerly classified as leiomyoblastoma, clear cell leiomyoma, and plexiform leiomyoma [228]. Epithelioid smooth muscle tumors have the same histologic appearance in the uterus as in other sites in the body. The mean age of women with epithelioid leiomyoma is in the fifth decade, with a range of 30–78 years [228, 340]. Epithelioid leiomyomas are yellow or gray and may contain areas of hemorrhage. They tend to be softer than the usual leiomyoma. Most

are solitary, and they can occur in any part of the uterus. The median diameter is 6–7 cm.

Microscopically, the cells are round or polygonal rather than spindle-shaped, and they are arranged in clusters or cords. The nuclei are round, relatively large, and centrally positioned. There are three basic subtypes of epithelioid leiomyoma: leiomyoblastoma, clear cell leiomyoma, and plexiform leiomyoma. Mixtures of the various patterns are common, providing the basis for designating all of these as epithelioid leiomyomas. Leiomyoblastoma is composed of round cells with eosin-ophilic cytoplasm (\bigcirc *Fig. 10.13*) rather than spindle cells. The cells in clear cell leiomyoma are polygonal and have abundant clear cytoplasm and well-defined cell membranes (\bigcirc *Fig. 10.14*). The cells may contain glycogen,

Fig. 10.13

Epithelioid smooth muscle tumor. Cellular tumor composed of poorly cohesive polygonal cells with eosinophilic cytoplasm

■ Fig. 10.14 Clear cell variant of epithelioid leiomyoma. Nests of cells with abundant clear cytoplasm

but there is minimal lipid and mucin is absent. The nucleus sometimes is displaced to the periphery of the cell, resulting in a signet-ring appearance. Plexiform leiomyoma is characterized by cords or nests of round cells with scanty to moderate amounts of cytoplasm. Transition to more typical spindled smooth muscle cells is often identified within an epithelioid leiomyoma. Immunohistochemical study confirms the myogenous phenotype of the tumor cells [47, 104, 192, 353]. Ultrastructural study reveals features of smooth muscle differentiation such as parallel cytoplasmic filaments, dense bodies, and basal lamina production [192, 196, 270]. The cells in some clear cell leiomyomas contain numerous mitochondria or cytoplasmic vacuoles.

Small plexiform leiomyomas that are detected only on microscopic examination are referred to as plexiform tumorlets (**>** *Fig.* 10.15; [206]). These lesions were formerly thought to be angiomas or endometrial stromal

Fig. 10.15

Plexiform tumorlet. This microscopic tumor is completely surrounded by normal myometrium (a) and consists of serpiginous cords of epithelioid smooth muscle cells (b) tumors, but ultrastructural examination revealed myofilaments and other features of smooth muscle cells [206, 310], and that the cells have a myogenous immunophenotype [104]. Plexiform tumorlets usually are solitary and submucosal, but they can occur anywhere in the myometrium and even in the endometrium. Multiple tumorlets are present in some patients [374].

The behavior of epithelioid smooth muscle neoplasms of the uterus is difficult to predict [69, 228, 340]. Small tumors that lack cytologic atypia, tumor cell necrosis, and an elevated mitotic index can be safely regarded as benign. Plexiform tumorlets invariably are benign. Epithelioid leiomyomas with circumscribed margins, extensive hyalinization, and predominance of clear cells generally are benign. The behavior of epithelioid leiomyomas with two or more of the following features is not well established: large size (>6 cm), moderate mitotic activity (2–4 MF/10 HPF), moderate to severe cytologic atypia, and necrosis.

The accumulated experience with epithelioid tumors as a group is limited and discourages dogmatism in predicting clinical course. Those neoplasms with moderate to severe atypia, without necrosis, and fewer than 5 MF/10HPF should be classified as STUMP because experience is too limited to be certain about their aggressive potential. Careful follow-up is warranted. Neoplasms with \geq 5 MF/10 HPF metastasize with sufficient frequency that all should be regarded as epithelioid leiomyosarcomas [228]. Epithelioid differentiation in more than just a few foci of a uterine smooth muscle tumor is a worrisome finding because the absence of cytologic atypia and tumor cell necrosis is no guarantee of a clinically benign course when the tumor contains \geq 5 MF/10 HPF [199], although the failure rate is probably quite low. All epithelioid smooth muscle tumors with tumor cell necrosis reviewed at Stanford have been clinically malignant. On the other hand, seven epithelioid tumors with <5 MF/10 HPF, with at most minimal cytologic atypia, and without necrosis behaved in a benign fashion. Most malignant epithelioid smooth muscle tumors are of the leiomyoblastoma type, although clear cell leiomyosarcoma has been reported [381]. The epithelioid appearance of these neoplasms raises a broad differential including carcinoma and epithelioid variants of gestational trophoblastic disease.

Myxoid Leiomyoma

Myxoid leiomyomas are soft and translucent. Microscopically, there is abundant amorphous myxoid material between the smooth muscle cells [269]. The margins of a myxoid leiomyoma are circumscribed, and neither cytologic atypia nor MF are present. We diagnose leiomyoma with myxoid stroma when the cells are small and uniform, atypia is absent or at most mild, and there are no more than 2 MF/10 HPF. Areas of ordinary leiomyoma should be present focally. Large myxoid smooth muscle tumors and those in which an infiltrating margin, cytologic atypia, or mitotic activity are observed microscopically should be regarded with suspicion. Some myxoid smooth muscle tumors exhibiting these features are clinically malignant even though they do not meet standard criteria for a diagnosis of leiomyosarcoma. Myxoid differentiation coupled with enlarged and atypical cells is an ominous finding. Four of seven such uterine tumors studied at Stanford progressed. We diagnose myxoid leiomyosarcoma in the presence of moderate to marked atypia with or without necrosis and with any mitotic index. The tumor margins are usually infiltrating.

Vascular Leiomyoma

Vascular leiomyomas contain numerous large-caliber vessels with muscular walls. It can be difficult to distinguish a vascular leiomyoma from a hemangioma or an arteriovenous malformation if the vascular component predominates. Vascular leiomyomas are well defined, circumscribed neoplasms that contain at least foci of typical spindled smooth muscle cells. Hemangiomas are very rare in the uterus and are usually of the cavernous type. Hemangiomas and arteriovenous malformations tend to be poorly defined grossly and microscopically and lack the sharp circumscription of a leiomyoma.

Leiomyoma with Other Elements

Some benign uterine neoplasms are composed of a mixture of smooth muscle cells and other elements. Endometrial stromal cells are prominent in some mixed tumors [317]. The natural history of these rare neoplasms is incompletely documented, although it appears that the rules for assessing malignancy in endometrial stromal tumors applies to mixed tumors as well. Infiltrative margins and/or vascular invasion are associated with a malignant clinical course, and the absence of these features with a benign one [317].

It is not uncommon to find scattered adipocytes in an otherwise typical leiomyoma. A leiomyoma that contains

Fig. 10.16 Lipoleiomyoma. The tumor is composed of an intermixture of fat cells, smooth muscle, and collagen

a striking amount of fat is called a lipoleiomyoma (> Fig. 10.16); if a vascular component is also present, it is designated as an angiolipoleiomyoma. Most such tumors occur in middle-aged or elderly women and may arise in any part of the uterus, including the cervix [432]. They average 6 cm in diameter and have soft yellow areas on the cut surface. Fat cells are generally found in circumscribed areas within the leiomyoma but may be present diffusely. Brown fat, skeletal muscle, and cartilage have been identified in leiomyomas [59, 137, 266, 440]. In most instances, the smooth muscle component predominates and is composed of spindled cells. Other types of leiomyoma, such as epithelioid leiomyoma [47], may also have a lipomatous component and fatty change is common in IVL. The vascular component of an angiolipoleiomyoma may be venous, arterial, or indeterminate. Only a few pure lipomas have been described in the uterus [106, 338]. Complex cytogenetic abnormalities have been described in a case of lipoleiomyoma [331].

Leiomyoma with Hematopoietic Cells

Large numbers of hematopoietic cells, which sometimes have no obvious etiology, may infiltrate leiomyomas. Leiomyomas may develop abscesses in the setting of bacterial infection. Peculiar infiltrates include extramedullary hematopoiesis in the absence of systemic disease [368], a prominent histiocytic infiltrate [5], a prominence of mast cells or eosinophils [89, 259, 324, 421], and, most importantly, a dense lymphoid infiltrate that can mimic lymphoma [130].

Smooth Muscle Proliferations with Unusual Growth Patterns, Diffuse Leiomyomatosis, and Myometrial Hypertrophy

Diffuse leiomyomatosis is an unusual condition in which innumerable small smooth muscle nodules produce symmetric enlargement of the uterus. The uterus may be greatly enlarged, weighing up to 1,000 g. The smooth muscle nodules range from microscopic to 3 cm in size, but most are less than 1 cm in diameter. They are composed of uniform, bland, spindled smooth muscle cells and are less circumscribed than typical leiomyomas. The clinical course may be complicated by hemorrhage, but the condition is benign [69, 166, 231, 291]. Myometrial hypertrophy is a condition in which the myometrium is thickened and the uterus is symmetrically enlarged. No specific gross or microscopic abnormality is noted; the uterus is abnormal in size only. Uterine weight increases with age and with increasing parity until the menopause. The average uterine weight decreases after the menopause. The weight beyond which the uterus is abnormally large, indicative of myometrial hypertrophy, is 130 g for the nulliparous uterus, 210 g for parity 1-3, and 250 g for parity of 4 and above [232].

Dissecting Leiomyoma

Dissecting leiomyoma refers to a benign smooth muscle proliferation with a border marked by the dissection of compressive tongues of smooth muscle into the surrounding myometrium and, occasionally, into the broad ligament and pelvis [357]. This pattern of infiltration may also be seen in IVL (see following). When edema and congestion are prominent, a uterine dissecting leiomyoma with extrauterine extension may resemble placental tissue, hence the name cotyledonoid dissecting leiomyoma [143, 358, 359].

Intravenous Leiomyomatosis and Leiomyoma with Vascular Invasion

IVL is a very rare smooth muscle tumor characterized by nodular masses of histologically benign smooth muscle cells growing within venous channels [67, 82, 292, 302, 307]. Women with IVL have a median age of 45 years; few are younger than 40 years. There is no racial predisposition, history of infertility, or decreased parity. The main symptoms are abnormal bleeding and pelvic discomfort. Most patients have a pelvic mass. Grossly, IVL is a complex coiled or nodular growth within the myometrium with convoluted, wormlike extensions into the uterine veins in the broad ligament or into other pelvic veins (**)** *Fig. 10.17*). The growth extends into the vena cava in more than 10% of patients, and in some it reaches as far as the heart [67, 82, 219, 399]. The wormlike masses vary from soft and spongy to rubbery and firm, and their color is pink-white or gray. Intravenous growth with an IVL-like pattern has been described in leiomyosarcoma [80], so it is important to carefully assess any such growth for features that might signify malignancy (high mitotic rate, significant nuclear atypia, and tumor cell necrosis).

Microscopically, tumor is found within venous channels lined by endothelium (> Fig. 10.18). Arteries are not involved. The histologic appearance is highly variable, even within the same tumor. The cellular composition of some examples of IVL is similar to a leiomyoma, but most contain prominent zones of fibrosis or hyalinization. Smooth muscle cells may be inconspicuous and difficult to identify. The intravenous growth is itself highly vascular (> Fig. 10.19), and in some cases contains so many small and large blood vessels that the process may resemble a vascular tumor. Any type of smooth muscle differentiation that occurs in a leiomyoma can be present in IVL [67]. Cellular, atypical, epithelioid, and lipoleiomyomatous growth patterns have all been described; these have the same behavior and prognosis as ordinary IVL [46, 67, 171].

IVL originates in vascular smooth muscle in some cases [307]. The tumor is predominantly or entirely intravascular in this situation, and there are many sites of attachment to the vein walls. Other examples develop by

■ Fig. 10.17 Intravenous leiomyomatosis. Brown and white plugs of intravascular tumor grow extensively in the myometrium

Intravenous leiomyomatosis. A plug of smooth muscle tumor grows within a large vein in the myometrium

Fig. 10.19

Intravenous leiomyomatosis. Nearly the entire tumor was within vascular spaces. Note that the intravascular tumor is highly vascular and extensively hyalinized

intravascular extension from a leiomyoma [302, 307]. In these cases the bulk of the tumor is extravascular and sites of origin from a vein wall are not found. Treatment is by total abdominal hysterectomy and bilateral salpingo-oophorectomy together with excision of any extrauterine extensions. IVL has a favorable prognosis even when it is incompletely excised [292]. Pelvic recurrence is infrequent and usually is amenable to surgical excision [117, 307]. Residual pelvic tumor may remain stable but progressive growth is possible. IVL is a hormonally dependent tumor, and progression is more likely in women whose treatment does not include bilateral salpingo-oophorectomy.

Long-term survival is possible after removal of plugs of tumor from the vena cava or right atrium or excision of nodules from the lung. In one case, leuprolide acetate induced tumor regression and rendered debulking surgery feasible in a patient with previously unresectable, widespread, retroperitoneal intravascular leiomyomatosis [416].

Benign Metastasizing Leiomyoma

Benign metastasizing leiomyoma is a nebulous condition in which "metastatic" smooth muscle tumor deposits in the lung, lymph nodes, or abdomen appear to be derived from a benign leiomyoma of the uterus. The lung is the most common site of involvement. One or multiple nodules of a low-grade smooth muscle tumor grow in an expansile pattern within the pulmonary parenchyma, often incorporating bronchioles (**)** Figs. 10.20a and b). Reports of this condition are often difficult to assess. Almost all cases of benign metastasizing leiomyoma occur in women, most with a history of pelvic surgery. The primary neoplasm, typically removed years before the metastatic deposits are detected, often has been inadequately studied. In some cases, the primary tumor was not examined histologically by the reporting author and, in others, the cytologic appearance, including mitotic counts, is not recorded for either the primary tumor or the alleged metastasis. A few examples may represent deportation metastases from IVL that reach the lungs, where they become implanted and grow as multiple intrapulmonary nodules of smooth muscle [237]. Others may represent a multifocal smooth muscle proliferation involving the uterus and extrauterine sites [62]. Most examples of "benign metastasizing leiomyoma," however, appear to be either a primary benign smooth muscle lesion of the lung in a woman with a history of uterine leiomyoma or pulmonary metastases from a morphologically noninformative smooth muscle neoplasm of the uterus [32, 82, 147, 437]. The findings of a recent cytogenetic study were most consistent with a monoclonal origin of both uterine and pulmonary tumors and the interpretation that the pulmonary tumors were metastatic [412]. The hormone dependence of this proliferation is suggested by the finding of estrogen and progesterone receptors in metastatic deposits [197] and the regression of tumors during pregnancy [185], after the menopause, and after oophorectomy [3]. The imaging characteristics of BML have been recently reviewed [82]. The differential diagnosis includes a pulmonary metastasis from a lowgrade ESS with smooth muscle or myofibroblastic differentiation [441].

Benign metastasizing leiomyoma. A circumscribed smooth muscle tumor is present in the lung (a). At high magnification, incorporated bronchioles are surrounded by cytologically bland smooth muscle cells (b)

Peritoneal Leiomyomas ("Parasitic" Leiomyomas)

On rare occasions, leiomyomas have been reported to "detach" from their initial subserosal location and "attach" to some other pelvic site. This improbable event presumably occurs through the mediation of a combination of infarction and inflammatory adhesions. A diagnosis of parasitic leiomyoma should be made with great caution because clinically malignant smooth muscle neoplasms arising in the retroperitoneum or gastrointestinal tract are notorious for being bland and having a low mitotic index. The plausibility of "parasitic leiomyomas" must be evaluated against the background of the infrequent occurrence of primary (single or multiple) smooth muscle neoplasms arising in other components of the female internal genitalia and the neighboring pelvic peritoneum [37, 242].

Disseminated Peritoneal Leiomyomatosis

Disseminated peritoneal leiomyomatosis (DPL) is a rare condition characterized by the presence of multiple smooth muscle, myofibroblastic, and fibroblastic nodules on the peritoneal surfaces of the pelvic and abdominal cavities in women of reproductive age [284, 411]. This condition is discussed in connection with leiomyoma of the uterus because it must be distinguished from metastatic leiomyosarcoma. Most cases are associated with pregnancy, an estrinizing granulosa tumor, or oral contraceptive use [411]. The most common presentation is as an unexpected finding at the time of cesarean section. DPL appears as multiple, small, granular white or tan nodules on the pelvic and abdominal peritoneum, on the surfaces of the uterus, adnexa, intestines, and in the omentum (> Figs. 10.21a and b). The nodules are distributed randomly, and most of them are less than 1 cm in diameter; this contrasts with metastatic leiomyosarcoma, in which the nodules tend to be fewer, larger, and invasive into adjacent tissues. Microscopically, the nodules consist of collagen, fibroblasts, myofibroblasts, smooth muscle cells, and, in pregnancy or the postpartum period, decidual cells (> Fig. 10.22). Spindle cells usually dominate, raising the possibility that disseminated peritoneal leiomyomatosis may be confused with a metastatic sarcoma. The clinical setting is quite different, however, as is the morphology of the cells. MF are infrequent in DPL, and nuclear atypia and pleomorphism are minimal or absent. Electron microscopic studies have shown that most nodules are composed of smooth muscle and decidual cells, although some are mixtures of decidua and fibroblasts or myofibroblasts [160, 301, 335, 411]. A cytogenetic study assessed the clonality of 42 tumorlets and 15 normal tissues from four women with DPL by analyzing X chromosome inactivation as indicated by the methylation status of the androgen receptor gene (HUMARA). In each of the four patients, the same parental X chromosome was nonrandomly inactivated in all tumorlets, consistent with a metastatic unicentric neoplasm or, alternatively, selection for an X-linked allele in clonal multicentric lesions [343]. Disseminated peritoneal leiomyomatosis is initiated or promoted by hormonal factors in most cases. Estrogen and progesterone receptors may be demonstrated within DPL by biochemical or immunohistochemical methods [111]. DPL generally regresses or remains static after removal of the hormonal stimulus (i.e., after delivery), so radical attempts at excision are unnecessary [411]. In keeping with a hormonally dependent process, DPL may regress during therapy with

Disseminated peritoneal leiomyomatosis. Disseminated peritoneal leiomyomatosis presents grossly as multiple or numerous small nodules of smooth muscle in the omentum (a) or on the peritoneum. A low-power photomicrograph illustrates multiple nodules of smooth muscle cells surrounded by omental fat (b)

Fig. 10.22

Disseminated peritoneal leiomyomatosis. The peritoneal nodules consist of histologically bland spindle-shaped smooth muscle cells; mitotic figures are absent

a GnRH agonist [169]. The peritoneal smooth muscle nodules may enlarge again when the GnRH agonist is discontinued or if the patient becomes pregnant. A few cases of malignant DPL have been reported [31]. Several were distinguished from typical cases of DPL by not having an exposure to estrogen or associated uterine leiomyomas and by absence of estrogen and progesterone receptors in their tumors.

Leiomyosarcoma

Leiomyosarcoma represents about 1.3% of uterine malignancies and more than 50% of uterine sarcomas, excluding carcinosarcoma [1]. Approximately 1 of every 800 smooth muscle tumors of the uterus is a leiomyosarcoma, but less than 1% of women thought clinically to have leiomyoma prove to have leiomyosarcoma [238].

Clinical Features

The median age of women with leiomyosarcoma is 50-55 years [1, 157], nearly a decade older than women with leiomyomas, although the disease is well known to occur in women in the third decade of life. Leiomyosarcoma is more prevalent in African-American women than in white women [48]. There is no relationship with gravidity or parity. The clinical presentation is nonspecific. The main symptoms are abnormal vaginal bleeding, lower abdominal pain, or a pelvic or abdominal mass [157]. The average duration of symptoms before diagnosis is 5 months [233]. There appears to be little support for the clinical dictum that a rapidly enlarging uterine smooth muscle neoplasm is indicative of leiomyosarcoma. In one study, only 1 of 371 women with this finding proved to have a leiomyosarcoma [327]. Unlike MMMT, leiomyosarcoma is seldom associated with a history of pelvic radiation.

Gross Findings

Most leiomyosarcomas are intramural, and 50–75% are solitary masses [371]. A higher proportion involves the cervix than is the case with leiomyoma. Leiomyosarcoma averages 6–9 cm in diameter and is soft or fleshy with poorly defined margins [1]. The cut surface is gray-yellow or pink, often with areas of necrosis and hemorrhage (\bigcirc *Fig. 10.23*). Leiomyosarcoma tends to be larger and softer than leiomyoma; it has a more irregular margin, and it is more likely to be hemorrhagic and necrotic

Leiomyosarcoma. Leiomyosarcoma is typically a solitary neoplasm, softer than the usual leiomyoma, and with areas of necrosis and hemorrhage on the cut surface

Table 10.3

Comparison of the gross pathology of leiomyoma and leiomyosarcoma

Leiomyoma	Leiomyosarcoma
Usually multiple	Usually solitary (50–75%)
Variable size, usually 3–5 cm	Large, usually 5–10 cm or larger
Firm, whorled cut surface	Soft, fleshy cut surface
White	Yellow or tan
Hemorrhage and necrosis (infarction-type) infrequent	Hemorrhage and necrosis (coagulative tumor cell-type) frequent

(Table 10.3). On the other hand, most smooth muscle neoplasms that have a peculiar gross appearance are found to be benign and to exhibit some form of "degeneration," usually ischemic. The diagnostic usefulness of imaging studies in separating benign from malignant smooth muscle neoplasms has recently been discussed [372].

Microscopic Findings

The usual leiomyosarcoma is composed of fascicles of spindle cells with abundant eosinophilic cytoplasm (\bigcirc *Fig. 10.24*). Longitudinal cytoplasmic fibrils, best appreciated with a trichrome stain, are frequently present. The nuclei are fusiform, usually have rounded ends, and are hyperchromatic with coarse chromatin and prominent

Fig. 10.24

Leiomyosarcoma. The tumor cells are spindle-shaped with eosinophilic cytoplasm. The nuclei are fusiform, hyperchromatic, and atypical, and there are many mitotic figures

Fig. 10.25

Leiomyosarcoma. The tumor cells vary in size and shape. Several mitotic figures are present including an abnormal one

nucleoli (\bigcirc *Fig. 10.25*). Cellular pleomorphism can be marked in poorly differentiated neoplasms (\bigcirc *Fig. 10.26*). Multinucleated tumor cells are found in 50% of leiomyosarcomas. Giant cells resembling osteoclasts are occasionally present [95, 262, 328] and, rarely, xanthoma cells may be prominent [164]. Many leiomyosarcomas invade the surrounding myometrium, but a leiomyosarcoma with a circumscribed margin can give rise to metastases. Vascular invasion is identified in 10–22% of leiomyosarcomas. Tumor cell necrosis is typically prominent but need not be present. The mitotic index is typically in

Leiomyosarcoma. The tumor cell nuclei are pleomorphic, with some giant nuclei and an atypical mitotic figure

excess of 15 MF/10 HPF [332]. The main criteria used to diagnose leiomyosarcoma of the uterus are the presence of nuclear atypia, a high mitotic index, and coagulative tumor cell necrosis (**>** *Table 10.4*).

Myxoid leiomyosarcoma is a large, gelatinous neoplasm that usually appears circumscribed on gross examination [226, 369]. Microscopically, the smooth muscle cells are usually widely separated by myxoid material (**)** Fig. 10.27; [216]). The characteristic low cellularity partly accounts for the low mitotic index in most myxoid leiomyosarcomas. Sometimes, however, the mitotic index is high and there is a high degree of atypia. In addition to the myxoid appearance, other microscopic features that help identify the tumor as a leiomyosarcoma include myometrial infiltration and vascular invasion. One unusual myxoid leiomyosarcoma arose within a leiomyoma [286]. Despite the low mitotic counts, myxoid leiomyosarcoma has the same unfavorable prognosis as typical leiomyosarcoma. Myxoid smooth muscle tumors of the uterus must be regarded with suspicion, and any myxoid smooth muscle tumor with significant nuclear atypia, regardless of the mitotic count or the presence or absence of necrosis should be classified as a leiomyosarcoma. It is critical to distinguish the myxoid differentiation found in myxoid leiomyosarcomas from the vastly more prevalent hydropic changes seen in degenerating leiomyomas [78]. In addition, myxoid leiomvosarcoma must be differentiated from an inflammatory myofibroblastic tumor (IMT; see section ♦ Inflammatory Myofibroblastic Tumor; [344]). In myxoid leiomyosarcoma, not only is the stroma myxoid but the cells are enlarged with hyperchromatic nuclei and

Table 10.4

Histologic criteria for the diagnosis of uterine smooth muscle tumors with standard smooth muscle differentiation

Tumor cell necrosis	Atypia	MF/10 HPF	Diagnosis
Present	Diffuse moderate to severe	Any level	Leiomyosarcoma
Present	None to mild	≥10	Leiomyosarcoma
Present	None to mild	<10	STUMP (rule out infarcted leiomyoma)
Absent	Diffuse ≥10 moderate to severe		Leiomyosarcoma
Absent	Diffuse moderate to severe	<5	Atypical leiomyoma with low risk of recurrence
Absent	Diffuse moderate to severe	5–9 or atypical mitotic figures	STUMP
Absent	None to mild	<5	Leiomyoma
Absent	None to mild	≥5	Mitotically active leiomyoma
Absent	Focal moderate to severe	≥5	STUMP
Absent	Focal moderate to severe	<5	Atypical leiomyoma

pleomorphism is usually obvious. The usual case of myxoid leiomyosarcoma bears a striking resemblance to soft tissue myxoid "malignant fibrous histiocytoma."

Epithelioid leiomyosarcomas are composed of round or polygonal cells and exhibit one of the patterns of epithelioid differentiation (**>** *Fig. 10.28*). The leiomyoblastoma pattern is most common, although clear cell epithelioid leiomyosarcomas have also been reported [340, 380, 381]. The usual features of malignancy seen in more conventional leiomyosarcomas are generally present: cytologic atypia, tumor cell necrosis, and a high mitotic index [69, 212, 287]. Epithelioid smooth muscle tumors with significant nuclear atypia and either necrosis 474

or \geq 5 MF/10 HPF are classified as leiomyosarcomas [228, 340].

Finally, there is the rare, otherwise conventional smooth muscle tumor with a low mitotic count that proves to be clinically malignant. Unless the tumor is invasive or contains abnormal MF or areas of tumor cell necrosis, there are no good grounds for suspecting that it is a leiomyosarcoma until it announces itself by metastasizing. Doubtless, the pulmonary metastases from some "benign metastasizing leiomyomas" originate from neoplasms in this category.

Immunohistochemistry

Immunohistochemistry is generally not required for the diagnosis of leiomyosarcoma, but immunostains are

b

Fig. 10.27

Myxoid leiomyosarcoma. The abundant myxoid stroma widely separates bundles of smooth muscle cells, resulting in a hypocellular appearance (a). As shown here (b), the degree of nuclear atypia can be deceptively bland, and, because the tumor cells are widely separated by myoid stroma, the number of mitotic figures per 10 HPF is often low occasionally necessary to differentiate leiomyosarcoma from other uterine malignancies such as undifferentiated endometrial sarcoma (UES) or sarcomatoid carcinoma. Immunostains can confirm that extrauterine sarcoma deposits show smooth muscle differentiation and hence are compatible with metastatic leiomyosarcoma. Recently published studies suggest that immunohistochemistry may play a role in the classification of atypical smooth muscle tumors that are difficult to recognize as leiomyosarcoma using standard criteria.

A variety of antibodies can be used to confirm that a uterine tumor exhibits smooth muscle differentiation (Table 10.5). Experience is greatest with smooth muscle actin, desmin, and caldesmon, but calponin and smooth muscle myosin are also occasionally used for this purpose. Cytoplasmic staining is observed in smooth muscle cells with all of these markers, although staining for one or more of them can be lost in poorly differentiated leiomyosarcomas. Myofibroblasts can also stain with smooth muscle markers, particularly smooth muscle actin, so positive staining with one of these markers is not conclusive evidence of smooth muscle differentiation. CD10 is generally used as a marker of endometrial stromal differentiation, but as experience with this antibody has accumulated it has become clear that some smooth muscle tumors are also CD10 positive, although staining is often weak and focal [277, 414]. Leiomyosarcoma appears more

■ Fig. 10.28 Epithelioid leiomyosarcoma of the "leiomyoblastoma" type. The tumor cells are polygonal with pale cytoplasm and atypical nuclei. Mitotic figures are not numerous, but there was extensive coagulative tumor cell necrosis

Table 10.5

Immunohistochemical features of leiomyosarcoma and leiomyoma

likely than other types of smooth muscle tumors to stain for CD10. In one study, eight of nine leiomyosarcomas showed staining for CD10 (1+ to 3+ intensity, staining in 5–60% of tumor cells) [320]. Histone deacetylase 8 (HDAC8) has been proposed as a marker of smooth muscle differentiation and has been reported to stain leiomyosarcoma with a frequency similar to that obtained with other markers, although with less intensity; it does not appear to be widely used [100]. Myometrial smooth muscle cells are frequently immunoreactive for cytokeratin, so it is not surprising that occasional leiomyosarcomas show positive cytoplasmic staining for cytokeratin [320].

Immunohistochemistry can, in some cases, suggest that a problematic smooth muscle tumor is a leiomyosarcoma (**2** *Table 10.5*). Mutation of the p53 gene or positive staining for p53 (strong nuclear staining in >50% of tumor cell nuclei) is reported mainly in leiomyosarcoma (**2** *Fig. 10.29*), although unfortunately only a minority of tumors is p53 positive [149, 313]. Different results were reported in one study, in which atypical leiomyomas and STUMPs were reported to stain with the same frequency

Positive staining for p16 in leiomyosarcoma. Nearly all tumor cells show strong nuclear and/or cytoplasmic staining. Staining must be strong and diffuse to be of significance

and intensity as leiomyosarcoma [60]. Reported results can be difficult to interpret because of differing criteria for leiomyosarcoma, use of different antibodies, failure to clearly report the intensity and extent of staining, acceptance of low levels of staining as positive, or lack of clinical follow-up [11, 41, 101, 170, 235, 239]. To ensure reproducible results strong nuclear staining (2-3+) should be present in >50% of tumor cell nuclei. More recently gene expression studies have shown overexpression of p16 in leiomyosarcoma [386], suggesting that immunostaining for p16 might be helpful in the differential diagnosis of problematic smooth muscle tumors. Studies of p16 staining in uterine smooth muscle tumors [23, 44, 60, 149, 313] have generally found diffuse strong staining in leiomyosarcoma (> Fig. 10.30), despite differences in diagnostic criteria and antibodies. Staining is cytoplasmic or nuclear or is present in both sites. Some authors have found little staining for p16 in STUMPs and atypical leiomyomas, while others have shown considerable overlap in staining [60, 313]. Clinical follow-up has been

reported in only a few cases, and some examples of p16 positive STUMPs have proven to be clinically malignant [23, 194], suggesting that diffuse strong staining for p16 may help to define a group of STUMPs that should be suspected of actually being leiomyosarcomas, particularly if p53 is also overexpressed. Loss of staining for progesterone receptors has been proposed as a possible marker for leiomyosarcoma [433]. Staining for progesterone receptors is lost in 40-80% of leiomyosarcomas, but it is retained in 70-100% of STUMPs and in most leiomyomas [43, 241, 285, 447]. Staining for estrogen receptors is more variable. Staining for hormone receptors tends to be positive in STUMPs, whether or not they subsequently recur or metastasize, so staining for hormone receptors does not appear to be helpful in subclassifying STUMPs into highand low-risk categories [194]. In summary, immunohistochemistry may be helpful in the diagnosis of leiomyosarcoma. Diffuse strong staining for p16, especially when accompanied by diffuse strong staining for p53 supports a diagnosis of leiomyosarcoma. However, such staining is not an absolute criterion for a diagnosis of leiomvosarcoma, and the immunostain results must be interpreted in conjunction with the histologic findings. Light microscopic evaluation still forms the basis for classification of uterine smooth muscle tumors.

Cytogenetics

The cytogenetics of leiomyosarcoma are even more complicated and varied than those of leiomyoma. A wide variety of chromosomal changes have been described, but no specific diagnostically useful findings have emerged [363]. A translocation that is often present in leiomyomas, t(12;14), has not been identified in leiomyosarcoma, suggesting that leiomyosarcoma is generally not derived from a preexisting leiomyoma.

Clinical Behavior and Treatment

In the past, the staging system for uterine corpus carcinomas was used for uterine sarcomas. However, a new staging system designed to reflect the different biological behavior of sarcomas has been introduced (**>** *Table 10.2*; [131]).

A recent retrospective review of uterine leiomyosarcomas treated at the Mayo Clinic provides a clinicopathologic portrait of leiomyosarcoma as currently defined. Sixty-eight percent of the 208 patients reviewed presented with disease confined to the uterus. Six percent had cervical involvement; approximately half had cervical involvement only. Nine percent were Stage III and 20% Stage IV [157]. Patients with leiomyosarcoma relapse both loco-regionally and hematogenously. A recent review of 71 uterine leiomyosarcomas reports relapses in the following sites as the sole site: vagina, 22%; pelvis, 19%, lung, 22%; bone, 9%; and retroperitoneum, 12%. Relapse in both lung and pelvis occurred in 16% of patients [157].

The incidence of lymph node metastasis varies from series to series, but it is substantially lower than that found in clinical stage I and II high-risk endometrial carcinomas [157]. In a Gynecologic Oncology Group (GOG) study, 83% of 59 clinical stage I and II leiomyosarcoma patients were surgical stage I; 2 of 59 (3%) had lymph node involvement, 2 had adnexal involvement, and 1 had positive peritoneal cytology [258]. Three of 37 women studied at Memorial Sloan Kettering Cancer Center had positive lymph nodes, but no women with stage I or II tumors had lymph node metastases [240]. Lymph node involvement is higher in series reporting advanced-stage leiomyosarcoma, and figures as high as 44% are reported in autopsy series [133, 355]. Goff et al. found in their series of 15 surgically staged patients that lymph nodes were involved only when there was peritoneal disease [158]. Moreover, a high percentage of lymph node-negative patients failed. In view of this, there would appear to be little role for lymph node sampling in this disease.

Leiomyosarcoma is a highly malignant neoplasm with poor survival rates when tumors are classified with contemporary criteria. For postmenopausal women, primary therapy for early-stage leiomyosarcoma is total abdominal hysterectomy and bilateral salpingo-oophorectomy. Therapy in premenopausal women is more controversial. The ovaries are only rarely the site of metastatic disease in clinically low-stage leiomyosarcoma; in the GOG study, only 2 of 59 patients had this finding [258], and ovarian metastases were present in only 2 of 71 women studied at Memorial Sloan Kettering Cancer Center [240]. Moreover, there is no evidence that oophorectomy influences the results of therapy [151, 157, 233]. Accordingly, ovarian conservation is reasonable in premenopausal women. On the other hand, patients with low-grade smooth muscle neoplasms metastatic to the lung have responded to oophorectomy alone [3].

The literature provides conflicting reports on the efficacy of radiotherapy and chemotherapy in the management of leiomyosarcoma [144, 145, 155, 157, 178, 268, 402, 448]. Two series reported no effect of radiotherapy,

[33, 183], whereas the GOG series showed a lower relapse rate in patients with early-stage leiomyosarcoma when they were treated with combined radiation and surgery compared to patients treated with surgery alone (none versus 17%) [258]. Two recent reports on the use of radiation therapy to treat women with early stage (stage I or II) leiomyosarcoma detected no survival benefit for women who were treated with radiotherapy [348, 439]. The role of radiotherapy would appear to be limited given the conflicting reports on the radiosensitivity of leiomyosarcoma and its noncontroversial tendency to spread hematogenously. Advocates of adjuvant radiotherapy have argued that although survival is not changed, pelvic radiation prevents local and regional recurrences and thus is associated with an improvement in the quality of remaining life [151, 157, 183]. A recently reported randomized study that evaluated the value of adjuvant pelvic radiotherapy in women with stage I or II leiomyosarcoma found no increase in local control in radiated women [348].

Recurrent or metastatic leiomyosarcoma is very difficult to treat. A minority of patients responds to chemotherapy with doxorubicin [402, 403]. Localized pelvic or abdominal recurrences and solitary pulmonary metastases occasionally are amenable to surgical resection [108, 245]. Given the poor results obtained by surgery alone in earlystage leiomyosarcoma, there is an urgent need for effective adjuvant chemotherapy; unfortunately, no active regimen has been identified.

The variation in survival rates reported historically for leiomyosarcoma is largely a result of the use of different criteria for its diagnosis. Overall, 5-year survival rates in series using modern criteria range from 15% to 35% [41, 233, 332]. When only stage I and II tumors are considered, the 5-year survival rate is 40–70% [41, 145, 233, 268, 304, 305, 329, 332, 438]. The 3-year progression-free interval was 31% in a GOG series of 59 early-stage leiomyosarcomas; the first recurrence was in the pelvis in 14% of cases and in the lung in 41% [258].

The prognosis of leiomyosarcoma depends chiefly on stage. For stage I tumors, some investigators have found the size of the neoplasm to be an important prognostic factor [1]. In Evans' series, all patients with tumors larger than 5 cm died of disease, while only three of eight patients with tumors smaller than 5 cm died of disease [119]. In another series of metastasizing leiomyosarcomas, only 20% were less than 5 cm [199]. Premenopausal women have had a more favorable outcome in some series but not in others. Several series, including the large GOG study of early-stage leiomyosarcoma, have found mitotic index to be of prognostic significance [1, 145, 233, 258, 329, 332],

whereas others have not [119]. A modification of the classification of [32] was employed as a grading scheme in one study and found to provide independent prognostic information [41]. A grading scheme designed for soft tissue neoplasms has been tested in uterine sarcomas and shown to have no prognostic significance [329, 332].

What should be incorporated in the pathology report in the face of these conflicting claims about prognostically relevant features? We do not grade leiomyosarcomas, as no universally agreed-upon grading scheme exists, but do comment on the features listed here: maximum tumor diameter, mitotic index, the presence or absence of necrosis and its extent if present, the nature of the tumor periphery (invasive or circumscribed), and the presence or absence of vascular space involvement.

A variety of practical issues relating to the management of leiomyosarcoma (including the problem of a diagnosis of leiomyosarcoma in a premenopausal patient after a myomectomy) has recently been presented [372].

Smooth Muscle Tumor of Uncertain Malignant Potential (STUMP)

This diagnosis is used when there is significant doubt about the failure rate associated with a particular combination of histologic features. With the acquisition of more clinicopathologic information about smooth muscle neoplasms, the size of this category has diminished. Some of the situations for which we currently employ this designation include the following:

- The available clinicopathologic information about a differentiated type is scant, and there is, for whatever reason, some chance that the neoplasm might not be benign; this is true of myxoid and epithelioid neoplasms that lack tumor cell necrosis, have midrange atypia, and have moderately high mitotic indices.
- 2. There is uncertainty concerning the type of smooth muscle differentiation present, which would make a difference in the prediction of its clinical behavior.
- 3. There is uncertainty about the mitotic index, which would make a difference in the prediction made about the clinical behavior of the neoplasm. This situation most frequently occurs in smooth muscle neoplasms with standard smooth muscle differentiation that lack tumor cell necrosis, have moderate to severe atypia, have a mitotic index in the neighborhood of 10 MF/10 HPF, and have structures that could be regarded either as abnormal MF or smudged karyorrhectic nuclei, because counting them as MF would result in

a leiomyosarcoma diagnosis and as smudged nuclei would result in a diagnosis of atypical leiomyoma.

4. There is uncertainty about the presence or type of tumor cell necrosis. Sometimes the distinction between hyaline/infarction necrosis and tumor cell necrosis is ambiguous. There may be widespread individual cell necrosis or a pattern that could represent either early infarction or tumor cell necrosis [194].

Ip et al. recently reviewed cases of STUMP with adequate follow-up reported in the literature [194]. Depending on the subcategory of STUMP, 4–27% of tumors proved to be clinically malignant (i.e., they recurred or metastasized). In contrast to typical examples of leiomyosarcoma, recurrences in patients with STUMPs are often detected after a long interval, and long survival is possible after a recurrence. As discussed above in the section on leiomyosarcoma, histologic parameters together with the results of immunostaining for p16 and p53 may help to stratify patients with STUMPs into lowand high-risk categories. Diffuse strong staining for p16, especially when accompanied by diffuse strong staining for p53, appears to signify that a STUMP should be viewed as high risk [23, 194].

PEComa

PEComa is a rare, recently described neoplasm composed of cells showing "perivascular epithelioid cell" (PEC) differentiation [136, 419]. These cells, for which there is no known normal counterpart, have clear to eosinophilic cytoplasm and exhibit positive staining for smooth muscle and melanocytic markers [265]. In particular, HMB-45, Melan A, and microphthalmia transcription factor (MiTF) positivity is characteristic and smooth muscle markers (smooth muscle actin and desmin) are often positive. The PEC family of tumors includes, in addition to PEComa, angiomyolipoma and clear cell tumors of the lung and pancreas.

PEComas are neoplasms of adulthood, and when they involve the uterus they typically present either as a mass or cause uterine bleeding; they may be associated with lymphangioleiomyomatosis (LAM) and tuberous sclerosis. PEComas are usually solitary neoplasms ranging in size from 0.5 to 16.0 cm, although rarely multiple lesions are described. They may be either circumscribed or infiltrative with a nondistinctive texture and coloration. Microscopically, the low power impression is of either a compressive or, less commonly, an infiltrative neoplasm. Sometimes there is a tongue-like pattern of invasion of the myometrium reminiscent of the type of invasion seen in low-grade ESS (**)** *Fig.* 10.31; [419]).

The tumor cells range from epithelioid to spindled, and they have moderate to abundant, clear-toeosinophilic cytoplasm and well-defined cell borders (**)** *Fig. 10.32*). The tumor cell cytoplasm sometimes has a distinctive granular or finely vacuolated bubbly

Fig. 10.31

PEComa. In this uterine PEComa, tongues of pale tumors cells push through the myometrium in a pattern that is somewhat reminiscent of an endometrial stromal sarcoma

Fig. 10.32

PEComa. The tumor is composed of nests and sheets of epithelioid tumor cells with flocculent eosinophilic cytoplasm and vesicular nuclei with coarse chromatin and conspicuous nucleoli appearance, particularly in spindle cells. The degree of nuclear atypia and the mitotic index are characteristically low and necrosis is uncommon, but tumors with significant atypia and frequent MF occur. A variant with abundant hyalinized stroma that can partially obscure the tumor cells has been reported [184].

Immunohistochemical study is essential to confirm the diagnosis. The most characteristic finding is patchy, positive HMB-45 staining of tumor cell cytoplasm (> Fig. 10.33). Other melanocytic markers such as Melan-A and microphthalmia transcription factor (MiTF) are also often positive; S-100 can be positive but it is more often negative [136]. Positive staining for smooth muscle markers is also typical. Smooth muscle actin is the smooth muscle marker that is most likely to be positive, but some tumors also stain for caldesmon or desmin [140]. Cytokeratin, CD117, and CD34 are generally negative. A minority of tumors shows positive staining for TFE3, a potential pitfall in the differential diagnosis with alveolar soft part sarcoma (ASPS; [136]). However, ASPS does not show staining for HMB-45 or smooth muscle actin. Electron microscopic study of one uterine PEComa that showed positive immunostaining for HMB-45 revealed premelanosomes in the tumor cells [326].

Both benign and malignant variants of PEComa (based on the extent of tumor at diagnosis or clinical follow-up) have been reported [107, 165]. In one recent review, 44% of corpus cases were classified as malignant and 56% as benign [121, 122]. Features proposed as being predictive of an unfavorable outcome include large size

Fig. 10.33 Positive staining for HMB-45 in a uterine PEComa. Staining is typically patchy and often of medium intensity

(>5 cm), high cellularity, significant nuclear atypia, mitotic activity (>1 MF/10 HPF), coagulative tumor cell necrosis, invasive growth, and lymphovascular space invasion [136]. Firm criteria for malignancy, as exist for uterine smooth muscle tumors, remain to be delineated. Benign tumors are those that are small (<5 cm), with low cellularity, a noninvasive periphery and absence of lymphovascular space invasion, a low mitotic count, and absence of nuclear atypia or tumor cell necrosis.

The differential diagnosis includes ESS (HMB-45 negative), metastatic melanoma (S100 positive), and epithelioid smooth muscle neoplasms. In the uterus, there is dispute about whether PEComas are a distinct type of neoplasm or a variant of a smooth muscle neoplasm. Fueling this dispute is the non-specificity of HMB-45 positivity in mesenchymal neoplasms of the uterus. HMB-45 positivity has been reported in over one third of conventional uterine leiomyosarcomas [382], in epithelioid areas of otherwise conventional uterine leiomyosarcomas [190, 380], and in metastases from an epithelioid leiomyosarcoma [379]. It has been suggested that positive immunostaining for CD1a favors a diagnosis of PEComa over an epithelioid smooth muscle tumor [123], but the validity of this test needs to be verified by further study. Until the controversy is resolved, it is best to classify a tumor with the morphologic and immunohistochemical features of leiomyosarcoma as such, regardless of whether it stains for HMB-45, while noting the presence of features of a PEComa if present. Tumors that do not meet criteria for leiomyosarcoma and that exhibit the morphologic features of a PEComa, including positive staining for HMB-45, can be designated as PEComas, and grouped into benign and uncertain malignant potential groups based on the morphologic features noted above.

Lymphangioleiomyomatosis (LAM) and angiomyolipoma are two conditions in the same family as PEComa that are occasionally detected in the uterus. Angiomyolipoma is a benign tumor that contains abnormal blood vessels, fat, and spindled or epithelioid smooth muscle cells in varying proportions. HMB-45 positive tumor cells are present in the fat and among the smooth muscle cells. LAM is generally a microscopic finding in the uterus [168, 415]. It consists of dilated lymphovascular spaces associated with smooth muscle cells with flocculent eosinophilic cytoplasm (> Fig. 10.34), some of which show positive staining for HMB-45. There is a strong association between angiomyolipoma and LAM of the uterus and tuberous sclerosis, although not every patient with angiomyolipoma or LAM carries a diagnosis of tuberous sclerosis.

Endometrial Stromal Tumors

Endometrial stromal tumors are rare and can be benign or malignant (**)** *Table 10.6*). Benign endometrial stromal tumors are called stromal nodules; they are circumscribed, expansile, and do not invade the myometrium. Malignant stromal tumors are endometrial sarcomas. The more common low-grade sarcomas are called ESS, and the highgrade sarcomas are called UES. Endometrial sarcomas infiltrate the myometrium, invade vascular spaces, and have the capability to invade adjacent tissues and to metastasize. Several variants of endometrial stromal tumors exist, including tumors with histologic features

Fig. 10.34

Lymphangioleiomyomatosis involving the myometrium.

The tumor cells are usually spindled with oval nuclei and flocculent eosinophilic cytoplasm. The growth is centered on dilated lymphovascular spaces, and intravascular growth is typically present, often at the periphery of the area of involvement. Sometimes, it mimics the appearance of intravascular endometrial stromal sarcoma

Table 10.6

Classification of endometrial stromal tumors

reminiscent of ovarian sex cord-stromal tumors and tumors with smooth muscle differentiation. Most endometrial stromal tumors originate in the uterus, but rare examples arise outside the uterus, presumably in endometriosis [25, 58, 141, 220, 443].

Endometrial Stromal Nodule

Endometrial stromal nodules are rare benign tumors composed mainly of endometrial stromal cells. [109, 126, 410] They represent less than a quarter of endometrial stromal tumors.

Clinical Features

Endometrial stromal nodules have been reported in women from 23 to 86 years of age. The average patient age is around 50 years, and about 75% of patients are premenopausal. There is no racial predisposition. The main symptom is abnormal uterine bleeding, which is occasionally severe enough to cause anemia. Pelvic or abdominal discomfort is a frequent complaint. Physical examination typically reveals uterine enlargement or a uterine mass. The average duration of symptoms before diagnosis is about 2 months. About 10% of patients are asymptomatic, and their tumors are found incidentally when hysterectomy is performed for another condition.

Gross Findings

Endometrial stromal nodules have a circumscribed contour and range from <1 cm to >20 cm in diameter; the average size is 5–6 cm (**>** *Fig.* 10.35). Many stromal nodules are polypoid and protrude into the uterine cavity.

Tumor	Category	Margin	Nuclear atypia	Nuclear pleomorphism	Usual mitotic activity (MF/10 HPF)
SN	Benign	Circumscribed	Minimal	Minimal	<3
ESS	Malignant, low grade	Invasive	Minimal	Minimal	<3
UES, monomorphic	Malignant, high grade	Invasive	Moderate to marked	Minimal to moderate	>10
UES, pleomorphic	Malignant, high grade	Invasive	Marked	Marked	>10

SN, Endometrial stromal nodule; ESS, Endometrial stromal sarcoma; UES, Undifferentiated endometrial sarcoma

Some of these are located entirely within the endometrium while others are submucosal. Nearly half of all stromal nodules are located entirely within the myometrium with no apparent connection to the endometrium. One unusual tumor was embedded in a term placenta [208]. Stromal nodules have fleshy-yellow or tan cut surfaces and they tend to bulge above the surrounding myometrium. Cystic changes are not uncommon and rare tumors con-

tain foci of hemorrhage or necrosis. About 5% of patients

have two or more nodules. The cervix is seldom involved.

Microscopic Findings

Stromal nodules have expansile, noninfiltrative margins that compress the surrounding endometrium and myometrium (\bigcirc *Fig.* 10.36). Minor irregularities of the margin are common. Rarely one or a few fingerlike protrusions of tumor push into the adjacent myometrium, or small satellite nodules are present in the immediately adjacent myometrium (\bigcirc *Fig.* 10.37). As long as these protrusions or satellites do not extend more than 3 mm from the main nodule and there is no vascular invasion the tumor is still regarded as a stromal nodule [109, 410]. More extensive invasion or vascular invasion indicates that the tumor is a stromal sarcoma, not a stromal nodule. It is important to be aware of the gross pathologic

Fig. 10.35

Endometrial stromal nodule. The nodule is circumscribed with no evidence of invasion into the surrounding myometrium. It has a homogeneous tan cut surface, quite different from a leiomyoma. There is central cystic change appearance of a stromal nodule and to know which sections are from the interior of the tumor and which show the interface with the surrounding myometrium. Alternating areas of stromal, fibrous, and smooth muscle differentiation within a stromal nodule can be misinterpreted as myoinvasion if endometrial stromal cells interdigitate with well-developed bundles of metaplastic smooth muscle.

Endometrial stromal nodules consist of cells that closely resemble normal proliferative-phase endometrial stromal cells. The tumor cells have uniform, small, darkly staining, round or oval nuclei with finely granular chromatin and inconspicuous nucleoli (> Fig. 10.38). The cytoplasm varies from scanty to moderate, and cell borders tend to be poorly defined. A reticulin network encircles individual cells. Mitotic activity ranges from none to more than 15 MF/10 HPF but it is usually low (<3 MF/10 HPF). MF cannot be identified in about 50% of stromal nodules, and >5 MF/10 HPF are detected in only 5-10% of them. Myxoid or fibrous stromal changes occasionally occur in stromal nodules, and if extensive they can obscure the diagnosis [322]. In such cases it is essential to thoroughly study the tumor to find foci of typical endometrial stromal differentiation. Smooth muscle differentiation is common in endometrial stromal nodules (\bigcirc Fig. 10.39). The smooth muscle cells are typically spindle-shaped with fusiform blunt-ended nuclei and fibrillar eosinophilic cytoplasm, but they are occasionally epithelioid with rounded nuclei and moderate eosinophilic cytoplasm. Epithelioid smooth muscle cells are often embedded in aggregates of hyalinized collagen. In the past, endometrial tumors with extensive smooth stromal muscle

• Fig. 10.36 Endometrial stromal nodule. Note the circumscribed pushing margin. Expansile growth without invasion into the surrounding myometrium characterizes a stromal nodule

Endometrial stromal nodule. This nodule has a mainly circumscribed periphery, but there is a focal irregularity with a small satellite nodule. As long as irregularities or satellites extend no more than 3 mm from the main nodule and there is no vascular invasion, a diagnosis of stromal nodule is still appropriate. If the extent of invasion is >3 mm or there is vascular invasion, the tumor should be classified as an endometrial stromal sarcoma

Fig. 10.38

Endometrial stromal nodule. The tumor is cellular and is composed of uniform bland endometrial stromal cells with round to oval nuclei and scanty cytoplasm. Mitotic figures are infrequent. Note the conspicuous evenly distributed small arterioles

differentiation (>30%) were classified as combined stromal–smooth muscle tumors [317], but since it appears that the endometrial stromal cell component determines the clinical behavior, it makes sense to classify all such tumors as endometrial stromal nodules with smooth muscle differentiation.

Fig. 10.39

Endometrial stromal nodule with smooth muscle differentiation. Bundles of spindled smooth muscle cells (*bottom*) are juxtaposed with sheets of small dark stromal cells (*top*)

Stromal nodules are highly vascular. Small uniformly distributed arterioles are invariably present and can be readily appreciated at low magnification in most, but not all, stromal nodules; sometimes it is necessary to search for them at higher magnification. Large thick-walled blood vessels are occasionally present, especially in areas of smooth muscle differentiation. Hyaline plaques and areas of hyaline fibrosis are common in stromal nodules. Epithelial or sex cord-like arrangements of cells, such as cords or trabeculae of tumor cells or gland-like structures, are sometimes seen in stromal nodules (> Fig. 10.40). If sex cord-like differentiation is especially prominent, a uterine tumor resembling an ovarian sex cord tumor (UTROSCT) should be considered. Uncommon findings that are occasionally noted in stromal nodules include predominance of epithelioid stromal cells with abundant eosinophilic cytoplasm [316], striated muscle cells [251], decidual changes, aggregates of foam cells, cysts, areas of infarction, and calcifications.

Immunohistochemistry and Molecular Pathology

Immunohistochemistry can help confirm the diagnosis of a stromal nodule and it is helpful in the differential diagnosis between a stromal nodule and a highly cellular leiomyoma. Stromal nodules exhibit variable staining for smooth muscle actin and other smooth muscle markers such as desmin and caldesmon [320, 321]. Staining is often weak and focal; staining for desmin and caldesmon is absent in most stromal tumors [104, 309]. Foci of

Focal sex cord-like differentiation in an endometrial stromal nodule. Cords and gland like arrangements of low columnar cells are surrounded by fibrous and endometrial-type stroma

Fig. 10.41

Smooth muscle differentiation in an endometrial stromal nodule. The bundles of smooth muscle cells show strong immunoreactivity for smooth muscle actin, while the surrounding endometrial stromal cells show no staining

smooth muscle differentiation are of course usually positive for all smooth muscle markers (**>** *Fig. 10.41*). CD10 is a good marker for endometrial stromal cells and is positive in nearly all stromal nodules [277]. In stromal nodules with smooth muscle differentiation, staining for CD10 is present in smooth muscle cells as well as in endometrial stromal cells [320]. Endometrial stromal cells show nuclear staining for WT-1 and the cells in stromal nodules are positive for this marker in a majority of cases [401]. Immunostains for estrogen and progesterone receptors are generally positive in endometrial stromal nodules, and some of them exhibit staining for androgen receptors as well [288].

Cytogenetic abnormalities occur in endometrial stomal neoplasms, including endometrial stromal nodules. The most common abnormality is a t(7;17)(p15q21) that results in a JAZF1–JJAZ1 gene fusion [221]. The translocation, which was present in four of four stromal nodules in a recent study [308], can be detected by traditional cytogenetics, as well as by molecular pathologic tests such as reverse transcriptase–polymerase chain reaction and fluorescence in situ hybridization. In stromal nodules with smooth muscle differentiation, the translocation is present both in the endometrial stromal component and in the smooth muscle component, suggesting a common cell of origin for both elements [318]. At present, testing for the translocation is a research procedure, not a clinical diagnostic test.

Differential Diagnosis

The main differential diagnostic considerations are lowgrade ESS and highly cellular leiomyoma. Diagnosis of a low-grade ESS requires identification of more extensive myoinvasion than is allowable in a stromal nodule: invasion >3 mm from the periphery of the nodule or into blood vessels. The maximum allowable distance of invasion of 3 mm is an arbitrary one, chosen to minimize the likelihood that a tumor designated as a stromal nodule will prove to be malignant. When an endometrial stromal tumor is identified in an endometrial biopsy or curettage, it is difficult or impossible to determine whether it is invasive, since the tumor margin cannot be adequately evaluated. The likely diagnosis in such cases is a lowgrade ESS, since stromal sarcomas are far more common than stromal nodules, but it is often necessary to make the nonspecific diagnosis of an "endometrial stromal tumor." It is then usually necessary for the patient to have a hysterectomy for diagnostic purposes to provide adequate visualization of the periphery of the tumor. In some cases, it is possible to identify myoinvasion or vascular invasion in curetted tissue fragments, indicating that the tumor is a stromal sarcoma. It is important to be cautious when considering a diagnosis of stromal sarcoma in curettings, since fragments of a stromal nodule with smooth muscle differentiation can simulate myoinvasion and prompt a mistaken diagnosis of stromal sarcoma [251].

Cellular leiomyomas, especially the variant designated as highly cellular leiomyoma, can be misdiagnosed as endometrial stromal nodules, which they closely resemble

Table 10.7

Immunohistochemical findings in endometrial stromal and smooth muscle tumors

Antibody	Stromal tumor	Smooth muscle tumor
Smooth muscle actin	0 to ++	++ to +++
Desmin	0 to +	++ to +++
Caldesmon	0	++ to +++
CD10	+ to +++	0 to +

Fig. 10.42

Highly cellular leiomyoma. The tumor is circumscribed and cellular like a stromal nodule, but the tumor cells are slightly larger and have more abundant eosinophilic cytoplasm. The blood vessels are larger than in a stromal nodule. The tumor cells showed strong positive staining for desmin, but were CD10 negative

microscopically [321]. They are circumscribed tumors that are composed of small round to oval cells with scanty cytoplasm (> Fig. 10.42). Highly cellular leiomyomas often interdigitate with the surrounding myometrium, and hence microscopically they sometimes appear less circumscribed than a stromal nodule. It is not uncommon to see a transition from round cells with scanty cytoplasm in the center of the tumor to short spindled cells with more abundant eosinophilic cytoplasm at the periphery, to easily recognizable spindle-shaped smooth muscle cells in the surrounding myometrium. Fascicular growth of tumor cells is usually present, at least focally. The cells in highly cellular leiomyomas tend to be larger than those in stromal nodules, and they may have a distinctive rim of eosinophilic cytoplasm. Leiomyomas lack the numerous arterioles that are present in stromal nodules, but they often contain conspicuous large thick-walled blood vessels. Immunohistochemistry can help in the differential diagnosis. Smooth muscle tumors tend to be positive for all commonly used smooth muscle markers, such as smooth muscle actin, smooth muscle myosin, desmin and caldesmon (**)** Table 10.7). They are less likely than stromal nodules to stain for CD10, although some do; staining for CD10, when present, is likely to be weak or focal. Highly cellular leiomyoma shows positive nuclear staining for WT-1, so this marker is not helpful in the distinction between a stromal nodule and a highly cellular leiomyoma. Since the staining patterns of stromal nodules and highly cellular leiomyomas overlap, it is important to

perform a panel of immunostains, typically including CD10, smooth muscle actin, desmin, and caldesmon, and to interpret the results in conjunction with the histology of the tumor.

Clinical Behavior and Treatment

With one exception [214], which was probably an ESS, all stromal nodules reported to date have had a benign clinical evolution [57, 410]. Nevertheless, hysterectomy is usually the appropriate therapy because the periphery of the tumor must be thoroughly evaluated to be certain that it is completely circumscribed and noninvasive. In occasional cases, usually involving tumors occurring in young women, small nodules that can be completely excised by polypectomy or myomectomy may be treated by local excision rather than hysterectomy. Six of the 60 patients reported by Tavassoli and Norris were treated in this fashion and none had a recurrence [410]. In one case, excision of a stromal nodule was possible after a course of treatment with leuprolide acetate [367]. Neither minor irregularities of the margin nor the presence of frequent MF appear to imply an unfavorable prognosis. It is possible that patients with limited myoinvasion beyond 3 mm (i.e., 3 mm to 1 cm and no vascular invasion) may have a favorable outcome, but there is insufficient follow-up of such patients to be certain. It has been proposed that tumors of this type be designated "endometrial stromal tumors with limited infiltration" [109] or as "low grade endometrial stromal sarcoma with limited infiltration" [26].

Endometrial Stromal Sarcoma (ESS)

ESS is a tumor of endometrial stromal cells that invades the myometrium. ESS was traditionally divided into two categories, low-grade and high-grade ESS, but in the current WHO classification only low-grade stromal sarcoma (LGSS) is called ESS [409]. High-grade tumors are now designated as UES. In this chapter (**>** *Table* 10.6), we designate LGSS as "endometrial stromal sarcoma (ESS)" and high-grade tumors as "undifferentiated endometrial sarcoma (UES)." The prevalence of ESS is difficult to estimate because of diagnosis and classification issues. In a recent large study from Norway (which excluded carcinosarcoma), 20% of uterine sarcomas were ESS and 6% were UES [1].

Clinical Features

ESS occurs at an earlier age than most other uterine malignancies. The mean age is between 42 and 53 years [56, 236], and more than 50% of patients are premenopausal. Rare examples occur in young women or girls. There is no association with any of the endometrial carcinoma risk factors, but occasional patients have a history of prior pelvic irradiation. A few cases of ESS have been reported in women treated for breast cancer with tamoxifen. The main symptoms are abnormal vaginal bleeding and abdominal pain [215]. The uterus is typically enlarged and has an irregular contour. A few women have bulky polypoid tumors that protrude from the cervical os. The usual clinical impression is that the patient has a uterine leiomyoma that is causing an exceptional degree of bleeding. Occasional patients present with intra-abdominal or pulmonary metastases. ESS usually cannot be detected on Papanicolaou smears because the cells lack sufficient atypia to permit their differentiation from benign endometrial stromal cells [337].

Stromal tumors that involve the endometrium can be recognized in endometrial biopsies and curettings. A definitive diagnosis of stromal sarcoma can be made if myometrial invasion is identified in the tissue fragments or with imaging studies, but a hysterectomy is usually required to permit the thorough evaluation of the tumor margin necessary to distinguish an ESS from a benign stromal nodule. Because ESS are considerably more common than stromal nodules, a stromal tumor found in an endometrial biopsy or curettage is likely to be malignant. As discussed earlier, endometrial stromal tumors must be differentiated from highly cellular leiomyomas because the treatment of these tumors is quite different. At surgery, ESS may resemble IVL or a leiomyoma that has extended into the parametrium or broad ligament. These entities can usually be distinguished on frozen section examination.

Gross Findings

ESS usually involves the endometrium, sometimes extensively. It forms soft, tan, smooth-surfaced polyps that are occasionally partly infarcted and hemorrhagic (\bigcirc *Fig.* 10.43). By definition, ESS invades the myometrium. There are three main patterns of growth within the myometrium. In the first, the myometrium is diffusely thickened, but a clearly defined tumor is not evident. In the second, there is a nodular tumor with soft, tan or yellow-orange cut surfaces, as opposed to the white, whorled, firm surface of a leiomyoma. In the third, and most frequent, pattern of growth the myometrium is permeated by poorly demarcated pink, tan, or yellow cords and nodules of tumor (\bigcirc *Fig.* 10.44).

ESS grows beyond the uterus as infiltrating masses of tan or white tumor that can be palpated as firm cords in the parauterine tissues. Pink or tan strands of tumor protrude from the cut surface of the infiltrated tissues and sometimes can be pulled from tissue spaces and vessels. Intravenous growth extending into the inferior vena cava has been reported, and in very rare cases there is extension or metastasis to the heart [252, 404].

Fig. 10.43

Endometrial stromal sarcoma. Fleshy tan-white polypoid tumor grows into the endometrial cavity and cords of tumor extensively infiltrate the myometrium, resulting in a thickened uterine wall almost entirely infiltrated by tumor

Endometrial stromal sarcoma. The cut surface of endometrial stromal sarcoma often has a trabeculated appearance caused by diffuse myometrial permeation by cords and nodules of yellow tan tumor. Sometimes, tumor can be grossly identified within vascular spaces. This appearance is quite different from what is seen on the cut surface of a leiomyoma

Microscopic Findings

ESS cells resemble proliferative phase or hyperplastic endometrial stromal cells. ESS are low-grade tumors with cells of relatively uniform size and shape, imparting a monotonous appearance to the tumor. The tumor cells have round or ovoid nuclei with finely granular dispersed chromatin and small, inconspicuous nucleoli (> Fig. 10.45). The cytoplasm is amphophilic, and the cell borders are poorly defined. Rare tumors contain cells with bizarre or multiple nuclei; the nuclei can appear degenerated and have the type of smudged chromatin seen in "symplastic" leiomyomas [27]. Some ESS consist predominantly of spindle-shaped cells that are fibroblastic or myofibroblastic in appearance with fusiform nuclei and elongated cell bodies (> Fig. 10.46) [322, 441]. Such tumors have variable amounts of collagen in the background and at the extreme can appear fibrous. Other unusual variants include tumors in which the cells have clear cytoplasm, abundant eosinophilic cytoplasm resulting in an epithelioid appearance [316, 159], abundant granular eosinophilic cytoplasm resulting in an oxyphilic appearance, and hyaline perinuclear cytoplasmic inclusions resulting in a rhabdoid appearance [273]. Reticulin fibers surround individual cells or small groups of cells in a basket-weave pattern. Mitotic activity is low in most ESS. There are typically <3 MF/10 HPF, but there

Fig. 10.45

Endometrial stromal sarcoma. Endometrial stromal sarcoma is composed of cells that resemble the stromal cells in proliferative endometrium. They have uniform round or oval nuclei, finely granular chromatin, small or no nucleoli, and scanty cytoplasm with ill-defined cell borders

Fig. 10.46

Fibroblastic/myofibroblastic variant of endometrial stromal sarcoma. The tumor cells have oval or fusiform nuclei and are spindled with eosinophilic cytoplasm. There is fibrillar collagenous matrix in the background

can be greater mitotic activity in neoplasms that are otherwise typical of ESS; occasionally there are >10 MF/10 HPF [118]. Proliferation of small vessels and arterioles resembling endometrial spiral arterioles is a characteristic finding (\bigcirc *Fig.* 10.47) that is generally present at least focally in an ESS. The arterioles tend to be uniformly distributed among the stromal cells, and capillaries and small veins are often conspicuous as well. Occasionally whorls of tumor cells surround the arterioles.

Endometrial stromal sarcoma. Note the numerous small blood vessels distributed relatively uniformly among the tumor cells

Fig. 10.48

Endometrial stromal sarcoma. Eosinophilic hyaline material in an endometrial stromal sarcoma. Hyaline plaques and nodules are commonly present in endometrial stromal sarcomas and endometrial stromal nodules, and favor the diagnosis of a stromal tumor over a smooth muscle tumor

Plaques and zones of hyaline fibrosis (**)** *Fig. 10.48*) are common in LGSS, and aggregates of foam cells or foci of necrosis are occasionally noted. Rarely, abundant myxoid stroma widely separates the tumor cells (**)** *Fig. 10.49*; [322]). Tumors with abundant myxoid stroma are classified as myxoid variants of ESS. The stromal cells can show focal or diffuse decidual changes in patients who are pregnant or taking exogenous progestins. Smooth muscle differentiation is not uncommonly present in ESS, as it is in stromal nodules. Tumors in which the proportion of smooth muscle cells exceeds 30% have been classified as

Fig. 10.49 Myxoid variant of endometrial stromal sarcoma. Abundant pale myxoid stroma separates the tumor cells. Scattered inflammatory cells are also present

combined stromal–smooth muscle tumors, but since the stromal component appears to determine the clinical behavior we favor classifying such tumors as ESS with smooth muscle differentiation. Smooth muscle differentiation can take the form of typical smooth muscle cells growing as bundles of spindle-shaped myoid cells with fibrillar eosinophilic cytoplasm, as epithelioid cells that are sometimes embedded in collagen resulting in a "starburst"-like appearance, or as whorls of cells resulting in a vaguely meningothelial appearance [446]. More unusual types of differentiation that occasionally occur in ESS include the presence of striated muscle cells and fat; the clinical significance of striated muscle cells in an ESS is unclear [27].

ESS invades the myometrium and may extensively permeate it (> Figs. 10.50 and > 10.51). Invasion of vascular channels is a characteristic finding (> Fig. 10.52). Immunohistochemical staining for blood vascular and lymphovascular endothelial cells indicates that ESS mainly invades blood vessels. Rare ESS have been identified in association with placental tissues, usually in decidua adjacent to the placenta [210]. Epithelial-like differentiation occurs in about 25% of ESS. It is highly variable in its appearance and can take the form of trabecular cords of epithelioid cells, mesothelial-like tubules lined by cuboidal or low columnar cells with eosinophilic cytoplasm, endometrial-type glands, or glands lined by clear or vacuolated cells (> Fig. 10.53). The epithelial-like pattern is cordlike or trabecular and reminiscent of an ovarian sex cord tumor in some instances. In other tumors, glands lined by columnar endometrial type cells are present focally or extensively within the ESS (> Fig. 10.54) [77].
Endometrial glandular differentiation can make it difficult to recognize that the tumor is a stromal sarcoma, not florid adenomyosis [275]. Findings that favor an ESS with glandular differentiation include an invasive growth pattern, vascular invasion, and the absence of glands in parts of the tumor, which then have the typical appearance of ESS. Glandular differentiation can be present in the uterine primary or in metastatic sites [50, 77].

Immunohistochemistry and Molecular Pathology

Immunostains for cytoplasmic thin and intermediate filaments can be useful in the diagnosis of ESS. Although stromal sarcoma cells are immunoreactive for vimentin, other tumors in the differential diagnosis, such as smooth muscle tumors, are also vimentin positive. Staining for vimentin is therefore mainly used to verify that a tumor is

Fig. 10.50

Endometrial stromal sarcoma. Whole mount showing extensive myometrial invasion by blue stained tongues and nests of tumor cells

Fig. 10.52

Endometrial stromal sarcoma. Vascular invasion is a common finding in endometrial stromal sarcoma. Immunohistochemical staining reveals that the vascular endothelial cells typically stain for CD31 but not for D2-40, suggesting that the invaded vessels are veins, not lymphatic vessels

Fig. 10.51

Endometrial stromal sarcoma. Irregular tongues and prongs of tumor cells invade the myometrium, pushing between bundles of smooth muscle cells

Mesenchymal Tumors of the Uterus

Glands in endometrial stromal sarcoma. Rare endometrial stromal sarcomas contain endometrial-type glands within myoinvasive nests of endometrial stromal cells

Fig. 10.56

Weak desmin staining in an endometrial stromal sarcoma. The surrounding smooth muscle fascicles are strongly positive

Fig. 10.55 No staining for desmin in this endometrial stromal sarcoma. The myometrium, on the left, is strongly positive

adequately preserved for immunohistochemical testing. Immunoreactivity for actin and desmin has been reported in ESS, but our experience, like that of others, is that most ESS either lack these filaments or express them only weakly. Actin, as detected by antibodies to smooth muscle actin, is the more likely of the two to be expressed, and occasional tumors exhibit diffuse strong staining for actin filaments. ESS cells generally either do not stain for desmin (\bigcirc *Fig.* 10.55) or show only focal and weak reactivity (\bigcirc *Fig.* 10.56). Although occasional ESS exhibit diffuse strong staining for desmin, this is uncommon and diffuse strong staining for both actin and desmin suggests that the tumor is a small cell smooth muscle tumor that

simulates a stromal neoplasm or, particularly if the staining is focal, that there is smooth muscle differentiation in the tumor. Of the muscle markers, caldesmon is the one that is least likely to stain ESS tumor cells [360]; it usually stains only areas of smooth muscle differentiation. Staining for keratin is reported in 0–50% of ESS (\bigcirc *Fig.* 10.57; [6]). The frequency of staining depends in part on the keratin antibody that is used. A keratin cocktail that includes AE1/AE3 is most likely to show positive staining, which appears to be mainly due to staining for CK19 [6]. Some authors report that ESS are frequently cytokeratin positive [38], although our experience, like that of others [35], is that only occasional ESS are keratin

Fig. 10.58

Strong staining for CD10 in endometrial stromal sarcoma. Invasive nests of endometrial stromal sarcoma are strongly CD10 positive, while the myometrium is completely CD10 negative

positive. Positive staining can be diffuse or confined to the epithelial-like structures seen in some ESS. Staining for EMA is negative. CD10 is the most useful positive marker for ESS () Fig. 10.58; [8, 35, 64]). The tumor cell cytoplasm often shows strong positive staining for CD10 (> Fig. 10.59), although in some tumors staining is variable and present only focally [277]. Smooth muscle tumors tend to be CD10 negative or show focal weak staining. WT-1 is positive in the tumor cell nuclei in most ESS [8, 84]. Nuclear staining for beta-catenin is reported to be present in ESS, but not in cellular leiomyomas, although the proportion of ESS that show positive staining is as low as 40% [201, 227, 298]. The epithelial or sex cord-like structures that are present in about a quarter of ESS have a mixed epithelial-myogenic phenotype [249]. They may stain for cytokeratin but staining for EMA is negative. They also tend to stain strongly for vimentin, muscle-specific actin, and, in some instances, desmin [315]. Occasionally, these epithelial-like structures stain for calretinin, and the ones that resemble sex cord derivatives can be immunoreactive for inhibin and CD99 (see section **V** Uterine Tumors Resembling an Ovarian Sex Cord Tumor) [28]. ESS is not immunoreactive for CD34; this helps in the evaluation of extrauterine metastases, where the differential diagnosis may include such CD34-positive tumors as hemangiopericytoma and solitary fibrous tumor [35].

Immunostains for proliferation markers such as Ki-67 (MIB-1) stain the nuclei of cycling tumor cells; the percentage of positive nuclei generally correlates with the degree of mitotic activity, which in ESS tends to be low.

Fig. 10.59 Strong positive cytoplasmic staining for CD10 in endometrial stromal sarcoma. This is a characteristic of endometrial stromal sarcomas

Fig. 10.60 Strong nuclear staining for progesterone receptors, in this endometrial stromal sarcoma. Staining for estrogen receptors was also positive

Estrogen and progesterone receptors can be demonstrated in most ESS (**>** *Fig. 10.60*; [35, 351]), and some exhibit positive nuclear staining for androgen receptors [288]. Positive immunohistochemical staining for hormone receptors can be used to guide therapy in those instances in which the clinician is contemplating treatment with progestins or some other form of hormonal therapy. ESS rarely show staining for CD117 (c-KIT) or show c-kit mutations [218, 295, 320]. Nevertheless, a few responses to imatinib therapy have been reported.

A variety of cytogenetic abnormalities have been reported in ESS [364]. The most common is a recurrent translocation involving chromosomes 7 and 17 [t(7;17)(p15;q21)] [94]. Other abnormalities include rearrangements involving the short arm of chromosome 7, especially 7p21~p15 and the short arm of chromosome 6, particularly 6p21. As a result of the (7;17)(p15;q21) translocation, two genes JAZF1 at 7p15 and JJAZ1 (more recently designated as SUZ12) at 17q21 are fused [187, 221]. In the initial report, the fusion was detected in three of three stromal nodules and five of five ESS [221]. Subsequent studies have shown that the fusion can be identified in a majority of ESS but not all of them, and that it can be detected by fluorescence in situ hybridization as well as by reverse transcriptase-polymerase chain reaction testing [187, 189, 227, 308]. A JAZF1/JJAZ1 fusion is less likely to be found ESS variants such as fibrous, myxoid, or epithelioid ESS [189]. The mechanism by which the fusion is involved in the pathogenesis of ESS is unknown.

Chromosomal band $7\sim p21 \rightarrow p15$ is rearranged with other chromosomes than 17 in some ESS [279]. In some tumors, rearrangement with 6p21 results in fusion of the PHD finger protein 1 (PHF1) gene at 6p21 with the JAZF1 gene at 7p15, leading to the formation of a JAZF1/PHF1 fusion gene [280]. Chromosomal band 6p21 is rearranged with translocation partners other than chromosome 7 in some tumors. In about a third of reported tumors no abnormality of 7p15 or 6p21 has been identified [279]. Thus, while alterations involving chromosomes 6, 7, and 17, presumably affecting the PHF1, JAZF1, and JJAZ1 genes, are common in ESS, they are not present in every tumor.

Differential Diagnosis

ESS must be differentiated from other types of endometrial stromal neoplasms. The differential diagnosis between an endometrial stromal nodule and an ESS is based on the presence of myometrial invasion in ESS. This is discussed above, in the section on endometrial stromal nodules. The criteria for differentiating between an ESS and a UES have shifted in recent years, and the differential diagnosis relies less on mitotic counts than in the past. We discuss differential diagnostic criteria in the next section, after we present the pathologic features of UES.

Several uncommon smooth muscle tumors have overlapping features with ESS. It is important to differentiate them from ESS, because their treatment and prognosis is different. Highly cellular leiomyoma is most often confused with an endometrial stromal nodule, but when it has an irregular interdigitating interface with the surrounding myometrium or is detected in an endometrial biopsy or curettage it can mimic an ESS. Highly cellular leiomyoma does not exhibit the type of infiltrative growth into the myometrium that is seen in ESS, nor does it invade vascular spaces. The tumor cells tend to be larger than endometrial stromal cells, and it is often possible to identify more typical spindle-shaped smooth muscle cells, particularly at the interface with the surrounding myometrium. Large thick-walled blood vessels are commonly present, and the small arterioles that are characteristic of ESS are generally not present. Immunohistochemistry can be helpful, since highly cellular leiomyoma tends to show strong diffuse staining for smooth muscle markers such as smooth muscle actin, smooth muscle myosin, desmin, and caldesmon, and extensive staining for CD10 is unusual [8, 65]. IVL can simulate a vascular invasive ESS, particularly when the tumor cells have an epithelioid appearance. However, IVL tends to be a predominantly intravascular tumor, while ESS is primarily extravascular. The tumor cells in IVL tend to be larger than stromal cells. They often have conspicuous eosinophilic cytoplasm, some may be spindle-shaped, and they stain for smooth muscle markers, but usually not for CD10. Prominent large blood vessels and hyalinization can be conspicuous in the intravenous tumor plugs in IVL. Rare tumors show features of both ESS and IVL [277].

Tumors of perivascular epithelioid cells (PEComas) occasionally occur in the uterus [121, 136, 419]. Most are relatively circumscribed neoplasms composed of epithelioid or spindle-shaped cells with moderate to abundant eosinophilic or clear cytoplasm. They tend to grow around or into lymphatic vessels in the myometrium. They often pose a differential diagnostic problem, but it is usually with smooth muscle tumors of various types. Rare perivascular epithelioid cell tumors show tongue-like infiltration of the myometrium, and these need to be differentiated from ESS [419]. The cells in perivascular epithelioid cell tumors have the appearance of modified smooth muscle cells. The tumor cells are larger and have more abundant pale or eosinophilic cytoplasm than the cells of an ESS, and the cytoplasm often has a granular or flocculent character. Immunohistochemistry is particularly helpful in this differential diagnosis, as PEComa cells show at least patchy staining for HMB-45 and various smooth muscle markers, and lack staining for CD10.

Finally, several benign conditions can potentially be confused with ESS. These include adenomyosis with sparse glands, "intravascular" adenomyosis, and intravascular menstrual endometrium. These are illustrated later in this chapter, in the section on adenomyosis. In older

women, foci of adenomyosis can contain few or even no glands, resulting in findings that might be confused with ESS [161]. However, adenomyosis with sparse glands is a focal microscopic finding unassociated with a tumor mass, and it is usually seen in association with foci of typical adenomyosis in which glands are readily apparent. The stromal cells in adenomyosis with sparse glands are atrophic, and sometimes the foci have a fibrotic appearance. Distribution of the stromal cells tends to be zonal, with low cellularity centrally, resulting in a pale appearance, and greater cellularity at the periphery, resulting in a dark blue-purple rim. Occasionally, small foci of adenomyosis appear to be within vascular spaces [362]. Particularly when glands are sparse, this finding raises the differential diagnosis of ESS. Intravascular adenomyosis is a microscopic finding that is not associated with a tumor mass, glands are usually present among the stromal cells, and foci of typical adenomyosis are generally present in the adjacent myometrium. Rarely, fragments of menstrual or non-menstrual endometrium are detected within vascular spaces in a hysterectomy specimen [29]. These are likely an artifact associated with surgery or tissue processing. They are differentiated from ESS by the presence of glands among the stromal cells and absence of a tumor mass.

Clinical Behavior and Treatment

The extent of tumor, the type of surgical intervention, and, possibly, certain pathologic parameters determine the risk of recurrence. The tumor stage is the most significant prognostic factor. Hysterectomy and bilateral salpingooophorectomy is the standard treatment for stage I stromal sarcoma, with debulking of extrauterine tumor performed in more advanced cases. Some gynecologic oncologists remove the adnexa, even in young women, because adnexal spread is not always visible at surgery, ESS generally contain estrogen receptors and the residual tumor cells might be stimulated by estrogen secreted by the ovaries, and some studies have suggested that recurrence is more frequent when the adnexal structures are conserved [248]. A number of studies suggest, however, that salpingo-oophorectomy may not be necessary in young women whose adnexa appear normal, as an adverse outcome has not observed in patients whose ovaries have been conserved [12, 56, 57, 247]. Conservative approaches to treatment are sometimes considered in young women when preservation of fertility is an important consideration. If the uterus is small, and if the tumor is low grade and circumscribed or delimited on hysteroscopy or MRI, gynecologic oncologists sometimes attempt to treat ESS by local excision. Unfortunately, our experience has been that this is rarely successful and the tumor tends to recur within a year or two.

Even when the tumor appears confined to the uterus (stage I), there is a high risk of pelvic recurrence, ranging from 25% to 50% [42, 57, 146]. The risk of recurrence is even greater in patients with advanced-stage tumors [57]. Some oncologists recommend postoperative progestin therapy for ESS with the hope of reducing the risk of recurrence [63], but many patients are unable to tolerate long-term treatment; more recently aromatase inhibitors have been used as they are better tolerated [350]. ESS grows slowly, and recurrences are often not detected until many years after initial treatment. Most recurrences are in the pelvis and involve the pelvic soft tissues, ureters, bladder, vagina, or bowel [146]. Metastases in the abdomen involve the peritoneal surfaces or omentum. A few patients develop pulmonary metastases, which can be difficult to diagnose, especially if the interval between resection of the primary tumor and detection of the metastases is long [2, 24, 256, 365]. Recurrent or metastatic ESS can be stabilized or suppressed with progestational agents in more than 50% of patients [63, 93, 336]. Tumors with a high level of progesterone receptors are most likely to respond to progestin therapy. A few patients with recurrent tumors have been treated with GnRHa or aromatase inhibitors with favorable results in reported cases [52, 223, 243, 336]. Recurrent or metastatic ESS that do not respond to treatment with progestins can sometimes be treated surgically or with radiotherapy. Chemotherapy tends to be ineffective. ESS is a slowly progressive tumor and, in those patients who ultimately die of tumor, the median time from diagnosis to death ranges up to about 11 years. Despite the high frequency of recurrences, women with stage I low-grade ESS have a 5-year survival rate in excess of 80% [236]. The outcome is less favorable for women with advanced-stage tumors, for whom 5-year survival rates of 40-50% have been reported. Recurrent ESS occasionally transform into higher-grade sarcomas, with increased nuclear atypia and mitotic activity and loss of response to hormone therapy [15].

Undifferentiated Endometrial Sarcoma (UES)

Most monophasic endometrial sarcomas are low-grade tumors, classified, as indicated above, as ESS. Only about a quarter of endometrial sarcomas are high grade, based on their pathologic features and clinical behavior. In one recent study, 6% of uterine sarcomas were classified as high grade (UES) and 20% as low grade (ESS) [1]. Some high-grade endometrial sarcomas are composed of monotonous cells that bear at least some resemblance to endometrial stromal cells. Others consist of pleomorphic cells reminiscent of the cells in the mesenchymal component of a carcinosarcoma. The former were designated as high-grade ESS in the past, but in the current WHO classification of uterine tumors all high-grade endometrial sarcomas are grouped together in the UES category [409]. Nevertheless, the histology, immunohistochemistry, and molecular genetics of UES suggest a relationship between monomorphic UES and ESS, while pleomorphic UES appears to be unrelated to ESS.

Clinical Features

The average age of women with UES is 55–60 years [99]; in one study, monomorphic tumors occurred in younger patients than pleomorphic tumors [227]. The most common symptom is abnormal uterine bleeding. Uterine enlargement is the most common physical finding. In some patients the tumor prolapses through the cervical os. A significant proportion of patients have extrauterine tumor spread at diagnosis, either to the pelvic lymph nodes, the upper abdomen, or to distant sites such as the lungs (i.e., stage III or IV tumors) [236].

Gross Findings

UES grow as soft, fleshy, polypoid tumors that bulge into, and often fill, the endometrial cavity (**>** *Fig. 10.61*). Multiple masses of soft, white-to-tan tumor invade the underlying myometrium on a broad front. Hemorrhage and necrosis are frequently present.

Microscopic Findings

UES most often grows as a polypoid tumor that projects into the endometrial cavity and invades the underlying myometrium. Myometrial invasion tends to be along a broad front (\bigcirc *Fig.* 10.62), with destruction and replacement of involved areas of myometrium. Tumor cell necrosis is generally present and can be extensive (\bigcirc *Fig.* 10.63). The uniform proliferation of small blood vessels that is seen in ESS is not present in UES [118], where there is a haphazard distribution of variably sized blood vessels.

Fig. 10.61

Undifferentiated endometrial sarcoma. The tumor is polypoid and fills the endometrial cavity. The cut surface is tan-white, and there are extensive zones of necrosis at the top

Fig. 10.62 Undifferentiated endometrial sarcoma. There is extensive deep myoinvasion.

Vascular invasion by tongues and plugs of tumor is present in most tumors (\bigcirc *Fig.* 10.64). UES can be divided into monomorphic and pleomorphic variants; the former were previously designated as high-grade ESS. Monomorphic UES are composed of relatively uniform tumor cells that bear some resemblance to endometrial stromal cells. However, the tumor cells are larger and have medium-sized atypical nuclei (\bigcirc *Fig.* 10.65). The chromatin ranges from finely granular to coarse and nucleoli are of small to medium size. Tumor cell cytoplasm is eosinophilic or amphophilic and cell borders are indistinct. MF tend to be numerous. Fibromyxoid patterns of growth in which the tumor cells are spindled or separated by myxoid

Undifferentiated endometrial sarcoma with coagulative tumor cell necrosis, (on the left,) is often present. Only ghostlike outlines of the degenerative tumor cells are visible in the necrotic zone

Fig. 10.65

Undifferentiated endometrial sarcoma, monomorphic type. The cells have relatively uniform nuclei that bear some resemblance to endometrial stromal cells. However, they are larger and more atypical with coarse chromatin and small nucleoli. Mitotic figures are typically numerous

Fig. 10.64

Vascular invasion by an undifferentiated endometrial sarcoma. The endothelial cells lining a vein are immunoreactive for CD31, while the tumor cells in the vein lumen show no staining

Fig. 10.66

Undifferentiated endometrial sarcoma, pleomorphic type. The tumor cells vary greatly in size and shape. The nuclei are markedly atypical and range from medium-sized to large. Multinucleated cells are present. The cytoplasm is eosinophilic and varies from scant to abundant

stroma are occasionally present in UES. In pleomorphic UES the tumor cells are large and atypical with considerable variation in nuclear size and shape and prominent nucleoli (**?** *Fig. 10.66*). Giant cells, some with multiple nuclei, are present in some tumors. MF are numerous, and atypical MF are often noted. Spindle-shaped cells tend to predominate in pleomorphic UES, but epithelioid or rhabdoid cells are present in many tumors and predominate in some of them. The cytoplasm, which ranges from eosinophilic to amphophilic, is more abundant and better delimited than in monomorphic UES. Mitotic activity is variable in both types of UES but there are usually \geq 10 MF/10 HPF, and not uncommonly there are \geq 20 MF/10 HPF in the most active areas. The finding of occasional cases in which there is an admixture of ESS and UES, usually of the monomorphic type, indicates that, at least occasionally, an ESS can evolve into a higher-grade sarcoma [61, 227].

Immunohistochemistry and Molecular Pathology

Immunohistochemistry is not as helpful in the evaluation of UES as it is in ESS. This is partly because UES comprises a heterogeneous group of neoplasms and partly because reactivity for many antigens, including hormone receptors, is lost in some of these poorly differentiated tumors. Some UES lack staining for CD10, while staining is present in others (**)** Fig. 10.67). When present, staining for CD10 tends to be focal and of variable intensity [8, 201]. Staining for smooth muscle markers is absent in most tumors, and when present it is weak and focal [8]. Staining for smooth muscle markers is seen less often in UES than in ESS. Nuclear staining for beta-catenin is reported to be present in a majority of UES, but this is not associated with betacatenin mutations, which are not present [201]. Estrogen and progesterone receptors are present in about 50% of monomorphic UES, but they are rarely present in pleomorphic UES [227].

The (7;17)(p15;q21) translocation that is present in low-grade endometrial stromal tumors, in which two genes, JAZF1 at 7p15 and JJAZ1 (more recently designated as SUZ12) at 17q21 are fused, has also been detected in some UES. In the initial study reporting the JAZF1/JJAZ1 fusion, it was detected in three of seven high-grade stromal sarcomas [221]. The authors commented that two of the high-grade stromal sarcomas would be classified as "undifferentiated ESS" by some, and that of these two, one showed the fusion and the other did not. More

Fig. 10.67

Positive staining for CD10 in this undifferentiated endometrial sarcoma. Note absence of staining in the myometrium. Other examples of UES show minimal or no staining for CD10 recently, the fusion was detected in one of three monomorphic UES, but in none of three pleomorphic UES [227]. In the same study, the fusion transcript was detected in 50% of ESS. In another study, the fusion transcript was not detected in either of two UES [187]. A study of genes that are deregulated in endometrial sarcomas revealed that some of the most deregulated genes were those of secreted frizzled-related proteins, which are thought to be modulators of the Wnt-signaling pathway [188]. Decreased expression of secreted frizzledrelated protein 4 was detected in both ESS and UES.

Differential Diagnosis

Distinction between ESS and UES can be difficult, since the tumor cells can have a somewhat similar appearance. The tumor cells in UES tend to be larger and to exhibit greater nuclear atypia. Mitotic activity is no longer considered to be the only criterion for distinguishing between ESS and UES, as it once was. Occasional ESS have >10 MF/10 HPF and UES can have <10 MF/10 HPF. As a general rule, however, MF are infrequent in ESS and they are numerous, usually >10/10 HPF, in UES. The uniform distribution of small arterioles that is characteristic of ESS is absent in most UES. When ESS invades the myometrium tongues of tumor cells, often with smooth or rounded contours, appear to push between smooth muscle bundles. On the other hand, UES invades the myometrium on a broad front with destruction of the myometrium.

Leiomyosarcoma is almost always considered in the differential diagnosis of UES. Small cell and epithelioid variants of leiomyosarcoma can mimic monomorphic UES, and other types of leiomyosarcoma can resemble pleomorphic UES. The location of the tumor can help in the differential diagnosis. UES usually involves the endometrium as well as the myometrium, while leiomyosarcoma tends to be limited to the myometrium. The presence of areas typical of leiomyosarcoma, with tumor cells having fusiform nuclei with rounded ends and fibrillar eosinophilic cytoplasm favors a diagnosis of leiomyosarcoma. Staining for actin, desmin, and caldesmon can help in the differential diagnosis since leiomyosarcoma is often immunoreactive for these markers, whereas UES is typically negative. Strong positive staining for actin, desmin, and/or caldesmon therefore favors leiomyosarcoma, but negative staining is uninformative, because a significant proportion of poorly differentiated leiomyosarcomas also fail to stain for these filaments.

Rhabdomyosarcoma is uncommon in the uterus, but it does occur, usually in older women in the same age

range as UES. If rhabdomyoblastic differentiation is not appreciated, the tumor is likely to be misdiagnosed as UES. Diagnostic rhabdomyoblasts range from round cells with round or oval nuclei and rims of eosinophilic cytoplasm to spindle cells with fusiform nuclei and abundant eosinophilic cytoplasm, in which cross striations can sometimes be identified. Less-differentiated rhabdomyoblasts cannot be differentiated from UES cells by routine microscopic examination. Immunohistochemistry is essential for the diagnosis of rhabdomyosarcoma. There is strong cytoplasmic staining for desmin, and there is nuclear staining for myogenin. Staining for both of these markers tends to be patchy within the tumor, and usually more cells stain for desmin than for myogenin. Myogenin is the more specific marker, as it stains only cells showing striated muscle differentiation, while desmin stains smooth muscle cells as well as rhabdomyosarcoma cells.

Adenosarcoma, especially when there is sarcomatous stromal overgrowth, and carcinosarcoma (MMMT) both enter the differential diagnosis of UES. These tumors both have epithelial as well as mesenchymal components. In adenosarcoma, the epithelium is histologically benign, while the epithelial component of a carcinosarcoma is a carcinoma. The mesenchymal components of these tumors frequently resemble UES, either of monomorphic or polymorphic type. The key to the correct diagnosis is to note that the tumor has an epithelial component. This is usually not difficult in an adequately sampled carcinosarcoma. Adenosarcoma poses greater diagnostic difficulty, since it is sometimes difficult to decide whether benign glands represent part of the tumor or entrapped glands where the tumor infiltrates the endometrium or foci of adenomyosis. When glands are distributed throughout the mesenchymal component, even in relatively small numbers, a diagnosis of adenosarcoma is appropriate.

Undifferentiated endometrial carcinoma must be differentiated from UES, especially monomorphic UES. Undifferentiated endometrial carcinoma has only been widely recognized as a distinct clinicopathologic entity for a few years [10], and it is likely that undifferentiated carcinomas have been misdiagnosed as undifferentiated sarcomas or high-grade ESS in the past. Undifferentiated carcinomas are composed of sheets of poorly cohesive, intermediate-sized cells, which sometimes have a rhabdoid appearance, with eosinophilic cytoplasm and eccentric nuclei [10]. They differ from UES in that the cells are rarely spindle-shaped or pleomorphic, at least some tumor cells express cytokeratins (especially CK18) and EMA, and lymph node metastases are frequently present at the time of diagnosis.

Clinical Behavior and Treatment

UES is relatively uncommon, and its clinical behavior is difficult to evaluate because differences in diagnostic criteria make it impossible to differentiate between treatment results for ESS and UES in many series. Also, some reports have included other types of high-grade sarcomas such as rhabdomyosarcoma or leiomyosarcoma.

Treatment includes hysterectomy and, in most cases, radiation therapy and/or chemotherapy depending on the stage of the tumor. Reported 5-year survival rates vary. In recent reports in which diagnostic criteria are clear, survival has been poor, and related to stage. Most women with extrauterine disease at diagnosis develop recurrences and die of tumor [42, 227]. Women with stage I tumors have a better prognosis, but a stage I tumor is no guarantee of survival, as shown in Evans' original study in which six of seven patients with UES, all confined to the uterus at diagnosis, died of tumor [118]. In a study of Italian women with UES, 55% of patients with disease confined to the uterus had a recurrence, as did 75% of those with extrauterine disease at diagnosis [146]. Overall survival is significantly lower for women with UES than for those with ESS [146, 236]. In one study, cytoreductive surgery improved survival for patients with extrauterine tumor spread [236]. Pelvic recurrences are fewer, and survival is better in patients with low-stage disease who are treated with combined surgery and radiotherapy. Recurrence outside the radiation field is the most common reason for treatment failure in a patient who has had combined therapy. An effective chemotherapy regimen is not available, and most UES do not express progesterone receptors or respond to hormonal therapy.

Endometrial Stromal Tumor Variants

There are two types of neoplasms containing endometrial stroma that can be viewed as variants of endometrial stromal nodules or sarcomas. One is a combined smooth muscle–stromal tumor and the other is a tumor that resembles, at least focally, an ovarian sex cord tumor.

Combined Stromal–Smooth Muscle Tumor

Focal areas of smooth muscle differentiation are commonly observed in endometrial stromal tumors, but tumors with extensive areas of both smooth muscle and endometrial stromal differentiation are rare. It is

sometimes possible to demonstrate the (7;17)(p15;q21)translocation that characterizes endometrial stromal tumors in both the stromal and smooth muscle components of combined tumors [318]. Since smooth muscle cells are more differentiated than stromal cells, this likely indicates that the smooth muscle element of combined tumors is derived from the stromal component by a process of metaplasia. We currently classify combined tumors as endometrial stromal nodules or ESS with smooth muscle differentiation, depending on whether the tumor margin is circumscribed (stromal nodule) or invasive (stromal sarcoma), since the clinical behavior is determined by the stromal component. Tumors with prominent smooth muscle differentiation are discussed at greater length here. In the past, combined smooth muscle-stromal tumors were arbitrarily defined as neoplasms having at least 30% of each component [69, 317, 410]. The components tend to be sharply demarcated, although they occasionally merge into each other. Tumors with circumscribed margins are more common than those with infiltrating margins.

The stromal elements are typical of an endometrial stromal neoplasm and consist of uniform small cells with round nuclei and scanty cytoplasm. Small thin-walled blood vessels are scattered uniformly throughout the stromal component, and epithelial-like structures are present in some tumors. The immunophenotype of the stromal cells is identical to that observed in other endometrial stromal tumors. In most tumors, the stromal cells do not stain for desmin or caldesmon, or only scattered cells stain. Staining for smooth muscle actin shows a similar pattern, although in some tumors staining is more extensive or more intense. The smooth muscle elements grow in fascicles (> Fig. 10.68), irregular circumscribed aggregates of spindle cells surrounded by stromal cells, or nodules within which the tumor cells are embedded in collagenous stroma, sometimes resulting in a "starburst"-like appearance (> Fig. 10.69). The smooth muscle cells vary in appearance from typical spindle-shaped smooth muscle cells with abundant eosinophilic cytoplasm to rounded epithelioid cells with clear or amphophilic cytoplasm; the latter type predominate in the collagenous nodules. Despite their variable appearance, the smooth muscle cells have a typical immunophenotype and show uniform strong positive staining for smooth muscle actin (> Fig. 10.70), desmin (> Fig. 10.71), and caldesmon (> Fig. 10.72). Large, thick-walled blood vessels are typically present in the smooth muscle areas.

The clinical evolution of combined smooth muscle– stromal tumors is poorly documented, but tumors with an infiltrative margin are ESS capable of recurrence or

Fig. 10.68

Endometrial stromal tumor with smooth muscle differentiation. In this example, the two components are separate. A small amount of the endometrial stromal component is present at the upper right. The smooth muscle component grows as fascicles of spindle-shaped cells with eosinophilic cytoplasm

Fig. 10.69

Endometrial stromal tumor with starburst pattern and smooth muscle differentiation. Epithelioid smooth muscle cells are embedded in a collagenous matrix and appear to radiate from the center. Smaller endometrial stromal cells surround this structure, and are best seen at the right

metastasis, whereas those with a circumscribed margin are benign endometrial stromal nodules [69, 317]. A tumor in which the smooth muscle elements show features of leiomyosarcoma such as significant nuclear atypia, a high mitotic rate, and necrosis presumably would have the potential to metastasize, but no case of this type with documented metastases has been reported to date. Some neoplasms that were reported as "stromomyomas" are endometrial stromal tumors in

Endometrial stromal tumor with smooth muscle

differentiation. Strong positive staining for smooth muscle actin differentiates the smooth muscle elements in this endometrial stromal tumor with smooth muscle differentiation from the surrounding stromal cells, which are SMA negative

Fig. 10.71

Endometrial stromal tumor with smooth muscle differentiation. The smooth muscle cells show strong desmin positivity, while the stromal cells do not stain for desmin

which there are trabeculae and cords of cells that exhibit ultrastructural features of smooth muscle differentiation [408]. This finding is not surprising because the epitheliallike structures commonly seen in endometrial stromal tumors often have a myogenous immunophenotype, and such tumors are best classified as endometrial stromal tumors, not combined neoplasms. At present, the diagnosis of a combined tumor is based solely on the presence of significant amounts of both elements as recognized by routine light microscopy.

Fig. 10.72 Endometrial stror

Endometrial stromal nodule with extensive smooth muscle differentiation. The smooth muscle cells are immunoreactive for caldesmon, while the stromal cells show no staining

Uterine Tumors with Sex Cord-like Elements

The tumors in this category were initially described by Clement and Scully, who separated them into two types [72, 91]. Type I tumors are endometrial stromal nodules or sarcomas, some having been shown to harbor the JAZF1–JJAZ1 gene fusion [187, 318], in which there are significant areas (>10% of the tumor) of epithelial-like structures that have an appearance reminiscent of an ovarian sex cord-stromal tumor. Tumors of this type are commonly referred to as endometrial stromal tumors with sex cord-like elements (ESTSCLE). The sex cord-like cells range from small, cuboidal, or polygonal cells with scanty amphophilic or eosinophilic cytoplasm to plump polygonal cells with pale foamy or granular eosinophilic cytoplasm. Their nuclei often resemble those of the surrounding stromal cells. The sex cord-like cells grow in cords, trabeculae, or nests, or form tubules (**>** *Fig. 10.73*). Immunohistochemical tests to elucidate their nature yield variable results. There is most often a mixed epithelialmyoid phenotype, with immunoreactivity for cytokeratin and actin, and, in some cases, desmin [28, 249]. Immunostains for EMA are almost always negative. In accord with the resemblance to a sex cord tumor, immunoreactivity for sex cord markers such as calretinin, inhibin, and CD 99 are detected in the sex cord-like structures in about a third of type I tumors [28, 195].

Type II tumors, which consist predominantly or exclusively of sex cord-like elements, are often referred to as uterine tumors resembling ovarian sex cord tumors

Uterine tumor resembling an ovarian sex cord tumor (UTROSCT). Trabeculae of darkly stained cells resemble ovarian sex cords. The nuclei of the cells in the cords resemble those in the surrounding stromal cells in this stromal tumor with prominent sex cord elements (ESTSCLE)

(UTROSCT). UTROSCT are intramural or submucosal nodules surrounded by myometrium or polypoid tumors that grow into the endometrial cavity. They are yellow or tan and have a circumscribed or slightly irregular periphery. The average diameter is 6-7 cm. Microscopically, most are circumscribed, but examples with infiltrative margins and, rarely, vascular invasion have been reported [195, 395]. The tumor cells form plexiform cords, trabeculae, and nests, and may line well-formed tubules with lumens (**>** *Fig. 10.74*). Glomeruloid formations or tubules with a retiform appearance are occasionally present [92, 195]. In some tumors, retiform tubules dominate the histologic picture, and it has been proposed that these neoplasms should be designated as retiform uterine tumors resembling ovarian sex cord tumors (RUTROSCT) [303]. The tumor cells have uniform small bland nuclei with inconspicuous nucleoli, and MF are rare, typically <3 MF/10 HPF. The cytoplasm varies from scant to moderate and eosinophilic to abundant and foamy, and the cells are cuboidal or columnar in shape. Sertoliform cells, polygonal cells with eosinophilic or foamy cytoplasm (> Fig. 10.75), or cells resembling granulosa cells are present in some tumors. The stroma ranges from endometrial-like to hyaline or fibrous and smooth muscle is present in some type II tumors. Stroma accounts for less than 50% of the tumor and is often scanty in type II tumors. The histogenesis of type II tumors is unclear, with an origin from endometrial stroma or uncommitted cells in the uterus having been proposed. Recently, it has been shown that these tumors do not

Fig. 10.74 Uterine tumor resembling an ovarian sex cord tumor (UTROSCT). The low columnar tumor cells grow in a tubular pattern with scanty stroma

harbor the JAZF1–JJAZ1 gene fusion that characterizes endometrial stromal tumors, indicating that they are unlikely to be endometrial stromal neoplasms [395]. Diverse immunohistochemical results have been described in tumors of this type, but the sex cord-like structures are usually immunoreactive for vimentin, cytokeratin, sex cord markers including calretinin (**>** *Fig.* 10.76), inhibin (**>** *Fig.* 10.77), CD 99, Melan-A, CD56, WT-1, and, often, smooth muscle actin or desmin [28, 191, 195, 224, 320]. Immunostains for EMA have been reported as negative in most tumors, but weak to moderate staining was reported in one study of four cases [191]. Positive staining for estrogen and progesterone receptors is often present [224]. Positive staining for two or more markers of sex cord differentiation is seen in most UTROSCT [195]. The immunophenotype, together with the absence of heterologous mesenchymal elements and clear-cut carcinoma, helps to differentiate these rare tumors from a MMMT.

Clinically, uterine tumors with sex cord-like elements occur in middle-aged women; the average age is around 50

• Fig. 10.76 Uterine tumor resembling an ovarian sex cord tumor (UTROSCT). Sex cord-like tubules show strong positive staining for calretinin in this UTROSCT

Fig. 10.77

Uterine tumor resembling an ovarian sex cord tumor

(UTROSCT). Cord-like arrangements of cells, many with foamy cytoplasm, show modest but definite staining for inhibin in this UTROSCT

[91, 395]. The main symptom is abnormal bleeding or pelvic pain. Most patients have an enlarged uterus or a palpable uterine mass. Although type I and II tumors have a similar presentation, the clinical behavior differs. Type I tumors (ESTSCLE) are endometrial stromal tumors with a focal sex cord pattern; those with circumscribed margins are benign, but those with infiltrating margins behave as low-grade ESS. In Clement and Scully's initial report, three of five patients with follow-up had recurrences and two died [72]. In their review of the literature, Baker et al. found that about 15% of reported cases were known to have recurred [28]. Type II tumors (UTROSCT), on the other hand, usually have a benign clinical evolution, although rare examples exhibit more aggressive behavior [36]. Conservative management may be possible in a young woman when conservation of fertility is a consideration [179].

Mixed Epithelial–Mesenchymal Tumors

Mixed epithelial–mesenchymal tumors contain both epithelial and mesenchymal elements as active participants in the neoplastic process (**)** *Table 10.8*). The tumors in this group are morphologically, but perhaps not histogenetically, related. The mixed epithelial–mesenchymal tumor group includes adenofibroma and adenosarcoma. MMMT, or carcinosarcoma, is included in this group in many classifications of uterine tumors, including the one published by the WHO [409]. Recent biologic and clinical

Table 10.8

Mixed epithelial-mesenchymal tumors of the uterus

Tumor	Malignant potential	Epithelium	Mesenchymal component
Adenofibroma	None; benign	Benign	Benign, homologous
Adenosarcoma	Low	Benign	Malignant, homologous or heterologous ^a
Carcinosarcoma (mixed müllerian tumor)	High	Carcinoma	Malignant, high grade, homologous or heterologous

^aUsually low grade and homologous, but can be high grade and heterologous especially in cases with sarcomatous stromal overgrowth (see text).

studies, however, suggest a close relationship between MMMT and endometrial carcinoma, and MMMT is often considered to be a special type of sarcomatoid or metaplastic carcinoma. In this book, MMMT is discussed in **O** Chap. 9, Endometrial Carcinoma.

Adenofibroma

Adenofibroma is a benign biphasic neoplasm that typically occurs in the endometrium, although occasionally it arises in the cervix or at an extrauterine location [445].

Clinical Features

Women with adenofibroma tend to be elderly [445]. The median age is 68 years, and most patients are peri- or postmenopausal. Despite a predilection for the elderly, adenofibroma occurs in women of all ages, from <20 years to >80 years. There is no known association with race, nor does adenofibroma have the epidemiologic features of endometrial carcinoma. Abnormal vaginal bleeding is the most frequent complaint. Less common findings include abdominal pain, abdominal enlargement, or a polypoid tumor projecting from the cervix. Some patients have a history of prior removal of polyps.

Gross Findings

Adenofibroma is a lobulated polypoid tumor that can arise anywhere in the uterus or in the cervix. It varies from soft to firm and is tan or brown. About 50% of adenofibromas contain small cysts that give the cut surface a spongy or mucoid appearance. The tumor ranges from 2 to 20 cm in maximum diameter, with a median of 7 cm. A large adenofibroma may fill the endometrial cavity and enlarge the uterus.

Microscopic Findings

Adenofibroma is composed of a mixture of histologically bland epithelium and mesenchyme. It originates in the endometrium or cervix. Broad papillary or polypoid stromal fronds covered by epithelium project from the surface of the neoplasm or extend into cystic spaces within it (**>** *Fig. 10.78*). Columnar or cuboidal epithelial cells, most often of endometrioid type, line cysts and cleft-like spaces. A mixture of various types of epithelia, including

Fig. 10.78 Adenofibroma. Cleft-like glands and polypoid stromal projections are lined by benign epithelium in adenofibroma

endocervical, tubal, and squamous, often occurs within the same neoplasm. The epithelium can be hyperplastic and stratified, but when this is the case the possibility that the tumor might be an atypical polypoid adenomyoma should be carefully considered. Endometrioid and serous carcinoma have both been reported in an adenofibroma; in such cases the behavior is determined by the carcinoma and the patient should be treated accordingly [282, 423].

The mesenchymal component is usually fibrous, consisting of fibroblasts and collagen (\bigcirc *Fig. 10.79*), but mixtures of endometrial stromal cells and fibroblasts are present in some neoplasms. The cellularity of the stroma is generally low, and there is no periglandular condensation of stromal cells. The mesenchymal cells exhibit no nuclear atypia or mitotic activity. Rarely, histologically benign heterologous elements such as fat or skeletal muscle are present [182, 384]. Adenofibromas are usually confined to the endometrium or cervical mucosa, and do not invade the underlying myometrium or cervical stroma (\bigcirc *Fig. 10.80*). Two unique adenofibromas that invaded the myometrium, and, in one case, myometrial veins, have, however, been reported [75].

Differential Diagnosis

It can be difficult to differentiate between an adenofibroma and a benign endometrial or endocervical polyp. A papillary configuration or a vaguely "phyllodeslike" pattern in which polypoid stromal cores covered by benign epithelium project from the surface or into cystically dilated glands favors an adenofibroma. The

Adenofibroma. The epithelium in an adenofibroma is benign, and in this example it is of endometrioid type. The stromal cells are benign and have pale oval or fusiform nuclei and ill-defined cell borders. No mitotic figures are present. The background contains delicate collagen fibers and blood vessels are conspicuous

Fig. 10.80 Adenofibroma. A typical superficial tumor that is limited to the endometrium and does not invade the myometrium

stromal component of an adenofibroma tends to be more fibrous and more uniform than the stroma of a typical polyp.

The most important differential diagnosis is with adenosarcoma since these tumors have a somewhat similar appearance at low magnification. In the past, this differential diagnosis rested on finding hypercellular or atypical stroma with >4 MF/10 HPF in an adenosarcoma

[204, 445]. Over time the diagnostic criteria for adenosarcoma have been broadened to the point that some authors now doubt the existence of adenofibromas [148]. We think that adenofibroma can be diagnosed, but it is necessary to examine the entire tumor to rule out the presence of abnormal areas indicative of adenosarcoma; this usually requires a hysterectomy. Features that are indicative of adenosarcoma include hypercellular periglandular stroma, stromal cell atypia, and virtually any detectable mitotic activity. A practical approach is to classify any tumor with the appropriate architecture, a cellular or atypical stroma, and more than a rare MF as an adenosarcoma. Occasionally, a problematic adenofibromatous tumor occurs in a young woman where conservation of fertility is an important consideration. Such tumors can be designated as "atypical adenofibromatous tumors," but the pathology report should contain a note cautioning that a recurrence could have fully developed features of an adenosarcoma.

Clinical Behavior and Treatment

Hysterectomy is the preferred treatment for an adenofibroma because the neoplasm may recur if it is incompletely curetted or excised. Hysterectomy ensures complete removal, and also permits the thorough sampling needed to exclude an adenosarcoma. Conservative therapy, such as hysteroscopy with repeat curettage, can be considered in situations in which hysterectomy is not the first choice of treatment, such as in a young woman who wishes to preserve her fertility. Adenofibroma is benign and no tumor-related deaths have been reported. Both of the previously mentioned patients with myoinvasive adenofibromas were well after hysterectomy [75], but the prognosis is less clear-cut when an adenofibroma exhibits unusual gross or microscopic features.

Adenosarcoma

Initially reported by Clement and Scully [71], adenosarcoma is a biphasic tumor with benign epithelial elements and a sarcomatous stroma. It most often occurs in the endometrium, but it is also found in the cervix and in extrauterine pelvic locations [73, 114, 148, 193, 198], such as the fallopian tube, ovary, and paraovarian tissues. Rarely, synchronous tumors occur in the uterus and an extrauterine site, such as the ovary.

Mesenchymal Tumors of the Uterus

Clinical Features

Adenosarcoma occurs in women of all ages. The median age is 50–59 years, with a range of 15–90 years [40, 76, 148, 204, 445]. Extrauterine adenosarcoma occurs in younger women and is more aggressive than its uterine counterpart.

There is no association of adenosarcoma with obesity or hypertension. A few patients have a history of prior pelvic radiation [76]. Occasional patients are diabetic. A few cases of adenosarcoma have been reported in women who have been treated for breast cancer with tamoxifen [19, 70, 148, 290]. Some patients have recurrent cervical or endometrial polyps and give a history of one or more prior polypectomies.

The most common presenting symptom is abnormal vaginal bleeding [424]. Vaginal discharge, pain, nonspecific urinary symptoms, a palpable pelvic mass, and a tumor protruding from the cervix are other common signs and symptoms. Most patients have stage I tumors at the time of diagnosis [40, 76, 148, 445].

Gross Findings

Adenosarcoma most often arises in the endometrium and fills the uterine cavity, often resulting in an enlarged uterus [76]. Rare tumors grow as nodules in the myometrium, presumably arising in adenomyosis [162, 314]. Adenosarcoma arises in the cervix in 5–10% of cases [148, 198, 204, 213, 260]. Adenosarcoma is usually polypoid and averages 5–6 cm in maximum dimension (\triangleright *Fig. 10.81*), although it occasionally grows as multiple papillary or polypoid masses. It can be either soft or firm. The cut surface is tan, brown, or gray, and zones of hemorrhage and necrosis are observed in about 25% of adenosarcomas. Small cysts are present in most tumors.

Microscopic Findings

Tubular glands and cleft-like spaces are distributed throughout the tumor, and papillary stromal fronds covered by epithelium project from the surface and into cysts (**>** *Fig. 10.82*), resulting in a phyllodes tumor-like appearance [76, 445]. The surface and glandular epithelium most often resembles inactive or proliferative endometrial epithelium. Many other types of epithelium also occur in adenosarcoma, including secretory, mucinous, squamous, and clear cell. The epithelium typically is cytologically bland, but hyperplastic and even atypical hyperplastic

Fig. 10.81

Adenosarcoma. A polypoid tumor arises in the endometrium and fills the endometrial cavity

Fig. 10.82

Adenosarcoma. Papillary stromal fronds are lined by benign epithelium. The stroma is hypercellular, and the cellularity is greatest beneath the epithelium

epithelium is occasionally noted [148]. By definition, carcinoma is not present in adenosarcoma (see **7** *Table 10.8*), but cases have been reported in which adenocarcinoma is present in the endometrium adjacent to the adenosarcoma [76]. Glands are often present in areas of myometrial invasion, which are observed in 15–52% of adenosarcomas, suggesting that the epithelium is an actively proliferating part of the neoplasm.

The mesenchymal component of an adenosarcoma is generally a low-grade homologous sarcoma such as ESS or a fibroblastic/myofibroblastic sarcoma resembling the fibroblastic variant of ESS (**>** *Fig. 10.83*; [76, 148, 390]),

Adenosarcoma. The stroma of an adenosarcoma is more cellular than that of an adenofibroma, especially in the vicinity of the epithelial component. The stromal cells usually resemble endometrial stromal cells or fibroblasts. The nuclei can be relatively uniform but, as in this case, atypia and pleomorphism can be conspicuous

although high-grade sarcoma can be present, even in cases without sarcomatous overgrowth. Smooth muscle is present in some tumors and can be conspicuous [125]. Periglandular stromal hypercellularity is a characteristic feature of adenosarcoma (> Fig. 10.84), and hypercellular stromal cuffs surround glands or form a band beneath the surface at least focally in almost every case. The degree of mesenchymal cell nuclear atypia is variable, but it is mild to moderate in most tumors. MF are readily identified in most tumors and generally number 2-4/10 HPF or more [76, 148, 204, 445]. MF tend to be most numerous in the cellular stromal cuffs around the glands. Neoplasms with the morphologic features of adenosarcoma (cellular stroma, periglandular cuffing, stromal cell atypia, and, in some cases, myometrial invasion), but in which mitotic activity is inconspicuous, can recur, or metastasize [76, 148]. Therefore, a neoplasm with the typical appearance of an adenosarcoma in which atypical, hypercellular stroma is condensed around the epithelial elements should be diagnosed as an adenosarcoma even if there are only 1-2 MF/10 HPF [76]. Adenosarcomas often contain bland areas indistinguishable from adenofibroma, so extensive microscopic study may be required to identify a sarcomatous component.

Trabecular, insular, or tubular arrangements of plump epithelial-like cells, some having abundant foamy cytoplasm, are present in about 5% of adenosarcomas (**)** *Fig. 10.85*) [74, 148, 181]. These structures, which are designated as sex cord-like elements, resemble the sex

Fig. 10.84 Adenosarcoma. Periglandular stromal hypercellularity is a characteristic of adenosarcoma

Fig. 10.85 Adenosarcoma. Sex cord-like trabeculae or tubules are occasionally present in the stroma of an adenosarcoma

cord-like structures commonly seen in endometrial stromal tumors. Heterologous mesenchymal elements are present in 20–25% of adenosarcomas. Striated muscle (rhabdomyosarcoma) is the most common heterologous element, but cartilage, fat, and other elements are occasionally observed [229].

Sarcomatous overgrowth, which is present in about 10% of adenosarcomas, is said to occur when the sarcomatous component of the tumor occupies 25% or more of the total tumor volume [40, 68, 204]. Epithelial elements are absent in the region of sarcomatous overgrowth and the mesenchymal component is typically of high grade, with increased cellularity and mitotic activity and greater nuclear atypia (\bigcirc *Fig. 10.86*) as compared to the appearance of the background adenosarcoma [68].

Adenosarcoma with sarcomatous overgrowth.

A high-grade spindle cell sarcoma has developed in an adenosarcoma and comprises more than 25% of the tumor volume

Fig. 10.87

Adenosarcoma with rhabdomyosarcoma in zones of sarcomatous overgrowth. Rhabdomyoblasts are round or spindle-shaped and have prominent eosinophilic cytoplasm. It is sometimes possible to identify crossstriations, but these days immunohistochemistry is typically used to confirm the presence of rhabdomyoblasts

The sarcoma can be stromal sarcoma, fibrosarcoma, or leiomyosarcoma, or a mixture of elements [204]. Heterologous elements, particularly rhabdomyosarcoma (\bigcirc *Fig. 10.87*), may occur in, and be limited to, the zone of sarcomatous overgrowth [148, 204]. The zones of pure sarcomatous growth can be present in or constitute the entire myoinvasive component of an adenosarcoma. Lymphovascular space invasion, which is rare in

adenosarcoma, is most often found in zones of sarcomatous overgrowth [204].

Immunohistochemistry

The epithelial component of adenosarcoma is keratin positive, and it usually stains for estrogen and progesterone receptors. The mesenchymal component often resembles ESS, so it is not surprising that adenosarcoma and ESS share many immunophenotypic features. The mesenchymal cells in adenosarcoma typically show cytoplasmic staining for CD10, and there is nuclear staining for estrogen and progesterone receptors (ER and PR) and for WT-1 [13, 14, 148, 281, 390]. Staining is often most conspicuous in the periglandular stromal cuffs where the cell density is greatest. Staining for CD10 and hormone receptors is often weaker or lost in areas of high-grade sarcomatous overgrowth, which demonstrate increased levels of nuclear staining for the proliferation marker Ki-67 (MIB-1) and, often, for p53 [148, 390]. Focal staining for keratin, sometimes with a dot-like pattern, is occasionally noted and patchy weak staining for smooth muscle actin and/or desmin is present in many adenosarcomas. Areas of smooth muscle and rhabdomyosarcomatous differentiation show strong positive cytoplasmic staining for desmin [390], and the latter show positive nuclear staining for myogenin.

Differential Diagnosis

The differential diagnosis includes benign entities such as endometrial and endocervical polyps and adenofibroma, as well as various malignant tumors, including ESS, other uterine sarcomas, and, in young patients with cervical tumors, botryoid rhabdomyosarcoma.

Many patients with adenosarcoma give a history of prior removal of "polyps." In general, polyps are smaller than adenosarcomas. Microscopically, the stroma of benign polyps tends to be fibrous and few if any MF are present. Polyps often have conspicuous central blood vessels. Problems arise when large polyps have more cellular zones with endometrial type stroma, where mitotic activity can overlap with the lower end of the range seen in adenosarcoma [174]. However, polyps lack the characteristic architecture of an adenosarcoma, they do not have periglandular stromal hypercellularity, nuclear atypia is usually absent, and mitotic activity at the level commonly present in adenosarcoma (>4 MF/10 HPF) is not seen.

Bizarre stromal cells are occasionally present in polyps, but these appear to represent a degenerative phenomenon, since the cells have smudged nuclear chromatin and they are not mitotically active [406].

Adenofibroma is a rare benign tumor of the cervix or endometrium. The overall architecture is similar to adenosarcoma, but the stroma is predominantly fibrous and less cellular than that of an adenosarcoma, with no condensation of stromal cells around the epithelial elements. The stromal cells are bland, and MF are absent or difficult to find. Some adenosarcomas contain bland areas similar in appearance to an adenofibroma, so the diagnosis of an adenofibroma generally requires hysterectomy so that the entire tumor can be evaluated microscopically. Several authors have noted that it is occasionally difficult to differentiate between an adenofibroma and a low-grade adenosarcoma [76, 148].

The stroma of an adenosarcoma tends to resemble an ESS or one of its variants, so the differential diagnosis includes ESS. ESS can incorporate benign glands at its periphery, but glands tend to be absent away from the edges of the tumor, while in adenosarcoma glands are distributed throughout the tumor. Stromal sarcoma often contains epithelial or sex cord-like elements, but these do not resemble the type of epithelium present in adenosarcoma. Rare stromal sarcomas contain endometrial type glands. These are often irregularly distributed in the tumor such that many areas lack glands. Also, the stroma does not condense around the glands, and the phyllodeslike architecture of an adenosarcoma is not seen.

Other pure sarcomas of the uterus or cervix can incorporate benign glands at their periphery. However, no glands are present in most parts of the tumor and the sarcoma tends to be of significantly higher grade than the mesenchymal element of an adenosarcoma. A high-grade mesenchymal component is present in an adenosarcoma with stromal overgrowth, but such tumors invariably have areas with the typical architecture and low-grade mesenchymal elements that characterize an adenosarcoma.

In a young patient, a botryoid rhabdomyosarcoma of the cervix enters the differential diagnosis. Botryoid rhabdomyosarcomas have a polypoid surface contour similar to that seen in adenosarcoma and the hypercellular subsurface zone commonly referred to as the "cambium layer," which resembles the type of stromal hypercellularity that is seen around epithelial elements in an adenosarcoma [98, 127]. However, glands are usually not distributed throughout a rhabdomyosarcoma and the mesenchymal cells, some of which are usually recognizable as rhabdomyoblasts, tend to be more primitive and mitotically active than the stromal cells of an adenosarcoma. Immature cartilage is present in many cervical rhabdomyosarcomas.

Carcinosarcoma, like adenosarcoma, has both epithelial and mesenchymal components. However, in carcinosarcoma the epithelial component is an adenocarcinoma or an undifferentiated carcinoma and the mesenchymal component is a sarcoma, usually of high grade.

Clinical Behavior and Treatment

Adenosarcoma is usually treated by hysterectomy and bilateral salpingo-oophorectomy, although a few young patients have been treated by local excision of the tumor [76, 445]. Metastasis to lymph nodes is rare, although occasional patients whose tumors show sarcomatous overgrowth have pelvic lymph node metastases [204, 375]. The role of postoperative pelvic radiation and chemotherapy is unclear. Adenosarcoma is not as aggressive as MMMT, but it recurs in 25-40% of patients and occasionally follows an aggressive course. Recurrence is generally in the pelvis or vagina, but distant metastases occur in 5% of patients (Clement and Scully 1990). Recurrences typically consist exclusively of the sarcomatous component, but both epithelium and stroma are occasionally present. Pathologic features of the primary tumor that are associated with an increased risk of recurrence or metastasis are extrauterine spread at diagnosis; myometrial invasion, especially into the outer half of the myometrium; and sarcomatous overgrowth of the mesenchymal component [76, 148, 204, 225, 424, 445]. Patients with adenosarcoma with sarcomatous overgrowth of the mesenchymal component have a prognosis similar to that of women with carcinosarcoma [225]. Invasion of capillary-lymphatic spaces in the myometrium or the presence of rhabdomyosarcoma in zones of sarcomatous overgrowth also portend an unfavorable outcome. There is no clear correlation between the prognosis and the mitotic rate in the mesenchymal component. Extended clinical observation is necessary because there is typically a long (3.5-5 years) interval between treatment and recurrence. About a quarter of patients with adenosarcoma die of tumor, often more than 5 years after initial diagnosis.

Homologous and Heterologous Sarcomas

The tumors in this category are high-grade sarcomas that often resemble the mesenchymal component of a MMMT. Most pleomorphic homologous sarcomas arise in the endometrium and consist of round or spindled cells with variable amounts of cytoplasm and pleomorphic atypical nuclei. These are a type of undifferentiated endometrial sarcoma, and are discussed above in the section on Undifferentiated Endometrial Sarcoma. Some may result from sarcomatous stromal overgrowth in an adenosarcoma or carcinosarcoma or by dedifferentiated sarcomas are of endometrial origin, a few appear to arise in the myometrium, either from nonspecific mesenchymal elements or by dedifferentiation of a leiomyosarcoma.

Pure heterologous sarcomas occasionally arise in the uterus. Some are assumed to represent complete heterologous stromal overgrowth in an adenosarcoma or carcinosarcoma. Rhabdomyosarcoma, which is discussed below, is by far the most common heterologous uterine sarcoma [127, 323], but chondrosarcoma [296], osteosarcoma [115], liposarcoma [30], and tumors containing mixtures of heterologous elements also occur. Histologically benign heterotopic bone, cartilage, and fat are occasionally found in the uterus, and rare benign tumors contain one or more of these elements [293, 356]. They should not be mistaken for heterologous sarcomas or carcinosarcomas, in which the mesenchymal elements are histologically malignant.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant neoplasm that displays skeletal muscle differentiation. It is the most common soft tissue tumor in children and approximately 20% of pediatric rhabdomyosarcomas originate in the genital tract. In adults, rhabdomyosarcoma of the female genital tract is a rare tumor [129, 175, 250]. Most of the clinical and pathologic data about rhabdomyosarcoma derive from cooperative group trials assessing multimodality treatment for pediatric rhabdomyosarcoma at various anatomic locations, including the female genital tract [17, 87, 200, 264, 347].

Largely based on pediatric data, rhabdomyosarcoma is categorized into three major variants with significant differences in clinical behavior and prognosis. The most common and generally most favorable variant is embryonal rhabdomyosarcoma, which includes botryoid, spindle cell, and anaplastic histologic subtypes. The recently described sclerosing rhabdomyosarcoma may be related to embryonal rhabdomyosarcoma [135]. The other two types of rhabdomyosarcoma, alveolar and pleomorphic rhabdomyosarcoma, are less common and usually have a significantly less favorable clinical outcome.

Clinical Features

In adults, the median age at diagnosis of female genital tract rhabdomyosarcoma is in the fifth to seventh decade and the most common presenting symptom is abnormal vaginal bleeding [127, 323]. The majority of women, approximately 75%, present with local or regional disease. The primary site is the cervix in approximately one half of women, making it the most common site of origin of genital tract rhabdomyosarcoma in adults; only 20% of tumors are uterine. Children and young adults with cervical or uterine rhabdomyosarcoma present with vaginal bleeding or with a polypoid tumor that protrudes from the vagina.

Gross Findings

Cervical rhabdomyosarcomas are mainly polypoid graytan or red tumors. Botryoid rhabdomyosarcoma, the most common type in the cervix, is often described as resembling a cluster of grapes. Uterine rhabdomyosarcoma tends to be a polypoid endometrial tumor that grows into the uterine cavity and invades the myometrium. Some rhabdomyosarcomas are nodular tumors located entirely within the myometrium. The average tumor size at presentation is about 3 cm, but many tumors are larger and measure 10–15 cm or more.

Microscopic Findings

Rhabdomyosarcomas of the cervix are more common than those of the uterine corpus, and most are embryonal rhabdomyosarcomas of the botryoid subtype. Botryoid rhabdomyosarcomas are polypoid tumors that have a densely cellular zone of primitive cells beneath the surface epithelium (the "cambium layer"; > Fig. 10.88; [98]). The substance of the polyps is generally myxoid or edematous, with varying cellularity. The tumor cells are rhabdomyoblasts that range from undifferentiated small round cells with hyperchromatic nuclei and scanty cytoplasm ("small round blue cells") to strap-shaped cells with eosinophilic cytoplasm and easily appreciated crossstriations. Interestingly, foci of immature-appearing cartilage are admixed with the rhabdomyoblasts in a significant minority of cases [98, 127]. The non-polypoid and infiltrative portions of the tumors are usually histologically indistinguishable from embryonal rhabdomyosarcomas of the usual (non-botryoid) sort with cellular zones that alternate with paucicellular zones with

Botryoid rhabdomyosarcoma. These tumors are typically composed of grape-like tumors with a paucicellular matrix that appears myxoid or edematous. Condensation of primitive cells beneath the overlying epithelium and alongside any entrapped epithelium (so-called cambium layer) is common. Phyllodes-like architecture and intraglandular stromal papillae, seen in adenosarcoma, are lacking

a myxoid or edematous matrix. An unusual botryoid rhabdomyosarcoma that contained areas with a more pleomorphic pattern has been reported [186].

Rhabdomyosarcomas of the uterine body in older patients are often high-grade pleomorphic sarcomas composed of round, polygonal, or spindle-shaped cells admixed with aggregates of large rhabdomyoblasts [323]. The rhabdomyoblasts range from round cells with prominent perinuclear rims of eosinophilic cytoplasm to spindle- or tadpole-shaped cells with fibrillar eosinophilic cytoplasm.

In the female genital tract, alveolar rhabdomyosarcoma occurs most often in the vulva. Although occasionally reported, it is uncommon in the uterine body and cervix [54, 352]. The tumor cells tend to be larger than those in embryonal rhabdomyosarcoma. In some tumors round or irregular spaces are surrounded by tumor cells, resulting in an alveolar appearance. Tumor cells often seem to cling to the conspicuous fibrovascular septae that traverse sheets of tumor cells. In other tumors there is solid growth of tumor cells with no alveolar spaces. Regardless of the growth pattern, the tumor cells have a distinctive cytologic appearance with round nuclei, larger than those in embryonal rhabdomyosarcoma, and scanty cytoplasm. Multinucleated tumor cells are commonly present. Round and spindled cells with brightly eosinophilic cytoplasm are present in most cases and are important clues to the diagnosis. Tumor cells with cross striations can generally be identified.

Fig. 10.89 Botryoid rhabdomyosarcoma. Myogenin expression in tumor cell nuclei confirms rhabdomyoblastic differentiation

Immunohistochemistry and Molecular Pathology

The typical immunophenotype includes expression of desmin, muscle-specific actin, myogenin, and Myo-D1 (> Fig. 10.89). Staining for these markers is present in greater than 90% of rhabdomyosarcomas [55, 90]. Desmin and muscle-specific actin are not specific for rhabdomyosarcoma, as positive staining is also found in tissues demonstrating smooth muscle and myofibroblastic differentiation. Myogenin and Myo-D1 are nuclear regulatory proteins that are expressed early in skeletal muscle differentiation. Myogenin is the more widely used of the two because there are fewer technical problems associated with its use. In general, the expression of these markers is negatively correlated with differentiation; nuclear staining is widespread in tumors with numerous differentiated rhabdomyoblasts, but only scattered myogenin positive cells are found in rhabdomyosarcomas composed predominantly of undifferentiated cells with few histologically recognizable rhabdomyoblasts.

Expression of myogenin and Myo-D1 is common to all tumors demonstrating skeletal muscle differentiation, which means that tumors other than pure rhabdomyosarcoma (e.g., carcinosarcoma containing rhabdomyoblasts) must be excluded before using myogenin or Myo-D1 immunoreactivity to confirm a diagnosis of rhabdomyosarcoma. Rhabdomyosarcoma may rarely express markers that are more commonly expressed in its histologic mimics, including staining for CD99 (O13), cytokeratin, S100, or WT1. Occasional tumors show co-expression of neuroendocrine markers such as chromogranin and synaptophysin along with desmin and myogenin. Such neoplasms have been referred to as "ectomesenchymomas."

Immunohistochemistry may help with the subclassification of rhabdomyosarcoma. Staining for myogenin is likely to be strong and diffuse in alveolar rhabdomyosarcoma; staining is weaker and more focal in embryonal rhabdomyosarcoma [176, 289]. Positive nuclear staining for PAX-5 is reported to be present in about two thirds of alveolar rhabdomyosarcomas, but staining tends to be absent in embryonal rhabdomyosarcoma [400]. In a limited number of cases with genetic correlation, staining occurred only in tumors that had one of the characteristic translocations, but there was no correlation with a specific translocation [400]. A panel of four immunostains, AP2β, P-cadherin, epidermal growth factor receptor (EGFR), and fibrillin-2, is reported to differentiate between translocation positive alveolar rhabdomyosarcoma (positive for AP2ß and P-cadherin) and embryonal rhabdomyosarcoma (positive for EGFR and fibrillin-2); translocation-negative alveolar rhabdomyosarcoma can be suspected if staining for all four markers is absent [429]. This immunohistochemical panel does not appear to be in widespread use.

A majority of alveolar rhabdomyosarcomas exhibit a clonal chromosomal translocation, either t(2;13) (q35;q14), resulting in a PAX3–FKHR fusion, or t(1;13) (p36;q14), resulting in a PAX7–FKHR fusion. There appears to be a survival difference between patients whose tumors have the PAX3–FKHR fusion and those whose tumors have the PAX7–FKHR fusion, with the former having a significantly worse prognosis, at least when metastatic disease develops [388].

Differential Diagnosis

Myxoid leiomyosarcoma may resemble embryonal rhabdomyosarcoma, and pleomorphic leiomyosarcoma can appear similar to pleomorphic rhabdomyosarcoma. Embryonal rhabdomyosarcoma, when spindled and growing in fascicles, frequently has a subtle moth-eaten appearance that results from a heterogeneous admixture of cells, some containing densely eosinophilic cytoplasm and others clear or amphophilic cytoplasm (\bigcirc *Fig.* 10.90). Round rhabdomyoblasts with bright-red cytoplasm are often haphazardly intermixed. The low-power appearance of leiomyosarcoma, in contrast, is generally more uniform. Most embryonal rhabdomyosarcomas with an infiltrative, spindle cell appearance underlie a botryoid tumor and/or are clearly epitheliotropic. Leiomyosarcomas, in contrast, are usually more deeply seated lesions.

Fig. 10.90

Rhabdomyosarcomas with spindle cell morphology may mimic leiomyosarcoma. As compared to leiomyosarcomas, rhabdomyosarcomas more frequently lack an eosinophilic appearance at low power and instead demonstrate a subtle moth-eaten look owing to the admixture of round and spindled rhabdomyoblasts

Immunohistochemistry is useful for distinguishing rhabdomyosarcoma from leiomyosarcoma. Diffuse desmin expression is present in both, but only rhabdomyosarcoma shows staining for myogenin. Caldesmon can be positive in leiomyosarcoma, but it is generally negative in rhabdomyosarcoma.

Adenosarcoma and embryonal rhabdomyosarcoma both show polypoid growth and stromal condensation beneath epithelium, but botryoid rhabdomyosarcoma more typically contains conspicuous myxoid stroma, and has a sprinkling of small cellular aggregates of dark blue, primitive and mitotically active cells in a paucicellular background. These features can sometimes be appreciated macroscopically, such that gross inspection of a glass slide can suggest the correct diagnosis. In contrast to adenosarcoma, rhabdomyosarcoma does not exhibit phyllodes-like growth or intraglandular stromal papillae. Adenosarcomas with stromal overgrowth frequently contain rhabdomyoblastic foci. It is unclear whether there are significant clinical differences between such tumors and pure rhabdomyosarcoma. Some rhabdomyosarcomas might represent adenosarcomas with complete heterologous stromal overgrowth.

Stromal-predominant carcinosarcoma is excluded by a careful search for a malignant epithelial component. The presence of any type of carcinoma indicates that the tumor is a carcinosarcoma. It is generally assumed that some genital pleomorphic rhabdomyosarcomas represent carcinosarcomas in which the epithelial component is overgrown by the sarcomatous mesenchymal component.

Pleomorphic undifferentiated sarcoma can resemble rhabdomyosarcoma, as it is composed of mitotically active atypical round or spindle cells. However, rhabdomyoblasts with eosinophilic cytoplasm are not present, and there is no staining for myoid markers such as desmin and myogenin.

Undifferentiated carcinoma also enters the differential diagnosis as it consists of medium-sized round cells with scanty cytoplasm with no obvious glandular differentiation. Undifferentiated carcinoma may show areas of cellular cohesion, and the tumor cells show at least focal staining for keratin or EMA. Staining for markers of myoid differentiation is absent.

Clinical Behavior and Treatment

Most adult patients are treated surgically, with or without chemotherapy and radiation therapy. In a recent retrospective review of genital tract rhabdomyosarcoma in adults, the median time to progression was only 9 months and the median disease-specific survival was 21 months; the 5-year disease-specific survival was only 29% [127]. Neither age nor stage correlated with survival. Women with cervical rhabdomyosarcoma had a longer time to progression than women with disease at other gynecologic sites and women with an embryonal rhabdomyosarcoma had improved progression free survivals compared to those with non-embryonal types of rhabdomyosarcoma. Other authors have reported similar poor survival rates in adults with genital tract rhabdomyosarcoma [276, 323].

Children with genital tract rhabdomyosarcoma are generally treated by biopsy to establish the diagnosis, followed by chemotherapy and in some instances radiation. Primary surgical management, as used in adults, is very uncommon. The poor survival statistics for adults with genital tract rhabdomyosarcoma contrast sharply with the rather favorable survival rates in pediatric rhabdomyosarcoma: 5-year overall survival of 82%, with 94% survival for patients with the botryoid histologic subtype of rhabdomyosarcoma and 66% survival for those with non-embryonal variants of rhabdomyosarcoma [22, 244].

Alveolar Soft Part Sarcoma (ASPS)

ASPS is uncommon in the female genital tract, but it occasionally occurs in the vagina, cervix, or uterus.

Uterine tumors have been described in the endometrium, lower uterine segment, and myometrium [209, 299, 346]. The average patient age is about 30 years, and most patients present because of abnormal bleeding [299].

ASPS is composed of cells with abundant clear to eosinophilic cytoplasm that grow in solid nests or, when there is loss of cellular cohesion, an alveolar pattern (> Fig. 10.91). The tumor cell cytoplasm is filled with granules and crystals that are PAS-positive and diastaseresistant. Nuclei are usually round with prominent nucleoli. The fibrovascular framework that supports the nests and alveoli can be conspicuous. ASPS that arise in the soft tissues frequently show vascular invasion, but this is uncommon in gynecologic cases. Alveolar soft part sarcomas are characterized by a chromosomal translocation, t(x;17)(p11;q25), in which the TFE3 transcription factor gene on chromosome Xp11 is fused to a novel gene on chromosome17q25 [230]. An immunohistochemical stain for the TFE3 protein, which is a nuclear antigen, can be used as a diagnostic adjunct to recognize tumors with this translocation or other abnormalities involving TFE3 [20, 21, 209, 354]. Alveolar soft part sarcomas show variable, but usually weak or negative immunoreactivity for keratins, desmin, smooth muscle actin, S100, and HMB45.

The differential diagnosis of ASPS includes adenocarcinoma, epithelioid smooth muscle tumor, PEComa, metastatic melanoma, and a uterine tumor resembling UTROSCT. Adenocarcinoma, epithelioid smooth muscle tumor, metastatic melanoma, and UTROSCT all have a different immunophenotype than ASPS, but the immunohistochemical features of PEComa and ASPS can sometimes be similar. This is because rare PEComas express

Fig. 10.91

Alveolar soft part sarcoma. The tumor is formed of nested aggregates of epithelioid tumor cells with granular or crystalline cytoplasm TFE3 and, at the same time, show only weak HMB45 expression [136]. Any appreciable desmin staining or staining with markers such as tyrosinase, microphthalmia transcription factor, or Melan-A would support PEComa over ASPS.

Gynecologic ASPS has a relatively good prognosis compared to soft tissue ASPS, but the number of cases and the length of follow-up reported are insufficient to draw definitive conclusions. In the largest series of nine patients, one patient died of tumor but the other eight were alive with no evidence of tumor, 9 months to 17 years after diagnosis [299].

Primitive Neuroectodermal Tumor

Primitive neuroectodermal tumor (PNET) only rarely arises in the uterus [97, 138, 177, 387]. PNET can occur at any age, but most are found in postmenopausal women. The median age in the largest series was 58 years, and most patients had stage III or stage IV tumors [116]. The usual clinical presentation is with abnormal vaginal bleeding.

PNET is a soft, fleshy, gray or white polypoid mass that originates in the endometrium and invades the myometrium. Microscopically, PNET is composed of small cells with round to oval hyperchromatic nuclei and scanty cytoplasm (**?** *Fig. 10.92*). MF are usually numerous. Evidence of neuroectodermal differentiation includes

Fig. 10.92

Primitive neuroectodermal tumor of the uterus. The tumor is composed of small cells with hyperchromatic nuclei, coarse chromatin, and scanty cytoplasm, arranged in nests and trabeculae. Rosettes or pseudorosettes are seen in some cases. This case was immunoreactive for CD56, chromogranin, and neurofilament the presence of a fibrillary background or the formation of rosettes or pseudo-rosettes.

Immunostains are generally positive for one or more neural or neuroendocrine marker, and staining for keratin is generally absent. The most useful immunostains are keratin, which is generally negative, and synaptophysin and neurofilament, which are usually positive. Staining for other neuroectodermal markers such as chromogranin, neuron-specific enolase, and CD56 is more variable but occasionally one or more are positive. Many uterine PNET, especially those with a t(11;22) express CD99 in a diffuse, membranous pattern, as well as FLI-1. Positive staining for CD99 is not proof that a tumor is a peripheraltype PNET, since tumors without evidence of a translocation frequently show CD99 staining [116].

Uterine PNET appear to fall into two categories. Some have a chromosomal translocation, usually t(11;22) resulting in a fusion between the EWS and FLI1 genes. These demonstrate histologic, immunohistochemical, and biologic similarities to peripheral PNET (pPNET; [39, 383, 422]). Other uterine PNET, including all tested tumors in the largest reported series, lack evidence of an EWSR1 rearrangement, and are thus more akin to the central type of PNET [116].

Mixtures of PNET and other tumor types are occasionally seen. PNET has been reported in association with various types of sarcoma, with carcinosarcoma and adenosarcoma and with endometrioid adenocarcinoma [116, 142, 383]. When associated with carcinosarcoma or adenosarcoma, PNET is viewed by some as a form of heterologous differentiation.

Too few patients have been studied to define the clinical behavior and most appropriate treatment for PNET of the uterus. Women with stage I neoplasms can be cured, but more advanced tumors are frequently fatal. In the only large series reported to date 7 of 13 patients with follow-up died of tumor and 6 were alive with no evidence of disease [116].

Miscellaneous Mesenchymal Tumors and Conditions: Inflammatory Myofibroblastic Tumor (IMT)

IMT, also known as inflammatory pseudotumor, is a benign but potentially locally aggressive proliferation of myofibroblasts [153, 344]. IMT occurs in all age groups, including premenopausal women and children. The presentation is with symptoms related to the presence of a mass, such as pain or pressure, but some patients have constitutional symptoms including fever, weight loss, and fatigue.

Grossly, the tumors range up to 12 cm in maximum diameter. They are firm or soft, and the cut surfaces are tan or white and often mucoid. Microscopically, the myofibroblasts are spindle-shaped or stellate and have pale eosinophilic cytoplasm (> Fig. 10.93). Their nuclei are granular or vesicular, and they may have prominent nucleoli. Mitotic activity is variable, but the mitotic index is generally <10/10 HPF and atypical MF are not present. The background is frequently edematous [378], and lymphocytes and plasma cells are scattered among the myofibroblasts. Immunohistochemical stains for smooth muscle actin or desmin typically are positive, although staining may be focal. Staining for specific markers of smooth muscle differentiation, such as caldesmon, tends to be absent. IMT may show cytoplasmic staining for ALK-1, a useful diagnostic feature.

IMT is a benign lesion that does not metastasize. Recurrences of uterine IMT have not been reported, but there is a local recurrence rate of about 15% in patients with extrauterine IMT. IMT were initially considered to be inflammatory pseudotumors, but the documentation of the clonal nature of some IMT and the demonstration of chromosomal rearrangements involving the ALK locus region indicate that it may be more appropriate to view them as true neoplasms [234, 398].

Adenomyosis and Adenomyoma

Adenomyosis is a common condition, detected in 15–30% of hysterectomy specimens [373]. It is characterized by the

Fig. 10.93

Inflammatory myofibroblastic tumor. The tumor is a histologically low-grade spindle cell proliferation of largely mitotically inactive spindle cells set in a myxoid and inflammatory background (Courtesy of Joseph Rabban, M.D.) presence of endometrial glands and stroma within the myometrium [34]. Adenomyomas are uncommon tumorlike masses composed of endometrial glands, stroma, and smooth muscle. They differ from adenomyosis mainly in that they are circumscribed nodular masses.

Clinical Features

Patients are typically pre- or perimenopausal women who present with abnormal bleeding and dysmenorrhea. Symptoms tend to be more severe in women with deep myometrial involvement [246]. The uterus is enlarged and may harbor other lesions associated with hyperestrinism [203]. Adenomyosis is usually most extensive in the posterior wall, which may be thickened. A clinical diagnosis of adenomyosis can often be confirmed by imaging studies such as transvaginal ultrasonography or MRI.

Pathologic Findings

On gross examination, the cut surface of the myometrium is trabeculated and contains hemorrhagic foci, but a distinct tumor nodule is not present. Small blood-filled cysts may be noted.

Adenomyosis is a condition in which rounded or irregular foci of endometrial stroma and glands are present in the myometrium (\bigcirc *Fig. 10.94*). The lower border of the endometrium is irregular and dips into the superficial myometrium. To avoid misclassifying a normal

G Fig. 10.94

Adenomyosis. The periphery of this focus of adenomyosis containing endometrial hyperplasia is relatively lacking in endometrial stroma. This focus can be recognized as adenomyosis because of its lobular shape and the circumferential smooth muscle hypertrophy that surrounds it histologic finding as adenomyosis, it is advisable to make the diagnosis only when the distance between the lower border of the endometrium and the adenomyosis exceeds one half of a low-power field (about 2.5 mm), an admittedly arbitrary measurement. Adenomyosis exhibits a varied functional response to ovarian hormones. Proliferative glands and stroma generally are observed in the first half of the menstrual cycle. Adenomyosis may not respond to physiologic levels of progesterone, and secretory changes frequently are absent or incomplete during the second half of the cycle.

There are variants of adenomyosis that pathologists should be aware of as they can suggest a malignant tumor. In one, endometrial tissue protrudes into myometrial vessels, simulating vascular invasion by a neoplasm, such as ESS (> Fig. 10.95a). Intravascular endometrial tissue, consisting of endometrial stroma and glands or endometrial stroma alone, can be found in as many as 20% of uteri with adenomyosis [362]. It usually appears to originate in the perivascular region and push into the vessel lumen; immunostains reveal the intravascular adenomyosis to be covered by a layer of CD31-positive endothelial cells () Fig. 10.95b). Other problematic variants of adenomyosis include those where either the glandular or stromal component is altered or sparse. A low power key to recognizing these as adenomyosis is the circumferential muscular hypertrophy that surrounds foci of adenomyosis and the maintenance of a lobular appearance without surrounding stromal desmoplasia. In the gland-poor variant that tends to occur in elderly women, sometimes designated "adenomyosis with sparse glands," glands are few in number and some adenomyotic foci consist mainly or exclusively of endometrial stromal cells [161]. Careful evaluation reveals that these variants of adenomyosis lack features of malignancy and are almost always accompanied by foci of typical adenomyosis. The presence of the stroma-poor variant can be suspected at low-power examination, using the criteria discussed above. In this variant, the stroma is frequently less cellular centrally than at the periphery, resulting in a focus of adenomyosis with a pale center and a darkly stained peripheral zone (> Fig. 10.96). The stroma can be atrophic and fibrotic and may resemble the stroma of an atrophic endometrial polyp, with the acquisition of an eosinophilic, fibrillary appearance and loss of the monotonous, blue ovoid cells more typically associated with endometrial stroma. The eosinophilic, fibrillary appearance may superficially resemble myometrium, but high power examination can reveal a clear demarcation between the surrounding, hypertrophic, well-organized bundles of myometrium and the disorganized, thin fibrils of altered endometrial stroma [9].

Fig. 10.95

(a) Intravascular endometrial tissue in a patient with

adenomyosis. In this example no glands are present, raising the possibility of endometrial stromal sarcoma. However, there was no mass and no myoinvasive stromal tumor was present. Typical foci of adenomyosis were widely present in the region. (b) Intravascular endometrial tissue in a patient with adenomyosis. An immunostain for CD31 reveals that the vein is lined by a layer of endothelial cells. The intravascular endometrial tissue is completely covered by a layer of CD31-positive endothelial cells, suggesting that it is actually extravascular and has protruded into the vein lumen, pushing the endothelium over it

Most examples of adenomyosis contain endometrial stroma with a CD10-positive immunophenotype [297, 394]. The eosinophilic, fibrillary stroma described previously in atrophic adenomyosis frequently expresses CD10 only weakly or focally, so absent CD10 staining does not entirely exclude the presence of endometrial stroma and adenomyosis.

An adenomyoma is a circumscribed, nodular aggregate of smooth muscle, endometrial glands, and, usually,

Adenomyosis with sparse glands. Nearby foci of adenomyosis contained both glands and stroma, but this one consists of stroma only. The center is less cellular and appears pale. The periphery is more cellular and therefore is more darkly stained

endometrial stroma [152, 202, 405]. It may be located within the myometrium, or it may involve or originate in the endometrium and grow as a polyp. About 2% of endometrial polyps are adenomyomas. A rare variant of an adenomyomatous polyp, the atypical polypoid adenomyoma, has atypical hyperplastic glands that usually contain foci of squamous metaplasia (see **O** Chap. 7, Benign Diseases of the Endometrium).

Adenomatoid Tumor

Adenomatoid tumors are distinctive genital tract neoplasms of mesothelial origin that occur in both men and women [102, 300]. In women they occur in the uterus, the fallopian tube, and the ovary [444].

Clinical Features

Adenomatoid tumors typically occur in women of reproductive age; the median age is 42 years. There is no evidence that they impair fertility, and they are usually incidental findings in uteri removed for other causes. Adenomatoid tumors are found in about 1% of hysterectomy specimens, but no specific symptoms have been attributed to them. Adenomatoid tumors are benign. Rarely, an adenomatoid tumor merges with another type of mesothelioma that has the potential for recurrence.

Fig. 10.97

Adenomatoid tumor within hypertrophic myometrium. Variably sized tubules are lined by flattened or cuboidal mesothelial cells

Pathologic Findings

Adenomatoid tumors are usually located subserosally in the cornual myometrium. They are typically small, measuring 0.5–1 cm in diameter, but some are larger and giant and cystic adenomatoid tumors have been reported. Adenomatoid tumors are round and rubbery and are often thought to be leiomyomas. The cut surfaces are gray or tan and may have a spongy appearance due to the presence of uniform small cysts.

Microscopically, adenomatoid tumors tend to be circumscribed, although rare diffuse variants have been described. They consist of tubules and cords of varying size and shape that are lined by flat or cuboidal epithelial cells (> Fig. 10.97). Collagen, elastic tissue, and smooth muscle surround the epithelial elements. The smooth muscle may predominate such that the tumor appears at first glance to be a leiomyoma or lipoleiomyoma. The cuboidal epithelial cells have cytologically bland, eccentric, round nuclei and abundant pale cytoplasm. The cytoplasm is often vacuolated, sometimes to the extent that some tumor cells resemble signet-ring cells. The growth of the epithelial cells between smooth muscle bundles and the presence of signet-ring-like cells may raise the suspicion of metastatic adenocarcinoma. Nuclear atypia, however, is absent or minimal, MF are infrequent, and stains for mucin are negative. When the cells lining the tubules are flattened, an adenomatoid tumor may resemble a hemangioma or lymphangioma. However, the lumens do not contain blood, and immunostains for such vascular markers as factor VIII-related antigen and CD 31 are negative. Ultrastructural and immunohistochemical

studies reveal that the epithelial cells in adenomatoid tumors have a mesothelial phenotype. Immunostains are positive for cytokeratin and vimentin and for such meso-thelial cell-associated antigens as calretinin, WT1, and D2-40 [370]. Stains for adenocarcinoma-associated antigens such as CD 15, CEA, B72.3, and Ber-EP4 are usually negative.

Vascular Tumors

Hemangiomas of the uterus, like those at other sites, are composed of neoplastic vessels lined by flat or cuboidal endothelial cells. The endothelial cells have bland nuclei and MF are rare or, most typically, absent. Uterine hemangiomas can be subclassified as capillary, cavernous, or venous, depending on the appearance of the vessels [255, 435]. There are no clinical differences between the subtypes. Capillary hemangiomas of the cervix are the most common vascular tumors of the uterus. Hemangiomas of the corpus are uncommon, and they vary considerably in size. Large hemangiomas can extend through the full thickness of the myometrium and can result in severe bleeding that requires a hysterectomy. Arteriovenous malformations can occur in the uterus [132, 257]. They are differentiated from venous hemangiomas by the presence of thick-walled vessels of both arterial and venous types. The histologic distinction between a hemangioma and a vascular malformation can be difficult, but it is not critical because their clinical features are similar. A few examples of angiosarcoma of the uterus have been reported [53, 229, 283, 366, 407, 436]. Angiosarcoma is a large, hemorrhagic, and often extensively necrotic tumor that grows in the myometrium. It consists of anastomosing vascular channels that are lined by atypical cuboidal or "tombstone"-shaped endothelial cells (> Fig. 10.98). Many MF are usually present. Some high-grade angiosarcomas consist partly or completely of solid sheets of difficult-to-recognize epithelioid endothelial cells [407]. When these cells predominate, the nature of the tumor can be determined by identifying characteristic foci of vascular growth, often at the periphery of the tumor, and by positive immunohistochemical stains for markers of vascular differentiation such as factor VIII-related antigen or CD 31. Angiosarcoma extensively invades and replaces the myometrium and has a poor prognosis.

In the past, a few uterine tumors have been reported as hemangiopericytomas. Most of these appear to have been endometrial stromal nodules or low-grade ESS that were misdiagnosed as hemangiopericytomas. Whether true hemangiopericytomas occur in the uterus is unclear, but

Fig. 10.98

Angiosarcoma of the uterus. The growth is partly solid but vascular lumens are readily identified. The malignant cells are cuboidal or polygonal and have atypical hyperchromatic nuclei. Numerous mitotic figures were visible at higher magnification. A benign gland is surrounded by tumor (*lower center*)

Fig. 10.99

Endometrial stromal tumor. Many endometrial stromal tumors contain collagen bundles and stag horn vessels that recall hemangiopericytoma and solitary fibrous tumor. Immunohistochemical stains can be used to distinguish between these entities

if they do, they are certainly very rare. Rare solitary fibrous tumors of the uterus have been reported, however [66, 430]. Whenever a diagnosis of hemangiopericytoma of the uterus is considered, the possibility that the tumor is an endometrial stromal tumor must be excluded. Occasional endometrial stroma sarcomas that metastasize to extrauterine sites can resemble hemangiopericytoma and solitary fibrous tumor (\bigcirc *Fig. 10.99*); endometrial stromal tumors express ER, PR, and CD10 and lack diffuse CD34, in contrast to hemangiopericytoma and solitary fibrous tumor, which express CD34 diffusely and can occasionally express weak CD10 and PR [35].

Lymphoma

Lymphoma rarely occurs with initial signs or symptoms suggestive of a uterine tumor, but when it does, the cervix is involved three times more often than is the endometrium [172]. Most patients are older than 20 years and present with an abdominal or pelvic mass, abnormal vaginal bleeding, a vaginal discharge, or pelvic discomfort. Diffuse large cell lymphomas of B-cell type are most common [18, 139, 222, 420]. An 80-90% survival rate has been reported for women with localized lymphomas of the uterus and vagina [172, 397, 420]. The differential diagnosis includes a leiomyoma with a heavy lymphocytic infiltrate and an inflammatory lymphoma-like lesion (pseudolymphoma). Rare leiomyomas contain a heavy lymphocytic infiltrate; however, these are circumscribed tumors in which there are recognizable areas of residual smooth muscle tumor [45, 130]. Additionally, the lymphocytic infiltrate consists of a mixture of cell types. Inflammatory "pseudolymphomas" mainly involve the cervical or endometrial surface or are just beneath it, whereas lymphoma is larger and more deeply situated [442]. Uterine involvement as a manifestation of leukemia is very rare [150, 172, 207, 319].

Inflammatory processes contain a heterogeneous population of lymphoid cells in contrast to the more monomorphic population seen in most lymphomas, and they are polyclonal. The differential diagnosis also includes neoplastic entities, including small cell carcinoma, undifferentiated carcinoma, and IMT, entities discussed elsewhere in this text.

Other Paratubal/Para-ovarian and Pelvic Ligament	
Lesions	572

The Italian physician and anatomist Gabriele Falloppio provided the first detailed and accurate description of the oviducts in humans in 1561 A.D. and designated it the "*Uteri Tuba*" [88]. This organ was eventually named after him. Since that time, a wide variety of non-neoplastic and neoplastic diseases of the fallopian tube has become recognized, but it is only recently that the pathogenesis of fallopian tube carcinoma is beginning to be understood.

Surgical specimens removed specifically for lesions of the fallopian tube are much less common than specimens from other sites in the gynecologic tract; nonetheless, the fallopian tube is frequently examined by the surgical pathologist because it accompanies specimens that were removed for lesions of other gynecologic organs, and the tube plays an important role in reproduction, including problems related to infertility. The majority of fallopian tube lesions examined by the surgical pathologist are nonneoplastic. Benign and malignant tumors of the fallopian tube are uncommon, but, as discussed below, early carcinomas of the fimbriated end of the fallopian tube are becoming more frequently recognized because of complete examination of all fallopian tube tissue submitted as part of prophylactic bilateral salpingo-oophorectomy specimens or major resections for ovarian carcinoma.

This chapter provides a detailed discussion of normal fallopian tube (embryology, gross anatomy, and histology) and gross examination, non-neoplastic lesions, benign and malignant tumors, and gestational trophoblastic disease of the fallopian tube. Paratubal/para-ovarian and pelvic ligament lesions are presented as well.

Normal Fallopian Tube and Gross Examination

Embryology

Regardless of genetic sex, the paired müllerian (paramesonephric) ducts develop on the anterolateral surface of the paired urogenital ridges in both females and males beginning in the sixth week of embryonic life [171, 172, 199]. At the cranial end of the urogenital ridge, the peritoneum gives rise to a population of epithelial cells, which segregate from the peritoneal layer [91]. This new population proliferates and forms the longitudinally oriented müllerian ducts [91, 175]. The mesenchyme surrounding the luminal epithelial layer of the müllerian duct is also derived from the peritoneum. Cranially, the ducts open into the peritoneal cavity. Each of the paired ducts grows caudally in the urogenital ridge immediately lateral to and using the wolffian (mesonephric) duct as a guide.

Spatially lateral to the cranial aspect of the wolffian ducts. the müllerian ducts then ventrally cross the wolffian ducts. The longitudinally oriented and caudal portions of the müllerian ducts now lie medial to the wolffian ducts as they enter the pelvis. The caudal ends of the müllerian ducts abut on the posterior wall of the urogenital sinus immediately between the two wolffian ducts. In the eighth week of embryonic life, these caudal ends of the paired müllerian ducts fuse with each other but are still separated by a septum (**)** *Figs. 11.1* and **)** *11.2*). All these developments occur in both female and male fetuses and are completed before the testis (if the embryo is male) begins to secrete müllerian inhibiting substance (MIS), also known as anti-müllerian hormone (In the absence of MIS, the müllerian ducts develop passively to form the fallopian tubes, uterus, and vaginal wall. Likewise, in the absence of testosterone, the wolffian ducts regress.). In the development of the female, the first two parts of the müllerian duct (the cranial longitudinal segment, which opens into the peritoneal cavity and the transverse portion, which crosses the wolffian duct) form the fallopian tube. The cranial-most aspect of the first part forms the fimbriated end, and the caudal-most segment of the müllerian duct (the fused portion) forms the uterus. During the growth of the second portion of the müllerian duct (the transverse segment that crosses the wolffian duct), the urogenital ridges form a transverse pelvic fold. After the fusion of the caudal segment of the müllerian duct, the transverse pelvic fold extends laterally from the fused müllerian duct toward the pelvic sidewall (> Fig. 11.2). This pelvic fold forms the broad ligament to which the fallopian tube is attached.

The lumen of the fallopian tube is initially oval to round and lined by immature columnar epithelium, but the mucosa forms plicae at week 14. In week 16, the fallopian tube begins an active growth phase and starts to coil. Smooth muscle appears in the walls of the genital canal between 18 and 20 weeks. The fallopian tube muscular wall develops only around the müllerian duct, so that the wolffian duct remnants are external to the true wall of the canal. From the 22nd to 36th week, there is an increase in the growth and coiling of the fallopian tube at a rate of approximately 3 mm/week [108]. Fimbriae do not develop until the 20th week, at which time only three to four are present in each fallopian tube [226]. The fimbriae increase in number throughout gestation, and at term, six to eight are present in each tube. The number continues to increase after birth.

Important genes in the embryologic development of the müllerian duct include the *Wnt* family, *Lim1*, *Pax2*, and *Emx2* [243]. In addition, the *Hox* family of genes (*Hox*

(a) Diagram of ventral aspect of coronal section through female embryo at the end of the eighth week. The arrangement of the müllerian (*red*) and wolffian (mesonephric) (*blue*) ducts is shown. The cranial portion of the müllerian duct is lateral to the wolffian duct. The former grows in a caudal direction and crosses ventral to the latter and is in a medial position at the caudal end. The caudal ends of the müllerian ducts fuse, which eventually form the uterus. (b) The developed fallopian tube with accompanying wolffian remnants. The *red* and *blue* structures correspond to their precursors in (a) (From Sadler TW. *Langman's Medical Embryology, 6th Edition*. Baltimore: Williams & Wilkins; 1990:Figs. 15–22. *Printed with permission from Lippincott Williams & Wilkins*)

in mice, HOX in humans) is particularly essential for development of this anatomic structure [65, 228, 243]. The Hox family represents four clusters of genes (Hoxa through Hoxd), which encode transcription factors that direct embryogenesis. Their main function is to control patterning and positional identity along a developing axis, such as the hindbrain, axial skeleton, and limbs. One of the anatomic sites controlled by the Hoxa cluster during embryogenesis is the müllerian duct, in which each Hoxa gene controls the morphogenesis of different segments along the developing axis of the müllerian duct. Hoxa-9 through Hoxa-13 are sequentially located in tandem with one another in the same region of the chromosome. It has been shown in mice that the physical order of the Hoxa genes on the chromosome corresponds to the same spatial order of the different segments of the developing müllerian duct (i.e., Hoxa-9 is expressed in the fallopian tube, Hoxa-10 and -11 in the uterine corpus, Hoxa-11 in

the uterine cervix, and *Hoxa-13* in the upper vagina). This same spatial organization of *Hoxa* genes with their respective derivatives of the different segments of the müllerian duct is also maintained in humans [228]. Thus, interaction between *HOXA-9* and presumably several other non-HOX genes determines the proper development of the human fallopian tube.

Gross Anatomy

The fallopian tube is located anterior to the ovary. The tube extends medially from the area of its corresponding ovary to its origin in the posterosuperior aspect of the uterine fundus. In an adult during the reproductive years, its length is usually between 9 and 12 cm. The tube at the ovarian end opens to the peritoneal cavity and is composed of about 25 finger-like extensions of the tube – the

Diagram of transverse section of female embryo. (a) through (c) show progressively lower levels through urogenital ridge. The müllerian (paramesonephric) ducts (*orange*) eventually fuse and are then located medial to the wolffian ducts (*blue*). The fusion of the müllerian ducts creates a transverse fold, which becomes the broad ligament (c) (From Sadler TW. *Langman's Medical Embryology, 6th Edition*. Baltimore: Williams & Wilkins; 1990:Figs. 15–23. *Printed with permission from Lippincott Williams & Wilkins*)

fimbriae. The fallopian tube consists of five main segments. From medial to lateral, they are the intramural (interstitial) portion, isthmus, ampulla, infundibulum, and fimbriated end (> Fig. 11.3). The fimbriae attach to the expanded end of the tube, the infundibulum, which is about 1 cm long and 1 cm in diameter. The infundibulum lies within a few millimeters of the lateral or tubal end of the ovary. It narrows gradually to about 4 mm in diameter and merges medially with the ampullary portion of the tube, which extends about 6 cm, passing anteriorly around the ovary. At a point characterized by relative thickening of the muscular wall along with a smaller diameter compared with the ampulla, the isthmic portion begins and extends about 2 cm toward the uterus. Within the myometrium, the tube extends as a 1 cm-long intramural segment until it joins the extension of the endometrial cavity at the uterotubal junction. Throughout its extrauterine course, the tube lays in a peritoneal fold along the superior margin of the broad ligament – the mesosalpinx.

The arterial blood supply has a dual origin from branches of the ovarian and uterine arteries. Tubal branches of the uterine artery pass in the mesosalpinx laterally from the cornu of the uterus to anastomose with tubal branches of the ovarian artery. Venous drainage parallels the arterial supply via anastomosing tubal branches of uterine and ovarian veins, also located in the mesosalpinx. The arterial and venous distributions for lateral portions of the tube are supplied by the ovarian vessels whereas the uterine vessels supply the medial portions of the tube. Drainage from the ovarian veins is to the inferior vena cava on the right and renal vein on the left. Drainage from the uterine plexus is to the internal iliac vein. Tubal lymphatics typically drain into ovarian and uterine vessels. The former and latter drain into the para-aortic and internal iliac lymph nodes, respectively.

The nerve supply of the tube is both sympathetic and parasympathetic. Sympathetic fibers from T10 through L2 synapse in the celiac, aortic, renal, inferior mesenteric, cervicovaginal, and possibly presacral plexuses. Sensory pain fibers pass along with the sympathetic nerves to the spinal cord at the level of T10–T12. Parasympathetic fibers from the vagus nerve supply the lateral portion of the tube via postganglionic fibers from the ovarian plexus whereas the medial portion is innervated via S2–S4 parasympathetic fibers synapsing in the pelvic plexuses.

Histology

A mucosa, wall of smooth muscle (muscularis or myosalpinx), and serosa constitute the three layers of the fallopian tube. The mucosal layer lies directly on the muscularis. It consists of a luminal epithelial lining and a scanty underlying lamina propria containing vessels and spindle or oval mesenchymal cells. Although the lamina propria may be small in area, this is the site of decidua in 5-12% of postpartum tubes (\bigcirc *Fig. 11.4*), and decidua

Posterior aspect (*upper*) and coronal section (*lower*) of fallopian tube including anatomic relationships with adjacent structures. All five segments of the fallopian tube (intramural segment, isthmus, ampulla, infundibulum, and fimbriated end) are illustrated (From Netter FH. *Atlas of Human Anatomy*. West Caldwell: CIBA-GEIGY Corporation; 1989:Plate 350. *Printed with permission from Elsevier, Inc. All rights reserved*)

may be seen in 80% of tubes removed for ectopic pregnancy [89]. The stroma of the plicae of the fallopian tube tends to be more fibrotic in the postmenopausal years. The mucosa increases significantly in its gross structural complexity as the lumen enlarges from the uterine to the ovarian ends. The interstitial/intramural portion contains a mostly flat mucosa with minimal undulation. It is lined by endometrium in the most proximal portion at the junction of the endometrial cavity and tubal ostium. Farther away from the tubal ostium, the mucosa of the interstitial/intramural portion is lined by an epithelial lining that is more typical of distal portions of the tube but with lesser numbers of ciliated cells. The isthmus shows slightly greater undulation than is seen in the interstitial/intramural portion and contains a limited number of blunted plicae (\bigcirc *Fig.* 11.5). In the ampulla, the plicae are frond-like and delicate, and both secondary and tertiary branches may be appreciated (\bigcirc *Fig.* 11.6). The infundibular and fimbriated end plical patterns are similar to that of the ampulla except that the plicae of the fimbriated end are essentially exophytic and have no underlying smooth muscle wall. A distinct fimbria, the *fimbria ovarica*, runs from the tubal ostium to one pole of the ovary and is involved in ovum pick-up, in which there appears to be a realignment of fimbriae in their relationship to the ovary itself.

Decidua. The plicae are expanded due to decidual change within the lamina propria. The decidual cells have cytologic features similar to those of endometrial decidua. Scattered lymphocytes are present in the background

Fig. 11.6

Ampulla. In comparison with the interstitial (intramural) segment and isthmus, the ampulla has a greater diameter of the entire cross section of the tube, greater diameter of the lumen, and thinner muscularis. The plical architecture of the ampulla is more complex than that of the interstitial (intramural) segment and isthmus

Fig. 11.5

Isthmus. The appearance is similar to the interstitial (intramural) segment except that the mucosa shows slightly more undulation with a limited number of blunted plicae

The epithelium of the mucosa is composed of a single layer of cells, or it may be pseudostratified. It predominantly consists of ciliated and secretory cells; the latter are more numerous (\bigcirc *Fig.* 11.7). A third cell, the intercalated ("peg") cell, is thought to exist. Some believe that this is a variant of the secretory cell, but it is not reliably identified on H&E sections. Ciliated cells are more abundant in the lateral portions of the tube, and the secretory cells are

Fig. 11.7 Mucosa of the fallopian tube. The epithelium contains a mixture of ciliated (arrow) and secretory (arrowhead) cells

more numerous in the medial portions. The ciliated cell is columnar or round and has a mild to moderate amount of eosinophilic or clear cytoplasm. The nucleus is oval to round, and the chromatin is moderately granular and slightly basophilic. Ultrastructurally, each of the cilia is composed of a central pair of microtubules that is surrounded by nine outer doublet microtubules. In Kartagener's syndrome, where cilia are scanty and structurally/functionally defective, fertility is impaired but not abolished [94]. The reader is referred elsewhere for additional details regarding the structure and physiology of fallopian tube cilia [147].

The secretory cell also is columnar and approximately the same height as the ciliated cell but often narrower with scant eosinophilic cytoplasm. Its nucleus is columnar, and it is thinner and slightly darker than the nucleus of the ciliated cell. Immunohistochemically, the normal mucosal epithelium of the fallopian tube frequently and diffusely expresses WT-1, ER, and PR, and the Ki-67 labeling index is typically <5%. The secretory cell exhibits the immunophenotype HMFG2(+)/ PAX8(+)/p73(-) [28, 140, 201].

The morphologic characteristics of the tubal epithelium change during life. Ciliated cells appear during early fetal development and persist until the postmenopausal years. At this time, as circulating estrogen levels drop, the cilia are gradually lost. Estrogen therapy in postmenopausal women, however, restores both the cilia and the ability to transport particulate matter. The presence of estrogen receptor in the fallopian tube also supports that estrogen is involved with ciliogenesis. The characteristics of the tubal epithelium change during the course of the menstrual cycle [61]. Early in the cycle, the cells are of low height, and the secretory cells appear relatively inactive. As ovulation approaches, probably under the influence of an increasing amount of estrogen, the secretory cells become prominent and actually project above the luminal border of the ciliated cells. In association with the effects of estrogen and progesterone, changes in cilial maturity and repeated ciliation and deciliation occur during the menstrual cycle, including maximal ciliation around the time of ovulation [61, 235]. Additional details of fallopian tube physiology are available elsewhere [112].

In addition to the three epithelial cell types described above, scattered lymphocytes may be seen located basally above the basement membrane. Immunohistological analysis of these lymphocytes indicates a preponderance of the T-cytotoxic/suppressor subtype, consistent with formation of mucosal-associated lymphoid tissue (MALT) [163].

The tubal muscularis generally has two layers: an inner circular layer and outer longitudinal layer. The circular layer forms the major muscle mass of the tube. Its thickness varies, being greater in the isthmus and lesser in the ampulla/infundibulum. The outer longitudinal layer is easily overlooked, as it is composed of inconspicuous bundles of smooth muscle interspersed with loose connective tissue containing numerous small blood vessels. At the uterine end, beginning in the intramural tube and

Fig. 11.8

Wolffian (mesonephric) duct remnants. The tubules are invested by abundant muscular stroma. *Inset:* They are round and lined by a single layer of bland cuboidal cells. This example is non-ciliated, but other cases may contain cilia

extending laterally about 2 cm, there is, in addition, an inner longitudinal layer. The serosa is lined by flattened mesothelial cells. Beneath the mesothelium lies a small amount of connective tissue containing a few collagen fibers and blood vessels.

The wolffian or mesonephric duct develops in close proximity to the fallopian tube, and remnants from it normally persist throughout adult life. These remnants consist of 10–15 mesonephric tubules lying within abundant muscular stroma just peripheral to the fallopian tube. The tubules (epoöphoron) are lined by a single layer of low-columnar or cuboidal epithelium containing non-ciliated or ciliated cells (\bigcirc *Fig. 11.8*).

Gross Examination

Salpingectomy for Benign Disease, with or Without Hysterectomy

In hysterectomies with benign disease, both fallopian tubes should be measured in the longitudinal and transverse dimensions. The serosa should be examined for gross lesions. The patency of the fimbriated end can be determined with a blunt probe. If a lesion is present, it should be measured, its location (corneal/intramural, isthmic, ampullary, infundibular, or fimbriated end) noted, and its relationship to the lumen and serosa described. The entire length of the tube should be transversely cut ("bread loafed") to identify lesions within the lumen. Grossly visible lesions should be sampled. For grossly unremarkable tubes, standard sections include ≥ 1 block from each side.

Hysterectomy and/or Oophorectomy with Salpingectomy for Non-fallopian Tube Malignant Disease

In hysterectomies for malignant disease, attention should be given to identifying involvement of the fallopian tubes, especially since focal disease may upstage the patient. The tubes should be examined, measured, and cut as described above. In cases of ovarian, peritoneal, or endometrial serous carcinomas, it is advisable to submit all tissue from both fallopian tubes for histologic examination to identify tubal intraepithelial carcinoma (TIC), especially in the fimbriated end (see **O** Carcinoma section below).

Total or Partial Salpingectomy for Tubal Ectopic Pregnancy

The external appearance of the specimen should be carefully examined, and blood distending the lumen should be sought and sampled. If the tubal pregnancy is apparent, its site and location should be noted as described previously and sampled. A rupture site if present should be described and sampled. If the ectopic pregnancy is not obvious, extensive sampling may be necessary. Even a tubal abortion leaves foci of trophoblast at the implantation site. Blood clot in the tube or as a separate specimen should be sampled for microscopic examination to identify trophoblastic cells or chorionic villi.

Bilateral Partial Salpingectomy for Tubal Sterilization

The most important thing in this setting is to document that the tube has been completely transected. This requires complete cross sectioning of the entire tube, and submitting the entire specimen for histologic examination.

Prophylactic Bilateral Salpingo-Oophorectomy

Measurements should be made as specified above. The fimbriated end should be amputated from the rest of the tube and serially sectioned at 2-mm intervals along the long axis. The entire length of the remaining tube should be cut perpendicular to the long axis ("bread loafed") at 2-mm intervals (**>** *Fig. 11.9*). The ovary should also be cut perpendicular to the long axis ("bread loafed") at 2-mm intervals. All fallopian tube and ovarian tissue should be submitted for histologic examination. Although there is no standard in terms of how many H&E slides need to be prepared from each block, our routine practice is one H&E slide per block; however, it has been recognized that in anecdotal cases, additional deeper H&E levels may identify a small tubal intraepithelial carcinoma not present on the initial H&E level.

Fig. 11.9

Sectioning of fallopian tube from a prophylactic bilateral salpingo-oophorectomy specimen. (a) Diagram of fallopian tube prior to (*upper*) and during (*lower*) sectioning. From the proximal-most end of the fallopian tube to the beginning of the fimbriated end, transverse sections (*solid, vertical/diagonal, and red lines*) should be cut at 2-mm intervals. The fimbriated end should be amputated (*dashed, vertical, and red lines*). The fimbriated end should be cut at 2-mm intervals parallel to the long axis of the fallopian tube (*solid, horizontal, and red lines*). All gross tissue should be submitted for histologic examination. (b) Gross photograph of fallopian tube after complete sectioning as per (a)

Salpingectomy for Tubal Neoplasms, with or Without Hysterectomy and/or Oophorectomy

A protocol for gross examination of a tube with carcinoma has been developed by the Association of Directors of Anatomic and Surgical Pathology [146]. This protocol also lists the essential clinical, gross, and histologic information which should be included in the pathology report. The size of the specimen and tumor should be recorded, as should the exact location of the tumor within the tube. The external surface should be examined for visible disease, and any lesions should be sampled. It is important to note whether the fimbriated end is open or closed, the latter being determined by having a hydrosalpinx-like, hematosalpinx-like, or pyosalpinx-like gross appearance. At least three sections from the tumor should be obtained. Sections should show the relationship of the tumor with mucosa, depth of invasion, and serosa.

Non-neoplastic Lesions of Fallopian Tube

Metaplasia, Hyperplasia, and Other Epithelial/Non-Epithelial Changes

The tubal epithelium may undergo various metaplastic changes, including squamous, transitional, mucinous, or oncocytic type (**>** *Fig. 11.10*) [68, 193, 214]. Mucinous metaplasia may be associated with Peutz–Jeghers

Fig. 11.10

Squamotransitional cell metaplasia. he upper center portion shows more squamous differentiation while the lower left portion shows more transitional cell differentiation. Other cases may be of pure squamous or transitional cell type syndrome and can also accompany chronic inflammation. Arias-Stella reaction can occur with intrauterine pregnancy. Mucosal hyperplasia of variable degree and extent, which may be bilateral, is frequent [162, 200, 241, 242]. It is nonspecific, without clinical significance, and can be associated with various conditions and lesions. The hyperplastic epithelium can show stratification, loss of cell polarity, crowding of cells, and small papillary tufts; however, mitotic activity is usually low. In the setting of inflammation, mucosal distortion (including plical blunting and stromal fibrosis) may be seen. Nuclear atypia can be present but is typically mild [107]. In some cases, particularly those associated with marked salpingitis, the degree of hyperplasia (including cribriform architecture)

Fig. 11.11

Epithelial hyperplasia. In the setting of inflammation, mucosal distortion may be seen. (a) Marked distortion of the plicae is present in this case of florid salpingitis. Other foci (b) show glandular epithelium with cribriform architecture. The nuclei exhibit only mild atypia and are mitotically inactive. Ciliated cells can still be identified

Thermal artifact. This appearance may falsely suggest adenocarcinoma because of the distorted and stratified epithelium with darkly staining nuclei. However, closer magnification will show nuclei with the streaming effect that is characteristic of thermal injury

can simulate carcinoma (**)** *Fig.* 11.11) [43, 64]. This differential diagnosis is diagnosed below in the section on carcinoma. Severe epithelial changes that mimic early adenocarcinoma may be produced by thermal artifact (**)** *Fig.* 11.12).

Psammoma bodies ("salpingoliths") are an occasional finding. They are nonspecific and can be seen with normal-appearing epithelium or in various miscellaneous settings, such as chronic salpingitis associated with IgG antibodies to *Chlamydia*, ovarian serous tumors, or otherwise normal epithelium [152, 216].

Nests of cells morphologically similar to ovarian hilus cells have been described in the mid-portion of the tube. In the absence of either Reinke crystals or close association with nonmyelinated nerve fibers, it is difficult to exclude the possibility of an adrenal rest. Hilus cell nests with Reinke crystals may be seen, however, in fimbrial stroma. Ectopic pancreatic tissue or sex cord inclusions (**)** *Fig.* 11.13) can rarely occur.

The tubal serosa, by invagination, may give rise to a number of benign inclusion cysts. The simplest is a 1- to 2-mm unilocular cyst lying directly beneath the serosal surface lined by one or more layers of mesothelial cells – a mesothelial inclusion cyst. By a process of transitional cell metaplasia, small Walthard nests can arise as 1- to 2-mm yellow-white nodules beneath the serosa. Histologically, the Walthard nest may be solid or cystic and resemble urothelium (\bigcirc *Fig. 11.14*). The cells

Fig. 11.13

Sex cord inclusions in the fimbriated end of the fallopian tube. Immunohistochemical stains for inhibin and calretinin were diffusely positive. The ovaries were thoroughly sampled, and an ovarian mass was not present. Photo courtesy of Dr. Kathleen Cho (Univ. of Michigan Medical School)

have nuclei that are irregularly ovoid with a longitudinal nuclear groove, giving them a coffee-bean appearance. Both mesothelial inclusion cysts and Walthard nests are common incidental findings of no clinical importance.

Endometriosis and Endosalpingiosis

Normally, endometrial tissue can be found within the mucosa of the intramural and isthmic portions of the fallopian tube. The presence of endometrial tissue within the lumen has been referred to as "endometrial colonization"; however, it is unclear whether this is a variant of normal as opposed to true endometriosis. Endometriosis of the tube can be found within the lumen or myosalpinx or on the serosa. In occasional cases, the configuration of endometriosis may produce a mass clinically or grossly simulating a tumor ("polypoid endometriosis") [180]. A form of endometriosis designated "post-salpingectomy endometriosis" occurs in the tip of the proximal stump of the fallopian tube years after tubal ligation [44]. This form is apparently common. Endosalpingiosis is ectopic tubaltype epithelium involving the serosal surface of the tube. Both endometriosis and endosalpingiosis are discussed in detail in **O** Chap. 13, Diseases of the Peritoneum.

Salpingitis Isthmica Nodosa

Salpingitis isthmica nodosa (SIN) is a pseudoinfiltrative lesion consisting of diverticula of tubal epithelium in the isthmus. It occurs in women between the ages of 25 and 60 years (average, 30 years). SIN is often bilateral. The external gross appearance is that of one or more nodularities in the isthmus, ranging up to 1–2 cm in diameter. The serosa is smooth. Grossly, the tissue is firm, and careful inspection may disclose some of the dilated diverticula.

Histologically at low-power magnification, round to elongated dilated glands proliferate through the muscularis, which is usually accompanied by nodular smooth muscle hyperplasia and mural thickening (> Fig. 11.15). The glands proliferate in a circumferential and swirling pattern around the centrally dilated lumen of the fallopian tube. In some sections, it may be possible to appreciate a communication with the central lumen, indicating a diverticular process. The glands are composed of a single layer of bland tubal-type epithelium. An altered stromal reaction is typically absent. However, SIN is frequently associated with chronic salpingitis [132]. Endometrioid stromal cells lying beneath the diverticula may be abundant; however, they are usually sparse or absent. If both glands and stroma are present, it may be difficult to distinguish SIN from tubal endometriosis in some cases.

The etiology is unknown, but post-inflammatory distortion and an adenomyosis-like process are possibilities. An important complication of SIN is infertility, and there is a strong association with ectopic tubal pregnancy

Fig. 11.15
