The diagnosis of β-thalassemia major can be strongly suspected on clinical grounds. *Hb electrophoresis* shows profound reduction or absence of HbA and increased levels of HbF. The HbA2 level may be normal or increased. Similar but less profound changes are noted in patients affected by β-thalassemia intermedia. *Prenatal diagnosis* of β-thalassemia is challenging due to the diversity of causative mutations, but can be made in specialized centers by DNA analysis. In fact, thalassemia was the first disease diagnosed by DNA-based tests, opening the way for the field of molecular diagnostics. The diagnosis of β-thalassemia minor is made by Hb electrophoresis, which typically reveals a reduced level of HbA ($\alpha_2\beta_2$) and an increased level of HbA2 ($\alpha_2\delta_2$). HbH disease can be diagnosed by detection of β4 tetramers by electrophoresis.

## Glucose-6-Phosphate Dehydrogenase Deficiency

Red cells are constantly exposed to both endogenous and exogenous oxidants, which are normally inactivated by reduced glutathione (GSH). Abnormalities affecting the enzymes responsible for the synthesis of GSH leave red cells vulnerable to oxidative injury and lead to hemolytic anemias. By far the most common of these anemias is that caused by glucose-6-phosphate dehydrogenase (G6PD) deficiency. The G6PD gene is on the X chromosome. More than 400 G6PD variants have been identified, but only a few are associated with disease. One of the most important variants is G6PD $A^-$, which is carried by approximately 10% of black males in the United States. G6PD $A^-$ has a normal enzymatic activity but a decreased half-life. Because red cells do not synthesize proteins, older G6PD $A^-$ red cells become progressively deficient in enzyme activity and the reduced form of glutathione. This in turn renders older red cells more sensitive to oxidant stress.

### PATHOGENESIS

**G6PD deficiency produces no symptoms until the patient is exposed to an environmental factor (most commonly infectious agents or drugs) that produces oxidants.** The drugs incriminated include antimalarials (e.g., primaquine), sulfonamides, nitrofurantoin, phenacetin, aspirin (in large doses), and vitamin K derivatives. More commonly, episodes of hemolysis are triggered by **infections,** which induce phagocytes to generate oxidants as part of the normal host response. These oxidants, such as hydrogen peroxide, are normally sopped up by GSH, which is converted to oxidized glutathione in the process. Because regeneration of GSH is impaired in G6PD-deficient cells, oxidants are free to "attack" other red cell components including globin chains, which have sulfhydryl groups that are susceptible to oxidation. Oxidized hemoglobin denatures and precipitates, forming intracellular inclusions called **Heinz bodies,** which can damage the cell membrane sufficiently to cause intravascular hemolysis. Other, less severely damaged cells lose their deformability and suffer further injury when splenic phagocytes attempt to "pluck out" the Heinz bodies, creating so-called **bite cells** (Fig. 11–7). Such cells become trapped upon recirculation to the spleen and are destroyed by phagocytes (extravascular hemolysis).

### Clinical Features

Drug-induced hemolysis is acute and of variable severity. Typically, patients develop hemolysis after a lag of 2 or 3 days. Since G6PD is X-linked, the red cells of affected males are uniformly deficient and vulnerable to oxidant injury. By contrast, random inactivation of one X chromosome in heterozygous females (Chapter 6) creates two populations of red cells, one normal and the other G6PD-deficient. Most carrier females are unaffected except for those with a large proportion of deficient red cells (a chance situation known as *unfavorable lyonization*). In the case of the G6PD

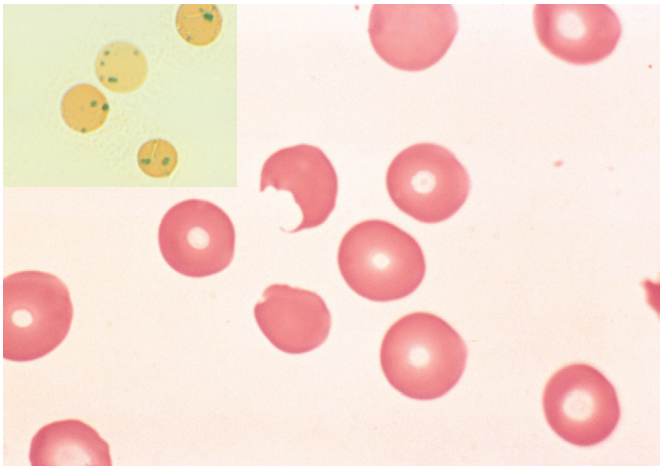

**Figure 11–7** Glucose-6-phosphate dehydrogenase deficiency after oxidant drug exposure—peripheral blood smear. **Inset,** Red cells with precipitates of denatured globin (Heinz bodies) revealed by supravital staining. As the splenic macrophages pluck out these inclusions, "bite cells" like the one in this smear are produced.

*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

$A^-$ variant, it is mainly older red cells that are susceptible to lysis. Since the marrow compensates for the anemia by producing new resistant red cells, the hemolysis abates even if the drug exposure continues. In other variants such as G6PD Mediterranean, found mainly in the Middle East, the enzyme deficiency and the hemolysis that occur on exposure to oxidants are more severe.

## Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare disorder worthy of mention because it is the only hemolytic anemia that results from an *acquired somatic mutation in myeloid stem cells.*

### PATHOGENESIS

PNH stems from **acquired mutations in gene PIGA,** which is required for the synthesis of phosphatidylinositol glycan (PIG), a membrane anchor that is a component of many proteins. Without the "PIG-tail," these proteins cannot be expressed on the cell surface. The affected proteins include several that limit the activation of complement. As a result, PIGA-deficient precursors give rise to red cells that are **inordinately sensitive to complement-mediated lysis.** Leukocytes are also deficient in these protective proteins, but nucleated cells are generally less sensitive to complement than are red cells, and as a result the red cells take the brunt of the attack. The paroxysmal nocturnal hemolysis that gives the disorder its name occurs because the fixation of complement is enhanced by the slight decrease in blood pH that accompanies sleep (owing to $CO_2$ retention). However, most patients present less dramatically with anemia due to chronic low-level hemolysis. Another complication that is often serious and sometimes fatal is **venous thrombosis.** The etiopathogenesis of the prothrombotic state is somehow also related to the activity of the complement membrane attack complex, as inhibitors of this complex (described below) greatly lessen the incidence of thrombosis.

Because *PIGA* is X-linked, normal cells have only a single active *PIGA* gene, mutation of which is sufficient to give rise to PIGA deficiency. Because all myeloid lineages are affected in PNH, the responsible **mutations must occur in an early myeloid progenitor with self-renewal capacity.** Remarkably, many normal individuals harbor small numbers of bone marrow cells bearing *PIGA* mutations identical to those that cause PNH. It is believed that clinically evident PNH occurs only in rare instances in which the *PIGA* mutant clone has a survival advantage. One setting in which this may be true is in primary bone marrow failure (aplastic anemia), which most often appears to be caused by immune-mediated destruction or suppression of marrow stem cells. It is hypothesized that PIGA-deficient stem cells somehow escape the immune attack and eventually replace the normal marrow elements. Targeted therapy with an antibody that inhibits the C5b–C9 membrane attack complex is effective at diminishing both the hemolysis and the thrombotic complications, but also places patients at high risk for *Neisseria* infections, including meningococcal sepsis.

## Immunohemolytic Anemias

Some individuals develop antibodies that recognize determinants on red cell membranes and cause hemolytic anemia. These antibodies may arise spontaneously or be induced by exogenous agents such as drugs or chemicals. Immunohemolytic anemias are uncommon and classified on the basis of (1) the nature of the antibody and (2) the presence of predisposing conditions (summarized in Table 11–4).

The diagnosis of immunohemolytic anemias depends on the detection of antibodies and/or complement on red cells. This is done with the *direct Coombs antiglobulin test,* in which the patient's red cells are incubated with antibodies against human immunoglobulin or complement. In a positive test result, these antibodies cause the patient's red cells to clump (agglutinate). The *indirect Coombs test,* which assesses the ability of the patient's serum to agglutinate test red cells bearing defined surface determinants, can then be used to characterize the target of the antibody.

### *Warm Antibody Immunohemolytic Anemias*

Warm antibody immunohemolytic anemias are caused by immunoglobulin G (IgG) or, rarely, IgA antibodies that are active at 37°C. More than 60% of cases are idiopathic

**Table 11–4** Classification of Immunohemolytic Anemias

| |
|---|
| **Warm Antibody Type** |
| *Primary* (idiopathic)<br>*Secondary*: B cell neoplasms (e.g., chronic lymphocytic leukemia), autoimmune disorders (e.g., systemic lupus erythematosus), drugs (e.g., α-methyldopa, penicillin, quinidine) |
| **Cold Antibody Type** |
| *Acute: Mycoplasma* infection, infectious mononucleosis<br>*Chronic*: idiopathic, B cell lymphoid neoplasms (e.g., lymphoplasmacytic lymphoma) |

(primary), while another 25% are secondary to an underlying disease affecting the immune system (e.g., systemic lupus erythematosus) or are induced by drugs. *The hemolysis usually results from the opsonization of red cells by the autoantibodies,* which leads to erythrophagocytosis in the spleen and elsewhere. In addition, incomplete consumption ("nibbling") of antibody-coated red cells by macrophages removes membrane. With loss of cell membrane the red cells are transformed into *spherocytes,* which are rapidly destroyed in the spleen, as described earlier for hereditary spherocytosis. The clinical severity of immunohemolytic anemias is quite variable. Most patients have chronic mild anemia with moderate splenomegaly and require no treatment.

The mechanisms of hemolysis induced by drugs are varied and in some instances poorly understood. Drugs such as α-methyldopa induce autoantibodies against intrinsic red cell constituents, in particular Rh blood group antigens. Presumably, the drug somehow alters the immunogenicity of native epitopes and thereby circumvents T cell tolerance (Chapter 4). Other drugs such as penicillin act as haptens, inducing an antibody response by binding covalently to red cell membrane proteins. Sometimes antibodies recognize a drug in the circulation and form immune complexes that are deposited on red cell membranes. Here they may fix complement or act as opsonins, either of which can lead to hemolysis.

### *Cold Antibody Immunohemolytic Anemias*

Cold antibody immunohemolytic anemias usually are caused by low-affinity IgM antibodies that bind to red cell membranes only at temperatures below 30°C, such as occur in distal parts of the body (e.g., ears, hands, and toes) in cold weather. Although bound IgM fixes complement well, the latter steps of the complement fixation cascade occur inefficiently at temperatures lower than 37°C. As a result, most cells with bound IgM pick up some C3b but are not lysed intravascularly. When these cells travel to warmer areas, the weakly bound IgM antibody is released, but the coating of C3b remains. Because C3b is an opsonin (Chapter 2), the cells are phagocytosed by macrophages, mainly in the spleen and liver; hence, the *hemolysis is extravascular*. Binding of pentavalent IgM also cross-links red cells and causes them to clump (agglutinate). *Sludging of blood in capillaries due to agglutination often produces Raynaud phenomenon* in the extremities of affected individuals. Cold agglutinins sometimes also appear transiently during recovery from pneumonia caused by *Mycoplasma* spp. and infectious mononucleosis, producing a mild anemia of little clinical importance. More important chronic forms of cold agglutinin hemolytic anemia occur in association with certain B cell neoplasms or as an idiopathic condition.

## Hemolytic Anemias Resulting from Mechanical Trauma to Red Cells

Abnormal mechanical forces result in red cell hemolysis in a variety of circumstances. *Traumatic hemolysis* can occur incidentally during any activity involving repeated physical blows or their equivalent (e.g., marathon racing, karate chopping, bongo drumming) but is of little clinical importance. More significant mechanical hemolysis is sometimes

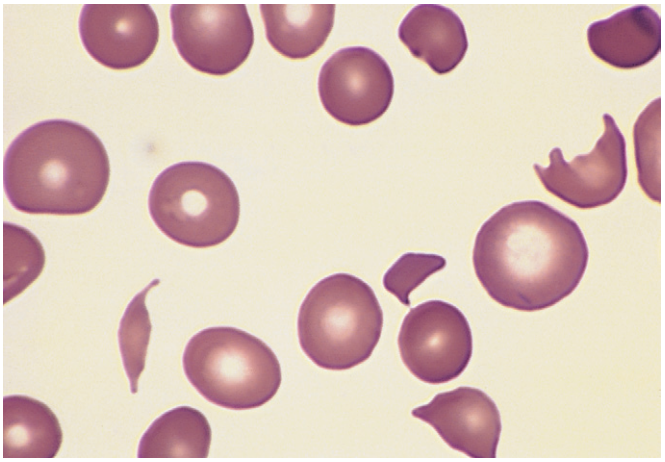

**Figure 11–8** Microangiopathic hemolytic anemia—peripheral blood smear. This specimen from a patient with hemolytic uremic syndrome contains several fragmented red cells.

*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

produced by defective cardiac valve prostheses (the blender effect), which can create sufficiently turbulent blood flow to shear red cells. *Microangiopathic hemolytic anemia* is observed in pathologic states in which small vessels become partially obstructed or narrowed by lesions that predispose passing red cells to mechanical damage. The most frequent of these conditions is disseminated intravascular coagulation (DIC) (see later), in which vessels are narrowed by the intravascular deposition of fibrin. Other causes of microangiopathic hemolytic anemia include malignant hypertension, systemic lupus erythematosus, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and disseminated cancer. The morphologic alterations in the injured red cells (*schistocytes*) are striking and quite characteristic; "burr cells," "helmet cells," and "triangle cells" may be seen (Fig. 11–8). While microangiopathic hemolysis is not usually in and of itself a major clinical problem, it often points to a serious underlying condition.

## Malaria

It is estimated that malaria affects 500 million and kills more than 1 million people per year, making it one of the most widespread afflictions of humans. Malaria is endemic in Asia and Africa, but with widespread jet travel cases are now seen all over the world. It is caused by one of four types of protozoa. Of these, the most important is *Plasmodium falciparum*, which causes tertian malaria (falciparum malaria), a serious disorder with a high fatality rate. The other three species of *Plasmodium* that infect humans—*Plasmodium malariae, Plasmodium vivax,* and *Plasmodium ovale*—cause relatively benign disease. All forms are transmitted by the bite of female *Anopheles* mosquitoes, and humans are the only natural reservoir.

### PATHOGENESIS

The life cycle of plasmodia is complex. As mosquitoes feed on human blood, sporozoites are introduced from the saliva

and within a few minutes infect liver cells. Here the parasites multiply rapidly to form a schizont containing thousands of merozoites. After a period of days to several weeks that varies with the *Plasmodium* species, the infected hepatocytes release the merozoites, which quickly infect red cells. Intraerythrocytic parasites either continue asexual reproduction to produce more merozoites or give rise to **gametocytes** capable of infecting the next hungry mosquito. During their asexual reproduction in red cells, each of the four forms of malaria develops into **trophozoites** with a somewhat distinctive appearance. Thus, **the species of malaria that is responsible for an infection can be identified in appropriately stained thick smears of peripheral blood.** The asexual phase is completed when the trophozoites give rise to new merozoites, which escape by lysing the red cells.

### Clinical Features

The distinctive clinical and anatomic features of malaria are related to the following factors:

- Showers of new merozoites are released from the red cells at intervals of approximately 48 hours for *P. vivax, P. ovale,* and *P. falciparum* and 72 hours for *P. malariae.* The episodic shaking, chills, and fever coincide with this release.
- The parasites destroy large numbers of infected red cells, thereby causing a hemolytic anemia.
- A characteristic brown malarial pigment derived from hemoglobin called hematin is released from the ruptured red cells and produces discoloration of the spleen, liver, lymph nodes, and bone marrow.
- Activation of defense mechanisms in the host leads to a marked hyperplasia of mononuclear phagocytes, producing massive splenomegaly and occasional hepatomegaly.

*Fatal falciparum malaria often involves the brain, a complication known as cerebral malaria.* Normally, red cells bear negatively charged surfaces that interact poorly with endothelial cells. Infection of red cells with *P. falciparum* induces the appearance of positively charged surface knobs containing parasite-encoded proteins, which bind to adhesion molecules expressed on activated endothelium. Several endothelial cell adhesion molecules, including intercellular adhesion molecule-1 (ICAM-1), have been proposed to mediate this interaction, which leads to the trapping of red cells in postcapillary venules. In an unfortunate minority of patients, mainly children, this process involves cerebral vessels, which become engorged and occluded. *Cerebral malaria* is rapidly progressive; convulsions, coma, and death usually occur within days to weeks. Fortunately, falciparum malaria usually pursues a chronic course, which may be punctuated at any time by *blackwater fever.* The trigger is obscure for this uncommon complication, which is associated with massive intravascular hemolysis, hemoglobinemia, hemoglobinuria, and jaundice.

With appropriate chemotherapy, the prognosis for patients with most forms of malaria is good; however, treatment of falciparum malaria is becoming more difficult with the emergence of drug-resistant strains. Because of the potentially serious consequences of the disease, early diagnosis and treatment are important. The ultimate solution is an effective vaccine, which is long-sought but still elusive.

## SUMMARY

### Hemolytic Anemias

**Hereditary Spherocytosis**

- Autosomal dominant disorder caused by mutations that affect the red cell membrane skeleton, leading to loss of membrane and eventual conversion of red cells to spherocytes, which are phagocytosed and removed in the spleen
- Manifested by anemia, splenomegaly

**Sickle Cell Anemia**

- Autosomal recessive disorder resulting from a mutation in β-globin that causes deoxygenated hemoglobin to self-associate into long polymers that distort (sickle) the red cell
- Blockage of vessels by sickled cells causes pain crises and tissue infarction, particularly of the marrow and spleen
- Red cell membrane damage caused by repeated bouts of sickling results in a moderate to severe hemolytic anemia

**Thalassemias**

- Autosomal codominant disorders caused by mutations in α- or β-globin that reduce hemoglobin synthesis, resulting in a microcytic, hypochromic anemia. In β-thalassemia, unpaired α-globin chains form aggregates that damage red cell precursors and further impair erythropoiesis.

**Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency**

- X-linked disorder caused by mutations that destabilize G6PD, making red cells susceptible to oxidant damage

**Immunohemolytic Anemias**

- Caused by antibodies against either normal red cell constituents or antigens modified by haptens (such as drugs)
- Antibody binding results in either red cell opsonization and extravascular hemolysis or (uncommonly) complement fixation and intravascular hemolysis

**Malaria**

- Intracellular red cell parasite that causes chronic hemolysis of variable severity
- Falciparum malaria may be fatal due to the propensity of infected red cells to adhere to small vessels in the brain (cerebral malaria)

# ANEMIAS OF DIMINISHED ERYTHROPOIESIS

The category of anemias involving diminished erythropoiesis includes anemias that are caused by an inadequate dietary supply of nutrients, particularly iron, folic acid, and vitamin $B_{12}$. Other anemias of this type are those associated with bone marrow failure (aplastic anemia), systemic

inflammation (anemia of chronic disease), or bone marrow infiltration by tumor or inflammatory cells (myelophthisic anemia). In this section, some common examples of anemias of these types are discussed individually.

## Iron Deficiency Anemia

About 10% of people living in developed countries and 25% to 50% of those in developing countries are anemic. In both settings, *the most frequent cause of anemia is iron deficiency.* The factors responsible for iron deficiency differ in various populations and are best understood in the context of normal iron metabolism.

The normal total body iron mass is about 2.5 g for women and 3.5 g for men. Approximately 80% of functional body iron is present in hemoglobin, with the remainder being found in myoglobin and iron-containing enzymes (e.g., catalase, cytochromes). The iron storage pool, consisting of hemosiderin and ferritin-bound iron in the liver, spleen, bone marrow, and skeletal muscle, contains on average 15% to 20% of total body iron. Because *serum ferritin* is largely derived from this storage pool, the serum ferritin level is a good measure of iron stores. *Assessment of bone marrow iron* is another reliable but more invasive method for estimating iron stores. Iron is transported in the plasma bound to the protein *transferrin.* In normal persons, transferrin is about 33% saturated with iron, yielding serum iron levels that average 120 µg/dL in men and 100 µg/dL in women. Thus, the normal total iron-binding capacity of serum is 300 to 350 µg/dL.

In keeping with the high prevalence of iron deficiency, evolutionary pressures have yielded metabolic pathways that are strongly biased toward iron retention. There is no regulated pathway for iron excretion, which is limited to the 1 to 2 mg/day that is lost through the shedding of mucosal and skin epithelial cells. *Iron balance is maintained largely by regulating the absorption of dietary iron.* The normal daily Western diet contains 10 to 20 mg of iron. Most of this is found in heme within meat and poultry, with the remainder present as inorganic iron in vegetables. About 20% of heme iron and 1% to 2% of nonheme iron are absorbable; hence, the average Western diet contains sufficient iron to balance fixed daily losses.

Iron is absorbed in the duodenum (Fig. 11–9). Nonheme iron is carried across the apical and basolateral membranes of enterocytes by distinct transporters. After reduction by ferric reductase, ferrous iron ($Fe^{2+}$) is transported across the apical membrane by divalent metal transporter-1 (DMT1). A second transporter, ferroportin, then moves iron from the cytoplasm to the plasma across the basolateral membrane. The newly absorbed iron is next oxidized by hephaestin and ceruloplasmin to ferric iron ($Fe^{3+}$), the form of iron that binds to transferrin. Both DMT1 and ferroportin are widely distributed in the body and are involved in iron transport in other tissues as well. As depicted in Figure 11–9, only a fraction of the iron that enters enterocytes is delivered to transferrin by ferroportin. The remainder is incorporated into cytoplasmic ferritin and lost through the exfoliation of mucosal cells.

When the body is replete with iron, most iron entering duodenal cells is "handed off" to ferritin, whereas transfer to plasma transferrin is enhanced when iron is deficient or erythropoiesis is inefficient. This balance is regulated by hepcidin, a small hepatic peptide that is synthesized and secreted in an iron-dependent fashion. Plasma hepcidin binds ferroportin and induces its internalization and degradation; thus, when hepcidin concentrations are high, ferroportin levels fall and less iron is absorbed. Conversely, when hepcidin levels are low (as occurs in hemochromatosis) (Chapter 15), basolateral transport of iron is increased, eventually leading to systemic iron overload.

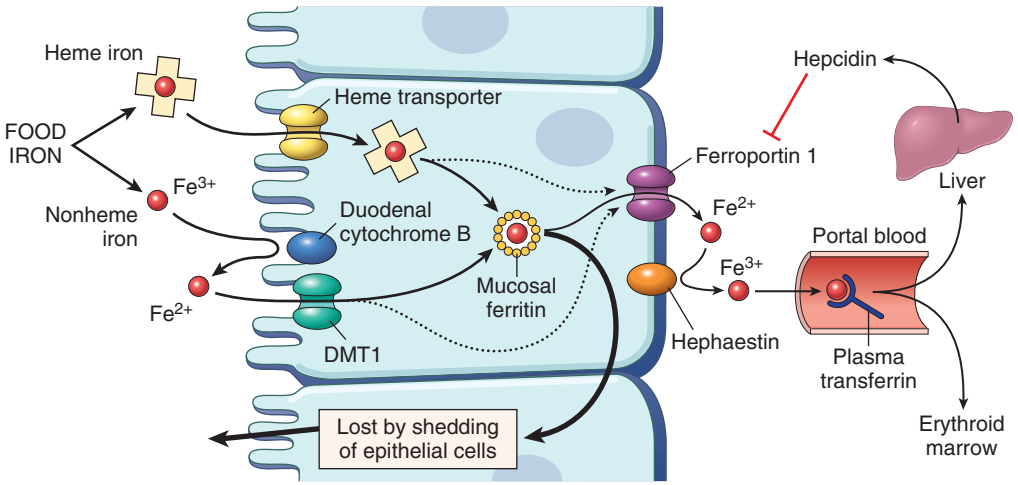

**Figure 11–9** Regulation of iron absorption. Duodenal epithelial cell uptake of heme and nonheme iron discussed in the text is depicted. When the storage sites of the body are replete with iron and erythropoietic activity is normal, plasma hepcidin levels are high. This situation leads to downregulation of ferroportin and trapping of most of the absorbed iron, which is lost when duodenal epithelial cells are shed into the gut. Conversely, when body iron stores decrease or erythropoiesis is stimulated, hepcidin levels fall and ferroportin activity increases, allowing a greater fraction of the absorbed iron to be transferred into plasma transferrin. DMT1, divalent metal transporter-1.

## PATHOGENESIS

Iron deficiency arises in a variety of settings:

- **Chronic blood loss is the most important cause of iron deficiency anemia in the Western world;** the most common sources of bleeding are the gastrointestinal tract (e.g., peptic ulcers, colonic cancer, hemorrhoids) and the female genital tract (e.g., menorrhagia, metrorrhagia, cancers).
- **In the developing world, low intake and poor bioavailability due to predominantly vegetarian diets are the most common causes of iron deficiency.** In the United States, low dietary intake is an infrequent culprit but is sometimes culpable in infants fed exclusively milk, the impoverished, the elderly, and teenagers subsisting predominantly on junk food.
- Increased demands not met by normal dietary intake occur worldwide during pregnancy and infancy.
- Malabsorption can occur with celiac disease or after gastrectomy (Chapter 14).

Regardless of the cause, iron deficiency develops insidiously. Iron stores are depleted first, marked by a decline in serum ferritin and the absence of stainable iron in the bone marrow. These changes are followed by a decrease in serum iron and a rise in the serum transferrin. Ultimately, the capacity to synthesize hemoglobin, myoglobin, and other iron-containing proteins is diminished, leading to microcytic anemia, impaired work and cognitive performance, and even reduced immunocompetence.

### Clinical Features

In most instances, iron deficiency anemia is usually mild and asymptomatic. Nonspecific manifestations, such as weakness, listlessness, and pallor, may be present in severe cases. With long-standing anemia, abnormalities of the fingernails, including thinning, flattening, and "spooning," may appear. A curious but characteristic neurobehavioral complication is *pica,* the compunction to consume nonfoodstuffs such as dirt or clay.

In peripheral smears red cells are *microcytic* and *hypochromic* (Fig. 11–10). *Diagnostic criteria* include anemia, hypochromic and microcytic red cell indices, low serum ferritin and iron levels, low transferrin saturation, increased total iron-binding capacity, and, ultimately, response to iron therapy. For unclear reasons, the platelet count often is elevated. Erythropoietin levels are increased, but the marrow response is blunted by the iron deficiency; thus, marrow cellularity usually is only slightly increased.

Persons often die with iron deficiency anemia, but virtually never of it. An important point is that in well-nourished persons, microcytic hypochromic anemia is not a disease but rather a symptom of some underlying disorder.

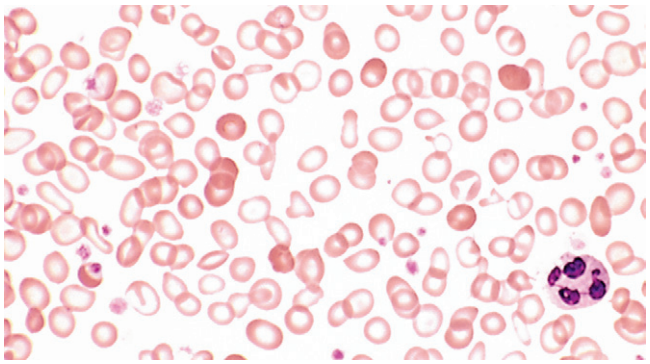

**Figure 11–10** Iron deficiency anemia—peripheral blood smear. Note the increased central pallor of most of the red cells. Scattered, fully hemoglobinized cells, from a recent blood transfusion, stand out in contrast.

*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

## Anemia of Chronic Disease

Anemia associated with chronic disease is the most common form of anemia in hospitalized patients. It superficially resembles the anemia of iron deficiency but arises instead from the suppression of erythropoiesis by systemic inflammation. It occurs in a variety of disorders associated with sustained inflammation, including:

- Chronic microbial infections, such as osteomyelitis, bacterial endocarditis, and lung abscess
- Chronic immune disorders, such as rheumatoid arthritis and regional enteritis
- Neoplasms, such as Hodgkin lymphoma and carcinomas of the lung and breast

## PATHOGENESIS

**The anemia of chronic disease stems from high levels of plasma hepcidin,** which blocks the transfer of iron to erythroid precursors by downregulating ferroportin in macrophages. The elevated hepcidin levels are caused by pro-inflammatory cytokines such as IL-6, which increase hepatic hepcidin synthesis. In addition, chronic inflammation blunts erythropoietin synthesis by the kidney, lowering red cell production by the marrow. The functional advantages of these adaptations in the face of systemic inflammation are unclear; they may serve to inhibit the growth of iron-dependent microorganisms or to augment certain aspects of host immunity.

### Clinical Features

As in anemia of iron deficiency, the serum iron levels usually are low in the anemia of chronic disease, and the red cells may even be slightly hypochromic and microcytic. Unlike iron deficiency anemia, however, *storage iron in the bone marrow is increased, the serum ferritin concentration is elevated, and the total iron-binding capacity is reduced.* Administration of erythropoietin and iron can improve the anemia, but only effective treatment of the underlying condition is curative.

## Megaloblastic Anemias

The two principal causes of megaloblastic anemia are folate deficiency and vitamin $B_{12}$ deficiency. Both vitamins are required for DNA synthesis and the effects of their deficiency on hematopoiesis are essentially identical. However, the causes and consequences of folate and vitamin $B_{12}$ deficiency differ in important ways.

### PATHOGENESIS

The morphologic hallmark of megaloblastic anemia is the presence of megaloblasts, enlarged erythroid precursors that give rise to abnormally large red cells (macrocytes). Granulocyte precursors are also increased in size. Underlying this **cellular gigantism** is a defect in DNA synthesis that impairs nuclear maturation and cell division. Because the synthesis of RNA and cytoplasmic elements proceeds at a normal rate and thus outpaces that of the nucleus, the hematopoietic precursors show **nuclear-cytoplasmic asynchrony.** This maturational derangement contributes to the anemia in several ways. Many megaloblasts are so defective in DNA synthesis that they undergo apoptosis in the marrow (**ineffective hematopoiesis**). Others mature into red cells but do so after fewer cell divisions, further diminishing the output of red cells. Granulocyte and platelet precursors are also affected (although not as severely) and most patients present with pancytopenia (anemia, thrombocytopenia, and granulocytopenia).

### MORPHOLOGY

Certain morphologic features are common to all forms of megaloblastic anemia. The bone marrow is markedly hypercellular and contains numerous megaloblastic erythroid progenitors. **Megaloblasts** are larger than normal erythroid progenitors (normoblasts) and have delicate, finely reticulated nuclear chromatin (indicative of nuclear immaturity) (Fig. 11–11). As megaloblasts differentiate and acquire hemoglobin, the nucleus retains its finely distributed chromatin and fails to undergo the chromatin clumping typical of normoblasts. The granulocytic precursors also demonstrate nuclear-cytoplasmic asynchrony, yielding **giant metamyelocytes.** Megakaryocytes may also be abnormally large and have bizarre multilobed nuclei.

In the peripheral blood the earliest change is the appearance of **hypersegmented neutrophils,** which appear before the onset of anemia. Normal neutrophils have three or four nuclear lobes, but in megaloblastic anemias they often have five or more. The red cells typically include large, **egg-shaped macro-ovalocytes;** the mean cell volume often is greater than 110 fL (normal, 82 to 92 fL). Although macrocytes appear hyperchromic, in reality the mean cell hemoglobin concentration is normal. Large, misshapen platelets also may be seen. Morphologic changes in other systems, especially the gastrointestinal tract, also occur, giving rise to some of the clinical manifestations.

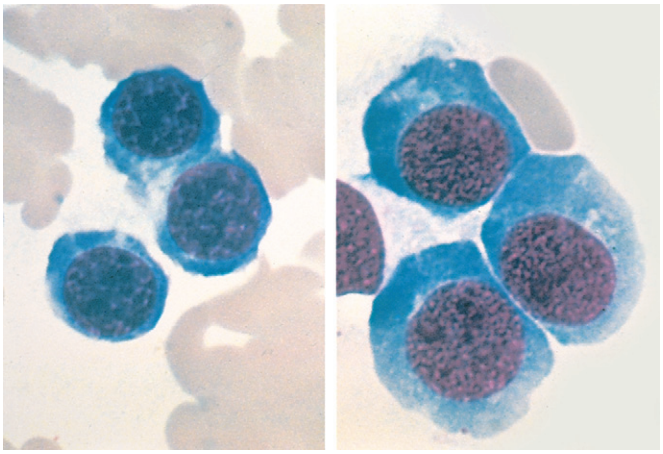

**Figure 11–11** Comparison of normoblasts (*left*) and megaloblasts (*right*)—bone marrow aspirate. Megaloblasts are larger, have relatively immature nuclei with finely reticulated chromatin, and abundant basophilic cytoplasm.

*(Courtesy of Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

### *Folate (Folic Acid) Deficiency Anemia*

Megaloblastic anemia secondary to folate deficiency is not common, but marginal folate stores occur with surprising frequency even in apparently healthy persons. The risk of clinically significant folate deficiency is high in those with a poor diet (the economically deprived, the indigent, and the elderly) or increased metabolic needs (pregnant women and patients with chronic hemolytic anemias).

Folate is present in nearly all foods but is destroyed by 10 to 15 minutes of cooking. Thus, the best sources are fresh uncooked vegetables and fruits. Food folates are predominantly in polyglutamate form and must be split into monoglutamates for absorption, a conversion that is hampered by concurrent consumption of acidic foods and substances found in beans and other legumes. Phenytoin (dilantin) and a few other drugs also inhibit folate absorption, while others, such as methotrexate, inhibit folate metabolism. The principal site of intestinal absorption is the upper third of the small intestine; thus, malabsorptive disorders that affect this level of the gut, such as celiac disease and tropical sprue, can impair folate uptake.

### PATHOGENESIS

The metabolism and functions of folate are complex. Here, it is sufficient to note that after absorption folate is transported in the blood mainly as a monoglutamate. Within cells it is further metabolized to several derivatives, but its conversion from dihydrofolate to tetrahydrofolate by dihydrofolate reductase is particularly important. **Tetrahydrofolate acts as an acceptor and donor of one-carbon units** in several reactions that are required for the synthesis of **purines and thymidylate,** the building blocks of DNA, and its deficiency accounts for the defect in DNA replication that underlies megaloblastic anemia.

Clinical Features

The onset of the anemia of folate deficiency is insidious, being associated with nonspecific symptoms such as weakness and easy fatigability. The clinical picture may be complicated by the coexistent deficiency of other vitamins, especially in alcoholics. Because the cells lining the gastrointestinal tract, like the hematopoietic system, turn over rapidly, symptoms referable to the alimentary tract, such as sore tongue, are common. *Unlike in vitamin $B_{12}$ deficiency, neurologic abnormalities do not occur.*

The diagnosis of a megaloblastic anemia is readily made from examination of smears of peripheral blood and bone marrow. The anemia of folate deficiency is best distinguished from that of vitamin $B_{12}$ deficiency by measuring serum and red cell folate and vitamin $B_{12}$ levels.

### *Vitamin $B_{12}$ (Cobalamin) Deficiency Anemia (Pernicious Anemia)*

Inadequate levels of vitamin $B_{12}$ (also known as cobalamin) result in a megaloblastic anemia identical to that seen with folate deficiency. However, vitamin $B_{12}$ deficiency can also cause a demyelinating disorder of the peripheral nerves and the spinal cord. There are many causes of vitamin $B_{12}$ deficiency. The term *pernicious anemia,* a relic of days when the cause and therapy of this condition were unknown, applies to vitamin $B_{12}$ deficiency that results from defects involving intrinsic factor. Intrinsic factor plays a critical role in the absorption of vitamin $B_{12}$, a multistep process that proceeds as follows:

1. Peptic digestion releases dietary vitamin $B_{12}$, allowing it to bind a salivary protein called *haptocorrin.*
2. On entering the duodenum, haptocorrin–$B_{12}$ complexes are processed by pancreatic proteases; this releases $B_{12}$, which attaches to *intrinsic factor* secreted from the parietal cells of the gastric fundic mucosa.
3. The intrinsic factor–$B_{12}$ complexes pass to the distal ileum and attach to *cubulin,* a receptor for intrinsic factor, and are taken up into enterocytes.
4. The absorbed vitamin $B_{12}$ is transferred across the basolateral membranes of enterocytes to plasma *transcobalamin,* which delivers vitamin $B_{12}$ to the liver and other cells of the body.

## PATHOGENESIS

**Long-standing malabsorption underlies the vast majority of cases of vitamin $B_{12}$ deficiency.** Vitamin $B_{12}$ is abundant in all food derived from animals, including eggs and dairy products, and is resistant to cooking and boiling. Even bacterial contamination of water and nonanimal foods can provide adequate amounts. As a result, deficiencies due to diet are rare, being confined to strict vegans. Once vitamin $B_{12}$ is absorbed, the body handles it very efficiently. It is stored in the liver, which normally contains reserves sufficient to support bodily needs for 5 to 20 years.

**Pernicious anemia is the most frequent cause of vitamin $B_{12}$ deficiency.** This disease seems to stem from an autoimmune reaction against parietal cells and intrinsic factor itself, which produces gastric mucosal atrophy (Chapter 14). Several associations favor an autoimmune basis:

- Autoantibodies are present in the serum and gastric juice of most patients. Three types of antibodies have been found: **parietal canalicular antibodies,** which bind to the mucosal parietal cells; **blocking antibodies,** which disrupt the binding of vitamin $B_{12}$ to intrinsic factor; and **intrinsic factor–$B_{12}$ complex antibodies,** which prevent the complex from binding to cubulin.
- Pernicious anemia frequently occurs concomitantly with other autoimmune diseases, such as Hashimoto thyroiditis, Addison disease, and type I diabetes mellitus.
- Serum antibodies to intrinsic factor are often present in patients with other autoimmune diseases.

Chronic vitamin $B_{12}$ malabsorption is also seen after gastrectomy (owing to loss of intrinsic factor–producing cells) or ileal resection (owing to loss of intrinsic factor–$B_{12}$ complex–absorbing cells), and in disorders that disrupt the function of the distal ileum (such as Crohn disease, tropical sprue, and Whipple disease). Particularly in older persons, gastric atrophy and achlorhydria may interfere with the production of acid and pepsin, which are needed to release the vitamin $B_{12}$ from its bound form in food.

The metabolic defects responsible for the anemia are intertwined with folate metabolism. Vitamin $B_{12}$ is required for recycling of tetrahydrofolate, the form of folate that is needed for DNA synthesis. In keeping with this relationship, the anemia of vitamin $B_{12}$ deficiency is reversed with administration of folate. By contrast, folate administration does not prevent and may in fact worsen the neurologic symptoms. The main neurologic lesions associated with vitamin $B_{12}$ deficiency are **demyelination of the posterior and lateral columns of the spinal cord,** sometimes beginning in the peripheral nerves. In time, axonal degeneration may supervene. The severity of the neurologic manifestations is not related to the degree of anemia. Indeed, the neurologic disease may occur in the absence of overt megaloblastic anemia.

Clinical Features

The manifestations of vitamin $B_{12}$ deficiency are nonspecific. As with all anemias, findings include pallor, easy fatigability, and, in severe cases, dyspnea and even congestive heart failure. The increased destruction of erythroid progenitors may give rise to mild jaundice. Gastrointestinal signs and symptoms similar to those of folate deficiency are seen. The spinal cord disease begins with symmetric numbness, tingling, and burning in feet or hands, followed by unsteadiness of gait and loss of position sense, particularly in the toes. Although the anemia responds dramatically to parenteral vitamin $B_{12}$, the neurologic manifestations often fail to resolve. As discussed in Chapter 14, patients with pernicious anemia have an increased risk for the development of gastric carcinoma.

The diagnostic features of pernicious anemia include (1) low serum vitamin $B_{12}$ levels, (2) normal or elevated serum folate levels, (3) serum antibodies to intrinsic factor, (4) moderate to severe megaloblastic anemia, (5) leukopenia with hypersegmented granulocytes, and (6) a dramatic reticulocytic response (within 2 to 3 days) to parenteral administration of vitamin $B_{12}$.

## Aplastic Anemia

Aplastic anemia is a disorder in which *multipotent myeloid stem cells are suppressed, leading to bone marrow failure and pancytopenia*. It must be distinguished from pure red cell aplasia, in which only erythroid progenitors are affected and anemia is the only manifestation.

### PATHOGENESIS

In more than half of the cases, aplastic anemia is **idiopathic.** In the remainder, an exposure to a **known myelotoxic agent,** such as a drug or a chemical, can be identified. With some agents, the marrow damage is predictable, dose-related, and reversible. Included in this category are antineoplastic drugs (e.g., alkylating agents, antimetabolites), benzene, and chloramphenicol. In other instances, marrow toxicity occurs as an "idiosyncratic" or hypersensitivity reaction to small doses of known myelotoxic drugs (e.g., chloramphenicol) or to drugs such as sulfonamides, which are not myelotoxic in other persons. Aplastic anemia sometimes arises after certain viral infections, most often community-acquired viral hepatitis. The specific virus responsible is not known; hepatitis viruses A, B, and C are not the culprits. Marrow aplasia develops insidiously several months after recovery from the hepatitis and follows a relentless course.

The pathogenic events leading to marrow failure remain vague, but it seems that **autoreactive T cells** play an important role. This is supported by a variety of experimental data and clinical experience showing that aplastic anemia responds to immunosuppressive therapy aimed at T cells in 70% to 80% of cases. Much less clear are the events that trigger the T cell attack on marrow stem cells; viral antigens, drug-derived haptens, and/or genetic damage may create neoantigens within stem cells that serve as targets for the immune system.

Rare but interesting genetic conditions also are associated with marrow failure. From 5% to 10% of patients with "acquired" aplastic anemia have inherited **defects in telomerase,** which as noted earlier is needed for the maintenance and stability of chromosomes. It is hypothesized that the defect in telomerase leads to premature senescence of hematopoietic stem cells. Of further interest, the bone marrow cells in up to 50% of sporadic cases have unusually short telomeres, possibly as a consequence of as-yet undiscovered defects in telomerase, or of excessive replication of hematopoietic stem cells, which may lead to premature senescence. Some children with Fanconi anemia, an inherited disorder of DNA repair, also develop marrow aplasia.

### MORPHOLOGY

The bone marrow in aplastic anemia is markedly hypocellular, with greater than 90% of the intertrabecular space being occupied by fat. The limited cellularity often consists only of lymphocytes and plasma cells. Anemia may cause fatty change in the liver. Thrombocytopenia and granulocytopenia may result in hemorrhages and bacterial infections, respectively. The requirement for transfusions may eventually lead to hemosiderosis.

### Clinical Course

Aplastic anemia affects persons of all ages and both sexes. The slowly progressive *anemia* causes the insidious development of weakness, pallor, and dyspnea. *Thrombocytopenia* often manifests with petechiae and ecchymoses. *Granulocytopenia* may be manifested by frequent and persistent minor infections or by the sudden onset of chills, fever, and prostration. It is important to separate aplastic anemia from anemias caused by marrow infiltration (myelophthisic anemia), "aleukemic leukemia," and granulomatous diseases, which may have similar clinical presentations but are easily distinguished on examination of the bone marrow. Aplastic anemia does not cause splenomegaly; if it is present, another diagnosis should be sought. Typically, the red cells are normochromic and normocytic or slightly macrocytic. *Reticulocytes are reduced* in number (reticulocytopenia).

The prognosis is unpredictable. Withdrawal of drugs sometimes leads to remission, but this is the exception rather than the rule. The idiopathic form carries a poor prognosis if left untreated. Bone marrow transplantation often is curative, particularly in nontransfused patients younger than 40 years of age. Transfusions sensitize patients to alloantigens, producing a high rate of engraftment failure; thus, they must be minimized in persons eligible for bone marrow transplantation. Successful transplantation requires "conditioning" with high doses of immunosuppressive radiation or chemotherapy, reinforcing the notion that autoimmunity has an important role in the disease. As mentioned earlier, patients who are poor transplantation candidates often benefit from immunosuppressive therapy.

## Myelophthisic Anemia

Myelophthisic anemia is caused by *extensive infiltration of the marrow by tumors or other lesions*. It most commonly is associated with metastatic breast, lung, or prostate cancer. Other tumors, advanced tuberculosis, lipid storage disorders, and osteosclerosis can produce a similar clinical picture. The principal manifestations include anemia and thrombocytopenia; in general, the white cell series is less affected. Characteristically misshapen red cells, some *resembling teardrops,* are seen in the peripheral blood. Immature granulocytic and erythrocytic precursors also may be present (*leukoerythroblastosis*) along with mild leukocytosis. Treatment is directed at the underlying condition.

### SUMMARY

#### Anemias of Diminished Erythropoiesis

**Iron Deficiency Anemia**

- Caused by chronic bleeding or inadequate iron intake; results in insufficient hemoglobin synthesis and hypochromic, microcytic red cells

**Anemia of Chronic Disease**

- Caused by inflammatory cytokines, which increase hepcidin levels and thereby sequester iron in macrophages, and also suppress erythropoietin production

**Megaloblastic Anemia**
- Caused by deficiencies of folate or vitamin $B_{12}$ that lead to inadequate synthesis of thymidine and defective DNA replication
- Results in enlarged abnormal hematopoietic precursors (megaloblasts), ineffective hematopoiesis, macrocytic anemia, and (in most cases) pancytopenia

**Aplastic Anemia**
- Caused by bone marrow failure (hypocellularity) due to diverse causes, including exposures to toxins and radiation, idiosyncratic reactions to drugs and viruses, and inherited defects in telomerase and DNA repair

**Myelophthisic Anemia**
- Caused by replacement of the bone marrow by infiltrative processes such as metastatic carcinoma and granulomatous disease
- Leads to the appearance of early erythroid and granulocytic precursors (leukoerythroblastosis) and teardrop-shaped red cells in the peripheral blood

## POLYCYTHEMIA

Polycythemia, or *erythrocytosis,* denotes an increase in red cells per unit volume of peripheral blood, usually in association with an increase in hemoglobin concentration. Polycythemia may be *absolute* (defined as an increase in total red cell mass) or *relative.* Relative polycythemia results from dehydration, such as occurs with water deprivation, prolonged vomiting, diarrhea, or the excessive use of diuretics. Absolute polycythemia is described as *primary* when the increased red cell mass results from an autonomous proliferation of erythroid progenitors, and *secondary* when the excessive proliferation stems from elevated levels of erythropoietin. Primary polycythemia (polycythemia vera) is a clonal, neoplastic myeloproliferative disorder considered later in this chapter. The increases in erythropoietin that cause secondary forms of absolute polycythemia have a variety of causes (Table 11–5).

**Table 11–5** Pathophysiologic Classification of Polycythemia

| |
|---|
| **Relative** |
| Reduced plasma volume (hemoconcentration) |
| **Absolute** |
| Primary |
| Abnormal proliferation of myeloid stem cells, normal or low erythropoietin levels (polycythemia vera); inherited activating mutations in the erythropoietin receptor (rare) |
| Secondary |
| Increased erythropoietin levels<br>*Adaptive:* lung disease, high-altitude living, cyanotic heart disease<br>*Paraneoplastic:* erythropoietin-secreting tumors (e.g., renal cell carcinoma, hepatomacellular carcinoma, cerebellar hemangioblastoma)<br>*Surreptitious:* endurance athletes |

# WHITE CELL DISORDERS

Disorders of white cells include deficiencies (leukopenias) and proliferations, which may be reactive or neoplastic. Reactive proliferation in response to a primary, often microbial, disease is common. Neoplastic disorders, though less common, are more ominous: They cause approximately 9% of all cancer deaths in adults and a staggering 40% in children younger than 15 years of age.

Presented next are brief descriptions of some non-neoplastic conditions, followed by more detailed considerations of the malignant proliferations of white cells.

## NON-NEOPLASTIC DISORDERS OF WHITE CELLS

### Leukopenia

Leukopenia results most commonly from a decrease in granulocytes, the most numerous circulating white cells. Lymphopenia is much less common; it is associated with rare congenital immunodeficiency diseases, advanced human immunodeficiency virus (HIV) infection, and treatment with high doses of corticosteroids. Only the more common leukopenias of granulocytes are discussed here.

#### *Neutropenia/Agranulocytosis*

A reduction in the number of granulocytes in blood is known as *neutropenia* or, when severe, *agranulocytosis.* Neutropenic persons are susceptible to bacterial and fungal infections, in whom they can be fatal. The risk of infection rises sharply as the neutrophil count falls below 500 cells/μL.

#### PATHOGENESIS

The mechanisms underlying neutropenia can be divided into two broad categories:
- **Decreased granulocyte production.** Clinically important reductions in granulopoiesis are most often caused by marrow failure (as occurs in aplastic anemia), extensive replacement of the marrow by tumor (such as in leukemias), or cancer chemotherapy. Alternatively, some neutropenias are isolated, with only the differentiation of committed granulocytic precursors being affected. The forms of neutropenia are most often caused by certain drugs or, less commonly, by neoplastic proliferations of cytotoxic T cells and natural killer (NK) cells.

- **Increased granulocyte destruction.** This can be encountered with immune-mediated injury (triggered in some cases by drugs) or in overwhelming bacterial, fungal, or rickettsial infections due to increased peripheral utilization. Splenomegaly also can lead to the sequestration and accelerated removal of neutrophils.

## MORPHOLOGY

The alterations in the bone marrow depend on the underlying cause of the neutropenia. **Marrow hypercellularity** is seen when there is excessive neutrophil destruction or ineffective granulopoiesis, such as occurs in megaloblastic anemia. By contrast, **agents such as drugs that cause neutropenia do so by suppressing granulocytopoiesis,** thus decreasing the numbers of granulocytic precursors. Erythropoiesis and megakaryopoiesis can be normal if the responsible agent specifically affects granulocytes, but most myelotoxic drugs reduce marrow elements from all lineages.

### Clinical Features

The initial symptoms often are malaise, chills, and fever, with subsequent marked weakness and fatigability. Infections constitute the major problem. They commonly take the form of ulcerating, necrotizing lesions of the gingiva, floor of the mouth, buccal mucosa, pharynx, or other sites within the oral cavity (agranulocytic angina). Owing to the lack of leukocytes, such lesions often contain large masses or sheets of microorganisms. In addition to removal of the offending drug and control of infection, treatment efforts may also include granulocyte colony-stimulating factor, which stimulates neutrophil production by the bone marrow.

## Reactive Leukocytosis

An increase in the number of white cells in the blood is common in a variety of inflammatory states caused by microbial and nonmicrobial stimuli. Leukocytoses are relatively nonspecific and are classified according to the particular white cell series that is affected (Table 11–6). As discussed later on, in some cases reactive leukocytosis may mimic leukemia. Such *"leukemoid" reactions* must be distinguished from true white cell malignancies. Infectious mononucleosis merits separate consideration because it gives rise to a distinctive syndrome associated with lymphocytosis.

### *Infectious Mononucleosis*

Infectious mononucleosis is an acute, self-limited disease of adolescents and young adults that is caused by Epstein-Barr virus (EBV), a member of the herpesvirus family. The infection is characterized by (1) fever, sore throat, and generalized lymphadenitis and (2) a lymphocytosis of activated, CD8+ T cells. Of note, cytomegalovirus infection induces a similar syndrome that can be differentiated only by serologic methods.

EBV is ubiquitous in all human populations. In the developing world, EBV infection in early childhood is nearly universal. At this age, symptomatic disease is uncommon, and even though infected hosts mount an immune response (described later), more than half continue to shed virus. By contrast, in developed countries with better standards of hygiene, infection usually is delayed until adolescence or young adulthood. For unclear reasons, only about 20% of healthy seropositive persons in developed countries shed the virus, and only about 50% of those who are exposed to the virus acquire the infection.

**Table 11–6** Causes of Leukocytosis

| |
|---|
| **Neutrophilic Leukocytosis** |
| Acute bacterial infections (especially those caused by pyogenic organisms); sterile inflammation caused by, for example, tissue necrosis (myocardial infarction, burns) |
| **Eosinophilic Leukocytosis (Eosinophilia)** |
| Allergic disorders such as asthma, hay fever, allergic skin diseases (e.g., pemphigus, dermatitis herpetiformis); parasitic infestations; drug reactions; certain malignancies (e.g., Hodgkin lymphoma and some non-Hodgkin lymphomas); collagen-vascular disorders and some vasculitides; atheroembolic disease (transient) |
| **Basophilic Leukocytosis (Basophilia)** |
| Rare, often indicative of a myeloproliferative disease (e.g., chronic myelogenous leukemia) |
| **Monocytosis** |
| Chronic infections (e.g., tuberculosis), bacterial endocarditis, rickettsiosis, and malaria; collagen vascular diseases (e.g., systemic lupus erythematosus); and inflammatory bowel diseases (e.g., ulcerative colitis) |
| **Lymphocytosis** |
| Accompanies monocytosis in many disorders associated with chronic immunologic stimulation (e.g., tuberculosis, brucellosis); viral infections (e.g., hepatitis A, cytomegalovirus, Epstein-Barr virus); *Bordetella pertussis* infection |

## PATHOGENESIS

Transmission to a seronegative "kissing cousin" usually involves direct oral contact. It is hypothesized (but has not been proved) that the virus initially infects oropharyngeal epithelial cells and then spreads to underlying lymphoid tissue (tonsils and adenoids), where mature B cells are infected. The infection of B cells takes one of two forms. In a minority of cells, the infection is lytic, leading to viral replication and eventual cell lysis accompanied by the release of virions. In most cells, however, the infection is nonproductive, and the virus persists in latent form as an extrachromosomal episome. **B cells that are latently infected with EBV undergo polyclonal activation and proliferation,** as a result of the action of several EBV proteins (Chapter 5). These cells disseminate in the circulation and secrete antibodies with several specificities, including the well-known heterophil anti-sheep red cell antibodies that are detected in diagnostic tests for mononucleosis. During acute infections, EBV is shed in the saliva; it is not known if the source of these virions is oropharyngeal epithelial cells or B cells.

A normal immune response is extremely important in controlling the proliferation of EBV-infected B cells and the spread of the virus. Early in the course of the infection, IgM

antibodies are formed against viral capsid antigens. Later the serologic response shifts to IgG antibodies, which persist for life. More important in the control of the EBV-positive B cell proliferation are cytotoxic CD8+ T cells and NK cells. **Virus-specific CD8+ T cells appear in the circulation as atypical lymphocytes, a finding that is characteristic of mononucleosis.** In otherwise healthy persons, the fully developed humoral and cellular responses to EBV act as brakes on viral shedding. In most cases, however, a small number of latently infected EBV-positive B cells escape the immune response and persist for the life of the patient. As described later, impaired T cell immunity in the host can have disastrous consequences.

## MORPHOLOGY

The major alterations involve the blood, lymph nodes, spleen, liver, central nervous system, and occasionally other organs. There is peripheral blood **leukocytosis**; the white cell count is usually between 12,000 and 18,000 cells/μL. Typically more than half of these cells are large **atypical lymphocytes,** 12 to 16 μm in diameter, with an oval, indented, or folded nucleus and abundant cytoplasm with a few azurophilic granules (Fig. 11–12). These atypical lymphocytes, which are sufficiently distinctive to suggest the diagnosis, are mainly CD8+ T cells.

**Lymphadenopathy** is common and is most prominent in the posterior cervical, axillary, and groin regions. On histologic examination, the enlarged nodes are flooded by atypical lymphocytes, which occupy the paracortical (T cell) areas. A few cells resembling Reed-Sternberg cells, the hallmark of Hodgkin lymphoma, often are seen. Because of these atypical features, special tests are sometimes needed to distinguish the reactive changes of mononucleosis from lymphoma.

The **spleen** is enlarged in most cases, weighing between 300 and 500 g, and exhibits a heavy infiltration of atypical lymphocytes. As a result of the rapid increase in splenic size and the infiltration of the trabeculae and capsule by the lymphocytes, such spleens are fragile and prone to rupture after even minor trauma.

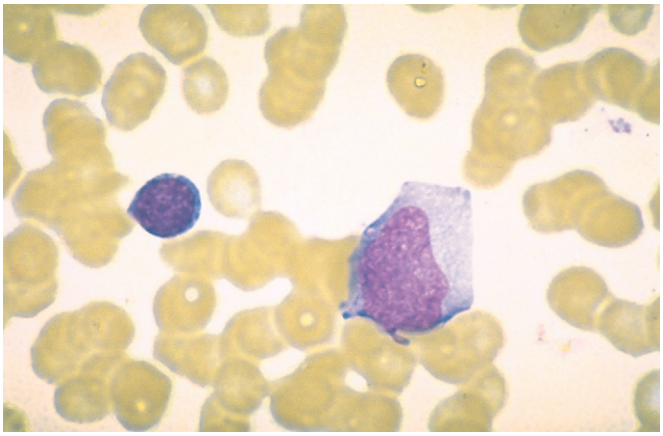

**Figure 11–12** Atypical lymphocytes in infectious mononucleosis—peripheral blood smear. The cell on the *left* is a normal small resting lymphocyte with a compact nucleus and scant cytoplasm. By contrast, the atypical lymphocyte on the *right* has abundant cytoplasm and a large nucleus with dispersed chromatin.

Atypical lymphocytes usually also infiltrate the portal areas and sinusoids of the **liver.** Scattered apoptotic cells or foci of parenchymal necrosis associated with a lymphocytic infiltrate also may be present—a picture that can be difficult to distinguish from that in other forms of viral hepatitis.

### Clinical Features

Although mononucleosis classically manifests with fever, sore throat, lymphadenitis, and the other features mentioned earlier, atypical presentations are not unusual. Sometimes there is little or no fever and only fatigue and lymphadenopathy, raising the specter of lymphoma; fever of unknown origin, unassociated with lymphadenopathy or other localized findings; hepatitis that is difficult to differentiate from one of the hepatotropic viral syndromes (Chapter 15); or a febrile rash resembling rubella. Ultimately, the diagnosis depends on the following findings, in increasing order of specificity: (1) lymphocytosis with the characteristic atypical lymphocytes in the peripheral blood, (2) a positive heterophil reaction (Monospot test), and (3) a rising titer of antibodies specific for EBV antigens (viral capsid antigens, early antigens, or Epstein-Barr nuclear antigen). In most patients, mononucleosis resolves within 4 to 6 weeks, but sometimes the fatigue lasts longer. Occasionally, one or more complications supervene. Perhaps the most common of these is hepatic dysfunction, associated with jaundice, elevated hepatic enzyme levels, disturbed appetite, and, rarely, even liver failure. Other complications involve the nervous system, kidneys, bone marrow, lungs, eyes, heart, and spleen (including fatal splenic rupture).

EBV is a potent transforming virus that plays a role in the pathogenesis of a number of human malignancies, including several types of B cell lymphoma (Chapter 5). A serious complication in those lacking T cell immunity (such as organ and bone marrow transplant recipients and HIV-infected individuals) is unimpeded EBV-driven B cell proliferation. This process can be initiated by an acute infection or the reactivation of a latent B cell infection and generally begins as a polyclonal proliferation that transforms to overt monoclonal B cell lymphoma over time. Reconstitution of immunity (e.g., by cessation of immunosuppressive drugs) is sometimes sufficient to cause complete regression of the B cell proliferation, which is uniformly fatal if left untreated.

The importance of T cells and NK cells in the control of EBV infection is driven home by X-linked lymphoproliferative syndrome, a rare inherited immunodeficiency characterized by an ineffective immune response to EBV. Most affected boys have mutations in the *SH2D1A* gene, which encodes a signaling protein that participates in the activation of T cells and NK cells and in antibody production. In more than 50% of cases, EBV causes an acute overwhelming infection that is usually fatal. Others succumb to lymphoma or infections related to hypogammaglobulinemia, the basis of which is not understood.

## Reactive Lymphadenitis

Infections and nonmicrobial inflammatory stimuli often activate immune cells residing in lymph nodes, which act as defensive barriers. Any immune response against foreign

antigens can lead to lymph node enlargement (lymphadenopathy). The infections causing lymphadenitis are varied and numerous, and may be acute or chronic. In most instances the histologic appearance of the lymph node reaction is nonspecific. A somewhat distinctive form of lymphadenitis that occurs with cat-scratch disease is described separately later.

### *Acute Nonspecific Lymphadenitis*

This form of lymphadenitis may be isolated to a group of nodes draining a local infection, or be generalized, as in systemic infectious and inflammatory conditions.

#### MORPHOLOGY

Inflamed nodes in acute nonspecific lymphadenitis are swollen, gray-red, and engorged. Histologically, there are **large germinal centers** containing numerous mitotic figures. When the cause is a pyogenic organism, a neutrophilic infiltrate is seen around the follicles and within the lymphoid sinuses. With severe infections, the centers of follicles can undergo necrosis, leading to the formation of an abscess.

Affected nodes are tender and may become fluctuant if abscess formation is extensive. The overlying skin is frequently red and may develop draining sinuses. With control of the infection the lymph nodes may revert to a normal "resting" appearance or if damaged undergo scarring.

### *Chronic Nonspecific Lymphadenitis*

Depending on the causative agent, chronic nonspecific lymphadenitis can assume one of three patterns: follicular hyperplasia, paracortical hyperplasia, or sinus histiocytosis.

#### MORPHOLOGY

**Follicular Hyperplasia.** This pattern occurs with infections or inflammatory processes that activate B cells, which migrate into B cell follicles and create the **follicular (or germinal center) reaction.** The reactive follicles contain numerous activated B cells, scattered T cells, and phagocytic macrophages containing nuclear debris (tingible body macrophages), and a meshwork of antigen-presenting follicular dendritic cells. Causes of follicular hyperplasia include **rheumatoid arthritis, toxoplasmosis,** and early **HIV infection.** This form of lymphadenitis can be confused morphologically with follicular lymphoma (discussed later). Findings that favor follicular hyperplasia are (1) the preservation of the lymph node architecture; (2) variation in the shape and size of the germinal centers; (3) the presence of a mixture of germinal center lymphocytes of varying shape and size; and (4) prominent phagocytic and mitotic activity in germinal centers.

**Paracortical Hyperplasia.** This pattern is caused by immune reactions involving the **T cell regions** of the lymph node. When activated, parafollicular T cells transform into large proliferating immunoblasts that can efface the B cell follicles. Paracortical hyperplasia is encountered in **viral infections** (such as EBV), after certain **vaccinations** (e.g., smallpox), and in immune reactions induced by **drugs** (especially phenytoin).

**Sinus Histiocytosis.** This reactive pattern is characterized by distention and prominence of the lymphatic sinusoids, owing to a marked **hypertrophy of lining endothelial cells** and an **infiltrate of macrophages (histiocytes).** It often is encountered in lymph nodes draining cancers and may represent an immune response to the tumor or its products.

### *Cat-Scratch Disease*

Cat-scratch disease is a self-limited lymphadenitis caused by the bacterium *Bartonella henselae.* It is primarily a disease of childhood; 90% of the patients are younger than 18 years of age. It manifests with regional lymphadenopathy, most frequently in the axilla and the neck. The nodal enlargement appears approximately 2 weeks after a feline scratch or, less commonly, after a splinter or thorn injury. An inflammatory nodule, vesicle, or eschar is sometimes visible at the site of the skin injury. In most patients the lymph node enlargement regresses over a period of 2 to 4 months. Encephalitis, osteomyelitis, or thrombocytopenia may develop in rare patients.

#### MORPHOLOGY

The nodal changes in cat-scratch disease are quite characteristic. Initially sarcoid-like granulomas form, but these then undergo central necrosis associated with an infiltrate of neutrophils. These **irregular stellate necrotizing granulomas** are similar in appearance to those seen in a limited number of other infections, such as lymphogranuloma venereum. The microbe is extracellular and can be visualized with silver stains. The diagnosis is based on a history of exposure to cats, the characteristic clinical findings, a positive result on serologic testing for antibodies to *Bartonella*, and the distinctive morphologic changes in the lymph nodes.

## NEOPLASTIC PROLIFERATIONS OF WHITE CELLS

Tumors are the most important disorders of white cells. They can be divided into three broad categories based on the origin of the tumor cells:

- *Lymphoid neoplasms,* which include non-Hodgkin lymphomas (NHLs), Hodgkin lymphomas, lymphocytic leukemias, and plasma cell neoplasms and related disorders. In many instances tumors are composed of cells resembling some normal stage of lymphocyte differentiation, a feature that serves as one of the bases for their classification.
- *Myeloid neoplasms* arise from progenitor cells that give rise to the formed elements of the blood: granulocytes, red cells, and platelets. The myeloid neoplasms fall into three fairly distinct subcategories: *acute myeloid leukemias,* in which immature progenitor cells accumulate in the bone marrow; *myeloproliferative disorders,* in which an inappropriate increase in the production of formed

blood elements leads to elevated blood cell counts; and *myelodysplastic syndromes,* which are characteristically associated with ineffective hematopoiesis and cytopenias.
- *Histiocytic neoplasms* include proliferative lesions of macrophages and dendritic cells. Of special interest is a spectrum of proliferations of Langerhans cells (*Langerhans cell histiocytoses*).

## Lymphoid Neoplasms

The numerous lymphoid neoplasms vary widely in their clinical presentation and behavior, and thus present challenges to students and clinicians alike. Some characteristically manifest as *leukemias,* with involvement of the bone marrow and the peripheral blood. Others tend to manifest as *lymphomas,* tumors that produce masses in lymph nodes or other tissues. *Plasma cell tumors* usually arise within the bones and manifest as discrete masses, causing systemic symptoms related to the production of a complete or partial monoclonal immunoglobulin. While these tendencies are reflected in the names given to these entities, in reality all lymphoid neoplasms have the potential to spread to lymph nodes and various tissues throughout the body, especially the liver, spleen, bone marrow, and peripheral blood. *Because of their overlapping clinical behavior, the various lymphoid neoplasms can be distinguished with certainty only by the morphologic and molecular characteristics of the tumor cells.* Stated another way, for purposes of diagnosis and prognostication, it is most important to focus on what the tumor cell is, not where it resides in the patient.

Two groups of lymphomas are recognized: *Hodgkin lymphomas* and *non-Hodgkin lymphomas.* Although both arise most commonly in lymphoid tissues, Hodgkin lymphoma is set apart by the presence of distinctive neoplastic Reed-Sternberg giant cells (see later), which usually are greatly outnumbered by non-neoplastic inflammatory cells. The biologic behavior and clinical treatment of Hodgkin lymphoma also are different from those of NHLs, making the distinction of practical importance.

Historically, few areas of pathology evoked as much controversy and confusion as the classification of lymphoid neoplasms, which is perhaps inevitable in view of the intrinsic complexity of the immune system, from which they arise. Great progress has been made over the past several decades, however, and an international working group of pathologists, molecular biologists, and clinicians working on behalf of the World Health Organization (WHO) has formulated a widely accepted classification scheme that relies on a combination of morphologic, phenotypic, genotypic, and clinical features. As background for the subsequent discussion of this classification, certain important principles warrant consideration:

- B and T cell tumors often are composed of cells that are arrested at or derived from a specific stage of their normal differentiation (Fig. 11–13). The diagnosis and classification of these tumors rely heavily on tests (either immunohistochemistry or flow cytometry) that detect lineage-specific antigens (e.g., B cell, T cell, and NK cell markers) and markers of maturity. By convention, many such markers are identified by their cluster of differentiation (CD) number.
- The most common lymphomas are derived from germinal center or post–germinal center B cells. This conclusion is drawn from molecular analyses showing that most B cell lymphomas have undergone somatic hypermutation, an event confined to germinal center B cells. Normal germinal center B cells also undergo immunoglobulin class switching, an event that allows B cells to express immunoglobulins other than IgM. Class switching and somatic hypermutation are mistake-prone forms of regulated genomic instability, which places germinal center B cells at high risk for potentially transforming mutations. In fact, many of the recurrent chromosomal translocations found in mature B cell malignancies involve the immunoglobulin loci and appear to stem from "accidents" during attempted diversification of the immunoglobulin genes. In this regard, it is interesting that mature T cells, which are genomically stable, give rise to lymphomas infrequently and only very rarely have chromosomal translocations involving the T cell receptor loci.
- All lymphoid neoplasms are derived from a single transformed cell and are therefore clonal. As described in Chapter 4, differentiating precursor B and T cells rearrange their antigen receptor genes, thereby ensuring that each lymphocyte makes a single, unique antigen receptor. Because antigen receptor gene rearrangement virtually always precedes transformation, the daughter cells derived from a given malignant progenitor share the same antigen receptor gene configuration and synthesize identical antigen receptor proteins (either immunoglobulins or T cell receptors). Thus, analyses of antigen receptor genes and their protein products can be used to differentiate clonal neoplasms from polyclonal, reactive processes.
- Lymphoid neoplasms often disrupt normal immune function. Both immunodeficiency (as evident by increased susceptibility to infection) and autoimmunity may be seen, sometimes in the same patient. Ironically, patients with inherited or acquired immunodeficiency are themselves at high risk for the development of certain lymphoid neoplasms, particularly those associated with EBV infection.
- Although NHLs often manifest at a particular tissue site, sensitive molecular assays usually show the tumor to be widely disseminated at diagnosis. As a result, with few exceptions, only systemic therapies are curative. By contrast, Hodgkin lymphoma often arises at a single site and spreads in a predictable fashion to contiguous lymph node groups. For this reason, early in its course, it is sometimes treated with local therapy alone.

The WHO classification of lymphoid neoplasms considers the morphology, cell of origin (determined by immunophenotyping), clinical features, and genotype (e.g., karyotype, presence of viral genomes) of each entity. It encompasses all lymphoid neoplasms, including leukemias and multiple myeloma, and separates them on the basis of origin into three major categories: (1) tumors of B cells, (2) tumors of T cells and NK cells, and (3) Hodgkin lymphoma.

An updated version of the WHO classification of lymphoid neoplasms is presented in Table 11–7. As is evident, the diagnostic entities are numerous. The focus here is on the following subsets of neoplasms:

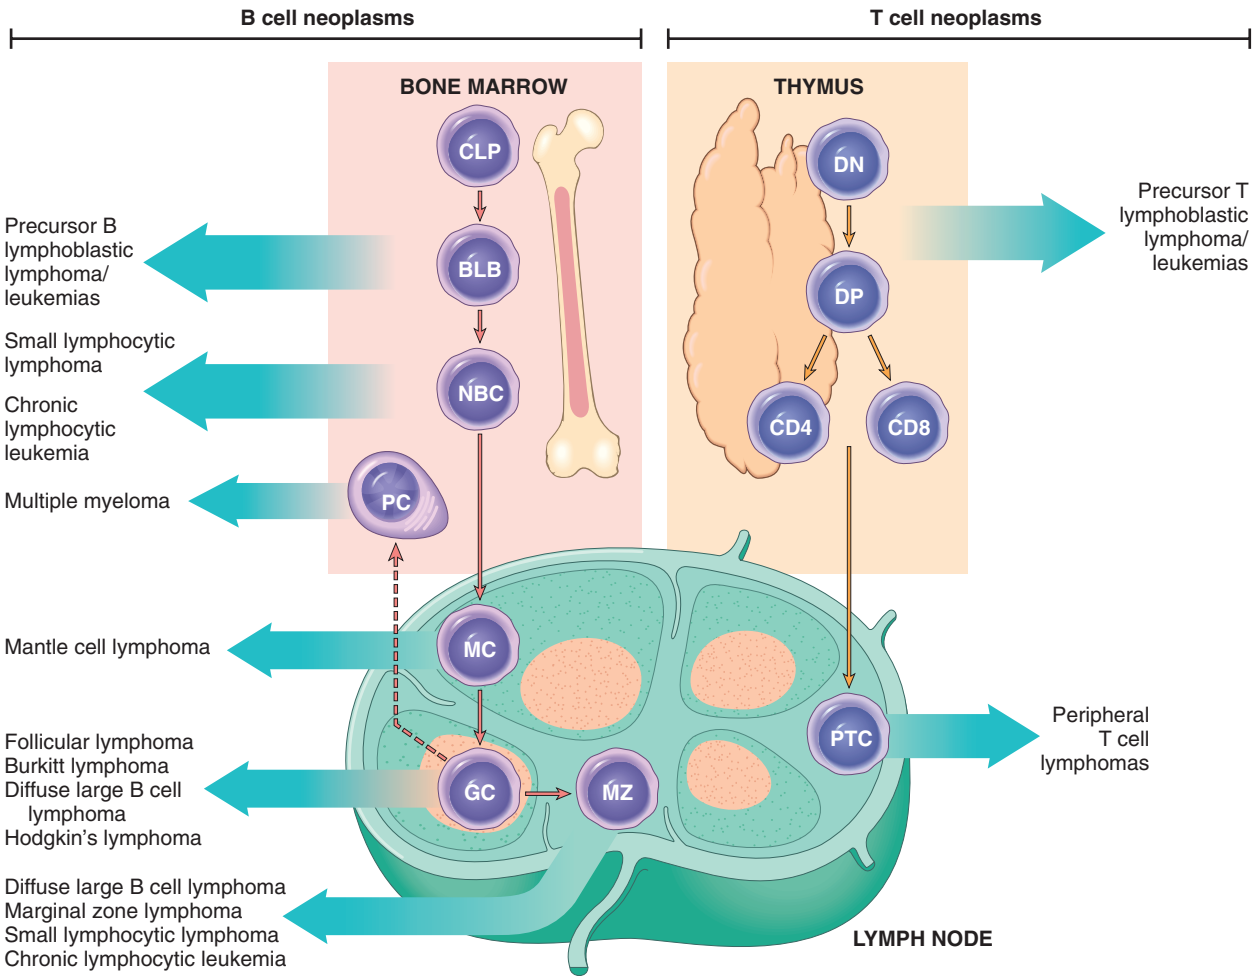

**Figure 11–13** Origin of lymphoid neoplasms. Stages of B and T cell differentiation from which specific lymphoid and tumors emerge are shown. BLB, pre-B lymphoblast; CLP, common lymphoid progenitor; DN, CD4–/CD8– (double-negative) pro-T cell; DP, CD4+/CD8+ (double-positive) pre-T cell; GC, germinal center B cell; MC, mantle zone B cell; MZ, marginal zone B cell; NBC, naive B cell; PC, plasma cell; PTC, peripheral T cell.

- Precursor B and T cell lymphoblastic lymphoma/leukemia—commonly called acute lymphoblastic leukemia (ALL)
- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- Follicular lymphoma
- Mantle cell lymphoma
- Diffuse large B cell lymphomas
- Burkitt lymphoma
- Multiple myeloma and related plasma cell tumors
- Hodgkin lymphoma

Together these neoplasms constitute more than 90% of the lymphoid tumors seen in the United States.

The salient features of the more common lymphoid leukemias, non-Hodgkin lymphomas, and plasma cell tumors are summarized in Table 11–8. Hodgkin lymphomas will be discussed later. Also included in the following discussion are a few of the uncommon entities with distinctive clinicopathologic features.

### *Acute Lymphoblastic Leukemia/Lymphoblastic Lymphoma*

Acute lymphoblastic leukemia (ALL) and lymphoblastic lymphoma are aggressive tumors, composed of immature lymphocytes (lymphoblasts), that occur predominantly in children and young adults. The various lymphoblastic tumors are morphologically indistinguishable, often cause similar signs and symptoms, and are treated similarly. These tumors are therefore considered together here.

Just as B cell precursors normally develop within the bone marrow, pre-B cell tumors usually manifest in the bone marrow and peripheral blood as leukemias. Similarly, pre-T cell tumors commonly manifest as masses involving the thymus, the normal site of early T cell differentiation. However, pre-T cell "lymphomas" often progress rapidly to a leukemic phase, and other pre-T cell tumors seem to involve only the marrow at presentation. Hence, *both pre-B and pre-T cell tumors usually take on the clinical appearance of ALL at some time during their course.* As a group, ALLs constitute 80% of childhood leukemia, peaking in incidence at age 4, with most cases being of pre-B cell origin. The pre-T cell tumors are most common in male patients between 15 and 20 years of age.

NK, natural killer; WHO, World Health Organization.

The pathogenesis, laboratory findings, and clinical features of ALL closely resemble those of acute myeloid leukemia (AML), the other major type of acute leukemia. Because of these similarities, the features common to the acute leukemias are reviewed first, followed by a discussion of those specific to ALL.

## PATHOGENESIS

The principal pathogenic defect in acute leukemia and lymphoblastic lymphoma is a block in differentiation. This "maturation arrest" stems from **acquired mutations in specific transcription factors that regulate the differentiation of immature lymphoid or myeloid progenitors.** Normal B cell, T cell, and myeloid differentiation are regulated by different lineage-specific transcription factors; accordingly, the mutated transcription factor genes found in acute leukemias derived from each of these lineages also are distinct. The most commonly mutated transcription factor genes are *TEL1*, *AML1*, *E2A*, *PAX5*, and *EBF* in ALLs of B cell origin (B-ALLs) and *TAL1* and *NOTCH1* in T cell ALLs (T-ALLs).

Acute leukemias also are associated with complementary acquired mutations that allow the tumor cells to proliferate in a growth factor–independent fashion. In B-ALL, one of the most important mutations of this type is a *BCR-ABL* fusion gene created by a (9;22) translocation (the so-called Philadelphia chromosome, for the city of its discovery). As discussed later on, the same translocation also is found in chronic myelogenous leukemia (CML). The *BCR-ABL* fusion gene encodes a BCR-ABL tyrosine kinase that constitutively activates the same pathways that are normally stimulated by growth factors. Some T-ALLs are associated with a different ABL fusion gene, *NUP214-ABL*, which has functional consequences similar to those of *BCR-ABL*.

**In tumors manifesting as "leukemias," blasts accumulating in the marrow suppress the growth of normal hematopoietic cells** by physical displacement and by other, poorly understood mechanisms. Eventually this suppression produces bone marrow failure, which accounts for the major clinical manifestations. The therapeutic goal, therefore, is to reduce the leukemic clone sufficiently to allow normal hematopoiesis to resume.

### Clinical Features of Acute Leukemias

Acute leukemias have the following characteristics:

- *Abrupt, stormy onset.* Most patients present for medical attention within 3 months of the onset of symptoms.
- *Clinical signs and symptoms related to suppressed marrow function,* including fatigue (due to anemia), fever (reflecting infections resulting from neutropenia), and bleeding (petechiae, ecchymoses, epistaxis, gum bleeding) secondary to thrombocytopenia
- *Bone pain and tenderness,* resulting from marrow expansion and infiltration of the subperiosteum
- *Generalized lymphadenopathy, splenomegaly, and hepatomegaly due to dissemination of the leukemic cells.* These are more pronounced in ALL than in AML.
- *Central nervous system manifestations,* including headache, vomiting, and nerve palsies resulting from meningeal spread. These are more common in children than in adults and in ALL than in AML.

### Laboratory Findings in Acute Leukemias

The diagnosis of acute leukemia rests on the identification of blasts. The peripheral blood sometimes contains no blasts (aleukemic leukemia); in such cases the diagnosis can be established only by marrow examination.

The white cell count is variable; it may be greater than 100,000 cells/μL but in about half of the patients is less than 10,000 cells/μL. Anemia is almost always present, and the platelet count usually is below 100,000/μL. Neutropenia is another common finding.

## MORPHOLOGY

**Because of differing responses to therapy, it is of great practical importance to distinguish ALL from AML.** By definition, in ALL blasts compose more than 25% of the marrow cellularity. In Wright-Giemsa–stained preparations, lymphoblasts have coarse, clumped chromatin, one or

**Table 11–8** Characteristics of the More Common Lymphoid Leukemias, Non-Hodgkin Lymphomas, and Plasma Cell Tumors

| Clinical Entity | Frequency | Salient Morphology | Immunophenotype | Comments |
|---|---|---|---|---|
| Precursor B cell lymphoblastic leukemia/ lymphoma | 85% of childhood acute leukemias | Lymphoblasts with irregular nuclear contours, condensed chromatin, small nucleoli, and scant, agranular cytoplasm | TdT+ immature B cells (CD19+, variable expression of other B cell markers) | Usually manifests as acute leukemia; less common in adults; prognosis is predicted by karyotype |
| Precursor T cell leukemia/ lymphoma | 15% of childhood acute leukemias; 40% of childhood lymphomas | Identical to precursor B cell lymphoblastic leukemia/ lymphoma | TdT+ immature T cells (CD2+, CD7+, variable expression of other T cell markers) | Most common in adolescent males; often manifests as a mediastinal mass associated with *NOTCH1* mutations |
| Small lymphocytic lymphoma/chronic lymphocytic leukemia | 3–4% of adult lymphomas; 30% of all leukemias | Small resting lymphocytes mixed with variable numbers of large activated cells; lymph nodes diffusely effaced | CD5+ B cell expressing surface immunoglobulin | Occurs in older adults; usually involves nodes, marrow, and spleen; most patients have peripheral blood involvement; indolent |
| Follicular lymphoma | 40% of adult lymphomas | Frequent small "cleaved" cells mixed with large cells; growth pattern usually is nodular (follicular) | CD10+, BCL2+ mature B cells that express surface immunoglobulin | Occurs in older adults; usually involves nodes, marrow, and spleen; associated with t(14;18); indolent |
| Mantle cell lymphoma | 3–4% of adult lymphomas | Small to intermediate-sized irregular lymphocytes growing in a diffuse pattern | CD5+ mature B cells that express cyclin D1 and have surface Ig | Occurs mainly in older males; usually involves nodes, marrow, spleen, and GI tract; t(11;14) is characteristic; moderately aggressive |
| Extranodal marginal zone lymphoma | ~5% of adult lymphomas | Malignant B cells home to epithelium, creating "lymphoepithelial lesions" | CD5–, CD10– mature B cells with surface immunoglobulin | Frequently occurs at extranodal sites involved by chronic inflammation; very indolent; may be cured by local excision |
| Diffuse large B cell lymphoma | 40–50% of adult lymphomas | Variable; most resemble large germinal center B cells; diffuse growth pattern | Mature B cells with variable expression of CD10 and surface immunoglobulin | Occurs in all age groups but most common in older adults; often arises at extranodal sites; aggressive |
| Burkitt lymphoma | <1% of lymphomas in the United States | Intermediate-sized round lymphoid cells with several nucleoli; diffuse growth pattern associated with apoptosis produces a "starry sky" appearance | Mature CD10+ B cells expressing surface immunoglobulin | Endemic in Africa, sporadic elsewhere; associated with immunosuppression and EBV (subset of cases); predominantly affects children; often manifests with visceral involvement; highly aggressive |
| Plasmacytoma/plasma cell myeloma | Most common lymphoid neoplasm in older adults | Plasma cells in sheets, sometimes with prominent nucleoli or inclusions containing immunoglobulins | Terminally differentiated plasma cells containing cytoplasmic immunoglobulins | Myeloma manifests as disseminated bone disease, often with destructive lytic lesions; hypercalcemia, renal insufficiency, and bacterial infections are common |
| Mycosis fungoides | Most common cutaneous lymphoid malignancy | In most cases, small lymphoid cells with markedly convoluted nuclei; cells often infiltrate the epidermis (Pautrier microabscesses) | CD4+ mature T cells | Manifests with localized or more generalized skin involvement; generally indolent<br>*Sézary syndrome*: a more aggressive variant characterized by diffuse skin erythema and peripheral blood involvement |
| Peripheral T cell lymphoma, not otherwise specified (NOS) | Most common adult T cell lymphoma | Variable; usually a spectrum of small to large lymphoid cells | Mature T cell phenotype (CD3+) | Probably spans a diverse collection of rare tumors; often disseminated, generally aggressive |

EBV, Epstein-Barr virus; GI, gastrointestinal; TdT, terminal deoxynucleotidyl transferase.

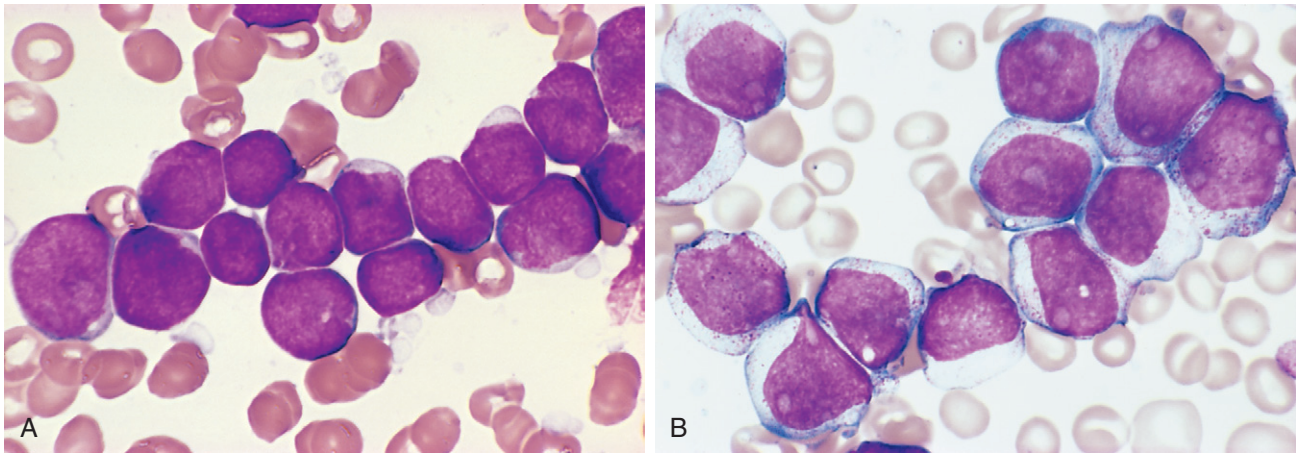

**Figure 11–14** Morphologic comparison of lymphoblasts and myeloblasts. **A,** Lymphoblastic leukemia/lymphoma. Lymphoblasts have condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm. **B,** Acute myeloid leukemia. Myeloblasts have delicate nuclear chromatin, prominent nucleoli, and fine azurophilic cytoplasmic granules.
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

two nucleoli, and scant agranular cytoplasm (Fig. 11–14, *A*), whereas myeloblasts have nuclei with finer chromatin and more cytoplasm, which often contains granules (Fig. 11–14, *B*). Lymphoblasts also often contain cytoplasmic glycogen granules that are periodic acid–Schiff–positive, whereas myeloblasts are often peroxidase-positive.

With completion of the foregoing "short course" in acute leukemia, our focus now returns to the ALLs; the AMLs are discussed later.

***Genetic Features.*** Approximately 90% of ALLs have nonrandom karyotypic abnormalities. Most common in childhood pre-B cell tumors are hyperdiploidy (more than 50 chromosomes/cell) and the presence of a cryptic (12;21) translocation involving the *TEL1* and *AML1* genes, while about 25% of adult pre-B cell tumors harbor the (9;22) translocation involving the *ABL* and *BCR* genes. Pre-T cell tumors are associated with diverse chromosomal aberrations, including frequent translocations involving the T cell receptor loci and transcription factor genes such as *TAL1*.

***Immunophenotypic Features.*** Immunophenotyping is very useful in subtyping lymphoblastic tumors and distinguishing them from AML. Terminal deoxynucleotidyl transferase (TdT), an enzyme specifically expressed in pre-B and pre-T cells, is present in more than 95% of cases. Further subtyping of ALL into pre-B and pre-T cell types relies on stains for lineage-specific markers, such as CD19 (B cell) and CD3 (T cell).

### Prognosis

Treatment of childhood ALL is one of the great success stories in oncology. Children 2 to 10 years of age have the best prognosis; with intensive chemotherapy up to 80% are cured. Other groups of patients do less well. Variables correlated with worse outcomes include male gender; age younger than 2 or older than 10 years; a high leukocyte count at diagnosis; and molecular evidence of persistent disease on day 28 of treatment. Age-dependent differences in the frequencies of various karyotypic abnormalities largely explain the relationship of age to outcome. Tumors with "good prognosis" chromosomal aberrations (such as the t[12;21] and hyperdiploidy) are common in the 2- to 10-year age group. By contrast, rearrangements of the gene *MLL* or the presence of a *BCR-ABL* fusion gene, both associated with poor outcomes in B cell tumors, are most common in children younger than 2 years of age and adults, respectively. None of the chromosomal rearrangements found in pre-T cell tumors is predictive of outcome.

## *Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma*

Chronic lymphocytic leukemia (CLL) and small lymphocytic lymphoma (SLL) are essentially identical, differing only in the extent of peripheral blood involvement. Somewhat arbitrarily, if the peripheral blood lymphocyte count exceeds 4000 cells/μL, the patient is diagnosed with CLL; if it does not, a diagnosis of SLL is made. Most patients with lymphoid neoplasms fit the diagnostic criteria for CLL, which is the most common leukemia of adults in the Western world. By contrast, SLL constitutes only 4% of NHLs. For unclear reasons, CLL/SLL is much less common in Asia.

### PATHOGENESIS

CLL/SLL is an indolent, slowly growing tumor, suggesting that increased tumor cell survival is more important than tumor cell proliferation in this disease. In line with this idea, the **tumor cells contain high levels of BCL2,** a protein that inhibits apoptosis (Chapters 1 and 5). Unlike in follicular lymphoma (discussed later), the *BCL2* gene is not rearranged. Some evidence suggests that *BCL2* is upregulated in the tumor cells as a consequence of the loss of several regulatory micro-RNAs that are encoded on chromosome 13.

Another important pathogenic aspect of CLL/SLL is **immune dysregulation.** Through unclear mechanisms, the accumulation of CLL/SLL cells suppresses normal B cell function, often resulting in **hypogammaglobulinemia.** Paradoxically, approximately 15% of patients have autoantibodies against their own red cells or platelets. When present, the

autoantibodies are made by nonmalignant bystander B cells, indicating that the tumor cells somehow impair immune tolerance. As time passes the tumor cells tend to displace the normal marrow elements, leading to anemia, neutropenia, and eventual thrombocytopenia.

## MORPHOLOGY

In SLL/CLL, sheets of small lymphocytes and scattered ill-defined foci of larger, actively dividing cells diffusely efface involved lymph nodes (Fig. 11–15, *A*). The predominant cells are small, resting lymphocytes with dark, round nuclei, and scanty cytoplasm (Fig. 11–15, *B*). The foci of mitotically active cells are called **proliferation centers,** which are pathognomonic for CLL/SLL. In addition to the lymph nodes, the bone marrow, spleen, and liver are involved in almost all cases. In most patients there is an absolute **lymphocytosis** featuring small, mature-looking lymphocytes. The circulating tumor cells are fragile and during the preparation of smears frequently are disrupted, producing characteristic **smudge cells.** Variable numbers of larger activated lymphocytes are also usually present in the blood smear.

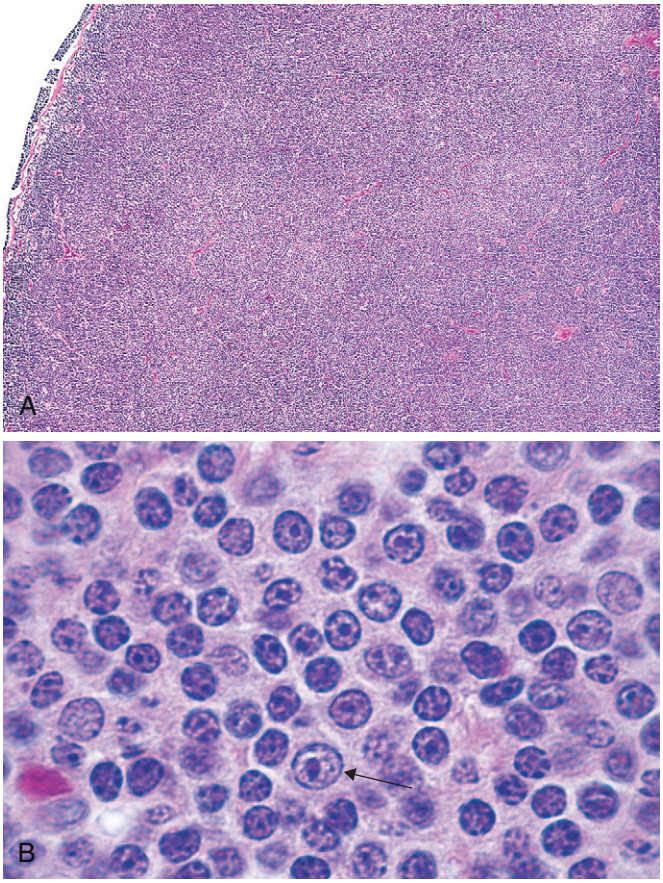

**Figure 11–15** Small lymphocytic lymphoma/chronic lymphocytic leukemia—lymph node. **A,** Low-power view shows diffuse effacement of nodal architecture. **B,** At high power, a majority of the tumor cells have the appearance of small, round lymphocytes. A "prolymphocyte," a larger cell with a centrally placed nucleolus, also is present in this field (*arrow*).

*(A, Courtesy of Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

***Immunophenotypic and Genetic Features.*** CLL/SLL is a neoplasm of mature B cells expressing the pan-B cell markers CD19, CD20, and CD23 and surface immunoglobulin heavy and light chains. The tumor cells also express CD5. This is a helpful diagnostic clue, since among B cell lymphomas only CLL/SLL and mantle cell lymphoma (discussed later) commonly express CD5. Approximately 50% of tumors have karyotypic abnormalities, the most common of which are trisomy 12 and deletions of chromosomes 11, 13, and 17. "Deep sequencing" of CLL/SLL cell genomes has identified activating mutations in the Notch1 receptor in a subset of cases that predict a worse outcome. Unlike in other B cell neoplasms, chromosomal translocations are rare.

### Clinical Features

When first detected, CLL/SLL is often asymptomatic. The most common clinical signs and symptoms are nonspecific and include easy fatigability, weight loss, and anorexia. Generalized *lymphadenopathy* and *hepatosplenomegaly* are present in 50% to 60% of patients. The leukocyte count may be increased only slightly (in SLL) or may exceed 200,000 cells/μL. *Hypogammaglobulinemia* develops in more than 50% of the patients, usually late in the course, and leads to an increased susceptibility to bacterial infections. Less commonly *autoimmune hemolytic anemia* and *thrombocytopenia* are seen. The course and prognosis are extremely variable. Many patients live more than 10 years after diagnosis and die of unrelated causes. The median survival is 4 to 6 years, however, and as time passes, CLL/SLL tends to transform to more aggressive tumors that resemble either prolymphocytic leukemia or diffuse large B cell lymphoma. Once transformation occurs, the median survival is less than 1 year.

### *Follicular Lymphoma*

This relatively common tumor constitutes 40% of the adult NHLs in the United States. Like CLL/SLL, it occurs much less frequently in Asian populations.

## PATHOGENESIS

As in CLL/SLL, the neoplastic cells characteristically express BCL2, a protein that is absent from normal germinal center B cells. **Greater than 85% of tumors have a characteristic (14;18) translocation** that fuses the *BCL2* gene on chromosome 18 to the *IgH* locus on chromosome 14. This chromosomal rearrangement explains the inappropriate "overexpression" of BCL2 protein in the tumor cells and contributes to tumor cell survival. Whole genome sequencing of follicular lymphomas has identified loss-of-function mutations in several genes encoding histone acetyl transferases in about a third of cases, suggesting that epigenetic changes also contribute to the genesis of these tumors.

## MORPHOLOGY

Lymph nodes usually are effaced by a distinctly **nodular proliferation** (Fig 11–16, *A*). The tumor cells resemble

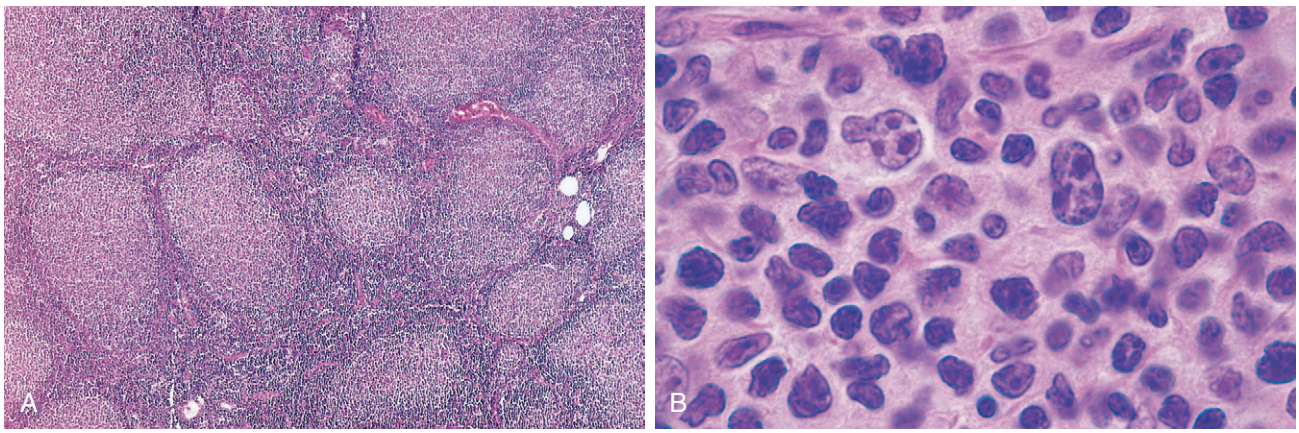

**Figure 11–16** Follicular lymphoma—lymph node. **A,** Nodular aggregates of lymphoma cells are present throughout. **B,** At high magnification, small lymphoid cells with condensed chromatin and irregular or cleaved nuclear outlines (centrocytes) are mixed with a population of larger cells with nucleoli (centroblasts).

*(A, Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

normal germinal center B cells. Most commonly the predominant neoplastic cells are slightly larger than resting lymphocytes that have angular "cleaved" nuclei with prominent indentations and linear infoldings (Fig. 11–16, *B*). The nuclear chromatin is coarse and condensed, and nucleoli are indistinct. These small, cleaved cells are mixed with variable numbers of larger cells with vesicular chromatin, several nucleoli, and modest amounts of cytoplasm. In most tumors, large cells are a minor component of the overall cellularity, mitoses are infrequent, and single necrotic cells (cells undergoing apoptosis) are not seen. These features help to distinguish follicular lymphoma from follicular hyperplasia, in which mitoses and apoptosis are prominent. Uncommonly, large cells predominate, a histologic pattern that correlates with a more aggressive clinical behavior.

***Immunophenotypic Features.*** These tumors express pan-B cell markers (CD19 and CD20), CD10, and BCL6, a transcription factor required for the generation of germinal center B cells.

### Clinical Features

Follicular lymphoma mainly occurs in adults older than 50 years of age and affects males and females equally. It usually manifests as *painless, generalized lymphadenopathy.* The bone marrow is almost always involved at diagnosis, while visceral disease is uncommon. While the natural history is prolonged (median survival, 7 to 9 years), *follicular lymphoma is not curable,* an unfortunate feature shared with most other relatively indolent lymphoid malignancies. As a result, therapy with cytotoxic drugs and rituximab (anti-CD20 antibody) is reserved for those with bulky, symptomatic disease. In about 40% of patients, follicular lymphoma progresses to diffuse large B cell lymphoma. This transformation is an ominous event, as tumors arising from such conversions are much less curable than de novo diffuse large B cell lymphomas, described later.

## *Mantle Cell Lymphoma*

Mantle cell lymphoma is composed of cells resembling the naive B cells found in the mantle zones of normal lymphoid follicles. It constitutes approximately 4% of all NHLs and occurs mainly in men older than 50 years of age.

### MORPHOLOGY

Mantle cell lymphoma may involve lymph nodes in a diffuse or vaguely nodular pattern. The tumor cells usually are slightly larger than normal lymphocytes and have an irregular nucleus, inconspicuous nucleoli, and scant cytoplasm. Less commonly, the cells are larger and morphologically resemble lymphoblasts. The bone marrow is involved in most cases and the peripheral blood in about 20% of cases. The tumor sometimes arises in the gastrointestinal tract, often manifesting as multifocal submucosal nodules that grossly resemble polyps (lymphomatoid polyposis).

***Immunophenotypic and Genetic Features.*** *Almost all tumors have an (11;14) translocation that fuses the cyclin D1 gene to the IgH locus.* This translocation dysregulates the expression of cyclin D1, a cell cycle regulator (Chapter 5), and is believed to be an important mediator of uncontrolled tumor cell growth. The tumor cells usually coexpress surface IgM and IgD, pan-B cell antigens (CD19 and CD20), and CD5. Mantle cell lymphoma is most readily distinguished from CLL/SLL by the absence of proliferation centers and the presence of cyclin D1 protein.

### Clinical Features

Most patients present with fatigue and lymphadenopathy and are found to have generalized disease involving the bone marrow, spleen, liver, and (often) the gastrointestinal tract. These tumors are moderately aggressive and incurable. The median survival is 3 to 5 years.

### *Diffuse Large B Cell Lymphoma*

Diffuse large B cell lymphoma is the *most common type of lymphoma in adults, accounting for approximately 50% of adult NHLs*. It includes several subtypes that share an aggressive natural history.

#### PATHOGENESIS

**About one third of tumors have rearrangements of the *BCL6* gene, located on 3q27, and an even higher fraction of tumors have activating point mutations in the BCL6 promoter.** Both aberrations result in increased levels of BCL6 protein, an important transcriptional regulator of gene expression in germinal center B cells. Another 30% of tumors have a (14;18) translocation involving the *BCL2* gene that results in overexpression of BCL2 protein. Some of these tumors may represent "transformed" follicular lymphomas. Indeed, like follicular lymphoma, about a third of diffuse large B cell lymphomas have loss-of-function mutations in genes encoding histone acetyl transferases, pointing to a potential role for epigenetic alterations in this tumor.

#### MORPHOLOGY

The neoplastic B cells are large (at least three to four times the size of resting lymphocytes) and vary in appearance from tumor to tumor. In many tumors, cells with round or oval nuclear contours, dispersed chromatin, several distinct nucleoli, and modest amounts of pale cytoplasm predominate (Fig. 11–17). In other tumors, the cells have a round or multilobate vesicular nucleus, one or two prominent centrally placed nucleoli, and abundant pale or basophilic cytoplasm. Occasionally, the tumor cells are highly anaplastic and include tumor giant cells resembling Reed-Sternberg cells, the malignant cells of Hodgkin lymphoma.

***Immunophenotypic Features.*** These mature B cell tumors express pan-B cell antigens, such as CD19 and CD20. Many also express surface IgM and/or IgG. Other antigens (e.g., CD10, BCL2) are variably expressed.

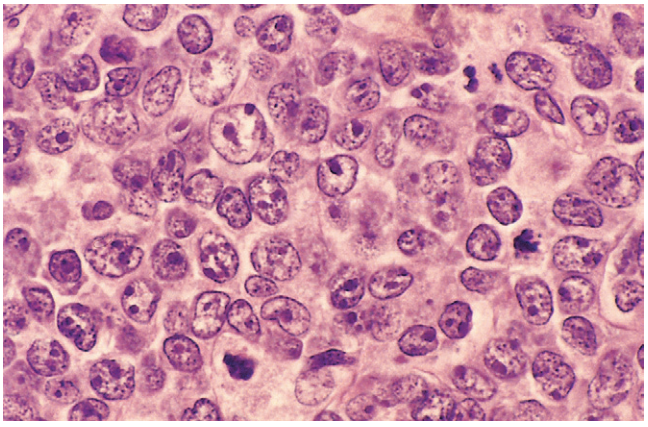

**Figure 11–17** Diffuse large B cell lymphoma—lymph node. The tumor cells have large nuclei with open chromatin and prominent nucleoli.
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

***Subtypes of Diffuse Large B Cell Lymphoma.*** Several distinctive clinicopathologic subtypes are included in the category of diffuse large B cell lymphoma. *EBV-associated diffuse large B cell lymphomas* arise in the setting of the acquired immunodeficiency syndrome (AIDS), iatrogenic immunosuppression (e.g., in transplant recipients), and the elderly. In the post-transplantation setting, these tumors often begin as EBV-driven polyclonal B cell proliferations that may regress if immune function is restored. Otherwise, transformation to clonal large B cell lymphoma is observed over weeks to months. *Kaposi sarcoma herpesvirus* (KSHV), also called *human herpesvirus type 8* (HHV-8), is associated with rare *primary effusion lymphomas,* which may arise within the pleural cavity, pericardium, or peritoneum. These lymphomas are latently infected with KSHV, which encodes proteins homologous to several known oncoproteins, including cyclin D1, and are confined to immunosuppressed hosts. Of note, KSHV also is associated with Kaposi sarcoma in patients with AIDS (Chapters 4 and 9). *Mediastinal large B cell lymphoma* occurs most often in young women and shows a predilection for spread to abdominal viscera and the central nervous system.

#### Clinical Features

Although the median age at presentation is about 60 years, diffuse large B cell lymphomas can occur at any age; they constitute about 15% of childhood lymphomas. Patients typically present with a rapidly enlarging, often symptomatic mass at one or several sites. *Extranodal presentations are common.* Although the gastrointestinal tract and the brain are among the more frequent extranodal sites, tumors can appear in virtually any organ or tissue. Unlike the more indolent lymphomas (e.g., follicular lymphoma), involvement of the liver, spleen, and bone marrow is not common at diagnosis.

*Without treatment, diffuse large cell B cell lymphomas are aggressive and rapidly fatal.* With intensive combination chemotherapy and anti-CD20 immunotherapy, complete remissions are achieved in 60% to 80% of the patients; of these, approximately 50% remain free of disease and appear to be cured. For those not so fortunate, other aggressive treatments (e.g., high-dose chemotherapy and hematopoietic stem cell transplantation) offer some hope. Microarray-based molecular profiling of these tumors can predict response to current therapies and is being used to identify new, targeted therapy approaches.

### *Burkitt Lymphoma*

Burkitt lymphoma is endemic in parts of Africa and occurs sporadically in other geographic areas, including the United States. Histologically, the African and nonendemic diseases are identical, although there are clinical and virologic differences.

#### PATHOGENESIS

**Burkitt lymphoma is highly associated with translocations involving the *MYC* gene on chromosome 8.** Most translocations fuse *MYC* with the *IgH* gene on chromosome 14, but variant translocations involving the κ and λ light

chain loci on chromosomes 2 and 22, respectively, are also observed. The net result of each is the same—the dysregulation and overexpression of MYC protein. The role of MYC in transformation is discussed in Chapter 5. In most endemic cases and about 20% of sporadic cases, the tumor cells are latently infected with EBV, but the role of EBV in the genesis of this tumor remains uncertain.

## MORPHOLOGY

The tumor cells are intermediate in size and typically have round or oval nuclei and two to five distinct nucleoli (Fig. 11–18). There is a moderate amount of basophilic or amphophilic cytoplasm that often contains small, lipid-filled vacuoles (a feature appreciated only on smears). **Very high rates of proliferation and apoptosis are characteristic,** the latter accounting for the presence of numerous tissue macrophages containing ingested nuclear debris. These benign macrophages often are surrounded by a clear space, creating a **"starry sky" pattern.**

### Immunophenotypic Features

These B cell tumors express surface IgM, the pan-B cell markers CD19 and CD20, and the germinal center B cell markers CD10 and BCL6.

### Clinical Features

Both the endemic and nonendemic sporadic forms affect mainly children and young adults. Burkitt lymphoma accounts for approximately 30% of childhood NHLs in the United States. In both settings, the disease usually arises at extranodal sites. Endemic tumors often manifest as maxillary or mandibular masses, whereas abdominal tumors involving the bowel, retroperitoneum, and ovaries are more common in North America. Leukemic presentations are uncommon but do occur and must be distinguished from ALL, which is treated with different drug regimens. Burkitt lymphoma is among the fastest-growing human neoplasms; however, with very aggressive chemotherapy regimens, a majority of patients can be cured.

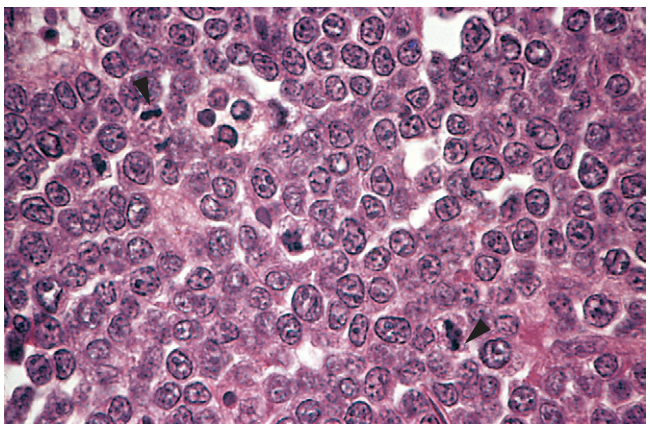

**Figure 11–18** Burkitt lymphoma—lymph node. The tumor cells and their nuclei are fairly uniform, giving a monotonous appearance. Note the high level of mitotic activity (*arrowheads*) and prominent nucleoli. The "starry sky" pattern produced by interspersed, lightly staining, normal macrophages is better appreciated at a lower magnification.

*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

## *Multiple Myeloma and Related Plasma Cell Tumors*

In virtually all cases, multiple myelomas and related plasma cell tumors secrete a single complete or partial immunoglobulin. Because these immunoglobulins can be detected in the serum, these disorders are also referred to as *monoclonal gammopathies,* and the associated immunoglobulin is often referred to as an *M protein.* Although M proteins may be indicative of overt malignancy, they also are found surprisingly often in otherwise normal elderly persons—a condition called monoclonal gammopathy of undetermined significance (MGUS), described later. Collectively, these disorders account for approximately 15% of the deaths that are caused by tumors of white blood cells. They are most common in middle-aged and elderly persons.

The plasma cell neoplasms can be divided into six major variants: (1) multiple myeloma, (2) solitary plasmacytoma, (3) lymphoplasmacytic lymphoma, (4) heavy-chain disease, (5) primary amyloidosis, and (6) MGUS. The focus here is on the most important of these disorders, multiple myeloma and lymphoplasmacytic lymphoma, with a brief discussion of the other disorders.

### Multiple Myeloma

Multiple myeloma is one of the most common lymphoid malignancies; approximately 20,000 new cases are diagnosed in the United States each year. The median age at diagnosis is 70 years of age, and it is more common in males and in people of African origin. *It principally involves the bone marrow and usually is associated with lytic lesions throughout the skeletal system.*

The most frequent M protein produced by myeloma cells is IgG (60%), followed by IgA (20% to 25%); only rarely are IgM, IgD, or IgE M proteins observed. In the remaining 15% to 20% of cases, the plasma cells produce *only* κ or λ light chains. Because of their low molecular weight, free light chains are excreted in the urine, where they are termed Bence Jones proteins. Even more commonly, malignant plasma cells secrete both complete immunoglobulins and free light chains and thus produce both M proteins and Bence Jones proteins. As described later on, the excess light chains have important pathogenic effects.

### Solitary Plasmacytoma

Sometimes plasma tumors manifest as *solitary plasmacytomas* involving the skeleton or the soft tissues. Solitary skeletal plasmacytomas tend to occur in the same locations as does multiple myeloma and usually progress to full-blown multiple myeloma over a period of 5 to 10 years; these tumors probably are best thought of as an early stage of multiple myeloma. Modestly elevated M proteins are present in some cases at diagnosis. By contrast, plasmacytomas that occur in soft tissues (most often the upper respiratory tract) spread infrequently and often are cured by local resection.

## PATHOGENESIS OF MYELOMA

As with most other B cell malignancies, myelomas often have chromosomal translocations involving the *IgH* locus on chromosome 14 and various other genes, including cyclin D1, fibroblast growth factor receptor 3, and cyclin D3 genes. Late in the course, translocations involving *MYC* are sometimes also observed. As might be surmised from this list of genes, **dysregulation of D cyclins is common in multiple myeloma.**

The proliferation of myeloma cells is supported by the cytokine interleukin 6 (IL-6), which is produced by fibroblasts and macrophages in the bone marrow stroma. The characteristic bone resorption results from the secretion of certain cytokines (e.g., IL-1β, tumor necrosis factor, IL-6) by myeloma cells. These cytokines stimulate production of another cytokine called RANK-ligand, which stimulates the differentiation and absorptive activity of osteoclasts (Chapter 20).

**Patients with myeloma are immunosuppressed.** Through uncertain mechanisms, **myeloma cells interfere with the function of normal plasma cells,** leading to defects in antibody production. Thus, although the plasma usually contains increased immunoglobulin owing to the presence of an M protein, the levels of functional antibodies often are profoundly depressed, leaving patients at high risk for bacterial infections.

**Renal dysfunction is a common, serious problem in myeloma.** It stems from several pathologic effects that may occur alone or in combination. Most important are obstructive proteinaceous casts, which often form in the distal convoluted tubules and the collecting ducts. The casts consist mostly of Bence Jones proteins along with variable amounts of complete immunoglobulins, Tamm-Horsfall protein, and albumin. Light chain deposition in the glomeruli or the interstitium, either as amyloid or linear deposits, also may contribute to renal dysfunction. Completing the assault on the kidney is hypercalcemia, which may lead to dehydration and renal stones, and frequent bouts of bacterial pyelonephritis, which stem in part from the hypogammaglobulinemia.

### Monoclonal Gammopathy of Undetermined Significance

*Monoclonal gammopathy of undetermined significance* (MGUS) is the term applied to an asymptomatic monoclonal gammopathy. M proteins are found in the serum of 1% to 3% of otherwise healthy persons older than age 50 years, making this the most common plasma cell proliferation. Despite its name, *it is increasingly apparent that MGUS is a precursor lesion with a tendency to evolve to multiple myeloma.* Among patients with MGUS, a symptomatic plasma cell tumor, most commonly multiple myeloma, develops at a rate of 1% per year. Moreover, the clonal plasma cells in MGUS contain the same chromosomal translocations found in full-blown multiple myeloma. A diagnosis of MGUS should be made only after careful exclusion of other monoclonal gammopathies, particularly multiple myeloma. In general, patients with MGUS have less than 3 g/dL of monoclonal protein in the serum and no Bence Jones proteinuria.

### Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma is included in the plasma cell neoplasms because the tumor cells secrete an M protein, most commonly IgM, but is otherwise distinct. It is composed of a mixture of B cells ranging from small lymphocytes to plasmacytic lymphocytes to plasma cells. It behaves like an *indolent B cell lymphoma* and commonly involves the lymph nodes, bone marrow, and spleen at presentation. Often the high levels of IgM cause the blood to become viscous, producing a syndrome called *Waldenström macroglobulinemia,* described later on. Other symptoms are related to the infiltration of various tissues, particularly the bone marrow, by tumor cells. The synthesis of immunoglobulin heavy and light chains usually is balanced, so free light chains and Bence Jones proteinuria are not seen. Unlike myeloma, this tumor does not produce lytic bone lesions and is only rarely associated with amyloidosis.

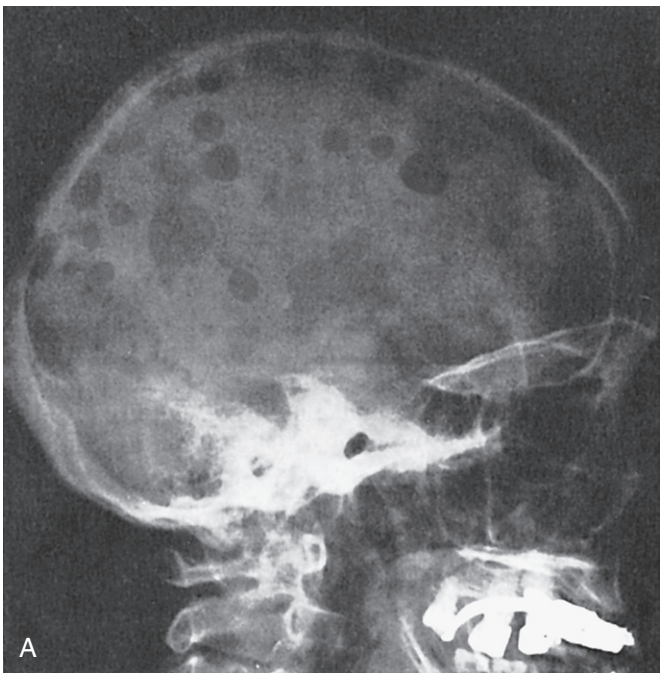
***Heavy-Chain Disease.*** Heavy-chain disease is not a specific entity but represents a group of proliferations in which only heavy chains are produced, most commonly IgA. IgA heavy-chain disease shows a predilection for lymphoid tissues in which IgA normally is produced, such as the small intestine and respiratory tract, and may represent a variant of extranodal marginal zone lymphoma (discussed later). The less common IgG heavy-chain disease often manifests with diffuse lymphadenopathy and hepatosplenomegaly and histologically resembles lymphoplasmacytic lymphoma.

***Primary Amyloidosis.*** As noted earlier (Chapter 4), a monoclonal proliferation of plasma cells that secrete free light chains underlies primary amyloidosis. The amyloid deposits (of AL type) consist of partially degraded light chains.

## MORPHOLOGY

**Multiple myeloma usually manifests with multifocal destructive skeletal lesions, which most commonly involve the vertebral column, ribs, skull, pelvis, femur, clavicle, and scapula.** The lesions generally arise in the medullary cavity, erode cancellous bone, and progressively destroy the cortical bone. This destructive process in turn often leads to **pathologic fractures,** most frequently in the vertebral column or femur. The bone lesions usually appear as **punched-out defects** 1 to 4 cm in diameter (Fig. 11–19, *A*), but in some cases diffuse skeletal demineralization is evident. Microscopic examination of the marrow reveals increased numbers of plasma cells, which usually constitute greater than 30% of the cellularity. Myeloma cells may resemble normal plasma cells but more often show abnormal features such as prominent nucleoli or abnormal cytoplasmic inclusions containing immunoglobulin (Fig. 11–19, *B*). With disease progression, plasma cells may infiltrate the spleen, liver, kidneys, lungs, lymph nodes, and other soft tissue sites. In terminal stages, a leukemic picture may emerge.

Renal involvement **(myeloma nephrosis)** is associated with proteinaceous casts in the distal convoluted tubules and the collecting ducts, consisting mostly of Bence Jones proteins along with variable amounts of complete immunoglobulins, Tamm-Horsfall protein, and albumin. Multinucleate giant cells derived from macrophages usually surround the



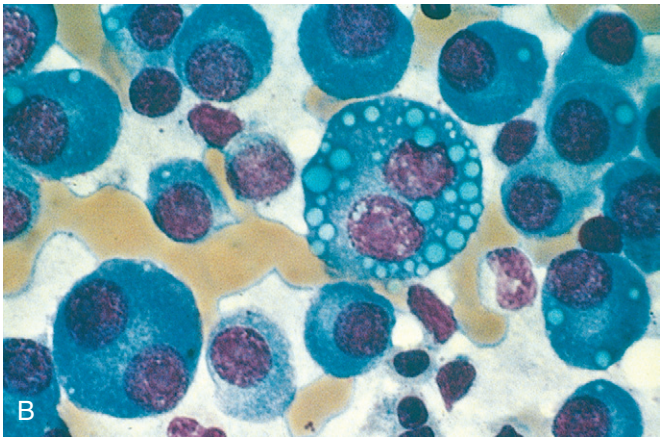


**Figure 11–19** Multiple myeloma. **A,** Radiograph of the skull, lateral view. The sharply punched-out bone defects are most obvious in the calvaria. **B,** Bone marrow aspirate. Normal marrow cells are largely replaced by plasma cells, including atypical forms with multiple nuclei, prominent nucleoli, and cytoplasmic droplets containing immunoglobulin.

casts. **Very often the epithelial cells adjacent to the casts become necrotic or atrophic owing to the toxic effects of Bence Jones proteins.** Other common pathologic processes involving the kidney include **metastatic calcification**, stemming from bone resorption and hypercalcemia; **light chain (AL) amyloidosis**, involving the renal glomeruli and vessel walls; and **bacterial pyelonephritis,** secondary to the increased susceptibility to bacterial infections. Rarely, interstitial infiltrates of neoplastic plasma cells are seen.

**In contrast with multiple myeloma, lymphoplasmacytic lymphoma is not associated with lytic skeletal lesions.** Instead the neoplastic cells diffusely infiltrate the bone marrow, lymph nodes, spleen, and sometimes the liver. Infiltrations of other organs also occur, particularly with disease progression. The cellular infiltrate consists of lymphocytes, plasma cells, and plasmacytic lymphocytes of intermediate differentiation. The remaining forms of plasma cell neoplasms have either already been described (e.g., primary amyloidosis) (Chapter 4) or are too rare to merit further description.

### Clinical Features

The clinical manifestations of plasma cell tumors are varied. They result from the destructive or otherwise damaging effects of tumor cells in various tissues and complications related to the complete or partial immunoglobulins secreted by the tumor cells.

The common clinicopathologic features of multiple myeloma can be summarized as follows:

- *Bone pain,* due to pathologic fractures. Pathologic fractures of vertebrae may lead to spinal cord impingement, an oncologic emergency.
- *Hypercalcemia* stemming from bone resorption leads to neurologic manifestations such as confusion and lethargy and contributes to renal dysfunction.
- *Anemia,* due to marrow replacement by tumor cells as well as suppression of hematopoiesis through uncertain mechanisms
- *Recurrent infections* with bacteria such as *S. aureus, S. pneumoniae,* and *E. coli,* resulting from the marked suppression of normal humoral immunity
- *Renal insufficiency* (in up to 50% of patients), resulting from the deleterious effect of Bence Jones proteins on renal tubular cells, as well as bacterial infections, hypercalcemia, and amyloidosis
- *AL-type amyloidosis* (5% to 10% of patients)
- Symptoms related to hyperviscosity may occur owing to excessive production and aggregation of M proteins but this clinical presentation is much more characteristic of lymphoplasmacytic lymphoma.

Multiple myeloma should be suspected when the characteristic focal, punched-out skeletal defects are present—especially when located in the vertebrae or calvaria. Electrophoresis of the serum and urine is an important diagnostic tool. In 99% of cases, either a monoclonal complete immunoglobulin or a monoclonal free immunoglobulin light chain is present in the serum, the urine, or both. In the few remaining cases, monoclonal free immunoglobulins can usually be detected within the plasma cells; in such cases the lesion is sometimes called nonsecretory myeloma. Examination of the bone marrow is used to confirm the presence of a plasma cell proliferation.

*Lymphoplasmacytic lymphoma* affects older persons; the peak incidence is between the sixth and seventh decades. Most clinical signs and symptoms are caused by secretion of IgM (macroglobulin) from the tumor cells. Because of their size, macroglobulins cause the blood to become viscous, giving rise to a syndrome, known as *Waldenström macroglobulinemia,* which is associated with the following features:

- *Visual impairment,* related to striking tortuosity and distention of retinal veins; retinal hemorrhages and exudates can also contribute to the visual problems

- *Neurologic problems* such as headaches, dizziness, tinnitus, deafness, and stupor, stemming from sluggish blood flow and sludging
- *Bleeding,* related to the formation of complexes between macroglobulins and clotting factors as well as interference with platelet function
- *Cryoglobulinemia,* related to precipitation of macroglobulins at low temperatures and producing symptoms such as Raynaud phenomenon and cold urticaria

Multiple myeloma is a progressive disease, with median survival of around 4 to 6 years. The picture for patients has brightened somewhat with the development of several new therapies, including proteasome inhibitors, which induce plasma cell apoptosis, and thalidomide analogues, which somehow alter the marrow microenvironment in a manner that inhibits myeloma cell growth and survival (recall that thalidomide was removed from the market because of its teratogenic effects in pregnant females). Lymphoplasmacytic lymphoma responds well for a time to relatively gentle chemotherapy regimens and plasmapheresis, which removes the macroglobulins; the median survival time is 4 to 5 years. At present, neither myeloma or lymphoplasmacytic lymphoma is curable.

### *Hodgkin Lymphoma*

Hodgkin lymphoma encompasses a distinctive group of neoplasms that are characterized by the presence of *a tumor giant cell, the Reed-Sternberg cell.* Unlike most NHLs, Hodgkin lymphomas arise in a single lymph node or chain of lymph nodes and typically spread in a stepwise fashion to anatomically contiguous nodes. Although the Hodgkin lymphomas are now understood to be unusual tumors of B cell origin, they are distinguished from the NHLs by their unusual pathologic and clinical features.

***Classification.*** Five subtypes of Hodgkin lymphoma are recognized: (1) nodular sclerosis, (2) mixed cellularity, (3) lymphocyte rich, (4) lymphocyte depletion, and (5) lymphocyte predominance. In the first four subtypes the Reed-Sternberg cells share certain morphologic and immunophenotypic features (described later), leading some researchers to lump together these entities under the rubric "classical Hodgkin lymphoma." The lymphocyte predominance type is set apart by the expression of germinal center B markers by the Reed-Sternberg cells. This subtype and the two most common forms of classical Hodgkin lymphoma, the nodular sclerosis and mixed-cellularity types, are discussed next.

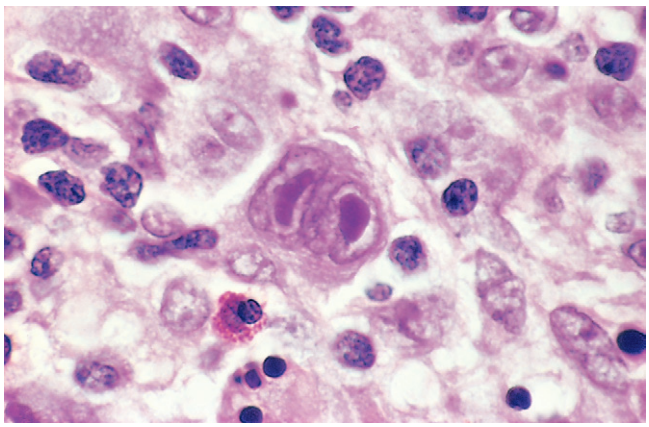

**Figure 11–20** Hodgkin lymphoma—lymph node. A binucleate Reed-Sternberg cell with large, inclusion-like nucleoli and abundant cytoplasm is surrounded by lymphocytes, macrophages, and an eosinophil.
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

## MORPHOLOGY

**The sine qua non of Hodgkin lymphoma is the Reed-Sternberg (RS) cell** (Fig. 11–20), a very large cell (15 to 45 μm in diameter) with an enormous multilobate nucleus, exceptionally prominent nucleoli and abundant, usually slightly eosinophilic cytoplasm. **Particularly characteristic are cells with two mirror-image nuclei or nuclear lobes, each containing a large (inclusion-like) acidophilic nucleolus surrounded by a clear zone, features that impart an owl-eye appearance.** The nuclear membrane is distinct. Typical RS cells and variants have a characteristic immunophenotype, as they express CD15 and CD30 and fail to express CD45 (common leukocyte antigen), B cell antigens, and T cell antigens. As we shall see, "classic" RS cells are common in the mixed-cellularity subtype, uncommon in the nodular sclerosis subtype, and rare in the lymphocyte-predominance subtype; in these latter two subtypes, other characteristic RS cell variants predominate.

**Nodular sclerosis Hodgkin lymphoma** is the most common form. It is equally frequent in men and in women and has a striking propensity to involve the lower cervical, supraclavicular, and mediastinal lymph nodes. Most patients are adolescents or young adults, and the overall prognosis is excellent. It is characterized morphologically by

- The presence of a particular variant of the RS cell, the lacunar cell (Fig. 11–21). This large cell has a single multilobate nucleus, multiple small nucleoli and abundant, pale-staining cytoplasm. In sections of formalin-fixed tissue, the cytoplasm often is torn away, leaving the nucleus lying in an empty space (a lacune). The immunophenotype of lacunar variants is identical to that of other RS cells found in classical subtypes.

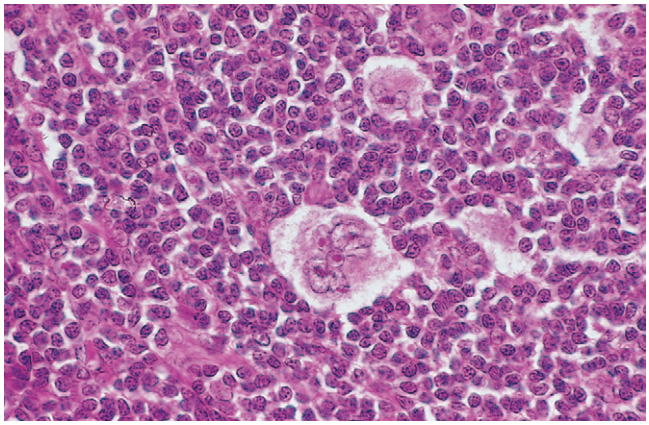

**Figure 11–21** Hodgkin lymphoma, nodular sclerosis type—lymph node. A distinctive "lacunar cell" with a multilobed nucleus containing many small nucleoli is seen lying within a clear space created by retraction of its cytoplasm. It is surrounded by lymphocytes.
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

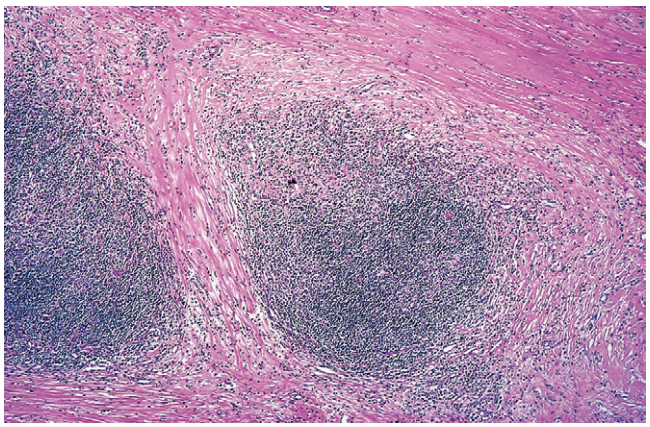

**Figure 11–22** Hodgkin lymphoma, nodular sclerosis type—lymph node. A low-power view shows well-defined bands of pink, acellular collagen that have subdivided the tumor cells into nodules.
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

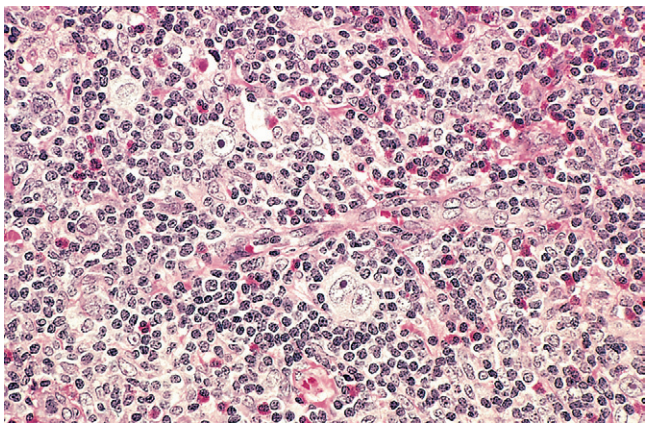

**Figure 11–23** Hodgkin lymphoma, mixed-cellularity type—lymph node. A diagnostic, binucleate Reed-Sternberg cell is surrounded by eosinophils, lymphocytes, and histiocytes.
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

- The presence of collagen bands that divide involved lymphoid tissue into circumscribed nodules (Fig. 11–22). The fibrosis may be scant or abundant and the cellular infiltrate contains varying proportions of lymphocytes, eosinophils, histiocytes, and lacunar cells.

**Mixed-cellularity Hodgkin lymphoma** is the most common form of Hodgkin lymphoma in patients older than 50 years of age and comprises about 25% of cases overall. There is a male predominance. Classic RS cells are plentiful within a heterogeneous inflammatory infiltrate containing small lymphocytes, eosinophils, plasma cells, and macrophages (Fig. 11–23). This subtype is more likely to be disseminated and to be associated with systemic manifestations than the nodular sclerosis subtype.

**Lymphocyte-Predominance Hodgkin lymphoma.** This subtype, accounting for about 5% of Hodgkin lymphoma, is characterized by the presence of lymphohistiocytic (L&H) variant RS cells that have a delicate multilobed, puffy nucleus resembling popped corn ("popcorn cell"). L&H variants usually are found within large nodules containing mainly small resting B cells admixed with a variable number of macrophages (Fig. 11–24). Other types of reactive cells, such as eosinophils, neutrophils, and plasma cells, are scanty or absent, and typical RS cells are rare. Unlike the Reed-Sternberg variants in "classical" forms of Hodgkin lymphoma, L&H variants express B cell markers (e.g., CD20) and usually fail to express CD15 and CD30. Most patients with this subtype present with isolated cervical or axillary lymphadenopathy, and the prognosis typically is excellent.

**Other Considerations in Histologic Diagnosis.** It is apparent that Hodgkin lymphoma spans a wide range of histologic patterns and that certain forms, with their characteristic fibrosis, eosinophils, neutrophils, and plasma cells, come deceptively close to simulating an inflammatory reactive process. **The histologic diagnosis of Hodgkin lymphoma rests on the definitive identification of RS cells or variants in the appropriate background of reactive cells.** Immunophenotyping plays an important adjunct role in distinguishing Hodgkin lymphoma from reactive conditions and other forms of lymphoma. In all subtypes, involvement of the spleen, liver, bone marrow, and other organs may appear in due course and takes the form of irregular nodules composed of a mixture of RS cells and reactive cells, similar to what is observed in lymph nodes.

## PATHOGENESIS

The origin of RS cells remained mysterious through the 19th and most of the 20th centuries but was finally solved by elegant molecular studies performed on single microdissected RS cells. These showed that every RS cell from any given case possessed the same immunoglobulin gene rearrangements. In addition these studies revealed that the rearranged immunoglobulin genes had undergone somatic hypermutation. As a result, it is now agreed that **Hodgkin lymphoma is a neoplasm arising from germinal center B cells.**

The events that transform these cells and alter their appearance and gene expression programs are still unclear.

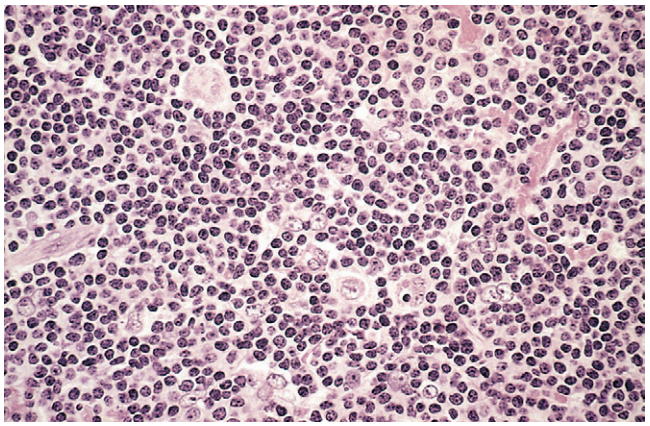

**Figure 11–24** Hodgkin lymphoma, lymphocyte-predominance type—lymph node. Numerous mature-looking lymphocytes surround scattered, large, pale-staining lymphocytic and histiocytic variants ("popcorn" cells).
*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

One clue stems from the involvement of EBV. **EBV is present in the RS cells in as many as 70% of cases of the mixed-cellularity subtype and a smaller fraction of other "classical" forms of Hodgkin lymphoma.** More important, the integration of the EBV genome is identical in all RS cells in a given case, indicating that infection precedes (and therefore may be related to) transformation and clonal expansion. Thus, as in Burkitt lymphoma and B cell lymphomas in immunodeficient patients, EBV infection probably is one of several steps contributing to tumor development, particularly of the mixed-cellularity subtype.

The characteristic non-neoplastic, inflammatory cell infiltrate is generated by a number of cytokines, some secreted by RS cells, including IL-5 (which attracts and activates eosinophils), transforming growth factor-β (a fibrogenic factor), and IL-13 (which may stimulate RS cells through an autocrine mechanism). Conversely, the responding inflammatory cells, rather than being innocent bystanders, produce additional factors such as CD30 ligand that aid the growth and survival of RS cells and contribute further to the tissue reaction.

***Staging and Clinical Features.*** Hodgkin lymphomas, like NHLs, usually manifest as painless lymphadenopathy. Although a definitive distinction from NHL can be made only by examination of a lymph node biopsy, several clinical features favor the diagnosis of Hodgkin lymphoma (Table 11–9). Once the diagnosis is established, *staging is used to guide therapy and determine prognosis* (Table 11–10). Younger patients with the more favorable subtypes tend to present with stage I or II disease and usually are free of systemic manifestations. Patients with advanced disease (stages III and IV) are more likely to have systemic complaints such as fever, weight loss, pruritus, and anemia. Due to the long-term complications of radiotherapy, even patients with stage I disease are now treated with systemic chemotherapy. More advanced disease generally is also treated with chemotherapy, sometimes with involved field radiotherapy at sites of bulky disease. The outlook for patients with Hodgkin lymphoma, even those with advanced disease, is very good. The 5-year survival rate for patients with stage I-A or II-A disease is close to 100%. Even with advanced disease (stage IV-A or IV-B), the overall 5-year disease-free survival rate is around 50%. Among long-term survivors treated with radiotherapy, a much higher risk of certain malignancies, including lung cancer, melanoma, and breast cancer, has been reported. These sobering results have spurred the development of new treatment regimens that minimize the use of radiotherapy and employ less toxic chemotherapeutic agents. Anti-CD30 antibodies have produced excellent responses in patients with disease that has failed conventional therapies and represent a promising "targeted" therapy.

**Table 11–9** Clinical Differences Between Hodgkin and Non-Hodgkin Lymphomas

| Hodgkin Lymphoma | Non-Hodgkin Lymphoma |
|---|---|
| More often localized to a single axial group of nodes (cervical, mediastinal, para-aortic) | More frequent involvement of multiple peripheral nodes |
| Orderly spread by contiguity | Noncontiguous spread |
| Mesenteric nodes and Waldeyer ring rarely involved | Mesenteric nodes and Waldeyer ring commonly involved |
| Extranodal involvement uncommon | Extranodal involvement common |

**Table 11–10** Clinical Staging of Hodgkin and Non-Hodgkin Lymphomas (Ann Arbor Classification)*

| Stage | Distribution of Disease |
|---|---|
| I | Involvement of a single lymph node region (I) or involvement of a single extralymphatic organ or tissue ($I_E$) |
| II | Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or with involvement of limited contiguous extralymphatic organs or tissue ($II_E$) |
| III | Involvement of lymph node regions on both sides of the diaphragm (III), which may include the spleen ($III_S$), limited contiguous extralymphatic organ or site ($III_E$), or both ($III_{ES}$) |
| IV | Multiple or disseminated foci of involvement of one or more extralymphatic organs or tissues with or without lymphatic involvement |

*All stages are further divided on the basis of the absence (A) or presence (B) of the following systemic symptoms and signs: significant fever, night sweats, unexplained loss of more than 10% of normal body weight.
From Carbone PT, et al: Symposium (Ann Arbor): staging in Hodgkin disease. Cancer Res 31:1707, 1971.

## *Miscellaneous Lymphoid Neoplasms*

Among the many other forms of lymphoid neoplasia in the WHO classification, several with distinctive or clinically important features merit brief discussion.

### Extranodal Marginal Zone Lymphoma

This indolent B cell tumor arises most commonly in epithelial tissues such as the stomach, salivary glands, small and large bowel, lungs, orbit, and breast. Extranodal marginal zone lymphomas tend to develop in the setting of autoimmune disorders (such as Sjögren syndrome and Hashimoto thyroiditis) or chronic infection (such as *H. pylori* gastritis), suggesting that sustained antigenic stimulation contributes to its development. In the case of *H. pylori*–associated gastric marginal zone lymphoma, eradication of the organism with antibiotic therapy often leads to regression of the tumor cells, which depend on cytokines secreted by *H. pylori*–specific T cells for their growth and survival (Chapter 5). When arising at other sites, these lymphomas are often cured by local excision or radiotherapy. Several recurrent cytogenetic abnormalities are recognized, the most common of which is a (11;18) translocation involving the *MALT1* and *IAP2* genes. Of clinical importance, the presence of the t(11;18) is highly predictive of the failure of gastric tumors to respond to antibiotic treatment.

### Hairy Cell Leukemia

Hairy cell leukemia is an uncommon, indolent B cell neoplasm characterized by the presence of leukemic cells with fine, hairlike cytoplasmic projections. The tumor cells express pan-B cell markers (CD19 and CD20), surface immunoglobulin, and CD11c and CD103; the latter two antigens are not present on most other B cell tumors, making them diagnostically useful. Virtually all cases are associated with activating mutations in the serine/threonine kinase BRAF, which is also mutated in diverse other cancers (Chapter 5).

Hairy cell leukemia occurs mainly in older males and its manifestations result from infiltration of bone marrow and spleen. *Splenomegaly,* often massive, is the most

common and sometimes only physical finding. *Pancytopenia,* resulting from marrow infiltration and splenic sequestration, is seen in more than half of cases. Lymph node involvement is seen only rarely. *Leukocytosis is uncommon,* being present in 15% to 20% of patients, but scattered "hairy cells" can be identified in the peripheral blood smear in most cases. The disease is indolent but progressive if untreated; pancytopenia and infections cause the major clinical problems. Unlike most other indolent lymphoid neoplasms, this tumor is extremely sensitive to chemotherapeutic agents, particularly purine nucleosides. Complete durable responses are the rule and the overall prognosis is excellent.

### Mycosis Fungoides and Sézary Syndrome

These tumors of neoplastic CD4+ T cells home to the skin; as a result, they often are referred to as *cutaneous T cell lymphoma.* Mycosis fungoides usually manifests as a nonspecific erythrodermic rash that progresses over time to a plaque phase and then to a tumor phase. Histologically, neoplastic T cells, often with a cerebriform appearance produced by marked infolding of the nuclear membranes, infiltrate the epidermis and upper dermis. With disease progression, both nodal and visceral dissemination appear. Sézary syndrome is a clinical variant characterized by (1) a generalized exfoliative erythroderma and (2) tumor cells (Sézary cells) in the peripheral blood. Circulating tumor cells also are present in as many as 25% of cases of plaque- or tumor-phase mycosis fungoides. Patients diagnosed with early-phase mycosis fungoides often survive for many years, whereas patients with tumor-phase disease, visceral disease, or Sézary syndrome survive on average for 1 to 3 years.

### Adult T Cell Leukemia/Lymphoma

*This is a neoplasm of CD4+ T cells that is caused by a retrovirus, human T cell leukemia virus type 1 (HTLV-1).* HTLV-1 infection is endemic in southern Japan, the Caribbean basin, and West Africa, and occurs sporadically elsewhere, including in the southeastern United States. The pathogenesis of this tumor is discussed in Chapter 5. In addition to lymphoid malignancies, HTLV-1 infection also can cause *transverse myelitis,* a progressive demyelinating disease affecting the central nervous system and the spinal cord.

Adult T cell leukemia/lymphoma commonly is associated with skin lesions, lymphadenopathy, hepatosplenomegaly, hypercalcemia, and variable numbers of malignant lymphocytes in the peripheral blood. In addition to CD4, the leukemic cells express high levels of CD25, the IL-2 receptor α chain. In most cases the tumor is very aggressive and responds poorly to treatment. The median survival time is about 8 months. In 15% to 20% of patients the disease follows a chronic course resembling that of mycosis fungoides.

### Peripheral T Cell Lymphomas

This heterogeneous group of tumors makes up 10% to 15% of adult NHLs. Although several rare distinctive subtypes fall under this heading, most tumors in this group are unclassifiable. In general, these are aggressive tumors that respond poorly to therapy. Moreover, because these are tumors of functional T cells, patients often suffer from symptoms related to tumor-derived inflammatory products, even when the tumor burden is relatively low.

## SUMMARY

### Lymphoid Neoplasms

- Classification is based on cell of origin and stage of differentiation.
- Most common types in children are acute lymphoblastic leukemias/lymphoblastic lymphomas derived from precursor B and T cells.
  - These highly aggressive tumors manifest with signs and symptoms of bone marrow failure, or as rapidly growing masses.
  - Tumor cells contain genetic lesions that block differentiation, leading to the accumulation of immature, nonfunctional blasts.
- Most common types in adults are non-Hodgkin lymphomas derived from germinal center B cells.

**Small Lymphocytic Lymphoma/Chronic Lymphocytic Leukemia**

- This tumor of mature B cells usually manifests with bone marrow and lymph node involvement.
- An indolent course, commonly associated with immune abnormalities, including an increased susceptibility to infection and autoimmune disorders, is typical.

**Follicular Lymphoma**

- Tumor cells recapitulate the growth pattern of normal germinal center B cells; most cases are associated with a (14;18) translocation that results in the overexpression of BCL2.

**Mantle Cell Lymphoma**

- This tumor of mature B cells usually manifests with advanced disease involving lymph nodes, bone marrow, and extranodal sites such as the gut.
- An association with an (11;14) translocation that results in overexpression of cyclin D1, a regulator of cell cycle progression, is recognized.

**Diffuse Large B Cell Lymphoma**

- This heterogeneous group of mature B cell tumors shares a large cell morphology and aggressive clinical behavior and represents the most common type of lymphoma.
- Rearrangements or mutations of *BCL6* gene are recognized associations; one third arise from follicular lymphomas and carry a (14;18) translocation involving *BCL2.*

**Burkitt Lymphoma**

- This very aggressive tumor of mature B cells usually arises at extranodal sites.
- A uniform association with translocations involving the *MYC* proto-oncogene has been established.
- Tumor cells often are latently infected by Epstein-Barr virus (EBV).

**Multiple Myeloma**

- This plasma cell tumor often manifests with multiple lytic bone lesions associated with pathologic fractures and hypercalcemia.
- Neoplastic plasma cells suppress normal humoral immunity and secrete partial immunoglobulins that are nephrotoxic.

**Hodgkin Lymphoma**

- This unusual tumor consists mostly of reactive lymphocytes, macrophages, and stromal cells.
- Malignant Reed-Sternberg cells make up a minor part of the tumor mass.

Table 11–8 lists features of specific entities.

## Myeloid Neoplasms

*Myeloid neoplasms arise from hematopoietic progenitors and typically give rise to clonal proliferations that replace normal bone marrow cells.* There are three broad categories of myeloid neoplasia. In the *acute myeloid leukemias* (AMLs), the neoplastic cells are blocked at an early stage of myeloid cell development. Immature myeloid cells (blasts) accumulate in the marrow and replace normal elements, and frequently circulate in the peripheral blood. In the *myeloproliferative disorders,* the neoplastic clone continues to undergo terminal differentiation but exhibits increased or dysregulated growth. Commonly, these are associated with an increase in one or more of the formed elements (red cells, platelets, and/or granulocytes) in the peripheral blood. In the *myelodysplastic syndromes,* terminal differentiation occurs but in a disordered and ineffective fashion, leading to the appearance of dysplastic marrow precursors and peripheral blood cytopenias.

Although these three categories provide a useful starting point, the divisions between the myeloid neoplasms sometimes blur. Both myelodysplastic syndromes and myeloproliferative disorders often transform to AML, and some neoplasms have features of both myelodysplasia and myeloproliferative disorders. Because all myeloid neoplasms arise from early multipotent progenitors, the close relationship among these disorders is not surprising.

### *Acute Myeloid Leukemia*

AML primarily affects older adults; the median age is 50 years. It is very heterogeneous, as discussed later on. The clinical signs and symptoms closely resemble those produced by ALL and usually are related to the replacement of normal marrow elements by leukemic blasts. Fatigue, pallor, abnormal bleeding, and infections are common in newly diagnosed patients, who typically present within a few weeks of the onset of symptoms. Splenomegaly and lymphadenopathy generally are less prominent than in ALL, but on rare occasions AML mimics a lymphoma by manifesting as a discrete tissue mass (a so-called granulocytic sarcoma). The diagnosis and classification of AML are based on morphologic, histochemical, immunophenotypic, and karyotypic findings. Of these, the karyotype is most predictive of outcome.

### PATHOGENESIS

**Most AMLs harbor mutations in genes encoding transcription factors that are required for normal myeloid cell differentiation.** These mutations interfere with the differentiation of early myeloid cells, leading to the accumulation of myeloid precursors (blasts) in the marrow.

Of particular interest is the (15;17) translocation in acute promyelocytic leukemia, which results in the fusion of the retinoic acid receptor α (*RARA*) gene on chromosome 17 and the *PML* gene on chromosome 15. The chimeric gene produces a PML/RARα fusion protein that blocks myeloid differentiation at the promyelocytic stage, probably in part by inhibiting the function of normal retinoic acid receptors. Remarkably, pharmacologic doses of all-*trans* retinoic acid (ATRA), an analogue of vitamin A (Chapter 7), overcome this block and induce the neoplastic promyelocytes to rapidly differentiate into neutrophils. Because neutrophils die after an average lifespan of 6 hours, ATRA treatment rapidly clears the tumor. The effect is very specific; AMLs without translocations involving *RARA* do not respond to ATRA. More recently, **it has been noted that the combination of ATRA and arsenic trioxide, a salt that induces the degradation of the PML/RARA fusion protein, is even more effective than ATRA alone, producing cures in more than 80% of patients.** This is an important example of a highly effective therapy targeted at a tumor-specific molecular defect.

Other work using transgenic or "knock-in" mice has shown that the mutations in transcription factors found in AML are not sufficient to cause the disease. Some of the other mutations implicated in AML have no effect on differentiation but instead enhance cellular proliferation and survival. One example involves FLT3, a receptor tyrosine kinase that is activated by mutations in a number of AML subtypes, including acute promyelocytic leukemia. Putative collaborating mutations in several other tyrosine kinase genes and in *RAS*, an oncogene that is mutated in diverse forms of cancer, also have been detected.

### MORPHOLOGY

By definition, in AML myeloid blasts or promyelocytes make up more than 20% of the bone marrow cellular component. **Myeloblasts** (precursors of granulocytes) have delicate nuclear chromatin, three to five nucleoli, and fine azurophilic cytoplasmic granules (Fig. 11–14, *B*). **Auer rods,** distinctive red-staining rodlike structures, may be present in myeloblasts or more differentiated cells; they are particularly numerous in acute promyelocytic leukemia (Fig. 11–25). Auer rods are specific for neoplastic myeloblasts and thus a helpful diagnostic clue when present. In other subtypes of AML, monoblasts, erythroblasts, or megakaryoblasts predominate.

***Classification.*** *AMLs are diverse in terms of genetics, cellular lineage, and degree of maturation.* The WHO classification relies on all of these features to divide AML into four categories (Table 11–11): (1) AMLs associated with specific genetic aberrations, which are important because they predict outcome and guide therapy; (2) AMLs with dysplasia, many of which arise from myelodysplastic syndromes; (3) AMLs occurring after genotoxic chemotherapy; and (4) AMLs lacking any of the foregoing features. AMLs in the last category are subclassified on the basis of the predominant line of differentiation that the tumor exhibits.

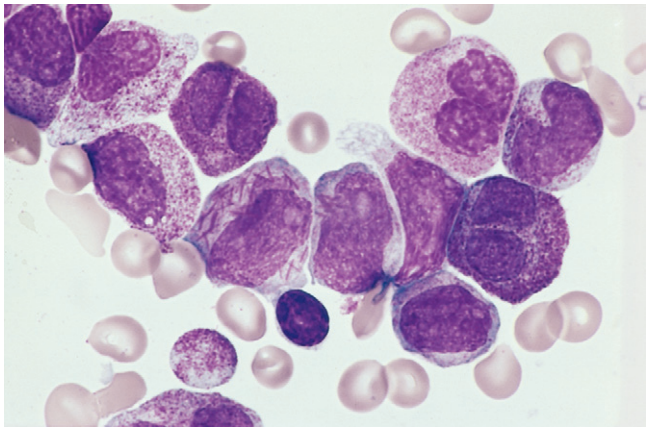

**Figure 11–25** Acute promyelocytic leukemia—bone marrow aspirate. The neoplastic promyelocytes have abnormally coarse and numerous azurophilic granules. Other characteristic findings include the presence of several cells with bilobed nuclei and a cell in the center of the field that contains multiple needle-like Auer rods.

*(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

***Immunophenotype.*** The expression of immunologic markers is heterogeneous in AML. Most tumors express some combination of myeloid-associated antigens, such as CD13, CD14, CD15, CD64, or CD117 (cKIT). CD33 is expressed on pluripotent stem cells but is retained on myeloid progenitor cells. Such markers are helpful in distinguishing AML from ALL (as shown in Fig. 11–14) and in identifying AMLs with only minimal differentiation.

***Prognosis.*** AML is a devastating disease. Tumors with "good-risk" karyotypic abnormalities (t[8;21], inv[16]) are associated with a 50% chance of long-term disease-free survival, but the overall survival in all patients is only 15% to 30% with conventional chemotherapy. A bright spot is the improvement in outcomes in acute promyelocytic leukemia brought about by targeted treatment with ATRA and arsenic salts. An increasing number of patients with AML are being treated with more aggressive approaches, such as allogeneic hematopoietic stem cell transplantation.

**Table 11–11** WHO Classification of Acute Myeloid Leukemia (AML)

| Class | Prognosis |
|---|---|
| **I. AML with Recurrent Chromosomal Translocations** | |
| AML with t(8;21)(q22;q22); *CBFA/ETO* fusion gene | Favorable |
| AML with inv(16)(p13;q22); *CBFB/MYH11* fusion gene | Favorable |
| AML with t(15;17)(q22;q21.1); *PML/RARA* fusion gene | Favorable |
| AML with t(11q23;variant); *MLL* fusion genes | Poor |
| AML with mutated *NPM1* | Variable |
| **II. AML with Multilineage Dysplasia** | |
| With previous myelodysplastic syndrome | Very poor |
| Without previous myelodysplastic syndrome | Poor |
| **III. AML, Therapy-Related** | |
| Alkylating agent–related | Very poor |
| Epipodophyllotoxin-related | Very poor |
| **IV. AML, Not Otherwise Classified** | |
| Subclasses defined by extent and type of differentiation (e.g., myelocytic, monocytic) | Intermediate |

NPM1, nucleophosmin 1; WHO, World Health Organization.

### *Myelodysplastic Syndromes*

In myelodysplastic syndromes (MDSs), the bone marrow is partly or wholly replaced by the clonal progeny of a transformed multipotent stem cell that retains the capacity to differentiate into red cells, granulocytes, and platelets, but in a manner that is both ineffective and disordered. As a result, the marrow usually is hypercellular or normocellular, but the peripheral blood shows one or more cytopenias. The abnormal stem cell clone in the bone marrow is genetically unstable and prone to the acquisition of additional mutations and the eventual transformation to AML. Most cases are idiopathic, but some develop after chemotherapy with alkylating agents or exposure to ionizing radiation therapy.

## PATHOGENESIS

The pathogenesis of MDS is poorly understood. Cytogenetic studies reveal clonal abnormalities in up to 70% of cases. Translocations generally are lacking, whereas losses or gains of whole chromosomes or parts thereof are frequent. Some **common karyotypic abnormalities include monosomy 5 or 7; deletions of 5q, 7q, and 20q;** and trisomy 8. Recent work suggests that the critical region deleted on 5q contains genes encoding a ribosomal protein and several microRNAs. Loss of all of these genes appears to contribute to a subtype of MDS called the 5q– syndrome. This syndrome occurs more often in women, is associated with severe anemia and preserved or elevated platelet counts, and often responds to treatment with analogs of thalidomide, which are believed to influence the interaction of hematopoietic progenitors and marrow stromal cells.

## MORPHOLOGY

In MDSs, the marrow is populated by abnormal-appearing hematopoietic precursors. Some of the more common abnormalities include **megaloblastoid erythroid precursors** resembling those seen in the megaloblastic anemias, erythroid forms with iron deposits within their mitochondria **(ringed sideroblasts),** granulocyte precursors with **abnormal granules** or nuclear maturation, and small megakaryocytes with single small nuclei or multiple separate nuclei.

*Although these syndromes often are described as rare, it is now appreciated that MDS is about as common as AML, affecting up to 15,000 patients per year in the United States.* Most persons with MDS are between 50 and 70 years of age. As a result of cytopenias, many suffer from infections, symptoms related to anemia, and hemorrhages. The response to conventional chemotherapy usually is poor, perhaps because MDS arises in a background of stem cell damage. Transformation to AML occurs in 10% to 40%. The prognosis is variable; the median survival time ranges from 9

to 29 months and is worse in patients with increased marrow blasts or cytogenetic abnormalities at the time of diagnosis.

### *Chronic Myeloproliferative Disorders*

Chronic myeloproliferative disorders are marked by the hyperproliferation of neoplastic myeloid progenitors that retain the capacity for terminal differentiation; as a result, there is an increase in one or more formed elements of the peripheral blood. The neoplastic progenitors tend to seed secondary hematopoietic organs (the spleen, liver, and lymph nodes), resulting in hepatosplenomegaly (caused by neoplastic extramedullary hematopoiesis). *A common theme is the association of these disorders with activating mutations in tyrosine kinases, which generate constitutive signals mimicking those that are normally produced in response to hematopoietic growth factors.* This insight provides a satisfying explanation for the observed overproduction of myeloid cells and is important therapeutically because of the availability of tyrosine kinase inhibitors.

Four major diagnostic entities are recognized: chronic myelogenous leukemia (CML), polycythemia vera, primary myelofibrosis, and essential thrombocythemia. CML is separated from the others by its association with a characteristic abnormality, the *BCR-ABL* fusion gene, which produces a constitutively active BCR-ABL tyrosine kinase. The remaining *BCR-ABL*–negative myeloproliferative disorders show considerable clinical and genetic overlap. The most common genetic abnormalities in the "BCR-ABL–negative" myeloproliferative disorders are activating mutations in the tyrosine kinase JAK2, which occur in virtually all cases of polycythemia vera and about 50% of cases of primary myelofibrosis and essential thrombocythemia. Some rare myeloproliferative disorders are associated with activating mutations in other tyrosine kinases, such as platelet-derived growth factor receptor-α and platelet-derived growth factor receptor-β. In addition, all myeloproliferative disorders have variable propensities to transform to a "spent phase" resembling primary myelofibrosis or to a "blast crisis" identical to acute leukemia, both presumably triggered by the acquisition of other somatic mutations. Only CML, polycythemia vera, and primary myelofibrosis are presented here, as essential thrombocythemia and other myeloproliferative disorders are too infrequent to merit discussion.

### Chronic Myelogenous Leukemia

CML principally affects adults between 25 and 60 years of age. The peak incidence is in the fourth and fifth decades of life. About 4500 new cases are diagnosed per year in the United States.

## PATHOGENESIS

**CML is always associated with the presence of a BCR-ABL fusion gene.** In about 95% of cases, the *BCR-ABL* gene is the product of a balanced (9;22) translocation that moves *ABL* from chromosome 9 to a position on chromosome 22 adjacent to *BCR*. In the remaining 5% of cases, a *BCR-ABL* fusion gene is created by cytogenetically cryptic or complex rearrangements involving more than two chromosomes. The *BCR-ABL* fusion gene is present in granulocytic, erythroid, megakaryocytic, and B cell precursors, and in some cases T cell precursors as well, indicating that the tumor arises from a transformed hematopoietic stem cell. Although the Ph chromosome is highly characteristic of CML, it also is present in 25% of adult B cell–ALLs and a small subset of AMLs.

As described in Chapter 5, the *BCR-ABL* gene encodes a fusion protein consisting of portions of BCR and the tyrosine kinase domain of ABL. Normal myeloid progenitors depend on signals generated by growth factors and their receptors for growth and survival. **The growth factor dependence of CML progenitors is greatly decreased by constitutive signals generated by BCR-ABL that mimic the effects of growth factor receptor activation.** Importantly, because BCR-ABL does not inhibit differentiation, the early disease course is marked by excessive hematopoiesis. Although the *BCR-ABL* fusion gene is present in multiple lineages, for unclear reasons the pro-growth effects of BCR-ABL are confined mainly to the granulocyte and megakaryocyte lineages.

## MORPHOLOGY

The peripheral blood findings are highly characteristic. The leukocyte count is elevated, often exceeding 100,000 cells/μL. **The circulating cells are predominantly neutrophils, metamyelocytes, and myelocytes** (Fig. 11–26), but **basophils** and **eosinophils** are also prominent and platelets are usually increased. A small proportion of myeloblasts, usually less than 5%, are often seen in the peripheral blood. The bone marrow is hypercellular owing to increased numbers of granulocytic and megakaryocytic precursors. Myeloblasts usually are only slightly increased. The red pulp of the enlarged spleen resembles bone marrow because of the presence of extensive extramedullary hematopoiesis. This burgeoning proliferation often compromises the local blood supply, leading to splenic infarcts.

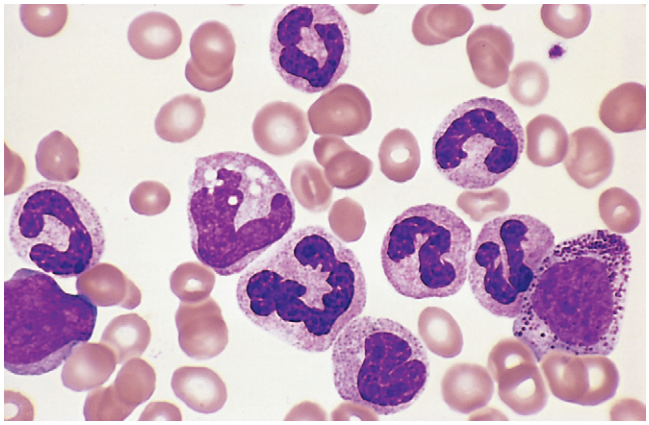

**Figure 11–26** Chronic myelogenous leukemia—peripheral blood smear. Granulocytic forms at various stages of differentiation are present. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

### Clinical Features

The onset of CML often is insidious, as the initial symptoms usually are nonspecific (e.g., easy fatigability, weakness, weight loss). Sometimes the first symptom is a dragging sensation in the abdomen caused by *splenomegaly.* On occasion it may be necessary to distinguish CML from a "leukemoid reaction," a dramatic elevation of the granulocyte count in response to infection, stress, chronic inflammation, and certain neoplasms. This distinction can be achieved definitively by testing for the presence of the *BCR-ABL* fusion gene, which can be done by karyotyping, fluorescence in situ hybridization, or PCR assay.

The natural history of CML initially is one of slow progression. Even without treatment, the median survival is 3 years. After a variable (and unpredictable) period, approximately half of CML cases enter an accelerated phase marked by increasing anemia and new thrombocytopenia, the appearance of additional cytogenetic abnormalities, and finally transformation into a picture resembling acute leukemia (blast crisis). In the remaining 50% of cases, blast crisis occurs abruptly, without an accelerated phase. Of note, in 30% of cases the blast crisis resembles precursor-B cell ALL, further attesting to the origin of CML from hematopoietic stem cells. In the remaining 70% of cases, the blast crisis resembles AML. Less commonly, CML progresses to a phase of extensive bone marrow fibrosis resembling primary myelofibrosis.

Fortunately for those affected, the natural history of CML has been altered dramatically by the emergence of targeted therapy. Inhibitors of the BCR-ABL tyrosine kinase, such as imatinib and nilotinib, induce complete remission in a high fraction of patients with little associated toxicity. Treatment with tyrosine kinase inhibitors, particularly in patients with early disease, induces sustained remissions and may prevent the appearance of blast crisis by suppressing the proliferative drive that leads to the acquisition of additional mutations. When patients on tyrosine kinase inhibitors relapse, their tumors frequently are found to have acquired mutations in the kinase domain of BCR-ABL that prevent the drugs from binding. In retrospective studies, these mutations have been shown to be present in small numbers of cells at the time of diagnosis. The selective outgrowth of these cells is explained by the powerful antitumor effects of BCR-ABL inhibitors, and indicates that many resistant tumors are still "addicted" to the pro-growth signals created by BCR-ABL. For those with resistant disease, hematopoietic stem cell transplantation is curative in 70% of patients, but carries with it substantial risks, particularly in the aged.

## Polycythemia Vera

Polycythemia vera is characterized by an excessive proliferation of erythroid, granulocytic, and megakaryocytic elements (panmyelosis), but *most clinical signs and symptoms are related to an absolute increase in red cell mass.* Polycythemia vera must be distinguished from relative polycythemia, which results from hemoconcentration. Unlike reactive forms of absolute polycythemia, polycythemia vera is associated with *low levels of serum erythropoietin,* which is a reflection of the growth factor–independent growth of the neoplastic clone. This behavior stems from the presence of activating mutations in JAK2, a tyrosine kinase that acts in the signaling pathways downstream of the erythropoietin receptor and other growth factor receptors. The most common JAK2 mutation, a valine-to-phenylalanine substitution at residue 617, sharply lowers the dependence of hematopoietic cells on growth factors for growth and survival, suggesting that it is an important part of the pathogenesis of the disorder.

### MORPHOLOGY

The major anatomic changes in polycythemia vera stem from increases in blood volume and viscosity brought about by the polycythemia. Plethoric congestion of many tissues is characteristic. The liver is enlarged and often contains small foci of extramedullary hematopoiesis. The spleen usually is slightly enlarged (250 to 300 g) due to vascular congestion. **As a result of the increased viscosity and vascular stasis, thromboses and infarctions are common, particularly in the heart, spleen, and kidneys.** Hemorrhages also occur in about a third of the patients, probably as a result of excessive distention of blood vessels and abnormal platelet function. These most often affect the gastrointestinal tract, oropharynx, or brain. Hemorrhage may occur spontaneously but more often follows some minor trauma or surgical procedure. Platelets produced from the neoplastic clone often are dysfunctional, a derangement that contributes to the elevated risk of thrombosis and bleeding. As in CML, the peripheral blood often shows basophilia.

The bone marrow is hypercellular owing to increased numbers of erythroid, myeloid, and megakaryocytic forms. In addition, some degree of marrow fibrosis is present in 10% of patients at the time of diagnosis. In a subset of patients, this progresses to a spent phase where the marrow is largely replaced by fibroblasts and collagen.

### Clinical Course

Polycythemia vera appears insidiously, usually in late middle age. Patients are plethoric and often somewhat cyanotic. Histamine released from the neoplastic basophils may contribute to *pruritus* and also may account for the increased incidence of *peptic ulceration.* Other complaints are referable to the thrombotic and hemorrhagic tendencies and to hypertension. *Headache, dizziness, gastrointestinal symptoms, hematemesis, and melena* are common. Because of the high rate of cell turnover, symptomatic gout is seen in 5% to 10% of cases, and many more patients have asymptomatic hyperuricemia.

The diagnosis usually is made in the laboratory. *Red cell counts range from 6 to 10 million/μl and the hematocrit is often 60% or greater.* The granulocyte count can be as high as 50,000 cells/μL, and the platelet count is often over 400,000/μL. *Basophilia* is common. The platelets are functionally abnormal in most cases, and giant *platelets* and megakaryocyte fragments are often seen in the blood. About 30% of patients develop *thrombotic complications,* usually affecting the brain or heart. Hepatic vein thrombosis giving rise to the Budd-Chiari syndrome (Chapter 15) is an uncommon but grave complication. Minor *hemorrhages* (e.g., epistaxis and bleeding from gums) are common and life-threatening hemorrhages occur in 5% to 10% of patients. In those receiving no treatment, death occurs from

vascular complications within months; however, the median survival is increased to about 10 years by lowering the red cell count to near normal through repeated phlebotomy.

Unfortunately, prolonged survival has revealed a propensity for polycythemia vera to evolve to a "spent phase" resembling primary myelofibrosis. After an average interval of 10 years, 15% to 20% of cases undergo such a transformation. Owing to the extensive marrow fibrosis, hematopoiesis shifts to the spleen, which enlarges markedly. Transformation to a "blast crisis" identical to AML also occurs but much less frequently than in CML. Inhibitors that target JAK2 are in clinical trials at present.

### Primary Myelofibrosis

In the myeloproliferative disorder known as primary myelofibrosis, a "spent phase" of marrow fibrosis supervenes early in the disease course, often after a brief period of granulocytosis and thrombocytosis. As hematopoiesis shifts from the fibrotic marrow to the spleen, liver, and lymph nodes, extreme splenomegaly and hepatomegaly develop. The extramedullary hematopoiesis at these sites is disordered and inefficient, resulting in anemia and thrombocytopenia. Neutropenia also may occur but tends to be mild.

## PATHOGENESIS

The fibroblasts that lay down the collagen in the marrow are not neoplastic. Instead, the marrow fibrosis is secondary to derangements in the hematopoietic cells. It is believed that **the fibroblast proliferation is stimulated by platelet-derived growth factor and transforming growth factor β released from neoplastic megakaryocytes.** By the time patients come to clinical attention, marrow fibrosis and marked extramedullary hematopoiesis usually are evident. Less commonly, marrow fibrosis is mild at diagnosis and the clinical picture resembles that of other myeloproliferative disorders.

Of pathogenic and possible therapeutic importance, the same JAK2 mutation that is found in polycythemia vera (a valine-to-phenylalanine mutation at amino acid residue 617) is present in around half of cases of primary myelofibrosis (as well as a similar proportion of essential thrombocythemia cases)—a commonality that emphasizes the overlap between these entities. It is not yet known why tumors with the same mutation have such varied clinical pictures.

## MORPHOLOGY

The peripheral blood smear is markedly abnormal (Fig. 11–27). **Red cells often exhibit bizarre shapes (poikilocytes, teardrop cells),** and nucleated erythroid precursors are commonly present along with immature white cells (myelocytes and metamyelocytes), a combination of findings referred to as "leukoerythroblastosis." Abnormally large platelets often are present as well. The **spleen** usually is markedly enlarged, sometimes weighing as much as 4000 g, from the extensive extramedullary hematopoiesis. **Subcapsular splenic infarcts,** often multiple, are commonly present. Within areas of extramedullary hematopoiesis, megakaryocytes usually are numerous and often display bizarre morphologic features. Moderate **hepatomegaly** due to extramedullary hematopoiesis is commonplace. The **lymph nodes** also are involved by extramedullary hematopoiesis, but not to a degree sufficient to cause appreciable enlargement. The **bone marrow** in advanced cases is hypocellular and diffusely fibrotic, while early in the course it may be hypercellular and have only focal areas of fibrosis. Throughout the course, marrow megakaryocytes usually are increased in number and dysplastic.

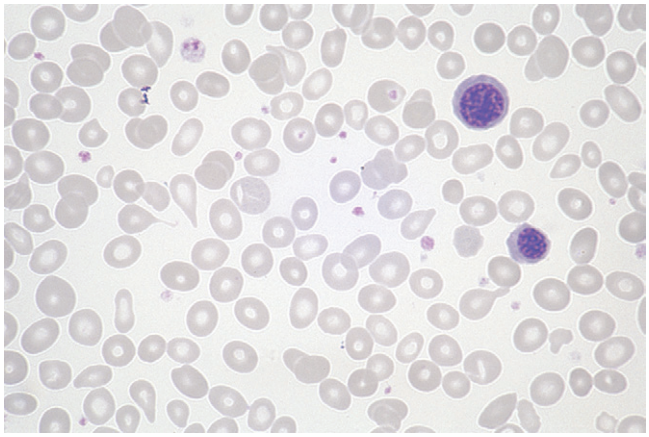

**Figure 11–27** Primary myelofibrosis—peripheral blood smear. Two nucleated erythroid precursors and several teardrop-shaped red cells (dacryocytes) are evident. Immature myeloid cells were present in other fields. An identical histologic picture can be seen in other diseases producing marrow distortion and fibrosis.

### Clinical Course

By the time most patients come to clinical attention, the disease has progressed to the phase of marrow fibrosis. Early stage disease may have features suggestive of CML, but *the Ph chromosome is absent.* Most patients have moderate to severe anemia at the time of diagnosis. The white blood cell count may be normal, reduced, or markedly elevated. Early in the course the platelet count is normal or elevated, but eventually patients develop thrombocytopenia. Because of a high rate of cell turnover, *hyperuricemia and gout* may complicate the picture.

The outcome of this disease is variable, but the median survival time is 4 to 5 years. There is a constant threat of thrombotic and hemorrhagic episodes stemming from platelet abnormalities. Splenic infarctions are common. From 5% to 15% of affected persons develop a blast crisis resembling AML.

## SUMMARY

### Myeloid Neoplasms

Myeloid tumors occur mainly in adults and fall into three major groups:

- **Acute myeloid leukemias (AMLs)**
  - Aggressive tumors comprised of immature myeloid lineage blasts, which replace the marrow and suppress normal hematopoiesis

- Associated with diverse acquired mutations that lead to expression of abnormal transcription factors, which interfere with myeloid differentiation
- **Myeloproliferative disorders**
  - Myeloid tumors in which production of formed myeloid elements is initially increased, leading to high blood counts and extramedullary hematopoiesis
  - Commonly associated with acquired mutations that lead to constitutive activation of tyrosine kinases, which mimic signals from normal growth factors. The most common pathogenic kinases are BCR-ABL (associated with CML) and mutated JAK2 (associated with polycythemia vera and primary myelofibrosis).
  - All can transform to acute leukemia and to a spent phase of marrow fibrosis associated with anemia, thrombocytopenia, and splenomegaly.
- **Myelodysplastic syndromes**
  - Poorly understood myeloid tumors characterized by disordered and ineffective hematopoiesis
  - Manifest with one or more cytopenias and progress in 10% to 40% of cases to AML

## Histiocytic Neoplasms

### *Langerhans Cell Histiocytoses*

The term *histiocytosis* is an "umbrella" designation for a variety of proliferative disorders of dendritic cells or macrophages. Some, such as very rare histiocytic lymphomas, are highly malignant neoplasms. Others, such as most histiocytic proliferations in lymph nodes, are completely benign and reactive. Between these two extremes lie a group of relatively rare tumors comprised of Langerhans cells, the *Langerhans cell histiocytoses*. As described in Chapter 4, Langerhans cells are immature dendritic cells found in the epidermis; similar cells are found in many other organs, and function to capture antigens and display them to T cells.

Langerhans cell proliferations take on different clinical forms, but all are believed to be variations of the same basic disorder. The proliferating Langerhans cells express MHC class II antigens, CD1a, and langerin. Langerin is a transmembrane protein found in *Birbeck granules,* cytoplasmic pentalaminar rodlike tubular structures that in electron micrographs have a characteristic periodicity and sometimes a dilated terminal end ("tennis racket" appearance). Under the light microscope, the proliferating Langerhans cells do not resemble their normal dendritic counterparts. Instead, they have abundant, often vacuolated cytoplasm and vesicular nuclei, an appearance more akin to that of tissue macrophages (called histiocytes by morphologists)—hence the term *Langerhans cell histiocytosis.*

Langerhans cell histiocytoses manifest as three relatively distinctive clinicopathologic entities. *Multisystem Langerhans cell histiocytosis (Letterer-Siwe disease)* usually occurs in children younger than 2 years of age. It typically manifests with multifocal cutaneous lesions that grossly resemble seborrheic skin eruptions and are composed of Langerhans cells. Most affected patients have hepatosplenomegaly, lymphadenopathy, pulmonary lesions, and (later in the course) destructive osteolytic bone lesions. Extensive infiltration of the marrow often leads to pancytopenia and predisposes the patient to recurrent infections such as otitis media and mastoiditis. The disease is rapidly fatal if untreated. With intensive chemotherapy, 50% of patients survive 5 years.

*Unisystem Langerhans cell histiocytosis (eosinophilic granuloma)* may be unifocal or multifocal. It is characterized by expanding, erosive accumulations of Langerhans cells, usually within the medullary cavities of bones or less commonly in the skin, lungs, or stomach. The Langerhans cells are admixed with variable numbers of lymphocytes, plasma cells, neutrophils, and eosinophils, which are usually, but not always, prominent. Virtually any bone in the skeletal system may be involved; the calvaria, ribs, and femur are most commonly affected. Unifocal disease most often involves the skeletal system. It may be asymptomatic or cause pain, tenderness and pathologic fractures. It is an indolent disorder that may heal spontaneously or be cured by local excision or irradiation. Multifocal unisystem disease usually affects children and typically manifests with multiple erosive bony masses that sometimes extend into soft tissues. In about 50% of cases, involvement of the posterior pituitary stalk of the hypothalamus leads to diabetes insipidus. The combination of calvarial bone defects, diabetes insipidus, and exophthalmos is referred to as the *Hand-Schüller-Christian triad.* Many patients experience spontaneous regressions; others are treated effectively with chemotherapy.

*A clue to the pathogenesis of Langerhans cell tumors lies in the discovery that the different clinical forms are frequently associated with an acquired mutation in the serine/threonine kinase BRAF,* a valine to glutamate substitution in residue 600 that leads to hyperactivity of the kinase. This same mutation is found in a variety of other tumors, including hairy cell leukemia, benign nevi, malignant melanoma, papillary thyroid carcinoma, and some colon cancers (Chapter 5). BRAF is a component of the Ras signaling pathway that drives cellular proliferation and survival, effects that likely contribute to the growth of the neoplastic Langerhans cells.

# BLEEDING DISORDERS

Bleeding disorders are characterized clinically by abnormal bleeding, which can appear spontaneously or follow some inciting event (e.g., trauma or surgery). As described in Chapter 3, normal clotting involves the vessel wall, the platelets, and the clotting factors. It follows that abnormalities in any of these components can lead to clinically significant bleeding. A review of the laboratory tests used in the evaluation of patients with a suspected bleeding

disorder, along with the principles involved, is presented next, followed by consideration of specific disorders of coagulation.

The most important tests for investigation of suspected coagulopathies include

- *Prothrombin time* (PT). This test assesses the extrinsic and common coagulation pathways. It measures the time (in seconds) needed for plasma to clot after addition of tissue thromboplastin (e.g., brain extract) and $Ca^{2+}$ ions. A prolonged PT can result from a deficiency of factor V, VII, or X or prothrombin or fibrinogen, or by an acquired inhibitor (typically an antibody) that interferes with the extrinsic pathway.
- *Partial thromboplastin time* (PTT). This test assesses the intrinsic and common coagulation pathways. It measures the time (in seconds) needed for the plasma to clot after the addition of kaolin, cephalin, and $Ca^{2+}$. Kaolin activates the contact-dependent factor XII and cephalin substitutes for platelet phospholipids. Prolongation of PTT can be caused by a deficiency of factor V, VIII, IX, X, XI, or XII or prothrombin or fibrinogen, or by an acquired inhibitor that interferes with the intrinsic pathway.
- *Platelet count.* This is obtained on anticoagulated blood using an electronic particle counter. The reference range is 150,000 to 450,000/μL. Counts outside this range must be confirmed by a visual inspection of a peripheral blood smear.
- *Tests of platelet function.* At present no single test provides an adequate assessment of the complex functions of platelets. Platelet aggregation tests that measure the response of platelets to certain agonists and qualitative and quantitative tests of von Willebrand factor (which you will recall is required for platelet adherence to subvascular collagen) are both commonly used in clinical practice. An older test, the bleeding time, has some value but is time-consuming and difficult to standardize and is therefore performed only rarely. Newer instrument-based assays that provide quantitative measures of platelet function show promise but are not yet available for routine use in the clinic.

Additional, more specialized tests are available that measure the levels of specific clotting factors and fibrin split products, or assess the presence of circulating anticoagulants.

Bleeding disorders may stem from abnormalities of vessels, platelets, or coagulation factors, alone or in combination. Bleeding due to *vascular fragility* is seen with vitamin C deficiency (scurvy) (Chapter 7), systemic amyloidosis (Chapter 4), chronic glucocorticoid use, rare inherited conditions affecting the connective tissues, and a large number of infectious and hypersensitivity vasculitides. These vasculitides include meningococcemia, infective endocarditis, the rickettsial diseases, typhoid, and Henoch-Schönlein purpura. Some of these conditions are discussed in other chapters; others are beyond the scope of this book. Bleeding that results purely from vascular fragility is characterized by the "spontaneous" appearance of petechiae and ecchymoses in the skin and mucous membranes (probably resulting from minor trauma). In most instances laboratory tests of coagulation are normal. *Bleeding also can be triggered by systemic conditions that inflame or damage endothelial cells.* If severe enough, such insults convert the vascular lining to a prothrombotic surface that activates coagulation throughout the circulatory system, a condition known as disseminated intravascular coagulation (DIC) (discussed in the next section). Paradoxically, in DIC, platelets and coagulation factors often are used up faster than they can be replaced, resulting in deficiencies that may lead to severe bleeding (a condition referred to as *consumptive coagulopathy*).

*Deficiencies of platelets* (thrombocytopenia) are an important cause of bleeding. These occur in a variety of clinical settings that are discussed later. Other bleeding disorders stem from *qualitative defects in platelet function.* Such defects may be *acquired,* as in uremia and certain myeloproliferative disorders and after aspirin ingestion; or *inherited,* as in von Willebrand disease and other rare congenital disorders. The clinical signs of inadequate platelet function include easy bruising, nosebleeds, excessive bleeding from minor trauma, and menorrhagia.

*In bleeding disorders stemming from defects in one or more coagulation factors, the PT, PTT, or both are prolonged.* Unlike platelet defects, petechiae and mucosal bleeding are usually absent. Instead, hemorrhages tend to occur in parts of the body that are subject to trauma, such as the joints of the lower extremities. Massive hemorrhage may occur after surgery, dental procedures, or severe trauma. This category includes the hemophilias, an important group of inherited coagulation disorders.

*It is not uncommon for bleeding to occur as a consequence of a mixture of defects.* This is the case in DIC, in which both thrombocytopenia and coagulation factor deficiencies contribute to bleeding, and in von Willebrand disease, a fairly common inherited disorder in which both platelet function and (to a lesser degree) coagulation factor function are abnormal.

With the foregoing overview as background, we now turn to specific bleeding disorders.

## DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) occurs as a complication of a wide variety of disorders. *DIC is caused by the systemic activation of coagulation and results in the formation of thrombi throughout the microcirculation. As a consequence, platelets and coagulation factors are consumed and, secondarily, fibrinolysis is activated.* Thus, DIC can give rise to either tissue hypoxia and microinfarcts caused by myriad microthrombi or to a bleeding disorder related to pathologic activation of fibrinolysis and the depletion of the elements required for hemostasis (hence the term *consumptive coagulopathy*). This entity probably causes bleeding more commonly than all of the congenital coagulation disorders combined.

### PATHOGENESIS

Before discussing the specific disorders associated with DIC, we will consider in a general way the pathogenic mechanisms

by which intravascular clotting occurs. Reference to earlier comments on normal blood coagulation (Chapter 3) may be helpful at this point. It suffices here to recall that clotting can be initiated by either the extrinsic pathway, which is triggered by the release of tissue factor (tissue thromboplastin); or the intrinsic pathway, which involves the activation of factor XII by surface contact, collagen, or other negatively charged substances. Both pathways lead to the generation of thrombin. Clotting normally is limited by the rapid clearance of activated clotting factors by the macrophages and the liver, endogenous anticoagulants (e.g., protein C), and the concomitant activation of fibrinolysis.

DIC usually is triggered by either (1) the release of tissue factor or thromboplastic substances into the circulation or (2) widespread endothelial cell damage (Fig. 11–28). Thromboplastic substances can be released into the circulation from a variety of sources—for example, the placenta in obstetric complications or certain types of cancer cells, particularly those of acute promyelocytic leukemia and adenocarcinomas. Cancer cells can also provoke coagulation in other ways, such as by releasing proteolytic enzymes and by expressing tissue factor. In gram-negative and gram-positive sepsis (important causes of DIC), endotoxins or exotoxins stimulate the release of tissue factor from monocytes. Activated monocytes also release IL-1 and tumor necrosis factor, both of which stimulate the expression of tissue factor on endothelial cells and simultaneously decrease the expression of thrombomodulin. The latter, you may recall, activates protein C, an anticoagulant (Chapter 3). The net result of these alterations is the enhanced generation of thrombin and the blunting of inhibitory pathways that limit coagulation.

Severe endothelial cell injury can initiate DIC by causing the release of tissue factor and by exposing subendothelial collagen and von Willebrand factor (vWF). However, even subtle forms of endothelial damage can unleash procoagulant activity by stimulating the increased expression of tissue factor on endothelial cell surfaces. Widespread endothelial injury can be produced by the deposition of antigen-antibody complexes (e.g., in systemic lupus erythematosus), by temperature extremes (e.g., after heat stroke or burn injury), or by infections (e.g., due to meningococci or rickettsiae). As discussed in Chapter 3, endothelial injury is an important consequence of endotoxemia, and, not surprisingly, DIC is a frequent complication of gram-negative sepsis.

Disorders associated with DIC are listed in Table 11–12. Of these, DIC is most often associated with sepsis, obstetric complications, malignancy, and major trauma (especially trauma to the brain). The initiating events in these conditions are multiple and often interrelated. For example, in obstetric conditions, tissue factor derived from the placenta, retained dead fetus, or amniotic fluid enters the circulation; however, shock, hypoxia, and acidosis often coexist and can lead to widespread endothelial injury. Trauma to the brain releases fat and phospholipids, which act as contact factors and thereby activate the intrinsic arm of the coagulation cascade.

Whatever the pathogenetic mechanism, DIC has two consequences. First, there is **widespread fibrin deposition within the microcirculation.** The associated obstruction leads to ischemia in the more severely affected or vulnerable organs and hemolysis as red cells are traumatized while passing through vessels narrowed by fibrin thrombi **(microangiopathic hemolytic anemia).** Second, a **bleeding diathesis** results from the depletion of platelets and clotting factors and the secondary release of plasminogen activators. Plasmin cleaves not only fibrin (fibrinolysis) but also factors V and VIII, thereby reducing their concentration further. In addition, fibrinolysis creates fibrin degradation products. These inhibit platelet aggregation, have antithrombin activity, and impair fibrin polymerization, all of which contribute to the hemostatic failure (Fig. 11–28).

### MORPHOLOGY

In DIC **microthrombi** are most often found in the arterioles and capillaries of the kidneys, adrenals, brain, and heart, but no organ is spared. The glomeruli contain small fibrin thrombi. These may be associated with only a subtle, reactive swelling of the endothelial cells or varying degrees of focal glomerulitis. The microvascular occlusions give rise to small infarcts in the renal cortex. In severe cases the ischemia can destroy the entire cortex and cause bilateral renal cortical necrosis. Involvement of the adrenal glands can produce the **Waterhouse-Friderichsen syndrome** (Chapter 19). Microinfarcts also are commonly encountered in the brain and are often surrounded by microscopic or gross foci of hemorrhage. These can give rise to bizarre neurologic signs. Similar changes are seen in the heart and often in the anterior pituitary. DIC may contribute to the development of **Sheehan postpartum pituitary necrosis** (Chapter 19). Eclampsia (toxemia of pregnancy) is a hypercoagulable state that may be associated with thromboses in the placenta, liver, kidneys, brain, and pituitary (Chapter 18). The bleeding tendency associated with DIC is manifested not only by larger-than-expected hemorrhages near foci of infarction but also by diffuse petechiae and ecchymoses on the skin, serosal linings of the body cavities, epicardium, endocardium, lungs, and mucosal lining of the urinary tract.

### Clinical Course

As might be imagined, depending on the balance between clotting and bleeding tendencies, the range of possible clinical manifestations is enormous. In general, *acute DIC (e.g., that associated with obstetric complications) is dominated by a bleeding diathesis, whereas chronic DIC (e.g., as occurs in those with cancer) tends to manifest with signs and symptoms related to thrombosis.* The abnormal clotting usually is confined to the microcirculation, but large vessels are involved on occasion. The manifestations may be minimal, or there may be shock, with acute renal failure, dyspnea, cyanosis, convulsions, and coma. Most often, attention is called to the presence of DIC by prolonged and copious postpartum bleeding or by the presence of petechiae and ecchymoses on the skin. These may be the only manifestations, or there may be severe hemorrhage into the gut or urinary tract. Laboratory evaluation reveals *thrombocytopenia and prolongation of the PT and the PTT* (from depletion of platelets, clotting factors, and fibrinogen). Fibrin split products are increased in the plasma.

The prognosis varies widely depending on the nature of the underlying disorder and the severity of the intravascular clotting and fibrinolysis. Acute DIC can be life-threatening and must be treated aggressively with anticoagulants such as heparin or the coagulants contained in fresh frozen plasma. Conversely, chronic DIC is sometimes identified unexpectedly by laboratory testing. In either circumstance, definitive treatment must be directed at the underlying cause.

## THROMBOCYTOPENIA

*Isolated thrombocytopenia is associated with a bleeding tendency and normal coagulation tests.* A count less than 150,000 platelets/μL generally is considered to constitute thrombocytopenia. However, only when platelet counts fall to 20,000 to 50,000 platelets/μL is there an increased risk of post-traumatic bleeding, and spontaneous bleeding becomes evident when counts fall below 20,000 platelets/μL. Most bleeding occurs from small, superficial blood vessels and produces petechiae or large ecchymoses in the skin, the mucous membranes of the gastrointestinal and urinary tracts, and other sites. Larger hemorrhages into the central nervous system are a major hazard in those with markedly depressed platelet counts.

The major causes of thrombocytopenia are listed in Table 11–13. Clinically important thrombocytopenia is confined to disorders with reduced production or increased destruction of platelets. When the cause is accelerated destruction of platelets, the bone marrow usually reveals a compensatory increase in the number of megakaryocytes. Hence, bone marrow examination can help to distinguish between the two major categories of thrombocytopenia. Also of note, *thrombocytopenia is one of the most common hematologic manifestations of AIDS.* It can occur early in the course of HIV infection and has a multifactorial basis, including immune complex–mediated platelet destruction, antiplatelet autoantibodies, and HIV-mediated suppression of megakaryocyte development and survival.

### Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) has two clinical subtypes. *Chronic ITP* is a relatively common disorder that tends to affect women between the ages of 20 and 40 years. *Acute ITP* is a self-limited form seen mostly in children after viral infections.

*Antibodies directed against platelet membrane glycoproteins IIb/IIIa or Ib/IX complexes can be detected in roughly 80% of*

**Table 11–13** Causes of Thrombocytopenia

| |
|---|
| **Decreased Production of Platelets** |
| Generalized Bone Marrow Dysfunction |
| Aplastic anemia: congenital and acquired<br>Marrow infiltration: leukemia, disseminated cancer |
| Selective Impairment of Platelet Production |
| Drug-induced: alcohol, thiazides, cytotoxic drugs<br>Infections: measles, HIV infection |
| Ineffective Megakaryopoiesis |
| Megaloblastic anemia<br>Paroxysmal nocturnal hemoglobinuria |
| **Decreased Platelet Survival** |
| Immunologic Destruction |
| Autoimmune: immune thrombocytopenic purpura, systemic lupus erythematosus<br>Isoimmune: post-transfusion and neonatal<br>Drug-associated: quinidine, heparin, sulfa compounds<br>Infections: infectious mononucleosis, HIV infection, cytomegalovirus infection |
| Nonimmunologic Destruction |
| Disseminated intravascular coagulation<br>Thrombotic thrombocytopenic purpura<br>Giant hemangiomas<br>Microangiopathic hemolytic anemias |
| **Sequestration** |
| Hypersplenism |
| **Dilutional** |
| Multiple transfusions (e.g., for massive blood loss) |

HIV, human immunodeficiency virus.

*cases of chronic ITP.* The spleen is an important site of antiplatelet antibody production and the major site of destruction of the IgG-coated platelets. Although splenomegaly is not a feature of uncomplicated chronic ITP, the importance of the spleen in the premature destruction of platelets is proved by the benefits of splenectomy, which normalizes the platelet count and induces a complete remission in more than two thirds of patients. The bone marrow usually contains increased numbers of megakaryocytes, a finding common to all forms of thrombocytopenia caused by accelerated platelet destruction.

The onset of chronic ITP is insidious. Common findings include petechiae, easy bruising, epistaxis, gum bleeding, and hemorrhages after minor trauma. Fortunately, more serious intracerebral or subarachnoid hemorrhages are uncommon. The diagnosis rests on the clinical features, the presence of thrombocytopenia, examination of the marrow, and the exclusion of secondary ITP. Reliable clinical tests for antiplatelet antibodies are not available.

## Heparin-Induced Thrombocytopenia

This special type of drug-induced thrombocytopenia (discussed in more detail in Chapter 3) merits brief mention because of its clinical importance. Moderate to severe thrombocytopenia develops in 3% to 5% of patients after 1 to 2 weeks of treatment with unfractionated heparin. The disorder is caused by IgG antibodies that bind to platelet factor 4 on platelet membranes in a heparin-dependent fashion. Resultant activation of the platelets induces their aggregation, thereby exacerbating the condition that heparin is used to treat—thrombosis. Both venous and arterial thromboses occur, even in the setting of marked thrombocytopenia, and can cause severe morbidity (e.g., loss of limbs) and death. Cessation of heparin therapy breaks the cycle of platelet activation and consumption. The risk of this complication is lowered (but not prevented entirely) by use of low-molecular-weight heparin preparations.

## Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

The term *thrombotic microangiopathies* encompasses a spectrum of clinical syndromes that include thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS). As originally defined, TTP is associated with the pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, transient neurologic deficits, and renal failure. HUS also is associated with microangiopathic hemolytic anemia and thrombocytopenia but is distinguished from TTP by the absence of neurologic symptoms, the dominance of acute renal failure, and frequent occurrence in children (Chapter 13). Clinical experience has blurred these distinctions, as many adults with TTP lack one or more of the five criteria, and some patients with HUS have fever and neurologic dysfunction. *Fundamental to both conditions is the widespread formation of platelet-rich thrombi in the microcirculation.* The consumption of platelets leads to thrombocytopenia, and the narrowing of blood vessels by the platelet-rich thrombi results in a microangiopathic hemolytic anemia.

### PATHOGENESIS

For many years the pathogenesis of TTP was enigmatic, although treatment with plasma exchange (initiated in the early 1970s) converted a disease that was almost uniformly fatal to one that is now successfully treated in more than 80% of affected persons. The underlying cause of most cases of TTP has now been elucidated. In brief, **symptomatic patients are deficient in the metalloprotease ADAMTS 13.** This enzyme degrades very-high-molecular-weight multimers of von Willebrand factor (vWF); hence, a deficiency of ADAMTS 13 allows abnormally large vWF multimers to accumulate in plasma. Under some circumstances, these colossal vWF multimers promote the formation of platelet microaggregates throughout the circulation. The superimposition of an endothelial cell injury (caused by some other condition) can further promote microaggregate formation, thus initiating or exacerbating clinically evident TTP.

ADAMTS 13 deficiency can be inherited or acquired, the latter by way of autoantibodies that bind and inhibit the metalloprotease. TTP must be considered in any patient with unexplained thrombocytopenia and microangiopathic hemolytic anemia, as any delay in diagnosis can be fatal.

Although clinically similar to TTP, HUS has a different pathogenesis. Most cases in children and elderly persons are triggered by infectious gastroenteritis caused by *E. coli* strain O157:H7. This organism elaborates a Shiga-like toxin that damages endothelial cells, which initiates platelet activation and aggregation. Affected persons often present with bloody diarrhea, followed a few days later by acute renal failure and microangiopathic anemia. Recovery is possible with supportive care and plasma exchange, but irreversible renal damage and death can occur in more severe cases. About 10% of cases of HUS are caused by inherited mutations or autoantibodies that lead to deficiency of factor H, factor I, or CD46, each of which is a negative regulator of the alternative complement cascade. The absence of these factors leads to uncontrolled complement activation after minor endothelial injury, resulting in thrombosis. HUS also can be seen after other exposures (e.g., to certain drugs or radiation) that damage endothelial cells. Here the prognosis is more guarded, as the underlying conditions that trigger these forms of HUS are often chronic or life-threatening.

Although DIC and the thrombotic microangiopathies share features such as microvascular occlusion and microangiopathic hemolytic anemia, they are pathogenically distinct. Unlike in DIC, in TTP and HUS activation of the coagulation cascade is not of primary importance, so results of laboratory tests of coagulation (such as the PT and the PTT) usually are normal.

## COAGULATION DISORDERS

Coagulation disorders result from either congenital or acquired deficiencies of clotting factors. *Acquired deficiencies are most common* and often involve several factors simultaneously. As discussed in Chapter 7, *vitamin K* is required for the synthesis of prothrombin and clotting factors VII, IX, and X, and its deficiency causes a severe coagulation defect. The liver synthesizes several coagulation factors and also removes many activated coagulation factors from the circulation; thus, *hepatic parenchymal diseases are common causes* of complex hemorrhagic diatheses. As already discussed, DIC also may lead to multiple concomitant factor deficiencies. Rarely, autoantibodies may cause acquired deficiencies limited to a single factor.

*Hereditary deficiencies* of each of the coagulation factors have been identified. Hemophilia A (a deficiency of factor VIII) and hemophilia B (Christmas disease, a deficiency of factor IX) are X-linked traits, whereas most deficiencies are autosomal recessive disorders. Of the inherited deficiencies, only von Willebrand disease, hemophilia A, and hemophilia B are sufficiently common to warrant further consideration.

### Deficiencies of Factor VIII–von Willebrand Factor Complex

Hemophilia A and von Willebrand disease are caused by qualitative or quantitative defects involving the factor VIII–von Willebrand factor (vWF) complex. As background for subsequent discussion of these disorders, it is useful to review the structure and function of these two proteins (Fig. 11–29).

As described earlier, factor VIII is an essential cofactor for factor IX, which activates factor X in the intrinsic coagulation pathway. *Circulating factor VIII binds noncovalently to vWF,* which exists as multimers of up to 20 MDa in weight. These two proteins are encoded by separate genes and are synthesized by different cells. Endothelial cells are the major source of plasma vWF, whereas most factor VIII is synthesized in the liver. vWF is found in the plasma (in association with factor VIII), in platelet granules, in endothelial cells within cytoplasmic vesicles called Weibel-Palade bodies, and in the subendothelium, where it binds to collagen.

When endothelial cells are stripped away by trauma or injury, subendothelial vWF is exposed and binds to platelets, mainly through glycoprotein Ib and to a lesser degree through glycoprotein IIb/IIIa (Fig. 11–29). *The most*

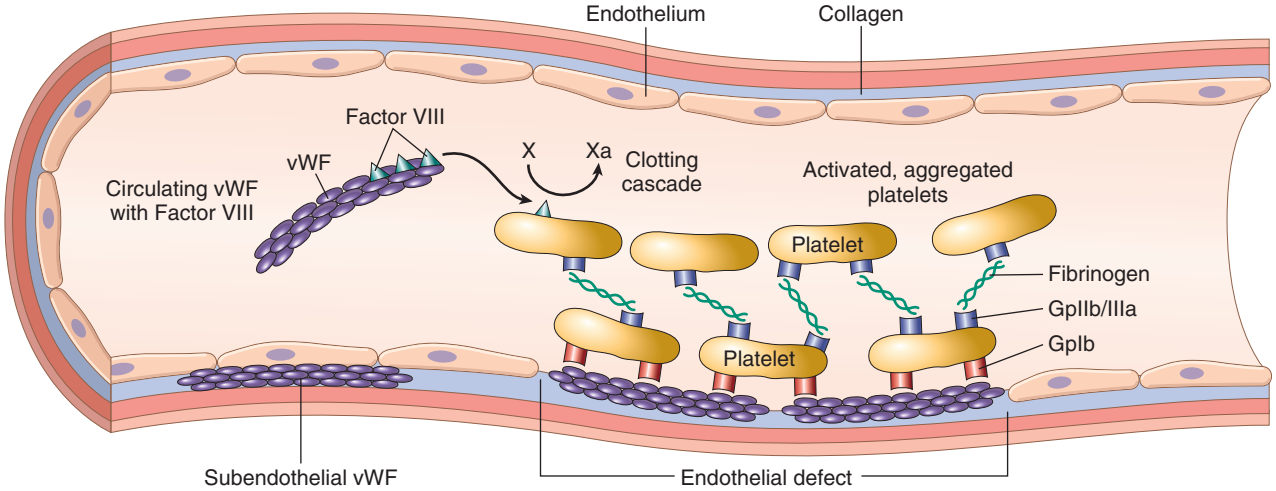

**Figure 11–29** Structure and function of factor VIII–von Willebrand factor (vWF) complex. Factor VIII and vWF circulate as a complex. vWF also is present in the subendothelial matrix of normal blood vessels. Factor VIII takes part in the coagulation cascade by activating factor X by means of factor IX (*not shown*). vWF causes adhesion of platelets to subendothelial collagen, primarily through the glycoprotein Ib (GpIb) platelet receptor.

*important function of vWF is to facilitate the adhesion of platelets to damaged blood vessel walls,* a crucial early event in the formation of a hemostatic plug. Inadequate platelet adhesion is believed to underlie the bleeding tendency in von Willebrand disease. In addition to its role in platelet adhesion, vWF also stabilizes factor VIII; thus, vWF deficiency leads to a secondary deficiency of factor VIII.

The various forms of von Willebrand disease are diagnosed by measuring the quantity, size, and function of vWF. vWF function is assessed using the ristocetin platelet agglutination test. Ristocetin somehow "activates" the bivalent binding of vWF and platelet membrane glycoprotein Ib, creating interplatelet "bridges" that cause platelets to clump (agglutination), an event that can be measured easily. Thus, ristocetin-dependent platelet agglutination serves as a useful bioassay for vWF.

With this background we now turn to the discussion of diseases resulting from deficiencies of factor VIII–vWF complex.

### *von Willebrand Disease*

von Willebrand disease is transmitted as an autosomal dominant disorder. It usually presents as *spontaneous bleeding from mucous membranes, excessive bleeding from wounds, and menorrhagia.* It is underrecognized, as the diagnosis requires sophisticated tests and the clinical manifestations often are quite mild. Actually, this disease is surprisingly prevalent, particularly in persons of European descent. *It is estimated that approximately 1% of people in the United States have von Willebrand disease, making it the most common inherited bleeding disorder.*

People with von Willebrand disease have compound defects in platelet function and coagulation, but in most cases only the platelet defect produces clinical findings. The exceptions are rare patients with homozygous von Willebrand disease, in whom there is a concomitant deficiency of factor VIII severe enough to produce features resembling those of hemophilia (described later on).

*The classic and most common variant of von Willebrand disease (type I) is an autosomal dominant disorder in which the quantity of circulating vWF is reduced.* There is also a measurable but clinically insignificant decrease in factor VIII levels. The other, less common varieties of von Willebrand disease are caused by mutations that produce both qualitative and quantitative defects in vWF. *Type II* is divided into several subtypes *characterized by the selective loss of high-molecular-weight multimers of vWF.* Because these large multimers are the most active form, there is a functional deficiency of vWF. In type IIA, the high-molecular-weight multimers are not synthesized, leading to a true deficiency. In type IIB, abnormal "hyperfunctional" high-molecular-weight multimers are synthesized that are rapidly removed from the circulation. These high-molecular-weight multimers cause spontaneous platelet aggregation (a situation reminiscent of the very-high-molecular-weight multimer aggregates seen in TTP); indeed, some people with type IIB von Willebrand disease have mild chronic thrombocytopenia, presumably due to platelet consumption.

### *Hemophilia A—Factor VIII Deficiency*

*Hemophilia A is the most common hereditary cause of serious bleeding.* It is an X-linked recessive disorder caused by reduced factor VIII activity. It primarily affects males. Much less commonly excessive bleeding occurs in heterozygous females, presumably due to preferential inactivation of the X chromosome carrying the normal factor VIII gene (unfavorable lyonization). *Approximately 30% of cases are caused by new mutations*; in the remainder, there is a positive family history. Severe hemophilia A is observed in people with marked deficiencies of factor VIII (activity levels less than 1% of normal). Milder deficiencies may only become apparent when other predisposing conditions, such as trauma, are also present. The varying degrees of factor VIII deficiency are explained by the existence of many different causative mutations. As in the thalassemias, several types of genetic lesions (e.g., deletions, inversions, splice junction mutations) have been identified. In about 10% of patients, the factor VIII concentration is normal by immunoassay, but the coagulant activity is low because of a mutation in factor VIII that causes a loss of function.

In symptomatic cases there is a tendency toward *easy bruising and massive hemorrhage after trauma or operative procedures.* In addition, "spontaneous" hemorrhages frequently are encountered in tissues that normally are subject to mechanical stress, particularly the joints, where recurrent bleeds (*hemarthroses*) lead to progressive deformities that can be crippling. *Petechiae are characteristically absent.* Specific assays for factor VIII are used to confirm the diagnosis of hemophilia A. Typically, patients with hemophilia A have a prolonged PTT that is corrected by mixing the patient's plasma with normal plasma. Specific factor assays are then used to confirm the deficiency of factor VIII. In approximately 15% of those with severe hemophilia A replacement therapy is complicated by the development of neutralizing antibodies against factor VIII, probably because factor VIII is seen by the immune system as a "foreign" antigen. In these persons, the PTT fails to correct in mixing studies.

Hemophilia A is treated with factor VIII infusions. Historically, factor VIII was prepared from human plasma, carrying with it the risk of transmission of viral diseases. As mentioned in Chapter 4, before 1985 thousands of hemophiliacs received factor VIII preparations contaminated with HIV. Subsequently, many became seropositive and developed AIDS. The availability and widespread use of recombinant factor VIII and more highly purified factor VIII concentrates have now eliminated the infectious risk of factor VIII replacement therapy.

### *Hemophilia B—Factor IX Deficiency*

Severe factor IX deficiency is an X-linked disorder that is indistinguishable clinically from hemophilia A but much less common. The PTT is prolonged. The diagnosis is made using specific assays of factor IX. It is treated by infusion of recombinant factor IX.

## SUMMARY

### Bleeding Disorders

**Disseminated Intravascular Coagulation**
- Syndrome in which systemic activation of the coagulation leads to consumption of coagulation factors and platelets
- Can be dominated by bleeding, vascular occlusion and tissue hypoxemia, or both
- Common triggers: sepsis, major trauma, certain cancers, obstetric complications

**Immune Thrombocytopenic Purpura**
- Caused by autoantibodies against platelet antigens
- May be triggered by drugs, infections, or lymphomas, or may be idiopathic

**Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome**
- Both manifest with thrombocytopenia, microangiopathic hemolytic anemia, and renal failure; fever and CNS involvement are more typical of TTP.
- *TTP*: Caused by acquired or inherited deficiencies of ADAMTS 13, a plasma metalloprotease that cleaves very-high-molecular-weight multimers of von Willebrand factor (vWF). Deficiency of ADAMTS 13 results in abnormally large vWF multimers that activate platelets.
- *Hemolytic uremic syndrome*: caused by deficiencies of complement regulatory proteins or agents that damage endothelial cells, such as a Shiga-like toxin elaborated by *E. coli* strain O157:H7. The endothelial injury initiates platelet activation, platelet aggregation, and microvascular thrombosis.

**von Willebrand Disease**
- Autosomal dominant disorder caused by mutations in vWF, a large protein that promotes the adhesion of platelets to subendothelial collagen
- Typically causes a mild to moderate bleeding disorder resembling that associated with thrombocytopenia

**Hemophilia**
- *Hemophilia A*: X-linked disorder caused by mutations in factor VIII. Affected males typically present with severe bleeding into soft tissues and joints and have a PTT.
- *Hemophilia B*: X-linked disorder caused by mutations in coagulation factor IX. It is clinically identical to hemophilia A.

# DISORDERS THAT AFFECT THE SPLEEN AND THYMUS

## SPLENOMEGALY

The spleen is frequently involved in a wide variety of systemic diseases. In virtually all instances, the spleen responds by enlarging (splenomegaly), an alteration that produces a set of stereotypical signs and symptoms. Evaluation of splenic enlargement is aided by recognition of the usual limits of splenomegaly produced by specific disorders. It would be erroneous to attribute an enlarged spleen pushing into the pelvis to vitamin $B_{12}$ deficiency, or to entertain a diagnosis of CML in the absence of splenomegaly. In the following list, disorders are grouped according to the degree of splenomegaly that they characteristically produce:

A. *Massive splenomegaly* (weight more than 1000 g)
- Myeloproliferative disorders (chronic myelogenous leukemia, primary myelofibrosis)
- Chronic lymphocytic leukemia and hairy cell leukemia
- Lymphomas
- Malaria
- Gaucher disease
- Primary tumors of the spleen (rare)

B. *Moderate splenomegaly* (weight 500 to 1000 g)
- Chronic congestive splenomegaly (portal hypertension or splenic vein obstruction)
- Acute leukemias (variable)
- Hereditary spherocytosis
- Thalassemia major
- Autoimmune hemolytic anemia
- Amyloidosis
- Niemann-Pick disease
- Chronic splenitis (especially with infective endocarditis)
- Tuberculosis, sarcoidosis, typhoid
- Metastatic carcinoma or sarcoma

C. *Mild splenomegaly* (weight less than 500 g)
- Acute splenitis
- Acute splenic congestion
- Infectious mononucleosis
- Miscellaneous disorders, including septicemia, systemic lupus erythematosus, and intra-abdominal infections

The microscopic changes associated with these diseases are discussed in the relevant sections of this and other chapters.

A chronically enlarged spleen often removes excessive numbers of one or more of the formed elements of blood, resulting in anemia, leukopenia, or thrombocytopenia. This is referred to as *hypersplenism,* a state that can be associated with many of the diseases listed previously. In addition, platelets are particularly susceptible to sequestration in the interstices of the red pulp; as a result, thrombocytopenia is more prevalent and severe in persons with splenomegaly than is anemia or neutropenia.

## DISORDERS OF THE THYMUS

As is well known, the thymus has a crucial role in T cell differentiation. It is not surprising, therefore, that the thymus can be involved by lymphomas, particularly those of T cell lineage (discussed earlier in this chapter). The

focus here is on the two most frequent (albeit still uncommon) disorders of the thymus: thymic hyperplasia and thymoma.

## Thymic Hyperplasia

Thymic enlargement often is associated with the presence of lymphoid follicles, or germinal centers, within the medulla. These germinal centers contain reactive B cells, which are only present in small numbers in normal thymuses. Thymic follicular hyperplasia is found in most patients with myasthenia gravis and sometimes also occurs in other autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis. The relationship between the thymus and myasthenia gravis is discussed in Chapter 21. Of significance, removal of the hyperplastic thymus is often beneficial early in the disease.

## Thymoma

Thymomas are tumors of thymic epithelial cells. Several classification systems for thymoma based on cytologic and biologic criteria have been proposed. One simple and clinically useful classification is as follows:

- Benign or encapsulated thymoma: cytologically and biologically benign
- Malignant thymoma
  - *Type I*: cytologically benign but infiltrative and locally aggressive
  - *Type II* (thymic carcinoma): cytologically and biologically malignant

### MORPHOLOGY

Macroscopically, thymomas are lobulated, firm, gray-white masses up to 15 to 20 cm in dimension. Most appear encapsulated, but in 20% to 25%, penetration of the capsule and infiltration of perithymic tissues and structures are seen. Microscopically, virtually all thymomas are made up of a mixture of epithelial tumor cells and non-neoplastic thymocytes (immature T cells). In **benign thymomas,** the epithelial cells are spindled or elongated and resemble those that normally populate the medulla. As a result, these are sometimes referred to as **medullary thymomas.** In other tumors, there is an admixture of the plumper, rounder, cortical-type epithelial cells; this pattern is sometimes referred to as a mixed thymoma. The medullary and mixed patterns account for 60% to 70% of all thymomas.

**Malignant thymoma type I** is cytologically bland but locally invasive; it accounts for 20% to 25% of all thymomas. These tumors also occasionally (and unpredictably) metastasize. They are composed of varying proportions of epithelial cells and reactive thymocytes. The epithelial cells usually have abundant cytoplasm and rounded vesicular nuclei, an appearance similar to normal thymic cortical epithelial cells; spindled epithelial cells are sometimes present as well. The epithelial cells often palisade around blood vessels. **The critical distinguishing feature is the penetration of the capsule with the invasion of surrounding structures.**

Malignant thymoma type II is perhaps better thought of as a form of **thymic carcinoma.** These tumors account for about 5% of thymomas. Macroscopically, they usually are fleshy, obviously invasive masses that often metastasize to such sites as the lungs. Microscopically, most resemble **squamous cell carcinoma.** The next most common type is **lymphoepithelioma-like carcinoma,** a tumor composed of anaplastic cortical-type epithelial cells mixed with large numbers of thymocytes. Tumors of this type are more common in Asian populations and sometimes contain the EBV genome.

### Clinical Features

Thymomas are rare. They may arise at any age, but most occur in middle-aged adults. In a large series about 30% were asymptomatic; 30% to 40% produced local manifestations such as cough, dyspnea, and superior vena cava syndrome; and the remainder were associated with a systemic disease, most commonly myasthenia gravis, in which a concomitant thymoma was discovered in 15% to 20% of patients. Removal of the tumor often leads to improvement of the neuromuscular disorder. Additional associations with thymoma include hypogammaglobulinemia, systemic lupus erythematosus, pure red cell aplasia, and nonthymic cancers.

Laryngeal Tumors 513

The major function of the lung is to replenish oxygen and excrete carbon dioxide from blood. Developmentally, the respiratory system is an outgrowth from the ventral wall of the foregut. The midline trachea develops two lateral outpocketings, the lung buds. The right lung bud eventually divides into three main bronchi, and the left into two main bronchi, thus giving rise to three lobes on the right and two on the left. The main bronchi branch dichotomously, giving rise to progressively smaller airways, termed *bronchioles,* which are distinguished from bronchi by the lack of cartilage and submucosal glands within their walls. Additional branching of bronchioles leads to *terminal bronchioles*; the part of the lung distal to the terminal bronchiole is called an *acinus.* Pulmonary acini are composed of *respiratory bronchioles* (emanating from the terminal bronchiole) that proceed into *alveolar ducts,* which immediately branch into *alveolar sacs,* the blind ends of the respiratory passages, whose walls are formed entirely of *alveoli,* the ultimate site of gas exchange. The microscopic structure of the alveolar walls (or alveolar septa) consists of the following components, proceeding from blood to air (Fig. 12–1):

- The capillary endothelium and basement membrane.
- The pulmonary interstitium is composed of fine elastic fibers, small bundles of collagen, a few fibroblast-like cells, smooth muscle cells, mast cells, and rare mononuclear cells. It is most prominent in thicker portions of the alveolar septum.
- Alveolar epithelium contains a continuous layer of two principal cell types: flattened, platelike type I pneumocytes covering 95% of the alveolar surface and rounded type II pneumocytes. The latter synthesize pulmonary surfactant and are the main cell type involved in repair of alveolar epithelium after damage to type I pneumocytes. The alveolar walls are not solid but are perforated by numerous pores of Kohn, which permit passage of air, bacteria, and exudates between adjacent alveoli.
- A few alveolar macrophages usually lie free within the alveolar space. In the adult, these macrophages often contain phagocytosed carbon particles.

There are multiple primary lung diseases that can broadly be divided into those primarily affecting (1) the airways,

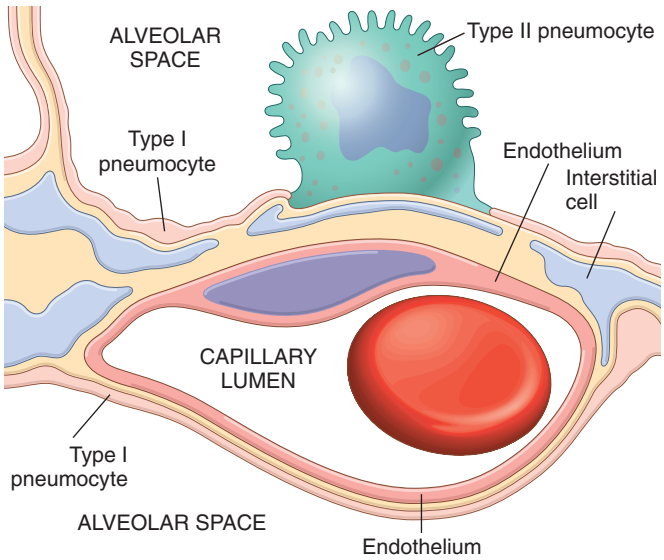

**Figure 12–1** Microscopic structure of the alveolar wall. Note that the basement membrane *(yellow)* is thin on one side and widened where it is continuous with the interstitial space. Portions of interstitial cells are shown.

(2) the interstitium, and (3) the pulmonary vascular system. This division into discrete compartments is, of course, deceptively neat. In reality, disease in one compartment often causes secondary alterations of morphology and function in other areas.

## ATELECTASIS (COLLAPSE)

Atelectasis, also known as collapse, is loss of lung volume caused by *inadequate expansion of air spaces.* It results in shunting of inadequately oxygenated blood from pulmonary arteries into veins, thus giving rise to a ventilation-perfusion imbalance and hypoxia. On the basis of the underlying mechanism or the distribution of alveolar collapse, atelectasis is classified into three forms (Fig. 12–2).

- *Resorption atelectasis.* Resorption atelectasis occurs when an obstruction prevents air from reaching distal airways. The air already present gradually becomes absorbed, and alveolar collapse follows. Depending on the level of airway obstruction, an entire lung, a complete lobe, or one or more segments may be involved. The most common cause of resorption collapse is obstruction of a bronchus by a mucous or mucopurulent plug. This frequently occurs postoperatively but also may complicate bronchial asthma, bronchiectasis, chronic bronchitis, tumor, or foreign body aspiration, particularly in children.
- *Compression atelectasis.* Compression atelectasis (sometimes called *passive* or *relaxation atelectasis*) is usually associated with accumulation of fluid, blood, or air within the pleural cavity, which mechanically collapses the adjacent lung. This is a frequent occurrence with pleural effusion, caused most commonly by congestive heart failure (CHF). Leakage of air into the pleural cavity (pneumothorax) also leads to compression atelectasis. Basal atelectasis resulting from the elevated position of the diaphragm commonly occurs in bedridden patients, in patients with ascites, and during and after surgery.
- *Contraction atelectasis.* Contraction (or *cicatrization*) atelectasis occurs when either local or generalized fibrotic changes in the lung or pleura hamper expansion and increase elastic recoil during expiration.

Atelectasis (except when caused by contraction) is potentially reversible and should be treated promptly to prevent hypoxemia and superimposed infection of the collapsed lung.

## ACUTE LUNG INJURY

The term *acute lung injury* encompasses a spectrum of bilateral pulmonary damage (endothelial and epithelial), which can be initiated by numerous conditions. Clinically, acute lung injury manifests as (1) acute onset of dyspnea, (2) decreased arterial oxygen pressure (hypoxemia), and (3) development of bilateral pulmonary infiltrates on the chest radiograph, all in the absence of clinical evidence of primary left-sided heart failure. Since the pulmonary infiltrates in acute lung injury are usually caused by damage to the alveolar capillary membrane, rather than by left-sided heart failure (Chapter 10), such accumulations constitute

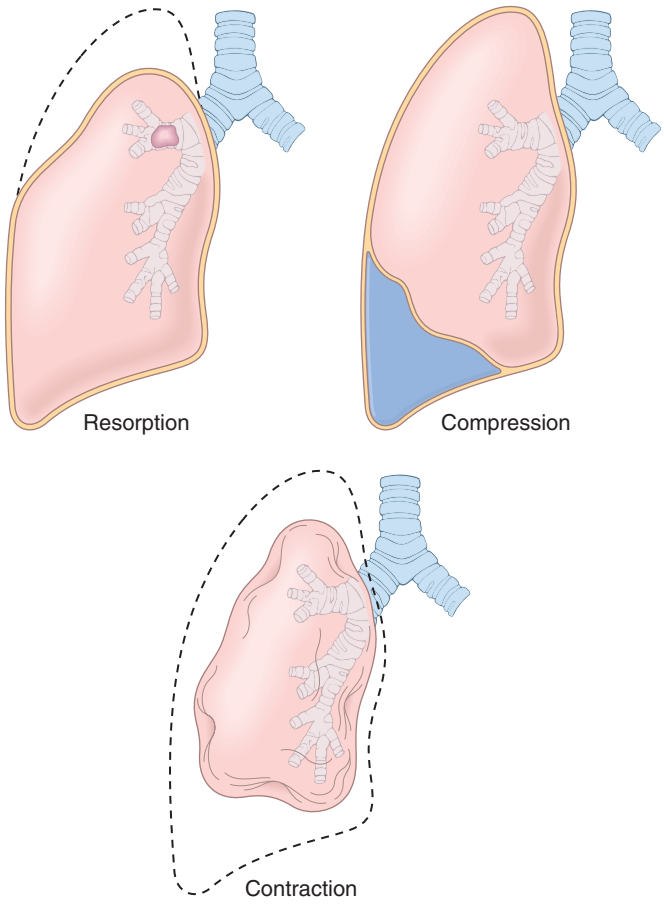

**Figure 12–2** Various forms of acquired atelectasis.

**Table 12–1** Clinical Disorders Associated with the Development of Acute Lung Injury/Acute Respiratory Distress Syndrome

| Direct Lung Injury | Indirect Lung Injury |
|---|---|
| **Common Causes** | |
| Pneumonia | Sepsis |
| Aspiration of gastric contents | Severe trauma with shock |
| **Uncommon Causes** | |
| Pulmonary contusion | Cardiopulmonary bypass |
| Fat embolism | Acute pancreatitis |
| Near-drowning | Drug overdose |
| Inhalational injury | Transfusion of blood products |
| Reperfusion injury after lung transplantation | Uremia |

an example of *noncardiogenic pulmonary edema.* Acute lung injury can progress to the more severe *acute respiratory distress syndrome,* described next.

## Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a clinical syndrome caused by diffuse alveolar capillary and epithelial damage. The usual course is characterized by rapid onset of life-threatening respiratory insufficiency, cyanosis, and severe arterial hypoxemia that is refractory to oxygen therapy and may progress to multisystem organ failure. The histologic manifestation of ARDS in the lungs is known as *diffuse alveolar damage* (DAD). ARDS can occur in a multitude of clinical settings and is associated with either direct injury to the lung or indirect injury in the setting of a systemic process (Table 12–1). It should be recalled that respiratory distress syndrome of the newborn is pathogenetically distinct; it is caused by a primary deficiency of surfactant.

### PATHOGENESIS

The alveolar-capillary membrane is formed by two separate barriers: the microvascular endothelium and the alveolar epithelium. **In ARDS, the integrity of this barrier is compromised by either endothelial or epithelial injury, or, more commonly, both.** The acute consequences of damage to the alveolar capillary membrane include increased vascular permeability and alveolar flooding, loss of diffusion capacity, and widespread surfactant abnormalities caused by damage to type II pneumocytes (Fig. 12–3). Although the cellular and molecular basis of acute lung injury and ARDS remains an area of active investigation, recent work suggests that in ARDS, **lung injury is caused by an imbalance of pro-inflammatory and anti-inflammatory mediators.** As early as 30 minutes after an acute insult, there is increased synthesis of interleukin 8 (IL-8), a potent neutrophil chemotactic and activating agent, by pulmonary macrophages. Release of this and similar mediators, such as IL-1 and tumor necrosis factor (TNF), leads to endothelial activation as well as sequestration and activation of neutrophils in pulmonary capillaries. **Neutrophils are thought to have an important role in the pathogenesis of ARDS.** Histologic examination of lungs early in the disease process shows increased numbers of neutrophils within the vascular space, the interstitium, and the alveoli. Activated neutrophils release a variety of products (e.g., oxidants, proteases, platelet-activating factor, leukotrienes) that cause damage to the alveolar epithelium and endothelium. Combined assault on the endothelium and epithelium perpetuates vascular leakiness and loss of surfactant that render the alveolar unit unable to expand. Of note, the destructive forces unleashed by neutrophils can be counteracted by an array of endogenous antiproteases, antioxidants, and anti-inflammatory cytokines (e.g., IL-10) that are upregulated by pro-inflammatory cytokines. In the end, it is the balance between the destructive and protective factors that determines the degree of tissue injury and clinical severity of ARDS.

### MORPHOLOGY

In the **acute phase of ARDS,** the lungs are dark red, firm, airless, and heavy. Microscopic examination reveals capillary congestion, necrosis of alveolar epithelial cells, interstitial and intra-alveolar edema and hemorrhage, and (particularly with sepsis) collections of neutrophils in capillaries. The most characteristic finding is the presence of **hyaline membranes,** particularly lining the distended alveolar ducts (Fig. 12–4). Such membranes consist of fibrin-rich edema fluid admixed with remnants of necrotic epithelial cells. Overall, the picture is remarkably similar to that seen in respiratory distress syndrome in the newborn (Chapter 6). In the **organizing stage,** vigorous proliferation of type II pneumocytes occurs in an attempt to regenerate the alveolar lining. Resolution is unusual; more commonly, there is organization of the fibrin exudates, with resultant intra-alveolar fibrosis. Marked thickening of the alveolar septa ensues, caused by proliferation of interstitial cells and deposition of collagen.

### Clinical Features

Approximately 85% of patients develop the clinical syndrome of acute lung injury or ARDS within 72 hours of the initiating insult. With improvements in supportive therapy, the mortality rate for the 190,000 ARDS cases occurring yearly has decreased from 60% to 40% in the last decade. Predictors of poor prognosis include advanced age, underlying bacteremia (sepsis), and the development of multisystem (especially cardiac, renal, or hepatic) failure. Should the patient survive the acute stage, diffuse interstitial fibrosis may occur, with continued compromise of respiratory function. However, in most patients who survive the acute insult and are spared the chronic sequelae, normal respiratory function returns within 6 to 12 months.

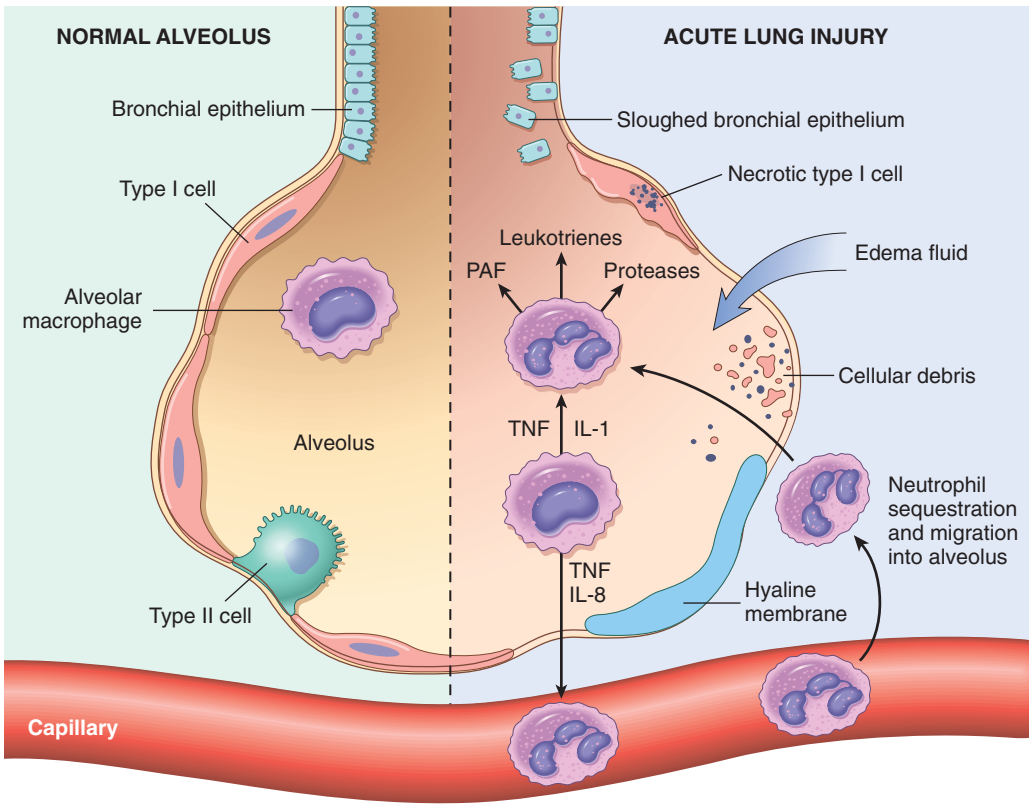

**Figure 12–3** The normal alveolus *(left)*, compared with the injured alveolus in the early phase of acute lung injury and the acute respiratory distress syndrome. Under the influence of proinflammatory cytokines such as interleukins IL-8 and IL-1 and tumor necrosis factor (TNF) (released by macrophages), neutrophils initially undergo sequestration in the pulmonary microvasculature, followed by margination and egress into the alveolar space, where they undergo activation. Activated neutrophils release a variety of factors such as leukotrienes, oxidants, proteases, and platelet-activating factor (PAF), which contribute to local tissue damage, accumulation of edema fluid in the air spaces, surfactant inactivation, and hyaline membrane formation. Subsequently, the release of macrophage-derived fibrogenic cytokines such as transforming growth factor-β (TGF-β) and platelet-derived growth factor (PGDF) stimulate fibroblast growth and collagen deposition associated with the healing phase of injury.
*(Modified from Ware LB: Pathophysiology of acute lung injury and the acute respiratory distress syndrome. Semin Respir Crit Care Med 27:337, 2006.)*

## SUMMARY

### Acute Respiratory Distress Syndrome

- ARDS is a clinical syndrome of progressive respiratory insufficiency caused by diffuse alveolar damage in the setting of sepsis, severe trauma, or diffuse pulmonary infection.
- Neutrophils and their products have a crucial role in the pathogenesis of ARDS by causing endothelial and epithelial injury.
- The characteristic histologic picture is that of alveolar edema, epithelial necrosis, accumulation of neutrophils, and presence of hyaline membranes lining the alveolar ducts.

## OBSTRUCTIVE VERSUS RESTRICTIVE PULMONARY DISEASES

Diffuse pulmonary diseases can be classified into two categories: (1) obstructive (airway) disease, characterized by limitation of airflow, usually resulting from an increase in resistance caused by partial or complete obstruction at any level, and (2) restrictive disease, characterized by reduced expansion of lung parenchyma accompanied by decreased total lung capacity.

*The major diffuse obstructive disorders* are *emphysema, chronic bronchitis, bronchiectasis, and asthma.* In patients with these diseases, forced vital capacity (FVC) is either normal or slightly decreased, while the expiratory flow rate, usually measured as the forced expiratory volume at 1 second ($FEV_1$), is significantly decreased. Thus, *the ratio of FEV to FVC is characteristically decreased.* Expiratory obstruction may result either from anatomic airway narrowing, classically observed in asthma, or from loss of elastic recoil, characteristic of emphysema.

By contrast, in *diffuse restrictive diseases,* FVC is reduced and the expiratory flow rate is normal or reduced proportionately. Hence, *the ratio of FEV to FVC is near normal.* The restrictive defect occurs in two general conditions: (1) *chest wall disorders in the presence of normal lungs* (e.g., with severe obesity, diseases of the pleura, and neuromuscular disorders, such as the Guillain-Barré syndrome [Chapter 21], that affect the respiratory muscles) and (2) *acute or chronic interstitial lung diseases.* The classic *acute* restrictive disease is ARDS, discussed earlier. *Chronic* restrictive diseases

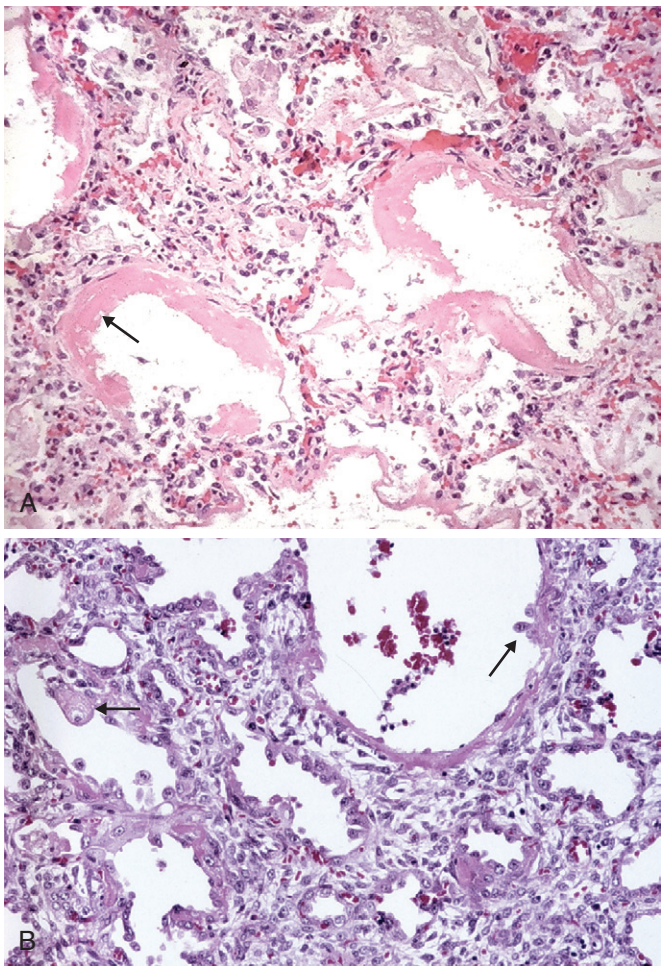

**Figure 12–4 A,** Diffuse alveolar damage in acute lung injury and acute respiratory distress syndrome. Some alveoli are collapsed; others are distended. Many are lined by bright pink hyaline membranes *(arrow)*. **B,** The healing stage is marked by resorption of hyaline membranes with thickening of alveolar septa containing inflammatory cells, fibroblasts, and collagen. Numerous reactive type II pneumocytes also are seen at this stage (*arrows*), associated with regeneration and repair.

(discussed later) include the pneumoconioses, interstitial fibrosis of unknown etiology, and most of the infiltrative conditions (e.g., sarcoidosis).

## OBSTRUCTIVE LUNG (AIRWAY) DISEASES

In their prototypical forms, the four disorders in this group—emphysema, chronic bronchitis, asthma, and bronchiectasis—have distinct clinical and anatomic characteristics (Table 12–2), but overlaps between emphysema, bronchitis, and asthma are common.

At the outset, it should be recognized that *the definition of emphysema is morphologic, whereas chronic bronchitis is defined on the basis of clinical features* such as the presence of chronic and recurrent cough with excessive mucus secretion. Second, the anatomic distribution is partially different; chronic bronchitis initially involves the large airways, whereas emphysema affects the *acinus.* In severe or advanced cases of both, small airway disease (chronic bronchiolitis) is characteristic. Although chronic bronchitis may exist without demonstrable emphysema, and almost pure emphysema may occur (particularly in patients with inherited $\alpha_1$-antitrypsin deficiency) (discussed later), the two diseases usually coexist. This is almost certainly because the major cause—cigarette smoking, especially long-term, heavy tobacco exposure—is common to both disorders. In view of their propensity to coexist, emphysema and chronic bronchitis often are clinically grouped together under the rubric of *chronic obstructive pulmonary disease* (COPD). COPD affects more than 10% of the U.S. adult population and is the fourth leading cause of death in this country. The primarily *irreversible* airflow obstruction of COPD distinguishes it from asthma, which, as described later, is characterized largely by *reversible* airflow obstruction; however, patients with COPD commonly have some degree of reversible obstruction as well (Fig. 12–5).

### Emphysema

Emphysema is characterized by *abnormal permanent enlargement of the air spaces* distal to the terminal bronchioles, accompanied by *destruction of their walls* without significant fibrosis.

**Table 12–2** Disorders Associated with Airflow Obstruction: The Spectrum of Chronic Obstructive Pulmonary Disease

| Clinical Entity | Anatomic Site | Major Pathologic Changes | Etiology | Signs/Symptoms |
|---|---|---|---|---|
| Chronic bronchitis | Bronchus | Mucous gland hypertrophy and hyperplasia, hypersecretion | Tobacco smoke, air pollutants | Cough, sputum production |
| Bronchiectasis | Bronchus | Airway dilation and scarring | Persistent or severe infections | Cough, purulent sputum, fever |
| Asthma | Bronchus | Smooth muscle hypertrophy and hyperplasia, excessive mucus, inflammation | Immunologic or undefined causes | Episodic wheezing, cough, dyspnea |
| Emphysema | Acinus | Air space enlargement, wall destruction | Tobacco smoke | Dyspnea |
| Small airway disease, bronchiolitis* | Bronchiole | Inflammatory scarring, partial obliteration of bronchioles | Tobacco smoke, air pollutants | Cough, dyspnea |

*Can be present in all forms of obstructive lung disease or by itself.

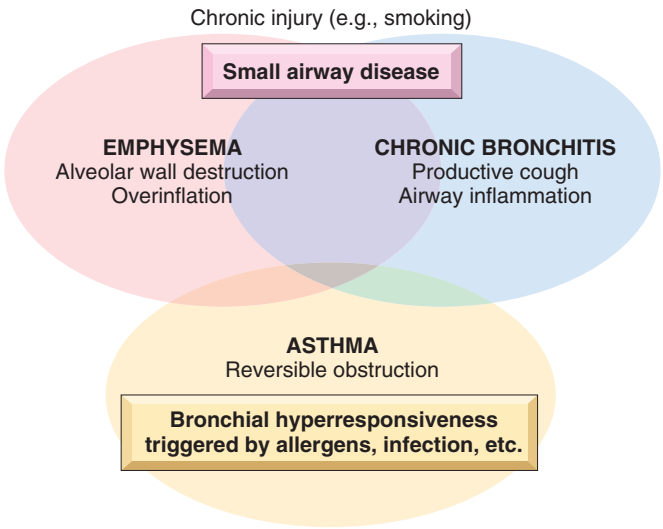

**Figure 12–5** Schematic representation of overlap between chronic obstructive lung diseases.

### *Types of Emphysema*

Emphysema is classified according to its *anatomic distribution* within the *lobule*; as described earlier, the acinus is the structure distal to terminal bronchioles, and a cluster of three to five acini is called a *lobule* (Fig. 12–6, *A*). There are four major types of emphysema: (1) centriacinar, (2) panacinar, (3) distal acinar, and (4) irregular. Only the first two types cause clinically significant airway obstruction, with centriacinar emphysema being about 20 times more common than panacinar disease.

#### Centriacinar (Centrilobular) Emphysema

The distinctive feature of centriacinar (centrilobular) emphysema is the pattern of involvement of the lobules: *The central or proximal parts of the acini, formed by respiratory bronchioles, are affected, while distal alveoli are spared.* Thus, both emphysematous and normal air spaces exist within the same acinus and lobule (Fig. 12–6, *B*). The lesions are more common and severe in the upper lobes, particularly in the apical segments. In severe centriacinar emphysema the distal acinus also becomes involved, and thus, the differentiation from panacinar emphysema becomes difficult. This type of emphysema is most commonly seen as a consequence of cigarette smoking in people who do not have congenital deficiency of $\alpha_1$-antitrypsin.

#### Panacinar (Panlobular) Emphysema

*In panacinar (panlobular) emphysema, the acini are uniformly enlarged,* from the level of the respiratory bronchiole to the terminal blind alveoli (Fig. 12–6, *C*). In contrast with centriacinar emphysema, panacinar emphysema tends to occur more commonly in the lower lung zones and is the type of emphysema that occurs in $\alpha_1$-antitrypsin deficiency.

#### Distal Acinar (Paraseptal) Emphysema

*In distal acinar (paraseptal) emphysema, the proximal portion of the acinus is normal but the distal part is primarily involved.* The emphysema is more striking adjacent to the pleura, along the lobular connective tissue septa, and at the margins of the lobules. It occurs adjacent to areas of fibrosis, scarring, or atelectasis and is usually more severe in the upper half of the lungs. The characteristic finding is the presence of multiple, contiguous, enlarged air spaces ranging in diameter from less than 0.5 mm to more than 2.0 cm, sometimes forming cystic structures that, with progressive enlargement, are referred to as *bullae.* The cause of this type of emphysema is unknown; it is seen most often in cases of spontaneous pneumothorax in young adults.

#### Irregular Emphysema

*Irregular emphysema, so named because the acinus is irregularly involved, is almost invariably associated with scarring,* such as that resulting from healed inflammatory diseases. Although clinically asymptomatic, this may be the most common form of emphysema.

## PATHOGENESIS

Exposure to toxic substances such as tobacco smoke and inhaled pollutants induces ongoing inflammation with accumulation of neutrophils, macrophages and lymphocytes in the lung. Elastases, cytokines (including IL-8) and oxidants are released causing epithelial injury and proteolysis of the extracellular matrix (ECM). Elastin degradation products further increase the inflammation. Unless checked by antielastases

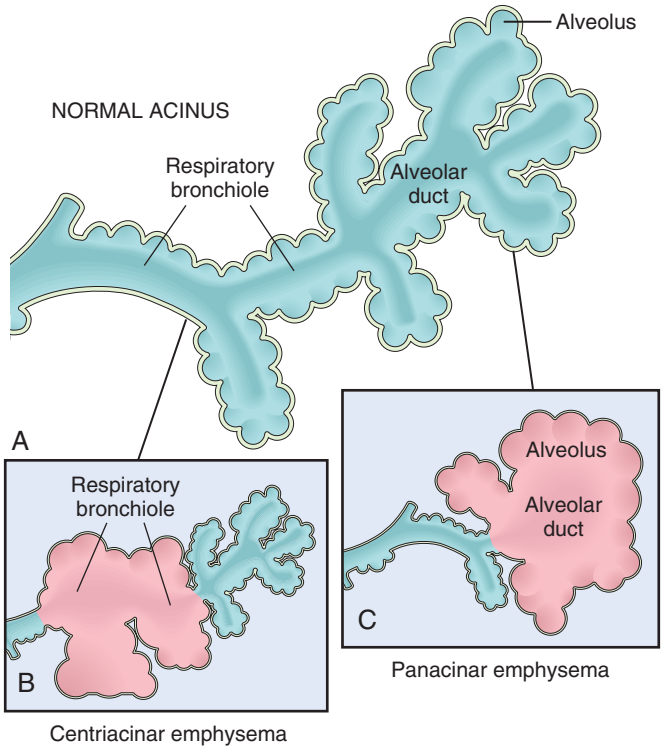

**Figure 12–6** Major patterns of emphysema. **A,** Diagram of normal structure of the acinus, the fundamental unit of the lung. **B,** Centriacinar emphysema with dilation that initially affects the respiratory bronchioles. **C,** Panacinar emphysema with initial distention of all the peripheral structures (i.e., the alveolus and alveolar duct); the disease later extends to affect the respiratory bronchioles.

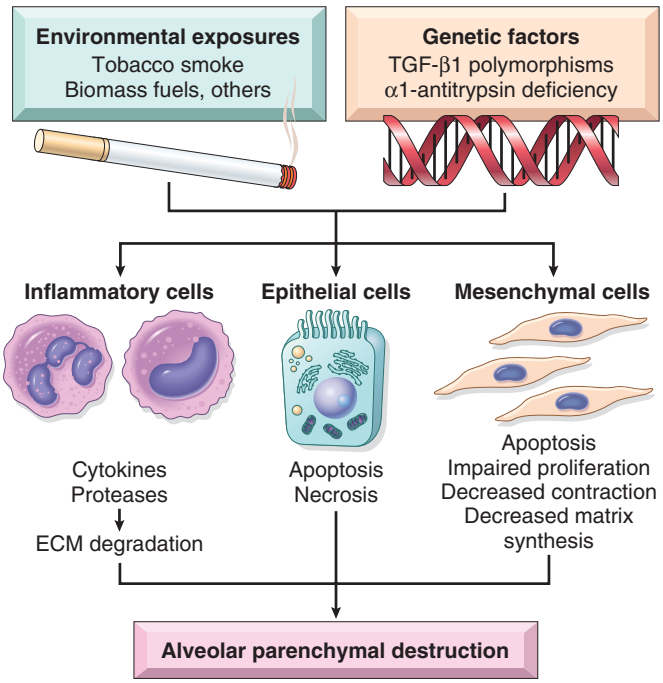

**Figure 12–7** Loss of cellular homeostasis in emphysema pathogenesis. Exposure to inhaled toxins (such as cigarette smoke) leads to epithelial cell death, inflammation, and extracellular matrix proteolysis. In susceptible persons, mesenchymal cell survival and reparative functions are impaired by direct effects of inhaled toxic substances and inflammatory mediators and by the loss of the peri- and extracellular matrix. The result is loss of structural cells of the alveolar wall and the associated matrix components.

*(Reproduced with permission from Horowitz JC, Martinez FJ, Thannickal VJ: Mesenchymal cell fate and phenotypes in the pathogenesis of emphysema. COPD 6:201, 2009.)*

(e.g., $\alpha_1$-antitrypsin) and antioxidants, the cycle of inflammation and ECM proteolysis continues. Indeed, more than 80% of patients with congenital $\alpha_1$-antitrypsin deficiency develop symptomatic panacinar emphysema, which occurs at an earlier age and with greater severity if the affected person smokes.

There is marked individual variation in susceptibility to the development of emphysema/COPD. Multiple genetic factors control the response to injury after smoking. For example, the *TGFB* gene exhibits polymorphisms that influence susceptibility to the development of COPD by regulating the response of mesenchymal cells to injury. For example, with certain polymorphisms, mesenchymal cell response to TGF-β signaling is reduced, which in turn results in inadequate repair of elastin injury caused by inhaled toxins. Matrix metalloproteinases (MMPs), especially MMP-9 and MMP-12, have also been shown to have a pathogenic role in emphysema. MMP-9 gene polymorphisms and higher levels of both MMP-9 and MMP-12 have been found in some emphysema patients. Moreover, MMP-12–deficient mice are protected from cigarette smoke–induced emphysema. Although much remains to be studied, the current understanding of emphysema pathogenesis is summarized in Figure 12–7.

Complex interactions between inflammatory mediators, cell signaling and inappropriate activation of repair mechanisms may result in very different diseases: tissue destruction without fibrosis (emphysema) or interstitial fibrosis (discussed later). Recent data indicate that mesenchymal cell response may be a key factor in determining which of these two processes ensues. In emphysema there is loss of not only epithelial and endothelial cells but also mesenchymal cells, leading to lack of extracellular matrix, the scaffolding upon which epithelial cells would have grown. Thus, **emphysema can be thought of as resulting from insufficient wound repair.** By contrast, patients with fibrosing lung diseases have excessive myofibroblastic or fibroblastic response to injury, leading to unchecked scarring.

## MORPHOLOGY

The diagnosis and classification of emphysema depend largely on the macroscopic appearance of the lung. **Panacinar emphysema,** when the pathologic process is well developed, produces pale, voluminous lungs that often obscure the heart when the anterior chest wall is removed at autopsy. The macroscopic features of **centriacinar emphysema** are less impressive. The lungs are a deeper pink than in panacinar emphysema and less voluminous, unless the disease is well advanced. Generally, in centriacinar emphysema the upper two thirds of the lungs are more severely affected than the lower lungs. Histologic examination reveals **destruction of alveolar walls without fibrosis, leading to enlarged air spaces** (Fig. 12–8). In addition to alveolar loss, the number of alveolar capillaries is diminished. Terminal and respiratory bronchioles may be deformed because of the loss of septa that help tether these structures in the parenchyma. With the **loss of elastic tissue** in the surrounding alveolar septa, radial traction on the small airways is reduced. As a result, they tend to collapse during expiration—an important cause of chronic airflow obstruction in severe emphysema. Bronchiolar inflammation and submucosal fibrosis are consistently present in advanced disease.

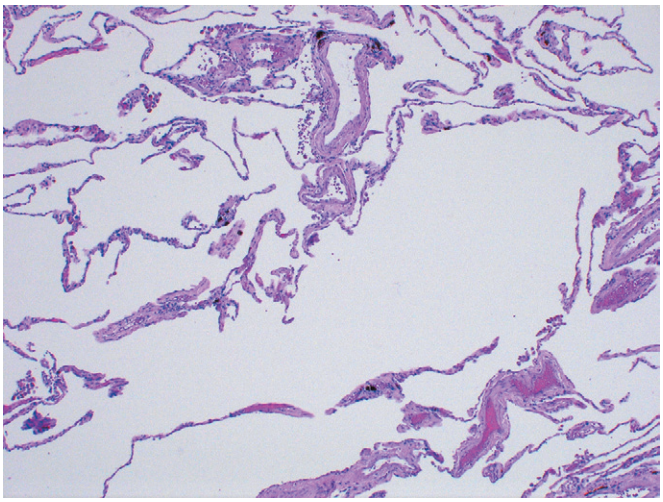

**Figure 12–8** Pulmonary emphysema. There is marked enlargement of air spaces, with destruction of alveolar septa but without fibrosis. Note presence of black anthracotic pigment.

### Clinical Features

*Dyspnea* usually is the first symptom; it begins insidiously but is steadily progressive. In patients with underlying chronic bronchitis or chronic asthmatic bronchitis, cough and wheezing may be the initial complaints. Weight loss is common and may be so severe as to suggest a hidden malignant tumor. Pulmonary function tests reveal reduced $FEV_1$ with normal or near-normal FVC. *Hence, the ratio of $FEV_1$ to FVC is reduced.*

The classic presentation in emphysema with no "bronchitic" component is one in which the patient is barrel-chested and dyspneic, with obviously prolonged expiration, sitting forward in a hunched-over position, attempting to squeeze the air out of the lungs with each expiratory effort. In these patients, air space enlargement is severe and diffusing capacity is low. Dyspnea and hyperventilation are prominent, so that until very late in the disease, gas exchange is adequate and blood gas values are relatively normal. Because of prominent dyspnea and adequate oxygenation of hemoglobin, these patients sometimes are called "pink puffers."

At the other extreme of the clinical presentation in emphysema is a patient who also has pronounced chronic bronchitis and a history of recurrent infections with purulent sputum. Dyspnea usually is less prominent, with diminished respiratory drive, so the patient retains carbon dioxide, becomes hypoxic, and often is cyanotic. For reasons not entirely clear, such patients tend to be obese—hence the designation "blue bloaters." Often they seek medical help after the onset of CHF (cor pulmonale) (Chapter 10) and associated edema.

Most patients with emphysema and COPD, however, fall somewhere between these two classic extremes. In all cases, *secondary pulmonary hypertension develops gradually,* arising from both hypoxia-induced pulmonary vascular spasm and loss of pulmonary capillary surface area from alveolar destruction. Death from emphysema is related to either pulmonary failure, with respiratory acidosis, hypoxia, and coma, or right-sided heart failure (cor pulmonale).

### *Conditions Related to Emphysema*

Several conditions resemble emphysema only superficially but nevertheless are (inappropriately) referred to as such:

- *Compensatory emphysema* is a term used to designate the compensatory dilation of alveoli in response to loss of lung substance elsewhere, such as occurs in residual lung parenchyma after surgical removal of a diseased lung or lobe.
- *Obstructive overinflation* refers to the condition in which the lung expands because air is trapped within it. A common cause is subtotal obstruction by a tumor or foreign object. Obstructive overinflation can be a life-threatening emergency if the affected portion extends sufficiently to compress the remaining normal lung.
- *Bullous emphysema* refers merely to any form of emphysema that produces large subpleural blebs or bullae (spaces greater than 1 cm in diameter in the distended state) (Fig. 12–9). Such blebs represent localized accentuations of one of the four forms of emphysema; most often the blebs are subpleural, and on occasion they may rupture, leading to pneumothorax.
- *Mediastinal (interstitial) emphysema* is the condition resulting when air enters the connective tissue stroma of the lung, mediastinum, and subcutaneous tissue. This may occur spontaneously with a sudden increase in intra-alveolar pressure (as with vomiting or violent coughing) resulting in a tear, with dissection of air into the interstitium. Sometimes it develops in children with whooping cough. It is particularly likely to occur in patients on respirators who have partial bronchiolar obstruction or in persons who suffer a perforating injury (e.g., a fractured rib). When the interstitial air enters the subcutaneous tissue, the patient may literally blow up like a balloon, with marked swelling of the head and neck and crackling crepitation all over the chest. In most instances, the air is resorbed spontaneously after the site of entry is sealed.

## SUMMARY

### Emphysema

- Emphysema is a chronic obstructive airway disease characterized by permanent enlargement of air spaces distal to terminal bronchioles.
- Subtypes include centriacinar (most common; smoking-related), panacinar (seen in $\alpha_1$-antitrypsin deficiency), distal acinar, and irregular.
- Smoking and inhaled pollutants cause ongoing accumulation of inflammatory cells, releasing elastases and oxidants, which destroy the alveolar walls without adequate mesenchymal repair response.
- Most patients with emphysema demonstrate elements of chronic bronchitis concurrently, since cigarette smoking is an underlying risk factor for both; patients with pure emphysema are characterized as "pink puffers."

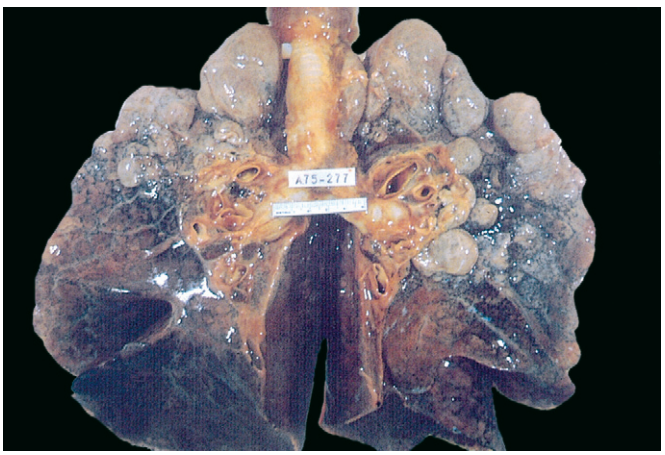

**Figure 12–9** Bullous emphysema with large apical and subpleural bullae. *(From the Teaching Collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

## Chronic Bronchitis

Chronic bronchitis is common among cigarette smokers and urban dwellers in smog-ridden cities; some studies indicate that 20% to 25% of men in the 40- to 65-year-old age group have the disease. The diagnosis of chronic bronchitis is made on clinical grounds: it is defined by the *presence of a persistent productive cough for at least 3 consecutive months in at least 2 consecutive years.* In early stages of the disease, the productive cough raises mucoid sputum, but airflow is not obstructed. Some patients with chronic bronchitis may demonstrate hyperresponsive airways with intermittent bronchospasm and wheezing. A subset of bronchitic patients, especially heavy smokers, develop chronic outflow obstruction, usually with associated emphysema.

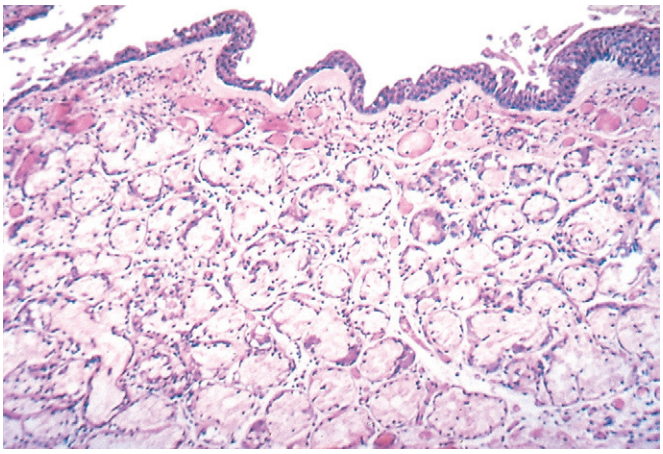

**Figure 12–10** Chronic bronchitis. The lumen of the bronchus is *above*. Note the marked thickening of the mucous gland layer (approximately twice-normal) and squamous metaplasia of lung epithelium.

*(From the Teaching Collection of the Department of Pathology, University of Texas, Southwestern Medical School, Dallas, Texas.)*

### PATHOGENESIS

The distinctive feature of chronic bronchitis is **hypersecretion of mucus,** beginning in the large airways. Although the single most important cause is cigarette smoking, other air pollutants, such as sulfur dioxide and nitrogen dioxide, may contribute. These environmental irritants induce hypertrophy of mucous glands in the trachea and main bronchi, leading to a marked increase in mucin-secreting goblet cells in the surface epithelium of smaller bronchi and bronchioles. In addition, these irritants cause inflammation with infiltration of CD8+ lymphocytes, macrophages, and neutrophils. In contrast with asthma, there are no eosinophils in chronic bronchitis. Whereas the defining feature of chronic bronchitis (mucus hypersecretion) is primarily a reflection of large bronchial involvement, **the morphologic basis of airflow obstruction in chronic bronchitis is more peripheral** and results from (1) **small airway disease,** induced by goblet cell metaplasia with mucous plugging of the bronchiolar lumen, inflammation, and bronchiolar wall fibrosis, and (2) **coexistent emphysema.** In general, while small airway disease (also known as chronic bronchiolitis) is an important component of early and relatively mild airflow obstruction, chronic bronchitis with significant airflow obstruction is almost always complicated by emphysema.

It is postulated that many of the respiratory epithelial effects of environmental irritants (e.g., mucus hypersecretion) are mediated by local release of T cell cytokines such as IL-13. The transcription of the mucin gene *MUC5AC* in bronchial epithelium and the production of neutrophil elastase are increased as a consequence of exposure to tobacco smoke. **Microbial infection** often is present but has a secondary role, chiefly by maintaining the inflammation and exacerbating symptoms.

### MORPHOLOGY

As seen in gross specimens, the mucosal lining of the larger airways usually is **hyperemic and swollen** by edema fluid. It often is covered by a layer of mucinous or mucopurulent **secretions.** The smaller bronchi and bronchioles also may be filled with similar secretions. On histologic examination, the diagnostic feature of chronic bronchitis in the trachea and larger bronchi is **enlargement of the mucus-secreting glands** (Fig. 12–10). The magnitude of the increase in size is assessed by the ratio of the thickness of the submucosal gland layer to that of the bronchial wall (the Reid index—normally 0.4). Inflammatory cells, largely mononuclear but sometimes admixed with neutrophils, are frequently present in variable density in the bronchial mucosa. **Chronic bronchiolitis** (small airway disease), characterized by goblet cell metaplasia, mucous plugging, inflammation, and fibrosis, is also present. In the most severe cases, there may be complete obliteration of the lumen as a consequence of fibrosis (bronchiolitis obliterans). It is the submucosal fibrosis that leads to luminal narrowing and airway obstruction. Changes of emphysema often co-exist.

### Clinical Features

In patients with chronic bronchitis, a prominent cough and the production of sputum may persist indefinitely without ventilatory dysfunction. As alluded to earlier, however, some patients develop significant COPD with outflow obstruction. This clinical syndrome is accompanied by hypercapnia, hypoxemia, and (in severe cases) cyanosis (hence the term "blue bloaters"). Differentiation of this form of COPD from that caused by emphysema can be made in the classic case, but many such patients have both conditions. With progression, chronic bronchitis is complicated by pulmonary hypertension and cardiac failure (Chapter 10). Recurrent infections and respiratory failure are constant threats.

### SUMMARY

#### Chronic Bronchitis

- Chronic bronchitis is defined as persistent productive cough for at least 3 consecutive months in at least 2 consecutive years.
- Cigarette smoking is the most important underlying risk factor; air pollutants also contribute.

- Chronic obstructive component largely results from small airway disease (chronic bronchiolitis) and coexistent emphysema.
- Histologic examination demonstrates enlargement of mucus-secreting glands, goblet cell metaplasia, and bronchiolar wall fibrosis.

## Asthma

Asthma is a chronic inflammatory disorder of the airways that causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and/or early in the morning. The hallmarks of the disease are *intermittent and reversible airway obstruction, chronic bronchial inflammation with eosinophils, bronchial smooth muscle cell hypertrophy and hyperreactivity, and increased mucus secretion.* Some of the stimuli that trigger attacks in patients would have little or no effect in persons with normal airways. Many cells play a role in the inflammatory response, in particular eosinophils, mast cells, macrophages, lymphocytes, neutrophils, and epithelial cells. Of note, there has been a significant increase in the incidence of asthma in the Western world over the past four decades. This epidemiologic observation has led to the "hygiene hypothesis," according to which the eradication of infections may alter immune homeostasis and promote allergic and other harmful immune responses.

Asthma may be categorized into *atopic* (evidence of allergen sensitization, often in a patient with a history of allergic rhinitis, eczema) and *nonatopic.* In either type, episodes of bronchospasm can be triggered by diverse mechanisms, such as respiratory infections (especially viral), environmental exposure to irritants (e.g., smoke, fumes), cold air, stress, and exercise. There is emerging evidence for differing patterns of inflammation: eosinophilic, neutrophilic, mixed inflammatory, and pauci-granulocytic. These subgroups may differ in etiology, immunopathology, and response to treatment. Asthma also may be classified according to the agents or events that trigger bronchoconstriction.

### PATHOGENESIS

The major etiologic factors of asthma are genetic predisposition to type I hypersensitivity (atopy), acute and chronic airway inflammation, and bronchial hyperresponsiveness to a variety of stimuli. **The inflammation involves many cell types and numerous inflammatory mediators, but the role of type 2 helper T ($T_H2$) cells may be critical to the pathogenesis of asthma.** The classic atopic form of asthma is associated with an excessive $T_H2$ reaction against environmental antigens. Cytokines produced by $T_H2$ cells account for most of the features of asthma—IL-4 stimulates IgE production, IL-5 activates eosinophils, and IL-13 stimulates mucus production and also promotes IgE production by B cells. IgE coats submucosal mast cells, which, on exposure to allergen, release granule contents. This induces two waves of reaction: an early (immediate) phase and a late phase (Fig. 12-11). The early reaction is dominated by bronchoconstriction, increased mucus production and variable vasodilation. Bronchoconstriction is triggered by direct stimulation of subepithelial vagal receptors. The late-phase reaction consists of inflammation, with activation of eosinophils, neutrophils, and T cells. In addition, epithelial cells are activated to produce chemokines that promote recruitment of more $T_H2$ cells and eosinophils (including eotaxin, a potent chemoattractant and activator of eosinophils), as well as other leukocytes, thus amplifying the inflammatory reaction. Repeated bouts of inflammation lead to structural changes in the bronchial wall, collectively referred to as **airway remodeling.** These changes include hypertrophy of bronchial smooth muscle and mucus glands, and increased vascularity and deposition of subepithelial collagen, which may occur as early as several years before initiation of symptoms.

Asthma is a complex genetic disorder in which multiple susceptibility genes interact with environmental factors to initiate the pathologic reaction. There is significant variation in the expression of these genes and in the combinations of polymorphisms that effect the immune response or tissue remodeling. One of the susceptibility loci is on the long arm of chromosome 5 (5q), where several genes involved in regulation of IgE synthesis and mast cell and eosinophil growth and differentiation map. The genes at this locus include *IL13* (genetic polymorphisms linked with susceptibility to the development of atopic asthma), CD14 (single-nucleotide polymorphisms associated with occupational asthma), class II HLA alleles (tendency to produce IgE antibodies), $\beta_2$-adrenergic receptor gene, and IL-4 receptor gene (atopy, total serum IgE level, and asthma). Another important locus is on 20q where ADAM-33 that regulates proliferation of bronchial smooth muscle and fibroblasts is located; this controls airway remodeling. Upregulation of various chitinase enzymes has been shown to be important in $T_H2$ inflammation and severity of asthma; high serum YKL-40 levels (a chitinase family member with no enzymatic activity) correlate with the severity of asthma.

### *Types of Asthma*

#### Atopic Asthma

This is the most common type of asthma, usually beginning in childhood, and is a classic example of *type I IgE–mediated hypersensitivity reaction* (Chapter 4). A positive family history of atopy and/or asthma is common, and asthmatic attacks are often preceded by allergic rhinitis, urticaria, or eczema. The disease is triggered by environmental antigens, such as dusts, pollen, animal dander, and foods. Infections can also trigger atopic asthma. A skin test with the offending antigen results in an immediate wheal-and-flare reaction. Atopic asthma also can be diagnosed based on serum radioallergosorbent tests (RASTs) that identify the presence of IgE specific for a panel of allergens.

#### Non-Atopic Asthma

Patients with nonatopic forms of asthma do not have evidence of allergen sensitization, and skin test results usually are negative. A positive family history of asthma is less common. Respiratory infections due to viruses (e.g., rhinovirus, parainfluenza virus) and inhaled air pollutants (e.g., sulfur dioxide, ozone, nitrogen dioxide) are common triggers. *It is thought that virus-induced inflammation of the*

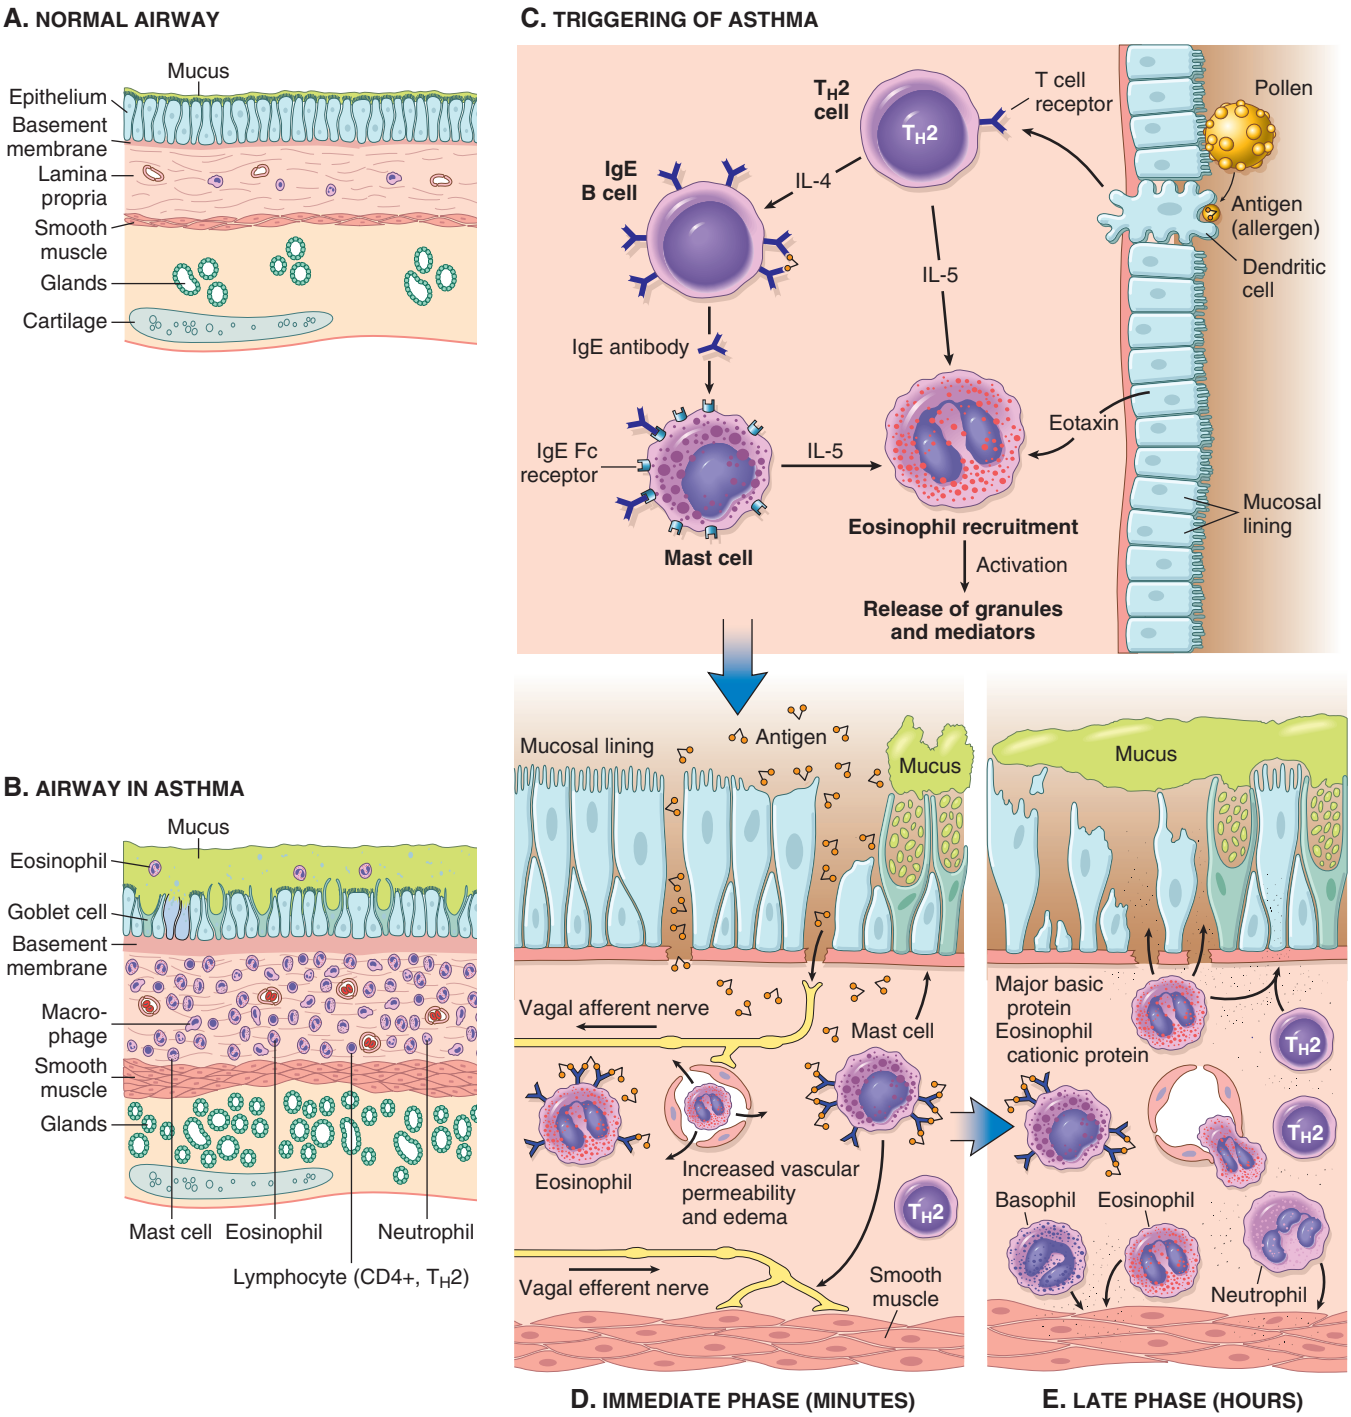

**Figure 12–11** **A** and **B**, Comparison of a normal bronchus with that in a patient with asthma. Note the accumulation of mucus in the bronchial lumen resulting from an increase in the number of mucus-secreting goblet cells in the mucosa and hypertrophy of submucosal glands. In addition, there is intense chronic inflammation due to recruitment of eosinophils, macrophages, and other inflammatory cells. Basement membrane underlying the mucosal epithelium is thickened, and smooth muscle cells exhibit hypertrophy and hyperplasia. **C,** Inhaled allergens (antigens) elicit a $T_H2$-dominated response favoring IgE production and eosinophil recruitment (priming or sensitization). **D,** On reexposure to antigen (Ag), the immediate reaction is triggered by antigen-induced cross-linking of IgE bound to IgE receptors on mast cells in the airways. These cells release preformed mediators. Collectively, either directly or through neuronal reflexes, the mediators induce bronchospasm, increase vascular permeability and mucus production, and recruit additional mediator-releasing cells from the blood. **E,** The arrival of recruited leukocytes (neutrophils, eosinophils, basophils, lymphocytes, and monocytes) signals the initiation of the late phase of asthma and a fresh round of mediator release from leukocytes, endothelium, and epithelial cells. Factors, particularly from eosinophils (e.g., major basic protein, eosinophil cationic protein), also cause damage to the epithelium. IgE, immunoglobulin E.

*respiratory mucosa lowers the threshold of the subepithelial vagal receptors to irritants.* Although the connections are not well understood, the ultimate humoral and cellular mediators of airway obstruction (e.g., eosinophils) are common to both atopic and nonatopic variants of asthma, so they are treated in a similar way.

### Drug-Induced Asthma

Several pharmacologic agents provoke asthma, *aspirin* being the most striking example. Patients with aspirin sensitivity present with recurrent rhinitis and nasal polyps, urticaria, and bronchospasm. The precise mechanism remains unknown, but it is presumed that aspirin inhibits the cyclooxygenase pathway of arachidonic acid metabolism without affecting the lipoxygenase route, thereby shifting the balance of production toward leukotrienes that cause bronchial spasm.

### Occupational Asthma

This form of asthma is stimulated by fumes (epoxy resins, plastics), organic and chemical dusts (wood, cotton, platinum), gases (toluene), and other chemicals. Asthma attacks usually develop after repeated exposure to the inciting antigen(s).

## MORPHOLOGY

The morphologic changes in asthma have been described in persons who die of prolonged severe attacks (status asthmaticus) and in mucosal biopsy specimens of persons challenged with allergens. In gross specimens obtained in fatal cases, the lungs are overdistended because of overinflation, and there may be small areas of atelectasis. The most striking macroscopic finding is occlusion of bronchi and bronchioles by thick, tenacious **mucous plugs.** Histologically, the mucous plugs contain whorls of shed epithelium **(Curschmann spirals).** Numerous eosinophils and **Charcot-Leyden crystals** (collections of crystalloids made up of eosinophil proteins) also are present. Other characteristic morphologic changes in asthma, collectively called "airway remodeling," include (Fig. 12–11, *B*):

- Thickening of airway wall
- Sub-basement membrane fibrosis (Fig. 12–12)
- Increased vascularity in submucosa
- An increase in size of the submucosal glands and goblet cell metaplasia of the airway epithelium
- Hypertrophy and/or hyperplasia of the bronchial muscle (this is the basis for the novel therapy of bronchial thermoplasty, which involves controlled delivery of thermal energy during bronchoscopy; this reduces the mass of smooth muscles which in turn reduces airway hyperresponsiveness)

### Clinical Features

An attack of asthma is characterized by severe dyspnea with wheezing; the chief difficulty lies in expiration. The victim labors to get air into the lungs and then cannot get it out, so that there is progressive hyperinflation of the lungs with air trapped distal to the bronchi, which are constricted and filled with mucus and debris. In the usual case, attacks last from 1 to several hours and subside either spontaneously or with therapy, usually bronchodilators and corticosteroids. Intervals between attacks are characteristically free from overt respiratory difficulties, but persistent, subtle deficits can be detected by spirometry. Occasionally a severe paroxysm occurs that does not respond to therapy and persists for days and even weeks (*status asthmaticus*). The associated hypercapnia, acidosis, and severe hypoxia may be fatal, although in most cases the condition is more disabling than lethal.

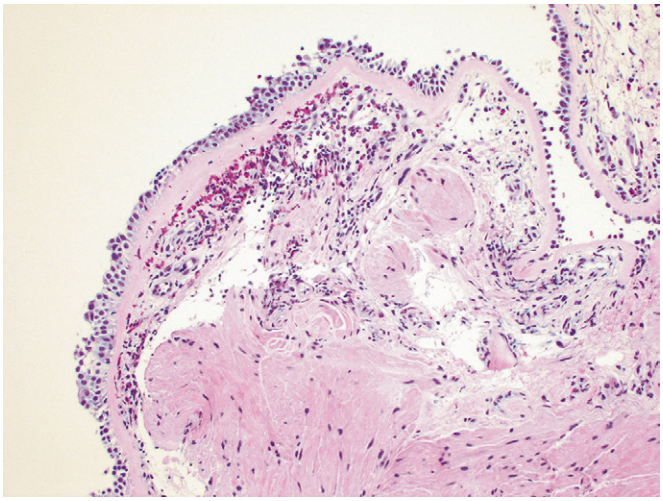

**Figure 12–12** Bronchial biopsy specimen from an asthmatic patient showing sub-basement membrane fibrosis, eosinophilic inflammation, and smooth muscle hyperplasia.

## SUMMARY

### Asthma

- Asthma is characterized by reversible bronchoconstriction caused by airway hyperresponsiveness to a variety of stimuli.
- Atopic asthma is caused by a $T_H2$ and IgE-mediated immunologic reaction to environmental allergens and is characterized by acute-phase (immediate) and late-phase reactions. The $T_H2$ cytokines IL-4, IL-5, and IL-13 are important mediators.
- Triggers for nonatopic asthma are less clear but include viral infections and inhaled air pollutants, which can also trigger atopic asthma.
- *Eosinophils* are key inflammatory cells found in almost all subtypes of asthma; eosinophil products such as major basic protein are responsible for airway damage.
- Airway remodeling (sub-basement membrane thickening and hypertrophy of bronchial glands and smooth muscle) adds an irreversible component to the obstructive disease.

## Bronchiectasis

Bronchiectasis is the permanent dilation of bronchi and bronchioles caused by destruction of the muscle and the supporting elastic tissue, resulting from or associated with

chronic necrotizing infections. It is not a primary disease but rather secondary to persisting infection or obstruction caused by a variety of conditions. Once developed, it gives rise to a characteristic symptom complex dominated by cough and expectoration of copious amounts of purulent sputum. Diagnosis depends on an appropriate history along with radiographic demonstration of bronchial dilation. The conditions that most commonly predispose to bronchiectasis include:

- *Bronchial obstruction.* Common causes are tumors, foreign bodies, and occasionally impaction of mucus. With these conditions, the bronchiectasis is localized to the obstructed lung segment. Bronchiectasis can also complicate atopic asthma and chronic bronchitis.
- Congenital or hereditary conditions—for example:
  - In *cystic fibrosis,* widespread severe bronchiectasis results from obstruction caused by the secretion of abnormally viscid mucus thus predisposing to infections of the bronchial tree. This is an important and serious complication (Chapter 6).
  - In *immunodeficiency states,* particularly immunoglobulin deficiencies, localized or diffuse bronchiectasis is likely to develop because of an increased susceptibility to repeated bacterial infections.
  - *Kartagener syndrome* is a rare autosomal recessive disorder that is frequently associated with bronchiectasis and with sterility in males. In this condition, structural abnormalities of the cilia impair mucociliary clearance in the airways, leading to persistent infections, and reduce the mobility of spermatozoa.
- *Necrotizing,* or *suppurative, pneumonia,* particularly with virulent organisms such as *Staphylococcus aureus* or *Klebsiella* spp., may predispose affected patients to development of bronchiectasis. Posttuberculosis bronchiectasis continues to be a significant cause of morbidity in endemic areas.

## PATHOGENESIS

Two processes are crucial and intertwined in the pathogenesis of bronchiectasis: **obstruction** and **chronic persistent infection.** Either of these may come first. Normal clearance mechanisms are hampered by obstruction, so secondary infection soon follows; conversely, chronic infection over time causes damage to bronchial walls, leading to weakening and dilation. For example, obstruction caused by a primary lung cancer or a foreign body impairs clearance of secretions, providing a favorable substrate for superimposed infection. The resultant inflammatory damage to the bronchial wall and the accumulating exudate further distend the airways, leading to irreversible dilation. Conversely, a persistent necrotizing inflammation in the bronchi or bronchioles may cause obstructive secretions, inflammation throughout the wall (with peribronchial fibrosis and traction on the walls), and eventually the train of events already described.

## MORPHOLOGY

Bronchiectasis usually affects the **lower lobes** bilaterally, particularly those air passages that are most vertical. When caused by tumors or aspiration of foreign bodies the involvement may be sharply localized to a single segment of the lungs. Usually, the most severe involvement is found in the more distal bronchi and bronchioles. The airways may be **dilated** to as much as four times their usual diameter and on gross examination of the lung can be followed almost to the pleural surfaces (Fig. 12–13). By contrast, in normal lungs, the bronchioles cannot be followed by ordinary gross examination beyond a point 2 to 3 cm from the pleural surfaces. The histologic findings vary with the activity and chronicity of the disease. In the full-blown active case, an **intense acute and chronic inflammatory exudate within the walls of the bronchi and bronchioles** and the desquamation of lining epithelium cause extensive areas of ulceration. In the usual case, a **mixed** flora can be cultured from the involved bronchi, including staphylococci, streptococci, pneumococci, enteric organisms, anaerobic and microaerophilic bacteria, and (particularly in children) *Haemophilus influenzae* and *Pseudomonas aeruginosa.* When healing occurs, the lining epithelium may regenerate completely; however, usually so much injury has occurred that abnormal dilation and scarring persist. Fibrosis of the bronchial and bronchiolar walls and **peribronchiolar fibrosis** develop in more chronic cases. In some instances, the necrosis destroys the bronchial or bronchiolar walls resulting in the formation of an abscess cavity within which a fungus ball may develop.

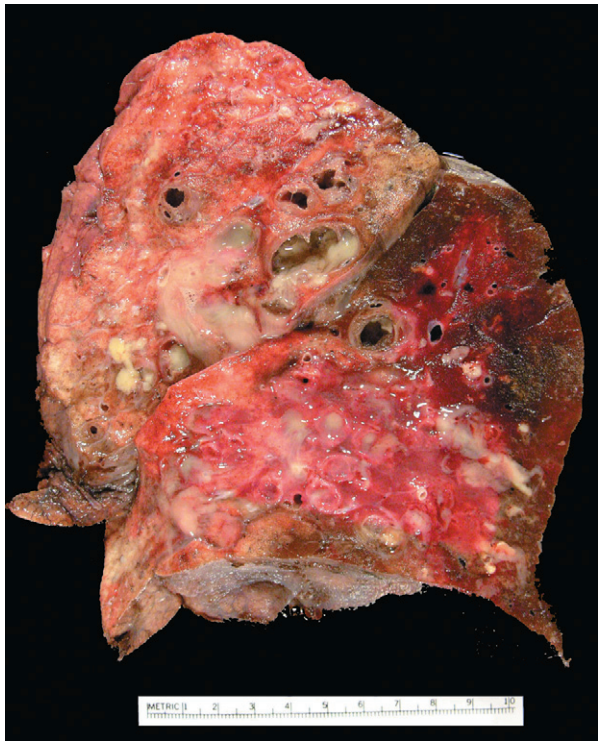

**Figure 12–13** Bronchiectasis in a patient with cystic fibrosis who underwent lung resection for transplantation. Cut surface of lung shows markedly dilated bronchi, filled with purulent mucus, which are seen extending to subpleural regions.

### Clinical Features

The clinical manifestations consist of severe, persistent cough with expectoration of mucopurulent, sometimes fetid, sputum. The sputum may contain flecks of blood; frank hemoptysis can occur. Symptoms often are episodic and are precipitated by upper respiratory tract infections or the introduction of new pathogenic agents. Clubbing of the fingers may develop. In cases of severe, widespread bronchiectasis, significant obstructive ventilatory defects are usual, with hypoxemia, hypercapnia, pulmonary hypertension, and (rarely) cor pulmonale. Metastatic brain abscesses and reactive amyloidosis (Chapter 4) are other, less frequent complications of bronchiectasis.

## CHRONIC INTERSTITIAL (RESTRICTIVE, INFILTRATIVE) LUNG DISEASES

Chronic interstitial diseases are a heterogeneous group of disorders characterized predominantly by bilateral, often patchy, and usually chronic involvement of the pulmonary connective tissue, principally the most peripheral and delicate interstitium in the alveolar walls. The pulmonary interstitium is composed of the basement membrane of the endothelial and epithelial cells (fused in the thinnest portions), collagen fibers, elastic tissue, fibroblasts, a few mast cells, and occasional mononuclear cells (Fig. 12–1). Many of the entities in this group are of unknown cause and pathogenesis; some have an intra-alveolar as well as an interstitial component, and there is frequent overlap in histologic features among the different conditions. Nevertheless, the similarity in clinical signs, symptoms, radiographic alterations, and pathophysiologic changes justifies their consideration as a group. *The hallmark feature of these disorders is reduced compliance (i.e., more pressure is required to expand the lungs because they are stiff), which in turn necessitates increased effort of breathing (dyspnea).* Furthermore, damage to the alveolar epithelium and interstitial vasculature produces abnormalities in the ventilation–perfusion ratio, leading to hypoxia. Chest radiographs show diffuse infiltration by small nodules, irregular lines, or "ground-glass shadows." With progression, patients can develop respiratory failure, often in association with pulmonary hypertension and cor pulmonale (Chapter 10). Advanced forms of these diseases may be difficult to differentiate because they result in scarring and gross destruction of the lung, referred to as end-stage or "honeycomb" lung. Chronic interstitial lung diseases are categorized based on clinicopathologic features and characteristic histology (Table 12–3).

**Table 12–3** Major Categories of Chronic Interstitial Lung Disease

| Desquamative interstitial pneumonia |
| Respiratory bronchiolitis |

### Fibrosing Diseases

#### *Idiopathic Pulmonary Fibrosis*

Idiopathic pulmonary fibrosis (IPF), also known as *cryptogenic fibrosing alveolitis,* refers to a pulmonary disorder of unknown etiology. It is characterized by patchy but progressive bilateral interstitial fibrosis, which in advanced cases results in severe hypoxemia and cyanosis. Males are affected more often than females, and approximately two thirds of patients are older than 60 years of age at presentation. The radiologic and histologic pattern of fibrosis is referred to as *usual interstitial pneumonia* (UIP), which is required for the diagnosis of IPF. Of note, however, similar pathologic changes in the lung may be present in well-defined entities such as asbestosis, the collagen vascular diseases, and a number of other conditions. Therefore, known causes must be ruled out before the appellation of *idiopathic* is used.

#### PATHOGENESIS

The current concept is that IPF is caused by "repeated cycles" of epithelial activation/injury by some unidentified agent (Fig. 12–14). Histopathologic features include inflammation and induction of $T_H2$ type T cell response with eosinophils, mast cells, IL-4, and IL-13 in the lesions. There has been considerable interest in the idea that "alternatively activated macrophages" are dominant in patients with lung fibrosis and may be important in its pathogenesis (Chapter 2). Abnormal epithelial repair at the sites of damage and inflammation gives rise to exuberant fibroblastic or myofibroblastic proliferation, leading to the characteristic fibroblastic foci. Although the mechanisms of abnormal repair are incompletely understood, recent data point to TGF-β1, which is released from injured type I pneumocytes and induces transformation of fibroblasts into myofibroblasts leading to excessive and continuing deposition of collagen and ECM. Some patients with familial IPF have mutations that shorten telomeres (Chapter 1) leading to rapid senescence and apoptosis of pneumocytes. TGF-β1 also downregulates fibroblast caveolin-1, which acts as an endogenous inhibitor of pulmonary fibrosis.

#### MORPHOLOGY

Grossly, the pleural surfaces of the lung have the appearance of cobblestones because of the retraction of scars along the interlobular septa. The cut surface shows fibrosis (firm, rubbery white areas), with lower lobe predominance and a

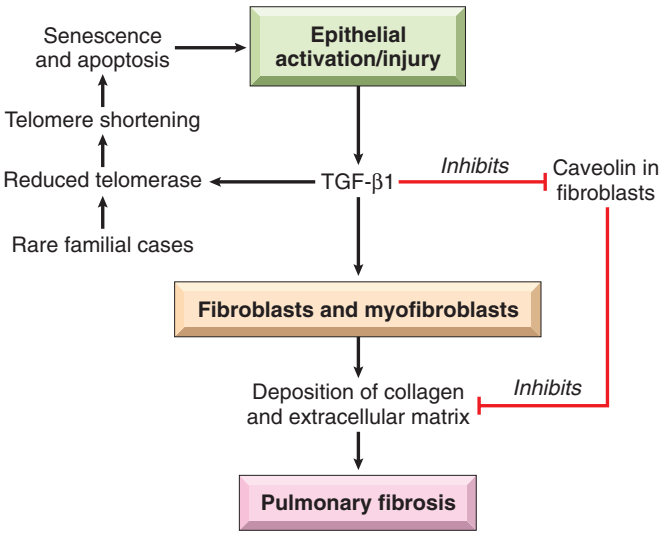

**Figure 12–14** Schematic representation of current understanding of the pathogenesis of idiopathic pulmonary fibrosis.

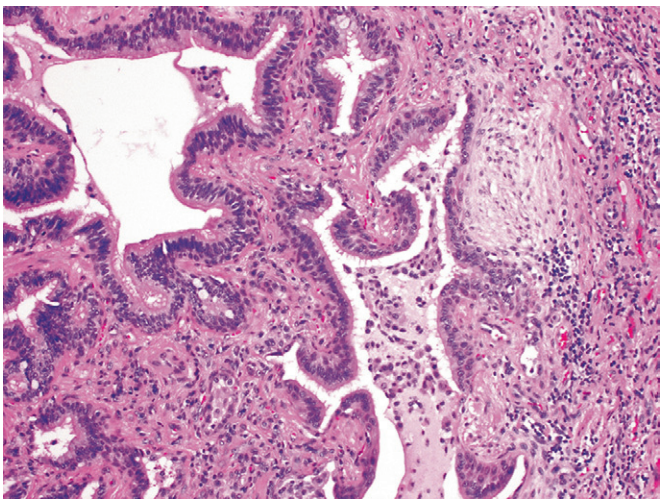

**Figure 12–16** Usual interstitial pneumonia. Fibroblastic focus with fibers running parallel to surface and bluish myxoid extracellular matrix. Honeycombing is present to the *left*.

distinctive distribution in the subpleural regions and along the interlobular septa. The pattern of fibrosis in IPF is referred to as **usual interstitial pneumonia** (UIP). The histologic hallmark of UIP is **patchy interstitial fibrosis,** which varies in intensity (Fig. 12–15) and worsens with time. The earliest lesions demonstrate exuberant fibroblastic proliferation and appear as **fibroblastic foci** (Fig. 12–16). Over time these areas become more collagenous and less cellular. Quite typical is the existence of both early and late lesions **(temporal heterogeneity).** The dense fibrosis causes collapse of alveolar walls and formation of cystic spaces lined by hyperplastic type II pneumocytes or bronchiolar epithelium **(honeycomb fibrosis).** The interstitial inflammation usually is patchy and consists of an alveolar septal infiltrate of mostly lymphocytes and occasional plasma cells, mast cells, and eosinophils. Secondary pulmonary hypertensive changes (intimal fibrosis and medial thickening of pulmonary arteries) are often present.

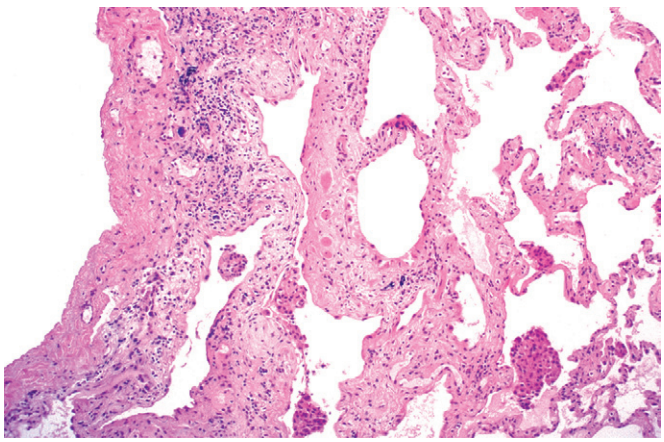

**Figure 12–15** Usual interstitial pneumonia. The fibrosis, which varies in intensity, is more pronounced in the subpleural region.

### Clinical Features

IPF usually manifests insidiously, with the gradual onset of a nonproductive cough and progressive dyspnea. On physical examination, most patients with IPF have characteristic "dry" or "Velcro"-like crackles during inspiration. Cyanosis, cor pulmonale, and peripheral edema may develop in later stages of the disease. The clinical and radiologic findings often are diagnostic; surgical lung biopsy is needed for diagnosis in selected cases. Unfortunately, progression of IPF is relentless despite medical therapy, and the mean survival is 3 years or less. Lung transplantation is the only definitive therapy available.

## *Nonspecific Interstitial Pneumonia*

Nonspecific interstitial pneumonia (NSIP) is a chronic bilateral interstitial lung disease of unknown etiology, which despite its nonspecific name, has distinct clinical, radiologic, and histologic features. It is important to recognize this disease, since it carries a much better prognosis than that for IPF. On the basis of the histologic appearance, NSIP is divided into cellular and fibrosing patterns. The *cellular pattern* features mild-to-moderate chronic interstitial inflammation (lymphocytes and a few plasma cells) in a uniform or patchy distribution. The *fibrosing pattern* consists of diffuse or patchy interstitial fibrosis, *without the temporal heterogeneity characteristic of UIP.* Fibroblastic foci and honeycombing are typically absent in both variants. Patients present with dyspnea and cough of several months' duration. Patients with the cellular pattern have a better outcome than those with the fibrosing pattern and UIP.

## *Cryptogenic Organizing Pneumonia*

*Cryptogenic organizing pneumonia* is synonymous with the previously popular designation *bronchiolitis obliterans organizing pneumonia* ("BOOP"); the former term is now preferred, however, because it emphasizes the unknown etiology of this clinicopathologic entity. Patients present with cough and dyspnea, and chest radiographs demonstrate subpleural or peribronchial patchy areas of air space

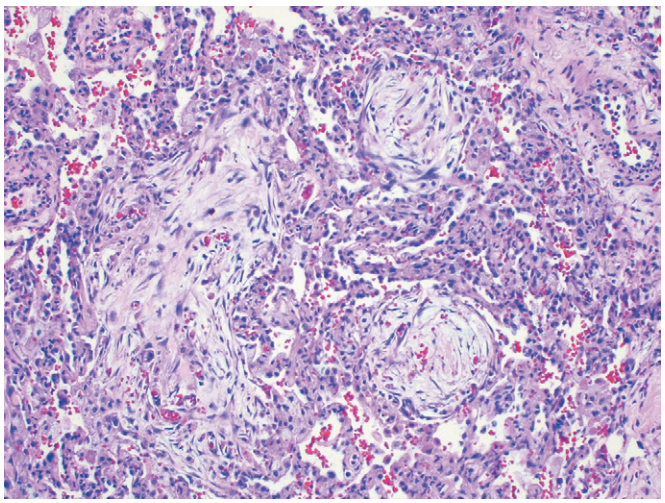

**Figure 12–17** Cryptogenic organizing pneumonia. Some alveolar spaces are filled with balls of fibroblasts (Masson bodies). Although compressed, adjacent alveoli are relatively normal.

consolidation. On histologic examination, cryptogenic organizing pneumonia is characterized by the presence of polypoid plugs of loose organizing connective tissue within alveolar ducts, alveoli, and often bronchioles (Fig. 12–17). The connective tissue is all of the same age, and the underlying lung architecture is normal. Some patients recover spontaneously, but most require treatment with oral steroids for 6 months or longer. Of note, organizing pneumonia with intra-alveolar fibrosis also can be seen as a response to infection (e.g., pneumonia) or inflammatory injury (e.g., collagen vascular disease, transplantation injury) to the lung; in such cases, the etiology obviously is not "cryptogenic," and the outcome is determined by the underlying disease.

### *Pulmonary Involvement in Collagen Vascular Diseases*

Many collagen vascular diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis, dermatomyositis-polymyositis) are associated with pulmonary manifestations. Several histologic variants can be seen, depending on the underlying disorder, with NSIP, UIP pattern (similar to that seen in IPF), vascular sclerosis, organizing pneumonia, and bronchiolitis (small airway disease, with or without fibrosis) being the most common. Pleural involvement (pleuritis, pleural nodules, and pleural effusion) may also be present. Pulmonary involvement in these diseases is usually associated with a poor prognosis, although it is still better than that with IPF.

## SUMMARY

### Chronic Interstitial Lung Diseases

- Diffuse interstitial fibrosis of the lung gives rise to restrictive lung diseases characterized by reduced lung compliance and reduced forced vital capacity (FVC). The ratio of FEV to FVC is normal.
- The diseases that cause diffuse interstitial fibrosis are heterogeneous. The unifying pathogenetic factor is injury to the alveoli with activation of macrophages and release of fibrogenic cytokines such as TGF-β.
- Idiopathic pulmonary fibrosis is prototypic of restrictive lung diseases. It is characterized by patchy interstitial fibrosis, fibroblastic foci, and formation of cystic spaces (honeycomb lung). This histologic pattern is known as *usual interstitial pneumonia* (UIP).

### *Pneumoconioses*

*Pneumoconiosis* is a term originally coined to describe the non-neoplastic lung reaction to inhalation of mineral dusts. The term has been broadened to include diseases induced by organic as well as inorganic particulates, and some experts also regard chemical fume- and vapor-induced non-neoplastic lung diseases as pneumoconioses. The mineral dust pneumoconioses—the three most common of which result from exposure to coal dust, silica, and asbestos—nearly always result from exposure in the workplace. However, the increased risk of cancer as a result of asbestos exposure extends to family members of asbestos workers and to other persons exposed to asbestos outside of the workplace. Table 12–4 indicates the pathologic conditions associated with each mineral dust and the major industries in which the dust exposure is sufficient to produce disease.

## PATHOGENESIS

The reaction of the lung to mineral dusts depends on many variables, including size, shape, solubility, and reactivity of the particles. For example, particles greater than 5 to 10 μm are unlikely to reach distal airways, whereas particles smaller than 0.5 μm move into and out of alveoli, often without substantial deposition and injury. **Particles that are 1 to 5 μm in diameter are the most dangerous, because they get lodged at the bifurcation of the distal airways.** Coal dust is relatively inert, and large amounts must be deposited in the lungs before lung disease is clinically detectable. Silica,

**Table 12–4** Mineral Dust–Induced Lung Disease

| Agent | Disease | Exposure |
|---|---|---|
| Coal dust | Simple coal worker's pneumoconiosis: macules and nodules<br>Complicated coal worker's pneumoconiosis: PMF | Coal mining |
| Silica | Silicosis | Sandblasting, quarrying, mining, stone cutting, foundry work, ceramics |
| Asbestos | Asbestosis, pleural effusions, pleural plaques, or diffuse fibrosis; mesothelioma; carcinoma of the lung and larynx | Mining, milling, and fabrication of ores and materials; installation and removal of insulation |

PMF, progressive massive fibrosis.

asbestos, and beryllium are more reactive than coal dust, resulting in fibrotic reactions at lower concentrations. Most inhaled dust is entrapped in the mucus blanket and rapidly removed from the lung by ciliary movement. However, some of the particles become impacted at alveolar duct bifurcations, where macrophages accumulate and engulf the trapped particulates. **The pulmonary alveolar macrophage is a key cellular element in the initiation and perpetuation of lung injury and fibrosis.** Many particles activate the inflammasome and induce IL-1 production. The more reactive particles trigger the macrophages to release a number of products that mediate an inflammatory response and initiate fibroblast proliferation and collagen deposition. Some of the inhaled particles may reach the lymphatics either by direct drainage or within migrating macrophages and thereby initiate an immune response to components of the particulates and/or to self-proteins that are modified by the particles. This then leads to an amplification and extension of the local reaction. **Tobacco smoking worsens the effects of all inhaled mineral dusts,** more so with asbestos than with any other particle.

### Coal Worker's Pneumoconiosis

Worldwide dust reduction in coal mines has greatly reduced the incidence of coal dust–induced disease. The spectrum of lung findings in coal workers is wide, ranging from *asymptomatic anthracosis,* in which pigment accumulates without a perceptible cellular reaction, to *simple coal worker's pneumoconiosis* (CWP), in which accumulations of macrophages occur with little to no pulmonary dysfunction, to *complicated CWP* or *progressive massive fibrosis* (PMF), in which fibrosis is extensive and lung function is compromised (Table 12–4). Although statistics vary, it seems that less than 10% of cases of simple CWP progress to PMF. Of note PMF is a generic term that applies to a confluent fibrosing reaction in the lung; this can be a complication of any one of the pneumoconioses discussed here.

Although coal is mainly carbon, coal mine dust contains a variety of trace metals, inorganic minerals, and crystalline silica. The ratio of carbon to contaminating chemicals and minerals ("coal rank") increases from bituminous to anthracite coal; in general, anthracite mining has been associated with a higher risk of CWP.

#### MORPHOLOGY

**Pulmonary anthracosis** is the most innocuous coal-induced pulmonary lesion in coal miners and also is commonly seen in all urban dwellers and tobacco smokers. Inhaled carbon pigment is engulfed by alveolar or interstitial macrophages, which then accumulate in the connective tissue along the lymphatics, including the pleural lymphatics, or in lymph nodes.

**Simple CWP** is characterized by **coal macules** and the somewhat larger **coal nodule.** The coal macule consists of dust-laden macrophages; in addition, the nodule contains small amounts of collagen fibers arrayed in a delicate network. Although these lesions are scattered throughout the lung, the upper lobes and upper zones of the lower lobes are more heavily involved. In due course, **centrilobular emphysema** can occur. Functionally significant emphysema is more common in the United Kingdom and Europe, probably because the coal rank is higher than in the United States.

**Complicated CWP (PMF)** occurs on a background of simple CWP by coalescence of coal nodules and generally requires many years to develop. It is characterized by usually multiple, intensely blackened scars larger than 2 cm, sometimes up to 10 cm in greatest diameter. On microscopic examination the lesions are seen to consist of dense collagen and pigment (Fig. 12–18).

#### Clinical Features

CWP is usually a benign disease that produces little decrement in lung function. In those in whom PMF develops, there is increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale. Progression from CWP to PMF has been linked to a variety of conditions including coal dust exposure level and total dust burden. Unfortunately, PMF has a tendency to progress even in the absence of further exposure. Once smoking-related risk has been taken into account, there is no increased frequency of lung carcinoma in coal miners, a feature that distinguishes CWP from both silica and asbestos exposures (discussed next).

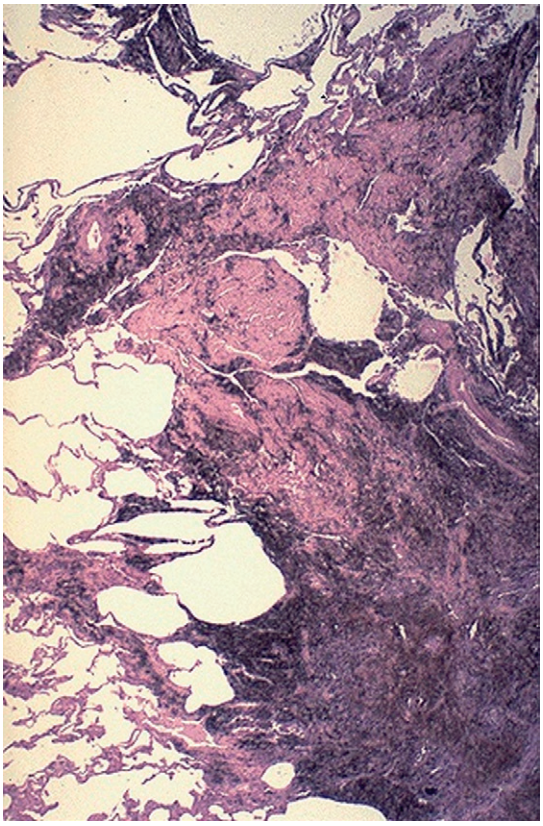

**Figure 12–18** Progressive massive fibrosis in a coal worker. Large amount of black pigment is associated with fibrosis.
*(From Klatt EC: Robbins and Cotran atlas of pathology, ed 2, Elsevier, p. 121.)*

### Silicosis

Silicosis *is currently the most prevalent chronic occupational disease in the world.* It is caused by inhalation of crystalline silica, mostly in occupational settings. Workers in several occupations but especially those involved in sandblasting and hard-rock mining are at particular risk. Silica occurs in both crystalline and amorphous forms, but crystalline forms (including quartz, cristobalite, and tridymite) are by far the most toxic and fibrogenic. Of these, quartz is most commonly implicated in silicosis. After inhalation the particles interact with epithelial cells and macrophages. *Ingested silica particles cause activation and release of mediators by pulmonary macrophages,* including IL-1, TNF, fibronectin, lipid mediators, oxygen-derived free radicals, and fibrogenic cytokines. Especially compelling is the evidence incriminating TNF, since anti-TNF monoclonal antibodies can block lung fibrosis in mice that are given silica intratracheally. *When mixed with other minerals, quartz has been observed to have a reduced fibrogenic effect.* This phenomenon is of practical importance, because quartz in the workplace is rarely pure. Thus, miners of the iron-containing ore hematite may have more quartz in their lungs than some quartz-exposed workers and yet have relatively mild lung disease, because the hematite provides a protective effect.

#### MORPHOLOGY

**Silicotic nodules** are characterized grossly in their early stages by tiny, barely palpable, discrete, pale-to-blackened (if coal dust is also present) nodules in the upper zones of the lungs (Fig. 12–19). Microscopically, the silicotic nodule demonstrates **concentrically arranged hyalinized collagen fibers** surrounding an amorphous center. The "whorled" appearance of the collagen fibers is quite distinctive for silicosis (Fig. 12–20). Examination of the nodules by **polarized microscopy reveals weakly birefringent silica** particles, primarily in the center of the nodules. As the disease progresses, the individual nodules may coalesce into hard, collagenous scars, with eventual progression to PMF. The intervening lung parenchyma may be compressed or overexpanded, and a honeycomb pattern may develop. Fibrotic lesions may also occur in the hilar lymph nodes and pleura. Sometimes, thin sheets of calcification occur in the lymph nodes and are appreciated radiographically as "eggshell" calcification (e.g., calcium surrounding a zone lacking calcification).

### Clinical Features

Silicosis usually is detected on routine chest radiographs obtained in asymptomatic workers. The radiographs typically show a fine nodularity in the upper zones of the lung, but pulmonary function is either normal or only moderately affected. Most patients do not develop shortness of breath until late in the course, after PMF is present. At this time, the disease may be progressive, even if the person is no longer exposed. Many patients with PMF develop pulmonary hypertension and cor pulmonale, as a result of chronic hypoxia-induced vasoconstriction and parenchymal destruction. The disease is slow to kill, but impaired pulmonary function may severely limit activity. *Silicosis is associated with an increased susceptibility to tuberculosis.* It is postulated that silicosis results in a depression of cell-mediated immunity, and crystalline silica may inhibit the ability of pulmonary macrophages to kill phagocytosed mycobacteria. Nodules of silicotuberculosis often contain a central zone of caseation. The relationship between silica and *lung cancer* has been a contentious issue. In 1997, based on evidence from several epidemiologic studies, the International Agency for Research on Cancer concluded that *crystalline silica* from occupational sources is carcinogenic in humans. However, this subject continues to be controversial.

### Asbestosis and Asbestos-Related Diseases

Asbestos is a family of crystalline hydrated silicates with a fibrous geometry. On the basis of epidemiologic studies, occupational exposure to asbestos is linked to (1) parenchymal interstitial fibrosis (*asbestosis*); (2) localized fibrous plaques or, rarely, diffuse fibrosis in the pleura; (3) pleural effusions; (4) lung carcinomas; (5) malignant pleural and peritoneal mesotheliomas; and (6) laryngeal carcinoma. An increased incidence of asbestos-related cancers in family members of asbestos workers has alerted the general public to the potential hazards of asbestos in the environment.

## PATHOGENESIS

Concentration, size, shape, and solubility of the different forms of asbestos dictate whether inhalation of the material will cause disease. There are two distinct forms of asbestos: **serpentine,** in which the fiber is curly and flexible, and **amphibole,** in which the fiber is straight, stiff, and brittle. Several subtypes of curly and straight asbestos fibers are recognized. The serpentine **chrysotile** accounts for most of the asbestos used in industry. Amphiboles, even though less prevalent, are more pathogenic than the serpentine chrysotile, but both types can produce asbestosis, lung cancer, and mesothelioma. The greater pathogenicity of straight and stiff amphiboles is apparently related to their structure. The serpentine chrysotiles, with their more flexible, curled structure, are likely to become impacted in the upper respiratory passages and removed by the mucociliary elevator. Those that are trapped in the lungs are gradually leached from the tissues, because they are more soluble than amphiboles. The straight, stiff amphiboles, in contrast, align themselves in the airstream and are hence delivered deeper into the lungs, where they may penetrate epithelial cells to reach the interstitium. Despite these differences, both asbestos forms are fibrogenic, and increasing exposure to either is associated with a higher incidence of all asbestos-related diseases. Asbestosis, like other pneumoconioses, causes fibrosis by a process involving interaction of particulates with lung macrophages.

In addition to cellular and fibrotic lung reactions, asbestos probably also functions as both a tumor initiator and a promoter. Some of the oncogenic effects of asbestos on the mesothelium are mediated by reactive free radicals generated by asbestos fibers, which preferentially localize in the distal lung close to the mesothelial layer. However, potentially toxic chemicals adsorbed onto the asbestos fibers undoubtedly contribute to the pathogenicity of the fibers. For example, **the adsorption of carcinogens in tobacco smoke onto asbestos fibers may well be important to the remarkable synergy between tobacco smoking and the development of lung carcinoma in asbestos workers.**

## MORPHOLOGY

**Asbestosis** is marked by diffuse pulmonary interstitial fibrosis. These changes are indistinguishable from UIP, except for the presence of **asbestos bodies,** which are seen as golden brown, fusiform or beaded rods with a translucent center.

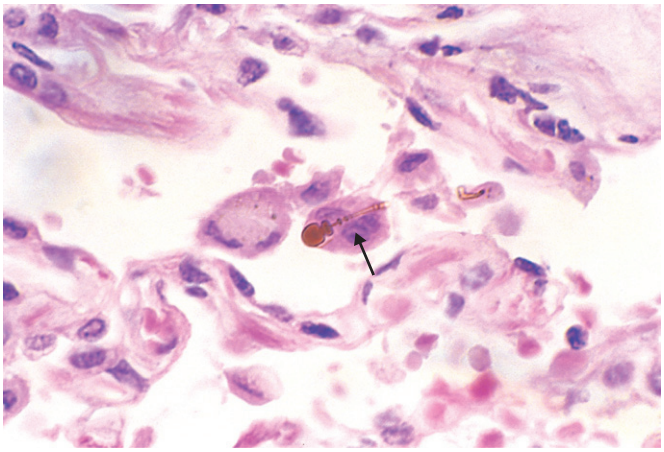

**Figure 12–21** High-power detail of an asbestos body, revealing the typical beading and knobbed ends *(arrow)*.

They consist of asbestos fibers coated with an iron-containing proteinaceous material (Fig. 12–21). Asbestos bodies apparently are formed when macrophages attempt to phagocytose asbestos fibers; the iron is derived from phagocyte ferritin. Asbestos bodies sometimes can be found in the lungs of normal persons, but usually in much lower concentrations and without an accompanying interstitial fibrosis.

In contrast with CWP and silicosis, asbestosis begins in the lower lobes and subpleurally, but the middle and upper lobes of the lungs become affected as fibrosis progresses. Contraction of the fibrous tissue distorts the normal architecture, creating enlarged air spaces enclosed within thick fibrous walls. In this way the affected regions become honeycombed. Simultaneously, fibrosis develops in the visceral pleura, causing adhesions between the lungs and the chest wall. The scarring may trap and narrow pulmonary arteries and arterioles, causing pulmonary hypertension and cor pulmonale.

**Pleural plaques** are the most common manifestation of asbestos exposure and are well-circumscribed plaques of dense collagen (Fig. 12–22), often containing calcium. They develop most frequently on the anterior and posterolateral aspects of the **parietal pleura** and over the domes of the diaphragm. They do not contain asbestos bodies, and only rarely do they occur in persons with no history or evidence of asbestos exposure. Uncommonly, asbestos exposure induces pleural effusion or diffuse pleural fibrosis.

### Clinical Features

The clinical findings in asbestosis are indistinguishable from those of any other chronic interstitial lung disease. Typically, progressively worsening dyspnea appears 10 to 20 years after exposure. The dyspnea is usually accompanied by a cough associated with production of sputum. The disease may remain static or progress to congestive heart failure, cor pulmonale, and death. Pleural plaques are usually asymptomatic and are detected on radiographs as circumscribed densities. *Both lung carcinoma and malignant mesothelioma develop in workers exposed to asbestos.* The risk of lung carcinoma is increased about five-fold for asbestos workers; the relative risk for mesothelioma, normally a very rare tumor (2 to 17 cases per 1 million persons), is more than 1000 times greater. Concomitant cigarette

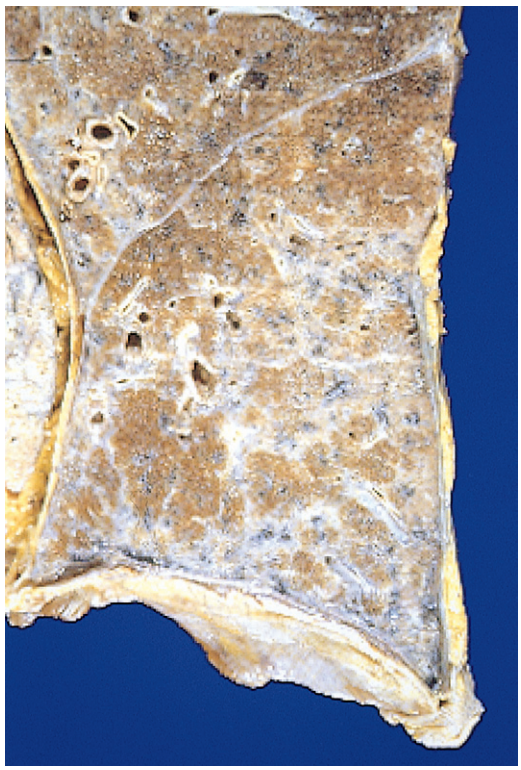

**Figure 12–22** Asbestosis. Markedly thickened visceral pleura covers the lateral and diaphragmatic surface of lung. Note also severe interstitial fibrosis diffusely affecting the lower lobe of the lung.

smoking greatly increases the risk of lung carcinoma but not that of mesothelioma. Lung or pleural cancer associated with asbestos exposure carries a particularly grim prognosis.

## SUMMARY

### Pneumoconioses

- Pneumoconioses encompass a group of chronic fibrosing diseases of the lung resulting from exposure to organic and inorganic particulates, most commonly mineral dust.
- Pulmonary alveolar macrophages play a central role in the pathogenesis of lung injury by promoting inflammation and producing reactive oxygen species and fibrogenic cytokines.
- Coal dust–induced disease varies from *asymptomatic anthracosis*, to *simple coal worker's pneumoconiosis* (coal macules or nodules, and centrilobular emphysema), to progressive massive fibrosis (PMF), manifested by increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale.
- Silicosis is the most common pneumoconiosis in the world, and crystalline silica (e.g., quartz) is the usual culprit.
- The manifestations of silicosis can range from asymptomatic silicotic nodules to PMF; persons with silicosis also have an increased susceptibility to tuberculosis. The relationship between silica exposure and subsequent lung cancer is controversial.
- Asbestos fibers come in two forms; the stiff *amphiboles* have a greater fibrogenic and carcinogenic potential than the serpentine *chrysotiles*.
- Asbestos exposure is linked with six disease processes: (1) parenchymal interstitial fibrosis (*asbestosis*); (2) localized fibrous plaques or, rarely, diffuse pleural fibrosis; (3) pleural effusions; (4) lung cancer; (5) malignant pleural and peritoneal mesotheliomas; and (6) laryngeal cancer.
- Cigarette smoking increases the risk of lung cancer in the setting of asbestos exposure; moreover, even family members of workers exposed to asbestos are at increased risk for cancer.

### *Drug- and Radiation-Induced Pulmonary Diseases*

Drugs can cause a variety of both acute and chronic alterations in respiratory structure and function. For example, *bleomycin,* an anticancer agent, causes pneumonitis and interstitial fibrosis, as a result of direct toxicity of the drug and by stimulating the influx of inflammatory cells into the alveoli. Similarly, *amiodarone,* an antiarrhythmic agent, also is associated with risk for pneumonitis and fibrosis. *Radiation pneumonitis* is a well-known complication of therapeutic irradiation of pulmonary and other thoracic tumors. *Acute radiation pneumonitis,* which typically occurs 1 to 6 months after therapy in as many as 20% of the patients, is manifested by fever, dyspnea out of proportion to the volume of irradiated lung, pleural effusion, and development of pulmonary infiltrates corresponding to the area of radiation. These signs and symptoms may resolve with corticosteroid therapy or progress to *chronic radiation pneumonitis,* associated with pulmonary fibrosis.

## Granulomatous Diseases

### *Sarcoidosis*

Although sarcoidosis is considered here as an example of a restrictive lung disease, it is important to note that sarcoidosis is a *multisystem disease of unknown etiology characterized by noncaseating granulomas in many tissues and organs.* Other diseases, including mycobacterial or fungal infections and berylliosis, sometimes also produce noncaseating granulomas; therefore, the histologic *diagnosis of sarcoidosis is one of exclusion.* Although the multisystem involvement of sarcoidosis can manifest in many clinical guises, bilateral hilar lymphadenopathy or lung involvement (or both), visible on chest radiographs, is the major presenting manifestation in most cases. Eye and skin involvement each occurs in about 25% of cases, and either may occasionally be the presenting feature of the disease.

#### Epidemiology

Sarcoidosis occurs throughout the world, affecting both genders and all races and age groups. There are, however, certain interesting epidemiologic trends, including:

- There is a consistent predilection for adults younger than 40 years of age.
- A high incidence has been noted in Danish and Swedish populations, and in the United States among African

Americans (in whom the frequency of involvement is 10 times greater than in whites).
- Sarcoidosis is one of the few pulmonary diseases with a higher prevalence among *nonsmokers.*

## ETIOLOGY AND PATHOGENESIS

Although the etiology of sarcoidosis remains unknown, several lines of evidence suggest that it is a disease of disordered immune regulation in genetically predisposed persons exposed to certain environmental agents. The role of each of these contributory influences is summarized in the following discussion.

Several **immunologic abnormalities** in sarcoidosis suggest the development of a cell-mediated response to an unidentified antigen. The process is driven by CD4+ helper T cells. These abnormalities include:

- Intra-alveolar and interstitial accumulation of CD4+ $T_H1$ cells
- Oligoclonal expansion of T cell subsets as determined by analysis of T cell receptor rearrangement
- Increases in T cell–derived $T_H1$ cytokines such as IL-2 and IFN-γ, resulting in T cell expansion and macrophage activation, respectively
- Increases in several cytokines in the local environment (IL-8, TNF, macrophage inflammatory protein-1α) that favor recruitment of additional T cells and monocytes and contribute to the formation of granulomas
- Anergy to common skin test antigens such as *Candida* or purified protein derivative (PPD), that may result from pulmonary recruitment of CD4+ T cells and consequent peripheral depletion
- Polyclonal hypergammaglobulinemia, another manifestation of $T_H$ cell dysregulation
- The role of genetic factors is suggested by familial and racial clustering of cases and association with certain human leukocyte antigen (HLA) genotypes (e.g., class I HLA-A1 and HLA-B8)

After lung transplantation, sarcoidosis recurs in the new lungs in 75% of patients. Finally, several putative "antigens" have been proposed as the inciting agent for sarcoidosis (e.g., viruses, mycobacteria, *Borrelia,* pollen), but thus far **there is no unequivocal evidence to suggest that sarcoidosis is caused by an infectious agent.**

## MORPHOLOGY

The diagnostic histopathologic feature of sarcoidosis is the **noncaseating epithelioid granuloma,** irrespective of the organ involved (Fig. 12–23). This is a discrete, compact collection of epithelioid cells rimmed by an outer zone of largely CD4+ T cells. The epithelioid cells are derived from macrophages and are characterized by abundant eosinophilic cytoplasm and vesicular nuclei. It is not uncommon to see intermixed multinucleate giant cells formed by fusion of macrophages. A thin layer of laminated fibroblasts is present peripheral to the granuloma; over time, these proliferate and lay down collagen that replaces the entire granuloma with a hyalinized scar. Two other microscopic features are sometimes seen in the granulomas: (1) **Schaumann bodies,** laminated concretions composed of calcium and proteins; and (2) **asteroid bodies,** stellate inclusions enclosed within giant cells. Their presence is not required for diagnosis of sarcoidosis—they also may occur in granulomas of other origins. Rarely, foci of central necrosis may be present in sarcoid granulomas, suggesting an infectious process. Caseation necrosis typical of tuberculosis is absent.

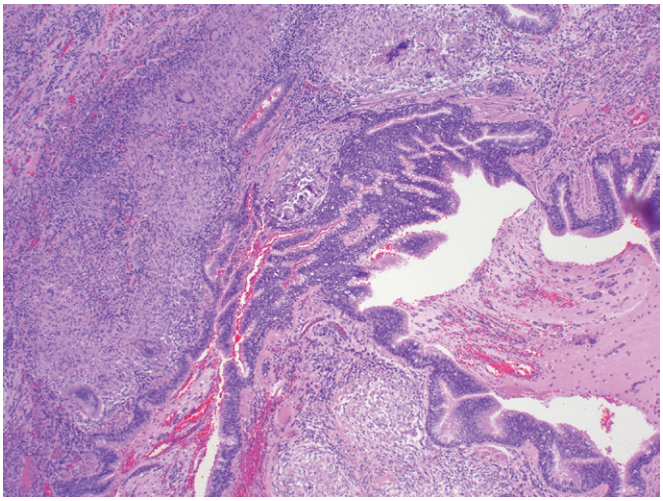

**Figure 12–23** Sarcoid. Characteristic peribronchial noncaseating granulomas with many giant cells.

The **lungs** are involved at some stage of the disease in 90% of patients. The granulomas predominantly involve the interstitium rather than air spaces, with some tendency to localize in the connective tissue around bronchioles and pulmonary venules and in the pleura ("lymphangitic" distribution). The bronchoalveolar lavage fluid contains abundant CD4+ T cells. In 5% to 15% of patients, the granulomas eventually are replaced by **diffuse interstitial fibrosis,** resulting in a so-called honeycomb lung.

Intrathoracic **hilar and paratracheal lymph nodes** are enlarged in 75% to 90% of patients, while a third present with peripheral lymphadenopathy. The nodes are characteristically painless and have a firm, rubbery texture. Unlike in tuberculosis, lymph nodes in sarcoidosis are "nonmatted" (nonadherent) and do not ulcerate.

**Skin lesions** are encountered in approximately 25% of patients. **Erythema nodosum,** the hallmark of acute sarcoidosis, consists of raised, red, tender nodules on the anterior aspects of the legs. Sarcoidal granulomas are uncommon in these lesions. By contrast, discrete painless subcutaneous nodules can also occur in sarcoidosis, and these usually reveal abundant noncaseating granulomas.

**Involvement of the eye and lacrimal glands occurs in about one fifth to one half of patients.** The ocular involvement takes the form of iritis or iridocyclitis and may be unilateral or bilateral. As a consequence, corneal opacities, glaucoma, and (less commonly) total loss of vision may develop. The posterior uveal tract also is affected, with resultant **choroiditis, retinitis,** and **optic nerve involvement.** These ocular lesions are frequently accompanied by inflammation in the lacrimal glands, with suppression of lacrimation **(sicca syndrome). Unilateral or bilateral parotitis with painful enlargement of the parotid glands**

occurs in less than 10% of patients with sarcoidosis; some go on to develop xerostomia (dry mouth). Combined uveoparotid involvement is designated **Mikulicz syndrome.**

**The spleen** may appear unaffected grossly, but in about three fourths of cases, it contains granulomas. In approximately 10%, it becomes clinically enlarged. **The liver** demonstrates microscopic granulomatous lesions, usually in the portal triads, about as often as the spleen, but only about one third of the patients demonstrate hepatomegaly or abnormal liver function. Sarcoid involvement of **bone marrow** is reported in as many as 40% of patients, although it rarely causes severe manifestations. Other findings may include hypercalcemia and hypercalciuria. These changes are not related to bone destruction but rather are caused by increased calcium absorption secondary to production of active vitamin D by the mononuclear phagocytes in the granulomas.

### Clinical Features

In many affected persons the disease is entirely asymptomatic, discovered on routine chest films as bilateral hilar adenopathy or as an incidental finding at autopsy. In others, peripheral lymphadenopathy, cutaneous lesions, eye involvement, splenomegaly, or hepatomegaly may be presenting manifestations. In about two thirds of symptomatic cases, there is gradual appearance of respiratory symptoms (shortness of breath, dry cough, or vague substernal discomfort) or constitutional signs and symptoms (fever, fatigue, weight loss, anorexia, night sweats). Because of the variable and nondiagnostic clinical features, resort is frequently made to lung or lymph node biopsies. *The presence of noncaseating granulomas is suggestive of sarcoidosis, but other identifiable causes of granulomatous inflammation must be excluded.*

Sarcoidosis follows an unpredictable course characterized by either progressive chronicity or periods of activity interspersed with remissions. The remissions may be spontaneous or initiated by steroid therapy and often are permanent. Overall, 65% to 70% of affected persons recover with minimal or no residual manifestations. Another 20% develop permanent lung dysfunction or visual impairment. Of the remaining 10% to 15%, most succumb to progressive pulmonary fibrosis and cor pulmonale.

**SUMMARY**

**Sarcoidosis**

- Sarcoidosis is a multisystem disease of unknown etiology; the diagnostic histopathologic feature is the presence of noncaseating granulomas in various tissues.
- Immunologic abnormalities include high levels of CD4+ T cells in the lung that secrete $T_H1$-dependent cytokines such as IFN-γ and IL-2 locally.
- Clinical manifestations include lymph node enlargement, eye involvement (sicca syndrome [dry eyes], iritis, or iridocyclitis), skin lesions (erythema nodosum, painless subcutaneous nodules), and visceral (liver, skin, marrow) involvement. Lung involvement occurs in 90% of cases, with formation of granulomas and interstitial fibrosis.

## *Hypersensitivity Pneumonitis*

Hypersensitivity pneumonitis is an immunologically mediated inflammatory lung disease that primarily affects the alveoli and is therefore often called *allergic alveolitis.* Most often it is an occupational disease that results from heightened sensitivity to inhaled antigens such as in moldy hay (Table 12–5). Unlike bronchial asthma, in which *bronchi are the focus of immunologically mediated injury, the damage in hypersensitivity pneumonitis occurs at the level of alveoli.* Hence, it manifests as a predominantly restrictive lung disease with decreased diffusion capacity, lung compliance, and total lung volume. The occupational exposures are diverse, but the syndromes share common clinical and pathologic findings and probably have a very similar pathophysiologic basis.

Several lines of evidence suggest that hypersensitivity pneumonitis is an immunologically mediated disease:

- Bronchoalveolar lavage specimens consistently demonstrate increased numbers of T lymphocytes of both CD4+ and CD8+ phenotype.

**Table 12–5** Selected Causes of Hypersensitivity Pneumonitis

| Syndrome | Exposure | Antigens |
|---|---|---|
| Fungal and Bacterial Antigens | | |
| Farmer's lung | Moldy hay | *Micropolyspora faeni* |
| Bagassosis | Moldy pressed sugar cane (bagasse) | Thermophilic actinomycetes |
| Maple bark disease | Moldy maple bark | *Cryptostroma corticale* |
| Humidifier lung | Cool-mist humidifier | Thermophilic actinomycetes, *Aureobasidium pullulans* |
| Malt worker's lung | Moldy barley | *Aspergillus clavatus* |
| Cheese washer's lung | Moldy cheese | *Penicillium casei* |
| Insect Products | | |
| Miller's lung | Dust-contaminated grain | *Sitophilus granarius* (wheat weevil) |
| Animal Products | | |
| Pigeon breeder's lung | Pigeon droppings | Pigeon serum proteins in droppings |
| Chemicals | | |
| Chemical worker's lung | Chemical industry | Trimellitic anhydride, isocyanates |

- Most patients with hypersensitivity pneumonitis have specific precipitating antibodies in their serum, and complement and immunoglobulins have been demonstrated within vessel walls by immunofluorescence, indicating type III hypersensitivity. The presence of noncaseating granulomas in two thirds of patients with this disorder suggests a role for type IV hypersensitivity as well.

In summary, hypersensitivity pneumonitis is an immunologically mediated response to an extrinsic antigen that involves both immune complex and delayed-type hypersensitivity reactions.

### MORPHOLOGY

The histopathologic picture in both acute and chronic forms of hypersensitivity pneumonitis includes patchy mononuclear cell infiltrates in the pulmonary interstitium, with a characteristic peribronchiolar accentuation. Lymphocytes predominate, but plasma cells and epithelioid cells also are present. In acute forms of the disease, variable numbers of neutrophils may also be seen. **Interstitial noncaseating granulomas** are present in more than two thirds of cases, usually in a peribronchiolar location (Fig. 12–24). In advanced chronic cases, diffuse interstitial fibrosis occurs.

#### Clinical Features

Hypersensitivity pneumonitis may manifest either as an *acute reaction,* with fever, cough, dyspnea, and constitutional signs and symptoms arising 4 to 8 hours after exposure, or as a *chronic disease* characterized by insidious onset of cough, dyspnea, malaise, and weight loss. With the acute form of this disease, the diagnosis is usually obvious because of the temporal relationship of symptom onset to exposure to the incriminating antigen. *If antigenic exposure is terminated after acute attacks of the disease,* complete resolution of pulmonary symptoms occurs within days. Failure to remove the inciting agent from the environment eventually results in an irreversible chronic interstitial pulmonary disease.

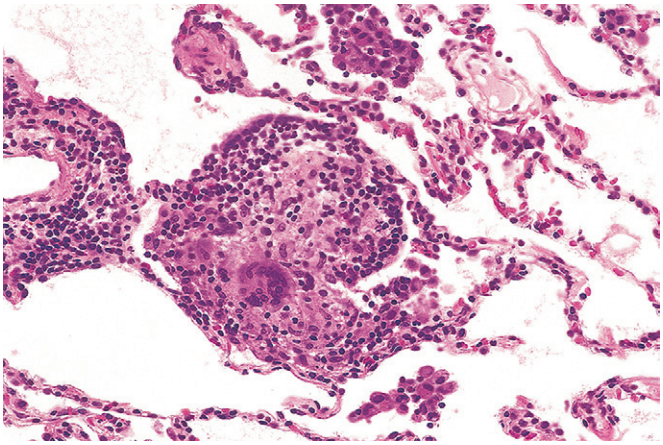

**Figure 12–24** Hypersensitivity pneumonitis, histologic appearance. Loosely formed interstitial granulomas and chronic inflammation are characteristic.

## Pulmonary Eosinophilia

A number of clinical and pathologic pulmonary entities are characterized by an infiltration and activation of eosinophils, the latter by elevated levels of alveolar IL-5. These diverse diseases generally are of immunologic origin, but the etiology is not understood. Pulmonary eosinophilia is divided into the following categories:

- *Acute eosinophilic pneumonia with respiratory failure,* characterized by rapid onset of fever, dyspnea, hypoxia, and diffuse pulmonary infiltrates on chest radiographs. The bronchoalveolar lavage fluid typically contains more than 25% eosinophils. There is prompt response to corticosteroids.
- *Simple pulmonary eosinophilia* (Loeffler syndrome), characterized by transient pulmonary lesions, eosinophilia in the blood, and a benign clinical course. The alveolar septa are thickened by an infiltrate containing eosinophils and occasional giant cells.
- *Tropical eosinophilia,* caused by infection with microfilariae and helminthic parasites
- *Secondary eosinophilia,* seen, for example, in association with asthma, drug allergies, and certain forms of vasculitis
- *Idiopathic chronic eosinophilic pneumonia,* characterized by aggregates of lymphocytes and eosinophils within the septal walls and the alveolar spaces, typically in the periphery of the lung fields, and accompanied by high fever, night sweats, and dyspnea. This is a disease of exclusion, once other causes of pulmonary eosinophilia have been ruled out.

## Smoking-Related Interstitial Diseases

The role of cigarette smoking in causing obstructive pulmonary disease (emphysema and chronic bronchitis) has been discussed. Smoking also is associated with restrictive or interstitial lung diseases. *Desquamative interstitial pneumonia* (DIP) and *respiratory bronchiolitis* are the two related examples of smoking-associated interstitial lung disease. The most striking histologic feature of DIP is the accumulation of large numbers of macrophages with abundant cytoplasm containing dusty-brown pigment (*smoker's macrophages*) in the air spaces (Fig. 12–25). The alveolar septa are thickened by a sparse inflammatory infiltrate (usually lymphocytes), and interstitial fibrosis, when present, is mild. Pulmonary functions usually show a mild restrictive abnormality, and patients with DIP typically have a good prognosis with excellent response to steroid therapy and smoking cessation. Respiratory bronchiolitis is a common histologic lesion found in smokers, characterized by the presence of pigmented intraluminal macrophages akin to those in DIP, but in a "bronchiolocentric" distribution (first- and second-order respiratory bronchioles). Mild peribronchiolar fibrosis also is seen. As with DIP, affected patients present with gradual onset of dyspnea and dry cough, and the symptoms recede with cessation of smoking.

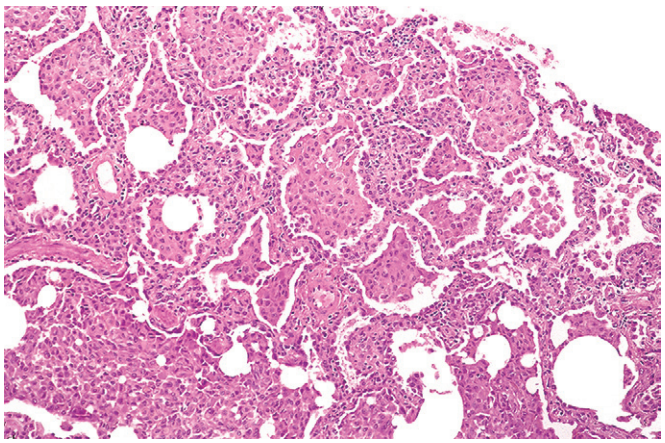

**Figure 12–25** Desquamative interstitial pneumonia. There is accumulation of large numbers of macrophages within the alveolar spaces with only slight fibrous thickening of the alveolar walls.

## PULMONARY DISEASES OF VASCULAR ORIGIN

### Pulmonary Embolism, Hemorrhage, and Infarction

Blood clots that occlude the large pulmonary arteries are almost always embolic in origin. More than 95% of all pulmonary emboli arise from thrombi within the large deep veins of the lower legs, typically originating in the popliteal vein and larger veins above it. Thromboembolism causes approximately 50,000 deaths per year in the United States. Even when not directly fatal, it can complicate the course of other diseases. The true incidence of nonfatal pulmonary embolism is not known. Some cases of embolism undoubtedly occur outside the hospital in ambulatory patients, in whom the emboli are small and clinically silent. Even among hospitalized patients, no more than one third are diagnosed before death. Autopsy data on the incidence of pulmonary embolism vary widely, ranging from 1% in the general hospitalized population, to 30% in persons dying after severe burns, trauma, or fractures.

The influences that predispose the patient to venous thrombosis in the legs are discussed in Chapter 3, but the following risk factors are paramount: (1) prolonged bedrest (particularly with immobilization of the legs); (2) surgery, especially orthopedic surgery, of knee and hip; (3) severe trauma (including burns or multiple fractures); (4) congestive heart failure; (5) in women, the period around parturition or oral contraception using birth control pills with high estrogen content; (6) disseminated cancer; and (7) primary disorders of hypercoagulability (e.g., factor V Leiden) (Chapter 3).

The pathophysiologic consequences of thromboembolism in the lung depend largely on the size of the embolus, which in turn dictates the size of the occluded pulmonary artery, and on the cardiopulmonary status of the patient. There are two important consequences of embolic pulmonary arterial occlusion: (1) an increase in pulmonary artery pressure from blockage of flow and, possibly, vasospasm caused by neurogenic mechanisms and/or release of mediators (e.g., thromboxane $A_2$, serotonin); and (2) ischemia of the downstream pulmonary parenchyma. Thus, occlusion of a *major vessel* results in a sudden increase in pulmonary artery pressure, diminished cardiac output, right-sided heart failure (*acute cor pulmonale*), or even death. Usually hypoxemia also develops, as a result of multiple mechanisms:

- *Perfusion of lung zones that have become atelectatic.* The alveolar collapse occurs in the ischemic areas because of a reduction in surfactant production and because pain associated with embolism leads to reduced movement of the chest wall; in addition, some of the pulmonary blood flow is redirected through areas of the lung that normally are hypoventilated.
- The decrease in cardiac output causes a *widening of the difference in arterial-venous oxygen saturation.*
- *Right-to-left shunting* of blood may occur through a patent foramen ovale, present in 30% of normal persons.
- If *smaller vessels* are occluded, the result is less catastrophic, and the event may even be clinically silent.

Recall that the lungs are oxygenated not only by the pulmonary arteries but also by bronchial arteries and directly from air in the alveoli. Thus, ischemic necrosis (infarction) is the exception rather than the rule, occurring in as few as 10% of patients with thromboemboli. It occurs only if there is compromise in cardiac function or bronchial circulation, or if the region of the lung at risk is underventilated as a result of underlying pulmonary disease.

#### MORPHOLOGY

The morphologic consequences of pulmonary embolism, as noted, depend on the size of the embolic mass and the general state of the circulation. A large embolus may embed in the main pulmonary artery or its major branches or lodge astride the bifurcation as a **saddle embolus** (Fig. 12–26). Death usually follows so suddenly from hypoxia or acute failure of the right side of the heart (acute cor pulmonale) that there is no time for morphologic alterations in the lung. Smaller emboli become impacted in medium-sized and small pulmonary arteries. With adequate circulation and bronchial arterial flow, the vitality of the lung parenchyma is maintained, but alveolar hemorrhage may occur as a result of ischemic damage to the endothelial cells.

With compromised cardiovascular status, as may occur with congestive heart failure, **infarction** results. The more peripheral the embolic occlusion, the higher the risk of infarction. About three fourths of all infarcts affect the lower lobes, and more than half are multiple. Characteristically, they are wedge-shaped, with their base at the pleural surface and the apex pointing toward the hilus of the lung. Pulmonary infarcts typically are hemorrhagic and appear as raised, red-blue areas in the early stages (Fig. 12–27). The adjacent pleural surface often is covered by a fibrinous exudate. If the occluded vessel can be identified, it usually is found near the apex of the infarcted area. The red cells begin to lyse within 48 hours, and the infarct pales, eventually becoming red-brown as hemosiderin is produced. In time, fibrous replacement begins at the margins as a gray-white peripheral zone and eventually converts the infarct into a scar. On histologic examination, the hallmark of fresh infarcts is coagulative necrosis of the lung parenchyma and hemorrhage.

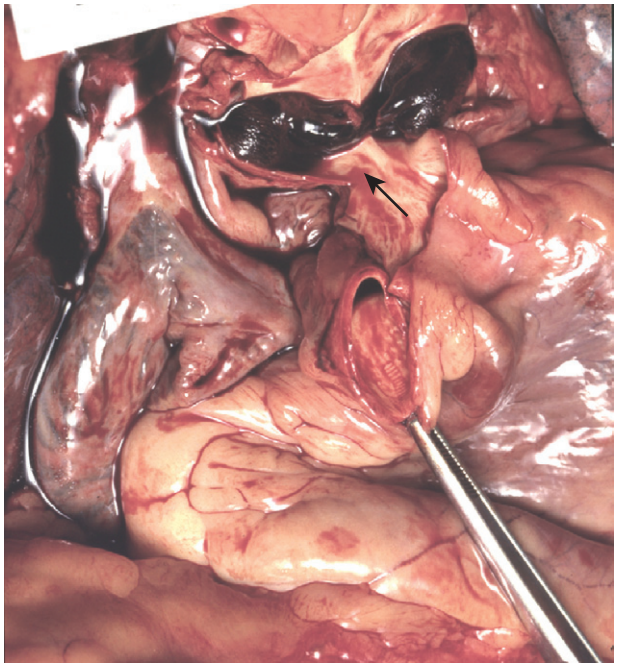

**Figure 12–26** Large saddle embolus from the femoral vein lying astride the main left and right pulmonary arteries.
*(Courtesy of Dr. Linda Margraf, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

### Clinical Features

The clinical consequences of pulmonary thromboembolism are summarized as follows:

- Most pulmonary emboli (60% to 80%) are clinically silent because they are small; the embolic mass is rapidly removed by fibrinolytic activity, and the bronchial circulation sustains the viability of the affected lung parenchyma until this is accomplished.
- In 5% of cases, sudden death, acute right-sided heart failure (acute cor pulmonale), or cardiovascular collapse (shock) may occur typically when more than 60% of the total pulmonary vasculature is obstructed by a large embolus or multiple simultaneous small emboli. Massive pulmonary embolism is one of the few causes of literally instantaneous death, even before the person experiences chest pain or dyspnea.
- Obstruction of relatively small to medium pulmonary branches (10% to 15% of cases) that behave as end arteries causes pulmonary infarction when some element of circulatory insufficiency is present. Typically, persons who sustain such infarction manifest dyspnea.
- In a small but significant subset of patients (accounting for less than 3% of cases), recurrent multiple emboli lead to pulmonary hypertension, chronic right-sided heart strain (chronic cor pulmonale), and, in time, pulmonary vascular sclerosis with progressively worsening dyspnea.

Emboli usually resolve after the initial acute event. They contract, and endogenous fibrinolytic activity may cause total lysis of the thrombus. However, in the presence of an underlying predisposing factor, a small, innocuous embolus may presage a larger one, and *patients who have experienced one pulmonary embolism have a 30% chance of developing a second.* Prophylactic therapy may include anticoagulation, early ambulation for postoperative and postparturient patients, application of elastic stockings, intermittent pneumatic calf compression, and isometric leg exercises for bedridden patients. Patients with pulmonary embolism are given anticoagulation therapy. Patients with massive pulmonary embolism are candidates for thrombolytic therapy.

Nonthrombotic forms of pulmonary embolism include several uncommon but potentially lethal forms, such as air, fat, and amniotic fluid embolism (Chapter 3). Intravenous drug abuse often is associated with foreign body embolism in the pulmonary microvasculature; the presence of magnesium trisilicate (talc) in the intravenous mixture elicits a granulomatous response within the interstitium or pulmonary arteries. Involvement of the interstitium may lead to fibrosis, while the latter leads to pulmonary hypertension. Residual talc crystals can be demonstrated within the granulomas using polarized light. Bone marrow embolism (presence of hematopoietic and fat elements within pulmonary circulation) can occur after massive trauma and in patients with bone infarction secondary to sickle cell anemia.

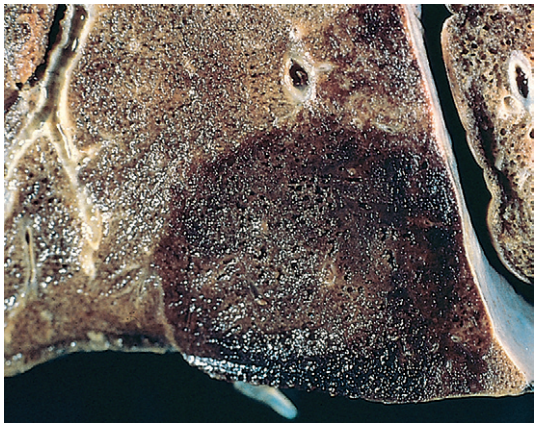

**Figure 12–27** A small, roughly wedge-shaped hemorrhagic pulmonary infarct of recent occurrence.

## SUMMARY

### Pulmonary Embolism

- Almost all large pulmonary artery thrombi are embolic in origin, usually arising from the deep veins of the lower leg.
- Risk factors include prolonged bedrest, leg surgery, severe trauma, CHF, use of oral contraceptives (especially those with high estrogen content), disseminated cancer, and genetic causes of hypercoagulability.
- The vast majority (60% to 80%) of emboli are clinically silent, a minority (5%) cause acute cor pulmonale, shock, or death (typically from large "saddle emboli"), and the remaining cause pulmonary infarction.
- Risk of recurrence is high.

## Pulmonary Hypertension

The pulmonary circulation normally is one of low resistance; pulmonary blood pressures are only about one eighth of systemic pressures. Pulmonary hypertension (when mean pulmonary pressures reach one fourth or more of systemic levels) is most often *secondary* to a decrease in the cross-sectional area of the pulmonary vascular bed, or to increased pulmonary vascular blood flow. The causes of secondary pulmonary hypertension include:

- *Chronic obstructive or interstitial lung disease,* which is accompanied by destruction of lung parenchyma and consequent reduction in alveolar capillaries. This causes increased pulmonary arterial resistance and secondarily, elevated arterial pressure.
- *Recurrent pulmonary emboli.* Presence of these emboli leads to a reduction in the functional cross-sectional area of the pulmonary vascular bed, leading in turn to increased vascular resistance.
- *Antecedent heart disease,* for example, *mitral stenosis,* which increases left atrial pressure, leading to higher pulmonary venous pressures, and ultimately pulmonary arterial hypertension. *Congenital left-to-right shunts* are another cause of secondary pulmonary hypertension.

Uncommonly, pulmonary hypertension exists even though all known causes of increased pulmonary pressure have been excluded; this is referred to as *primary,* or *idiopathic, pulmonary arterial hypertension.* Of these, the vast majority of cases are sporadic, and only 6% are familial with an autosomal dominant mode of inheritance.

### PATHOGENESIS

According to current thinking, **pulmonary endothelial cell and/or vascular smooth muscle dysfunction** is the probable underlying basis for most forms of pulmonary hypertension.

- In states of **secondary pulmonary hypertension,** endothelial cell dysfunction arises as a consequence of the underlying disorder (e.g., shear and mechanical injury due to increased blood flow in left-to-right shunts, or biochemical injury produced by fibrin in recurrent thromboembolism). Endothelial cell dysfunction reduces production of vasodilatory agents (e.g., nitric oxide, prostacyclin) while increasing synthesis of vasoconstrictive mediators like endothelin. In addition, there is production of growth factors and cytokines that induce the migration and replication of vascular smooth muscle and elaboration of extracellular matrix.
- In **primary pulmonary hypertension,** especially in the uncommon **familial form,** the TGF-β signaling pathway has emerged as a key mediator of endothelial and smooth muscle dysfunction. Specifically, germline mutations of **bone morphogenetic protein receptor type 2** (BMPR-2), a cell surface molecule that binds to a variety of TGF-β pathway ligands, have been demonstrated in 50% of familial cases. The *BMPR2* gene product is inhibitory in its effects on proliferation; hence, loss-of-function mutations of this gene result in abnormal vascular endothelial and pulmonary smooth muscle proliferation. The endothelial proliferations in these instances usually are **monoclonal,** reiterating the genetic basis of their origin. However, not all persons with germline mutations of *BMPR2* develop primary pulmonary hypertension, suggesting the existence of **modifier genes** that probably affect penetrance of this particular phenotype.
- Studies on sporadic forms of primary pulmonary hypertension point to a possible role for the **serotonin transporter gene** (*5HTT*). Specifically, pulmonary smooth muscle cells from some patients with primary pulmonary hypertension demonstrate increased proliferation on exposure to serotonin or serum. Genetic polymorphisms of *5HTT* that lead to enhanced expression of the transporter protein on vascular smooth muscle are postulated to cause their proliferation.

### MORPHOLOGY

Vascular alterations in all forms of pulmonary hypertension (primary and secondary) involve the entire arterial tree (Fig. 12–28) and include (1) in the **main elastic arteries,** atheromas similar to those in systemic atherosclerosis; (2) **in medium-sized muscular arteries,** proliferation of myointimal cells and smooth muscle cells, causing thickening of the intima and media with narrowing of the lumina; and (3) in **smaller arteries and arterioles,** thickening, medial hypertrophy, and reduplication of the internal and external elastic membranes. In these vessels, the wall thickness may exceed the diameter of the lumen, which is sometimes narrowed to the point of near-obliteration. Persons with idiopathic pulmonary arterial hypertension have characteristic **plexiform lesions,** in which endothelial proliferation forms multiple lumina within small arteries where they branch from a medium-sized artery.

### Clinical Features

Secondary pulmonary hypertension may develop at any age. The clinical features reflect the underlying disease, usually pulmonary or cardiac, with accentuation of respiratory insufficiency and right-sided heart strain. Primary pulmonary hypertension, on the other hand, is almost always encountered in young adults, more commonly women, and is marked by fatigue, syncope (particularly on exercise), dyspnea on exertion, and sometimes chest pain. Eventually severe respiratory insufficiency and cyanosis develop, and death usually results from right-sided heart failure (decompensated cor pulmonale) within 2 to 5 years of diagnosis. Some amelioration of the respiratory distress can be achieved by vasodilators and antithrombotic agents, and continuous prostacyclin infusions may prolong life (months to years), but without lung transplantation the prognosis is still grim.

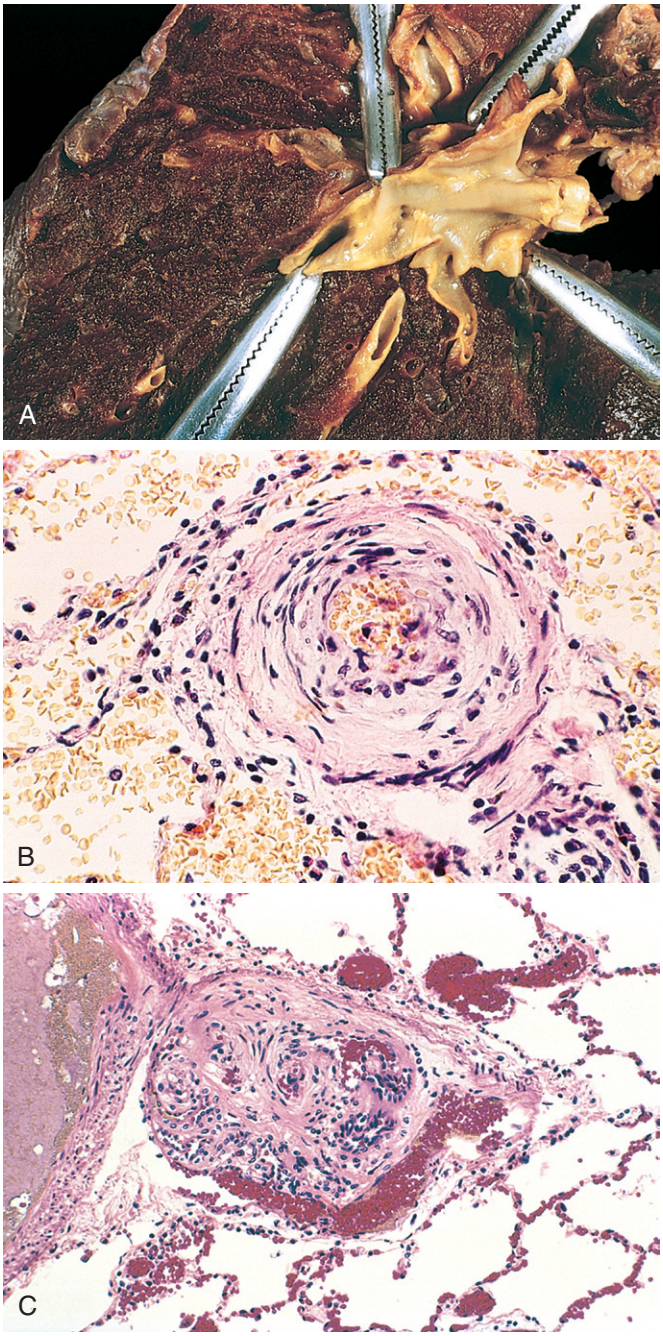

**Figure 12–28** Vascular changes in pulmonary hypertension. **A,** Gross photograph of atheroma, a finding usually limited to large vessels. **B,** Marked medial hypertrophy. **C,** Plexiform lesion characteristic of advanced pulmonary hypertension seen in small arteries.

## Diffuse Alveolar Hemorrhage Syndromes

While there may be several "secondary" causes of pulmonary hemorrhage (necrotizing bacterial pneumonia, passive venous congestion, bleeding diathesis), the diffuse alveolar hemorrhage syndromes constitute a group of "primary" immune-mediated diseases that manifest as the *triad of hemoptysis, anemia, and diffuse pulmonary infiltrates.*

### *Goodpasture Syndrome*

Goodpasture syndrome, the prototype disorder of this group, is an uncommon but intriguing condition characterized by a *proliferative, usually rapidly progressive, glomerulonephritis* (Chapter 13) and *hemorrhagic interstitial pneumonitis.* Both the renal and the pulmonary lesions are caused by antibodies targeted against the noncollagenous domain of the α3 chain of collagen IV. These antibodies can be detected in the serum of more than 90% of persons with Goodpasture syndrome.

#### MORPHOLOGY

The lungs are heavy, with areas of red-brown consolidation, due to **diffuse alveolar hemorrhage.** Microscopic examination demonstrates focal necrosis of alveolar walls associated with intra-alveolar hemorrhages, fibrous thickening of the septa, and hypertrophic type II pneumocytes. Presence of **hemosiderin,** both within macrophages and extracellularly, is characteristic, indicating earlier episode(s) of hemorrhage (Fig. 12–29). The characteristic **linear pattern of immunoglobulin deposition** (usually IgG, sometimes IgA or IgM) that is the hallmark diagnostic finding in renal biopsy specimens (Chapter 13) also may be seen along the alveolar septa.

Plasmapheresis and immunosuppressive therapy have markedly improved the once-dismal prognosis for this disease. Plasma exchange removes offending antibodies, and immunosuppressive drugs inhibit antibody production. With severe renal disease, renal transplantation is eventually required.

### *Idiopathic Pulmonary Hemosiderosis*

Idiopathic pulmonary hemosiderosis is a rare disease of uncertain etiology that has pulmonary manifestations and histologic features similar to those of Goodpasture syndrome, but there is no associated renal disease or circulating anti-basement membrane antibody. Most cases occur in children, although the disease is reported in adults as well, who have a better prognosis. With steroid and immunosuppressive therapy, survival has markedly improved from the historical 2.5 years; thus, an immune-mediated etiology is postulated.

### *Pulmonary Angiitis and Granulomatosis (Wegener Granulomatosis)*

More than 80% of patients with Wegener granulomatosis (WG) develop upper respiratory or pulmonary manifestations at some time in the course of their disease. It is described in Chapter 9. Here we list the salient pulmonary features. The lung lesions are characterized by a combination of necrotizing vasculitis ("angiitis") and parenchymal necrotizing granulomatous inflammation. The manifestations of WG can include both upper respiratory symptoms (chronic sinusitis, epistaxis, nasal perforation) and pulmonary signs and symptoms (cough, hemoptysis, chest pain). PR3-ANCAs are present in close to 95% of cases (Chapter 9).

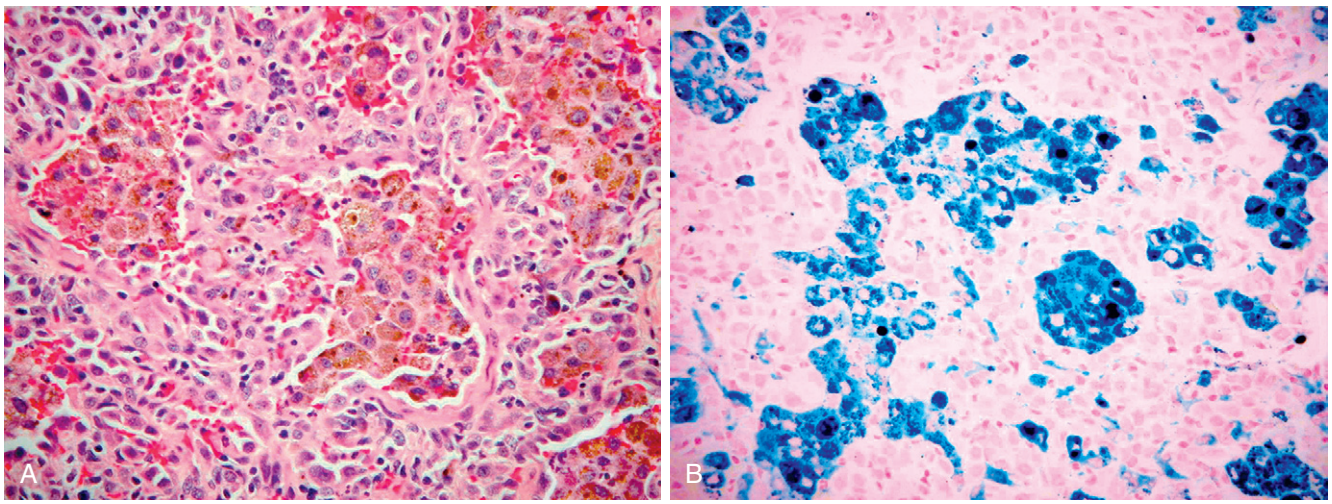

**Figure 12–29 A,** Lung biopsy specimen from a person with a diffuse alveolar hemorrhage syndrome demonstrates large numbers of intra-alveolar hemosiderin-laden macrophages on a background of thickened fibrous septa. **B,** The tissue has been stained with Prussian blue, an iron stain that highlights the abundant intracellular hemosiderin.

## PULMONARY INFECTIONS

Pulmonary infections in the form of pneumonia are responsible for one sixth of all deaths in the United States. This is not surprising because (1) the epithelial surfaces of the lung are constantly exposed to many liters of air containing various levels of microbial contaminants; (2) nasopharyngeal flora are regularly aspirated during sleep, even by healthy persons; and (3) other common lung diseases render the lung parenchyma vulnerable to virulent organisms. The normal lung parenchyma remains sterile because of the efficiency of a number of immune and nonimmune defense mechanisms in the respiratory system, extending from the nasopharynx all the way into the alveolar air spaces (Fig. 12–30).

Despite the multitude of defense mechanisms, "chinks in the armor" do exist, predisposing even healthy persons to infections. Defects in innate immunity (including neutrophil and complement defects) and humoral immunodeficiency typically lead to an increased incidence of infections with pyogenic bacteria. For example, it has been shown that patients with mutations in MyD88, the adaptor protein downstream of many Toll-like receptors (microbial sensors in innate immunity), are extremely susceptible to severe necrotizing pneumococcal infections (and not most other infections). On the other hand, defects in $T_H1$ cell–mediated immunity lead mainly to increased infections with intracellular microbes such as atypical mycobacteria. In addition to inherited anomalies, several aspects of lifestyle interfere with host immune defense mechanisms and facilitate infections. For example, cigarette smoke compromises mucociliary clearance and pulmonary macrophage activity, and alcohol not only impairs cough and epiglottic reflexes, thereby increasing the risk of aspiration, but also interferes with neutrophil mobilization and chemotaxis.

*Pneumonia can be very broadly defined as any infection in the lung.* The clinical presentation may be as an acute, fulminant clinical disease or as a chronic disease with a more protracted course. The histologic spectrum of pneumonia may range from a fibrinopurulent alveolar exudate seen in acute bacterial pneumonias, to mononuclear interstitial infiltrates in viral and other atypical pneumonias, to granulomas and cavitation seen in many of the chronic pneumonias. Acute bacterial pneumonias can manifest as one of two anatomic and radiographic patterns, referred to as *bronchopneumonia* and *lobar pneumonia*. Bronchopneumonia implies a patchy distribution of inflammation that generally involves more than one lobe (Fig. 12–31). This pattern results from an initial infection of the bronchi and bronchioles with extension into the adjacent alveoli. By contrast, in lobar pneumonia the contiguous air spaces of part or all of a lobe are homogeneously filled with an exudate that can be visualized on radiographs as a lobar or segmental consolidation (Fig. 12–31). *Streptococcus pneumoniae* is responsible for more than 90% of lobar pneumonias. The anatomic distinction between lobar pneumonia and bronchopneumonia can often become blurry, because (1) many organisms cause infections that can manifest with either of the two patterns of distribution, and (2) confluent bronchopneumonia can be hard to distinguish radiologically from lobar pneumonia. *Therefore, it is best to classify pneumonias either by the specific etiologic agent or, if no pathogen can be isolated, by the clinical setting in which infection occurs.* The latter approach considerably narrows the list of suspected pathogens for administering empirical antimicrobial therapy. Pneumonia can arise in seven distinct clinical settings, and the implicated pathogens are reasonably specific to each category, as summarized in Table 12–6.

### Community-Acquired Acute Pneumonias

Most community-acquired acute pneumonias are bacterial in origin. Not uncommonly, the infection follows a viral upper respiratory tract infection. The onset usually is abrupt, with high fever, shaking chills, pleuritic chest pain,

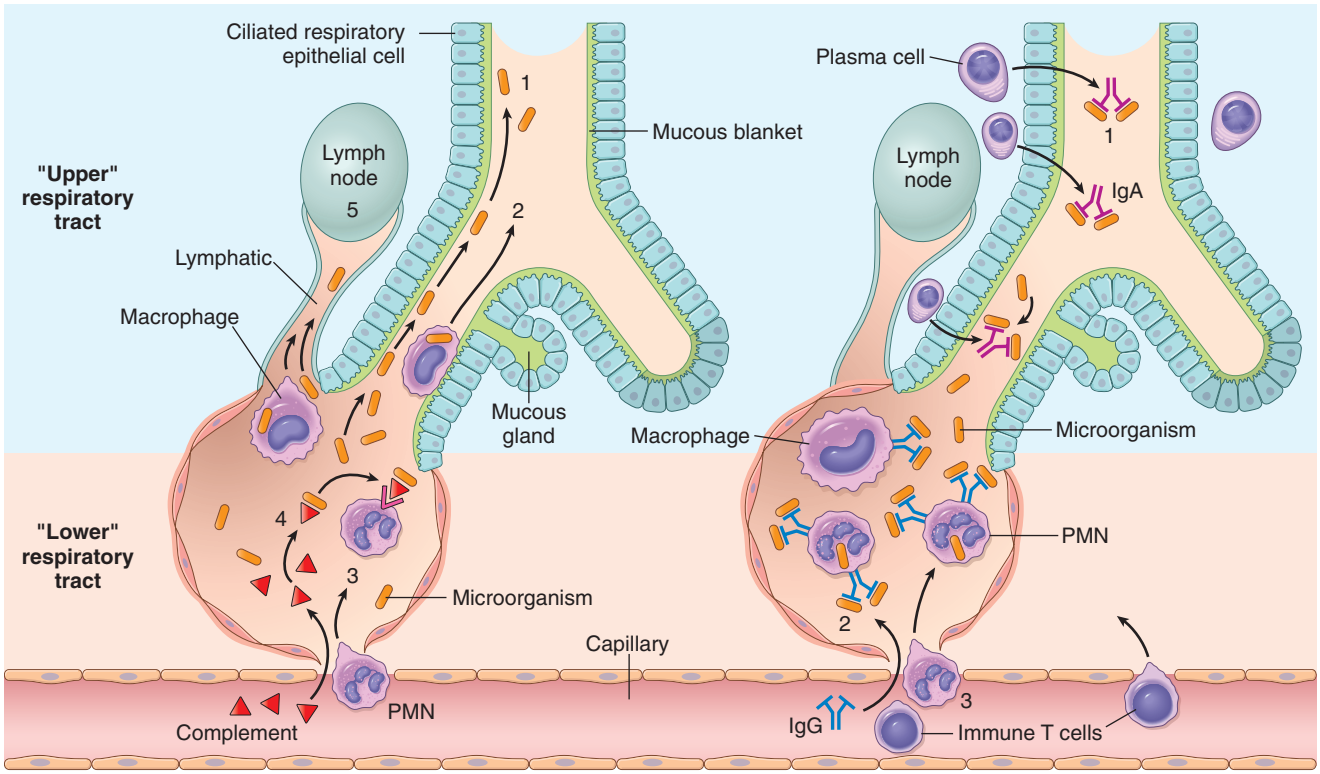

**Figure 12–30** Lung defense mechanisms. **A,** Innate defenses against infection: *1*, In the normal lung, removal of microbial organisms depends on entrapment in the mucous blanket and removal by means of the mucociliary elevator; *2*, phagocytosis by alveolar macrophages that can kill and degrade organisms and remove them from the air spaces by migrating onto the mucociliary elevator; or *3*, phagocytosis and killing by neutrophils recruited by macrophage factors. *4*, Serum complement may enter the alveoli and be activated by the alternative pathway to provide the opsonin C3b, which enhances phagocytosis. *5*, Organisms, including those ingested by phagocytes, may reach the draining lymph nodes to initiate immune responses. **B,** Additional mechanisms operate after development of adaptive immunity. *1*, Secreted IgA can block attachment of the microorganism to epithelium in the upper respiratory tract. *2*, In the lower respiratory tract, serum antibodies (IgM, IgG) are present in the alveolar lining fluid. They activate complement more efficiently by the classic pathway, yielding C3b *(not shown)*. In addition, IgG is opsonic. *3*, The accumulation of immune T cells is important for controlling infections by viruses and other intracellular microorganisms. PMN, polymorphonuclear cell.

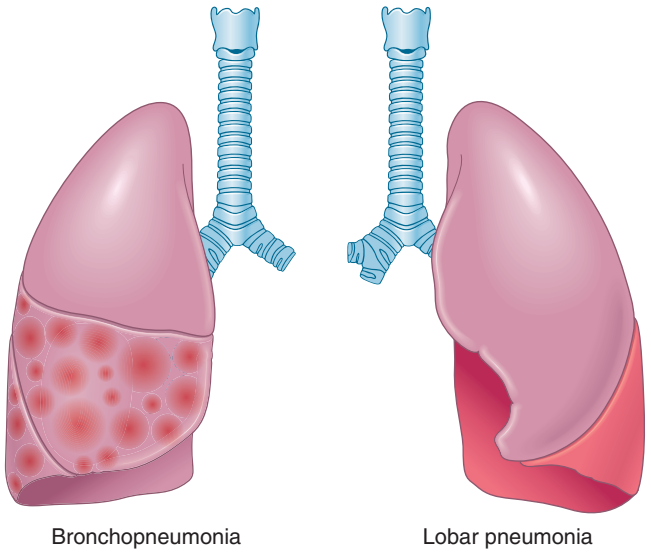

**Figure 12–31** The anatomic distribution of bronchopneumonia and lobar pneumonia.

and a productive mucopurulent cough; occasional patients may have hemoptysis. *S. pneumoniae* (i.e., the pneumococcus) is the most common cause of community-acquired acute pneumonia; hence, pneumococcal pneumonia is discussed as the prototype for this subgroup.

### Streptococcus pneumoniae *Infections*

*Pneumococcal infections occur with increased frequency in three subsets of patients:* (1) those with underlying chronic diseases such as CHF, COPD, or diabetes; (2) those with either congenital or acquired immunoglobulin defects (e.g., with the acquired immune deficiency syndrome [AIDS]); and (3) those with decreased or absent splenic function (e.g., sickle cell disease or after splenectomy). In the last group, such infections are more likely because the spleen contains the largest collection of phagocytes and is therefore the major organ responsible for removing pneumococci from the blood. The spleen is also an important organ for production of antibodies against polysaccharides, which are the dominant protective antibodies against encapsulated bacteria.

## MORPHOLOGY

With pneumococcal lung infection, either pattern of pneumonia, lobar or bronchopneumonia, may occur; the latter is much more prevalent at the extremes of age. Regardless of the distribution of the pneumonia, because pneumococcal lung infections usually are acquired by aspiration of pharyngeal flora (20% of adults harbor *S. pneumoniae* in the throat), the lower lobes or the right middle lobe is most frequently involved.

In the era before antibiotics, pneumococcal pneumonia involved entire or almost entire lobes and evolved through four stages: **congestion, red hepatization, gray hepatization,** and **resolution.** Early antibiotic therapy alters or halts this typical progression.

During the first stage, that of **congestion,** the affected lobe(s) is (are) heavy, red, and boggy; histologically, vascular congestion can be seen, with proteinaceous fluid, scattered neutrophils, and many bacteria in the alveoli. Within a few days, the stage of **red hepatization** ensues, in which the lung lobe has a liver-like consistency; the alveolar spaces are packed with neutrophils, red cells, and fibrin (Fig. 12–32, *A*). In the next stage, **gray hepatization,** the lung is dry, gray, and firm, because the red cells are lysed, while the fibrinosuppurative exudate persists within the alveoli (Fig. 12–33; see also Fig. 12–32, *B*). **Resolution** follows in uncomplicated cases, as exudates within the alveoli are enzymatically digested to produce granular, semifluid debris that is resorbed, ingested by macrophages, coughed up, or organized by fibroblasts growing into it (Fig. 12–32, *C*). The pleural reaction (fibrinous or fibrinopurulent **pleuritis**) may similarly resolve or undergo organization, leaving fibrous thickening or permanent adhesions.

In the **bronchopneumonic** pattern, foci of inflammatory consolidation are distributed in patches throughout one or several lobes, most frequently bilateral and basal. Well-developed lesions up to 3 or 4 cm in diameter are slightly elevated and are gray-red to yellow; confluence of these foci may occur in severe cases, producing the appearance of a lobar consolidation. The lung substance immediately surrounding areas of consolidation is usually hyperemic and edematous, but the large intervening areas are generally normal. Pleural involvement is less common than in lobar pneumonia. Histologically, the reaction consists of focal suppurative exudate that fills the bronchi, bronchioles, and adjacent alveolar spaces.

With appropriate therapy, complete restitution of the lung is the rule for both forms of pneumococcal pneumonia, but in occasional cases complications may occur: (1) tissue destruction and necrosis may lead to **abscess** formation; (2) suppurative material may accumulate in the pleural cavity, producing an **empyema;** (3) organization of the intra-alveolar exudate may convert areas of the lung into solid fibrous tissue; and (4) bacteremic dissemination may lead to **meningitis, arthritis,** or **infective endocarditis.** Complications are much more likely with serotype 3 pneumococci.

Examination of gram-stained sputum is an important step in the diagnosis of acute pneumonia. The presence of numerous neutrophils containing the typical gram-positive, lancet-shaped diplococci is good evidence of pneumococcal pneumonia; of note, however, *S. pneumoniae* is a part of the endogenous flora, so false-positive results may be obtained by this method. Isolation of pneumococci from blood cultures is more specific. During early phases of illness, blood cultures may be positive in 20% to 30% of persons with pneumonia. Whenever possible, antibiotic sensitivity should be determined. Commercial pneumococcal vaccines containing capsular polysaccharides from the common serotypes of the bacteria are available, and their proven efficacy mandates their use in persons at risk for pneumococcal infections (see earlier).

### *Pneumonias Caused by Other Important Pathogens*

Other organisms commonly implicated in community-acquired acute pneumonias include the following.

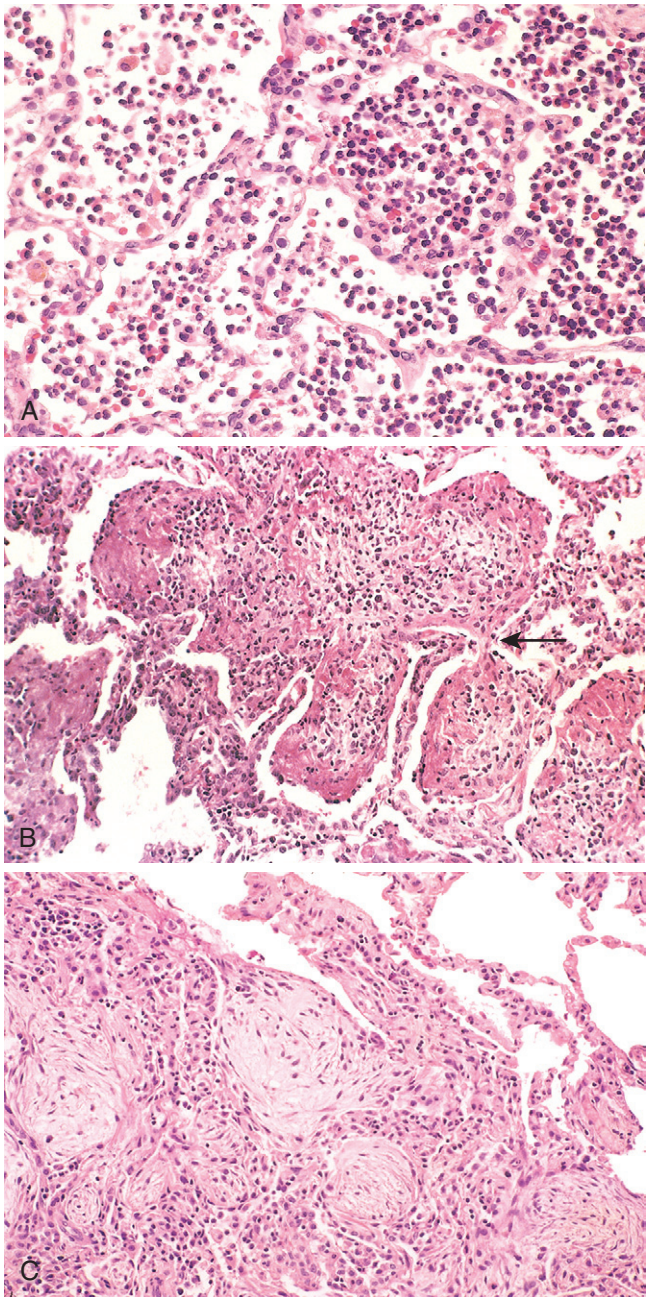

**Figure 12–32 A,** Acute pneumonia. The congested septal capillaries and extensive neutrophil exudation into alveoli correspond to early red hepatization. Fibrin nets have not yet formed. **B,** Early organization of intra-alveolar exudates, seen in areas to be streaming through the pores of Kohn (*arrow*). **C,** Advanced organizing pneumonia, featuring transformation of exudates to fibromyxoid masses richly infiltrated by macrophages and fibroblasts.

*Haemophilus influenzae*

- Both *encapsulated* and *unencapsulated* forms are important causes of community-acquired pneumonias. The former can cause a particularly life-threatening form of pneumonia in children, often after a respiratory viral infection.
- Adults at risk for developing infections include those with chronic pulmonary diseases such as chronic bronchitis, cystic fibrosis, and bronchiectasis. *H. influenzae is the most common bacterial cause of acute exacerbation of COPD.*
- Encapsulated *H. influenzae* type b was formerly an important cause of epiglottitis and suppurative meningitis in children, but vaccination against this organism in infancy has significantly reduced the risk.

*Moraxella catarrhalis*

- *M. catarrhalis* is being increasingly recognized as a cause of bacterial pneumonia, especially in elderly persons.
- It is the second most common bacterial cause of acute exacerbation of COPD in adults.
- Along with *S. pneumoniae* and *H. influenzae, M. catarrhalis* constitutes one of the three most common causes of otitis media (infection of the middle ear) in children.

*Staphylococcus aureus*

- *S. aureus* is an important cause of secondary bacterial pneumonia in children and healthy adults after viral respiratory illnesses (e.g., measles in children and influenza in both children and adults).
- Staphylococcal pneumonia is associated with a high incidence of complications, such as lung abscess and empyema.
- Staphylococcal pneumonia occurring in association with right-sided staphylococcal endocarditis is a serious complication of *intravenous drug abuse.*
- It is also an important cause of nosocomial pneumonia (discussed later).

*Klebsiella pneumoniae*

- *K. pneumoniae* is the most frequent cause of gram-negative bacterial pneumonia.

**Figure 12–33** Gross view of lobar pneumonia with gray hepatization. The lower lobe is uniformly consolidated.

- *Klebsiella*-related pneumonia frequently afflicts debilitated and malnourished persons, particularly *chronic alcoholics.*
- Thick and gelatinous sputum is characteristic, because the organism produces an abundant viscid capsular polysaccharide, which the patient may have difficulty coughing up.

*Pseudomonas aeruginosa*

- Although discussed here with community-acquired pathogens because of its association with infections in cystic fibrosis, *P. aeruginosa* most commonly is seen in nosocomial settings (discussed later).
- *Pseudomonas* pneumonia also is common in persons who are neutropenic, usually secondary to chemotherapy; in victims of extensive burns; and in patients requiring mechanical ventilation.
- *P. aeruginosa* has a propensity to invade blood vessels at the site of infection, with consequent extrapulmonary spread; *Pseudomonas* bacteremia is a fulminant disease, with death often occurring within a matter of days.
- Histologic examination reveals coagulative necrosis of the pulmonary parenchyma with organisms invading the walls of necrotic blood vessels (*Pseudomonas* vasculitis).

*Legionella pneumophila*

- *L. pneumophila* is the agent of Legionnaire disease, an eponym for the epidemic and sporadic forms of pneumonia caused by this organism. Pontiac fever is a related self-limited upper respiratory tract infection caused by *L. pneumophila,* without pneumonic symptoms.
- *L. pneumophila* flourishes in artificial aquatic environments, such as water-cooling towers and within the tubing system of domestic (potable) water supplies. The mode of transmission is thought to be either inhalation of aerosolized organisms or aspiration of contaminated drinking water.
- *Legionella* pneumonia is common in persons with some predisposing condition such as cardiac, renal, immunologic, or hematologic disease. *Organ transplant recipients are particularly susceptible.*
- *Legionella* pneumonia can be quite severe, frequently requiring hospitalization, and immunosuppressed persons may have a fatality rate of 30% to 50%.
- Rapid diagnosis is facilitated by demonstration of *Legionella* antigens in the urine or by a positive fluorescent antibody test on sputum samples; culture remains the standard diagnostic modality. PCR-based tests can be used on bronchial secretions in atypical cases.

## Community-Acquired Atypical Pneumonias

The term *primary atypical pneumonia* initially was applied to an acute febrile respiratory disease characterized by patchy inflammatory changes in the lungs, largely confined to the alveolar septa and pulmonary interstitium. The designation *atypical* denotes the moderate amounts of sputum, absence of physical findings of consolidation, only moderate elevation of white cell count, and lack of alveolar exudates. Atypical pneumonia is caused by a variety of organisms, *Mycoplasma pneumoniae* being the most common. *Mycoplasma* infections are particularly common among children and young adults. They occur sporadically or as local epidemics in closed communities (schools, military camps, prisons). Other etiologic agents are *viruses,* including influenza types A and B, the respiratory syncytial viruses, human metapneumovirus, adenovirus, rhinoviruses, rubeola virus, and varicella virus, and *Chlamydia pneumoniae* and *Coxiella burnetii* (the agent of Q fever) (Table 12–6). Nearly all of these agents can also cause a primarily upper respiratory tract infection ("common cold").

The common pathogenetic mechanism is attachment of the organisms to the respiratory epithelium followed by necrosis of the cells and an inflammatory response. When the process extends to alveoli, there is usually *interstitial* inflammation, but some outpouring of fluid into alveolar spaces may also occur, so that on chest films the changes may mimic those of bacterial pneumonia. Damage to and denudation of the respiratory epithelium inhibits mucociliary clearance and predisposes to secondary bacterial infections. Viral infections of the respiratory tract are well known for this complication. More serious lower respiratory tract infection is more likely to occur in infants, elderly persons, malnourished patients, alcoholics, and immunosuppressed persons. Not surprisingly, viruses and mycoplasmas frequently are involved in outbreaks of infection in hospitals.

### MORPHOLOGY

Regardless of cause, the morphologic patterns in atypical pneumonias are similar. The process may be patchy, or it may involve whole lobes bilaterally or unilaterally. Macroscopically, the affected areas are red-blue, congested, and subcrepitant. On histologic examination, the **inflammatory reaction is largely confined within the walls of the alveoli** (Fig. 12–34). The septa are widened and edematous; they usually contain a mononuclear inflammatory infiltrate of lymphocytes, histiocytes, and, occasionally, plasma cells. In contrast with bacterial pneumonias, alveolar spaces in atypical pneumonias are remarkably free of cellular exudate. In severe cases, however, full-blown diffuse alveolar damage with hyaline membranes may develop. In less severe, uncomplicated cases, subsidence of the disease is followed by reconstitution of the native architecture. Superimposed bacterial infection, as expected, results in a mixed histologic picture.

### Clinical Features

The clinical course of primary atypical pneumonia is extremely varied. It may masquerade as a severe upper respiratory tract infection or "chest cold" that goes undiagnosed, or it may manifest as a fulminant, life-threatening infection in immunocompromised patients. The initial presentation usually is that of an acute, nonspecific febrile illness characterized by fever, headache, and malaise and, later, cough with minimal sputum. Because the edema and exudation are both in a strategic position to cause an alveolocapillary block, there may be *respiratory distress seemingly out of proportion to the physical and radiographic findings.*

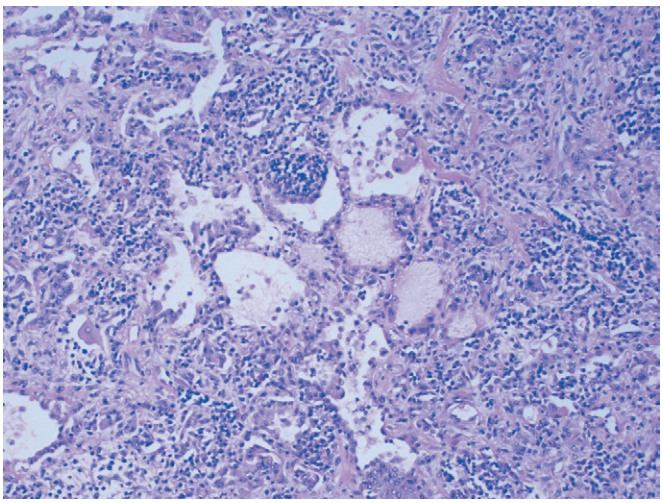

**Figure 12–34** Viral pneumonia. The thickened alveolar walls are infiltrated with lymphocytes and some plasma cells, which are spilling over into alveolar spaces. Note focal alveolar edema in the *center* and early fibrosis at *upper right*.

Identifying the causative agent can be difficult. Tests for *Mycoplasma* antigens and polymerase chain reaction (PCR) testing for *Mycoplasma* DNA are available. As a practical matter, patients with community-acquired pneumonia for which a bacterial agent seems unlikely are treated with a macrolide antibiotic effective against *Mycoplasma* and *Chlamydia pneumoniae,* because these are the most common pathogens producing treatable disease.

### *Influenza Infections*

Perhaps no other communicable disorder causes as much public distress in the developed world as the threat of an influenza epidemic. The influenza virus is a single-stranded RNA virus, bound by a nucleoprotein that determines the virus type—A, B, or C. The spherical surface of the virus is a lipid bilayer containing the viral hemagglutinin and neuraminidase, which determine the subtype (e.g., H1N1, H3N2). Host antibodies to the hemagglutinin and neuraminidase prevent and ameliorate, respectively, future infection with the influenza virus. The type A viruses infect humans, pigs, horses, and birds and are the major cause of *pandemic* and *epidemic* influenza infections. Epidemics of influenza occur through mutations of the hemagglutinin and neuraminidase antigens that allow the virus to escape most host antibodies (*antigenic drift*). Pandemics, which last longer and are more widespread than epidemics, may occur when both the hemagglutinin and neuraminidase are replaced through recombination of RNA segments with those of animal viruses, making all animals susceptible to the new influenza virus (*antigenic shift*). Commercially available influenza vaccines provide reasonable protection against the disease, especially in vulnerable infants and elderly persons. A particular subtype of avian influenza—"bird flu," caused by strain H5N1—has caused massive outbreaks in domesticated poultry in parts of Southeast Asia in the last several years; this strain is particularly dangerous, since it has the potential to "jump" to humans and thereby cause a worldwide influenza pandemic.

### *Influenza Virus Type A/H1N1 Infection*

In March 2009, a novel swine-origin influenza A virus, strain H1N1, was identified, which spread in the United States and worldwide, leading to a pandemic affecting more than half a million patients, with more than 6200 deaths by November 2009.

Most patients have only a self-limiting illness, with viral replication limited to pharynx and tracheobronchial tree. Pneumonia occurs in severe disease. Comorbid conditions such as obesity, heart disease, and COPD are seen in fatal cases. Unlike the usual seasonal influenza in which older patients are more at risk of dying, the H1N1 pandemic killed only a few patients over 60 years of age, suggesting that immunity is achieved with previous exposure. Pathologic findings at autopsy include acute tracheobronchitis, bronchiolitis, diffuse alveolar damage, pulmonary thrombosis, and alveolar hemorrhage. In addition, approximately half have bacterial superinfection.

## SUMMARY

### Acute Pneumonias

- *S. pneumoniae* (the pneumococcus) is the most common cause of community-acquired acute pneumonia, and the distribution of inflammation is usually lobar.
- Morphologically, lobar pneumonias evolve through four stages: congestion, red hepatization, gray hepatization, and resolution.
- Other common causes of acute pneumonias in the community include *H. influenzae* and *M. catarrhalis* (both associated with acute exacerbations of COPD), *S. aureus* (usually secondary to viral respiratory infections), *K. pneumoniae* (observed in patients who are chronic alcoholics), *P. aeruginosa* (seen in persons with cystic fibrosis, in burn victims, and in patients with neutropenia), and *L. pneumophila,* seen particularly in organ transplant recipients.
- In contrast with acute pneumonias, *atypical pneumonias* are characterized by respiratory distress out of proportion to the clinical and radiologic signs, and by inflammation that is predominantly confined to alveolar septa, with generally clear alveoli.
- The most common causes of atypical pneumonias include those caused by *M. pneumoniae*, viruses including influenza viruses types A and B, human metapneumovirus, *C. pneumoniae*, and *C. burnetii* (agent of Q fever).

## Hospital-Acquired Pneumonias

Nosocomial, or hospital-acquired, pneumonias are defined as pulmonary infections acquired in the course of a hospital stay. The specter of nosocomial pneumonia places an immense burden on the burgeoning costs of health care, in addition to the expected adverse impact on illness outcome. Nosocomial infections are common in hospitalized persons with severe underlying disease, those who are immunosuppressed, or those on prolonged antibiotic regimens. Those on mechanical ventilation represent a particularly high-risk group, and infections acquired in this setting

are given the distinctive designation *ventilator-associated pneumonia.* Gram-negative rods (members of Enterobacteriaceae and *Pseudomonas* spp.) and *S. aureus* are the most common isolates; unlike with community-acquired pneumonias, *S. pneumoniae* is not a major pathogen in nosocomial infections.

## Aspiration Pneumonia

Aspiration pneumonia occurs in debilitated patients or those who aspirate gastric contents either while unconscious (e.g., after a stroke) or during repeated vomiting. These patients have abnormal gag and swallowing reflexes that facilitate aspiration. The resultant pneumonia is partly chemical, resulting from the extremely irritating effects of the gastric acid, and partly bacterial. Although it is commonly assumed that anaerobic bacteria predominate, more recent studies implicate aerobes more commonly than anaerobes (Table 12–6). This type of pneumonia is often necrotizing, pursues a fulminant clinical course, and is a frequent cause of death in persons predisposed to aspiration. In those who survive, abscess formation is a common complication. Microaspiration, by contrast, occurs in many people, especially those with gastro-esophageal reflux, and may exacerbate other lung diseases but does not lead to pneumonia.

## Lung Abscess

*Lung abscess* refers to a localized area of suppurative necrosis within the pulmonary parenchyma, resulting in the formation of one or more large cavities. The term *necrotizing pneumonia* has been used to describe a similar process resulting in multiple small cavitations; necrotizing pneumonia often coexists or evolves into lung abscess, making this distinction somewhat arbitrary. The causative organism may be introduced into the lung by any of the following mechanisms:

- *Aspiration of infective material* from carious teeth or infected sinuses or tonsils, particularly likely during oral surgery, anesthesia, coma, or alcoholic intoxication and in debilitated patients with depressed cough reflexes
- *Aspiration of gastric contents,* usually accompanied by infectious organisms from the oropharynx
- *As a complication of necrotizing bacterial pneumonias,* particularly those caused by *S. aureus, Streptococcus pyogenes, K. pneumoniae, Pseudomonas* spp., and, rarely, type 3 pneumococci. Mycotic infections and bronchiectasis may also lead to lung abscesses.
- *Bronchial obstruction,* particularly with bronchogenic carcinoma obstructing a bronchus or bronchiole. Impaired drainage, distal atelectasis, and aspiration of blood and tumor fragments all contribute to the development of abscesses. An abscess may also form within an excavated necrotic portion of a tumor.
- *Septic embolism,* from septic thrombophlebitis or from infective endocarditis of the right side of the heart
- In addition, lung abscesses may result from *hematogenous spread of bacteria* in disseminated pyogenic infection. This occurs most characteristically in staphylococcal bacteremia and often results in multiple lung abscesses.

*Anaerobic bacteria are present in almost all lung abscesses,* sometimes in vast numbers, and they are the exclusive isolates in one third to two thirds of cases. The most frequently encountered anaerobes are commensals normally found in the oral cavity, principally species of *Prevotella, Fusobacterium, Bacteroides, Peptostreptococcus,* and microaerophilic streptococci.

### MORPHOLOGY

Abscesses range in diameter from a few millimeters to large cavities 5 to 6 cm across. The localization and number of abscesses depend on their mode of development. Pulmonary abscesses resulting from aspiration of infective material are much **more common on the right side** (with its more vertical airways) than on the left, and most are single. On the right side, they tend to occur in the posterior segment of the upper lobe and in the apical segments of the lower lobe, because these locations reflect the probable course of aspirated material when the patient is recumbent. Abscesses that develop in the course of pneumonia or bronchiectasis commonly are multiple, basal, and diffusely scattered. Septic emboli and abscesses arising from hematogenous seeding are commonly multiple and may affect any region of the lungs.

As the focus of suppuration enlarges, it almost inevitably ruptures into airways. Thus, the contained exudate may be partially drained, producing an air-fluid level on radiographic examination. Occasionally, abscesses rupture into the pleural cavity and produce bronchopleural fistulas, the consequence of which is **pneumothorax** or **empyema.** Other complications arise from embolization of septic material to the brain, giving rise to meningitis or brain abscess. On histologic examination, as expected with any abscess, the suppurative focus is surrounded by variable amounts of fibrous scarring and mononuclear infiltration (lymphocytes, plasma cells, macrophages), depending on the chronicity of the lesion.

### Clinical Features

The manifestations of a lung abscess are much like those of bronchiectasis and include a prominent cough that usually yields copious amounts of foul-smelling, purulent, or sanguineous sputum; occasionally, hemoptysis occurs. Spiking fever and malaise are common. Clubbing of the fingers, weight loss, and anemia may all occur. Infective abscesses occur in 10% to 15% of patients with bronchogenic carcinoma; thus, when a lung abscess is suspected in an older person, underlying carcinoma must be considered. Secondary amyloidosis (Chapter 4) may develop in chronic cases. Treatment includes antibiotic therapy and, if needed, surgical drainage. Overall, the mortality rate is in the range of 10%.

## Chronic Pneumonias

Chronic pneumonia most often is a localized lesion in an immunocompetent person, with or without regional lymph node involvement. There is typically granulomatous inflammation, which may be due to bacteria (e.g., *M. tuberculosis*) or fungi. In immunocompromised patients,

such as those with debilitating illness, on immunosuppressive regimens, or with human immunodeficiency virus (HIV) infection (see below), systemic dissemination of the causative organism, accompanied by widespread disease, is the usual presentation. Tuberculosis is by far the most important entity within the spectrum of chronic pneumonias; the World Health Organization (WHO) estimates that tuberculosis causes 6% of all deaths worldwide, *making it the most common cause of death resulting from a single infectious agent.*

### *Tuberculosis*

Tuberculosis is a communicable chronic granulomatous disease caused by *Mycobacterium tuberculosis.* It usually involves the lungs but may affect any organ or tissue in the body. Typically, the centers of tubercular granulomas undergo *caseous necrosis.*

#### Epidemiology

Among medically and economically deprived persons throughout the world, tuberculosis remains a leading cause of death. It is estimated that 1.7 billion people are infected worldwide, with 8 to 10 million new cases and 3 million deaths per year. In the Western world, deaths from tuberculosis peaked in 1800 and steadily declined throughout the 1800s and 1900s. However, in 1984 the decline in new cases stopped abruptly, a change that resulted from the increased incidence of tuberculosis in HIV-infected persons. As a consequence of intensive public health surveillance and tuberculosis prophylaxis among immunosuppressed persons, the incidence of tuberculosis in U.S.-born persons has declined since 1992. Currently, it is estimated that about 25,000 new cases with active tuberculosis arise in the United States annually, and nearly 40% of these are in immigrants from countries where tuberculosis is highly prevalent.

Tuberculosis flourishes under conditions of poverty, crowding, and chronic debilitating illness. Similarly, elderly persons, with their weakened defenses, are vulnerable. In the United States, tuberculosis is a disease of the elderly, the urban poor, patients with AIDS, and members of minority communities. African Americans, Native Americans, the Inuit (from Alaska), Hispanics, and immigrants from Southeast Asia have higher attack rates than those typical for other segments of the population. *Certain disease states also increase the risk:* diabetes mellitus, Hodgkin lymphoma, chronic lung disease (particularly silicosis), chronic renal failure, malnutrition, alcoholism, and immunosuppression. In areas of the world where HIV infection is prevalent, *it has become the single most important risk factor for the development of tuberculosis.*

It is important that *infection* be differentiated from *disease.* Infection implies seeding of a focus with organisms, which may or may not cause clinically significant tissue damage (i.e., disease). Although other routes may be involved, most infections are acquired by direct person-to-person transmission of airborne droplets of organisms from an active case to a susceptible host. In most persons, an asymptomatic focus of pulmonary infection appears that is self-limited, although uncommonly, primary tuberculosis may result in the development of fever and pleural effusions. Generally, the only evidence of infection, if any remains, is a tiny, telltale fibrocalcific nodule at the site of the infection. Viable organisms may remain dormant in such loci for decades, and possibly for the life of the host. Such persons are infected but do not have active disease and therefore cannot transmit organisms to others. Yet when their immune defenses are lowered, the infection may reactivate to produce communicable and potentially life-threatening disease.

Infection with *M. tuberculosis* typically leads to the development of delayed hypersensitivity, which can be detected by the tuberculin (Mantoux) test. About 2 to 4 weeks after the infection has begun, intracutaneous injection of 0.1 mL of PPD induces a visible and palpable induration (at least 5 mm in diameter) that peaks in 48 to 72 hours. Sometimes, more PPD is required to elicit the reaction, and unfortunately, in some responders, the standard dose may produce a large, necrotizing lesion. *A positive tuberculin skin test result* signifies cell-mediated hypersensitivity to tubercular antigens. It does not differentiate between infection and disease. A well-recognized limitation of this test is that *false-negative reactions (or skin test anergy) may be produced by certain viral infections, sarcoidosis, malnutrition, Hodgkin lymphoma, immunosuppression, and (notably) overwhelming active tuberculous disease.* False-positive reactions may result from infection by atypical mycobacteria.

About 80% of the population in certain Asian and African countries is tuberculin-positive. In contrast, in 1980, 5% to 10% of the U.S. population was positive, indicating the marked difference in rates of exposure to the tubercle bacillus. In general, 3% to 4% of previously unexposed persons acquire active tuberculosis during the first year after "tuberculin conversion," and no more than 15% do so thereafter. Thus, *only a small fraction of those who contract an infection develop active disease.*

#### Etiology

Mycobacteria are slender rods that are acid-fast (i.e., they have a high content of complex lipids that readily bind the Ziehl-Neelsen [carbol fuchsin] stain and subsequently stubbornly resist decolorization). *M. tuberculosis hominis* is responsible for most cases of tuberculosis; the reservoir of infection typically is found in persons with active pulmonary disease. Transmission usually is direct, by inhalation of airborne organisms in aerosols generated by expectoration or by exposure to contaminated secretions of infected persons. Oropharyngeal and intestinal tuberculosis contracted by drinking milk contaminated with *Mycobacterium bovis* infection is now rare in developed nations, but it is still seen in countries with tuberculous dairy cows and sales of unpasteurized milk. Other mycobacteria, particularly *Mycobacterium avium complex,* are much less virulent than *M. tuberculosis* and rarely cause disease in immunocompetent persons. However, they cause disease in 10% to 30% of patients with AIDS.

## PATHOGENESIS

The pathogenesis of tuberculosis in the previously **unexposed immunocompetent** person is centered on the development of a targeted cell-mediated immunity that confers **resistance** to the organism and results

in development of **tissue hypersensitivity** to tubercular antigens. The pathologic features of tuberculosis, such as caseating granulomas and cavitation, are the result of the destructive tissue hypersensitivity that is part and parcel of the host immune response. Because the effector cells for both processes are the same, the appearance of tissue hypersensitivity also signals the acquisition of immunity to the organism. The sequence of events from inhalation of the infectious inoculum to containment of the primary focus is illustrated in Fig. 12–35, A and B and is outlined next:

- Once a virulent strain of mycobacteria gains entry into the macrophage endosomes (a process mediated by several macrophage receptors, including the macrophage mannose receptor and complement receptors that recognize several components of the mycobacterial cell walls), the organisms are able to inhibit normal microbicidal responses by preventing the fusion of the lysosomes with the phagocytic vacuole. The prevention of phagolysosome formation allows unchecked mycobacterial proliferation. Thus, the earliest phase of primary tuberculosis (in the first 3 weeks) in the nonsensitized patient is characterized by bacillary proliferation within the pulmonary alveolar macrophages and air spaces, with resulting bacteremia and seeding of multiple sites. **Despite the bacteremia, most persons at this stage are asymptomatic or have a mild flu-like illness.**
- The genetic makeup of the patient may influence the course of the disease. In some people with polymorphisms of the **NRAMP1** (**n**atural **r**esistance–**a**ssociated **m**acrophage **p**rotein **1**) gene, the disease may progress from this point without development of an effective immune response. NRAMP1 is a transmembrane ion transport protein found in endosomes and lysosomes that is believed to contribute to microbial killing.
- The development of **cell-mediated immunity** occurs approximately 3 weeks after exposure. Processed mycobacterial antigens reach the draining lymph nodes and are presented to CD4 T cells by dendritic cells and macrophages. Under the influence of macrophage-secreted IL-12, CD4+ T cells of the $T_H1$ subset are generated that are capable of secreting IFN-γ.
- **IFN-γ released by the CD4+ T cells of the $T_H1$ subset is crucial in activating macrophages.** Activated macrophages, in turn, release a variety of mediators and upregulate expression of genes with important downstream effects, including (1) TNF, which is responsible for recruitment of monocytes, which in turn undergo activation and differentiation into the "epithelioid histiocytes"

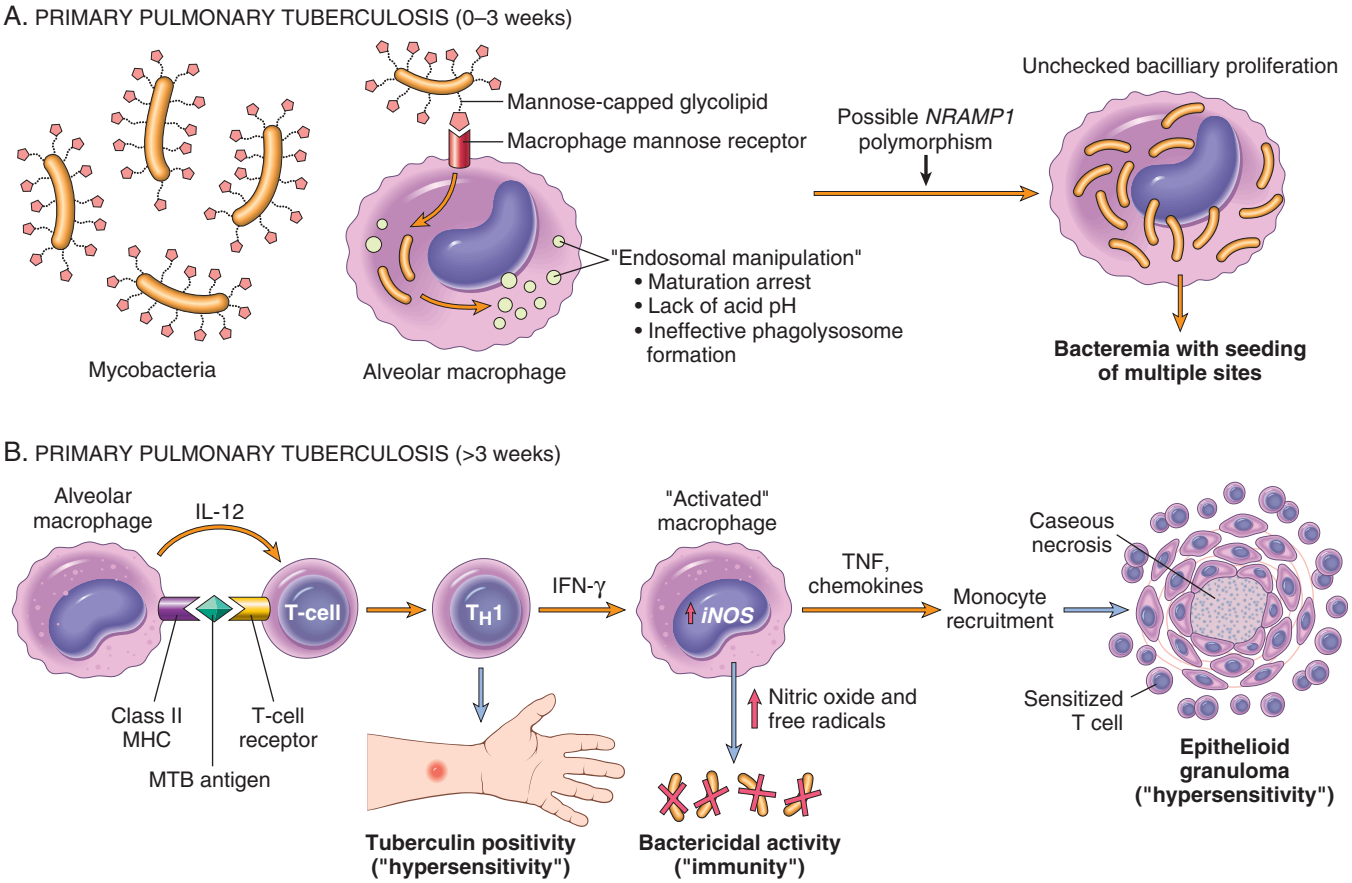

**Figure 12–35** Sequence of events in the natural history of primary pulmonary tuberculosis. This sequence commences with inhalation of virulent strains of *Mycobacterium* and culminates in the development of immunity and delayed hypersensitivity to the organism. **A,** Events occurring in the first 3 weeks after exposure. **B,** Events thereafter. The development of resistance to the organism is accompanied by conversion to a positive result on tuberculin skin testing. Cells and bacteria are not drawn to scale. IFN-γ, interferon γ; iNOS, inducible nitric oxide synthase; MHC, major histocompatibility complex; MTB, *Mycobacterium tuberculosis*; *NRAMP1*, gene encoding natural resistance–associated macrophage protein 1; TNF, tumor necrosis factor.

that characterize the granulomatous response; (2) expression of the **inducible nitric oxide synthase** *(iNOS)* gene, which results in elevated **nitric oxide** levels at the site of infection, with excellent antibacterial activity; and (3) generation of reactive oxygen species, which can have antibacterial activity. You will recall that nitric oxide is a powerful oxidizing agent that results in generation of reactive nitrogen intermediates and other free radicals capable of oxidative destruction of several mycobacterial constituents, from cell wall to DNA.

- Defects in any of the steps of a $T_H1$ response (including IL-12, IFN-γ, TNF, or nitric oxide production) result in poorly formed granulomas, absence of resistance, and disease progression. Persons with inherited mutations in any component of the $T_H1$ pathway are extremely susceptible to infections with mycobacteria.

**In summary, immunity to a tubercular infection is primarily mediated by $T_H1$ cells, which stimulate macrophages to kill bacteria.** This immune response, while largely effective, comes at the cost of hypersensitivity and the accompanying tissue destruction. Reactivation of the infection or reexposure to the bacilli in a previously sensitized host results in rapid mobilization of a defensive reaction but also increased tissue necrosis. Just as hypersensitivity and resistance appear in parallel, so, too, the loss of hypersensitivity (indicated by tuberculin negativity in a tuberculin-positive patient) may be an ominous sign that resistance to the organism has faded.

### Primary Tuberculosis

*Primary tuberculosis is the form of disease that develops in a previously unexposed and therefore unsensitized patient.* Elderly persons and profoundly immunosuppressed patients may lose their sensitivity to the tubercle bacillus, so they may develop primary tuberculosis more than once. About 5% of those newly infected acquire significant disease.

#### MORPHOLOGY

In countries in which bovine tuberculosis and infected milk have largely disappeared, primary tuberculosis almost always begins in the lungs. Typically, the inhaled bacilli implant in the distal air spaces of the lower part of the upper lobe or the upper part of the lower lobe, usually close to the pleura. As sensitization develops, a 1- to 1.5-cm area of gray-white inflammatory consolidation emerges, the **Ghon focus.** In most cases the center of this focus undergoes caseous necrosis. Tubercle bacilli, either free or within phagocytes, travel in lymph drainage to the regional nodes, which also often caseate. **This combination of parenchymal lesion and nodal involvement** is referred to as the Ghon complex (Fig. 12–36). During the first few weeks, there is also lymphatic and hematogenous dissemination to other parts of the body. In approximately 95% of cases, development of cell-mediated immunity controls the infection. Hence, the Ghon complex undergoes progressive fibrosis, often followed by radiologically detectable calcification **(Ranke complex),** and despite seeding of other organs, no lesions develop.

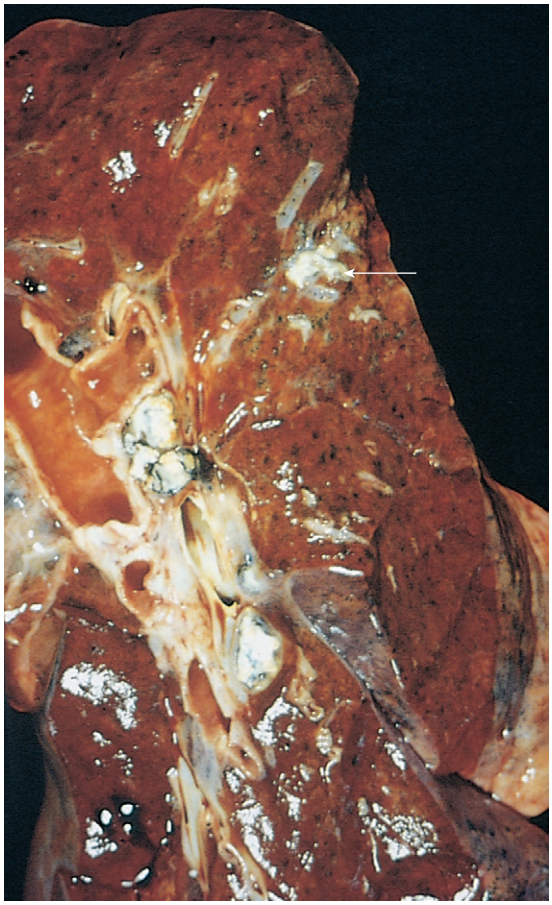

**Figure 12–36** Primary pulmonary tuberculosis, Ghon complex. The gray-white parenchymal focus *(arrow)* is under the pleura in the *lower part* of the upper lobe. Hilar lymph nodes with caseation are seen on the *left.*

On histologic examination, sites of active involvement are marked by a characteristic granulomatous inflammatory reaction that forms both caseating and noncaseating granulomas (Fig. 12–37, *A* to *C*), which consist of epithelioid histiocytes and multinucleate giant cells.

The major consequences of primary tuberculosis are that (1) it induces hypersensitivity and increased resistance; (2) the foci of scarring may harbor viable bacilli for years, perhaps for life, and thus be the nidus for *reactivation* at a later time when host defenses are compromised; and (3) uncommonly, it may lead to *progressive primary tuberculosis.* This complication occurs in patients who are immunocompromised or have nonspecific impairment of host defenses, as characteristic in malnourished children or in elderly persons. Certain racial groups, such as the Inuit, also are more prone to the development of progressive primary tuberculosis. The incidence of progressive primary tuberculosis is particularly high in HIV-positive patients with an advanced degree of immunosuppression (i.e., CD4+ counts below 200 cells/μL). Immunosuppression results in an inability to mount a CD4+ T cell–mediated immunologic reaction that would contain the primary focus; because hypersensitivity and resistance are most often concomitant factors, the lack of a tissue hypersensitivity reaction results

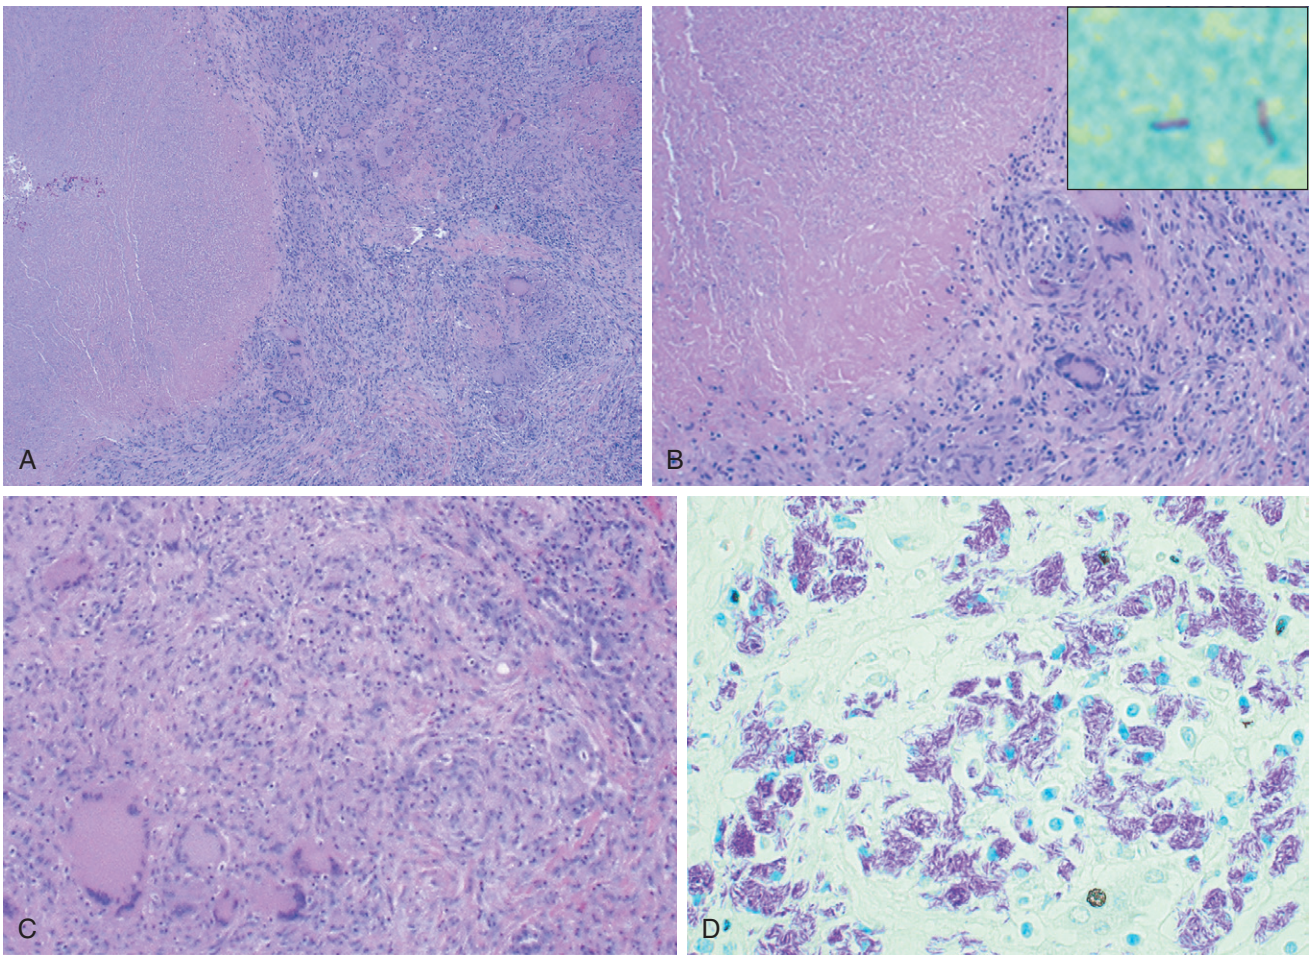

**Figure 12–37** The morphologic spectrum of tuberculosis. **A** and **B,** A characteristic tubercle at low magnification **(A)** and at higher power **(B)** shows central granular caseation surrounded by epithelioid and multinucleate giant cells. This is the usual response seen in persons who have developed cell-mediated immunity to the organism. *Inset:* Acid-fast stain shows rare positive organisms. **C,** Occasionally, even in immunocompetent patients, tubercular granulomas may not show central caseation; hence, irrespective of the presence or absence of caseous necrosis, use of special stains for acid-fast organisms is indicated when granulomas are present. **D,** In this specimen from an immunosuppressed patient, sheets of foamy macrophages packed with mycobacteria are seen (acid-fast stain).

in the absence of the characteristic caseating granulomas (*nonreactive tuberculosis*) (Fig. 12–37, *D*).

### Secondary Tuberculosis (Reactivation Tuberculosis)

*Secondary tuberculosis is the pattern of disease that arises in a previously sensitized host.* It may follow shortly after primary tuberculosis, but more commonly it arises from reactivation of dormant primary lesions many decades after initial infection, particularly when host resistance is weakened. It also may result from exogenous reinfection because of waning of the protection afforded by the primary disease or because of a large inoculum of virulent bacilli. Whatever the source of the organism, only a few patients (less than 5%) with primary disease subsequently develop secondary tuberculosis.

*Secondary pulmonary tuberculosis is classically localized to the apex of one or both upper lobes.* The reason is obscure but may relate to high oxygen tension in the apices. Because of the preexistence of hypersensitivity, the bacilli excite a prompt and marked tissue response that tends to wall off the focus. As a result of this localization, the regional lymph nodes are less prominently involved early in the disease than they are in primary tuberculosis. On the other hand, *cavitation occurs readily in the secondary form,* leading to erosion into and dissemination along airways. Such changes become an important source of infectivity, because the patient now produces sputum containing bacilli.

Secondary tuberculosis should always be an important consideration in HIV-positive patients who present with pulmonary disease. Of note, *although an increased risk of tuberculosis exists at all stages of HIV disease, the manifestations differ depending on the degree of immunosuppression.* For example, patients with less severe immunosuppression (CD4+ counts greater than 300 cells/$mm^3$) present with "usual" secondary tuberculosis (apical disease with cavitation) while those with more advanced immunosuppression (CD4+ counts below 200 cells/$mm^3$) present with a clinical picture that resembles progressive primary tuberculosis (lower and middle lobe consolidation, hilar lymphadenopathy, and noncavitary disease). The extent of immunosuppression also determines the frequency of extrapulmonary involvement, rising from 10% to 15% in mildly immunosuppressed patients to greater than 50% in those with severe immune deficiency.

## MORPHOLOGY

The initial lesion usually is a small focus of consolidation, less than 2 cm in diameter, within 1 to 2 cm of the **apical pleura.** Such foci are sharply circumscribed, firm, gray-white to yellow areas that have a variable amount of central caseation and peripheral fibrosis. In favorable cases, the initial parenchymal focus undergoes progressive fibrous encapsulation, leaving only fibrocalcific scars. Histologically, the active lesions show characteristic coalescent tubercles with central caseation. Although tubercle bacilli can be demonstrated by appropriate methods in early exudative and caseous phases of granuloma formation, it is usually impossible to find them in the late, fibrocalcific stages. Localized, apical, secondary pulmonary tuberculosis may heal with fibrosis either spontaneously or after therapy, or the disease may progress and extend along several different pathways.

**Progressive pulmonary tuberculosis** may ensue. The apical lesion enlarges with expansion of the area of caseation. Erosion into a bronchus evacuates the caseous center, creating a ragged, **irregular cavity lined by caseous material** that is poorly walled off by fibrous tissue (Fig. 12–38). Erosion of blood vessels results in hemoptysis. With adequate treatment, the process may be arrested, although healing by fibrosis often distorts the pulmonary architecture. Irregular cavities, now free of caseation necrosis, may remain or collapse in the surrounding fibrosis. If the treatment is inadequate, or if host defenses are impaired, the infection may spread by direct expansion, by means of dissemination through airways, lymphatic channels, or within the vascular system. **Miliary pulmonary disease** occurs when organisms drain through lymphatics into the lymphatic ducts, which empty into the venous return to the right side of the heart and thence into the pulmonary arteries. Individual lesions are either microscopic or small, visible (2 mm) foci of yellow-white consolidation scattered through the lung parenchyma (the word *miliary* is derived from the resemblance of these foci to millet seeds). With progressive pulmonary tuberculosis, the pleural cavity is invariably involved and serous **pleural effusions, tuberculous empyema,** or **obliterative fibrous pleuritis** may develop.

**Endobronchial, endotracheal,** and **laryngeal tuberculosis** may develop when infective material is spread either through lymphatic channels or from expectorated infectious material. The mucosal lining may be studded with minute granulomatous lesions, sometimes apparent only on microscopic examination.

**Systemic miliary tuberculosis** ensues when the organisms disseminate through the systemic arterial system to almost every organ in the body. Granulomas are the same as in the lung. Miliary tuberculosis is most prominent in the liver, bone marrow, spleen, adrenals, meninges, kidneys, fallopian tubes, and epididymis (Fig. 12–39).

**Isolated-organ tuberculosis** may appear in any one of the organs or tissues seeded hematogenously and may be the presenting manifestation of tuberculosis. Organs typically involved include the meninges (tuberculous meningitis), kidneys (renal tuberculosis), adrenals, bones (osteomyelitis), and fallopian tubes (salpingitis). When the vertebrae are affected, the condition is referred to as Pott disease. Paraspinal "cold" abscesses may track along the tissue planes to present as an abdominal or pelvic mass.

**Lymphadenitis** is the most frequent form of extrapulmonary tuberculosis, usually occurring in the cervical region ("scrofula"). Lymphadenopathy tends to be unifocal, and most patients do not have concurrent extranodal disease. HIV-positive patients, on the other hand, almost always have multifocal disease, systemic symptoms, and either pulmonary or other organ involvement by active tuberculosis.

In years past, **intestinal tuberculosis** contracted by the drinking of contaminated milk was fairly common as a primary focus of tuberculosis. In developed countries today, intestinal tuberculosis is more often a complication of protracted advanced secondary tuberculosis, secondary to the swallowing of coughed-up infective material. Typically, the organisms are trapped in mucosal lymphoid aggregates of the small and large bowel, which then undergo inflammatory enlargement with ulceration of the overlying mucosa, particularly in the ileum.

The many patterns of tuberculosis are depicted in Figure 12–40.

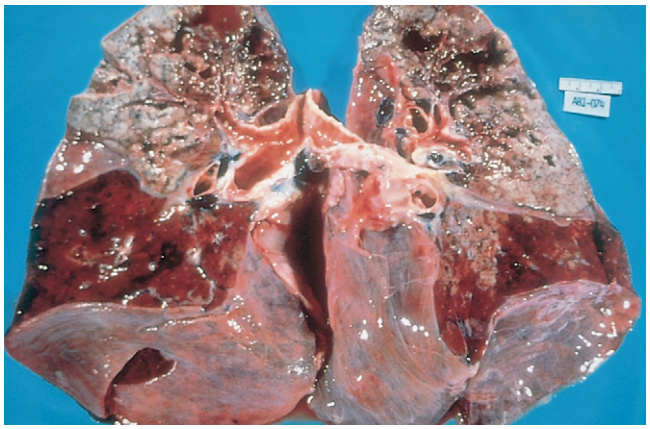

**Figure 12–38** Secondary pulmonary tuberculosis. The upper parts of both lungs are riddled with gray-white areas of caseation and multiple areas of softening and cavitation.

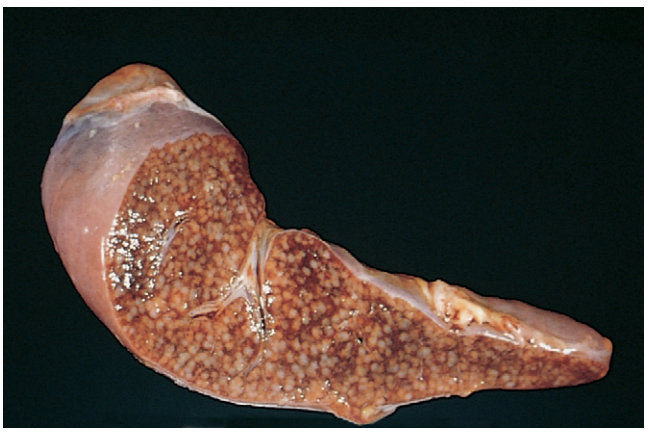

**Figure 12–39** Miliary tuberculosis of the spleen. The cut surface shows numerous gray-white granulomas.

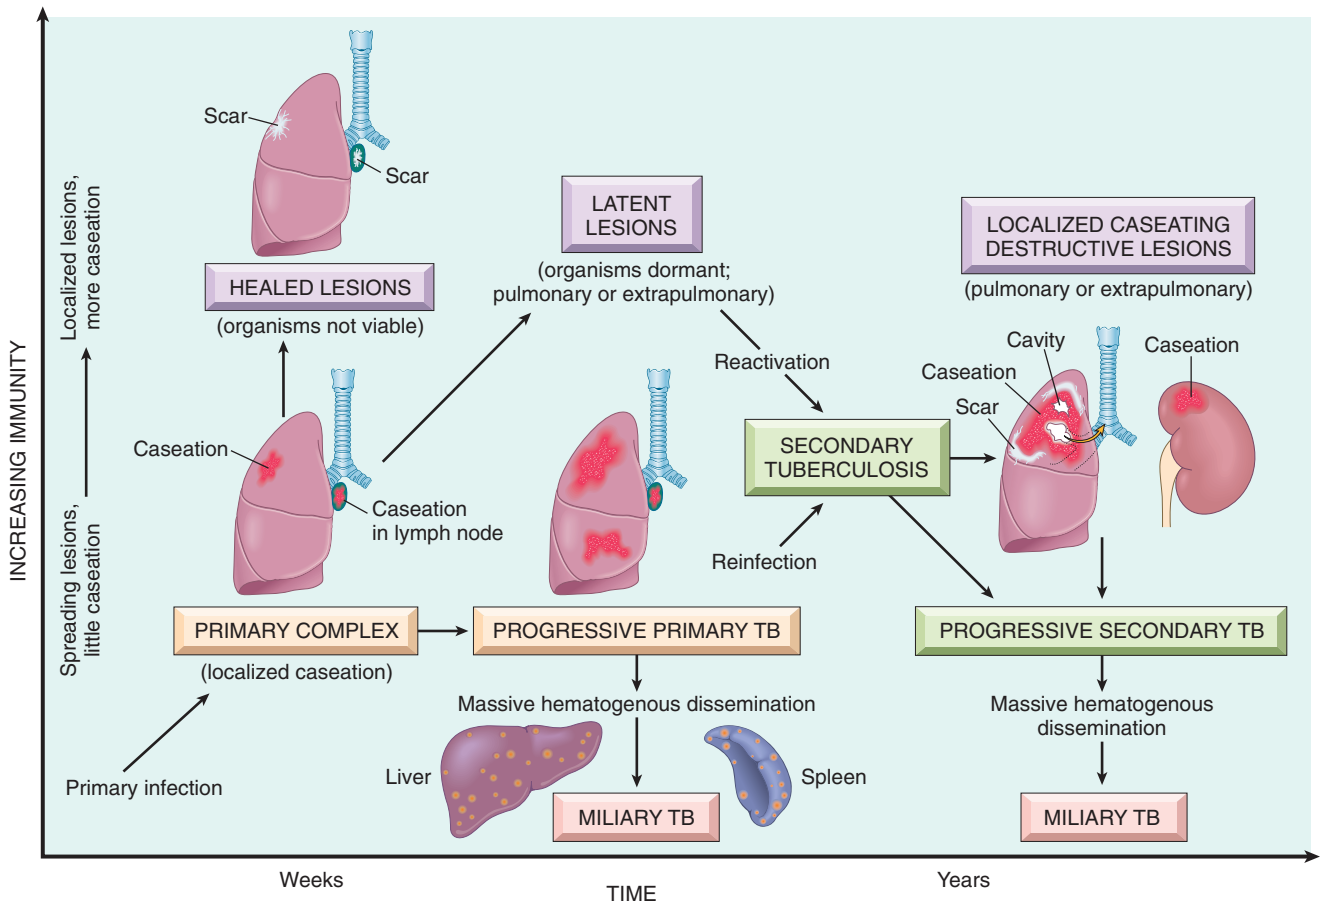

**Figure 12–40** The natural history and spectrum of tuberculosis.
*(Adapted from a sketch provided by Dr. R.K. Kumar, The University of New South Wales, School of Pathology, Sydney, Australia.)*

## Clinical Features

Localized secondary tuberculosis may be asymptomatic. When manifestations appear, they are usually *insidious* in onset, with gradual development of both systemic and localizing symptoms and signs. Systemic manifestations, probably related to the release of cytokines by activated macrophages (e.g., TNF and IL-1), often appear early in the disease course and include malaise, anorexia, weight loss, and fever. Commonly, the *fever is low grade* and remittent (appearing late each afternoon and then subsiding), and *night sweats* occur. With progressive pulmonary involvement, increasing amounts of sputum, at first mucoid and later purulent, appear. When cavitation is present, the sputum contains tubercle bacilli. Some degree of *hemoptysis* is present in about half of all cases of pulmonary tuberculosis. *Pleuritic pain* may result from extension of the infection to the pleural surfaces. Extrapulmonary manifestations of tuberculosis are legion and depend on the organ system involved (for example, tuberculous salpingitis may present as infertility, tuberculous meningitis with headache and neurologic deficits, Pott disease with back pain and paraplegia). The diagnosis of pulmonary disease is based in part on the history and on physical and radiographic findings of *consolidation or cavitation in the apices of the lungs.* Ultimately, however, *tubercle bacilli must be identified.*

The most common methodology for diagnosis of tuberculosis remains demonstration of acid-fast organisms in sputum by acid-fast stains or by use of fluorescent auramine rhodamine. Conventional cultures for mycobacteria require up to 10 weeks, but liquid media–based radiometric assays that detect mycobacterial metabolism are able to provide an answer within 2 weeks. PCR amplification can be performed on positive liquid media, as well as on tissue sections, to identify the mycobacterium. However, culture remains the standard diagnostic modality because it can identify the occasional PCR-negative case and also allows testing of drug susceptibility. Multidrug resistance (MDR), defined as resistance of mycobacteria to two or more of the primary drugs used for treatment of tuberculosis, is now seen more commonly, and the WHO estimates that 50 million people worldwide may be infected with multidrug-resistant tuberculosis.

The prognosis with tuberculosis generally is favorable if infection is localized to the lungs, but it worsens significantly when the disease occurs in aged, debilitated, or immunosuppressed persons, who are at high risk for the development of miliary tuberculosis, and in those with multidrug-resistant tuberculosis. Amyloidosis may develop in persistent cases.

## SUMMARY

### Tuberculosis

- Tuberculosis is a chronic granulomatous disease caused by *M. tuberculosis*, usually affecting the lungs, but virtually any extrapulmonary organ can be involved in isolated infection.
- Initial exposure to mycobacteria results in development of an immune response that confers resistance but also leads to hypersensitivity (as determined by a positive result on the *tuberculin skin test*).
- CD4+ T cells of the $T_H1$ subset have a crucial role in cell-mediated immunity against mycobacteria; mediators of inflammation and bacterial containment include IFN-γ, TNF, and nitric oxide.
- The histopathologic hallmark of host reaction to tuberculosis in immunocompetent persons is the presence of *granulomas*, usually with central caseating necrosis.
- Secondary (reactivation) tuberculosis arises in previously exposed persons when host immune defenses are compromised, and usually manifests as cavitary lesions in the lung apices.
- Both progressive primary tuberculosis and secondary tuberculosis can result in systemic seeding, causing life-threatening forms of disease such as miliary tuberculosis and tuberculous meningitis.
- HIV-seropositive status is a well-known risk factor for development or recrudescence of active tuberculosis.

### *Nontuberculous Mycobacterial Disease*

Nontuberculous mycobacteria most commonly cause chronic but clinically localized pulmonary disease in immunocompetent persons. In the United States, strains implicated most frequently include *Mycobacterium avium-intracellulare* (also called *M. avium* complex), *Mycobacterium kansasii,* and *Mycobacterium abscessus.* It is not uncommon for nontuberculous mycobacterial infection to manifest as upper lobe cavitary disease, mimicking tuberculosis, especially in patients with a long history of smoking or alcohol abuse. Concomitant chronic pulmonary disease (COPD, cystic fibrosis, pneumoconiosis) is often present.

In *immunosuppressed persons* (primarily HIV-seropositive patients), *M. avium* complex infection manifests as disseminated disease, associated with systemic signs and symptoms (fever, night sweats, weight loss). Hepatosplenomegaly and lymphadenopathy, signifying involvement of the mononuclear phagocyte system by the opportunistic pathogen, is common, as are gastrointestinal symptoms such as diarrhea and malabsorption. Pulmonary involvement is often indistinguishable from tuberculosis in patients with AIDS. Disseminated *M. avium* complex infection in patients with AIDS tends to occur late in the clinical course, when CD4+ counts have fallen below 100 cells/μL. Hence, tissue examination usually does not reveal granulomas; instead, foamy histiocytes "stuffed" with atypical mycobacteria typically are seen.

## Histoplasmosis, Coccidioidomycosis, and Blastomycosis

Infections caused by the dimorphic fungi, which include *Histoplasma capsulatum, Coccidioides immitis,* and *Blastomyces dermatitidis,* manifest either with isolated pulmonary involvement, as commonly seen in infected immunocompetent persons, or with disseminated disease in immunocompromised persons. T cell–mediated immune responses are critical for containing the infection, so persons with compromised cell-mediated immunity, such as those with HIV, are more prone to systemic disease. In part because of the overlap in clinical presentations, infectious diseases due to all three dimorphic fungi are considered together in this section.

### Epidemiology

Each of the dimorphic fungi has a typical geographic distribution, as follows:

- *H. capsulatum*: This fungus is endemic in the Ohio and central Mississippi River valleys and along the Appalachian mountains in the southeastern United States. Warm, moist soil, enriched by droppings from bats and birds, provides the ideal medium for the growth of the mycelial form, which produces infectious spores.
- *C. immitis*: This organism is endemic in the southwestern and far western regions of the United States, particularly in California's San Joaquin Valley, where coccidial infection is known as "valley fever."
- *B. dermatitidis*: The endemic area is confined in the United States to areas overlapping with those in which histoplasmosis is found.

## MORPHOLOGY

The yeast forms are fairly distinctive, which helps in the identification of individual fungi in tissue sections:

- *H. capsulatum*: round to oval, small yeast forms measuring 2 to 5 μm in diameter (Fig. 12–41, *A*)
- *C. immitis*: thick-walled, nonbudding spherules, 20 to 60 μm in diameter, often filled with small endospores (Fig. 12–41, *B*)
- *B. dermatitidis*: round to oval and larger than *Histoplasma* (5 to 25 μm in diameter); reproduce by characteristic broad-based budding (Fig. 12–41, *C* and *D*)

### Clinical Features

Clinical manifestations may take the form of (1) *acute (primary) pulmonary infection,* (2) *chronic (granulomatous) pulmonary disease,* or (3) *disseminated miliary disease.* The primary pulmonary nodules, composed of aggregates of macrophages stuffed with organisms, are associated with similar lesions in the regional lymph nodes. These lesions evolve into small granulomas complete with giant cells and may develop central necrosis and later fibrosis and calcification. *The similarity to primary tuberculosis is striking,* and differentiation requires identification of the

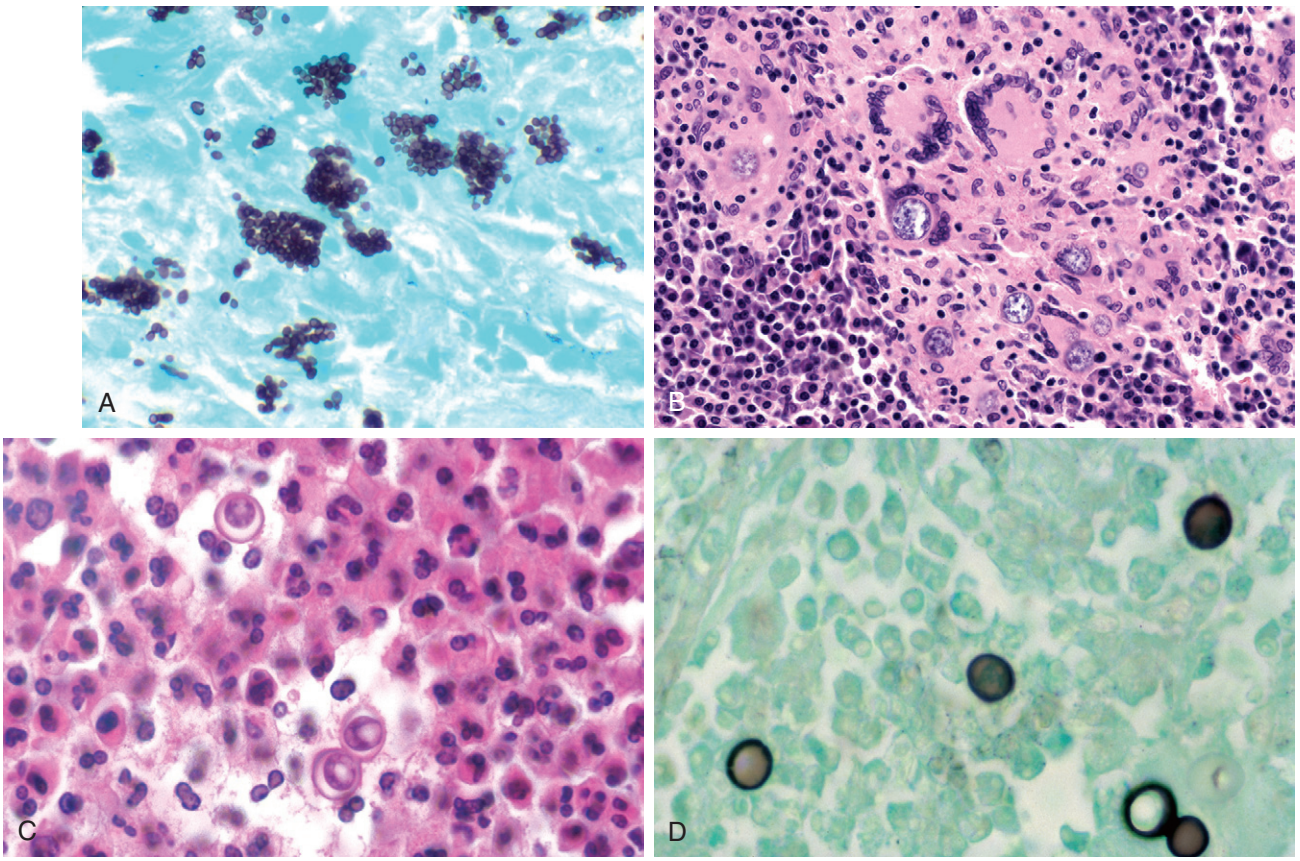

**Figure 12–41 A,** *Histoplasma capsulatum* yeast forms fill phagocytes in a lymph node of a patient with disseminated histoplasmosis (silver stain). **B,** Coccidioidomycosis with intact spherules within multinucleated giant cells. **C,** Blastomycosis, with rounded budding yeasts, larger than neutrophils. Note the characteristic thick wall and nuclei (not seen in other fungi). **D,** Silver stain highlights the broad-based budding seen in *Blastomyces immitis* organisms.

yeast forms (best seen with silver stains). The clinical symptoms and signs resemble those of a "flulike" syndrome, most often self-limited. In the vulnerable host, chronic cavitary pulmonary disease develops, with a predilection for the upper lobe, resembling the secondary form of tuberculosis. It is not uncommon for these fungi to give rise to perihilar mass lesions that resemble bronchogenic carcinoma radiologically. At this stage, manifestations may include cough, hemoptysis, and even dyspnea and chest pain.

In infants or immunocompromised adults, particularly those with HIV infection, disseminated disease (analogous to miliary tuberculosis) may develop. Under these circumstances there are no well-formed granulomas. Instead, focal collections of phagocytes stuffed with yeast forms are seen within cells of the mononuclear phagocyte system, including in the liver, spleen, lymph nodes, lymphoid tissue of the gastrointestinal tract, and bone marrow. The adrenals and meninges may also be involved, and in a minority of cases, ulcers form in the nose and mouth, on the tongue, or in the larynx. Disseminated disease is a hectic, febrile illness marked by hepatosplenomegaly, anemia, leukopenia, and thrombocytopenia. Cutaneous infections with disseminated *Blastomyces* organisms frequently induce striking epithelial hyperplasia, which may be mistaken for squamous cell carcinoma.

## Pneumonia in the Immunocompromised Host

The appearance of a pulmonary infiltrate and signs of infection (e.g., fever) are some of the most common and serious complications in a person in whom the immune and defense systems are suppressed by disease, by immunosuppression for organ transplantation and antitumor therapy, or by irradiation. A wide variety of so-called opportunistic pathogens, many of which rarely cause infection in normal persons, can be the infecting agents with these pneumonias, and often more than one agent is involved. Some of the more common pulmonary pathogens are (1) the bacterial agents *P. aeruginosa*, *Mycobacterium* spp., *L. pneumophila,* and *Listeria monocytogenes*; (2) the viral agents cytomegalovirus and herpesvirus; and (3) the fungal agents *P. jiroveci, Candida* spp., *Aspergillus* spp., and *Cryptococcus neoformans.*

### *Cytomegalovirus Infections*

Cytomegalovirus (CMV), a member of the herpesvirus family, may produce a variety of disease manifestations, depending partly on the age of the infected host but even more on the host's immune status. Cells infected by the virus exhibit gigantism of both the entire cell and its nucleus. Within the nucleus is an enlarged inclusion surrounded by a clear halo ("owl's eye"), which gives the

name to the classic form of symptomatic disease that occurs in neonates—cytomegalic inclusion disease. Although classic cytomegalic inclusion disease involves many organs, CMV infections are discussed here because in immunosuppressed adults, particularly patients with AIDS and recipients of allogeneic bone marrow transplants, CMV pneumonitis is a serious problem.

Transmission of CMV can occur by several mechanisms, depending on the age group affected:

- A fetus can be infected transplacentally from a newly acquired or reactivated infection in the mother (*congenital* CMV infection).
- The virus can be transmitted to the baby through cervical or vaginal secretions at birth, or, later, through breast milk from a mother who has active infection (*perinatal* CMV infection).
- Preschool children, especially in day care centers, can acquire it through saliva. Toddlers thus infected readily transmit the virus to their parents.
- In patients older than 15 years of age, the venereal route is the dominant mode of transmission, but spread also may occur through contact with respiratory secretions and by the fecal-oral route.
- Iatrogenic transmission can occur at any age through organ transplantation or blood transfusions.

### MORPHOLOGY

Histologically, the characteristic enlargement of cells can be appreciated. In the glandular organs, the parenchymal epithelial cells are affected; in the brain, the neurons; in the lungs, the alveolar macrophages and epithelial and endothelial cells; and in the kidneys, the tubular epithelial and glomerular endothelial cells. **Affected cells are strikingly enlarged, often to a diameter of 40 μm, and exhibit cellular and nuclear polymorphism.** Prominent intranuclear basophilic inclusions spanning half the nuclear diameter are usually set off from the nuclear membrane by a clear halo (Fig. 12–42). Within the cytoplasm of these cells, smaller basophilic inclusions may also be seen.

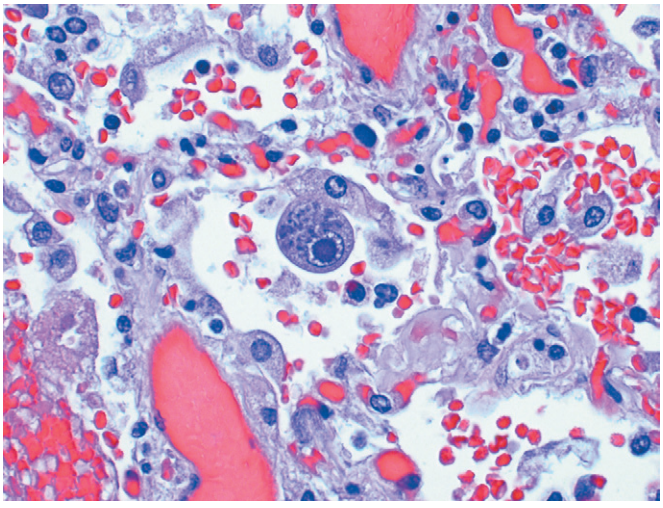

**Figure 12–42** Cytomegalovirus infection of the lung. A typical distinct nuclear and multiple cytoplasmic inclusions are seen in an enlarged cell.

#### Cytomegalovirus Mononucleosis

In healthy young children and adults, the disease is nearly always asymptomatic. In surveys around the world, 50% to 100% of adults demonstrate anti-CMV antibodies in the serum, indicating previous exposure. The most common *clinical manifestation of CMV infection* in immunocompetent hosts beyond the neonatal period is an infectious mononucleosis–like illness, with fever, atypical lymphocytosis, lymphadenopathy, and hepatomegaly accompanied by abnormal liver function test results, suggesting mild hepatitis. Most patients recover from CMV mononucleosis without any sequelae, although excretion of the virus may occur in body fluids for months to years. Irrespective of the presence or absence of symptoms after infection, a person once infected becomes seropositive for life. The virus remains latent within leukocytes, which are the major reservoirs.

#### Cytomegalovirus Infection in Immunosuppressed Persons

Immunosuppression-related CMV infection occurs most commonly in recipients of transplants (such as heart, liver, kidney, lung, or allogeneic stem cell) and in patients with AIDS. This can be either primary infection or reactivation of a latent infection. CMV is the most common opportunistic viral pathogen in AIDS.

In all of these settings, serious, life-threatening disseminated CMV infections primarily affect the lungs (pneumonitis), gastrointestinal tract (colitis), and retina (retinitis); the central nervous system usually is spared. In pneumonitis, an interstitial mononuclear infiltrate with foci of necrosis develops, accompanied by the typical enlarged cells with inclusions, which can progress to ARDS. Intestinal necrosis and ulceration can develop and be extensive, leading to the formation of "pseudomembranes" (Chapter 14) and debilitating diarrhea. CMV retinitis, by far the most common form of opportunistic CMV disease, can occur either alone or in combination with involvement of the lungs and intestinal tract. Diagnosis of CMV infection is made by demonstration of characteristic viral inclusions in tissue sections, successful viral culture, rising antiviral antibody titer, and qualitative or quantitative PCR assay–based detection of CMV DNA. The latter has revolutionized the approach to monitoring patients after transplantation.

### Pneumocystis *Pneumonia*

*P. jiroveci* (formerly known as *P. carinii*), an opportunistic infectious agent formerly considered to be a protozoan, is now classified as a fungus. Serologic evidence indicates that virtually all persons are exposed to *Pneumocystis* during the first few years of life, but in most the infection remains latent. Reactivation with development of clinical disease occurs almost exclusively in persons who are immunocompromised. Indeed, *P. jiroveci* is an extremely common cause of infection in patients with AIDS, and it also may infect severely malnourished infants and immunosuppressed persons (especially after organ transplantation or in persons receiving cytotoxic chemotherapy or corticosteroids). In patients with AIDS, the risk of acquiring *P. jiroveci* infections increases in inverse proportion to the CD4+ count, with counts less than 200 cells/μL having

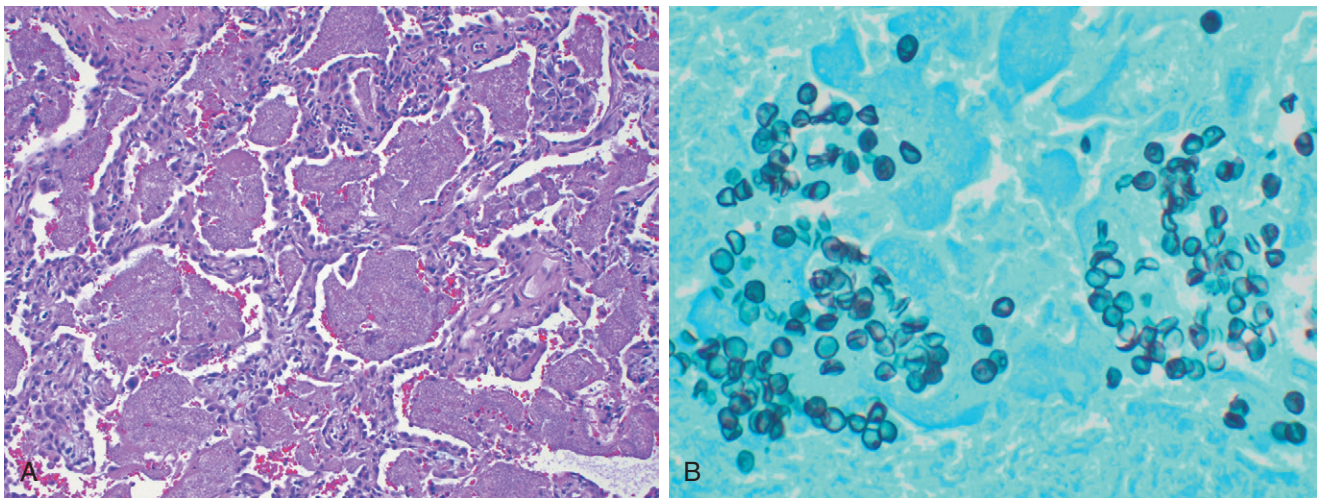

**Figure 12–43** *Pneumocystis* pneumonia. **A,** The alveoli are filled with a characteristic foamy acellular exudate. **B,** Silver stain demonstrates cup-shaped and round cysts within the exudate.

a strong predictive value. *Pneumocystis* infection is largely confined to the lung, where it produces an interstitial pneumonitis.

### MORPHOLOGY

Microscopically, involved areas of the lung demonstrate a characteristic **intra-alveolar foamy, pink-staining exudate** with hematoxylin-eosin (H&E) stain ("cotton candy" exudate) (Fig. 12–43, *A*). The septa are thickened by edema and a minimal mononuclear infiltrate. Special stains are required to visualize the organism. Silver stain of tissue sections reveals **round to cup-shaped cysts** (4 to 10 μm in diameter), often with intracystic bodies but without budding, in the alveolar exudates (Fig. 12–43, *B*).

The diagnosis of *Pneumocystis* pneumonia should be considered in any immunocompromised patient with respiratory symptoms and abnormal findings on the chest radiograph. Fever, dry cough, and dyspnea occur in 90% to 95% of patients, in whom radiographic evidence of bilateral perihilar and basilar infiltrates is typical. Hypoxia is frequent; pulmonary function studies show a restrictive lung defect. The most sensitive and effective method of diagnosis is to identify the organism in induced sputum or bronchoalveolar lavage fluid using immunofluorescence. If treatment is initiated before widespread involvement, the outlook for recovery is good; however, because residual organisms are likely to persist, particularly in patients with AIDS, relapses are common unless the underlying immunodeficiency is corrected or prophylactic therapy is given.

## Opportunistic Fungal Infections

### *Candidiasis*

*Candida albicans* is the most common disease-causing fungus. It is a normal inhabitant of the oral cavity, gastrointestinal tract, and vagina in many people. Even though systemic candidiasis (with associated pneumonia) is a disease that is restricted to immunocompromised patients, the protean manifestations of infections caused by *Candida* spp. are described in this section.

### MORPHOLOGY

In tissue sections, *C. albicans* demonstrates yeastlike forms (blastoconidia), pseudohyphae, and true hyphae (Fig. 12–44, *A*). Pseudohyphae are an important diagnostic clue for *C. albicans* and represent budding yeast cells joined end to end at constrictions, thus simulating true fungal hyphae. The organisms may be visible with routine H&E stains, but a variety of special "fungal" stains (Gomori methenamine-silver, periodic acid–Schiff) commonly are used to better highlight the pathogens.

#### Clinical Features

Candidiasis can involve the mucous membranes, skin, and deep organs (invasive candidiasis).

- The most common presentation with candidiasis is that of a superficial infection on mucosal surfaces of the oral cavity (thrush). Florid proliferation of the fungi creates gray-white, dirty-looking pseudomembranes composed of matted organisms and inflammatory debris. Deep to the surface, there is mucosal hyperemia and inflammation. This form of candidiasis is seen in newborns, debilitated patients, and children receiving oral corticosteroids for asthma, and after a course of broad-spectrum antibiotics that destroy competing normal bacterial flora. The other major risk group includes HIV-positive patients; patients with oral thrush not associated with an obvious underlying condition should be evaluated for HIV infection.
- *Candida* vaginitis is an extremely common form of vaginal infection in women, especially those who are diabetic or pregnant or on oral contraceptive pills.
- *Candida* esophagitis is common in patients with AIDS and in those with hematolymphoid malignancies. These

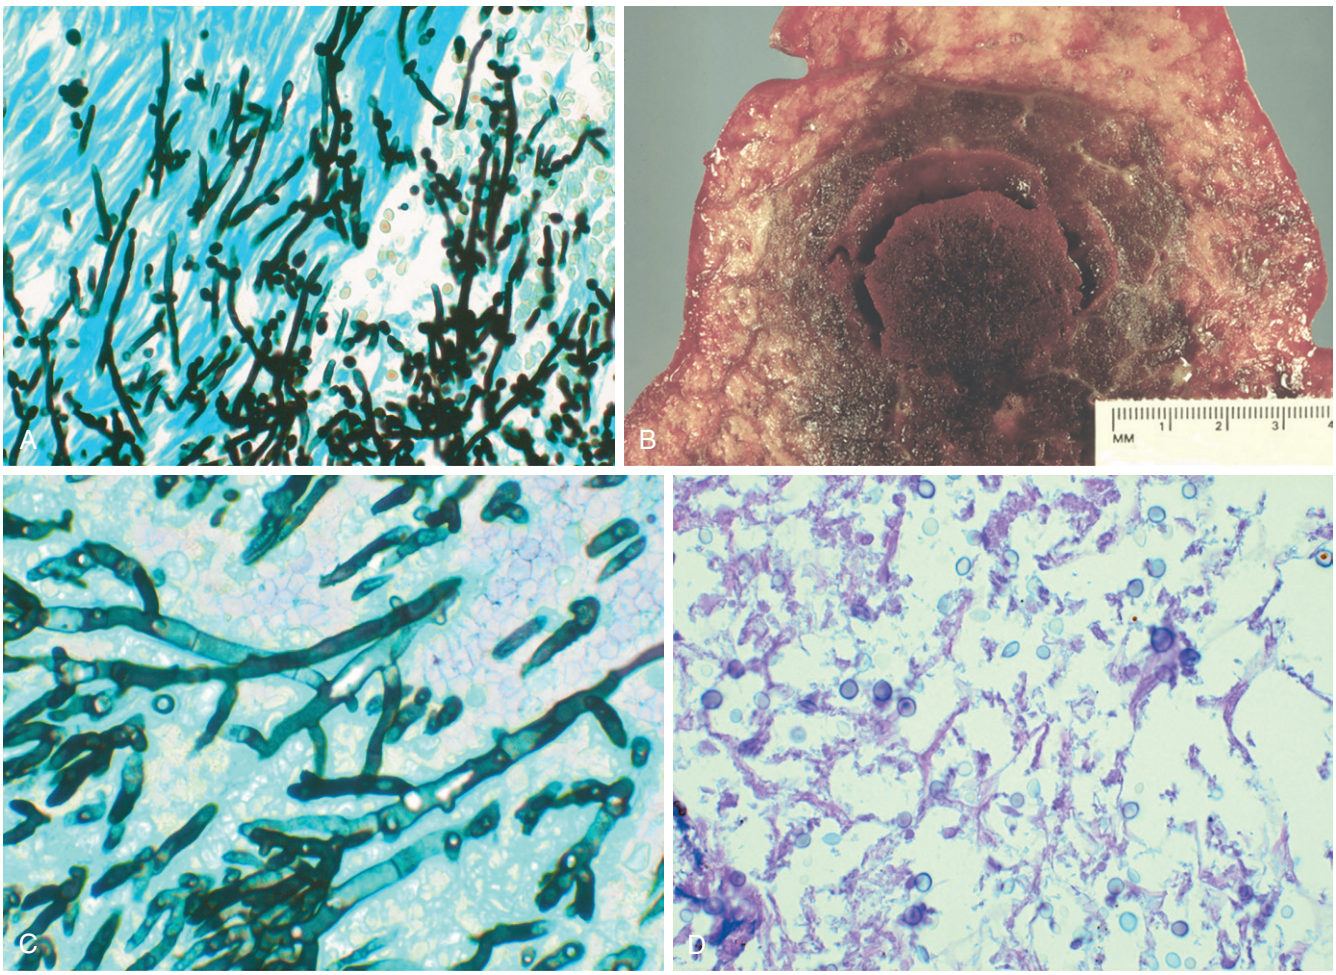

**Figure 12–44** The morphology of fungal infections. **A,** *Candida* organism has pseudohyphae and budding yeasts (silver stain). **B,** Invasive aspergillosis (gross appearance) of the lung in a bone marrow transplant recipient. **C,** Gomori methenamine-silver (GMS) stain shows septate hyphae with acute-angle branching, consistent with *Aspergillus*. **D,** Cryptococcosis of the lung in a patient with AIDS. The organisms are somewhat variable in size.

*(B, Courtesy of Dr. Dominick Cavuoti, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

patients present with dysphagia (painful swallowing) and retrosternal pain; endoscopy demonstrates white plaques and pseudomembranes resembling the changes of oral thrush on the esophageal mucosa.

- Cutaneous candidiasis can manifest in many different forms, including infection of the nail proper (*onychomycosis*), nail folds (*paronychia*), hair follicles (*folliculitis*), moist, intertriginous skin such as armpits or webs of the fingers and toes (*intertrigo*), and penile skin (*balanitis*). *Diaper rash* often is a cutaneous candidal infection seen in the perineum of infants, in the region of contact of wet diapers.
- Chronic mucocutaneous candidiasis is a chronic refractory disease afflicting the mucous membranes, skin, hair, and nails; it is associated with underlying T cell defects. Associated conditions include endocrinopathies (most commonly hypoparathyroidism and Addison disease) and the presence of autoantibodies. Disseminated candidiasis is rare in this disease. A recent finding is that the $T_H17$ subset of CD4+ T cells plays an especially important role in defense against *Candida* and a few other fungi. Patients with mutations affecting $T_H17$ responses are highly susceptible to severe mucocutaneous candidiasis (e.g., "Job syndrome").
- Invasive candidiasis implies blood-borne dissemination of organisms to various tissues or organs. Common patterns include (1) renal abscesses, (2) myocardial abscesses and endocarditis, (3) brain involvement (most commonly meningitis, but parenchymal microabscesses occur), (4) endophthalmitis (virtually any eye structure can be involved), (5) hepatic abscesses, and (6) *Candida* pneumonia, usually manifesting as bilateral nodular infiltrates, resembling *Pneumocystis* pneumonia (see earlier). Patients with acute leukemias who are profoundly neutropenic after chemotherapy are particularly prone to the development of systemic disease. *Candida* endocarditis is the most common fungal endocarditis, usually occurring in patients with prosthetic heart valves or in intravenous drug abusers.

### *Cryptococcosis*

*Cryptococcosis,* caused by *C. neoformans,* rarely occurs in healthy persons. It almost exclusively manifests as an opportunistic infection in immunocompromised hosts,

particularly patients with AIDS or hematolymphoid malignancies.

### MORPHOLOGY

The fungus, a 5- to 10-μm yeast, has a thick, gelatinous capsule and reproduces by budding (Fig. 12–44, *D*). Unlike in *Candida* infections, however, pseudohyphal or true hyphal forms are not seen. **The capsule is invaluable to diagnosis:** (1) In routine H&E stains, the capsule is not directly visible, but often a clear "halo" can be seen surrounding the individual fungi representing the area occupied by the capsule. India ink or periodic acid–Schiff staining effectively highlights the fungus. (2) The capsular polysaccharide antigen is the substrate for the cryptococcal latex agglutination assay, which is positive in more than 95% of patients infected with the organism.

#### Clinical Features

Human cryptococcosis usually manifests as pulmonary, central nervous system, or disseminated disease. Cryptococcus is most likely to be acquired by inhalation from the soil or from bird droppings. The fungus initially localizes in the lungs and then disseminates to other sites, particularly the meninges. Sites of involvement are marked by a variable tissue response, which ranges from florid proliferation of gelatinous organisms with a minimal or absent inflammatory cell infiltrate (in immunodeficient hosts) to a granulomatous reaction (in the more reactive host). In immunosuppressed patients, fungi grow in gelatinous masses within the meninges or expand the perivascular Virchow-Robin spaces, producing the so-called soap-bubble lesions.

### *The Opportunistic Molds*

*Mucormycosis* and *invasive aspergillosis* are uncommon infections almost always limited to immunocompromised hosts, particularly those with hematolymphoid malignancies or profound neutropenia, those undergoing corticosteroid therapy, or allogeneic stem cell transplant recipients.

### MORPHOLOGY

Mucormycosis is caused by the class of fungi known as Zygomycetes. Their hyphae are **nonseptate** and branch at right angles; by contrast, the hyphae of *Aspergillus* organisms are **septate** and branch at more acute angles (Fig. 12–44, *C*). *Rhizopus* and *Mucor* are the two fungi of medical importance within the Zygomycetes class. Both zygomycetes and *Aspergillus* cause a nondistinctive, suppurative, sometimes granulomatous reaction with a **predilection for invading blood vessel walls, causing vascular necrosis and infarction.**

#### Clinical Features

In *rhinocerebral* and *pulmonary mucormycosis,* zygomycetes have a propensity to colonize the nasal cavity or sinuses and then spread by direct extension into the brain, orbit, and other head and neck structures. Patients with diabetic ketoacidosis are most likely to develop a fulminant invasive form of rhinocerebral mucormycosis. Pulmonary disease can be localized (e.g., cavitary lesions) or may manifest radiologically with diffuse "miliary" involvement.

*Invasive aspergillosis* occurs almost exclusively in patients who are immunosuppressed. The fungus preferentially localizes to the lungs, and infection most often manifests as a necrotizing pneumonia (Fig. 12–44, *B*). Systemic dissemination, especially to the brain, is an often fatal complication.

*Allergic bronchopulmonary aspergillosis* occurs in patients with asthma who develop an exacerbation of symptoms caused by a type I hypersensitivity against the fungus growing in the bronchi. Such patients often have circulating IgE antibodies against *Aspergillus* and peripheral eosinophilia.

*Aspergilloma* ("fungus ball") formation occurs by colonization of preexisting pulmonary cavities (e.g., ectatic bronchi or lung cysts, posttuberculosis cavitary lesions) by the fungus. These masses may act as ball valves to occlude the cavity, thereby predisposing the patient to infection and hemoptysis.

## Pulmonary Disease in Human Immunodeficiency Virus Infection

Pulmonary disease continues to be the leading contributor to morbidity and mortality in HIV-infected persons. Although the use of potent antiretroviral agents and effective chemoprophylaxis has markedly decreased incidence and improved outcome, the plethora of entities involved makes diagnosis and treatment a distinct challenge.

- Despite the emphasis on "opportunistic" infections, it should be recognized that bacterial lower respiratory tract infection caused by the "usual" pathogens is one of the most serious pulmonary disorders in HIV infection. The implicated organisms include *S. pneumoniae, S. aureus, H. influenzae,* and gram-negative rods. Bacterial pneumonias in HIV-infected persons are more common, more severe, and more often associated with bacteremia than in those without HIV infection.
- Not all pulmonary infiltrates in HIV-infected persons are infectious. A host of noninfectious diseases, including Kaposi sarcoma (Chapters 4 and 9), pulmonary non-Hodgkin lymphoma (Chapter 11), and primary lung cancer, occur with increased frequency and must be excluded.
- *The CD4+ T cell count often is useful in narrowing the differential diagnosis.* As a rule of thumb, bacterial and tubercular infections are more likely at higher CD4+ counts (more than 200 cells/$mm^3$); *Pneumocystis* pneumonia usually occurs at CD4+ counts below 200 cells/$mm^3$, while CMV and *M. avium* complex infections are uncommon until the very late stages of immunosuppression (CD4+ counts below 50 cells/$mm^3$).

Finally, an important point is that pulmonary disease in HIV-infected persons may result from more than one cause, and that even common pathogens may be responsible for disease with atypical manifestations.

# LUNG TUMORS

Although lungs frequently are the site of metastases from cancers arising in extrathoracic organs, primary lung cancer is also a common disease. Roughly 95% of primary lung tumors are carcinomas; the remaining 5% constitute a miscellaneous group that includes carcinoids, mesenchymal malignancies (e.g., fibrosarcomas, leiomyomas), lymphomas, and a few benign lesions. The most common benign tumor is a spherical, small (3 to 4 cm), discrete "hamartoma" that often shows up as a so-called coin lesion on chest radiographs. It consists mainly of mature cartilage, but this is often admixed with fat, fibrous tissue, and blood vessels in various proportions. Clonal cytogenic abnormalities have been demonstrated, indicating that it is a benign neoplasm, although still commonly referred to as hamartoma.

## Carcinomas

Carcinoma of the lung (also known as "lung cancer") is without doubt the single most important cause of cancer-related deaths in industrialized countries. It has long held this position among males in the United States, accounting for about one third of cancer deaths in men, and has become the leading cause of cancer deaths in women as well. American Cancer Society estimates for 2011 included approximately 221,100 new cases of lung cancer and 156,900 deaths. The incidence among males is gradually decreasing, but it continues to increase among females, with more women dying each year from lung cancer than from breast cancers, since 1987. These statistics undoubtedly reflect the causal relationship of cigarette smoking and lung cancer. The peak incidence of lung cancer is in persons in their 50s and 60s. At diagnosis, more than 50% of patients already have distant metastatic disease, while a fourth have disease in the regional lymph nodes. The prognosis with lung cancer is dismal: The 5-year survival rate for all stages of lung cancer combined is about 16%, a figure that has not changed much over the last 30 years; even with disease localized to the lung, a 5-year survival rate of only 45% is typical.

The four major histologic types of carcinomas of the lung are adenocarcinoma, squamous cell carcinoma, small cell carcinoma, and large cell carcinoma (Table 12–7). In some cases there is a combination of histologic patterns (e.g., small cell carcinoma and adenocarcinoma). Of these, squamous cell and small cell carcinomas show the strongest association with smoking. Possibly because of changes in smoking patterns in the U.S., adenocarcinoma has replaced squamous cell carcinoma as the most common primary lung tumor in recent years. Adenocarcinomas also are by far the most common primary tumors arising in women, in never-smokers, and in persons younger than 45 years.

- Until recently, carcinomas of the lung were classified into two broad groups: small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC), with the latter including adenocarcinomas and squamous and large cell carcinomas.
- *The key reason for this historical distinction was that virtually all SCLCs have metastasized by the time of diagnosis and hence are not curable by surgery. Therefore, they are best treated by chemotherapy, with or without radiation therapy.* By contrast, NSCLCs were more likely to be resectable and usually responded poorly to chemotherapy; however, now therapies are available that target specific mutated gene products present in the various subtypes of NSCLC, mainly in adenocarcinomas. Thus, NSCLC must be subclassified into histologic and molecular subtypes.

**Table 12–7** Histologic Classification of Malignant Epithelial Lung Tumors

| |
|---|
| Adenocarcinoma* |
| Acinar, papillary, micropapillary, solid, lepidic predominant, mucinous subtypes |
| Squamous cell carcinoma |
| Large cell carcinoma |
| Large cell neuroendocrine carcinoma |
| Small cell carcinoma |
| Combined small cell carcinoma |
| Adenosquamous carcinoma |
| Carcinomas with pleomorphic, sarcomatoid, or sarcomatous elements |
| Spindle cell carcinoma |
| Giant cell carcinoma |
| Carcinoid tumor |
| Typical, atypical |
| Carcinomas of salivary gland type |
| Unclassified carcinoma |

*Adenocarcinoma and squamous cell and large cell carcinoma are collectively referred to as non–small cell lung carcinoma (NSCLC).

## ETIOLOGY AND PATHOGENESIS

Smoking-related carcinomas of the lung arise by a stepwise accumulation of a multitude of genetic abnormalities (estimated to be in the thousands for small cell carcinoma) that result in transformation of benign progenitor cells in the lung into neoplastic cells.

The sequence of molecular changes is not random but follows a predictable sequence that parallels the histologic progression toward cancer. Thus, inactivation of the putative tumor suppressor genes located on the short arm of chromosome 3 (3p) is a very early event, whereas *TP53* mutations or activation of the *KRAS* oncogene occurs relatively late. More important, it seems that certain genetic changes, such as loss of chromosomal material on 3p, can be found even in benign bronchial epithelium of persons with lung cancer, as well as in the respiratory epithelium of smokers **without** lung cancer, suggesting that large areas of the respiratory mucosa are mutagenized after exposure to carcinogens ("field effect"). On this fertile soil, those cells that accumulate additional mutations ultimately develop into cancer.

A subset of adenocarcinomas, particularly those arising in nonsmoking women of Far Eastern origin, harbor activating mutations of the **epidermal growth factor receptor (EGFR).** Of note, these tumors are sensitive to a class of agents that inhibit EGFR signaling, although the response often is short-lived. EGFR and K-RAS mutations (in 30% of adenocarcinomas) are mutually exclusive. Other mutations occurring in 4% to 6% of adenocarcinomas are EML4-ALK tyrosine kinase fusion genes and c-MET tyrosine kinase gene amplifications. These abnormalities, while rare, are important because of their therapeutic implications, as they can be targeted with tyrosine kinase inhibitors. Indeed, the identification of genetic alterations producing overactive EGFR, ALK, and MET has opened up a new era of "personalized" lung cancer therapy, in which the genetics of the tumor guides the selection of drugs.

With regard to carcinogenic influences, there is strong evidence that **cigarette smoking** and, to a much lesser extent, other environmental insults are the main culprits responsible for the genetic changes that give rise to lung cancers.

About 90% of lung cancers occur in active smokers or those who stopped recently. A nearly linear correlation has been recognized between the frequency of lung cancer and pack-years of cigarette smoking. The increased risk becomes 60 times greater among habitual heavy smokers (two packs a day for 20 years) than among nonsmokers. Since only 11% of heavy smokers develop lung cancer, however, other predisposing factors must be operative in the pathogenesis of this deadly disease. For reasons not entirely clear, women have a higher susceptibility to carcinogens in tobacco than men. Although cessation of smoking decreases the risk of developing lung cancer over time, it may never return to baseline levels. In fact, genetic changes that predate lung cancer can persist for many years in the bronchial epithelium of former smokers. Passive smoking (proximity to cigarette smokers) increases the risk of developing lung cancer to approximately twice that of nonsmokers. The smoking of pipes and cigars also increases the risk, but only modestly.

Other influences may act in concert with smoking or may by themselves be responsible for some lung cancers; witness the increased incidence of this form of neoplasia in miners of radioactive ores; asbestos workers; and workers exposed to dusts containing arsenic, chromium, uranium, nickel, vinyl chloride, and mustard gas. Exposure to asbestos increases the risk of lung cancer fivefold in nonsmokers. By contrast, **heavy smokers exposed to asbestos have an approximately 55 times greater risk for development of lung cancer than that for nonsmokers not exposed to asbestos.**

Even though smoking and other environmental influences are paramount in the causation of lung cancer, it is well known that all persons exposed to tobacco smoke do not develop cancer. It is very likely that the mutagenic effect of carcinogens is conditioned by hereditary (genetic) factors. Recall that many chemicals (procarcinogens) require metabolic activation via the P-450 monooxygenase enzyme system for conversion into ultimate carcinogens (Chapter 5). There is evidence that persons with specific genetic polymorphisms involving the P-450 genes have an increased capacity to metabolize procarcinogens derived from cigarette smoke, and thus conceivably incur the greatest risk for development of lung cancer. Similarly, persons whose peripheral blood lymphocytes undergo chromosomal breakages after exposure to tobacco-related carcinogens (mutagen sensitivity genotype) have a greater than 10-fold risk of developing lung cancer over that of control subjects.

The sequential changes leading to cancer have been best documented for squamous cell carcinomas, but they also are present in other histologic subtypes. In essence, there is a linear correlation between the intensity of exposure to cigarette smoke and the appearance of ever more worrisome epithelial changes that begin with rather innocuous basal cell hyperplasia and squamous metaplasia and progress to squamous dysplasia and carcinoma in situ, before culminating in invasive cancer. **Among the major histologic subtypes of lung cancer, squamous and small-cell carcinomas show the strongest association with tobacco exposure.**

## MORPHOLOGY

Carcinomas of the lung begin as small mucosal lesions that typically are firm and gray-white. They may arise as intraluminal masses, invade the bronchial mucosa, or form large bulky masses pushing into adjacent lung parenchyma. Some large masses undergo cavitation secondary to central necrosis or develop focal areas of hemorrhage. Finally, these tumors may extend to the pleura, invade the pleural cavity and chest wall, and spread to adjacent intrathoracic structures. More distant spread can occur by way of the lymphatics or the hematogenous route.

**Squamous cell carcinomas** are more common in men than in women and are closely correlated with a smoking history; they tend to **arise centrally in major bronchi** and eventually spread to local hilar nodes, but they disseminate outside the thorax later than do other histologic types. Large lesions may undergo central necrosis, giving rise to **cavitation.** The preneoplastic lesions that antedate, and usually accompany, invasive squamous cell carcinoma are well characterized. Squamous cell carcinomas often are preceded by the development, over years, of **squamous metaplasia or dysplasia** in the bronchial epithelium, which then transforms to **carcinoma in situ,** a phase that may last for several years (Fig. 12–45). By this time, atypical cells may be identified in cytologic smears of sputum or in bronchial lavage fluids or brushings, although the lesion is asymptomatic and undetectable on radiographs. Eventually, the small neoplasm reaches a symptomatic stage, when a well-defined tumor mass begins to obstruct the lumen of a major bronchus, often producing distal atelectasis and infection. Simultaneously, the lesion invades surrounding pulmonary substance (Fig. 12–46, *A*). On histologic examination, these tumors range from well-differentiated squamous cell neoplasms showing keratin pearls (Fig. 12–46, *B*) and intercellular bridges to poorly differentiated neoplasms exhibiting only minimal residual squamous cell features.

**Adenocarcinomas** may occur as central lesions like the squamous cell variant but usually are more **peripherally located,** many with a central scar. Adenocarcinomas are the most common type of lung cancer in women and nonsmokers. In general, adenocarcinomas grow slowly and form smaller masses than do the other subtypes, but they tend to metastasize widely at an early stage. On histologic examination, they may assume a variety of forms, including **acinar (gland-forming)** (Fig. 12–47, *C*), **papillary, mucinous** (formerly mucinous bronchioloalveolar carcinoma, which often is multifocal and may manifest as pneumonia-like consolidation), and **solid types.** The solid variant often requires demonstration of intracellular mucin production by special stains to establish its adenocarcinomatous lineage.

Although foci of squamous metaplasia and dysplasia may be present in the epithelium proximal to resected adenocarcinomas, these are not the precursor lesions for this tumor. The putative precursor of peripheral adenocarcinomas is thought to be **atypical adenomatous hyperplasia** (AAH) (Fig. 12–47, *A*) which progresses to adenocarcinoma in situ (formerly bronchioloalveolar carcinoma), minimally invasive adenocarcinoma (tumor less than 3 cm and invasive component measuring 5 mm or less), and invasive adenocarcinoma (tumor of any size that has invaded to depths greater than 5 mm). On microscopic examination, AAH is recognized as a

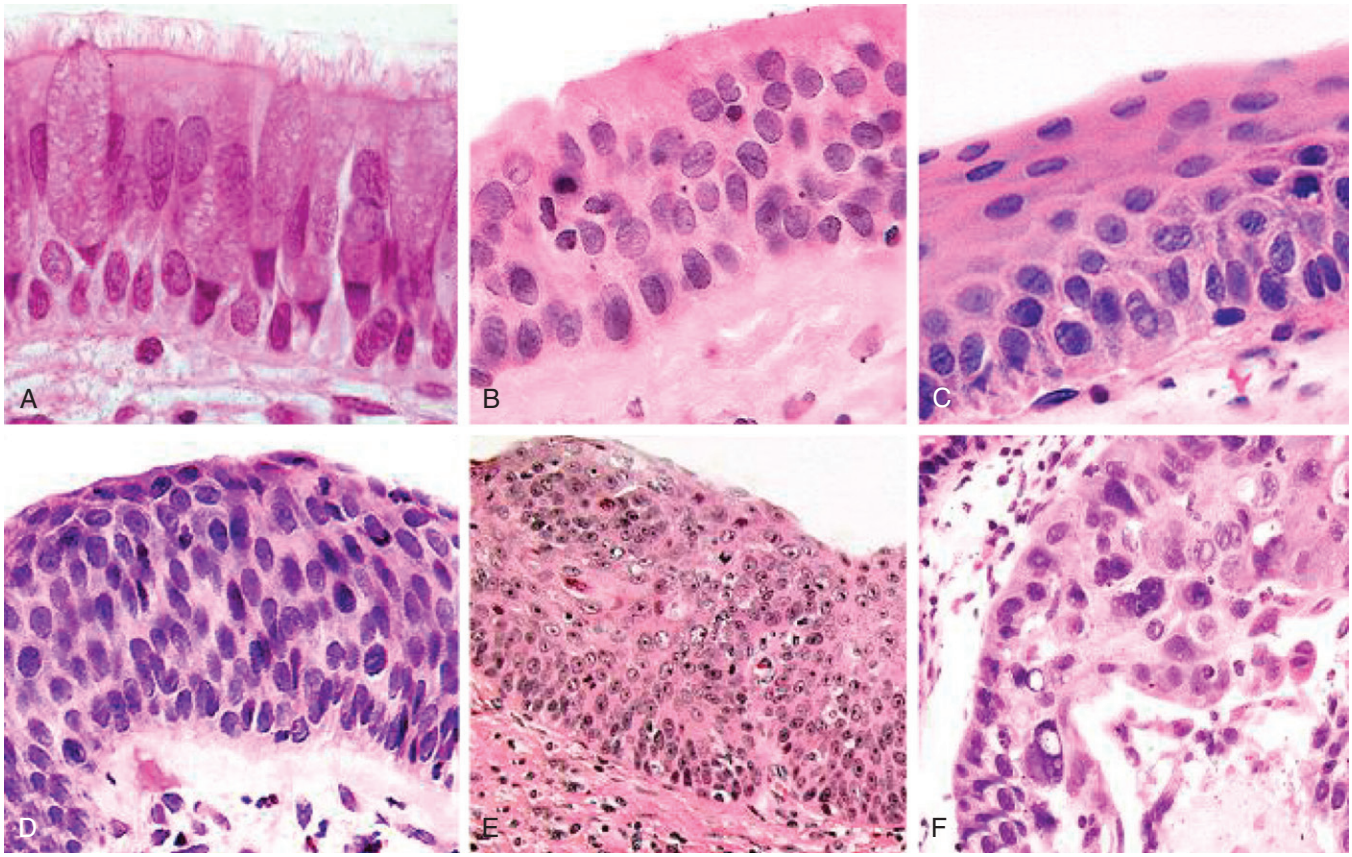

**Figure 12–45** Precursor lesions of squamous cell carcinomas that may antedate the appearance of invasive tumor by years. **A–C,** Some of the earliest (and "mild") changes in smoking-damaged respiratory epithelium include goblet cell hyperplasia (**A**), basal cell (or reserve cell) hyperplasia (**B**), and squamous metaplasia (**C**). **D,** More ominous changes include the appearance of squamous dysplasia, characterized by the presence of disordered squamous epithelium, with loss of nuclear polarity, nuclear hyperchromasia, pleomorphism, and mitotic figures. **E** and **F,** Squamous dysplasia may, in turn, progress through the stages of mild, moderate, and severe dysplasia. Carcinoma in situ (CIS) (**E**) is the stage that immediately precedes invasive squamous carcinoma (**F**). Apart from the lack of basement membrane disruption in CIS, the cytologic features of CIS are similar to those in frank carcinoma. Unless treated, CIS eventually progresses to invasive cancer.

F, Reproduced with permission from Travis WD, Colby TV, Corrin B, et al [eds]: World Health Organization Histological Typing of Lung and Pleural Tumours. Heidelberg, Springer, 1999.)*

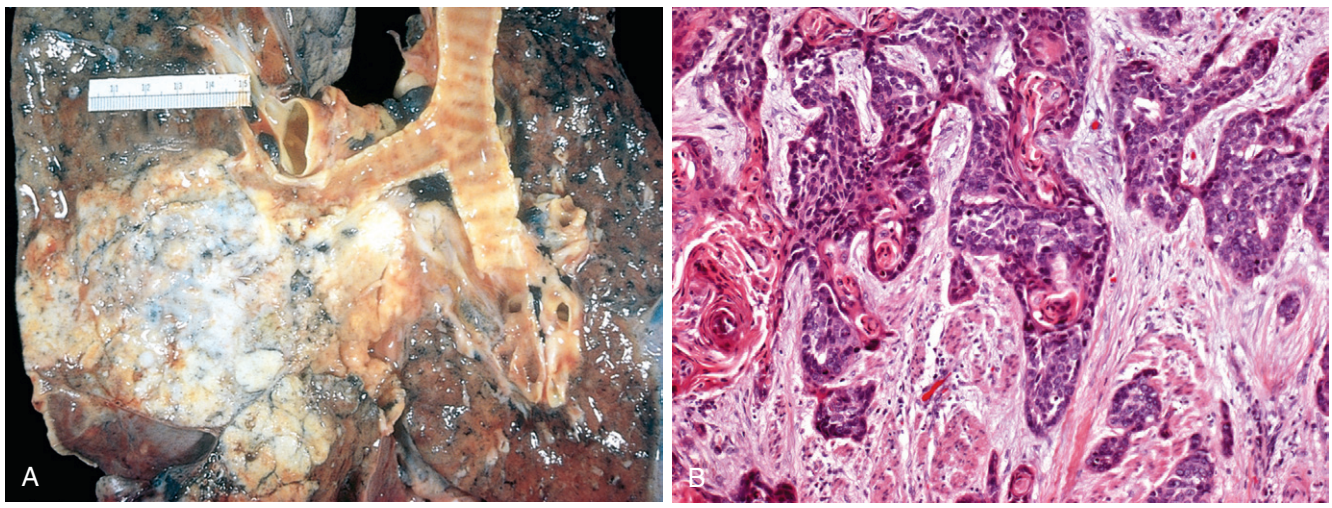

**Figure 12–46** **A**, Squamous cell carcinoma usually begins as a central (hilar) mass and grows contiguously into the peripheral parenchyma as seen here. **B,** Well-differentiated squamous cell carcinoma showing keratinization and pearls.

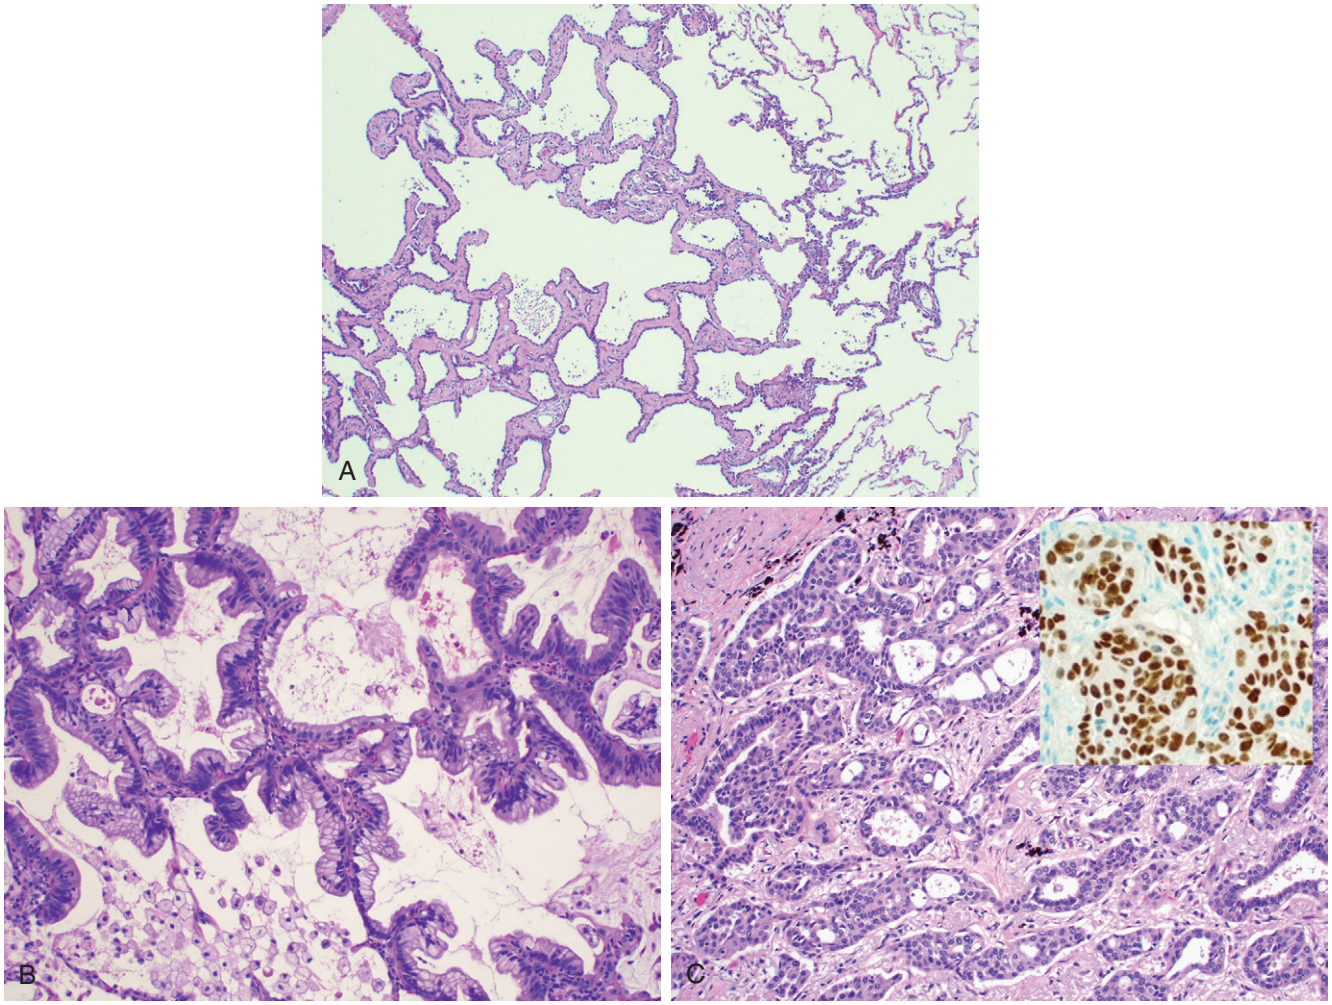

**Figure 12–47** Glandular lesions of the lung. **A,** Atypical adenomatous hyperplasia with cuboidal epithelium and mild interstitial fibrosis. **B,** Adenocarcinoma in situ, mucinous subtype, with characteristic growth along preexisting alveolar septa, without invasion. **C,** Gland-forming adenocarcinoma; inset shows thyroid transcription factor 1 (TTF-1) positivity, which is seen in a majority of pulmonary adenocarcinomas.

well-demarcated focus of epithelial proliferation (with a thickness of 5 mm or less) composed of cuboidal to low-columnar cells, which demonstrate cytologic atypia of variable degree such as nuclear hyperchromasia, pleomorphism, prominent nucleoli, but not to the extent seen in adenocarcinoma. Genetic analyses have shown that lesions of AAH are monoclonal, and they share many of the molecular aberrations associated with adenocarcinomas (e.g., *K-RAS* mutations).

**Adenocarcinoma in situ (AIS), formerly called bronchioloalveolar carcinoma,** often involves peripheral parts of the lung, as a single nodule. **The key features of AIS are diameter of 3 cm or less, growth along preexisting structures, and preservation of alveolar architecture** (Fig. 12–47, *B*). The tumor cells, which may be nonmucinous, mucinous, or mixed, grow in a monolayer along the alveolar septa, which serve as a scaffold (this has been termed a "lepidic" growth pattern, an allusion to the resemblance of neoplastic cells to butterflies sitting on a fence). By definition, AIS does not demonstrate destruction of alveolar architecture or stromal invasion with desmoplasia, features that would merit the diagnosis of frank adenocarcinoma. By analogy to the adenoma–carcinoma sequence in the colon, it is proposed that some invasive adenocarcinomas of the lung may arise through an atypical adenomatous hyperplasia–adenocarcinoma in situ–invasive adenocarcinoma sequence. Studies of lung injury models in mice have now identified a population of multipotent cells at the bronchioloalveolar duct junction, termed bronchioalveolar stem cells (BASCs). After peripheral lung injury, the multipotent BASCs undergo expansion, replenishing the normal cell types (bronchiolar Clara cells and alveolar cells) found in this location, thereby facilitating epithelial regeneration. It is postulated that BASCs incur the initiating oncogenic event (for example, a somatic *K-RAS* mutation) that enables these cells to escape normal "checkpoint" mechanisms and results in pulmonary adenocarcinomas.

**Large cell carcinomas** are undifferentiated malignant epithelial tumors that lack the cytologic features of small cell carcinoma and have no glandular or squamous differentiation. The cells typically have large nuclei, prominent nucleoli, and a moderate amount of cytoplasm. Large cell carcinomas probably represent squamous cell or adenocarcinomas that are so undifferentiated that they can no longer be recognized by means of light microscopy. On ultrastructural examination, however, minimal glandular or squamous differentiation is common.

**Small cell lung carcinomas** (SCLCs) generally appear as pale gray, **centrally located masses** with extension into

the lung parenchyma and early involvement of the hilar and mediastinal nodes. These cancers are composed of tumor cells with a round to fusiform shape, scant cytoplasm, and finely granular chromatin. Mitotic figures frequently are seen (Fig. 12–48). Despite the appellation of **small,** the neoplastic cells are usually twice the size of resting lymphocytes. Necrosis is invariably present and may be extensive. The tumor cells are markedly fragile and often show fragmentation and "crush artifact" in small biopsy specimens. Another feature of small cell carcinomas, best appreciated in cytologic specimens, is nuclear molding resulting from close apposition of tumor cells that have scant cytoplasm. These tumors often express a variety of neuroendocrine markers (Table 12–8) in addition to secreting a host of polypeptide hormones that may result in paraneoplastic syndromes (see below).

**Combined patterns** require no further comment. Of note, however, a significant minority of lung carcinomas reveal more than one line of cellular differentiation, sometimes several (Table 12–7), suggesting that all are derived from a multipotential progenitor cell.

For all of these neoplasms, it is possible to trace involvement of successive chains of nodes about the carina, in the mediastinum, and in the neck (scalene nodes) and clavicular regions and, sooner or later, distant metastases. Involvement of the left supraclavicular node (Virchow node) is particularly characteristic and sometimes calls attention to an occult primary tumor. These cancers, when advanced, often extend into the pleural or pericardial space, leading to inflammation and effusion. They may compress or infiltrate the superior vena cava to cause either venous congestion or the vena caval syndrome (Chapter 9). Apical neoplasms may invade the brachial or cervical sympathetic plexus to cause severe pain in the distribution of the ulnar nerve or to produce Horner syndrome (ipsilateral enophthalmos, ptosis, miosis, and anhidrosis). Such apical neoplasms sometimes are called **Pancoast tumors,** and the combination of clinical findings is known as Pancoast syndrome. Pancoast tumor often is accompanied by destruction of the first and second ribs and sometimes thoracic vertebrae. As with other cancers, tumor-node-metastasis (TNM) categories have been established to indicate the size and spread of the primary neoplasm.

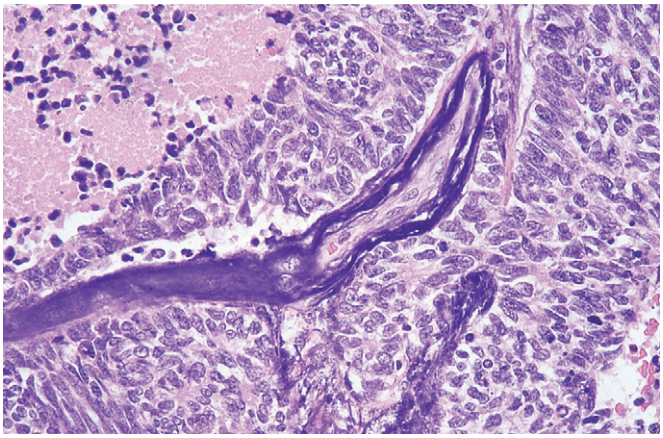

**Figure 12–48** Small cell carcinoma with small deeply basophilic cells and areas of necrosis (*top left*). Note basophilic staining of vascular walls due to encrustation by DNA from necrotic tumor cells (Azzopardi effect).

**Table 12–8** Comparison of Small Cell Lung Carcinoma (SCLC) and Non–Small Cell Lung Carcinoma (NSCLC)

| Feature | SCLC | NSCLC |
|---|---|---|
| Histology | Scant cytoplasm; small, hyperchromatic nuclei with fine chromatin pattern; nucleoli indistinct; diffuse sheets of cells | Abundant cytoplasm; pleomorphic nuclei with coarse chromatin pattern; nucleoli often prominent; glandular or squamous architecture |
| Neuroendocrine markers<br>For example, dense core granules on electron microscopy; expression of chromogranin, neuron-specific enolase, and synaptophysin | Usually present | Usually absent |
| Epithelial markers<br>Epithelial membrane antigen, carcinoembryonic antigen, and cytokeratin intermediate filaments | Present | Present |
| Mucin | Absent | Present in adenocarcinomas |
| Peptide hormone production | Adrenocorticotropic hormone, antidiuretic hormone, gastrin-releasing peptide, calcitonin | Parathyroid hormone–related peptide (PTH-rp) in squamous cell carcinoma |
| Tumor suppressor gene abnormalities | | |
| 3p deletions | >90% | >80% |
| Rb mutations | ~90% | ~20% |
| *p16/CDKN2A* mutations | ~10% | >50% |
| *P53* mutations | >90% | >50% |
| Dominant oncogene abnormalities | | |
| *KRAS* mutations | Rare | ~30% (adenocarcinomas) |
| *EGFR* mutations | Absent | ~20% (adenocarcinomas, nonsmokers, women) |
| ALK rearrangements | Absent | 4%–6% adenocarcinomas, nonsmokers, often have signet ring morphology |
| Response to chemotherapy and radiotherapy | Often complete response but recur invariably | Uncommonly, complete response |

### Clinical Course

Carcinomas of the lung are silent, insidious lesions that in many cases have spread so as to be unresectable before they produce symptoms. In some instances, chronic cough and expectoration call attention to still localized, resectable disease. By the time hoarseness, chest pain, superior vena cava syndrome, pericardial or pleural effusion, or persistent segmental atelectasis or pneumonitis makes its appearance, the prognosis is grim. Too often, the tumor presents with symptoms emanating from metastatic spread to the brain (mental or neurologic changes), liver (hepatomegaly), or bones (pain). Although the adrenals may be nearly obliterated by metastatic disease, adrenal insufficiency (Addison disease) is uncommon, because islands of cortical cells sufficient to maintain adrenal function usually persist.

Overall, NSCLCs carry a better prognosis than SCLCs. When NSCLCs (squamous cell carcinomas or adenocarcinomas) are detected before metastasis or local spread, cure is possible by lobectomy or pneumonectomy. SCLCs, on the other hand, have invariably spread by the time they are first detected, even if the primary tumor appears small and localized. Thus, surgical resection is not a viable treatment. They are very sensitive to chemotherapy but invariably recur. Median survival even with treatment is 1 year.

It is variously estimated that 3% to 10% of all patients with lung cancer develop clinically overt *paraneoplastic syndromes.* These include (1) hypercalcemia caused by secretion of a parathyroid hormone–related peptide (osteolytic lesions may also cause hypercalcemia, but this would not be a paraneoplastic syndrome [Chapter 5]); (2) Cushing syndrome (from increased production of adrenocorticotropic hormone); (3) syndrome of inappropriate secretion of antidiuretic hormone; (4) neuromuscular syndromes, including a myasthenic syndrome, peripheral neuropathy, and polymyositis; (5) clubbing of the fingers and hypertrophic pulmonary osteoarthropathy; and (6) coagulation abnormalities, including migratory thrombophlebitis, nonbacterial endocarditis, and disseminated intravascular coagulation. Secretion of calcitonin and other ectopic hormones also has been documented by assays, but these products usually do not provoke distinctive syndromes. Hypercalcemia most often is encountered with squamous cell neoplasms, the hematologic syndromes with adenocarcinomas. The remaining syndromes are much more common with small cell neoplasms, but exceptions abound.

## SUMMARY

### Carcinomas of the Lung

- The four major histologic subtypes are adenocarcinomas (most common), squamous cell carcinoma, large cell carcinoma, and small cell carcinoma.
- Each of these is clinically and genetically distinct. SCLCs are best treated by chemotherapy, because almost all are metastatic at presentation. The other carcinomas may be curable by surgery if limited to the lung. Combination chemotherapy also is available along with anti-EGFR therapy for those adenocarcinomas with EGFR mutations, and ALK inhibitors for those with ALK mutations.
- Smoking is the most important risk factor for lung cancer; in women and nonsmokers, adenocarcinomas are the most common cancers.
- Precursor lesions include squamous dysplasia (for squamous cancer) and atypical adenomatous hyperplasia and adenocarcinoma in situ (formerly bronchioloalveolar carcinoma) (for some adenocarcinomas).
- Tumors 3 cm or less in diameter characterized by pure growth along preexisting structures (lepidic pattern) without stromal invasion are now called adenocarcinoma in situ.
- Lung cancers, particularly SCLCs, can cause *paraneoplastic syndromes*.

## Carcinoid Tumors

Carcinoid tumors are malignant tumors composed of cells that contain dense-core neurosecretory granules in their cytoplasm and, rarely, may secrete hormonally active polypeptides. They are classified into typical (low-grade) and atypical (intermediate-grade) carcinoids; both are often resectable and curable. They occasionally occur as part of the multiple endocrine neoplasia syndrome (Chapter 19). Bronchial carcinoids occur at an early age (mean 40 years) and represent about 5% of all pulmonary neoplasms.

### MORPHOLOGY

Most carcinoids originate in main bronchi and grow in one of two patterns: (1) an obstructing polypoid, spherical, intraluminal mass (Fig. 12–49, *A*); or (2) a mucosal plaque penetrating the bronchial wall to fan out in the peribronchial tissue—the so-called collar-button lesion. Even these penetrating lesions push into the lung substance along a broad front and are therefore reasonably well demarcated. Peripheral carcinoids are less common. Although 5% to 15% of carcinoids have metastasized to the hilar nodes at presentation, distant metastases are rare. Histologically, **typical carcinoids,** like their counterparts in the intestinal tract, are composed of nests of uniform cells that have regular round nuclei with "salt-and-pepper" chromatin, absent or rare mitoses, and little pleomorphism (Fig. 12–49, *B*). **Atypical carcinoid** tumors display a higher mitotic rate (but less than small or large cell carcinomas) and focal necrosis. The atypical tumors have a higher incidence of lymph node and distant metastasis than typical carcinoids. Unlike typical carcinoids, the atypical subset demonstrates *TP53* mutations in 20% to 40% of cases. **Typical carcinoid, atypical carcinoid, and small cell carcinoma can be considered to represent a continuum of increasing histologic aggressiveness and malignant potential within the spectrum of pulmonary neuroendocrine neoplasms.**

Most carcinoid tumors manifest with signs and symptoms related to their intraluminal growth (i.e., they cause cough, hemoptysis, and recurrent bronchial and pulmonary infections). Peripheral tumors are often asymptomatic, being discovered incidentally on chest radiographs.

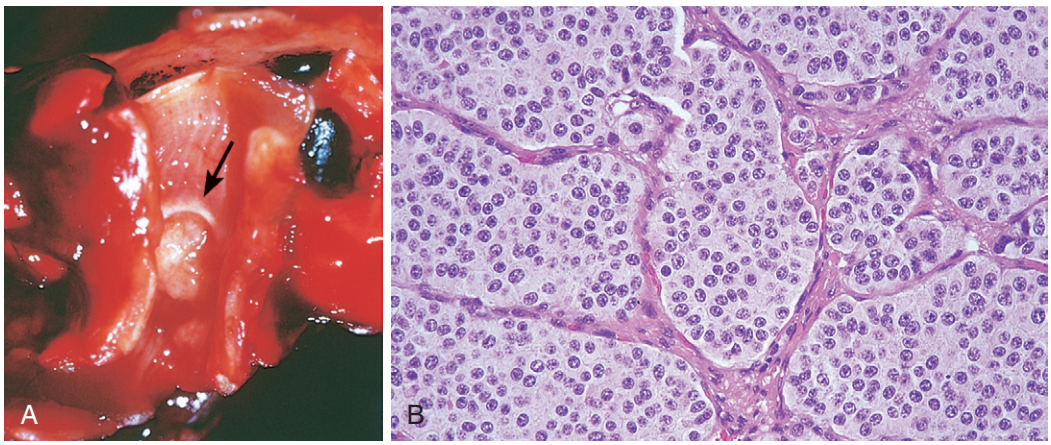

**Figure 12-49** Bronchial carcinoid. **A,** Carcinoid growing as a spherical, pale mass *(arrow)* protruding into the lumen of the bronchus. **B,** Histologic appearance demonstrating small, rounded, uniform nuclei and moderate cytoplasm.
*(Courtesy of Dr. Thomas Krausz, Department of Pathology, University of Chicago Pritzker School of Medicine, Chicago, Illinois.)*

Only rarely do they induce the *carcinoid syndrome,* characterized by intermittent attacks of diarrhea, flushing, and cyanosis. The reported 5- and 10-year survival rates for typical carcinoids are above 85%, while these rates drop to 56% and 35%, respectively, for atypical carcinoids. Only 5% of patients with the most aggressive neuroendocrine lung tumor—SCLC—are alive at 10 years.

## PLEURAL LESIONS

Pathologic involvement of the pleura is, with rare exceptions, a secondary complication of an underlying pulmonary disease. Evidence of secondary infection and pleural adhesions are particularly common findings at autopsy. Important primary disorders are (1) primary intrapleural bacterial infections and (2) a primary neoplasm of the pleura known as *malignant mesothelioma.*

### Pleural Effusion and Pleuritis

In pleural effusion (the presence of fluid in the pleural space) the fluid can be either a transudate or an exudate. When the pleural fluid is a transudate, the condition is termed *hydrothorax.* Hydrothorax from CHF probably is the most common cause of fluid accumulation in the pleural cavity. An exudate, characterized by protein content greater than 2.9gm/dL and, often, inflammatory cells, suggests pleuritis. The four principal causes of *pleural exudate* formation are (1) microbial invasion through either direct extension of a pulmonary infection or blood-borne seeding (*suppurative pleuritis* or *empyema*); (2) cancer (lung carcinoma, metastatic neoplasms to the lung or pleural surface, mesothelioma); (3) pulmonary infarction; and (4) viral pleuritis. Other, less common causes of exudative pleural effusions are systemic lupus erythematosus, rheumatoid arthritis, and uremia, as well as previous thoracic surgery. Malignant effusions characteristically are large and frequently bloody (*hemorrhagic pleuritis*). Cytologic examination may reveal malignant and inflammatory cells.

Whatever the cause, transudates and serous exudates usually are resorbed without residual effects if the inciting cause is controlled or remits. By contrast, fibrinous, hemorrhagic, and suppurative exudates may lead to fibrous organization, yielding adhesions or fibrous pleural thickening, and sometimes minimal to massive calcifications.

### Pneumothorax, Hemothorax, and Chylothorax

*Pneumothorax* refers to presence of air or other gas in the pleural sac. It may occur in young, apparently healthy adults, usually men without any known pulmonary disease (simple or spontaneous pneumothorax), or as a result of some thoracic or lung disorder (secondary pneumothorax), such as emphysema or a fractured rib. Secondary pneumothorax is the consequence of rupture of any pulmonary lesion situated close to the pleural surface that allows inspired air to gain access to the pleural cavity. Such pulmonary lesions include emphysema, lung abscess, tuberculosis, carcinoma, and many other, less common processes. Mechanical ventilatory support with high pressure also may trigger secondary pneumothorax.

There are several possible complications of pneumothorax. A ball-valve leak may create a tension pneumothorax that shifts the mediastinum. Compromise of the pulmonary circulation may follow and may even be fatal. If the leak seals and the lung is not reexpanded within a few weeks (either spontaneously or through medical or surgical intervention), so much scarring may occur that it can never be fully reexpanded. In these cases, serous fluid collects in the pleural cavity, creating hydropneumothorax. With prolonged collapse, the lung becomes vulnerable to infection, as does the pleural cavity when communication between it and the lung persists. Empyema is thus an important complication of pneumothorax (pyopneumothorax).

*Hemothorax,* the collection of whole blood (in contrast with bloody effusion) in the pleural cavity, is a complication of a ruptured intrathoracic aortic aneurysm that is almost always fatal. With hemothorax, in contrast with bloody pleural effusions, the blood clots within the pleural cavity.

*Chylothorax* is a pleural collection of a milky lymphatic fluid containing microglobules of lipid. The total volume

of fluid may not be large, but chylothorax is always significant because it implies obstruction of the major lymph ducts, usually by an intrathoracic cancer (e.g., a primary or secondary mediastinal neoplasm, such as a lymphoma).

### Malignant Mesothelioma

Malignant mesothelioma is a rare cancer of mesothelial cells, usually arising in the parietal or visceral pleura, although it also occurs, much less commonly, in the peritoneum and pericardium. It has assumed great importance because it is related to occupational exposure to asbestos in the air. Approximately 50% of persons with this cancer have a history of exposure to asbestos. Those who work directly with asbestos (shipyard workers, miners, insulators) are at greatest risk, but malignant mesotheliomas have appeared in persons whose only exposure was living in proximity to an asbestos factory or being a relative of an asbestos worker. The latent period for developing malignant mesothelioma is long, often 25 to 40 years after initial asbestos exposure, suggesting that multiple somatic genetic events are required for neoplastic conversion of a mesothelial cell. As stated earlier, *the combination of cigarette smoking and asbestos exposure greatly increases the risk of lung carcinoma, but it does not increase the risk of developing malignant mesothelioma.*

#### MORPHOLOGY

Malignant mesotheliomas are often preceded by extensive **pleural fibrosis and plaque formation,** readily seen on computed tomography scans. These tumors begin in a localized area and over time spread widely, either by contiguous growth or by diffusely seeding the pleural surfaces. At autopsy, the affected lung **typically is ensheathed by a yellow-white, firm, sometimes gelatinous layer of tumor** that obliterates the pleural space (Fig. 12–50). Distant metastases are rare. The neoplasm may directly invade the thoracic wall or the subpleural lung tissue. Normal mesothelial cells are biphasic, giving rise to pleural lining cells as well as the underlying fibrous tissue. Therefore, histologically, mesotheliomas conform to one of three patterns: (1) **epithelial,** in which cuboidal cells line tubular and microcystic spaces, into which small papillary buds project; this is the most common pattern and also the one most likely to be confused with a pulmonary adenocarcinoma; (2) **sarcomatous,** in which spindled and sometimes fibroblastic-appearing cells grow in nondistinctive sheets; and (3) **biphasic,** having both sarcomatous and epithelial areas.

Asbestos is not removed or metabolized from the lung, so the fibers remain in the body for life. Thus, the lifetime risk after exposure does not diminish over time (unlike with smoking, in which the risk decreases after cessation). It has been hypothesized that asbestos fibers preferentially gather near the mesothelial cell layer, where they generate reactive oxygen species, which cause DNA damage with potentially oncogenic mutations. Somatic mutations of two tumor suppressor genes (*p16/CDKN2A,* at chromosomal locus 9p21, and *NF2,* at chromosomal locus 22q12) have been observed in malignant mesotheliomas.

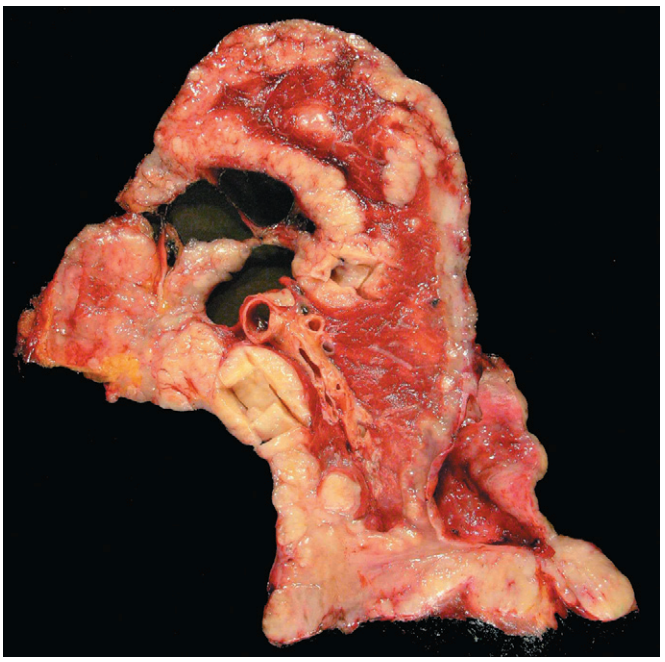

**Figure 12–50** Malignant mesothelioma. Note the thick, firm, white pleural tumor that ensheathes this bisected lung.

## LESIONS OF THE UPPER RESPIRATORY TRACT

### Acute Infections

Acute infections of the upper respiratory tract are among the most common afflictions of humans, most frequently manifesting as the "common cold." The clinical features are well known: nasal congestion accompanied by watery discharge; sneezing; scratchy, dry sore throat; and a slight increase in temperature that is more pronounced in young children. The most common pathogens are rhinoviruses, but coronaviruses, respiratory syncytial viruses, parainfluenza and influenza viruses, adenoviruses, enteroviruses, and sometimes even group A β-hemolytic streptococci have been implicated. In a significant number of cases (around 40%) the cause cannot be determined; perhaps new viruses will be discovered. Most of these infections occur in the fall and winter and are self-limiting (usually lasting for a week or less). In a minority of cases, colds may be complicated by the development of bacterial otitis media or sinusitis.

In addition to the common cold, infections of the upper respiratory tract may produce signs and symptoms localized to the pharynx, epiglottis, or larynx. *Acute pharyngitis,* manifesting as a sore throat, may be caused by a host of agents. Mild pharyngitis with minimal physical findings frequently accompanies a cold and is the most common form of pharyngitis. More severe forms with tonsillitis, associated with marked hyperemia and exudates, occur with β-hemolytic streptococcal and adenovirus infections. Streptococcal tonsillitis is important to recognize and treat early, because of the associated potential for development of peritonsillar abscesses ("quinsy") or for progression to poststreptococcal glomerulonephritis and acute rheumatic

fever. Coxsackievirus A infection may produce pharyngeal vesicles and ulcers (herpangina). Infectious mononucleosis, caused by Epstein-Barr virus (EBV), is an important cause of pharyngitis and bears the moniker of "kissing disease"—reflecting the common mode of transmission in previously nonexposed persons.

Acute *bacterial epiglottitis* is a syndrome predominantly affecting young children who have an infection of the epiglottis caused by *H. influenzae,* in which pain and airway obstruction are the major findings. The onset is abrupt. Failure to appreciate the need to maintain an open airway for a child with this condition can have fatal consequences. The advent of vaccination against *H. influenzae* has greatly decreased the incidence of this disease.

*Acute laryngitis* can result from inhalation of irritants or may be caused by allergic reactions. It may also be caused by the agents that produce the common cold and usually involve the pharynx and nasal passages as well as the larynx. Brief mention should be made of two uncommon but important forms of laryngitis: *tuberculous* and *diphtheritic.* The former is almost always a consequence of protracted active tuberculosis, during which infected sputum is coughed up. Diphtheritic laryngitis has fortunately become uncommon because of the widespread immunization of young children against diphtheria toxin. After it is inhaled, *Corynebacterium diphtheriae* implants on the mucosa of the upper airways, where it elaborates a powerful exotoxin that causes necrosis of the mucosal epithelium, accompanied by a dense fibrinopurulent exudate, to create the classic superficial, dirty-gray pseudomembrane of diphtheria. The major hazards of this infection are sloughing and aspiration of the pseudomembrane (causing obstruction of major airways) and absorption of bacterial exotoxins (producing myocarditis, peripheral neuropathy, or other tissue injury).

In children, parainfluenza virus is the most common cause of laryngotracheobronchitis, more commonly known as *croup,* but other agents such as respiratory syncytial virus also may precipitate this condition. Although self-limited, croup may cause frightening inspiratory stridor and harsh, persistent cough. In occasional cases, the laryngeal inflammatory reaction may narrow the airway sufficiently to result in respiratory failure. Viral infections in the upper respiratory tract predispose the patient to secondary bacterial infection, particularly by staphylococci, streptococci, and *H. influenzae.*

## Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is a rare neoplasm that merits comment because of (1) the strong epidemiologic links to EBV and (2) the high frequency of this form of cancer among the Chinese, which raises the possibility of viral oncogenesis on a background of genetic susceptibility. It is thought that EBV infects the host by first replicating in the nasopharyngeal epithelium and then infecting nearby tonsillar B lymphocytes. In some persons this leads to transformation of the epithelial cells. Unlike the case with Burkitt lymphoma (Chapter 11), another EBV-associated tumor, the EBV genome is found in virtually all nasopharyngeal carcinomas, including those that occur outside the endemic areas in Asia.

The three histologic variants are keratinizing squamous cell carcinoma, nonkeratinizing squamous cell carcinoma, and undifferentiated carcinoma; the last-mentioned is the most common and the one most closely linked with EBV. The undifferentiated neoplasm is characterized by large epithelial cells with indistinct cell borders (reflecting "syncytial" growth) and prominent eosinophilic nucleoli. As described in Chapter 11, in infectious mononucleosis, EBV directly infects B lymphocytes, after which a marked proliferation of reactive T lymphocytes causes atypical lymphocytosis, seen in the peripheral blood, and enlarged lymph nodes. Similarly, in nasopharyngeal carcinomas, a striking influx of mature lymphocytes often can be seen. These neoplasms are therefore referred to as "lymphoepitheliomas"—a misnomer, because the lymphocytes are not part of the neoplastic process, nor are the tumors benign. The presence of large neoplastic cells in a background of reactive lymphocytes may give rise to an appearance similar to that in non-Hodgkin lymphomas, and immunohistochemical stains may be required to prove the epithelial nature of the malignant cells. Nasopharyngeal carcinomas invade locally, spread to cervical lymph nodes, and then metastasize to distant sites. They tend to be radiosensitive, and 5-year survival rates of 50% are reported even for patients with advanced cancers.

## Laryngeal Tumors

A variety of non-neoplastic, benign, and malignant neoplasms of epithelial and mesenchymal origin may arise in the larynx, but only vocal cord nodules, papillomas, and squamous cell carcinomas are sufficiently common to merit comment. In all of these conditions, the most common presenting feature is hoarseness.

### *Nonmalignant Lesions*

*Vocal cord nodules* ("polyps") are smooth, hemispherical protrusions (usually less than 0.5 cm in diameter) located, most often, on the true vocal cords. The nodules are composed of fibrous tissue and covered by stratified squamous mucosa that usually is intact but can be ulcerated from contact trauma with the other vocal cord. These lesions occur chiefly in heavy smokers or singers (singer's nodes), suggesting that they are the result of chronic irritation or abuse.

*Laryngeal papilloma* or *squamous papilloma* of the larynx is a benign neoplasm, usually located on the true vocal cords, that forms a soft, raspberry-like excrescence rarely more than 1 cm in diameter. Histologically, it consists of multiple, slender, finger-like projections supported by central fibrovascular cores and covered by an orderly, typical, stratified squamous epithelium. When the papilloma is on the free edge of the vocal cord, trauma may lead to ulceration that can be accompanied by hemoptysis.

Papillomas usually are single in adults but often are multiple in children, in whom the condition is referred to as *recurrent respiratory papillomatosis* (RRP), since they typically tend to recur after excision. These lesions are caused by human papillomavirus (HPV) types 6 and 11, do not become malignant, and often spontaneously regress at puberty. Cancerous transformation is rare. The most likely cause for their occurrence in children is vertical

transmission from an infected mother during delivery. Therefore, the recent availability of an HPV vaccine that can protect women of reproductive age against infection with types 6 and 11 provides an opportunity for prevention of RRP in children.

### *Carcinoma of the Larynx*

Carcinoma of the larynx represents only 2% of all cancers. It most commonly occurs after age 40 years and is more common in men than in women (with a gender ratio of 7:1). Environmental influences are very important in its causation; nearly all cases occur in smokers, and alcohol and asbestos exposure may also play roles. Human papillomavirus sequences have been detected in about 15% of tumors, which tend to have a better prognosis than other carcinomas.

About 95% of laryngeal cancers are typical squamous cell carcinomas. Rarely, adenocarcinomas are seen, presumably arising from mucous glands. The tumor develops directly on the vocal cords (glottic tumors) in 60% to 75% of cases, but it may arise above the cords (supraglottic; 25% to 40%) or below the cords (subglottic; less than 5%). Squamous cell carcinomas of the larynx begin as in situ lesions that later appear as pearly gray, wrinkled plaques on the mucosal surface, ultimately ulcerating and fungating (Fig. 12–51). The glottic tumors are usually keratinizing, well- to moderately differentiated squamous cell carcinomas, although nonkeratinizing, poorly differentiated carcinomas may also be seen. As expected with lesions arising from recurrent exposure to environmental carcinogens, adjacent mucosa may demonstrate squamous cell hyperplasia with foci of dysplasia, or even carcinoma in situ.

Carcinoma of the larynx manifests itself clinically with persistent hoarseness. The location of the tumor within the larynx has a significant bearing on prognosis. For example, about 90% of glottic tumors are confined to the larynx at diagnosis. First, as a result of interference with vocal cord mobility, they develop symptoms early in the course of disease; second, the glottic region has a sparse lymphatic supply, and spread beyond the larynx is uncommon. By contrast, the supraglottic larynx is rich in lymphatic spaces, and nearly a third of these tumors metastasize to regional (cervical) lymph nodes. The subglottic tumors tend to remain clinically quiescent, usually manifesting as advanced disease. With surgery, radiation therapy, or combination treatment, many patients can be cured, but about one third die of the disease. The usual cause of death is infection of the distal respiratory passages or widespread metastases and cachexia.

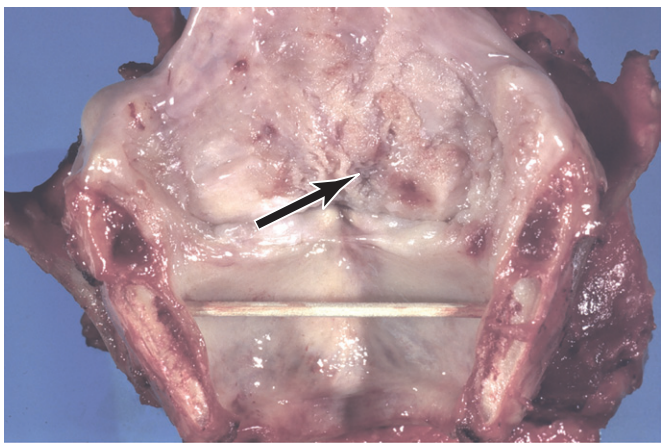

**Figure 12–51** Laryngeal squamous cell carcinoma *(arrow)* arising in a supraglottic location (above the true vocal cord).

Tumors of the Kidney 547

The kidney is a structurally complex organ that has evolved to carry out a number of important functions: excretion of the waste products of metabolism, regulation of body water and salt, maintenance of acid balance, and secretion of a variety of hormones and prostaglandins. Diseases of the kidney are as complex as its structure, but their study is facilitated by dividing them into those that affect its four components: glomeruli, tubules, interstitium, and blood vessels. This traditional approach is useful because the early manifestations of diseases that affect each of these components tend to be distinctive. Furthermore, some structures seem to be more vulnerable to specific forms of renal injury; for example, glomerular diseases are often immunologically mediated, whereas tubular and interstitial disorders are more likely to be caused by toxic or infectious agents. However, some disorders affect more than one structure, and functional interdependence of structures in the kidney means that damage to one component almost always secondarily affects the others. Thus, severe glomerular damage impairs the flow through the peritubular vascular system; conversely, tubular destruction, by increasing intraglomerular pressure and inducing cytokines and chemokines, may induce glomerular sclerosis. Whatever the origin, there is a tendency for chronic renal disease ultimately to damage all four components of the kidney, culminating in *end-stage kidney disease.* For these reasons, the early signs and symptoms of renal disease are particularly important in discerning the initiating cause of the disease, and therefore are referred to in the discussion of individual diseases. The functional reserve of the kidney is large, and much damage may occur before renal dysfunction becomes evident.

## CLINICAL MANIFESTATIONS OF RENAL DISEASES

The clinical manifestations of renal disease can be grouped into reasonably well-defined syndromes. Some are peculiar to glomerular diseases and others are shared by several renal disorders. Before we list the syndromes, a few terms must be defined.

*Azotemia* is an elevation of blood urea nitrogen and creatinine levels and usually reflects a decreased glomerular filtration rate (GFR). GFR may be decreased as a consequence of intrinsic renal disease or extrarenal causes. *Prerenal azotemia* is encountered when there is hypoperfusion of the kidneys, which decreases GFR *in the absence of parenchymal damage. Postrenal azotemia* results when urine flow is obstructed below the level of the kidney. Relief of the obstruction is followed by correction of the azotemia.

When azotemia gives rise to clinical manifestations and systemic biochemical abnormalities, it is termed *uremia.* Uremia is characterized not only by failure of renal excretory function but also by a host of metabolic and endocrine alterations incident to renal damage. There is, in addition, secondary gastrointestinal (e.g., uremic gastroenteritis); neuromuscular (e.g., peripheral neuropathy); and cardiovascular (e.g., uremic fibrinous pericarditis) involvement.

We now turn to a brief description of the major renal syndromes:

- *Nephritic syndrome* results from glomerular injury and is dominated by the acute onset of usually grossly visible hematuria (red blood cells and red cell casts in urine), proteinuria of mild to moderate degree, azotemia,

edema, and hypertension; it is the classic presentation of acute poststreptococcal glomerulonephritis.
- *Nephrotic syndrome* is a glomerular syndrome characterized by heavy proteinuria (excretion of greater than 3.5 g of protein/day in adults), hypoalbuminemia, severe edema, hyperlipidemia, and lipiduria (lipid in the urine).
- *Asymptomatic hematuria* or non-nephrotic *proteinuria,* or a combination of these two, is usually a manifestation of subtle or mild glomerular abnormalities.
- *Rapidly progressive glomerulonephritis* is associated with severe glomerular injury and results in loss of renal function in a few days or weeks. It is manifested by microscopic hematuria, dysmorphic red blood cells and red cell casts in the urine sediment, and mild to moderate proteinuria.
- *Acute kidney injury* is dominated by oliguria or anuria (no urine flow), and recent onset of azotemia. It can result from glomerular injury (such as rapidly progessive glomerulonephritis), interstitial injury, vascular injury (such as thrombotic microangiopathy), or acute tubular injury.
- *Chronic kidney disease,* characterized by prolonged symptoms and signs of uremia, is the result of progressive scarring in the kidney from any cause and may culminate in end-stage kidney disease, requiring dialysis or transplantation.
- *Urinary tract infection* is characterized by bacteriuria and pyuria (bacteria and leukocytes in the urine). The infection may be symptomatic or asymptomatic, and it may affect the kidney (*pyelonephritis*) or the bladder (*cystitis*) only.
- *Nephrolithiasis* (renal stones) is manifested by renal colic, hematuria (without red cell casts), and recurrent stone formation.

In addition to these renal syndromes, *urinary tract obstruction* and *renal tumors* also commonly present with signs and symptoms related to renal dysfunction and are discussed later.

## GLOMERULAR DISEASES

Disorders affecting the glomerulus encompass a clinically important category of renal disease. The glomerulus consists of an anastomosing network of capillaries invested by two layers of epithelium. The visceral epithelium (composed of podocytes) is an intrinsic part of the capillary wall, whereas the parietal epithelium lines Bowman space (urinary space), the cavity in which plasma ultrafiltrate first collects. The glomerular capillary wall is the filtration unit and consists of the following structures (Figs. 13–1 and 13–2):

- A thin layer of fenestrated *endothelial cells,* each fenestra being 70 to 100 nm in diameter.
- A *glomerular basement membrane* (GBM) with a thick, electron-dense central layer, the *lamina densa,* and thinner, electron-lucent peripheral layers, the *lamina rara interna* and *lamina rara externa.* The GBM consists of collagen (mostly type IV), laminin, polyanionic proteoglycans, fibronectin, and several other glycoproteins.
- *Podocytes,* which are structurally complex cells that possess interdigitating processes embedded in and adherent to the lamina rara externa of the basement membrane. Adjacent *foot processes* are separated by 20- to 30-nm-wide *filtration slits,* which are bridged by a thin slit diaphragm composed in large part of nephrin (see further on).
- The glomerular tuft is supported by *mesangial cells* lying between the capillaries. Basement membrane–like mesangial matrix forms a meshwork through which the mesangial cells are scattered. These cells, of mesenchymal origin, are contractile and are capable of proliferation, of laying down collagen and other matrix components, and of secreting a number of biologically active mediators.

Normally, the glomerular filtration system is extraordinarily permeable to water and small solutes and almost completely impermeable to molecules of the size and molecular charge of albumin (a 70,000-kDa protein). This selective permeability, called glomerular barrier function, discriminates among protein molecules according to their size (the larger, the less permeable), their charge (the more cationic, the more permeable), and their configuration. The characteristics of the normal barrier depend on the complex structure of the capillary wall, the integrity of the GBM, and the many anionic molecules present within the wall, including the acidic proteoglycans of the GBM and the sialoglycoproteins of epithelial and endothelial cell coats. *The podocyte is also crucial to the maintenance of glomerular barrier function*. Podocyte slit diaphragms are important diffusion barriers for plasma proteins, and podocytes are also largely responsible for synthesis of GBM components.

In the past few years, much has been learned about the molecular architecture of the glomerular filtration barrier. *Nephrin,* a transmembrane glycoprotein, is the major component of the slit diaphragms between adjacent foot processes. Nephrin molecules from adjacent foot processes bind to each other through disulfide bridges at the center of the slit diaphragm. The intracellular part of nephrin interacts with several cytoskeletal and signaling proteins (Fig. 13–1). Nephrin and its associated proteins, including *podocin,* have a crucial role in maintaining the selective permeability of the glomerular filtration barrier. This role is dramatically illustrated by rare hereditary diseases in which mutations of nephrin or its partner proteins are associated with abnormal leakage into the urine of plasma proteins, giving rise to the nephrotic syndrome (discussed later). This observation suggests that acquired defects in the function or structure of slit diaphragms constitute an important mechanism of proteinuria, the hallmark of the nephrotic syndrome.

Glomeruli may be injured by diverse mechanisms and in the course of a number of systemic diseases (Table 13–1). Immunologically mediated diseases such as systemic lupus erythematosus, vascular disorders such as hypertension and hemolytic uremic syndrome, metabolic diseases such as diabetes mellitus, and some purely hereditary conditions such as Alport syndrome often affect the glomerulus. These are termed *secondary glomerular diseases* to differentiate them from those in which the kidney is the only or predominant organ involved. The latter constitute

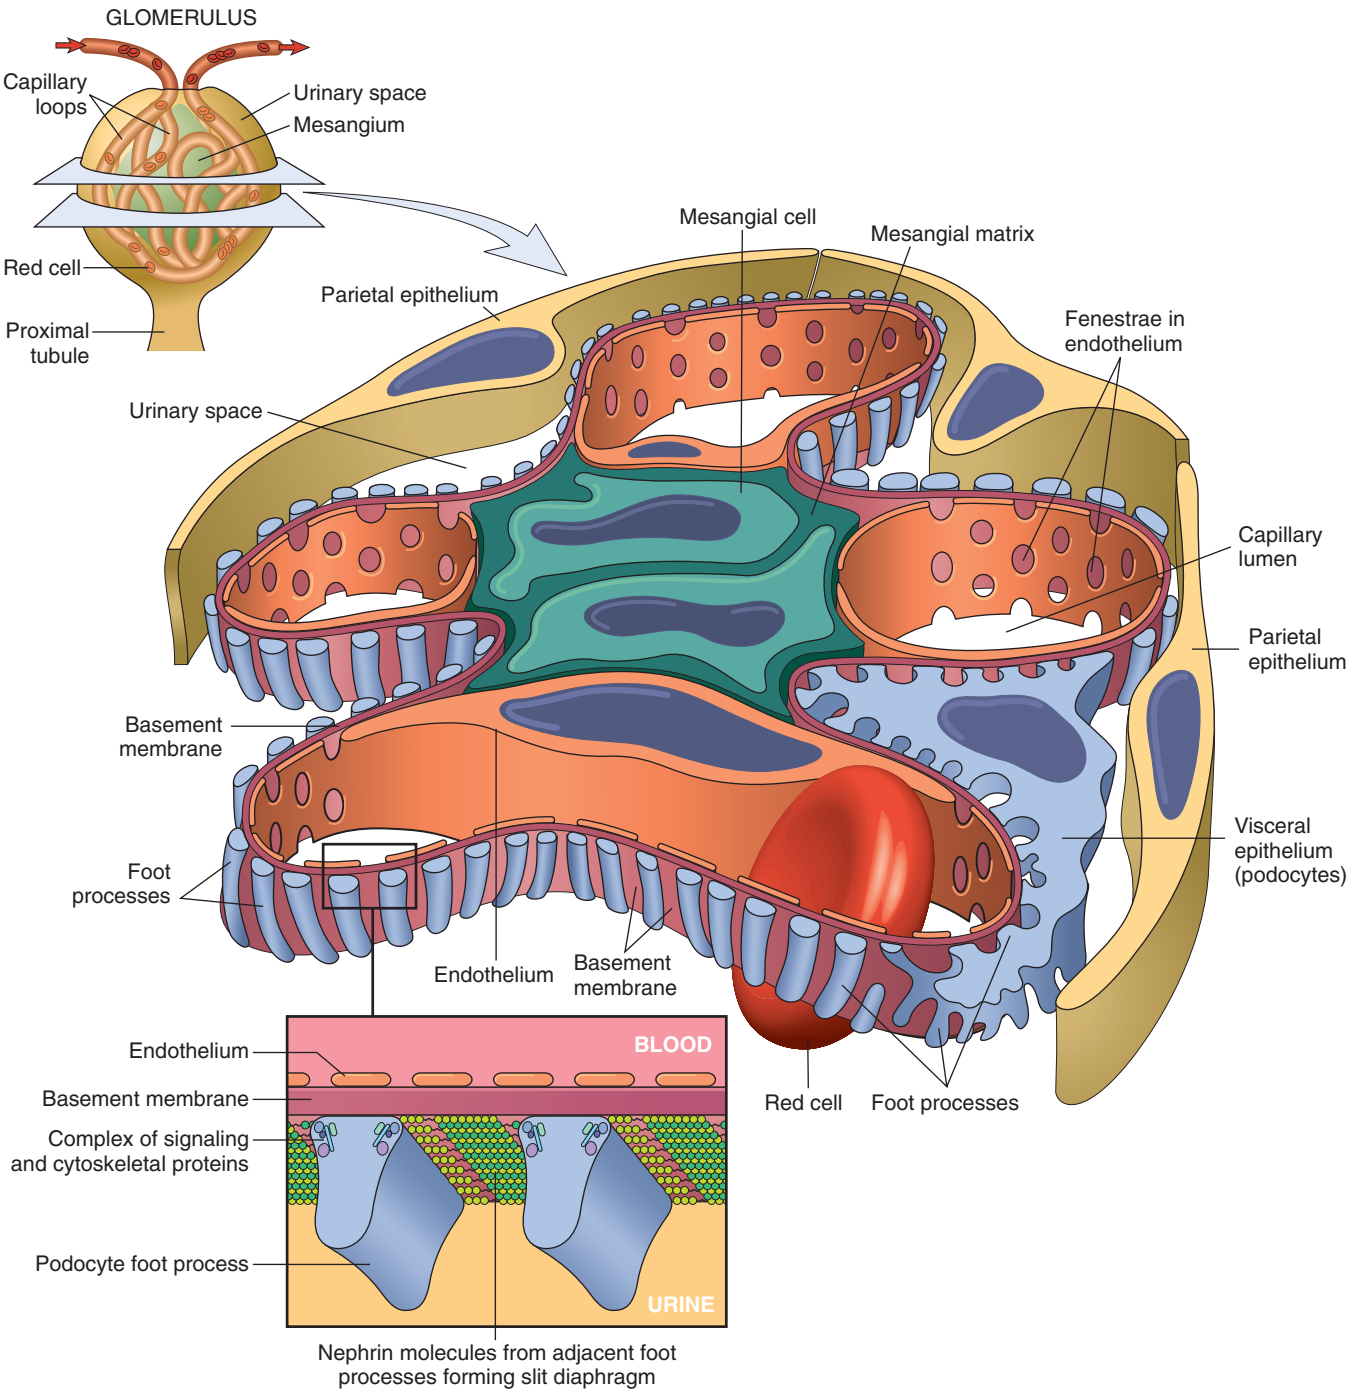

**Figure 13–1** Schematic diagram of a lobe of a normal glomerulus.

the various types of *primary glomerular diseases,* which are discussed later in this section. The glomerular alterations in systemic diseases are discussed elsewhere.

## Mechanisms of Glomerular Injury and Disease

Although little is known about the etiologic agents or triggering events, it is clear that immune mechanisms underlie most types of primary glomerular diseases and many of the secondary glomerular diseases. Under experimental conditions, glomerulonephritis (GN) can be readily induced by antibodies, and deposits of immunoglobulins, often with various components of complement, are found frequently in patients with GN. Cell-mediated immune mechanisms may also play a role in certain glomerular diseases.

Two forms of antibody-associated injury have been established: (1) injury resulting from deposition of soluble circulating antigen-antibody complexes in the glomerulus and (2) injury by antibodies reacting in situ within the glomerulus, either with insoluble fixed (intrinsic)

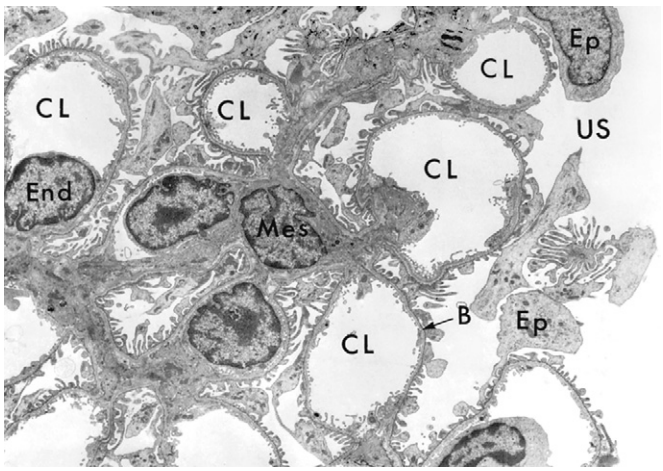

**Figure 13–2** Low-power electron micrograph of rat glomerulus. B, basement membrane; CL, capillary lumen; End, endothelium; Ep, visceral epithelial cells (podocytes) with foot processes; Mes, mesangium; US, urinary space.

glomerular antigens or with molecules planted within the glomerulus (Fig. 13–3). In addition, antibodies directed against glomerular cell components may cause glomerular injury. These pathways are not mutually exclusive, and in humans all may contribute to injury.

### *Glomerulonephritis Caused by Circulating Immune Complexes*

The pathogenesis of immune complex diseases is discussed in detail in Chapter 4. Presented here is a brief review of the salient features that relate to glomerular injury in GN.

With circulating immune complex–mediated disease, the glomerulus may be considered an "innocent bystander" because it does not incite the reaction. The antigen is not of glomerular origin. It may be endogenous, as in the GN associated with systemic lupus erythematosus, or it may be exogenous, as is probable in the GN that follows certain bacterial (streptococcal), viral (hepatitis B), parasitic (*Plasmodium falciparum* malaria), and spirochetal (*Treponema pallidum*) infections. Often the inciting antigen is unknown, as in most cases of membranoproliferative GN (MPGN).

Whatever the antigen may be, *antigen–antibody complexes* are formed in situ or in the circulation and are then trapped in the glomeruli, where they *produce injury, in large part through the activation of complement and the recruitment of leukocytes*. Injury also may occur through the engagement of Fc receptors on leukocytes independent of complement activation, as cross-linking of Fc receptors by IgG antibodies also results in leukocyte activation and degranulation. Regardless of the mechanism, the glomerular lesions usually consist of leukocytic infiltration (exudation) into glomeruli and variable proliferation of endothelial, mesangial, and parietal epithelial cells. Electron microscopy reveals the immune complexes as electron-dense deposits or clumps that lie at one of three sites: in the mesangium, between the endothelial cells and the GBM (subendothelial deposits), or between the outer surface of the GBM and the podocytes (subepithelial deposits). Deposits may be located at more than one site in a given case. The presence of immunoglobulins and complement in these deposits can be demonstrated by immunofluorescence microscopy (Fig. 13–4, *A*). *The pattern and location of immune complex deposition are helpful in distinguishing among various types of GN.*

Once deposited in the kidney, immune complexes may eventually be degraded or phagocytosed, mostly by infiltrating leukocytes and mesangial cells, and the inflammatory changes may then subside. Such a course occurs when the exposure to the inciting antigen is short-lived and limited, as in most cases of poststreptococcal or acute infection-related GN. However, if exposure to antigen is sustained over time, repeated cycles of immune complex formation, deposition, and injury may occur, leading to chronic GN. In some cases the source of chronic antigenic exposure is clear, such as in hepatitis B virus infection and self nuclear antigens in systemic lupus erythematosus. In other cases, however, the antigen is unknown. Circulating immune complex deposition as a mechanism of injury is well studied in animal models but is uncommonly identified in human disease.

### *Glomerulonephritis Caused by In Situ Immune Complexes*

*Antibody deposition in the glomerulus is a major pathway of glomerular injury.* As noted, antibodies in this form of injury react directly with fixed or planted antigens in the glomerulus. Immune reactions in situ, trapping of circulating complexes, interactions between these two events, and local hemodynamic and structural determinants in the glomerulus all contribute to the morphologic and functional alterations in GN. Antibodies also may react in situ with previously "planted" nonglomerular antigens, which may localize in the kidney by interacting with various intrinsic components of the glomerulus. Planted antigens include nucleosomal complexes (in patients with systemic lupus erythematosus); bacterial products, such as endostroptosin, a protein expressed by group A streptococci; large aggregated proteins (e.g., aggregated

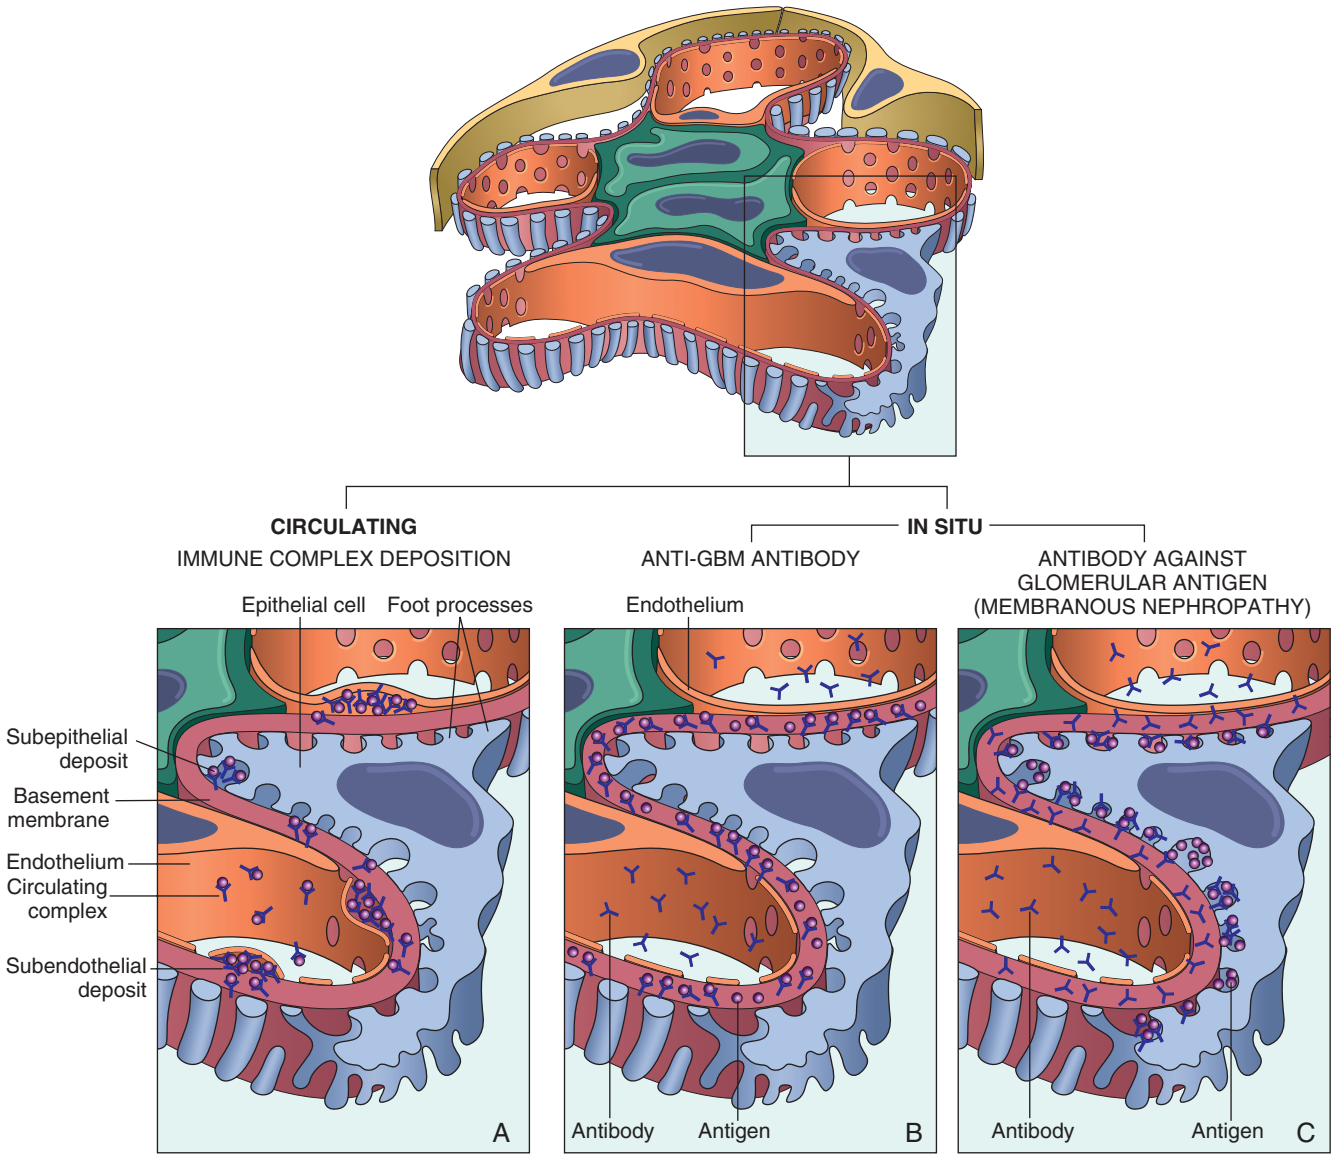

**Figure 13–3** Antibody-mediated glomerular injury. Injury can result either from the deposition of circulating immune complexes or from formation of complexes in situ. **A,** Deposition of circulating immune complexes gives a granular immunofluorescence pattern. **B,** Anti-glomerular basement membrane (anti-GBM) antibody glomerulonephritis is characterized by a linear immunofluorescence pattern. **C,** Antibodies against some glomerular components deposit in a granular pattern.

immunoglobulin G [IgG]), which tend to deposit in the mesangium; and immune complexes themselves, because they contain reactive sites for further interactions with free antibody, free antigen, or complement. Most of these planted antigens induce a granular pattern of immunoglobulin deposition as seen by immunofluorescence microscopy.

The following factors affect glomerular localization of antigen, antibody, or immune complexes: the molecular charge and size of the reactants; glomerular hemodynamics; mesangial function; and the integrity of the charge-selective glomerular barrier. The localization of antigen, antibody, or immune complexes in turn determines the glomerular injury response. Studies in experimental models have shown that complexes deposited in the endothelium or subendothelium elicit an inflammatory reaction in the glomerulus with infiltration of leukocytes and exuberant proliferation of glomerular resident cells. By contrast, antibodies directed to the subepithelial region of glomerular capillaries are largely noninflammatory and elicit lesions similar to those of Heymann nephritis or membranous nephropathy (discussed later).

### *Anti-Glomerular Basement Membrane Antibody–Mediated Glomerulonephritis*

The best-characterized disease in this group is classic anti-GBM antibody–mediated crescentic GN (Fig. 13–3, *B*). In this type of injury, antibodies are directed against fixed antigens in the GBM. It has its experimental counterpart in the nephritis of rodents called *nephrotoxic serum nephritis.* This is produced by injecting rats with anti-GBM antibodies produced by immunization of rabbits or other species with rat kidney. *Antibody–mediated GN in humans results*

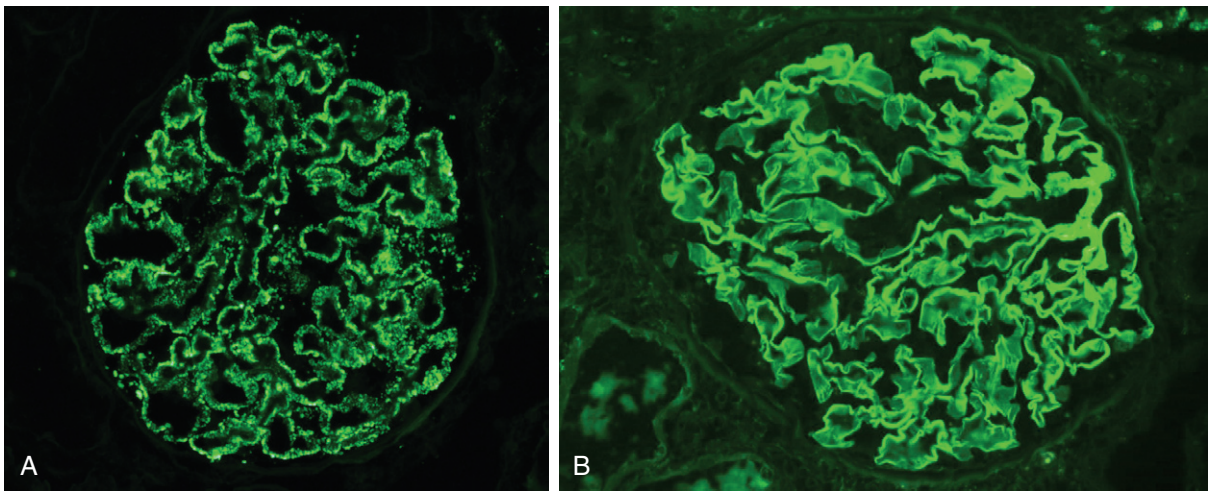

**Figure 13–4** Two patterns of deposition of immune complexes as seen by immunofluorescence microscopy. **A,** Granular, characteristic of circulating and in situ immune complex deposition. **B,** Linear, characteristic of classic anti-glomerular basement membrane (anti-GBM) antibody glomerulonephritis.

*from the formation of autoantibodies directed against the GBM.* Deposition of these antibodies creates a *linear pattern* of staining when the bound antibodies are visualized with immunofluorescence microscopy, in contrast with the granular pattern described for other forms of immune complex–mediated nephritis (Fig. 13–4, *B*). This distinction is useful in the diagnosis of glomerular disease. A conformational change in the α3 chain of the type IV collagen of the GBM appears to be key in inciting autoimmunity. Sometimes the anti-GBM antibodies cross-react with basement membranes of lung alveoli, resulting in simultaneous lung and kidney lesions (*Goodpasture syndrome*). Although anti-GBM antibody–mediated GN accounts for less than 1% of human GN cases, the resulting disease can be very serious. Many instances of anti-GBM antibody–mediated crescentic GN are characterized by very severe glomerular damage with necrosis and crescents and the development of the clinical syndrome of rapidly progressive GN (see below).

### *Mediators of Immune Injury*

Once immune reactants are localized in the glomerulus, how does glomerular damage ensue? A major pathway of antibody-initiated injury involves complement activation and recruitment of leukocytes (Fig. 13–5). Activation of complement via the classical pathway leads to the generation of chemotactic agents (mainly C5a) for neutrophils and monocytes. Neutrophils release proteases, which cause GBM degradation; oxygen-derived free radicals, which cause cell damage; and arachidonic acid metabolites, which contribute to reduction in GFR. This mechanism applies only to some types of GN, however, because many types show few neutrophils in the damaged glomeruli. In these cases neutrophil-independent but complement-dependent injury may occur, possibly caused by the C5b-C9 membrane attack complex, which is formed on the GBM and may induce sublytic epithelial cell injury and stimulate the secretion of various inflammatory mediators from

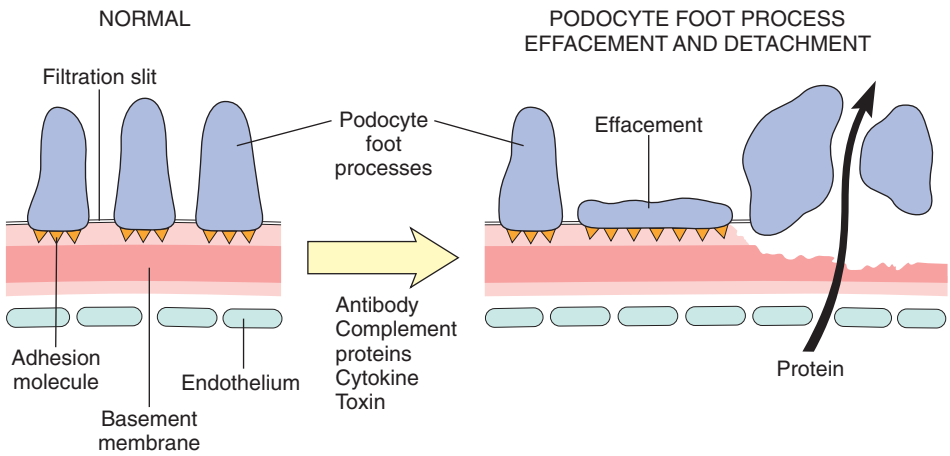

**Figure 13–5** Podocyte injury. The postulated sequence may be initiated by antibodies to podocyte antigens, toxins, cytokines, or other factors. The common features are podocyte injury leading to foot process effacement and variable degrees of podocyte detachment, and degradation of the basement membrane. These defects permit plasma proteins to be lost into the urinary space.

mesangial and epithelial cells. The alternative and mannose-binding lectin pathways of complement can be activated by cell injury or apoptosis, also leading to glomerular injury (Fig. 13–5).

Antibodies against glomerular cell antigens also may directly damage glomerular cells or slit diaphragms. Such antibodies are suspected of being involved in certain disorders in which immune complexes are not found. Other mediators of glomerular damage include the following:

- *Monocytes and macrophages,* which infiltrate the glomerulus in antibody- and cell-mediated reactions and, when activated, release diverse mediators
- Sensitized T cells, formed during the course of a cell-mediated immune reaction, can cause experimental glomerular injury. In some forms of experimental GN, the disease can be induced by transfer of sensitized T cells. T cell–mediated injury may account for the instances of GN in which either there are no deposits of antibodies or immune complexes or the deposits do not correlate with the severity of damage. However, it has been difficult to establish a causal role for T cells or cell-mediated immune responses in human GN.
- *Platelets,* which aggregate in the glomerulus during immune-mediated injury and release prostaglandins and growth factors
- *Resident glomerular cells* (epithelial, mesangial, and endothelial), which can be stimulated to secrete mediators such as cytokines (interleukin-1), arachidonic acid metabolites, growth factors, nitric oxide, and endothelin
- *Thrombin,* produced as a consequence of intraglomerular thrombosis, which causes leukocyte infiltration and glomerular cell proliferation by triggering protease-activated receptors (PARs)

In essence, virtually all of the mediators described in the discussion of inflammation in Chapter 2 may contribute to glomerular injury.

### *Other Mechanisms of Glomerular Injury*

Other mechanisms contribute to glomerular damage in certain primary renal disorders. Two that deserve special mention due to their importance are podocyte injury and nephron loss.

#### Podocyte Injury

Podocyte injury can be induced by antibodies to podocyte antigens; by toxins, as in an experimental model of proteinuria induced by the ribosome poison puromycin; conceivably by certain cytokines; or by still poorly characterized circulating factors, as in some cases of focal segmental glomerulosclerosis (see later). Podocyte injury is reflected by morphologic changes, which include effacement of foot processes, vacuolization, and retraction and detachment of cells from the GBM, and clinically by proteinuria. In most forms of glomerular injury, loss of normal slit diaphragms is key in the development of proteinuria (Fig. 13–5). Functional abnormalities of the slit diaphragm also may result from mutations in its structural components, such as nephrin and the associated podocin. Such mutations cause rare hereditary forms of the nephrotic syndrome.

#### Nephron Loss

Once renal disease, glomerular or otherwise, destroys sufficient nephrons to reduce the GFR to 30% to 50% of normal, progression to end-stage kidney disease proceeds inexorably at varying rates. Affected persons have proteinuria, and their kidneys show widespread *glomerulosclerosis.* Such progressive sclerosis may be initiated, at least in part, by the adaptive changes that occur in the remaining glomeruli not destroyed by the initial disease. These remaining glomeruli undergo hypertrophy to maintain renal function. This hypertrophy is associated with hemodynamic changes, including increases in single-nephron GFR, blood flow, and transcapillary pressure (capillary hypertension). These alterations ultimately become "maladaptive" and lead to further endothelial and podocyte injury, increased glomerular permeability to proteins, and accumulation of proteins and lipids in the mesangial matrix. This is followed by capillary obliteration, increased deposition of mesangial matrix and plasma proteins, and ultimately by segmental (affecting a portion) or global (complete) sclerosis of glomeruli. The latter results in further reductions in nephron mass and a vicious circle of progressive glomerulosclerosis.

## SUMMARY

### Glomerular Injury

- Antibody-mediated immune injury is an important mechanism of glomerular damage, mainly by way of complement- and leukocyte-mediated pathways. Antibodies also may be directly cytotoxic to cells in the glomerulus.
- The most common forms of antibody-mediated GN are caused by the formation of immune complexes, whether occurring in situ or by deposition of circulating immune complexes. These immune complexes may contain exogenous (e.g. microbial) circulating antigens or endogenous antigens (e.g. in membranous nephropathy). Immune complexes show a granular pattern of deposition.
- Autoantibodies against components of the GBM are the cause of anti-GBM-antibody–mediated disease, often associated with severe injury. The pattern of antibody deposition is linear.
- Immune complexes and antibodies cause injury by complement activation and leukocyte recruitment, with release of various mediators, and sometimes by direct podocyte damage.

We now turn to a consideration of specific types of GN and the glomerular syndromes they produce.

## The Nephrotic Syndrome

The nephrotic syndrome refers to a clinical complex that includes

- *Massive proteinuria,* with daily protein loss in the urine of 3.5 g or more in adults
- *Hypoalbuminemia,* with plasma albumin levels less than 3 g/dL

- *Generalized edema,* the most obvious clinical manifestation
- *Hyperlipidemia and lipiduria.*

The nephrotic syndrome has diverse causes that share a common pathophysiology (Table 13–2). In all there is a derangement in the capillary walls of the glomeruli that results in increased permeability to plasma proteins. Any increased permeability resulting from either structural or physicochemical alterations in the GBM allows protein to escape from the plasma into the glomerular filtrate. With long-standing or extremely heavy proteinuria, serum albumin is decreased, resulting in hypoalbuminemia and a drop in plasma colloid osmotic pressure. As discussed in Chapter 3, the resulting decrease in intravascular volume and renal blood flow triggers increased release of renin from renal juxtaglomerular cells. Renin in turn stimulates the angiotensin-aldosterone axis, which promotes the retention of salt and water by the kidney. This tendency is exacerbated by reductions in the cardiac secretion of natriuretic factors. In the face of continuing proteinuria, these alterations further aggravate the edema and if unchecked may lead to the development of generalized edema (termed *anasarca*). At the onset, there is little or no azotemia, hematuria, or hypertension.

The genesis of the hyperlipidemia is more obscure. Presumably, hypoalbuminemia triggers increased synthesis of lipoproteins in the liver or massive proteinuria causes loss of an inhibitor of their synthesis. There is also abnormal transport of circulating lipid particles and impairment of peripheral breakdown of lipoproteins. The lipiduria, in turn, reflects the increased permeability of the GBM to lipoproteins.

**Table 13–2** Causes of Nephrotic Syndrome

| Cause | Prevalence (%)* | |
|---|---|---|
| | Children | Adults |
| **Primary Glomerular Disease** | | |
| Membranous nephropathy | 5 | 30 |
| Minimal-change disease | 65 | 10 |
| Focal segmental glomerulosclerosis | 10 | 35 |
| Membranoproliferative glomerulonephritis | 10 | 10 |
| IgA nephropathy and others | 10 | 15 |
| **Systemic Diseases with Renal Manifestations** | | |
| Diabetes mellitus | | |
| Amyloidosis | | |
| Systemic lupus erythematosus | | |
| Ingestion of drugs (gold, penicillamine, "street heroin") | | |
| Infections (malaria, syphilis, hepatitis B, HIV infection) | | |
| Malignancy (carcinoma, melanoma) | | |
| Miscellaneous (bee sting allergy, hereditary nephritis) | | |

*Approximate prevalence of primary disease is 95% of the cases in children, 60% in adults. Approximate prevalence of systemic disease is 5% of the cases in children, 40% in adults.
HIV, human immunodeficiency virus.

The relative frequencies of the several causes of the nephrotic syndrome vary according to age (Table 13–2). In children 1 to 7 years of age, for example, the nephrotic syndrome is almost always caused by a lesion primary to the kidney, whereas among adults it often is due to renal manifestations of a systemic disease. The most frequent systemic causes of the nephrotic syndrome in adults are diabetes, amyloidosis, and systemic lupus erythematosus. The renal lesions produced by these disorders are described in Chapter 4. The most important of the primary glomerular lesions that characteristically lead to the nephrotic syndrome are focal and segmental glomerulosclerosis and minimal-change disease. The latter is more important in children; the former, in adults. Two other primary lesions, membranous nephropathy and membranoproliferative glomerulonephritis, also commonly produce the nephrotic syndrome. These four lesions are discussed individually next.

### *Minimal-Change Disease*

Minimal-change disease, a relatively benign disorder, is the most frequent cause of the nephrotic syndrome in children. Characteristically, the *glomeruli have a normal appearance by light microscopy but show diffuse effacement of podocyte foot processes when viewed with the electron microscope*. Although it may develop at any age, this condition is most common between the ages of 1 and 7 years.

The pathogenesis of proteinuria in minimal-change disease remains to be elucidated. On the basis of some experimental studies, the proteinuria has been attributed to a circulating, possibly T cell–derived, factor that causes podocyte damage and effacement of foot processes. Neither the nature of such a putative factor nor a causal role of T cells, however, is established in the human disease.

#### MORPHOLOGY

Under the light microscope, the glomeruli appear normal, thus giving rise to the name "minimal-change disease" (Fig. 13–6, *A*). The cells of the proximal convoluted tubules often are heavily laden with protein droplets and lipids, but this feature is secondary to tubular reabsorption of the lipoproteins passing through the diseased glomeruli. Even under the electron microscope, the GBM appears normal. The only obvious glomerular abnormality is the **uniform and diffuse effacement of the foot processes of the podocytes** (Fig. 13–6, *B*). The cytoplasm of the podocytes thus appears flattened over the external aspect of the GBM, obliterating the network of arcades between the podocytes and the GBM. There are also epithelial cell vacuolization, microvillus formation, and occasional focal detachments, suggesting some form of podocyte injury. With reversal of the changes in the podocytes (e.g., in response to corticosteroids), the proteinuria remits.

#### Clinical Course

The disease manifests with the insidious development of the nephrotic syndrome in an otherwise healthy child. There is no hypertension, and renal function is preserved in most of these patients. The protein loss usually is

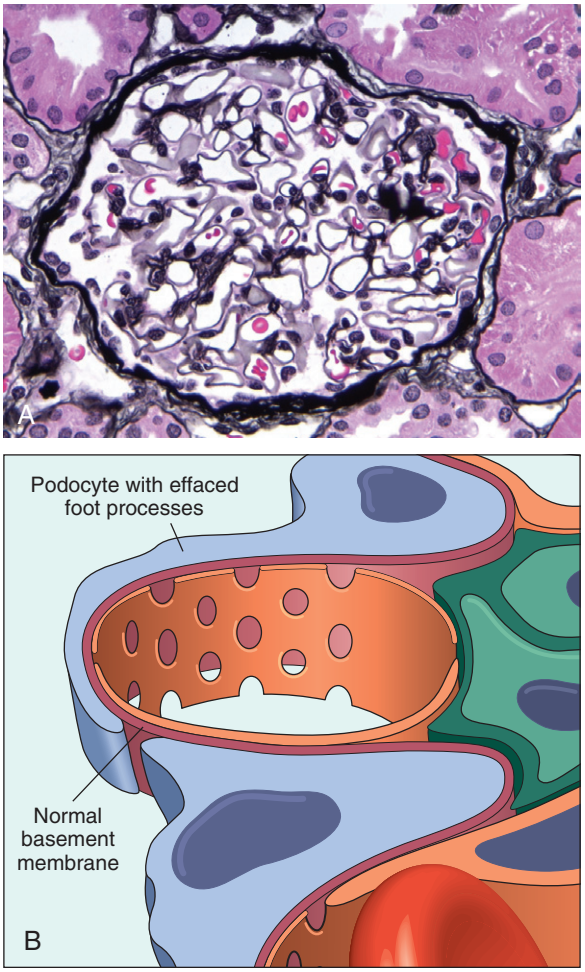

**Figure 13–6** Minimal-change disease. **A,** Under the light microscope the silver methenamine–stained glomerulus appears normal, with a delicate basement membrane. **B,** Schematic diagram illustrating diffuse effacement of foot processes of podocytes with no immune deposits.

confined to the smaller plasma proteins, chiefly albumin (selective proteinuria). The prognosis for children with this disorder is good. *More than 90% of children respond to a short course of corticosteroid therapy;* however, proteinuria recurs in more than two thirds of the initial responders, some of whom become steroid-dependent. Less than 5% develop chronic kidney disease after 25 years, and it is likely that most persons in this subgroup had nephrotic syndrome caused by focal and segmental glomerulosclerosis not detected by biopsy. Because of its responsiveness to therapy in children, minimal-change disease must be differentiated from other causes of the nephrotic syndrome in nonresponders. Adults with this disease also respond to steroid therapy, but the response is slower and relapses are more common.

### *Focal Segmental Glomerulosclerosis*

Focal segmental glomerulosclerosis (FSGS) is characterized histologically by sclerosis affecting some but not all glomeruli (*focal involvement*) and involving only segments of each affected glomerulus (*segmental involvement*). This histologic picture often is associated with the nephrotic syndrome. FSGS may be primary (idiopathic) or secondary to one of the following conditions:

- In association with other conditions, such as HIV infection (HIV nephropathy) or heroin abuse (heroin nephropathy)
- As a secondary event in other forms of GN (e.g., IgA nephropathy)
- As a maladaptation to nephron loss (as described earlier)
- In inherited or congenital forms. Autosomal dominant forms are associated with mutations in cytoskeletal proteins and podocin, both of which are required for the integrity of podocytes. In addition, a sequence variant in the apolipoprotein L1 gene (*APOL1*) on chromosome 22 appears to be strongly associated with an increased risk of FSGS and renal failure in individuals of African descent.

Primary FSGS accounts for approximately 20% to 30% of all cases of the nephrotic syndrome. It is an increasingly common cause of nephrotic syndrome in adults and remains a frequent cause in children.

#### PATHOGENESIS

The pathogenesis of primary FSGS is unknown. Some investigators have suggested that FSGS and minimal-change disease are part of a continuum and that minimal-change disease may transform into FSGS. Others believe them to be distinct clinicopathologic entities from the outset. In any case, **injury to the podocytes is thought to represent the initiating event of primary FSGS.** As with minimal-change disease, permeability-increasing factors produced by lymphocytes have been proposed. The deposition of hyaline masses in the glomeruli represents the entrapment of plasma proteins and lipids in foci of injury where sclerosis develops. IgM and complement proteins commonly seen in the lesion are also believed to result from nonspecific entrapment in damaged glomeruli. The recurrence of proteinuria and subsequent FSGS in a renal transplant in some patients who had FSGS, sometimes within 24 hours of transplantation, supports the idea that a circulating mediator is the cause of the podocyte damage in some cases.

#### MORPHOLOGY

In FSGS, the disease first affects only some of the glomeruli (hence the term ***focal***) and, in the case of primary FSGS, initially only the juxtamedullary glomeruli. With progression, eventually all levels of the cortex are affected. On histologic examination, FSGS is characterized by lesions occurring in some tufts within a glomerulus and sparing of the others (hence the term ***segmental***). Thus, the involvement is both focal and segmental (Fig. 13–7). The affected glomeruli exhibit **increased mesangial matrix, obliterated capillary lumina, and deposition of hyaline masses (hyalinosis) and lipid droplets.** In affected glomeruli, immunofluorescence microscopy often reveals nonspecific trapping of immunoglobulins, usually IgM, and complement

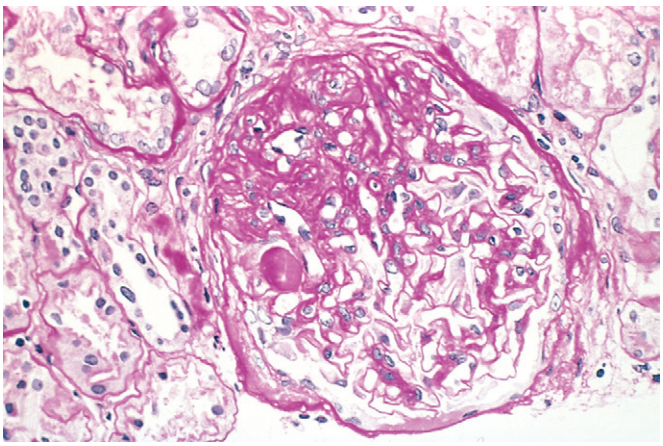

**Figure 13–7** High-power view of focal and segmental glomerulosclerosis (periodic acid–Schiff stain), seen as a mass of scarred, obliterated capillary lumens with accumulations of matrix material that has replaced a portion of the glomerulus.
*(Courtesy of Dr. H. Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts.)*

in the areas of hyalinosis. On electron microscopy, the podocytes exhibit **effacement of foot processes,** as in minimal-change disease.

In time, progression of the disease leads to global sclerosis of the glomeruli with pronounced tubular atrophy and interstitial fibrosis. This advanced picture is difficult to differentiate from other forms of chronic glomerular disease, described later on.

A morphologic variant called **collapsing glomerulopathy** is being increasingly reported. It is characterized by collapse of the glomerular tuft and podocyte hyperplasia. This is a more severe manifestation of FSGS that may be idiopathic or associated with HIV infection, drug-induced toxicities, and some microvascular injuries. It carries a particularly poor prognosis.

Clinical Course

*In children it is important to distinguish FSGS as a cause of the nephrotic syndrome from minimal-change disease,* because the clinical courses are markedly different. The incidence of hematuria and hypertension is higher in persons with FSGS than in those with minimal-change disease; the FSGS-associated proteinuria is nonselective; and in general the response to corticosteroid therapy is poor. At least 50% of patients with FSGS develop end-stage kidney disease within 10 years of diagnosis. Adults typically fare even less well than children.

### *Membranous Nephropathy*

Membranous nephropathy is a slowly progressive disease, most common between 30 and 60 years of age. *It is characterized morphologically by the presence of subepithelial immunoglobulin-containing deposits along the GBM.* Early in the disease, the glomeruli may appear normal by light microscopy, but well-developed cases show *diffuse thickening of the capillary wall.*

In about 85% of cases, membranous nephropathy is caused by autoantibodies that cross-react with antigens expressed by podocytes. In the remainder (secondary membranous nephropathy), it occurs secondary to other disorders, including

- Infections (chronic hepatitis B, syphilis, schistosomiasis, malaria)
- Malignant tumors, particularly carcinoma of the lung and colon and melanoma
- Systemic lupus erythematosus and other autoimmune conditions
- Exposure to inorganic salts (gold, mercury)
- Drugs (penicillamine, captopril, nonsteroidal anti-inflammatory agents)

#### PATHOGENESIS

**Membranous nephropathy is a form of chronic immune complex glomerulonephritis** induced by antibodies reacting in situ to endogenous or planted glomerular antigens. An endogenous podocyte antigen, the phospholipase $A_2$ receptor, is the antigen that is most often recognized by the causative autoantibodies.

The experimental model of membranous nephropathy is Heymann nephritis, which is induced in animals by immunization with renal tubular brush border proteins that also are present on podocytes. The antibodies that are produced react with an antigen located in the glomerular capillary wall, resulting in granular deposits **(in situ immune complex formation)** and proteinuria without severe inflammation.

A puzzling aspect of the disease is how antigen-antibody complexes cause capillary damage despite the absence of inflammatory cells. The likely answer is by activating complement, which is uniformly present in the lesions of membranous nephropathy. It is hypothesized that complement activation leads to assembly of the C5b-C9 membrane attack complex, which damages mesangial cells and podocytes directly, setting in motion events that cause the loss of slit filter integrity and proteinuria.

#### MORPHOLOGY

Histologically, the main feature in membranous nephropathy is **diffuse thickening of the capillary wall** (Fig. 13–8, *A*). Electron microscopy reveals that this thickening is caused in part by **subepithelial deposits,** which nestle against the GBM and are separated from each other by small, spikelike protrusions of GBM matrix that form in reaction to the deposits **(spike and dome pattern)** (Fig. 13–8, *B*). As the disease progresses, these spikes close over the deposits, incorporating them into the GBM. In addition, as in other causes of nephrotic syndrome, the podocytes show **effacement of foot processes.** Later in the disease, the incorporated deposits may be broken down and eventually disappear, leaving cavities within the GBM. Continued deposition of basement membrane matrix leads to progressive thickening of basement membranes. With further progression, the glomeruli can become sclerosed. Immunofluorescence microscopy shows typical **granular deposits** of immunoglobulins and complement along the GBM (Fig. 13–4, *A*).

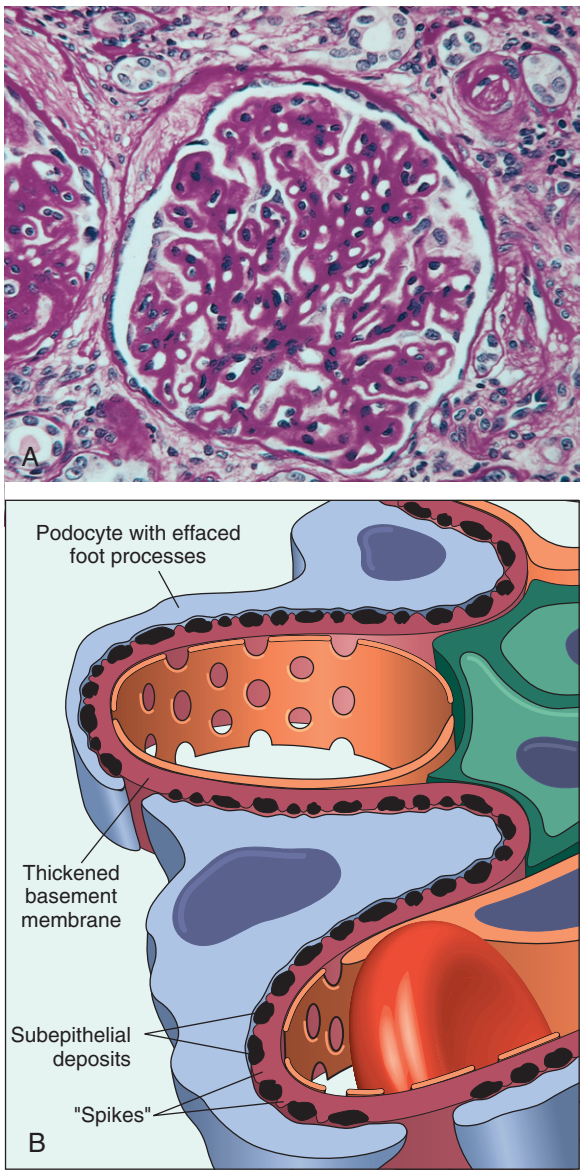

**Figure 13–8** Membranous nephropathy. **A,** Diffuse thickening of the glomerular basement membrane (periodic acid–Schiff stain). **B,** Schematic diagram illustrating subepithelial deposits, effacement of foot processes, and the presence of *spikes* of basement membrane material between the immune deposits.

### Clinical Course

Most cases of membranous nephropathy present as full-blown nephrotic syndrome, usually without antecedent illness; other individuals may have lesser degrees of proteinuria. In contrast with minimal-change disease, the proteinuria is nonselective, with urinary loss of globulins as well as smaller albumin molecules, and does not usually respond to corticosteroid therapy. Secondary causes of membranous nephropathy should be ruled out. Membranous nephropathy follows a notoriously variable and often indolent course. Overall, although proteinuria persists in greater than 60% of patients with membranous nephropathy, only about 40% suffer progressive disease terminating in renal failure after 2 to 20 years. An additional 10% to 30% have a more benign course with partial or complete remission of proteinuria.

## *Membranoproliferative Glomerulonephritis and Dense Deposit Disease*

Membranoproliferative GN (MPGN) is manifested histologically by alterations in the GBM and mesangium and by proliferation of glomerular cells. It accounts for 5% to 10% of cases of idiopathic nephrotic syndrome in children and adults. Some patients present only with hematuria or proteinuria in the non-nephrotic range; others exhibit a combined nephrotic–nephritic picture. Two major types of MPGN (I and II) have traditionally been recognized on the basis of distinct ultrastructural, immunofluorescence, microscopic, and pathogenic findings, but these are now recognized to be separate entities, termed MPGN type I and dense deposit disease (formerly MPGN type II). Of the two types of disease, MPGN type I is far more common (about 80% of cases).

### PATHOGENESIS

Different pathogenic mechanisms are involved in the development of MPGN and dense deposit disease.

- **Some cases of type I MPGN may be caused by circulating immune complexes,** akin to chronic serum sickness, or may be due to a planted antigen with subsequent *in situ* immune complex formation. In either case, the inciting antigen is not known. Type I MPGN also occurs in association with hepatitis B and C antigenemia, systemic lupus erythematosus, infected atrioventricular shunts, and extrarenal infections with persistent or episodic antigenemia.
- The pathogenesis of **dense deposit disease** is less clear. **The fundamental abnormality in dense deposit disease appears to be excessive complement activation.** Some patients have an autoantibody against C3 convertase, called **C3 nephritic factor,** which is believed to stabilize the enzyme and lead to uncontrolled cleavage of C3 and activation of the alternative complement pathway. Mutations in the gene encoding the complement regulatory protein **factor H** or autoantibodies to factor H have been described in some patients. These abnormalities result in excessive complement activation. Hypocomplementemia, more marked in dense deposit disease, is produced in part by excessive consumption of C3 and in part by reduced synthesis of C3 by the liver. It is still not clear how the complement abnormality induces the glomerular changes.

### MORPHOLOGY

By light microscopy, type I MPGN and many cases of dense deposit disease are similar. The glomeruli are large, with an accentuated **lobular appearance,** and show **proliferation of mesangial and endothelial cells** as well as infiltrating leukocytes (Fig. 13–9, *A*). The **GBM is thickened,** and the glomerular capillary wall often shows a double contour, or "tram track," appearance, especially evident with use of silver or periodic acid–Schiff (PAS) stains. This "**splitting**" **of the GBM** is due to extension of processes of mesangial and inflammatory cells into the peripheral capillary loops and deposition of mesangial matrix (Fig. 13–9, *B*).

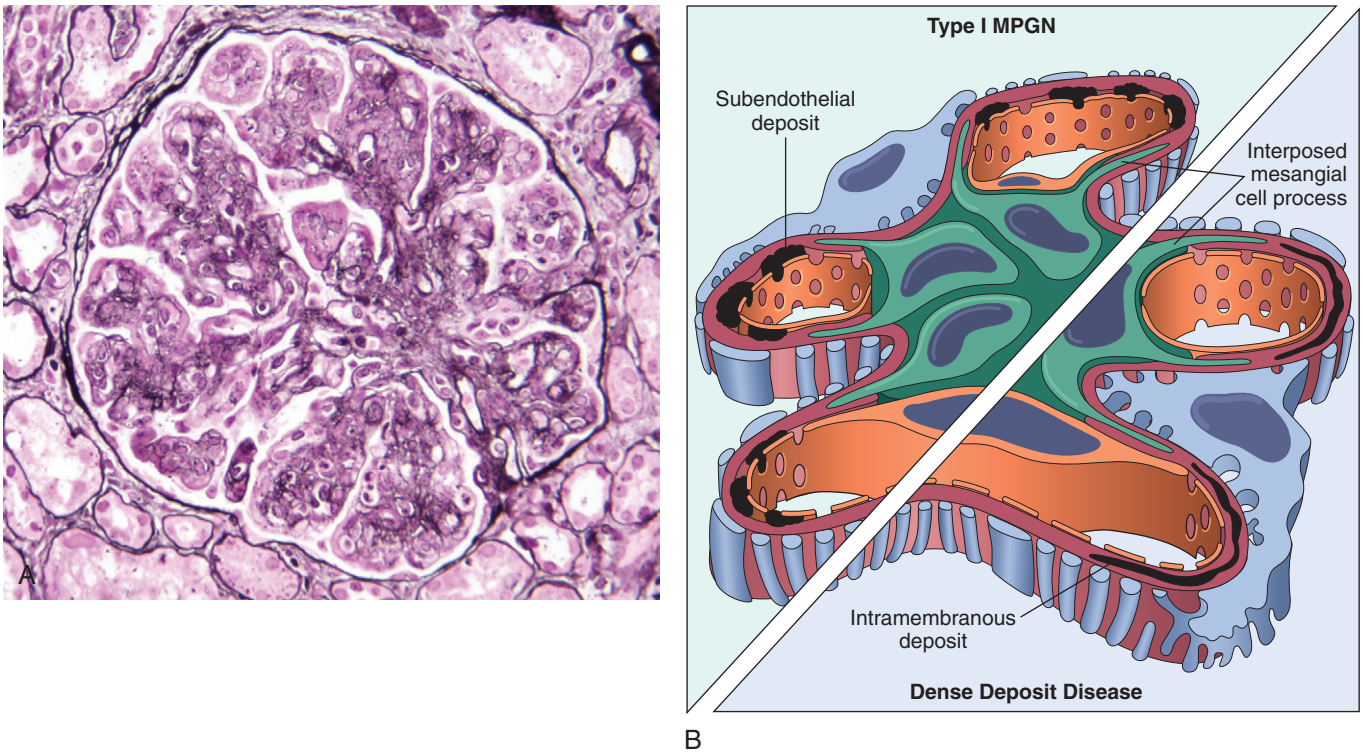

**Figure 13–9 A,** Membranoproliferative glomerulonephritis (MPGN), showing mesangial cell proliferation, basement membrane thickening, leukocyte infiltration, and accentuation of lobular architecture. **B,** Schematic representation of patterns in the two types of MPGN. In type I there are subendothelial deposits; in type II, now called dense deposit disease, intramembranous characteristically dense deposits are seen. In both types, mesangial interposition gives the appearance of split basement membranes when viewed by light microscopy.

**Type I MPGN** is characterized by discrete **subendothelial electron-dense deposits** (Fig. 13–9, *B*). By immunofluorescence microscopy, C3 is deposited in an irregular granular pattern, and IgG and early complement components (C1q and C4) often are also present, indicative of an immune complex pathogenesis.

By contrast, in the aptly named **dense deposit disease** the lamina densa and the subendothelial space of the GBM are transformed into an irregular, ribbon-like, extremely electron-dense structure, resulting from the deposition of material of unknown composition. C3 is present in irregular chunky and segmental linear foci in the basement membranes and in the mesangium. IgG and the early components of the classical complement pathway (C1q and C4) are usually absent.

### Clinical Course

The principal mode of presentation (in approximately 50% of cases) is the nephrotic syndrome, although MPGN or dense deposit disease may begin as acute nephritis or mild proteinuria. The prognosis of MPGN type I generally is poor. In one study, none of the 60 patients followed for 1 to 20 years showed complete remission. Forty percent progressed to end-stage renal failure, 30% had variable degrees of renal insufficiency, and the remaining 30% had persistent nephrotic syndrome without renal failure. Dense deposit disease carries an even worse prognosis, and it tends to recur more frequently in renal transplant recipients. MPGN type I may occur in association with other disorders (*secondary MPGN*), such as systemic lupus erythematosus, hepatitis B and C, chronic liver disease, and chronic bacterial infections. Indeed, many so-called idiopathic cases are believed to be associated with hepatitis C and related cryoglobulinemia.

## SUMMARY

### The Nephrotic Syndrome

- The nephrotic syndrome is characterized by proteinuria, which results in hypoalbuminemia and edema.
- Podocyte injury is an underlying mechanism of proteinuria, and may be the result of nonimmune causes (as in minimal-change disease and FSGS) or immune mechanisms (as in membranous nephropathy).
- *Minimal-change disease* is the most frequent cause of nephrotic syndrome in children; it is manifested by proteinuria and effacement of glomerular foot processes without antibody deposits; the pathogenesis is unknown; the disease responds well to steroid therapy.
- *FSGS* may be primary (podocyte injury by unknown mechanisms) or secondary (e.g., as a consequence of previous glomerulonephritis, hypertension, or infection such as with HIV); glomeruli show focal and segmental obliteration of capillary lumina, and loss of foot processes; the disease often is resistant to therapy and may progress to end-stage renal disease.

- *Membranous nephropathy* is caused by an autoimmune response, most often directed against the phospholipase $A_2$ receptor on podocytes; it is characterized by granular subepithelial deposits of antibodies with GBM thickening and loss of foot processes but little or no inflammation; the disease often is resistant to steroid therapy.
- MPGN and dense deposit disease are now recognized to be distinct entities. MPGN is caused by immune complex deposition; dense deposit disease is a consequence of complement dysregulation. Both may present with nephrotic and/or nephritic features.

## The Nephritic Syndrome

The nephritic syndrome is a clinical complex, usually of acute onset, characterized by (1) *hematuria* with dysmorphic red cells and red cell casts in the urine; (2) some degree of *oliguria and azotemia;* and (3) *hypertension.*

Although proteinuria and even edema also may be present, these usually are not as severe as in the nephrotic syndrome. The lesions that cause the nephritic syndrome have in common proliferation of the cells within the glomeruli, often accompanied by an inflammatory leukocytic infiltrate. This inflammatory reaction severely injures the capillary walls, permitting blood to pass into the urine and inducing hemodynamic changes that lead to a reduction in the GFR. The reduced GFR is manifested clinically by oliguria, fluid retention, and azotemia. Hypertension probably is a result of both the fluid retention and some augmented renin release from the ischemic kidneys.

The acute nephritic syndrome may be produced by systemic disorders such as systemic lupus erythematosus, or it may be secondary to primary glomerular disease. The latter is exemplified by acute postinfectious GN.

### *Acute Postinfectious (Poststreptococcal) Glomerulonephritis*

*Acute postinfectious GN, one of the more frequently occurring glomerular disorders, is caused by glomerular deposition of immune complexes resulting in proliferation of and damage to glomerular cells and infiltration of leukocytes, especially neutrophils.* The inciting antigen may be exogenous or endogenous. The prototypic exogenous pattern is seen in poststreptococcal GN. Infections by organisms other than streptococci may also be associated with postinfectious GN. These include certain pneumococcal and staphylococcal infections as well as several common viral diseases such as mumps, measles, chickenpox, and hepatitis B and C. Endogenous antigens, as occur in systemic lupus erythematosus, also may cause a proliferative GN but more commonly result in a membranous nephropathy (see earlier) lacking the neutrophil infiltrates that are characteristic of postinfectious GN.

The classic case of poststreptococcal GN develops in a child 1 to 4 weeks after they recover from a group A streptococcal infection. Only certain "nephritogenic" strains of β-hemolytic streptococci evoke glomerular disease. In most cases, the initial infection is localized to the pharynx or skin.

#### PATHOGENESIS

**Poststreptococcal GN is an immune complex disease** in which tissue injury is primarily caused by complement activation by the classical pathway. Typical features of immune complex disease, such as hypocomplementemia and granular deposits of IgG and complement on the GBM, are seen. The relevant antigens probably are streptococcal proteins. Specific antigens implicated in pathogenesis include streptococcal exotoxin B (Spe B) and streptococcal GAPDH. Both activate the alternative complement pathway and have affinity for glomerular proteins and plasmin. It is not clear if immune complexes are formed mainly in the circulation or in situ (the latter by binding of antibodies to bacterial antigens "planted" in the GBM).

#### MORPHOLOGY

By light microscopy, the most characteristic change in postinfectious GN is **increased cellularity** of the glomerular tufts that affects nearly all glomeruli—hence the term **diffuse** (Fig. 13–10, *A*). The increased cellularity is caused both by proliferation and swelling of endothelial and mesangial cells and by infiltrating neutrophils and monocytes. Sometimes there is necrosis of the capillary walls. In a few cases, "crescents" (described later) may be observed within the urinary space, formed in response to the severe inflammatory injury. Electron microscopy shows deposited immune complexes arrayed as subendothelial, intramembranous, or, most often, **subepithelial "humps"** nestled against the GBM (Fig. 13–10, *B*). Mesangial deposits also are occasionally present. Immunofluorescence studies reveal scattered **granular deposits of IgG and complement** within the capillary walls and some mesangial areas, corresponding to the deposits visualized by electron microscopy. These deposits usually are cleared over a period of about 2 months.

#### Clinical Course

The onset of the kidney disease tends to be abrupt, heralded by malaise, a slight fever, nausea, and the nephritic syndrome. In the usual case, oliguria, azotemia, and hypertension are only mild to moderate. Characteristically, there is gross hematuria, the urine appearing smoky brown rather than bright red. Some degree of proteinuria is a constant feature of the disease, and as mentioned earlier it occasionally may be severe enough to produce the nephrotic syndrome. Serum complement levels are low during the active phase of the disease, and serum anti–streptolysin O antibody titers are elevated in poststreptococcal cases.

Recovery occurs in most children in epidemic cases. Some children develop rapidly progressive GN owing to severe injury with formation of crescents, or chronic renal disease from secondary scarring. The prognosis in sporadic cases is less clear. In adults, 15% to 50% of affected persons develop end-stage renal disease over the ensuing few years or 1 to 2 decades, depending on the clinical and histologic severity. By contrast, in children, the prevalence of chronicity after sporadic cases of acute postinfectious GN is much lower.

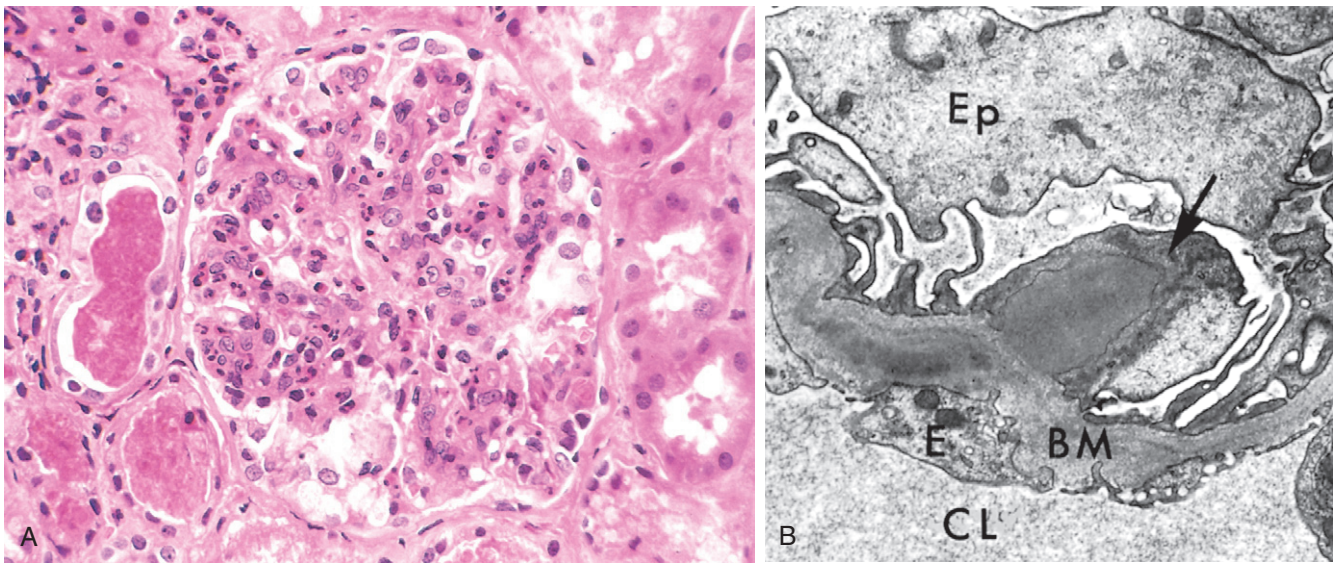

**Figure 13–10** Poststreptococcal glomerulonephritis. **A,** Glomerular hypercellularity is caused by intracapillary leukocytes and proliferation of intrinsic glomerular cells. Note the red cell casts in the tubules. **B,** Typical electron-dense subepithelial "hump" (*arrow*) and intramembranous deposits. BM, basement membrane; CL, capillary lumen; E, endothelial cell; Ep, visceral epithelial cells (podocytes).

### *IgA Nephropathy*

This condition usually affects children and young adults and begins as an episode of gross hematuria that occurs within 1 or 2 days of a nonspecific upper respiratory tract infection. Typically, the hematuria lasts several days and then subsides, only to recur every few months. It may be associated with local pain. *IgA nephropathy is one of the most common causes of recurrent microscopic or gross hematuria and is the most common glomerular disease revealed by renal biopsy worldwide.*

*The hallmark of the disease is the deposition of IgA in the mesangium.* Some workers have considered IgA nephropathy to be a localized variant of *Henoch-Schönlein purpura,* also characterized by IgA deposition in the mesangium. In contrast with IgA nephropathy, which is purely a renal disorder, Henoch-Schönlein purpura is a systemic syndrome involving the skin (purpuric rash), gastrointestinal tract (abdominal pain), joints (arthritis), and kidneys.

## PATHOGENESIS

Accumulating evidence suggests that IgA nephropathy is associated with an abnormality in IgA production and clearance, as well as antibodies against abnormally glycosylated IgA. IgA, the main immunoglobulin in mucosal secretions, is increased in 50% of patients with IgA nephropathy owing to increased production of the IgA1 subtype by plasma cells in the bone marrow. In addition, circulating IgA-containing immune complexes are present in some cases. A genetic influence is suggested by the occurrence of this condition in families and in HLA–identical siblings, and by the increased frequency of certain HLA and complement genotypes in some populations. Studies also suggest an abnormality in glycosylation of the IgA1 immunoglobulin that reduces plasma clearance and favors deposition in the mesangium. This abnormal IgA1 may also elicit glycan-specific IgG antibodies. The prominent mesangial deposition of IgA may stem from entrapment of IgA immune complexes, and the absence of C1q and C4 in glomeruli points to activation of the alternative complement pathway. Taken together, these clues suggest that in genetically susceptible individuals, respiratory or gastrointestinal exposure to microbial or other antigens (e.g., viruses, bacteria, food proteins) may lead to increased IgA synthesis, some of which is abnormally glycosylated, and deposition of IgA and IgA-containing immune complexes in the mesangium, where they activate the alternative complement pathway and initiate glomerular injury. In support of this scenario, IgA nephropathy occurs with increased frequency in individuals with celiac disease, in whom intestinal mucosal defects are seen, and in liver disease, in which there is defective hepatobiliary clearance of IgA complexes **(secondary IgA nephropathy).**

## MORPHOLOGY

Histologically, the lesions in IgA nephropathy vary considerably. The glomeruli may be normal or may show mesangial widening and segmental inflammation confined to some glomeruli (focal proliferative GN); diffuse mesangial proliferation (mesangioproliferative GN); or (rarely) overt crescentic GN. The characteristic immunofluorescence picture is of **mesangial deposition of IgA,** often with C3 and properdin and smaller amounts of IgG or IgM (Fig. 13–11). Early components of the classical complement pathway usually are absent. Electron microscopy confirms the presence of electron-dense deposits in the mesangium. The deposits may extend to the subendothelial area of adjacent capillary walls in a minority of cases, usually those with focal proliferation. Biopsy findings may help predict whether progression or response to intervention is likely.

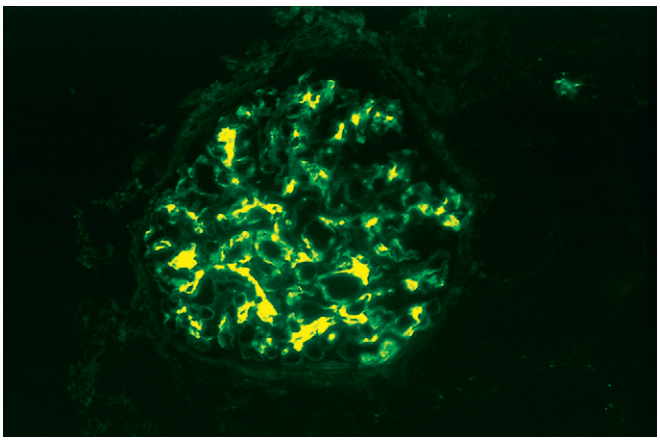

**Figure 13–11** IgA nephropathy. Characteristic immunofluorescence deposition of IgA, principally in mesangial regions, is evident. IgA, immunoglobulin A.

### Clinical Course

The disease most often affects children and young adults. More than half of those with IgA nephropathy present with gross hematuria after an infection of the respiratory or, less commonly, gastrointestinal or urinary tract; 30% to 40% have only microscopic hematuria, with or without proteinuria, and 5% to 10% develop a typical acute nephritic syndrome. The hematuria typically lasts for several days and then subsides, only to return every few months. The subsequent course is highly variable. Many patients maintain normal renal function for decades. Slow progression to chronic renal failure occurs in 25% to 50% of cases over a period of 20 years. Renal biopsy findings may help identify those with worse prognosis, as indicated by diffuse mesangial proliferation, segmental sclerosis, endocapillary proliferation, or tubulointerstitial fibrosis.

### *Hereditary Nephritis*

Hereditary nephritis refers to a group of hereditary glomerular diseases caused by *mutations in genes encoding GBM proteins*. The best-studied entity is *Alport syndrome*, in which nephritis is accompanied by nerve deafness and various eye disorders, including lens dislocation, posterior cataracts, and corneal dystrophy.

## PATHOGENESIS

The GBM is composed largely of type IV collagen, which is made up of heterotrimers of α3, α4, and α5 type IV collagen. This form of type IV collagen is crucial for normal function of the lens, cochlea, and glomerulus. Mutation of any one of the α chains results in defective heterotrimer assembly and, consequently, the disease manifestations of Alport syndrome.

## MORPHOLOGY

On histologic examination, glomeruli in hereditary nephritis appear unremarkable until late in the course, when secondary sclerosis may occur. In some kidneys, interstitial cells take on a foamy appearance as a result of accumulation of neutral fats and mucopolysaccharides **(foam cells)** as a reaction to marked proteinuria. With progression, increasing glomerulosclerosis, vascular sclerosis, tubular atrophy, and interstitial fibrosis are typical changes. Under the electron microscope, the **basement membrane of glomeruli is thin** and attenuated early in the course. Late in the course, the GBM develops irregular foci of thickening or attenuation with pronounced splitting and lamination of the lamina densa, yielding a **"basketweave"** appearance.

### Clinical Course

The inheritance is heterogeneous, being most commonly X-linked as a result of mutation of the gene encoding α5 type IV collagen. Males therefore tend to be affected more frequently and more severely than females and are more likely to develop renal failure. Rarely, inheritance is autosomal recessive or dominant, linked to defects in the genes that encode α3 or α4 type IV collagen. Persons with hereditary nephritis present at age 5 to 20 years with gross or microscopic hematuria and proteinuria, and overt renal failure occurs between 20 and 50 years of age.

Female carriers of X-linked Alport syndrome or carriers of either gender of the autosomal forms usually present with persistent hematuria, which most often is asymptomatic and is associated with a benign clinical course. In these patients, biopsy specimens show only thinning of the GBM.

## SUMMARY

### The Nephritic Syndrome

- The nephritic syndrome is characterized by hematuria, oliguria with azotemia, proteinuria, and hypertension.
- The most common cause is immunologically mediated glomerular injury; lesions are characterized by proliferative changes and leukocyte infiltration.
- *Acute postinfectious glomerulonephritis* typically occurs after streptococcal infection in children and young adults but may occur following infection with many other organisms; it is caused by deposition of immune complexes, mainly in the subepithelial spaces, with abundant neutrophils and proliferation of glomerular cells. Most affected children recover; the prognosis is worse in adults.
- *IgA nephropathy*, characterized by mesangial deposits of IgA-containing immune complexes, is the most common cause of the nephritic syndrome worldwide; it is also a common cause of recurrent hematuria; it commonly affects children and young adults and has a variable course.
- *Hereditary nephritis* (*Alport syndrome*) is caused by mutations in genes encoding GBM collagen; it manifests as hematuria and slowly progressing proteinuria and declining renal function; glomeruli appear normal by light microscopy until late in the disease course.

## Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a clinical syndrome and not a specific etiologic form of GN. It is characterized by progressive loss of renal function,

laboratory findings typical of the nephritic syndrome, and often severe oliguria. If untreated, it leads to death from renal failure within a period of weeks to months. *The characteristic histologic finding associated with RPGN is the presence of crescents* (crescentic GN).

## PATHOGENESIS

Crescentic GN may be caused by a number of different diseases, some restricted to the kidney and others systemic. Although no single mechanism can explain all cases, there is little doubt that in most cases the glomerular injury is immunologically mediated. The diseases causing crescentic GN may be associated with a known disorder or it may be idiopathic. When the cause can be identified, about 12% of the patients have anti-GBM antibody–mediated crescentic GN with or without lung involvement; 44% have immune complex GN with crescents; and the remaining 44% have pauci-immune crescentic GN. All have severe glomerular injury.

### *Anti-Glomerular Basement Membrane Antibody–Mediated Crescentic Glomerulonephritis*

*Anti-GBM antibody–mediated crescentic GN* is characterized by linear deposits of IgG and, in many cases, C3 on the GBM, as described earlier. In some patients, the anti-GBM antibodies also bind to pulmonary alveolar capillary basement membranes to produce the clinical picture of pulmonary hemorrhages associated with renal failure. These patients are said to have *Goodpasture syndrome,* to distinguish their condition from so-called idiopathic cases, in which renal involvement occurs in the absence of pulmonary disease. Anti-GBM antibodies are present in the serum and are helpful in diagnosis. It is important to recognize anti-GBM antibody–mediated crescentic GN, because affected persons benefit from plasmapheresis, which removes pathogenic antibodies from the circulation.

## MORPHOLOGY

The kidneys are enlarged and pale, often with **petechial hemorrhages** on the cortical surfaces. Glomeruli show segmental necrosis and GBM breaks, with resulting proliferation of the parietal epithelial cells in response to the exudation of plasma proteins and the deposition of fibrin in Bowman's space. These distinctive lesions of proliferation are called **crescents** owing to their shape as they fill Bowman's space. Crescents are formed both by proliferation of parietal cells and by migration of monocytes/macrophages into Bowman's space (Fig. 13–12). Smaller numbers of other types of leukocytes also may be present. The uninvolved portion of the glomerulus shows no proliferation. Immunofluorescence studies characteristically show strong staining of linear IgG and C3 deposits along the GBM (Fig. 13–4, *B*). These antibodies typically recognize type IV collagen. Because of the diffuse distribution of type IV collagen in the glomerulus, the density of antibody : antigen complexes is not high enough for them to be seen by electron microscopy. Electron microscopy may show distinct ruptures in the GBM. The crescents eventually obliterate Bowman's space and compress the glomeruli. In time, crescents may undergo scarring, and glomerulosclerosis develops.

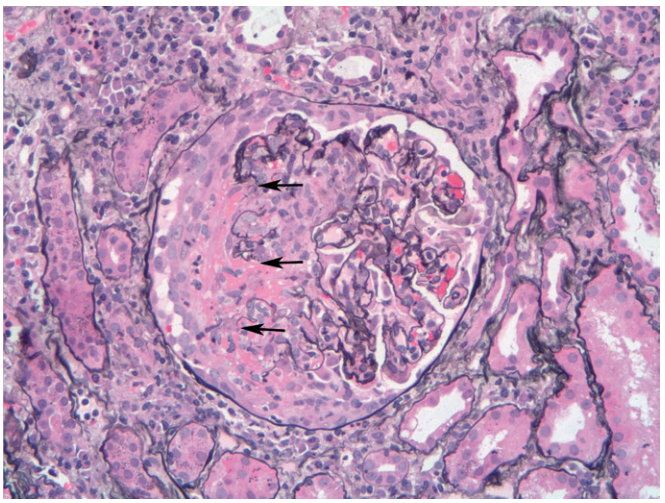

**Figure 13–12** Crescentic glomerulonephritis (GN) (Jones silver methenamine stain). Note the areas of necrosis with rupture of capillary loops (*arrows*) and destruction of normal glomerular structures, and the adjacent crescent-shaped mass of proliferating cells and leukocytes filling the urinary space. The segmental distribution of the necrotizing and crescentic GN is typical of ANCA (antineutrophil cytoplasmic antibody)-associated crescentic GN.

### *Immune Complex–Mediated Crescentic Glomerulonephritis*

Crescents can be a complication of any of the immune complex nephritides, including poststreptococcal GN, systemic lupus erythematosus, IgA nephropathy, and Henoch-Schönlein purpura. In some cases, immune complexes can be demonstrated but the underlying cause is undetermined. A consistent finding in this form of GN of any cause is the characteristic granular ("lumpy bumpy") pattern of staining of the GBM and/or mesangium for immunoglobulin and/or complement on immunofluorescence studies. This disorder usually does not respond to plasmapheresis.

## MORPHOLOGY

There is severe injury in the form of **segmental necrosis** and GBM breaks with resultant crescent formation, as described earlier. However, in contrast with crescentic GN associated with anti-GBM antibodies, segments of glomeruli without necrosis show evidence of the underlying immune complex GN (e.g., diffuse proliferation and leukocyte exudation in postinfectious GN or systemic lupus erythematosus; mesangial proliferation in IgA nephropathy or Henoch-Schönlein purpura). Immunofluorescence shows the characteristic **granular pattern** of immune complex disease, and electron microscopy demonstrates discrete deposits.

### *Pauci-Immune Crescentic Glomerulonephritis*

*Pauci-immune type crescentic GN* is defined by the lack of anti-GBM antibodies or of significant immune complex deposition detectable by immunofluorescence and electron microscopy. Antineutrophil cytoplasmic antibodies (ANCA) typically are found in the serum, which, as described in Chapter 9, have an etiopathogenic role in

some vasculitides. In some instances, therefore, crescentic GN is a component of a systemic vasculitis such as microscopic polyangiitis or Wegener granulomatosis. In many cases, however, pauci-immune crescentic GN is limited to the kidney and is thus called idiopathic.

### MORPHOLOGY

Glomeruli show **segmental necrosis** and GBM breaks with resulting crescent formation (see earlier). Uninvolved segments of glomeruli appear normal without proliferation or prominent inflammatory cell influx. In contrast with anti-GBM antibody disease, however, results of immunofluorescence studies for immunoglobulin and complement are negative or nearly so, and no deposits are detectable by electron microscopy.

#### Clinical Course

The onset of RPGN is much like that of the nephritic syndrome, except that the oliguria and azotemia are more pronounced. Proteinuria sometimes approaching nephrotic range may occur. Some affected persons become anuric and require long-term dialysis or transplantation. The prognosis can be roughly related to the fraction of involved glomeruli: Patients in whom crescents are present in less than 80% of the glomeruli have a better prognosis than those in whom the percentages of crescents are higher. Plasma exchange is of benefit in those with anti-GBM antibody GN and Goodpasture disease, as well as in some patients with ANCA-related pauci-immune crescentic GN.

### SUMMARY

#### Rapidly Progressive Glomerulonephritis

- RPGN is a clinical entity with features of the nephritic syndrome and rapid loss of renal function.
- RPGN is commonly associated with severe glomerular injury with necrosis and GBM breaks and subsequent proliferation of parietal epithelium (crescents).
- RPGN may be immune-mediated, as when autoantibodies to the GBM develop in anti-GBM antibody disease or when it arises consequent to immune complex deposition; it also can be pauci-immune, associated with antineutrophil cytoplasmic antibodies.

## DISEASES AFFECTING TUBULES AND INTERSTITIUM

Most forms of tubular injury also involve the interstitium, so the two are discussed together. Presented under this heading are diseases characterized by (1) inflammatory involvement of the tubules and interstitium (interstitial nephritis) or (2) ischemic or toxic tubular injury, leading to the morphologic appearance of *acute tubular injury* and the clinical syndrome of *acute kidney injury.*

### Tubulointerstitial Nephritis

Tubulointerstitial nephritis (TIN) refers to a group of inflammatory diseases of the kidneys that primarily involve the interstitium and tubules. The glomeruli may be spared altogether or affected only late in the course. In most cases of TIN caused by bacterial infection, the renal pelvis is prominently involved—hence the more descriptive term *pyelonephritis* (from *pyelo,* "pelvis"). The term *interstitial nephritis* generally is reserved for cases of TIN that are nonbacterial in origin. These include tubular injury resulting from drugs, metabolic disorders such as hypokalemia, physical injury such as irradiation, viral infections, and immune reactions. On the basis of clinical features and the character of the inflammatory exudate, TIN, regardless of the etiologic agent, can be divided into acute and chronic categories. Discussed next is acute pyelonephritis, which is always of bacterial origin, followed by consideration of other, nonbacterial forms of interstitial nephritis.

#### *Acute Pyelonephritis*

*Acute pyelonephritis, a common suppurative inflammation of the kidney and the renal pelvis, is caused by bacterial infection.* It is an important manifestation of urinary tract infection (UTI), which can involve the lower (cystitis, prostatitis, urethritis) or upper (pyelonephritis) urinary tract, or both. As we shall see, the great majority of cases of pyelonephritis are associated with infection of the lower urinary tract. Such infection, however, may remain localized without extending to involve the kidney. UTIs constitute an extremely common clinical problem.

### PATHOGENESIS

**The principal causative organisms in acute pyelonephritis are the enteric gram-negative rods.** *Escherichia coli* is by far the most common one. Other important organisms are *Proteus*, *Klebsiella*, *Enterobacter*, and *Pseudomonas;* these usually are associated with recurrent infections, especially in persons who undergo urinary tract manipulations or have congenital or acquired anomalies of the lower urinary tract (see later). Staphylococci and *Streptococcus faecalis* also may cause pyelonephritis, but they are uncommon pathogens in this setting.

Bacteria can reach the kidneys from the lower urinary tract (ascending infection) or through the bloodstream (hematogenous infection) (Fig. 13–13). **Ascending infection from the lower urinary tract is the most important and common route by which the bacteria reach the kidney.** Adhesion of bacteria to mucosal surfaces is followed by colonization of the distal urethra (and the introitus in females). Genetically determined properties of both the urothelium and the bacterial pathogens may facilitate adhesion to the urothelial lining by bacterial fimbriae (proteins that attach to receptors on the surface of urothelial cells), conferring susceptibility to infection. The organisms then reach the bladder, by expansive growth of the colonies and by moving against the flow of urine. This may occur during urethral instrumentation, including catheterization and cystoscopy. Although **hematogenous spread** is the far less

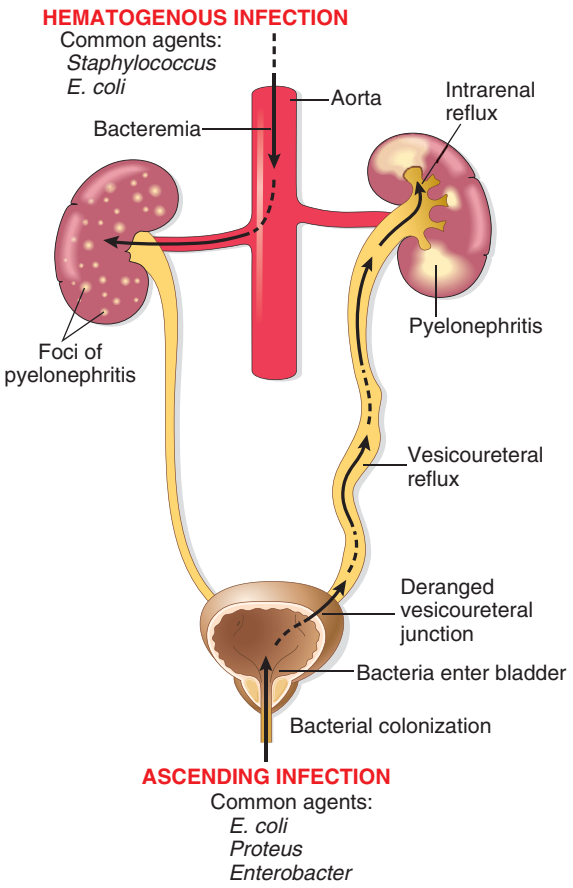

**Figure 13–13** Pathways of renal infection. Hematogenous infection results from bacteremic spread. More common is ascending infection, which results from a combination of urinary bladder infection, vesicoureteral reflux, and intrarenal reflux.

common of the two, acute pyelonephritis may result from seeding of the kidneys by bacteria in the course of septicemia or infective endocarditis.

In the absence of instrumentation, UTI most commonly affects females. Because of the close proximity of the female urethra to the rectum, colonization by enteric bacteria is favored. Furthermore, the short urethra, and trauma to the urethra during sexual intercourse, facilitate the entry of bacteria into the urinary bladder. Ordinarily, bladder urine is sterile, as a result of the antimicrobial properties of the bladder mucosa and the flushing mechanism associated with periodic voiding of urine. With outflow obstruction or bladder dysfunction, however, the natural defense mechanisms of the bladder are overwhelmed, setting the stage for UTI. In the presence of stasis, bacteria introduced into the bladder can multiply undisturbed, without being flushed out or destroyed by the bladder wall. From the contaminated bladder urine, the bacteria ascend along the ureters to infect the renal pelvis and parenchyma. Accordingly, UTI is particularly frequent among patients with urinary tract obstruction, as may occur with benign prostatic hyperplasia and uterine prolapse. UTI frequency also is increased in diabetes because of the increased susceptibility to infection and neurogenic bladder dysfunction, which in turn predisposes to stasis.

Incompetence of the vesicoureteral orifice, resulting in **vesicoureteral reflux** (VUR), is an important cause of ascending infection. The reflux allows bacteria to ascend the ureter into the pelvis. VUR is present in 20% to 40% of young children with UTI, usually as a consequence of a congenital defect that results in incompetence of the ureterovesical valve. VUR also can be acquired in persons with a flaccid bladder resulting from spinal cord injury or with neurogenic bladder dysfunction secondary to diabetes. VUR results in residual urine after voiding in the urinary tract, which favors bacterial growth. Furthermore, VUR affords a ready mechanism by which the infected bladder urine can be propelled up to the renal pelvis and farther into the renal parenchyma through open ducts at the tips of the papillae **(intrarenal reflux).**

## MORPHOLOGY

One or both kidneys may be involved. The affected kidney may be normal in size or enlarged. **Characteristically, discrete, yellowish, raised abscesses are grossly apparent on the renal surface** (Fig. 13–14). They may be widely scattered or limited to one region of the kidney, or they may coalesce to form a single large area of suppuration.

The characteristic histologic feature of acute pyelonephritis is liquefactive necrosis with abscess formation within the renal parenchyma. In the early stages pus formation (suppuration) is limited to the interstitial tissue, but later abscesses rupture into tubules. Large masses of intratubular neutrophils frequently extend within involved nephrons into the collecting ducts, giving rise to the characteristic white cell casts found in the urine. Typically, the glomeruli are not affected.

When obstruction is prominent, the pus may not drain and then fills the renal pelvis, calyces, and ureter, producing pyonephrosis.

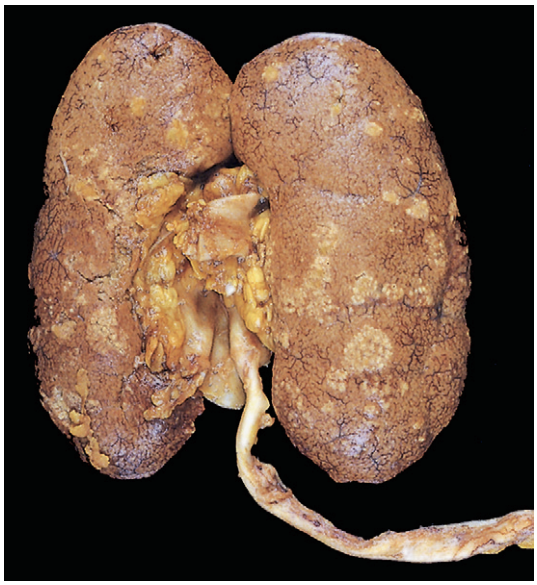

**Figure 13–14** Acute pyelonephritis. The cortical surface is studded with focal pale abscesses, more numerous in the upper pole and middle region of the kidney; the lower pole is relatively unaffected. Between the abscesses there is dark congestion of the renal surface.

A second (and fortunately infrequent) form of pyelonephritis is necrosis of the renal papillae, known as **papillary necrosis.** There are three predisposing conditions for this: diabetes, urinary tract obstruction, and analgesic abuse. This lesion consists of a combination of ischemic and suppurative necrosis of the tips of the renal pyramids (renal papillae). The pathognomonic gross feature of papillary necrosis is sharply defined gray-white to yellow necrosis of the apical two thirds of the pyramids. One papilla or several or all papillae may be affected. Microscopically, the papillary tips show characteristic coagulative necrosis, with surrounding neutrophilic infiltrate.

When the bladder is involved in a UTI, as is often the case, **acute** or **chronic cystitis** results. In long-standing cases associated with obstruction, the bladder may be grossly hypertrophic, with trabeculation of its walls, or it may be thinned and markedly distended from retention of urine.

### Clinical Course

Acute pyelonephritis often is associated with predisposing conditions, as described previously in the discussion of pathogenetic mechanisms. These factors include

- *Urinary obstruction,* either congenital or acquired
- *Instrumentation* of the urinary tract, most commonly catheterization
- *Vesicoureteral reflux*
- *Pregnancy*—4% to 6% of pregnant women develop bacteriuria sometime during pregnancy, and 20% to 40% of these eventually develop symptomatic urinary infection if not treated.
- *Female gender and patient age.* After the first year of life (an age by which congenital anomalies in males commonly become evident) and up to approximate age 40 years, infections are much more frequent in females. With increasing age, the incidence in males rises as a result of the development of prostatic hyperplasia, which causes urinary outflow obstruction.
- *Preexisting renal lesions,* causing intrarenal scarring and obstruction
- *Diabetes mellitus,* in which common predisposing factors are infection and bladder dysfunction
- *Immunosuppression and immunodeficiency*

The onset of uncomplicated acute pyelonephritis usually is sudden, with pain at the costovertebral angle and systemic evidence of infection, such as chills, fever, and malaise, and localizing urinary tract signs of dysuria, frequency, and urgency. The urine appears turgid due to the contained pus (pyuria). Even without antibiotic treatment, the disease tends to be benign and self-limited. The symptomatic phase of the disease typically lasts no longer than a week, although bacteriuria may persist much longer. The disease usually is unilateral, and affected persons thus do not develop renal failure because they still have one unaffected kidney. In cases in which predisposing factors are present, the disease may become recurrent or chronic, particularly when involvement is bilateral. The development of papillary necrosis is associated with a much poorer prognosis.

## *Chronic Pyelonephritis and Reflux Nephropathy*

*Chronic pyelonephritis* is defined here as a morphologic entity in which predominantly interstitial inflammation and scarring of the renal parenchyma are associated with grossly visible scarring and deformity of the pelvicalyceal system. Chronic pyelonephritis is an important cause of chronic renal failure. It can be divided into two forms: chronic obstructive pyelonephritis and chronic reflux–associated pyelonephritis.

### Chronic Obstructive Pyelonephritis

As noted, obstruction predisposes the kidney to infection. Recurrent infections superimposed on diffuse or localized obstructive lesions lead to recurrent bouts of renal inflammation and scarring, which eventually cause chronic pyelonephritis. The disease can be bilateral, as with congenital anomalies of the urethra (e.g., posterior urethral valves), resulting in fatal renal insufficiency unless the anomaly is corrected, or unilateral, such as occurs with calculi and unilateral obstructive lesions of the ureter.

### Chronic Reflux–Associated Pyelonephritis (Reflux Nephropathy)

This is the more common form of chronic pyelonephritic scarring and results from superimposition of a UTI on congenital vesicoureteral reflux and intrarenal reflux. Reflux may be unilateral or bilateral; thus, the resultant renal damage either may cause scarring and atrophy of one kidney or may involve both, potentially leading to chronic renal insufficiency.

### MORPHOLOGY

One or both kidneys may be involved, either diffusely or in patches. Even when involvement is bilateral, the kidneys are not equally damaged and therefore are not equally contracted. This **uneven scarring** is useful in differentiating chronic pyelonephritis from the more symmetrically contracted kidneys associated with vascular sclerosis (often referred to as "benign nephrosclerosis") and chronic GN. The hallmark of chronic pyelonephritis is **scarring involving the pelvis or calyces,** or both, leading to papillary blunting and marked **calyceal deformities** (Fig. 13–15).

The microscopic changes are largely nonspecific, and similar alterations may be seen with other chronic tubulointerstitial disorders such as analgesic nephropathy. The parenchyma shows the following features:

- Uneven interstitial fibrosis and an inflammatory infiltrate of lymphocytes, plasma cells, and occasionally neutrophils
- Dilation or contraction of tubules, with atrophy of the lining epithelium. Many of the dilated tubules contain pink to blue, glassy-appearing PAS-positive casts, known as colloid casts, that suggest the appearance of thyroid tissue—hence the descriptive term thyroidization. Often, neutrophils are seen within tubules.
- Chronic inflammatory cell infiltration and fibrosis involving the calyceal mucosa and wall
- Arteriolosclerosis caused by the frequently associated hypertension
- Glomerulosclerosis that usually develops as a secondary process caused by nephron loss (a maladaptation discussed earlier).

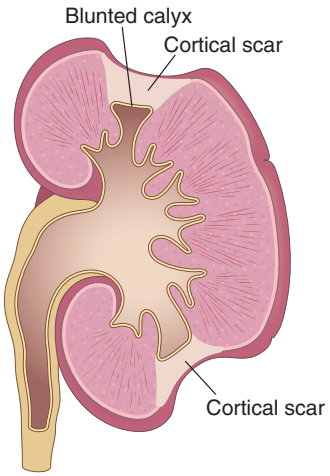

**Figure 13–15** Typical coarse scars of chronic pyelonephritis associated with vesicoureteral reflux. The scars are usually located at the upper or lower poles of the kidney and are associated with underlying blunted calyces.

### Clinical Course

Many persons with chronic pyelonephritis come to medical attention relatively late in the course of the disease, because of the gradual onset of renal insufficiency or because signs of kidney disease are noticed on routine laboratory tests. In other cases, the renal disease is heralded by the development of hypertension. The radiologic image is characteristic: The affected kidney is asymmetrically contracted, with some degree of blunting and deformity of the calyceal system (caliectasis). The presence or absence of significant bacteriuria is not particularly helpful diagnostically; its absence certainly should not rule out chronic pyelonephritis. If the disease is bilateral and progressive, tubular dysfunction occurs with loss of concentrating ability, manifested by polyuria and nocturia.

As noted earlier, some persons with chronic pyelonephritis or reflux nephropathy ultimately develop secondary glomerulosclerosis, associated with proteinuria; eventually, these injuries all contribute to progressive chronic kidney disease.

## *Drug-Induced Interstitial Nephritis*

In this era of widespread antibiotic and analgesic use, drugs have emerged as an important cause of renal injury. Acute drug-induced tubulointerstitial nephritis (TIN) occurs as an adverse reaction to any of an increasing number of drugs. Acute drug-induced TIN is associated most frequently with synthetic penicillins (methicillin, ampicillin), other synthetic antibiotics (rifampin), diuretics (thiazides), nonsteroidal anti-inflammatory agents, and numerous other drugs (phenindione, cimetidine).

### PATHOGENESIS

Many features of the disease suggest an immune mechanism. Clinical evidence of hypersensitivity includes latent period, eosinophilia and rash, the idiosyncratic nature of the drug reaction (i.e., the lack of dose dependency), and the recurrence of hypersensitivity after reexposure to the same drug or others that are similar in structure. Serum IgE levels are increased in some persons, suggesting type I hypersensitivity. In other cases the nature of the inflammatory infiltrate (discussed below) and the presence of positive skin tests to drugs suggest a T cell–mediated (type IV) hypersensitivity reaction.

The most likely sequence of pathogenic events is as follows: The drugs act as haptens that, during secretion by tubules, covalently bind to some cytoplasmic or extracellular component of tubular cells and become immunogenic. The resultant tubulointerstitial injury is then caused by IgE- and cell-mediated immune reactions to tubular cells or their basement membranes.

### MORPHOLOGY

The abnormalities in acute drug-induced nephritis are in the interstitium, which shows pronounced edema and infiltration by mononuclear cells, principally lymphocytes and macrophages (Fig. 13–16). Eosinophils and neutrophils may be present, often in large numbers. With some drugs (e.g., methicillin, thiazides, rifampin), interstitial non-necrotizing granulomas with giant cells may be seen. The glomeruli are normal except in some cases caused by nonsteroidal anti-inflammatory agents, in which the hypersensitivity reaction also leads to podocyte foot process effacement and the nephrotic syndrome.

### Clinical Course

The disease begins about 15 days (range, 2 to 40 days) after exposure to the drug and is characterized by *fever, eosinophilia* (which may be transient), *a rash* (in about 25% of persons), and *renal abnormalities.* Urinary findings include hematuria, minimal or no proteinuria, and leukocyturia (sometimes including eosinophils). A rising serum creatinine or acute kidney injury with oliguria develops in about 50% of cases, particularly in older patients. Clinical recognition of drug-induced kidney injury is imperative, because withdrawal of the offending drug is followed by recovery,

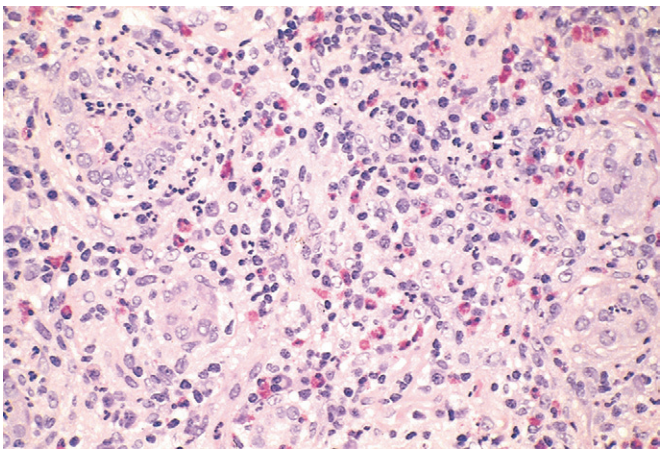

**Figure 13–16** Drug-induced interstitial nephritis, with prominent eosinophilic and mononuclear infiltrate.

*(Courtesy of Dr. H. Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts.)*

although it may take several months for renal function to return to normal.

## SUMMARY

### Tubulointerstitial Nephritis

- TIN consists of inflammatory disease primarily involving the renal tubules and interstitium.
- *Acute pyelonephritis* is a bacterial infection caused either by ascending infection as a result of reflux, obstruction, or other abnormality of the urinary tract, or by hematogenous spread of bacteria; characterized by abscess formation in the kidneys, sometimes with papillary necrosis.
- *Chronic pyelonephritis* usually is associated with urinary obstruction or reflux; results in scarring of the involved kidney, and gradual renal insufficiency.
- *Drug-induced interstitial nephritis* is an IgE- and T cell–mediated immune reaction to a drug; characterized by interstitial inflammation, often with abundant eosinophils, and edema.

## Acute Tubular Injury

Acute tubular injury (ATI) is a clinicopathologic entity characterized morphologically by damaged tubular epithelial cells and clinically by acute decline of renal function, with granular casts and tubular cells observed in the urine. *This constellation of changes, termed acute kidney injury, manifests clinically as decreased GFR.* When ATI is caused by acute kidney injury, there may be oliguria (defined as urine output of less than 400 mL/day). Other causes of acute kidney injury include (1) severe glomerular diseases manifesting clinically as RPGN; (2) acute tubular injury caused by diffuse renal vascular diseases, such as microscopic polyangiitis and thrombotic microangiopathies; and (3) acute drug-induced allergic interstitial nephritis, which often is not associated with tubular injury. These other disorders involving acute kidney injury are discussed elsewhere in this chapter.

ATI arises in a variety of clinical settings, so it occurs relatively frequently. Most of these clinical conditions, ranging from severe trauma to acute pancreatitis to septicemia, have in common a period of inadequate blood flow to all or regions of peripheral organs such as the kidney, sometimes in the setting of marked hypotension and shock. The pattern of ATI associated with generalized or localized reduction in blood flow is called *ischemic ATI.* Mismatched blood transfusions and other hemolytic crises, as well as myoglobinuria, also produce a clinical picture resembling that in ischemic ATI. A second pattern, called *nephrotoxic ATI,* is caused by a variety of poisons, including heavy metals (e.g., mercury); organic solvents (e.g., carbon tetrachloride); and a multitude of drugs such as gentamicin and other antibiotics, and radiographic contrast agents. ATI is often reversible, and proper recognition and management can mean the difference between full recovery and death.

## PATHOGENESIS

The decisive events in both ischemic and nephrotoxic ATI are believed to be

- Tubular injury. Tubular epithelial cells are particularly sensitive to anoxia and are also vulnerable to toxins (Fig. 13–17). Several factors predispose the tubules to toxic injury, including elevated intracellular concentrations of various molecules that are resorbed or secreted across the proximal tubule, as well as exposure to high concentrations of luminal solutes that are concentrated by the resorption of water from the glomerular filtrate.
- Persistent and severe disturbances in blood flow resulting in diminished oxygen and substrate delivery to tubular

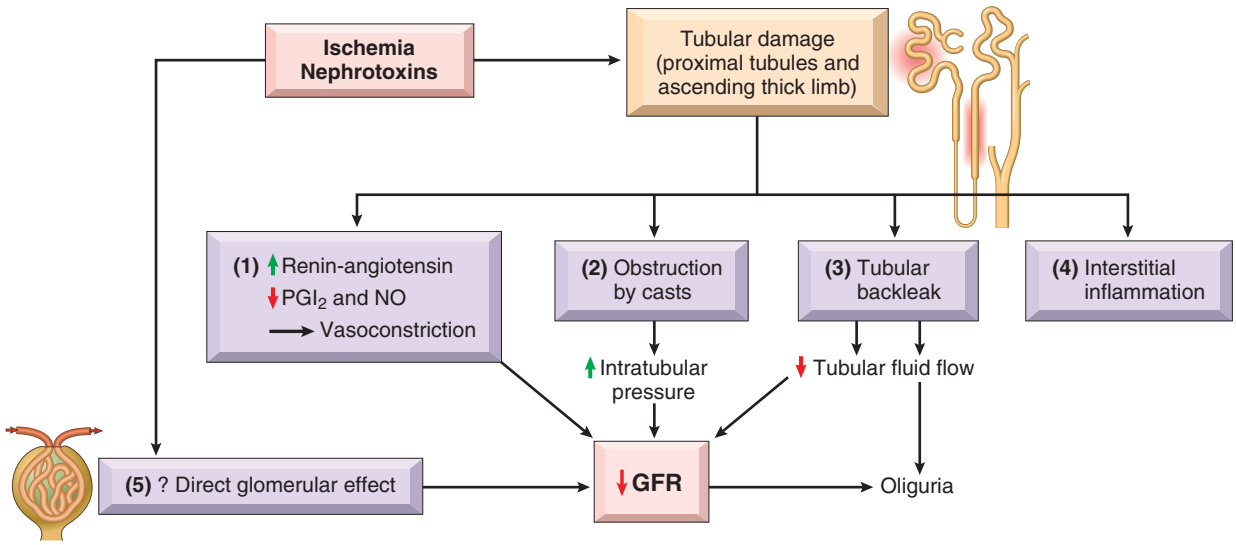

**Figure 13–17** Pathophysiologic mechanisms of acute kidney injury. Various injuries can directly damage tubules, which in turn decreases GFR by multiple mechanisms and also promotes vasoconstriction. Some injuries that cause tubular injury also directly decrease GFR by decreasing renal blood flow. NO, nitric oxide; $PGI_2$, prostaglandin $I_2$ (prostacyclin).
*(Modified from Lameire N, et al: JASN 12:S20-S32, 2001.)*

cells. Ischemia causes numerous structural alterations in epithelial cells. **Loss of cell polarity** is an early reversible event. It leads to the redistribution of membrane proteins (e.g., $Na^+$,$K^+$-ATPase) from the basolateral to the luminal surface of tubular cells, resulting in decreased sodium reabsorption by proximal tubules and hence increased sodium delivery to distal tubules. The latter, through a tubuloglomerular feedback system, contributes to preglomerular arteriolar vasoconstriction. Redistribution or alteration of integrins that anchor tubular cells results in their detachment from the basement membranes and their shedding into the urine. If sufficient tubular debris builds up it can block the outflow of urine (obstruction by casts), increasing intratubular pressure and thereby decreasing the GFR. Additionally, fluid from the damaged tubules may leak into the interstitium (backleak), resulting in increased interstitial pressure and collapse of the tubules. Ischemic tubular cells also express chemokines, cytokines, and adhesion molecules such as P-selectin that recruit leukocytes and can participate in tissue injury (interstitial inflammation).

Ischemic renal injury also is characterized by severe hemodynamic alterations that cause reduced GFR. The major one is intrarenal **vasoconstriction,** which results in both reduced glomerular plasma flow and reduced oxygen delivery to the tubules in the outer medulla (thick ascending limb and straight segment of the proximal tubule) (Fig. 13–17). Although a number of vasoconstrictor pathways have been implicated in this phenomenon (e.g., renin-angiotensin, thromboxane $A_2$, sympathetic nerve activity), the current opinion is that vasoconstriction is mediated by **sublethal endothelial injury,** leading to increased release of the endothelial vasoconstrictor **endothelin** and decreased production of vasodilatory **nitric oxide and prostaglandins.** Finally, some evidence points to a direct effect of ischemia or toxins on the glomerulus, causing a reduced effective glomerular filtration surface.

In addition to vasoconstriction, the pathogenesis of ATI may involve apoptosis and necrosis of tubular cells. Dead cells may elicit an inflammatory reaction (Chapter 2) that exacerbates the tubular injury and functional derangements.

## MORPHOLOGY

**Ischemic ATI** is characterized by lesions in the straight portions of the proximal tubule and the ascending thick limbs, but no segment of the proximal or distal tubules is spared. There is often a variety of **tubular injuries,** including attenuation of proximal tubular brush borders, blebbing and sloughing of brush borders, vacuolization of cells, and detachment of tubular cells from their underlying basement membranes with sloughing of cells into the urine. A striking additional finding is the presence of proteinaceous casts in the distal tubules and collecting ducts, which consist of Tamm-Horsfall protein (normally secreted by tubular epithelium) along with hemoglobin and other plasma proteins. When crush injuries have produced ATI, the casts also contain myoglobin. The interstitium usually shows generalized edema along with a mild inflammatory infiltrate consisting of polymorphonuclear leukocytes, lymphocytes, and plasma cells. The histologic picture in **toxic ATI** is basically similar, with some differences. Overt necrosis is most prominent in the proximal tubule, and the tubular basement membranes generally are spared.

If the patient survives for a week, epithelial regeneration becomes apparent in the form of a low cuboidal epithelial covering and mitotic activity in the surviving tubular epithelial cells. Acute kidney injury with underlying acute tubular injury as its cause may result in fibrosis rather than repair if the proximal tubular cells are arrested at $G_2$/M stage of the cell cycle after injury, as this arrest amplifies profibrotic mediators.

### Clinical Course

The clinical course of ischemic ATI initially is dominated by the inciting medical, surgical or obstetric event. Affected patients often present with manifestations of acute kidney injury, including *oliguria and decreased GFR*. Not all patients may manifest oliguria; some will have anuria, while in others, particularly if the injury is milder, the ATI may be nonoliguric. During acute kidney injury, the clinical picture is dominated by electrolyte abnormalities, acidosis and the signs and symptoms of uremia and fluid overload. Depending upon the severity and nature of the underlying injury and comorbid conditions, the prognosis varies. In the absence of careful supportive treatment or dialysis, patients may die. When the cause of acute kidney injury is ATI, repair and tubular regeneration lead to gradual clinical improvement. With supportive care, patients who do not die from the underlying precipitating problem have a good chance of recovering renal function unless kidney disease was present at the time of the acute insult. In those with preexisting kidney disease complete recovery is less certain, and progression over time to end-stage renal disease is unfortunately too frequent.

## SUMMARY

### Acute Tubular Injury

- ATI is the most common cause of acute kidney injury; its clinical manifestations are electrolyte abnormalities, acidosis, uremia, and signs of fluid overload, often with oliguria.
- ATI results from ischemic or toxic injury to renal tubules, and is associated with intrarenal vasoconstriction resulting in reduced GFR and diminished delivery of oxygen and nutrients to tubular epithelial cells.
- ATI is characterized morphologically by injury or necrosis of segments of the tubules (typically the proximal tubules), proteinaceous casts in distal tubules, and interstitial edema.

# DISEASES INVOLVING BLOOD VESSELS

Nearly all diseases of the kidney involve the renal blood vessels secondarily. Systemic vascular diseases, such as various forms of vasculitis, also involve renal blood vessels,

and often the effects on the kidney are clinically important (Chapter 9). The kidney is intimately involved in the pathogenesis of both essential and secondary hypertension. This section covers the renal lesions associated with benign and malignant hypertension.

## Arterionephrosclerosis

*Arterionephrosclerosis is the term used for the thickening and sclerosis of arterial walls and the renal changes associated with benign hypertension.* The characteristic morphologic alterations involve small arterioles and are called *hyaline arteriolosclerosis*. Some degree of arterionephrosclerosis, albeit mild, is present at autopsy in many persons older than 60 years of age. The frequency and severity of the lesions are increased at any age when hypertension is present.

### PATHOGENESIS

Of note, many renal diseases cause hypertension, which in turn is associated with arterionephrosclerosis. Thus, this renal lesion often is superimposed on other primary kidney diseases. Similar changes in arteries and arterioles are seen in individuals with chronic thrombotic microangiopathies. Whether hypertension causes the arterionephrosclerosis, or a subtle primary microvascular renal injury causes the hypertension, which in turn accelerates the sclerosis, is unknown. Recent studies implicate mutation in the apolipoprotein L1 gene (the same gene implicated in increased risk for FSGS) as tightly linked to the high incidence of arterionephrosclerosis observed in African Americans. The mechanisms of increased risk of kidney disease are unknown, but this mutation confers protection against trypanosomal disease, so its prevalence may have been influenced by natural selection.

### MORPHOLOGY

Grossly, the kidneys are **symmetrically atrophic,** each weighing 110 to 130 g. Typically the renal surface shows diffuse, fine granularity that resembles grain leather. Microscopically, the basic anatomic change is hyaline thickening of the walls of the small arteries and arterioles, known as **hyaline arteriolosclerosis.** This appears as a homogeneous, pink hyaline thickening, at the expense of the vessel lumina, with loss of underlying cellular detail (Fig. 13–18). The narrowing of the lumen results in markedly decreased blood flow through the affected vessels, with consequent ischemia in the organ served. All structures of the kidney show ischemic atrophy. In advanced cases of arterionephrosclerosis, the glomerular tufts may become sclerosed. Diffuse tubular atrophy and interstitial fibrosis are present. Often there is a scant interstitial lymphocytic infiltrate. The larger blood vessels (interlobar and arcuate arteries) show reduplication of internal elastic lamina along with fibrous thickening of the media **(fibroelastic hyperplasia)** and the subintima.

#### Clinical Course

This renal lesion alone rarely causes severe damage to the kidney except in persons with genetic susceptibility, such as African Americans, in whom it may lead to uremia and death. However, all patients with this lesion usually show some functional impairment, such as loss of concentrating ability or a variably diminished GFR. A mild degree of proteinuria is a frequent finding.

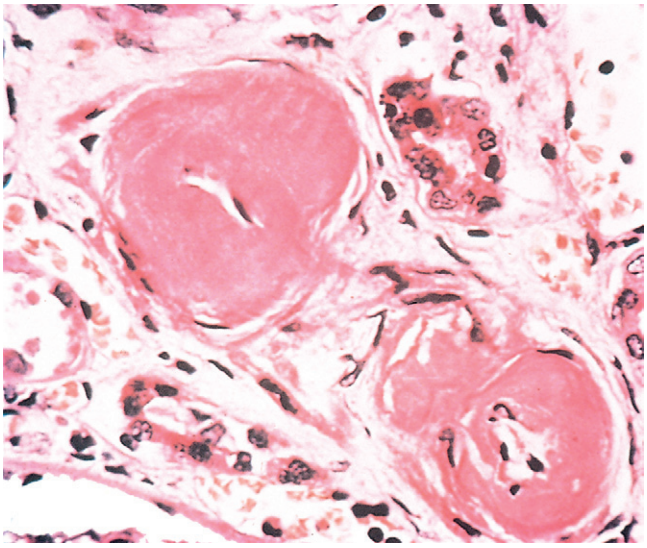

**Figure 13–18** Benign nephrosclerosis. High-power view of two arterioles with hyaline deposition, marked thickening of the walls, and a narrowed lumen.

*(Courtesy of Dr. M. A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, Texas.)*

## Malignant Hypertension

Malignant hypertension, defined as blood pressure usually greater than 200/120 mm Hg, is far less common in the United States than so-called "benign" hypertension and occurs in only about 5% of persons with elevated blood pressure. It may arise de novo (i.e., without preexisting hypertension), or it may appear suddenly in a person who had mild hypertension. The prevalence of malignant hypertension is higher in less developed countries.

### PATHOGENESIS

The basis for this turn for the worse in hypertensive subjects is unclear, but the following sequence is suggested: The initial event seems to be some form of vascular damage to the kidneys. This most commonly results from long-standing hypertension, with eventual injury to the arteriolar walls. The result is increased permeability of the small vessels to fibrinogen and other plasma proteins, endothelial injury, and platelet deposition. This leads to the appearance of **fibrinoid necrosis** of arterioles and small arteries and intravascular thrombosis. Mitogenic factors from platelets (e.g., platelet-derived growth factor) and plasma cause intimal hyperplasia of vessels, resulting in the **hyperplastic arteriolosclerosis** typical of organizing injury of malignant hypertension and of morphologically similar thrombotic microangiopathies (see later) and further narrowing of the lumina. The kidneys become markedly ischemic. With severe involvement of the renal afferent arterioles, the renin-angiotensin system receives

a powerful stimulus. This then sets up a self-perpetuating cycle in which angiotensin II causes intrarenal vasoconstriction and the attendant renal ischemia perpetuates renin secretion. Aldosterone levels also are elevated, and the resultant salt retention exacerbates the elevation of blood pressure.

## MORPHOLOGY

The kidney may be essentially normal in size or slightly shrunken, depending on the duration and severity of the hypertensive disease. Small, **pinpoint petechial hemorrhages** may appear on the cortical surface from rupture of arterioles or glomerular capillaries, giving the kidney a peculiar, **flea-bitten appearance.**

The microscopic changes reflect the pathogenetic events described earlier. Damage to the small vessels is manifested as **fibrinoid necrosis** of the arterioles (Fig. 13–19, *A*). The vessel walls show a homogeneous, granular eosinophilic appearance masking underlying detail. In the interlobular arteries and larger arterioles, proliferation of intimal cells after acute injury produces an onion-skin appearance (Fig. 13–19, *B*). This name is derived from the concentric arrangement of cells whose origin is believed to be intimal smooth muscle, although this issue has not been finally settled. This lesion, called **hyperplastic arteriolosclerosis,** causes marked narrowing of arterioles and small arteries, to the point of total obliteration. Necrosis also may involve glomeruli, with microthrombi within the glomeruli as well as necrotic arterioles. Similar lesions are seen in persons with acute thrombotic microangiopathies (described later), and in patients with scleroderma in renal crisis.

### Clinical Course

The full-blown syndrome of malignant hypertension is characterized by papilledema, encephalopathy, cardiovascular abnormalities, and renal failure. Most often, the early symptoms are related to *increased intracranial pressure* and include headache, nausea, vomiting, and visual impairment, particularly the development of scotomas, or "spots" before the eyes. At the onset of rapidly mounting blood pressure there is marked proteinuria and microscopic, or sometimes macroscopic, hematuria but no significant alteration in renal function. Soon, however, *acute kidney injury develops.* The syndrome represents a true medical emergency that requires prompt and aggressive antihypertensive therapy before irreversible renal lesions develop. About 50% of patients survive at least 5 years, and further progress is still being made. Ninety percent of deaths are caused by uremia and the other 10% by cerebral hemorrhage or cardiac failure.

## Thrombotic Microangiopathies

As described in Chapter 11, the term *thrombotic microangiopathy* refers to lesions seen in various clinical syndromes characterized morphologically by *widespread thrombosis in the microcirculation* and clinically by *microangiopathic hemolytic anemia, thrombocytopenia,* and, in certain instances, *renal failure.* Common causes of thrombotic microangiopathy include

- Childhood hemolytic uremic syndrome (HUS)
- Various forms of adult HUS
- Thrombotic thrombocytopenic purpura (TTP)
- Various drugs
- Malignant hypertension or scleroderma

## PATHOGENESIS

The major pathogenetic factors in the thrombotic microangiopathies are endothelial activation (the dominant abnormality in HUS) and platelet activation and aggregation (which is dominant in TTP). Both may be caused by a number of external insults and inherited mutations, and together they lead to excessive small vessel thrombosis, the hallmark of these diseases.

- **Childhood HUS** is the best-characterized of the renal syndromes associated with thrombotic microangiopathy. As many as 75% of cases follow intestinal infection with Shiga toxin–producing *E. coli*, such as occurs in epidemics

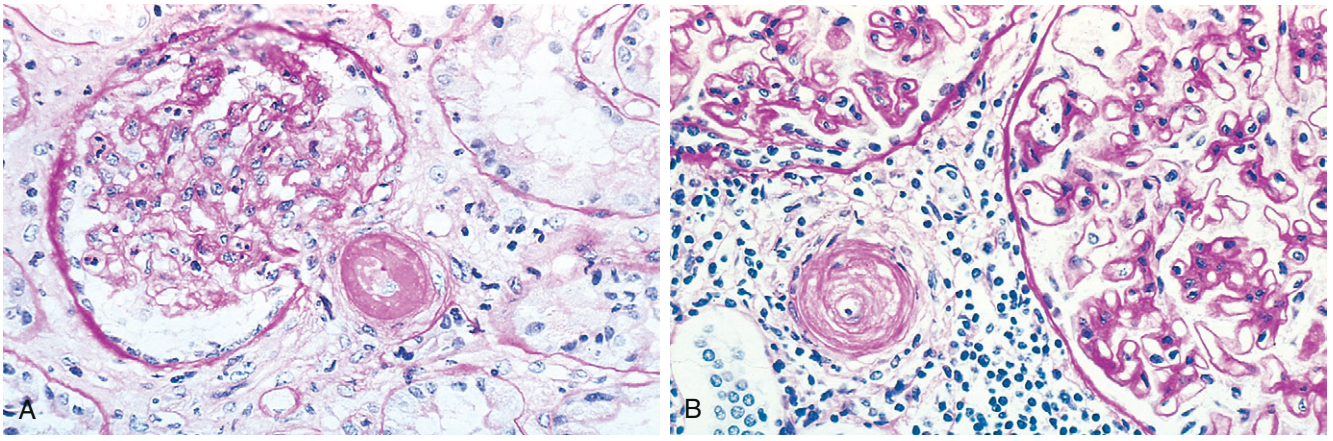

**Figure 13–19** Malignant hypertension. **A,** Fibrinoid necrosis of afferent arteriole (periodic acid–Schiff stain). **B,** Hyperplastic arteriolosclerosis (onion-skin lesion).
*(Courtesy of Dr. H. Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts.)*

caused by ingestion of infected ground meat (e.g., in hamburgers) and infections with *Shigella dysenteriae* type I. The pathogenesis of this syndrome is related to the effects of Shiga toxin, which is carried by neutrophils in the circulation. Renal glomerular endothelial cells are targets because the cells express the membrane receptor for the toxin. The toxin has multiple effects on the endothelium, including increased adhesion of leukocytes, increased endothelin production, and loss of endothelial nitric oxide (both favoring vasoconstriction), and (in the presence of cytokines, such as tumor necrosis factor) endothelial damage. The toxin also gains entry to the cells and directly causes cell death. The resultant endothelial damage leads to thrombosis, which is most prominent in glomerular capillaries, afferent arterioles, and interlobular arteries, as well as vasoconstriction, resulting in the characteristic thrombotic microangiopathy.

Approximately 10% of the cases of HUS in children are not preceded by diarrhea caused by Shiga toxin–producing bacteria. In a subset of these patients, mutational inactivation of complement regulatory proteins (e.g., factor H) allows uncontrolled complement activation after minor vascular injuries. These conditions promote the formation of thrombi.

- **Adult HUS.** In typical (epidemic, classic, diarrhea-positive) HUS, the trigger for endothelial injury and activation usually is a Shiga-like toxin, while in inherited forms of atypical HUS, the cause of endothelial injury appears to be excessive, inappropriate activation of complement. Many other forms of exposures and conditions, including drug toxicities, can occasionally precipitate a HUS-like picture, presumably also by injuring the endothelium.
- **TTP** often is caused by an acquired defect in proteolytic cleavage of von Willebrand factor (vWF) multimers due to autoantibodies, or more rarely, an inherited defect as seen in familial TTP (Chapter 11). Pathogenic autoantibodies, whether arising in a context of autoimmunity or drug-induced, typically are directed against ADAMTS 13 (a disintegrin and metalloprotease with thrombospondin-like motifs), a plasma protease that cleaves vWF multimers into smaller sizes. Autoantibody binding to ADAMTS 13 results in loss of function and increased levels of large vWF multimers in the circulation, which in turn can activate platelets spontaneously, leading to platelet aggregation and thrombosis. Genetic defects in ADAMTS 13 lead to a similar pattern of disease.

### MORPHOLOGY

In childhood HUS, there are lesions of classic **thrombotic microangiopathy** with fibrin thrombi predominantly involving glomeruli, and extending into arterioles and larger arteries in severe cases. Cortical necrosis may be present. Morphologic changes in glomeruli resulting from endothelial injury include widening of the subendothelial space in glomerular capillaries, duplication or splitting of GBMs, and lysis of mesangial cells with mesangial disintegration. Chronically, scarring of glomeruli may develop.

Clinical Course

Typically, childhood HUS is characterized by the sudden onset, usually after a gastrointestinal or flulike prodromal episode, of bleeding manifestations (especially hematemesis and melena), severe oliguria, hematuria, microangiopathic hemolytic anemia, and (in some persons) prominent neurologic changes. *This disease is one of the main causes of acute kidney injury in children.* If the acute kidney injury is managed properly with dialysis, most patients recover in a matter of weeks. The long-term prognosis (over 15 to 25 years), however, is not uniformly favorable, because in about 25% of these children, renal insufficiency eventually develops as a consequence of the secondary scarring. Although HUS and TTP have some overlapping clinical features, such as microangiopathic hemolytic anemia and thrombocytopenia, TTP more often has dominant involvement of the central nervous system and the kidneys are less commonly involved compared to HUS.

### SUMMARY

#### Vascular Diseases of the Kidney

- *Arterionephrosclerosis*: Progressive, chronic renal damage associated with hypertension. Characteristic features are hyaline arteriolosclerosis and narrowing of vascular lumina with resultant cortical atrophy.
- *Malignant hypertension*: Acute kidney injury associated with severe elevation of blood pressure. Arteries and arterioles show fibrinoid necrosis and hyperplasia of smooth muscle cells; petechial hemorrhages on the cortical surface.
- *Thrombotic microangiopathies*: Disorders characterized by fibrin thrombi in glomeruli and small vessels resulting in acute kidney injury. Childhood HUS is usually caused by endothelial injury by an *E. coli* toxin; TTP is often caused by defects in von Willebrand factor leading to excessive thrombosis, with platelet consumption.

## CHRONIC KIDNEY DISEASE

Chronic kidney disease is the result of progressive scarring resulting from any type of kidney disease. Alterations in the function of remaining initially intact nephrons are ultimately maladaptive and cause further scarring. This eventually results in an end-stage kidney where glomeruli, tubules, interstitium and vessels are sclerosed, regardless of the primary site of injury. Unless the disorder is treated with dialysis or transplantation, death from uremia results.

### MORPHOLOGY

Classically, the kidneys are **symmetrically contracted,** and their surfaces are red-brown and **diffusely granular** when the underlying disorder affects blood vessels or glomeruli. Kidneys damaged by chronic pyelonephritis are typically unevenly involved and have deep scars. Microscopically, the feature common to all cases is advanced scarring of the glomeruli, sometimes to the point of complete sclerosis (Fig. 13–20). This **obliteration of the glomeruli** is the end point of many diseases, and it is impossible to ascertain from

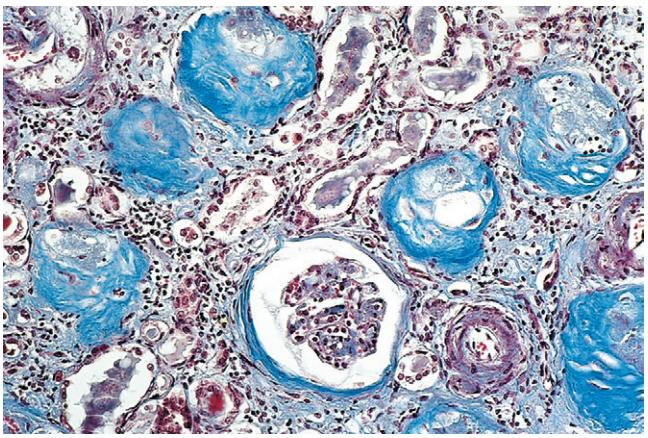

**Figure 13–20** Chronic glomerulonephritis. A Masson trichrome preparation shows complete replacement of virtually all glomeruli by blue-staining collagen.
*(Courtesy of Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, Texas.)*

such kidneys the nature of the initial lesion. There is also marked **interstitial fibrosis,** associated with atrophy and dropout of many of the tubules in the cortex, and diminution and loss of portions of the peritubular capillary network. The small and medium-sized arteries frequently are thick-walled, with narrowed lumina, secondary to hypertension. Lymphocytic (and, rarely, plasma cell) infiltrates are present in the fibrotic interstitial tissue. As damage to all structures progresses, it may become difficult to ascertain whether the primary lesion was glomerular, vascular, tubular, or interstitial. Such markedly damaged kidneys have been designated **end-stage kidneys.**

### Clinical Course

Chronic kidney disease may sometimes develop insidiously and be discovered only late in its course, after the onset of renal insufficiency. Frequently, renal disease is first detected with the discovery of proteinuria, hypertension, or azotemia on routine medical examination. Disease-specific findings may precede development of chronic kidney disease. In patients with glomerular disease resulting in nephrotic syndrome, as the glomeruli undergo sclerotic changes, the avenue for protein loss is progressively closed, and the nephrotic syndrome thus becomes less severe with more advanced disease. Some degree of proteinuria, however, is present in almost all cases. Hypertension is very common, and its effects may dominate the clinical picture. Although microscopic hematuria is usually present, grossly bloody urine is infrequent at this late stage.

Without treatment, the prognosis is poor; relentless progression to uremia and death is the rule. The rate of progression is extremely variable.

## CYSTIC DISEASES OF THE KIDNEY

Cystic diseases of the kidney are a heterogeneous group comprising hereditary, developmental, and acquired disorders. These diseases are important for several reasons:

- They are reasonably common and often present diagnostic problems for clinicians, radiologists, and pathologists.
- Some forms, such as adult polycystic disease, constitute major causes of chronic renal failure.
- Simple cysts can occasionally be confused with malignant tumors.

*An emerging theme in the pathophysiology of the hereditary cystic diseases is that the underlying defect is in the cilia–centrosome complex of tubular epithelial cells.* Such defects may interfere with fluid absorption or cellular maturation, resulting in cyst formation. A brief overview of simple cysts, the most common form, is presented next, followed by a more detailed discussion of polycystic kidney disease.

### Simple Cysts

Simple cysts are generally innocuous lesions that occur as multiple or single cystic spaces of variable size. Commonly, they are 1 to 5 cm in diameter; translucent; lined by a gray, glistening, smooth membrane; and filled with clear fluid. On microscopic examination, these membranes are seen to be composed of a single layer of cuboidal or flattened cuboidal epithelium, which in many instances may be completely atrophic. The cysts usually are confined to the cortex. Rarely, massive cysts as large as 10 cm in diameter are encountered.

Simple cysts constitute a common postmortem finding that has no clinical significance. The main importance of cysts lies in their differentiation from kidney tumors, when they are discovered either incidentally or during evaluation of hemorrhage and pain. Radiographic studies show that in contrast with renal tumors, renal cysts have smooth contours, are almost always avascular, and produce fluid rather than solid tissue signals on ultrasonography.

*Dialysis-associated acquired cysts* occur in the kidneys of patients with end-stage kidney disease who have undergone prolonged dialysis. They are present in both the cortex and the medulla and may bleed, causing hematuria. Occasionally, renal adenomas or even papillary adenocarcinomas arise in the walls of these cysts.

### Autosomal Dominant (Adult) Polycystic Kidney Disease

Adult polycystic kidney disease is characterized by multiple expanding cysts affecting both kidneys that ultimately destroy the intervening parenchyma. It is seen in approximately 1 in 500 to 1000 persons and accounts for 10% of cases of chronic kidney disease. This disease is genetically heterogeneous. It can be caused by inheritance of one of at least two autosomal dominant genes of very high penetrance. In 85% to 90% of families, *PKD1,* on the short arm of chromosome 16, is the defective gene. This gene encodes a large (460-kDa) and complex cell membrane–associated protein, called polycystin-1.

#### PATHOGENESIS

The polycystin molecule is mainly extracellular and has regions of homology with proteins involved in cell–cell or

cell–matrix adhesion (e.g., domains that bind collagen, laminin, and fibronectin). It also has several other domains including those that can bind receptor tyrosine phosphatases. The polycystins have been localized to the primary cilium of tubular cells, like the nephrocystins linked to medullary cystic disease that are discussed later on, giving rise to the concept of renal cystic diseases as a type of **ciliopathy.** Cilia are hairlike organelles that project into the lumina from the apical surface of tubular cells, where they serve as mechanosensors of fluid flow. Current evidence suggests that polycystin mutations produce defects in mechanosensing. This in turn alters downstream signaling events involving calcium influx, leading to dysregulation of cell polarity, proliferation, and cell-cell and cell-matrix adhesion. It is interesting to note that whereas germline mutations of the *PKD1* gene are present in all renal tubular cells of affected persons, cysts develop in only some tubules. This is most likely due to loss of both alleles of *PKD1*. Thus, as with tumor suppressor genes, a second "somatic hit" is required for expression of the disease. The *PKD2* gene, implicated in 10% to 15% of cases, resides on chromosome 4 and encodes **polycystin 2,** a smaller, 110-kD protein. Polycystin 2 is thought to function as a calcium-permeable membrane channel, and is also expressed in cilia. Although structurally distinct, polycystins 1 and 2 are believed to act together by forming heterodimers. Thus, mutation in either gene gives rise to essentially the same phenotype, although patients with *PKD2* mutations have a slower rate of disease progression as compared with patients with *PKD1* mutations.

## MORPHOLOGY

In autosomal dominant adult polycystic kidney disease, the kidney may reach enormous size, and weights of up to 4 kg for each kidney have been recorded. These **very large kidneys** are readily palpable abdominally as masses extending into the pelvis. On gross examination the kidney seems to be composed solely of a mass of cysts of various sizes up to 3 or 4 cm in diameter with no intervening parenchyma. The cysts are filled with fluid, which may be clear, turbid, or hemorrhagic (Fig. 13–21).

Cysts may arise at any level of the nephron, from tubules to collecting ducts, and therefore they have a variable, often atrophic, lining. Occasionally, Bowman's capsules are involved in the cyst formation, and in these cases glomerular tufts may be seen within the cystic space. The pressure of the expanding cysts leads to ischemic atrophy of the intervening renal substance. Some normal parenchyma may be dispersed among the cysts. Evidence of superimposed hypertension or infection is common. Asymptomatic liver cysts occur in one third of the patients.

### Clinical Course

Polycystic kidney disease in adults usually *does not produce symptoms until the fourth decade of life,* by which time the kidneys are quite large, although small cysts start to develop in adolescence. The most common presenting complaint is *flank pain* or a heavy, dragging sensation. Acute distention of a cyst, either by intracystic hemorrhage or by obstruction, may cause excruciating pain. Sometimes attention is first drawn to the lesion on palpation of an abdominal mass. *Intermittent gross hematuria* commonly occurs. The most important complications, because of their deleterious effect on already marginal renal function, are *hypertension and urinary infection.* Hypertension of variable severity develops in about 75% of persons with this disorder. Saccular aneurysms of the circle of Willis (Chapter 22) are present in 10% to 30% of patients and are associated with a high incidence of subarachnoid hemorrhage.

Although the disease is ultimately fatal, the outlook is generally better than with most chronic kidney diseases. The condition tends to be relatively stable and progresses

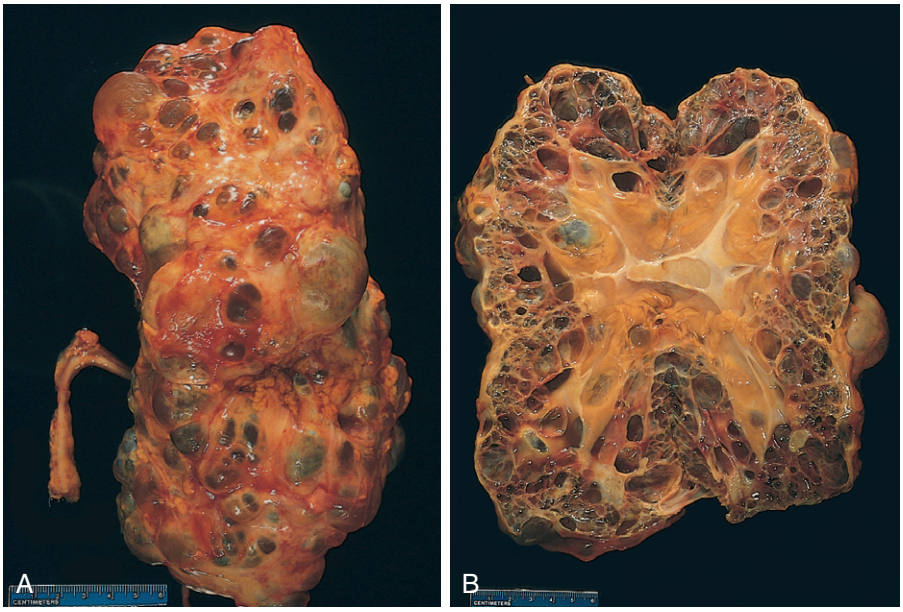

**Figure 13–21** Autosomal dominant adult polycystic kidney, viewed from the external surface (**A**) and bisected (**B**). The kidney is markedly enlarged (centimeter rule is shown for scale), with numerous dilated cysts.

very slowly. End-stage kidney disease occurs at about age 50, but there is wide variation in the course of this disorder, and nearly normal life spans are reported. Patients in whom the disease progresses to renal failure are treated by renal transplantation. Death usually results from uremia or hypertensive complications.

## Autosomal Recessive (Childhood) Polycystic Kidney Disease

The childhood form of polycystic kidney disease is a rare autosomal recessive disorder that is genetically distinct from adult polycystic kidney disease. It occurs in approximately 1 in 20,000 live births. Perinatal, neonatal, infantile, and juvenile subcategories have been defined, depending on age at presentation and the presence of associated hepatic lesions. All types result from mutations in the *PKHD1* gene, coding for a putative membrane receptor protein called *fibrocystin,* localized to the short arm of chromosome 6 (6p). Fibrocystin is found in cilia in tubular epithelial cells, but its function remains unknown.

### MORPHOLOGY

In autosomal recessive polycystic kidney disease, **numerous small cysts** in the cortex and medulla give the kidney a spongelike appearance. Dilated, elongated channels at right angles to the cortical surface completely replace the medulla and cortex. The cysts have a uniform lining of cuboidal cells, reflecting their origin from the collecting tubules. The disease is invariably bilateral. In almost all cases, findings include multiple epithelium-lined **cysts in the liver** and proliferation of portal bile ducts.

### Clinical Course

Perinatal and neonatal forms are most common; serious manifestations usually are present at birth, and young infants may die quickly from hepatic or renal failure. Patients who survive infancy develop liver cirrhosis (congenital hepatic fibrosis).

## Medullary Diseases with Cysts

There are two major types of cystic disease affecting the medulla: *medullary sponge kidney,* a relatively common and usually innocuous condition, occasionally associated with nephrolithiasis, which will not be discussed further, and *nephronophthisis-medullary cystic disease complex,* which is almost always associated with renal dysfunction.

Nephronophthisis–medullary cystic disease complex is an under-appreciated cause of chronic kidney disease that usually begins in childhood. Four variants of this disease complex are recognized on the basis of the timing of onset: infantile, juvenile, and adolescent nephronophthisis and medullary cystic disease developing later in adult life. The juvenile form is the most common. Approximately 15% to 20% of children with juvenile nephronophthisis have extrarenal manifestations, which most often appear as retinal abnormalities, including retinitis pigmentosa, and even early-onset blindness in the most severe form. Other abnormalities found in some persons include oculomotor apraxia, mental retardation, cerebellar malformations, and liver fibrosis. In aggregate, the various forms of nephronophthisis are now thought to be the most common genetic cause of end-stage renal disease in children and young adults.

At least nine gene loci (NHP1-NHP9) have been identified for the autosomal recessive forms of the nephronophthisis complex. The majority of these genes encode proteins that are components of epithelial cilia, as is the case with other types of polycystic disease. Two autosomal forms cause disease in adults; these are far less common.

### MORPHOLOGY

Pathologic features of medullary cystic disease include **small contracted kidneys.** Numerous small cysts lined by flattened or cuboidal epithelium are present, typically at the corticomedullary junction. Other pathologic changes are nonspecific, but most notably they include a chronic tubulointerstitial nephritis with tubular atrophy and thickened tubular basement membranes and progressive interstitial fibrosis.

### Clinical Course

The initial manifestations are usually polyuria and polydipsia, a consequence of diminished tubular function. Progression to end-stage kidney disease ensues over a 5- to 10-year period. The disease is difficult to diagnose, since there are no serologic markers and the cysts may be too small to be seen with radiologic imaging. Adding to this difficulty, cysts may not be apparent on renal biopsy if the corticomedullary junction is not well sampled. A positive family history and unexplained chronic renal failure in young patients should lead to suspicion of nephronophthisis.

### SUMMARY

#### Cystic Diseases

- *Adult polycystic kidney disease* is a disease of autosomal dominant inheritance caused by mutations in the genes encoding polycystin-1 or -2. It accounts for about 10% of cases of chronic renal failure; kidneys may be very large and contain many cysts.
- *Autosomal recessive (childhood) polycystic kidney disease* is caused by mutations in the gene encoding fibrocystin. It is less common than the adult form and strongly associated with liver abnormalities; kidneys contain numerous small cysts.
- *Nephronophthisis–medullary cystic disease complex* is being increasingly recognized as a cause of chronic kidney disease in children and young adults. Of autosomal recessive inheritance, it is associated with mutations in several genes that encode epithelial cell proteins called nephrocystins that may be involved in ciliary function; kidneys are contracted and contain multiple small cysts.

# URINARY OUTFLOW OBSTRUCTION

## Renal Stones

*Urolithiasis* is calculus formation at any level in the urinary collecting system, but most often the calculi arise in the kidney. They occur frequently, and it is estimated that by the age of 70 years, 11% of men and 5.6% of women in the United States will have experienced a symptomatic kidney stone. Symptomatic urolithiasis is more common in men than in women. A familial tendency toward stone formation has long been recognized.

### PATHOGENESIS

There are three major types of stones.

- About 80% of renal stones are composed of either calcium oxalate or calcium oxalate mixed with calcium phosphate.
- Ten percent are composed of magnesium ammonium phosphate.
- Six percent to 9% are either uric acid or cystine stones.

In all cases, an organic matrix of mucoprotein is present that makes up about 2.5% of the stone by weight (Table 13–3).

The cause of stone formation is often obscure, particularly in the case of calcium-containing stones. Probably involved is a confluence of predisposing conditions, including the concentration of the solute, changes in urine pH, and bacterial infections. The **most important cause is increased urinary concentration of the stone's constituents, so that it exceeds their solubility in urine (supersaturation).** As shown in Table 13–3, 50% of patients who develop **calcium stones** have hypercalciuria that is not associated with hypercalcemia. Most in this group absorb calcium from the gut in excessive amounts **(absorptive hypercalciuria)** and promptly excrete it in the urine, and some have a primary renal defect of calcium reabsorption **(renal hypercalciuria).**

The causes of the other types of renal stones are better understood. **Magnesium ammonium phosphate (struvite) stones** almost always occur in persons with a persistently alkaline urine resulting from UTIs. In particular, infections with urea-splitting bacteria, such as *Proteus vulgaris* and staphylococci, predispose individuals to urolithiasis. Moreover, bacteria may serve as particulate nidi for the formation of any kind of stone. In avitaminosis A, desquamated cells from the metaplastic epithelium of the collecting system act as nidi.

Gout and diseases involving rapid cell turnover, such as the leukemias, lead to high uric acid levels in the urine and the possibility of **uric acid stones.** About half of people with uric acid stones, however, have neither hyperuricemia nor increased urine urate but demonstrate an unexplained tendency to excrete a persistently acid urine (with a pH less than 5.5). This low pH favors uric acid stone formation—in contrast with the high pH that favors formation of stones containing calcium phosphate. **Cystine stones** are almost invariably associated with a genetically determined defect in the renal transport of certain amino acids, including cystine. Like uric acid stones, cystine stones are more likely to form when the urine is relatively acidic.

Urolithiasis also may result from the lack of substances that normally inhibit mineral precipitation. Inhibitors of crystal formation in urine include Tamm-Horsfall protein, osteopontin, pyrophosphate, mucopolysaccharides, diphosphonates, and a glycoprotein called nephrocalcin, but no deficiency of any of these substances has been consistently demonstrated in persons with urolithiasis.

**Table 13–3** Prevalence of Various Types of Renal Stones

| Stone | Distribution (%) |
|---|---|
| Calcium oxalate and/or calcium phosphate | 80 |
| Idiopathic hypercalciuria (50%) | |
| Hypercalcemia and hypercalciuria (10%) | |
| Hyperoxaluria (5%) | |
| Enteric (4.5%) | |
| Primary (0.5%) | |
| Hyperuricosuria (20%) | |
| No known metabolic abnormality (15% to 20%) | |
| Struvite ($Mg, NH_3, PO_4$) | 10 |
| Renal infection | |
| Uric acid | 6–7 |
| Associated with hyperuricemia | |
| Associated with hyperuricosuria | |
| Idiopathic (50% of uric acid stones) | |
| Cystine | 1–2 |
| Others or unknown | ±1–2 |

### MORPHOLOGY

Stones are unilateral in about 80% of patients. Common sites of formation are renal pelves and calyces and the bladder. Often, many stones are found in one kidney. They tend to be small (average diameter, 2 to 3 mm) and may be smooth or jagged. Occasionally, progressive accretion of salts leads to the development of branching structures known as **staghorn calculi,** which create a cast of the renal pelvis and calyceal system. These massive stones usually are composed of magnesium ammonium phosphate.

### Clinical Course

Stones may be present without producing either symptoms or significant renal damage. This is particularly true with large stones lodged in the renal pelvis. Smaller stones may pass into the ureter, where they may lodge, producing a typical intense pain known as *renal or ureteral colic,* characterized by paroxysms of flank pain radiating toward the groin. Often at this time there is *gross hematuria.* The clinical significance of stones lies in their capacity to obstruct urine flow or to produce sufficient trauma to cause ulceration and bleeding. In either case, they *predispose the sufferer to bacterial infection.* Fortunately, in most cases the diagnosis is readily made radiologically.

## Hydronephrosis

Hydronephrosis refers to dilation of the renal pelvis and calyces, with accompanying atrophy of the parenchyma, caused by obstruction to the outflow of urine. The

obstruction may be sudden or insidious, and it may occur at any level of the urinary tract, from the urethra to the renal pelvis. The most common causes are categorized as follows:

- *Congenital*: atresia of the urethra, valve formations in either ureter or urethra, aberrant renal artery compressing the ureter, renal ptosis with torsion, or kinking of the ureter
- *Acquired*
  - *Foreign bodies*: calculi, sloughed necrotic papillae
  - *Proliferative lesions*: benign prostatic hyperplasia, carcinoma of the prostate, bladder tumors (papilloma and carcinoma), contiguous malignant disease (retroperitoneal lymphoma, carcinoma of the cervix or uterus)
  - *Inflammation*: prostatitis, ureteritis, urethritis, retroperitoneal fibrosis
  - *Neurogenic*: spinal cord damage with paralysis of the bladder
  - *Normal pregnancy*: mild and reversible

Bilateral hydronephrosis occurs only when the obstruction is below the level of the ureters. If blockage is at the ureters or above, the lesion is unilateral. Sometimes obstruction is complete, allowing no urine to pass; usually it is only partial.

## PATHOGENESIS

Even with complete obstruction, glomerular filtration persists for some time, and the filtrate subsequently diffuses back into the renal interstitium and perirenal spaces, whence it ultimately returns to the lymphatic and venous systems. Because of the continued filtration, the **affected calyces and pelvis become dilated,** often markedly so. The unusually high pressure thus generated in the renal pelvis, as well as that transmitted back through the collecting ducts, causes compression of the renal vasculature. Both arterial insufficiency and venous stasis result, although the latter probably is more important. The most severe effects are seen in the papillae, because they are subjected to the greatest increases in pressure. Accordingly, **the initial functional disturbances are largely tubular, manifested primarily by impaired concentrating ability.** Only later does glomerular filtration begin to diminish. Experimental studies indicate that serious irreversible damage occurs in about 3 weeks with complete obstruction, and in 3 months with incomplete obstruction. In addition to functional changes, the obstruction also triggers an interstitial inflammatory reaction, leading eventually to interstitial fibrosis.

## MORPHOLOGY

**Bilateral** hydronephrosis (as well as unilateral hydronephrosis when the other kidney is already damaged or absent) leads to renal failure, and the onset of uremia tends to abort the natural course of the lesion. By contrast, **unilateral** involvement is associated with the full range of morphologic changes, which vary with the degree and speed of obstruction. With subtotal or intermittent obstruction, the kidney may be massively enlarged (lengths in the range of 20 cm), and the organ may consist almost entirely of the greatly distended pelvicalyceal system. The renal parenchyma itself is compressed and atrophied, with obliteration of the papillae and flattening of the pyramids (Fig. 13–22). On the other hand, when obstruction is sudden and complete, glomerular filtration is compromised relatively early, and as a consequence, renal function may cease while dilation is still comparatively slight. Depending on the level of the obstruction, one or both ureters may be dilated **(hydroureter).**

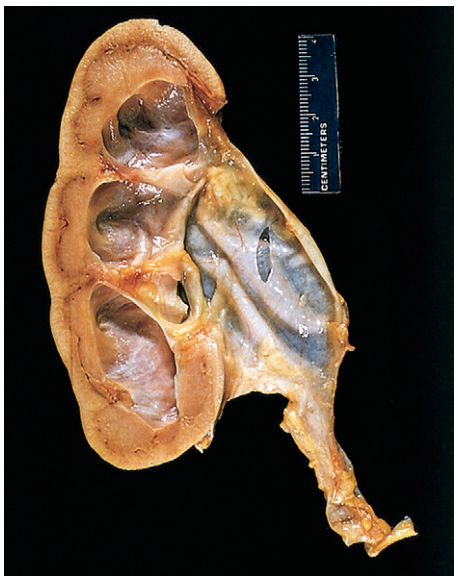

**Figure 13–22** Hydronephrosis of the kidney, with marked dilation of the pelvis and calyces and thinning of renal parenchyma.

On microscopic examination the early lesions show tubular dilation, followed by atrophy and fibrous replacement of the tubular epithelium with relative sparing of the glomeruli. Eventually, in severe cases the glomeruli also become atrophic and disappear, converting the entire kidney into a thin shell of fibrous tissue. With sudden and complete obstruction, there may be coagulative necrosis of the renal papillae, similar to the changes of papillary necrosis. In uncomplicated cases the accompanying inflammatory reaction is minimal. Superimposed pyelonephritis, however, is common.

### Clinical Course

*Bilateral* complete obstruction produces anuria, which is soon brought to medical attention. When the obstruction is below the bladder, the dominant symptoms are those of bladder distention. Paradoxically, incomplete bilateral obstruction causes polyuria rather than oliguria, as a result of defects in tubular concentrating mechanisms, and this may obscure the true nature of the disturbance. Unfortunately, *unilateral* hydronephrosis may remain completely silent for long periods unless the other kidney is for some reason not functioning. Often the enlarged kidney is discovered on routine physical examination. Sometimes the basic cause of the hydronephrosis, such as renal calculi or an obstructing tumor, produces symptoms that indirectly draw attention to the hydronephrosis. Removal of

obstruction within a few weeks usually permits full return of function; however, with time the changes become irreversible.

# TUMORS

Many types of benign and malignant tumors occur in the urinary tract. In general, benign tumors such as small (less than 0.5 cm in diameter) cortical papillary adenomas, which are found in 40% of adults, have no clinical significance. The most common malignant tumor of the kidney is renal cell carcinoma, followed in frequency by nephroblastoma (Wilms tumor) and by primary tumors of the calyces and pelvis. Other types of renal cancer are rare and need not be discussed here. *Tumors of the lower urinary tract are about twice as common as renal cell carcinomas.* They are described at the end of this section.

## Tumors of the Kidney

### *Oncocytoma*

Oncocytoma, a benign tumor that arises from the intercalated cells of collecting ducts, represents about 10% of renal tumors. These tumors are associated with genetic changes—loss of chromosomes 1, 14, and Y—that distinguish them from other renal neoplasms. Oncocytomas are histologically characterized by a plethora of mitochondria, providing the basis for their tan color and their finely granular eosinophilic cytoplasm that is seen histologically. A central stellate scar, which is another feature of oncocytomas, provides a characteristic appearance on imaging studies. Owing to their large size and clinical and radiologic similarity to some renal cell carcinomas, however, they are removed by nephrectomy, both to prevent such complications as spontaneous hemorrhage and to make a definitive diagnosis.

### *Renal Cell Carcinoma*

Renal cell carcinomas are derived from the renal tubular epithelium and hence they are located predominantly in the cortex. These tumors represent 80% to 85% of all primary malignant tumors of the kidney and 2% to 3% of all cancers in adults. These data translate into about 58,000 cases per year in the United States; 40% of patients die of the disease. Carcinomas of the kidney are most common from the sixth to seventh decades, and men are affected about twice as commonly as women. The risk of developing these tumors is higher in smokers, hypertensive or obese patients, and those who have had occupational exposure to cadmium. The risk of developing renal cell cancer is increased 30-fold in persons who acquire polycystic disease as a complication of chronic dialysis. The role of genetic factors in the causation of these cancers is discussed later on.

Renal cell cancers are classified on the basis of morphology and growth patterns. However, recent advances in the understanding of the genetic basis of renal carcinomas have led to a new classification that takes into account the molecular origins of these tumors. The three most common forms, discussed next, are clear cell carcinoma, papillary renal cell carcinoma, and chromophobe renal carcinoma.

#### Clear Cell Carcinomas

Clear cell carcinomas are the most common type, accounting for 65% of renal cell cancers. Histologically, they are composed of cells with clear cytoplasm. Although most are sporadic, they also occur in familial forms or in association with von Hippel-Lindau (VHL) disease. It is the study of VHL disease that has provided molecular insights into the causation of clear cell carcinomas. VHL disease is inherited as an autosomal dominant trait and is characterized by predisposition to a variety of neoplasms, but particularly to hemangioblastomas of the cerebellum and retina. Hundreds of bilateral renal cysts and bilateral, often multiple, clear cell carcinomas develop in 40% to 60% of affected persons. Those with VHL syndrome inherit a germline mutation of the *VHL* gene on chromosomal band 3p25 and lose the second allele by somatic mutation. Thus, the loss of both copies of this tumor suppressor gene is a key step in the development of clear cell carcinoma. The *VHL* gene is also involved in the majority of sporadic clear cell carcinomas. Cytogenetic abnormalities giving rise to loss of chromosomal segment 3p14 to 3p26 are often seen in sporadic renal cell cancers. This region harbors the *VHL* gene (3p25.3). The second, nondeleted allele is inactivated by a somatic mutation or hypermethylation in 60% of sporadic cases. Thus, homozygous loss of the *VHL* gene seems to be the common underlying molecular abnormality in both sporadic and familial forms of clear cell carcinomas. The VHL protein causes the degradation of hypoxia-induced factors (HIFs), and in the absence of VHL, HIFs are stabilized. HIFs are transcription factors that contribute to carcinogenesis by stimulating the expression of vascular endothelial growth factor (VEGF), an important angiogenic factor, as well as a number of other genes that drive tumor cell growth (Chapter 5). An uncommon familial form of clear cell carcinoma unrelated to VHL disease also is associated with cytogenetic abnormalities involving the short arm of chromosome 3 (3p). In addition, recent deep sequencing of clear cell carcinoma genomes has revealed frequent loss-of-function mutations in *SETD2, JARID1C,* and *UTX,* all of which encode proteins that regulate histone methylation, suggesting that changes in the "epigenome" have a central role in the genesis of this subtype of renal carcinoma.

#### Papillary Renal Cell Carcinomas

Papillary renal cell carcinomas account for 10% to 15% of all renal cancers. As the name indicates, they show a papillary growth pattern. These tumors are frequently multifocal and bilateral and appear as early-stage tumors. Like clear cell carcinomas, they occur in familial and sporadic forms, but unlike these tumors, papillary renal cancers are not associated with abnormalities of chromosome 3. The culprit in most cases of hereditary papillary renal cell cancers is the *MET* proto-oncogene, located on chromosomal sub-band 7q31. The *MET* gene is a tyrosine kinase receptor for the growth factor called hepatocyte growth factor. The increased dosage of the *MET* gene due to duplications of chromosome 7 seems to spur abnormal growth in the proximal tubular epithelial cell precursors of papillary carcinomas. In familial cases, genetic analysis shows activating mutations of *MET* in the germline, along with increased gene dosage in the cancers. Activating mutations of the *MET* gene also are found in a subset of

patients with sporadic forms of papillary renal cell carcinoma.

### Chromophobe Renal Carcinomas

Chromophobe renal carcinomas are the least common, representing 5% of all renal cell carcinomas. They arise from intercalated cells of collecting ducts. Their name derives from the observation that the tumor cells stain more darkly (i.e., they are less clear) than cells in clear cell carcinomas. These tumors are unique in having multiple losses of entire chromosomes, including chromosomes 1, 2, 6, 10, 13, 17, and 21. Thus, they show extreme hypodiploidy. Because of multiple losses, the "critical hit" has not been determined. In general, chromophobe renal cancers have a good prognosis.

## MORPHOLOGY

**Clear cell cancers** (the most common form of these renal carcinomas) usually are solitary and large when symptomatic (spherical masses 3 to 15 cm in diameter), but high-resolution radiographic techniques for investigation of unrelated problems sometimes detect smaller lesions incidentally. They may arise anywhere in the cortex. The cut surface of clear cell renal cell carcinomas is **yellow to orange to gray-white, with prominent areas of cystic softening or of hemorrhage,** either fresh or old (Fig. 13–23). The margins of the tumor are well defined. However, at times small processes project into the surrounding parenchyma and small satellite nodules are found, providing clear evidence of the aggressiveness of these lesions. As the tumor enlarges, it may fungate through the walls of the collecting system, extending through the calyces and pelvis as far as the ureter. Even more frequently, the **tumor invades the renal vein** and grows as a solid column within this vessel, sometimes extending in serpentine fashion as far as the inferior vena cava and even into the right side of the heart. Occasionally, direct invasion into the perinephric fat and adrenal gland may be seen.

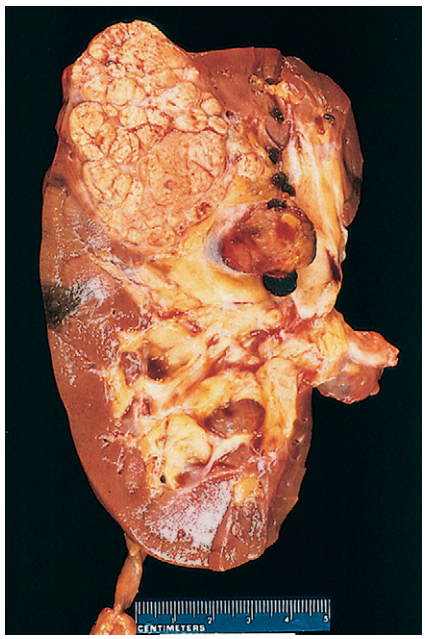

**Figure 13–23** Renal cell carcinoma: Representative cross-section showing yellowish, spherical neoplasm in one pole of the kidney. Note the tumor in the dilated, thrombosed renal vein.

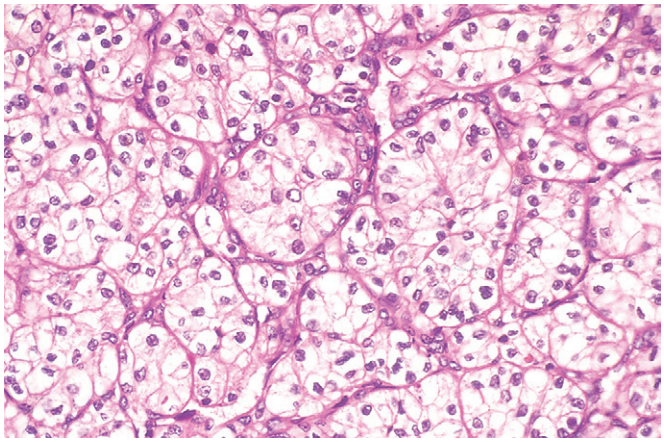

**Figure 13–24** High-power detail of the clear cell pattern of renal cell carcinoma.

Depending on the amounts of lipid and glycogen present, **the tumor cells of clear cell renal cell carcinoma may appear almost vacuolated or may be solid.** The classic vacuolated (lipid-laden), or clear cells are demarcated only by their cell membranes. The nuclei are usually small and round (Fig. 13–24). At the other extreme are granular cells, resembling the tubular epithelium, which have small, round, regular nuclei enclosed within granular pink cytoplasm. Some tumors are highly anaplastic, with numerous mitotic figures and markedly enlarged, hyperchromatic, pleomorphic nuclei. Between the extremes of clear cells and solid, granular cells, all intergradations may be found. The cellular arrangement, too, varies widely. The cells may form abortive tubules or may cluster in cords or disorganized masses. The stroma is usually scant but highly vascularized.

**Papillary renal cell carcinomas** exhibit various degrees of papilla formation with fibrovascular cores. They tend to be bilateral and multiple. They also may show gross evidence of necrosis, hemorrhage, and cystic degeneration, but they are less vibrantly orange-yellow because of their lower lipid content. The cells may have clear or, more commonly, pink cytoplasm. **Chromophobe-type renal cell carcinoma** tends to be grossly tan-brown. The cells usually have clear, flocculent cytoplasm with very prominent, distinct cell membranes. The nuclei are surrounded by halos of clear cytoplasm. Ultrastructurally, large numbers of characteristic macrovesicles are seen.

### Clinical Course

Renal cell carcinomas have several peculiar clinical characteristics that create especially difficult and challenging diagnostic problems. The signs and symptoms vary, but the *most frequent presenting manifestation is hematuria, occurring in more than 50% of cases.* Macroscopic hematuria tends to be intermittent and fleeting, superimposed on a steady microscopic hematuria. Less commonly the tumor may declare itself simply by virtue of its size, when it has grown large enough to produce flank pain and a *palpable mass*. Because of the widespread use of imaging studies for

unrelated conditions, even smaller tumors are detected. Extra-renal effects are *fever* and *polycythemia*, which, because they are nonspecific, may be misinterpreted for some time before their association with the renal tumor is appreciated. Polycythemia affects 5% to 10% of persons with this disease. It results from elaboration of erythropoietin by the cancer cells. Uncommonly, these tumors produce other hormone-like substances, resulting in hypercalcemia, hypertension, Cushing syndrome, or feminization or masculinization. These, as noted in Chapter 5, are *paraneoplastic syndromes*. In many patients, the primary tumor remains silent and is discovered only after its metastases have produced symptoms. The prevalent locations for metastases are the lungs and the bones. It must be apparent that renal cell carcinoma manifests in many ways, some quite devious, *but the triad of painless hematuria, a palpable abdominal mass, and dull flank pain is characteristic.*

## SUMMARY

### Renal Cell Carcinoma

Renal cell carcinomas account for 2% to 3% of all cancers in adults and are classified into three types:

- *Clear cell carcinomas* are the most common and are associated with homozygous loss of the VHL tumor suppressor protein; tumors frequently invade the renal vein.
- *Papillary renal cell carcinomas* frequently are associated with increased expression and activating mutations of the *MET* oncogene; they tend to be bilateral and multiple and show variable papilla formation.
- *Chromophobe renal cell carcinomas* are less common; tumor cells are not as clear as in the other renal cell carcinomas.

### *Wilms Tumor*

Although Wilms tumor occurs infrequently in adults, it is the third most common organ cancer in children younger than 10 years of age. These tumors contain a variety of cell and tissue components, all derived from the mesoderm. Wilms tumor, like retinoblastoma, may arise sporadically or be familial, with the susceptibility to tumorigenesis inherited as an autosomal dominant trait. This tumor is discussed in greater detail in Chapter 6 along with other tumors of childhood.

Tumors and other lesions of the lower urinary tract (ureters, bladder, and urethra) are described in Chapter 17.

Tumors of the Appendix 601

The gastrointestinal tract is a hollow tube consisting of the esophagus, stomach, small intestine, colon, rectum, and anus. Each region has unique, complementary, and highly integrated functions that together serve to regulate the intake, processing, and absorption of ingested nutrients and the disposal of waste products. The intestines also are the principal site at which the immune system interfaces with a diverse array of antigens present in food and gut microbes. Thus, it is not surprising that the small intestine and colon frequently are involved by infectious and inflammatory processes. Finally, the colon is the most common site of gastrointestinal neoplasia in Western populations. In this chapter we discuss the diseases that affect each section of the gastrointestinal tract. Disorders that typically involve more than one segment, such as Crohn disease, are considered with the most frequently involved region.

## ORAL CAVITY

Pathologic conditions of the oral cavity can be broadly divided into diseases affecting the oral mucosa, salivary glands, and jaws. Discussed next are the more common conditions affecting these sites. Although common, disorders affecting the teeth and supporting structures are not considered here. Reference should be made to specialized texts. Odontogenic cysts and tumors (benign and malignant), which are derived from the epithelial and/or

mesenchymal tissues associated with tooth development, also are discussed briefly.

## ORAL INFLAMMATORY LESIONS

### Aphthous Ulcers (Canker Sores)

These common superficial mucosal ulcerations affect up to 40% of the population. They are more common in the first two decades of life, extremely painful, and recurrent. Although the cause of aphthous ulcers is not known, they do tend to be more prevalent within some families and may be associated with celiac disease, inflammatory bowel disease (IBD), and Behçet disease. Lesions can be solitary or multiple; typically, they are shallow, hyperemic ulcerations covered by a thin exudate and rimmed by a narrow zone of erythema (Fig. 14–1). In most cases they resolve spontaneously in 7 to 10 days but can recur.

### Herpes Simplex Virus Infections

Most orofacial herpetic infections are caused by herpes simplex virus type 1 (HSV-1), with the remainder being caused by HSV-2 (genital herpes). With changing sexual practices, oral HSV-2 is increasingly common. Primary infections typically occur in children between 2 and 4 years of age and are often asymptomatic. However, in 10% to 20% of cases the primary infection manifests as *acute herpetic gingivostomatitis,* with abrupt onset of vesicles and ulcerations throughout the oral cavity. Most adults harbor latent HSV-1, and the virus can be reactivated, resulting in a so-called "cold sore" or *recurrent herpetic stomatitis*. Factors associated with HSV reactivation include trauma, allergies, exposure to ultraviolet light, upper respiratory tract infections, pregnancy, menstruation, immunosuppression, and exposure to extremes of temperature. These recurrent lesions, which occur at the site of primary inoculation or in adjacent mucosa innervated by the same ganglion, typically appear as groups of small (1 to 3 mm) vesicles. The lips (herpes labialis), nasal orifices, buccal mucosa, gingiva, and hard palate are the most common locations. Although lesions typically resolve within 7 to 10 days, they can persist in immunocompromised patients, who may require systemic antiviral therapy. Morphologically, the lesions resemble those seen in esophageal herpes (see Fig. 14–8) and genital herpes (Chapter 17). The infected cells become ballooned and have large eosinophilic intranuclear inclusions. Adjacent cells commonly fuse to form large multinucleated polykaryons.

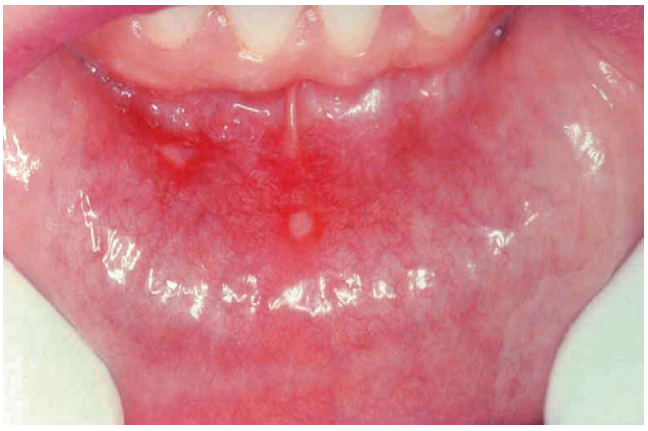

**Figure 14–1** Aphthous ulcer. Single ulceration with an erythematous halo surrounding a yellowish fibrinopurulent membrane.

### Oral Candidiasis (Thrush)

Candidiasis is the most common fungal infection of the oral cavity. *Candida albicans* is a normal component of the oral flora and only produces disease under unusual circumstances. Modifying factors include:

- Immunosuppression
- The strain of *C. albicans*
- The composition of the oral microbial flora (microbiota)

Broad-spectrum antibiotics that alter the normal microbiota can also promote oral candidiasis. The three major clinical forms of oral candidiasis are pseudomembranous, erythematous, and hyperplastic. The pseudomembranous form is most common and is known as *thrush*. This condition is characterized by a superficial, curdlike, gray to white inflammatory membrane composed of matted organisms enmeshed in a fibrinosuppurative exudate that can be readily scraped off to reveal an underlying erythematous base. In mildly immunosuppressed or debilitated individuals, such as diabetics, the infection usually remains superficial, but can spread to deep sites in association with more severe immunosuppression, including that seen in organ or hematopoietic stem cell transplant recipients, as well as patients with neutropenia, chemotherapy-induced immunosuppression, or AIDS.

#### SUMMARY

##### Oral Inflammatory Lesions

- *Aphthous ulcers* are painful superficial ulcers of unknown etiology that may be associated with systemic diseases.
- *Herpes simplex virus* causes a self-limited infection that presents with vesicles (cold sores, fever blisters) that rupture and heal, without scarring, and often leave latent virus in nerve ganglia. Reactivation can occur.
- *Oral candidiasis* may occur when the oral microbiota is altered (e.g., after antibiotic use). Invasive disease may occur in immunosuppressed individuals.

## PROLIFERATIVE AND NEOPLASTIC LESIONS OF THE ORAL CAVITY

### Fibrous Proliferative Lesions

*Fibromas* (Fig. 14–2, *A*) are submucosal nodular fibrous tissue masses that are formed when chronic irritation results in reactive connective tissue hyperplasia. They

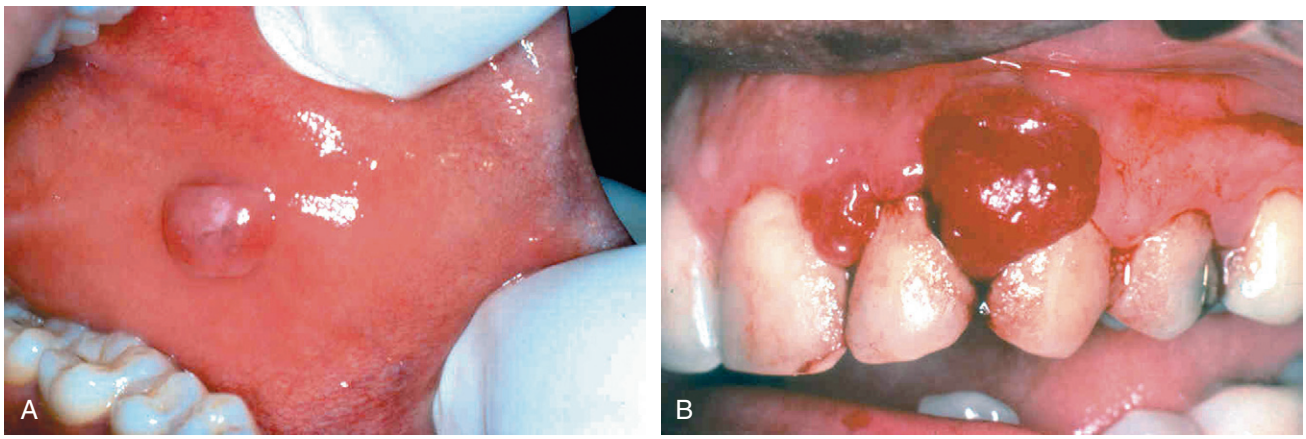

**Figure 14–2** Fibrous proliferations. **A,** Fibroma. Smooth pink exophytic nodule on the buccal mucosa. **B,** Pyogenic granuloma. Erythematous hemorrhagic exophytic mass arising from the gingival mucosa.

occur most often on the buccal mucosa along the bite line and are thought to be reactions to chronic irritation. Treatment is complete surgical excision and removal of the source of irritation.

*Pyogenic granulomas* (Fig. 14–2, *B*) are pedunculated masses usually found on the gingiva of children, young adults, and pregnant women. These lesions are richly vascular and typically are ulcerated, which gives them a red to purple color. In some cases, growth can be rapid and raise fear of a malignant neoplasm. However, histologic examination demonstrates a dense proliferation of immature vessels similar to that seen in granulation tissue. Pyogenic granulomas can regress, mature into dense fibrous masses, or develop into a peripheral ossifying fibroma. Complete surgical excision is definitive treatment.

## Leukoplakia and Erythroplakia

*Leukoplakia* is defined by the World Health Organization as "a white patch or plaque that cannot be scraped off and cannot be characterized clinically or pathologically as any other disease." This clinical term is reserved for lesions that arise in the oral cavity in the absence of any known etiologic factor (Fig. 14–3, *A*). Accordingly, white patches caused by obvious irritation or entities such as lichen planus and candidiasis are not considered leukoplakia. Approximately 3% of the world's population has leukoplakic lesions, of which 5% to 25% are premalignant and may progress to squamous cell carcinoma. *Thus, until proved otherwise by means of histologic evaluation, all leukoplakias must be considered precancerous.* A related but less common lesion, *erythroplakia,* is a red, velvety, possibly eroded area that is flat or slightly depressed relative to the surrounding mucosa. Erythroplakia is associated with a much greater risk of malignant transformation than leukoplakia. While leukoplakia and erythroplakia may be seen in adults at any age, they typically affect persons between the ages of 40 and 70 years, with a 2:1 male preponderance. *Although the etiology is multifactorial, tobacco use (cigarettes, pipes, cigars, and chewing tobacco) is the most common risk factor for leukoplakia and erythroplakia.*

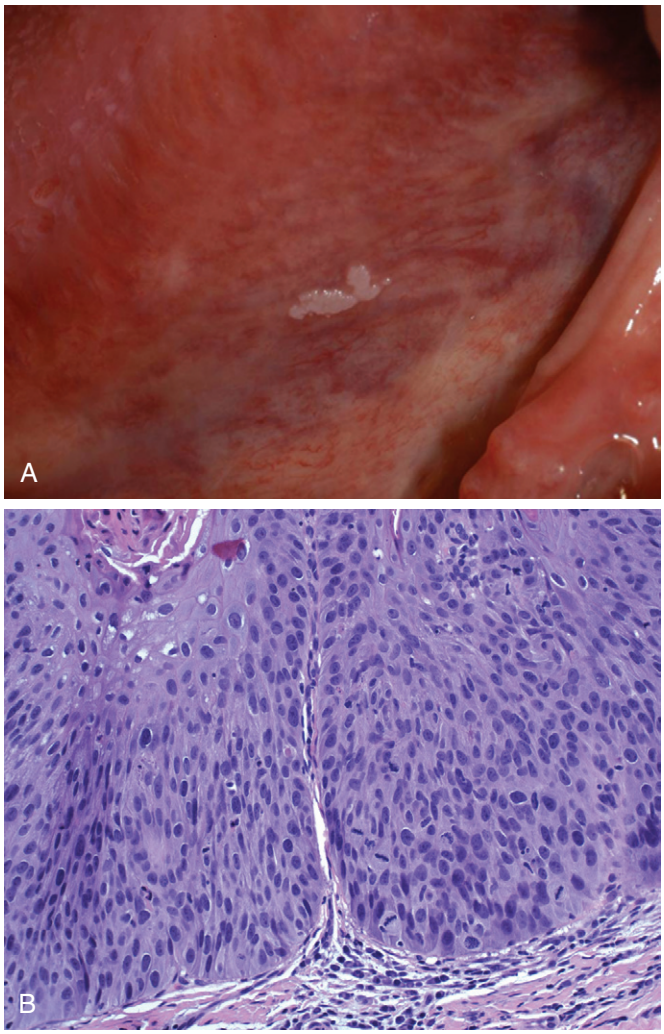

**Figure 14–3** Leukoplakia. **A,** Clinical appearance of leukoplakia is highly variable. In this example, the lesion is smooth with well-demarcated borders and minimal elevation. **B,** Histologic appearance of leukoplakia showing dysplasia, characterized by nuclear and cellular pleomorphism and loss of normal maturation.

### MORPHOLOGY

**Leukoplakia** includes a spectrum of histologic features ranging from **hyperkeratosis** overlying a thickened, acanthotic, but orderly mucosal lesions with marked **dysplasia** that sometimes merges with **carcinoma in situ** (Fig. 14–3, *B*). The most severe dysplastic changes are associated with erythroplakia, and more than 50% of these cases undergo malignant transformation. With increasing dysplasia and anaplasia, a subjacent inflammatory cell infiltrate of lymphocytes and macrophages is often present.

## Squamous Cell Carcinoma

Approximately 95% of cancers of the oral cavity are squamous cell carcinomas, with the remainder largely consisting of adenocarcinomas of salivary glands, as discussed later. This aggressive epithelial malignancy is the sixth most common neoplasm in the world today. Despite numerous advances in treatment, the overall long-term survival rate has been less than 50% for the past 50 years. This dismal outlook is due to several factors, most notably the fact that oral cancer often is diagnosed at an advanced stage.

Multiple primary tumors may be present at initial diagnosis but more often are detected later, at an estimated rate of 3% to 7% per year; patients who survive 5 years after diagnosis of the initial tumor have up to a 35% chance of developing at least one new primary tumor within that interval. The development of these secondary tumors can be particularly devastating for persons whose initial lesions were small. Thus, despite a 5-year survival rate greater than 50% for patients with small tumors, these patients often die of second primary tumors. Therefore, surveillance and early detection of new premalignant lesions are critical for the long-term survival of patients with oral squamous cell carcinoma.

The elevated risk of additional primary tumors in these patients has led to the concept of "field cancerization." This hypothesis suggests that multiple primary tumors develop independently as a result of years of chronic mucosal exposure to carcinogens such as alcohol or tobacco (described next).

### PATHOGENESIS

Squamous cancers of the oropharynx arise through two distinct pathogenic pathways. One group of tumors in the oral cavity occurs mainly in persons who are chronic alcohol and tobacco (both smoked and chewed) users. Deep sequencing of these cancers has revealed frequent mutations that bear a molecular signature consistent with exposure to carcinogens in tobacco. These mutations frequently involve *TP53* and genes that regulate the differentiation of squamous cells, such as *p63* and *NOTCH1*. The second group of tumors tends to occur in the tonsillar crypts or the base of the tongue and harbor oncogenic variants of human papillomavirus (HPV), particularly HPV-16. These tumors carry far fewer mutations than those associated with tobacco exposure and often overexpress p16, a cyclin-dependent kinase inhibitor. It is predicted that the incidence of HPV-associated oropharyngeal squamous cell carcinoma will surpass that of cervical cancer in the next decade, in part because the anatomic sites of origin—tonsillar crypts, base of tongue, and oropharynx—are not readily accessible or amenable to cytologic screening (unlike the cervix). Notably, the **prognosis for patients with HPV-positive tumors is better than for those with HPV-negative tumors.** The HPV vaccine, which is protective against cervical cancer, offers hope to limit the increasing frequency of HPV-associated oropharyngeal squamous cell carcinoma.

In India and southeast Asia, chewing of betel quid and paan are important predisposing factors. Betel quid is a "witch's brew" containing araca nut, slaked lime, and tobacco, all wrapped in betel nut leaf. It is likely that these tumors arise by a pathway similar to that characterized for tobacco use–associated tumors in the West.

### MORPHOLOGY

Squamous cell carcinoma may arise anywhere in the oral cavity. However, **the most common locations are the ventral surface of the tongue, floor of the mouth, lower lip, soft palate, and gingiva** (Fig. 14–4, *A*). In early stages, these cancers can appear as raised, firm, pearly plaques or as irregular, roughened, or verrucous mucosal thickenings. Either pattern may be superimposed on a background of a leukoplakia or erythroplakia. As these lesions enlarge, they typically form ulcerated and protruding masses that have irregular and indurated or rolled borders. Histopathologic analysis has shown that **squamous cell carcinoma develops from dysplastic precursor lesions.** Histologic patterns **range from well-differentiated keratinizing neoplasms** (Fig. 14–4, *B*) **to anaplastic, sometimes sarcomatoid tumors.** However, the degree of histologic differentiation, as determined by the relative degree of keratinization, does not necessarily correlate with biologic behavior. Typically, oral squamous cell carcinoma infiltrates locally before it metastasizes. The cervical lymph nodes are the most common sites of regional metastasis; frequent sites of distant metastases include the mediastinal lymph nodes, lungs, and liver.

### SUMMARY

#### Lesions of the Oral Cavity

- *Fibromas* and *pyogenic granulomas* are common reactive lesions of the oral mucosa.
- *Leukoplakias* are mucosal plaques that may undergo malignant transformation.
- The risk of malignant transformation is greater in *erythroplakia* (relative to leukoplakia).
- A majority of oral cavity cancers are *squamous cell carcinomas*.
- Oral squamous cell carcinomas are classically linked to tobacco and alcohol use, but the incidence of HPV-associated lesions is rising.

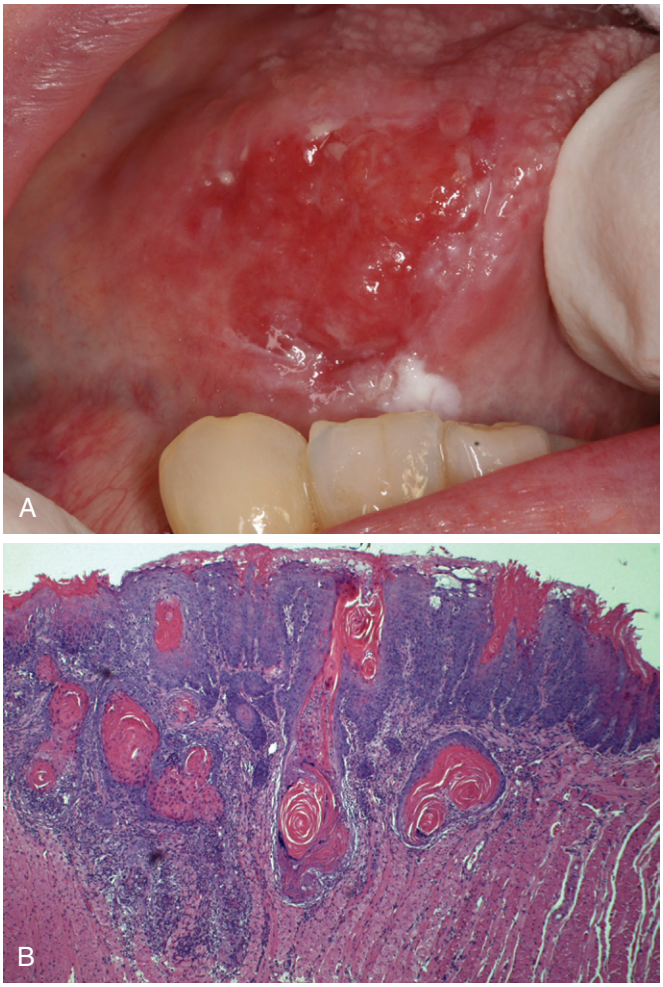

**Figure 14–4** Oral squamous cell carcinoma. **A,** Clinical appearance demonstrating ulceration and induration of the oral mucosa. **B,** Histologic appearance demonstrating numerous nests and islands of malignant keratinocytes invading the underlying connective tissue stroma.

## DISEASES OF SALIVARY GLANDS

There are three major salivary glands—parotid, submandibular, and sublingual—as well as innumerable minor salivary glands distributed throughout the oral mucosa. Inflammatory or neoplastic disease may develop within any of these.

### Xerostomia

Xerostomia is defined as a *dry mouth* resulting from a decrease in the production of saliva. Its incidence varies among populations, but has been reported in more than 20% of individuals above the age of 70 years. It is a major feature of the autoimmune disorder Sjögren syndrome, in which it usually is accompanied by dry eyes (Chapter 4). A lack of salivary secretions is also a major complication of radiation therapy. However, xerostomia is most frequently observed as a result of many commonly prescribed classes of medications including anticholinergic, antidepressant/antipsychotic, diuretic, antihypertensive, sedative, muscle relaxant, analgesic, and antihistaminic agents. The oral cavity may merely reveal dry mucosa and/or atrophy of the papillae of the tongue, with fissuring and ulcerations, or, in Sjögren syndrome, concomitant inflammatory enlargement of the salivary glands. Complications of xerostomia include increased rates of dental caries and candidiasis, as well as difficulty in swallowing and speaking.

### Sialadenitis

Sialadenitis, or inflammation of the salivary glands, may be induced by trauma, viral or bacterial infection, or autoimmune disease. The most common form of *viral sialadenitis is mumps,* which may produce enlargement of all salivary glands but predominantly involves the parotids. The mumps virus is a paramyxovirus related to the influenza and parainfluenza viruses. Mumps produces interstitial inflammation marked by a mononuclear inflammatory infiltrate. While mumps in children is most often a self-limited benign condition, in adults it can cause pancreatitis or orchitis; the latter sometimes causes sterility.

The *mucocele* is the most common inflammatory lesion of the salivary glands, and results from either blockage or rupture of a salivary gland duct, with consequent leakage of saliva into the surrounding connective tissue stroma. Mucocele occurs most often in toddlers, young adults, and the aged, and typically manifests as a fluctuant swelling of the lower lip that may change in size, particularly in association with meals (Fig. 14–5, *A*). Histologic examination demonstrates a cystlike space lined by inflammatory granulation tissue or fibrous connective tissue that is filled with mucin and inflammatory cells, particularly macrophages (Fig. 14–5, *B*). Complete excision of the cyst and the minor salivary gland lobule constitutes definitive treatment.

*Bacterial sialadenitis* is a common infection that most often involves the major salivary glands, particularly the submandibular glands. The most frequent pathogens are *Staphylococcus aureus* and *Streptococcus viridans.* Duct obstruction by stones (*sialolithiasis*) is a common antecedent to infection; it may also be induced by impacted food debris or by edema consequent to injury. Dehydration and decreased secretory function also may predispose to bacterial invasion and sometimes are associated with long-term phenothiazine therapy, which suppresses salivary secretion. Systemic dehydration, with decreased salivary secretions, may predispose to suppurative bacterial parotitis in elderly patients following major thoracic or abdominal surgery. This obstructive process and bacterial invasion lead to a nonspecific inflammation of the affected glands that may be largely interstitial or, when induced by staphylococcal or other pyogens, may be associated with overt suppurative necrosis and abscess formation.

Autoimmune sialadenitis, also called Sjögren syndrome, is discussed in Chapter 4.

### Neoplasms

Despite their relatively simple morphology, the salivary glands give rise to at least 30 histologically distinct tumors. As indicated in Table 14–1, a small number of these neoplasms account for more than 90% of tumors. Overall,

salivary gland tumors are relatively uncommon and represent less than 2% of all human tumors. Approximately 65% to 80% arise within the parotid, 10% in the submandibular gland, and the remainder in the minor salivary glands, including the sublingual glands. Approximately 15% to 30% of tumors in the parotid glands are malignant. By contrast, approximately 40% of submandibular, 50% of minor salivary gland, and 70% to 90% of sublingual tumors are cancerous. *Thus, the likelihood that a salivary gland tumor is malignant is inversely proportional, roughly, to the size of the gland.*

Salivary gland tumors usually occur in adults, with a slight female predominance, but about 5% occur in children younger than 16 years of age. Whatever the histologic pattern, parotid gland neoplasms produce swelling in front of and below the ear. In general, when they are first diagnosed, both benign and malignant lesions are usually 4 to 6 cm in diameter and are mobile on palpation except in the case of neglected malignant tumors. Benign tumors may be present for months to several years before coming to clinical attention, while cancers more often come to attention promptly, probably because of their more rapid growth. However, there are no reliable criteria to differentiate benign from malignant lesions on clinical grounds, and histopathologic evaluation is essential.

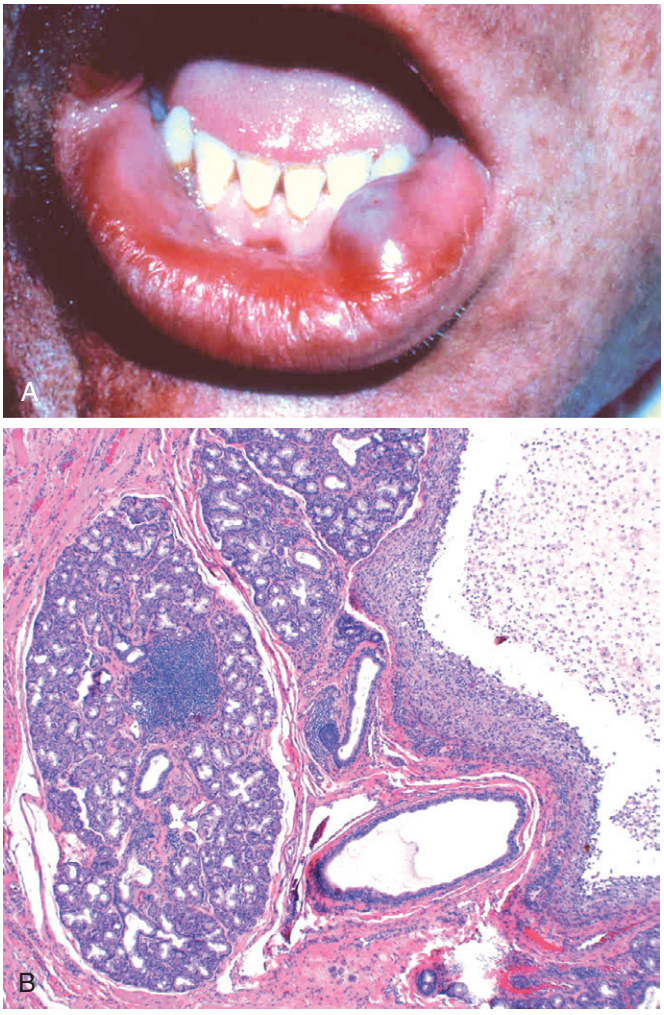

**Figure 14–5** Mucocele. **A,** Fluctuant fluid-filled lesion on the lower lip subsequent to trauma. **B,** Cystlike cavity *(right)* filled with mucinous material and lined by organizing granulation tissue.

**Table 14–1** Histopathologic Classification and Prevalence of the Most Common Benign and Malignant Salivary Gland Tumors

| Benign | Malignant |
|---|---|
| Pleomorphic adenoma (50%) | Mucoepidermoid carcinoma (15%) |
| Warthin tumor (5%) | Acinic cell carcinoma (6%) |
| Oncocytoma (2%) | Adenocarcinoma NOS (6%) |
| Cystadenoma (2%) | Adenoid cystic carcinoma (4%) |
| Basal cell adenoma (2%) | Malignant mixed tumor (3%) |

NOS, not otherwise specified.
Data from Ellis GL, Auclair PL, Gnepp DR: Surgical Pathology of the Salivary Glands, Vol 25: Major Problems in Pathology, Philadelphia, WB Saunders, 1991.

### *Pleomorphic Adenoma*

Pleomorphic adenomas present as painless, slow-growing, mobile discrete masses. They represent about *60% of tumors in the parotid,* are less common in the submandibular glands, and are relatively rare in the minor salivary glands. Pleomorphic adenomas are benign tumors that consist of a mixture of ductal (epithelial) and myoepithelial cells, so they exhibit both epithelial and mesenchymal differentiation. Epithelial elements are dispersed throughout the matrix, which may contain variable mixtures of myxoid, hyaline, chondroid (cartilaginous), and even osseous tissue. In some pleomorphic adenomas, the epithelial elements predominate; in others, they are present only in widely dispersed foci. This histologic diversity has given rise to the alternative, albeit less preferred name *mixed tumor.* The tumors consistently overexpress the transcription factor PLAG1, often because of chromosomal rearrangements involving the *PLAG1* gene, but how PLAG1 contributes to tumor development is unknown.

Pleomorphic adenomas recur if incompletely excised: Recurrence rates approach 25% after simple enucleation of the tumor, but are only 4% after wider resection. In both settings, recurrence stems from a failure to recognize minute extensions of tumor into surrounding soft tissues.

Carcinoma arising in a pleomorphic adenoma is referred to variously as a *carcinoma ex pleomorphic adenoma* or *malignant mixed tumor.* The incidence of malignant transformation increases with time from 2% of tumors present for less than 5 years to almost 10% for those present for more than 15 years. The cancer usually takes the form of an adenocarcinoma or undifferentiated carcinoma. Unfortunately, these are among the most aggressive malignant neoplasms of salivary glands, with mortality rates of 30% to 50% at 5 years.

#### MORPHOLOGY

Pleomorphic adenomas typically manifest as rounded, well-demarcated masses rarely exceeding 6 cm in the greatest dimension. Although they are encapsulated, in some locations (particularly the palate), the capsule is not fully developed, and expansile growth produces protrusions into the surrounding tissues. The cut surface is gray-white and typically contains myxoid and blue translucent chondroid (cartilage-like) areas. **The most striking histologic feature is their characteristic heterogeneity.** Epithelial

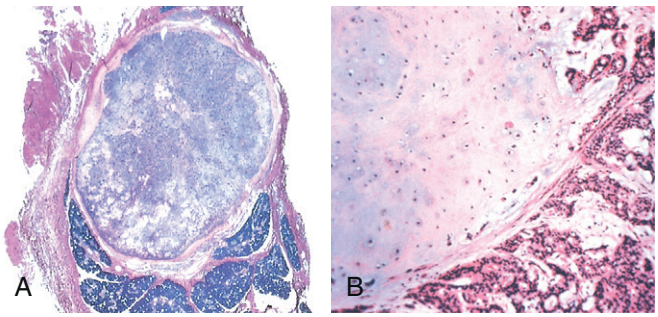

**Figure 14–6** Pleomorphic adenoma. **A,** Low-power view showing a well-demarcated tumor with adjacent normal salivary gland parenchyma. **B,** High-power view showing epithelial cells as well as myoepithelial cells within chondroid matrix material.

elements resembling ductal or myoepithelial cells are arranged in **ducts, acini, irregular tubules, strands, or even sheets.** These typically are dispersed within a **mesenchyme-like background of loose myxoid tissue** containing **islands of chondroid** and, rarely, foci of bone (Fig. 14–6). Sometimes the epithelial cells form well-developed ducts lined by cuboidal to columnar cells with an underlying layer of deeply chromatic, small myoepithelial cells. In other instances there may be strands or sheets of myoepithelial cells. Islands of well-differentiated squamous epithelium also may be present. In most cases, no epithelial dysplasia or mitotic activity is evident. No difference in biologic behavior has been observed between the tumors composed largely of epithelial elements and those composed largely of mesenchymal elements.

### *Mucoepidermoid Carcinoma*

Mucoepidermoid carcinomas are composed of variable mixtures of squamous cells, mucus-secreting cells, and intermediate cells. These neoplasms represent about 15% of all salivary gland tumors, and while they occur mainly (60% to 70%) in the parotids, they account for a large fraction of salivary gland neoplasms in the other glands, particularly the minor salivary glands. Overall, mucoepidermoid carcinoma is the most common form of primary *malignant* tumor of the salivary glands. It is commonly associated with chromosome rearrangements involving *MAML2,* a gene that encodes a signaling protein in the Notch pathway.

#### MORPHOLOGY

Mucoepidermoid carcinomas can grow as large as 8 cm in diameter and, although they are apparently circumscribed, they lack well-defined capsules and often are infiltrative. The cut surface is pale gray to white and frequently demonstrates small, mucinous cysts. On histologic examination, these tumors contain **cords, sheets, or cysts lined by squamous, mucous, or intermediate cells.** The latter is a hybrid cell type with both squamous features and mucus-filled vacuoles, which are most easily detected with mucin stains. Cytologically, tumor cells may be benign-appearing or highly anaplastic and unmistakably malignant. On this basis, mucoepidermoid carcinomas are subclassified as low-, intermediate-, or high-grade.

Clinical course and prognosis depend on histologic grade. Low-grade tumors may invade locally and recur in about 15% of cases but metastasize only rarely and afford a 5-year survival rate over 90%. By contrast, high-grade neoplasms and, to a lesser extent, intermediate-grade tumors are invasive and difficult to excise. As a result, they recur in 25% to 30% of cases, and about 30% metastasize to distant sites. The 5-year survival rate is only 50%.

#### SUMMARY

**Diseases of Salivary Glands**

- *Sialadenitis* (inflammation of the salivary glands) can be caused by trauma, infection (such as mumps), or an autoimmune reaction.
- *Pleomorphic adenoma* is a slow-growing neoplasm composed of a heterogeneous mixture of epithelial and mesenchymal cells.
- *Mucoepidermoid carcinoma* is a malignant neoplasm of variable biologic aggressiveness that is composed of a mixture of squamous and mucous cells.

## ODONTOGENIC CYSTS AND TUMORS

In contrast with other skeletal sites, epithelium-lined cysts are common in the jaws. A majority of these cysts are derived from remnants of odontogenic epithelium. In general, these cysts are subclassified as either inflammatory or developmental. Only the most common of these lesions are considered here.

The *dentigerous cyst* originates around the crown of an unerupted tooth and is thought to be the result of a degeneration of the dental follicle (primordial tissue that makes the enamel surface of teeth). On radiographic evaluation, these unilocular lesions most often are associated with impacted third molar (wisdom) teeth. They are lined by a thin, stratified squamous epithelium that typically is associated with a dense chronic inflammatory infiltrate within the underlying connective tissue. Complete removal is curative.

Odontogenic keratocysts can occur at any age but are most frequent in persons between 10 and 40 years of age, have a male predominance, and typically are located within the posterior mandible. Differentiation of the *odontogenic keratocyst* from other odontogenic cysts is important because it is locally aggressive and has a high recurrence rate. On radiographic evaluation, odontogenic keratocysts are seen as well-defined unilocular or multilocular radiolucencies. On histologic examination, the cyst lining consists of a thin layer of parakeratinized or orthokeratinized stratified squamous epithelium with a prominent basal cell layer and a corrugated luminal epithelial surface. Treatment requires aggressive and complete removal; recurrence rates of up to 60% are associated with inadequate resection. Multiple odontogenic keratocysts may occur, particularly in patients with the nevoid basal cell carcinoma syndrome (Gorlin syndrome).

In contrast with the developmental cysts just described, the *periapical cyst* has an inflammatory etiology. These

extremely common lesions occur at the tooth apex as a result of long-standing pulpitis, which may be caused by advanced caries or trauma. Necrosis of the pulpal tissue, which can traverse the length of the root and exit the apex of the tooth into the surrounding alveolar bone, can lead to a periapical abscess. Over time, granulation tissue (with or without an epithelial lining) may develop. These are often designated *periapical granuloma.* Although the lesion does not show true granulomatous inflammation, old terminology, like bad habits, is difficult to shed. Periapical inflammatory lesions persist as a result of bacteria or other offensive agents in the area. Successful treatment, therefore, necessitates the complete removal of the offending material followed by restoration or extraction of the tooth.

*Odontogenic tumors* are a complex group of lesions with diverse histologic appearances and clinical behaviors. Some are true neoplasms, either benign or malignant, while others are thought to be hamartomatous. Odontogenic tumors are derived from odontogenic epithelium, ectomesenchyme, or both. The two most common and clinically significant tumors are ameloblastoma and odontoma.

*Ameloblastoma*s arise from odontogenic epithelium and do not demonstrate chondroid or osseous differentiation. These typically cystic lesions are slow-growing and, despite being locally invasive, have an indolent course.

*Odontoma*, the most common type of odontogenic tumor, arises from epithelium but shows extensive deposition of enamel and dentin. Odontomas are cured by local excision.

### SUMMARY

#### Odontogenic Cysts and Tumors

- The jaws are a common site of epithelium-lined cysts derived from odontogenic remnants.
- The *odontogenic keratocyst* is locally aggressive, with a high recurrence rate.
- The *periapical cyst* is a reactive, inflammatory lesion associated with caries or dental trauma.
- The most common *odontogenic tumors* are *ameloblastoma* and *odontoma.*

# ESOPHAGUS

The esophagus develops from the cranial portion of the foregut. It is a hollow, highly distensible muscular tube that extends from the epiglottis to the gastroesophageal junction, located just above the diaphragm. Acquired diseases of the esophagus run the gamut from lethal cancers to "heartburn," with clinical manifestations ranging from chronic and incapacitating disease to mere annoyance.

## OBSTRUCTIVE AND VASCULAR DISEASES

### Mechanical Obstruction

Atresia, fistulas, and duplications may occur in any part of the gastrointestinal tract. When they involve the esophagus, they are discovered shortly after birth, usually because of regurgitation during feeding, and must be corrected promptly. Absence, or *agenesis,* of the esophagus is extremely rare. *Atresia,* in which a thin, noncanalized cord replaces a segment of esophagus, is more common. Atresia occurs most commonly at or near the tracheal bifurcation and usually is associated with a *fistula* connecting the upper or lower esophageal pouches to a bronchus or the trachea. This abnormal connection can result in aspiration, suffocation, pneumonia, or severe fluid and electrolyte imbalances.

Passage of food can be impeded by esophageal *stenosis.* The narrowing generally is caused by fibrous thickening of the submucosa, atrophy of the muscularis propria, and secondary epithelial damage. *Stenosis most often is due to inflammation and scarring, which may be caused by chronic gastroesophageal reflux, irradiation, or caustic injury.* Stenosis-associated dysphagia usually is progressive; difficulty eating solids typically occurs long before problems with liquids.

### Functional Obstruction

Efficient delivery of food and fluids to the stomach requires a coordinated wave of peristaltic contractions. Esophageal dysmotility interferes with this process and can take several forms, all of which are characterized by discoordinated contraction or spasm of the muscularis. Because it increases esophageal wall stress, spasm also can cause small *diverticula* to form.

Increased *lower esophageal sphincter* (LES) tone can result from impaired smooth muscle relaxation with consequent functional esophageal obstruction. *Achalasia is characterized by the triad of incomplete LES relaxation, increased LES tone, and esophageal aperistalsis.* Primary achalasia is caused by failure of distal esophageal inhibitory neurons and is, by definition, idiopathic. Degenerative changes in neural innervation, either intrinsic to the esophagus or within the extraesophageal vagus nerve or the dorsal motor nucleus of the vagus, also may occur. Secondary achalasia may arise in Chagas disease, in which *Trypanosoma cruzi* infection causes destruction of the myenteric plexus, failure of LES relaxation, and esophageal dilatation. Duodenal, colonic, and ureteric myenteric plexuses also can be affected in Chagas disease. Achalasia-like disease may be caused by diabetic autonomic neuropathy; infiltrative disorders such as malignancy, amyloidosis, or sarcoidosis; and lesions of dorsal motor nuclei, which may be produced by polio or surgical ablation.

### Ectopia

Ectopic tissues (*developmental rests*) are common in the gastrointestinal tract. The most frequent site of *ectopic gastric mucosa* is the upper third of the esophagus, where it is referred to as an *inlet patch.* Although the presence of such tissue generally is asymptomatic, acid released by gastric

mucosa within the esophagus can result in dysphagia, esophagitis, Barrett esophagus, or, rarely, adenocarcinoma. *Gastric heterotopia,* small patches of ectopic gastric mucosa in the small bowel or colon, may manifest with occult blood loss secondary to peptic ulceration of adjacent mucosa.

### Esophageal Varices

Instead of returning directly to the heart, venous blood from the gastrointestinal tract is delivered to the liver via the portal vein before reaching the inferior vena cava. This circulatory pattern is responsible for the *first-pass effect,* in which drugs and other materials absorbed in the intestines are processed by the liver before entering the systemic circulation. Diseases that impede this flow cause portal hypertension, which can lead to the development of esophageal varices, an important cause of esophageal bleeding.

#### PATHOGENESIS

One of the few sites where the splanchnic and systemic venous circulations can communicate is the esophagus. Thus, portal hypertension induces development of collateral channels that allow portal blood to shunt into the caval system. However, these collateral veins enlarge the subepithelial and submucosal venous plexi within the distal esophagus. These vessels, termed **varices,** develop in 90% of cirrhotic patients, most commonly in association with alcoholic liver disease. Worldwide, hepatic schistosomiasis is the second most common cause of varices. A more detailed consideration of portal hypertension is given in Chapter 15.

#### MORPHOLOGY

Varices can be detected by angiography (Fig. 14–7, *A*) and appear as tortuous dilated veins lying primarily within the submucosa of the distal esophagus and proximal stomach. Varices may not be obvious on gross inspection of surgical or postmortem specimens, because they collapse in the absence of blood flow (Fig. 14–7, *B*). The overlying mucosa can be intact (Fig. 14–7, *C*) but is ulcerated and necrotic if rupture has occurred.

#### Clinical Features

Varices often are asymptomatic, but their rupture can lead to massive hematemesis and death. Variceal rupture therefore constitutes a medical emergency. Despite intervention, as many as half of the patients die from the first bleeding episode, either as a direct consequence of hemorrhage or due to hepatic coma triggered by the protein load that results from intraluminal bleeding and hypovolemic shock. Among those who survive, additional episodes of hemorrhage, each potentially fatal, occur in more than 50% of cases. As a result, greater than half of the deaths associated with advanced cirrhosis result from variceal rupture.

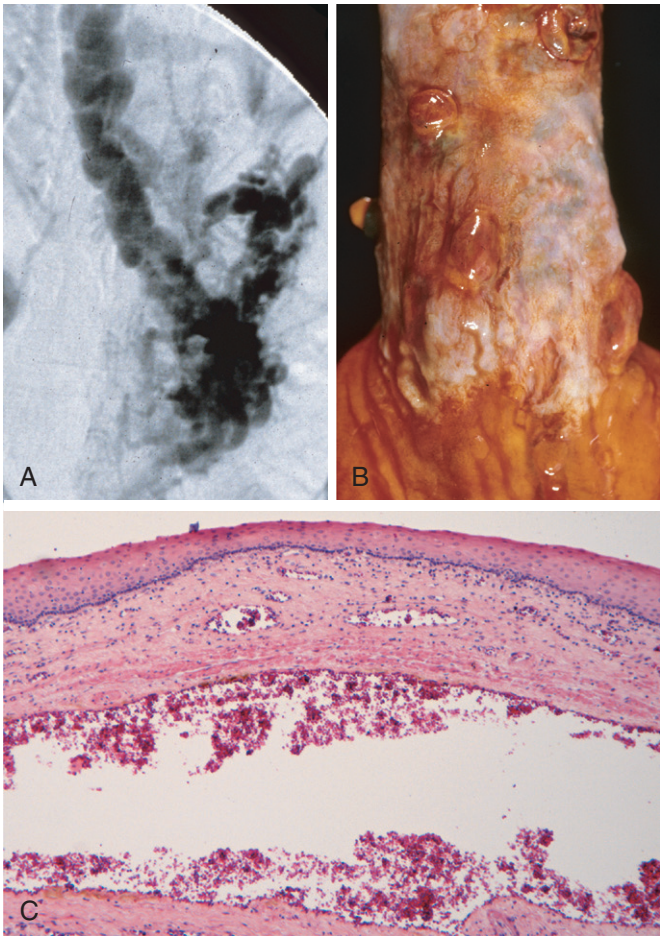

**Figure 14–7** Esophageal varices. **A,** Angiogram showing several tortuous esophageal varices. Although the angiogram is striking, endoscopy is more commonly used to identify varices. **B,** Collapsed varices are present in this postmortem specimen corresponding to the angiogram in **A.** The polypoid areas are sites of variceal hemorrhage that were ligated with bands. **C,** Dilated varices beneath intact squamous mucosa.

## ESOPHAGITIS

### Lacerations

The most common esophageal lacerations are *Mallory-Weiss tears,* which are often associated with severe retching or vomiting, as may occur with acute alcohol intoxication. Normally, a reflex relaxation of the gastroesophageal musculature precedes the antiperistaltic contractile wave associated with vomiting. This relaxation is thought to fail during prolonged vomiting, with the result that refluxing gastric contents overwhelm the gastric inlet and cause the esophageal wall to stretch and tear. Patients often present with hematemesis.

The roughly linear lacerations of *Mallory-Weiss syndrome* are longitudinally oriented, range in length from millimeters to several centimeters, and usually cross the gastroesophageal junction. These tears are superficial and do not generally require surgical intervention; healing tends to be rapid and complete. By contrast, *Boerhaave syndrome,* characterized by transmural esophageal tears and mediastinitis, occurs rarely and is a catastrophic event. The factors

giving rise to this syndrome are similar to those for Mallory-Weiss tears, but more severe.

## Chemical and Infectious Esophagitis

The stratified squamous mucosa of the esophagus may be damaged by a variety of irritants including alcohol, corrosive acids or alkalis, excessively hot fluids, and heavy smoking. Medicinal pills may lodge and dissolve in the esophagus, rather than passing into the stomach intact, resulting in a condition termed *pill-induced esophagitis.* Esophagitis due to chemical injury generally causes only self-limited pain, particularly *odynophagia* (pain with swallowing). Hemorrhage, stricture, or perforation may occur in severe cases. Iatrogenic esophageal injury may be caused by cytotoxic *chemotherapy, radiation therapy,* or *graft-versus-host disease.* The morphologic changes are nonspecific with ulceration and accumulation of neutrophils. Irradiation causes blood vessel thickening adding some element of ischemic injury.

Infectious esophagitis may occur in otherwise healthy persons but is most frequent in those who are debilitated or immunosuppressed. In these patients, esophageal infection by *herpes simplex viruses, cytomegalovirus* (CMV), or *fungal organisms* is common. Among fungi, *Candida* is the most common pathogen, although *mucormycosis* and *aspergillosis* may also occur. The esophagus may also be involved in desquamative skin diseases such as *bullous pemphigoid* and *epidermolysis bullosa* and, rarely, *Crohn disease.*

Infection by fungi or bacteria can be primary or complicate a preexisting ulcer. Nonpathogenic oral bacteria frequently are found in ulcer beds, while pathogenic organisms, which account for about 10% of infectious esophagitis cases, may invade the lamina propria and cause necrosis of overlying mucosa. Candidiasis, in its most advanced form, is characterized by adherent, gray-white pseudomembranes composed of densely matted fungal hyphae and inflammatory cells covering the esophageal mucosa.

The endoscopic appearance often provides a clue to the identity of the infectious agent in viral esophagitis. Herpesviruses typically cause punched-out ulcers (Fig. 14–8, *A*), and histopathologic analysis demonstrates nuclear viral inclusions within a rim of degenerating epithelial cells at the ulcer edge (Fig. 14–8, *B*). By contrast, CMV causes shallower ulcerations and characteristic nuclear and cytoplasmic inclusions within capillary endothelium and stromal cells (Fig. 14–8, *C*). Immunohistochemical staining for viral antigens can be used as an ancillary diagnostic tool.

## Reflux Esophagitis

The stratified squamous epithelium of the esophagus is resistant to abrasion from foods but is sensitive to acid. The submucosal glands of the proximal and distal esophagus contribute to mucosal protection by secreting mucin and bicarbonate. More important, constant LES tone prevents reflux of acidic gastric contents, which are under positive pressure. Reflux of gastric contents into the lower esophagus is the most frequent cause of esophagitis and the most common outpatient gastrointestinal diagnosis in the United States. The associated clinical condition is termed *gastroesophageal reflux disease* (GERD).

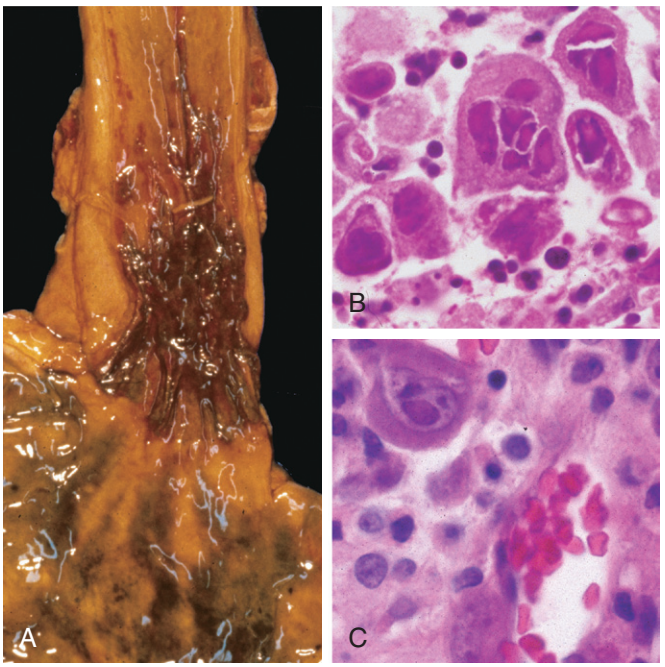

**Figure 14–8** Viral esophagitis. **A,** Postmortem specimen with multiple herpetic ulcers in the distal esophagus. **B,** Multinucleate squamous cells containing herpesvirus nuclear inclusions. **C,** Cytomegalovirus-infected endothelial cells with nuclear and cytoplasmic inclusions.

### PATHOGENESIS

Reflux of gastric juices is central to the development of mucosal injury in GERD. In severe cases, duodenal bile reflux may exacerbate the damage. Conditions that decrease LES tone or increase abdominal pressure contribute to GERD and include alcohol and tobacco use, obesity, central nervous system depressants, pregnancy, hiatal hernia (discussed later), delayed gastric emptying, and increased gastric volume. In many cases, no definitive cause is identified.

### MORPHOLOGY

Simple **hyperemia,** evident to the endoscopist as redness, may be the only alteration. In mild GERD the mucosal histology is often unremarkable. With more significant disease, **eosinophils** are recruited into the squamous mucosa, followed by neutrophils, which usually are associated with more severe injury (Fig. 14–9, *A*). **Basal zone hyperplasia** exceeding 20% of the total epithelial thickness and elongation of lamina propria papillae, such that they extend into the upper third of the epithelium, also may be present.

#### Clinical Features

GERD is most common in adults older than 40 years of age but also occurs in infants and children. The most frequently reported symptoms are heartburn, dysphagia, and, less often, noticeable regurgitation of sour-tasting gastric contents. Rarely, chronic GERD is punctuated by attacks of

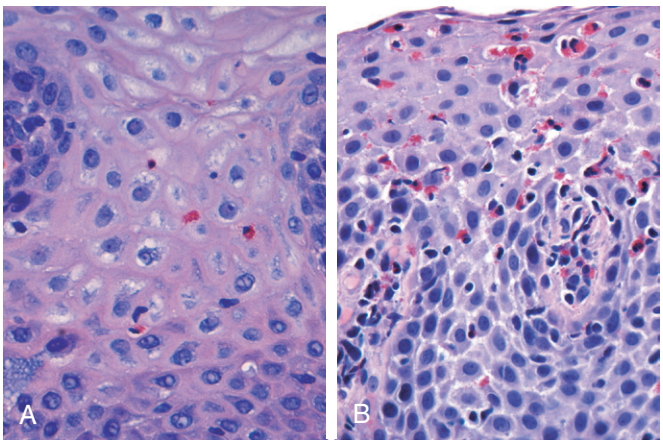

**Figure 14–9** Esophagitis. **A,** Reflux esophagitis with scattered intraepithelial eosinophils. **B,** Eosinophilic esophagitis with numerous intraepithelial eosinophils.

severe chest pain that may be mistaken for heart disease. Treatment with proton pump inhibitors reduces gastric acidity and typically provides symptomatic relief. While the severity of symptoms is not closely related to the degree of histologic damage, the latter tends to increase with disease duration. Complications of reflux esophagitis include esophageal ulceration, hematemesis, melena, stricture development, and Barrett esophagus.

*Hiatal hernia* is characterized by separation of the diaphragmatic crura and protrusion of the stomach into the thorax through the resulting gap. Congenital hiatal hernias are recognized in infants and children, but many are acquired in later life. Hiatal hernia is asymptomatic in more than 90% of adult cases. Thus, symptoms, which are similar to GERD, are often associated with other causes of LES incompetence.

## Eosinophilic Esophagitis

The incidence of eosinophilic esophagitis is increasing markedly. Symptoms include food impaction and dysphagia in adults and feeding intolerance or GERD-like symptoms in children. The cardinal histologic feature is epithelial infiltration by large numbers of eosinophils, particularly superficially (Fig. 14–9, *B*) and at sites far from the gastroesophageal junction. Their abundance can help to differentiate eosinophilic esophagitis from GERD, Crohn disease, and other causes of esophagitis. Certain clinical characteristics, particularly failure of high-dose proton pump inhibitor treatment and the absence of acid reflux, are also typical. A majority of persons with eosinophilic esophagitis are atopic, and many have atopic dermatitis, allergic rhinitis, asthma, or modest peripheral eosinophilia. Treatments include dietary restrictions to prevent exposure to food allergens, such as cow milk and soy products, and topical or systemic corticosteroids.

## Barrett Esophagus

*Barrett esophagus* is a complication of chronic GERD that is characterized by *intestinal metaplasia within the esophageal squamous mucosa*. The incidence of Barrett esophagus is rising; it is estimated to occur in as many as 10% of persons with symptomatic GERD. White males are affected most often and typically present between 40 and 60 years of age. The greatest concern in Barrett esophagus is that *it confers an increased risk of esophageal adenocarcinoma*. Molecular studies suggest that Barrett epithelium may be more similar to adenocarcinoma than to normal esophageal epithelium, consistent with the view that Barrett esophagus is a premalignant condition. In keeping with this, epithelial *dysplasia*, considered to be a preinvasive lesion, develops in 0.2% to 1.0% of persons with Barrett esophagus each year; its incidence increases with duration of symptoms and increasing patient age. Although the vast majority of esophageal adenocarcinomas are associated with Barrett esophagus, it should be noted that most persons with Barrett esophagus do not develop esophageal cancer.

### MORPHOLOGY

Barrett esophagus is recognized endoscopically as tongues or patches of red, velvety mucosa extending upward from the gastroesophageal junction. This metaplastic mucosa alternates with residual smooth, pale squamous (esophageal) mucosa proximally and interfaces with light-brown columnar (gastric) mucosa distally (Fig. 14–10, *A* and *B*). High-resolution endoscopes have increased the sensitivity of Barrett esophagus detection.

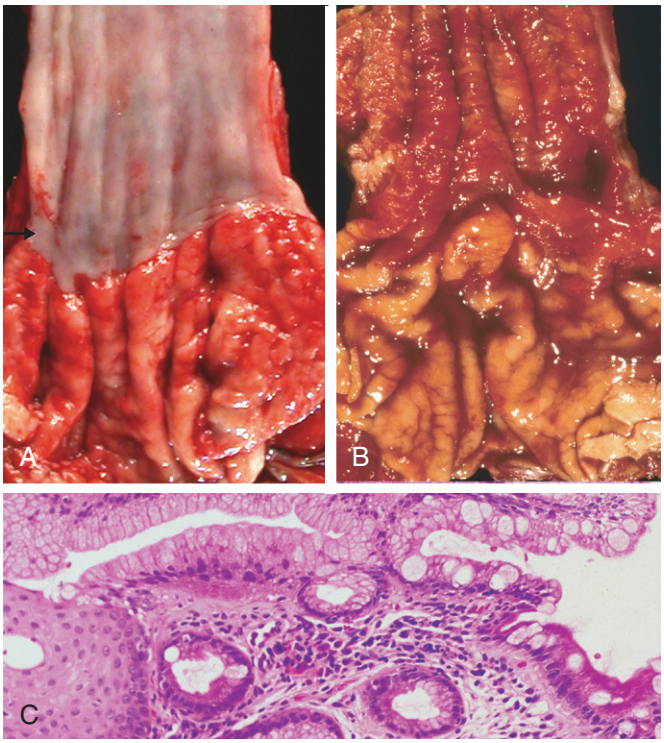

**Figure 14–10** Barrett esophagus. **A,** Normal gastroesophageal junction. **B,** Barrett esophagus. Note the small islands of paler squamous mucosa within the Barrett mucosa. **C,** Histologic appearance of the gastroesophageal junction in Barrett esophagus. Note the transition between esophageal squamous mucosa (*left*) and metaplastic mucosa containing goblet cells (*right*).

Most authors require both endoscopic evidence of abnormal mucosa above the gastroesophageal junction and histologically documented gastric or intestinal metaplasia for diagnosis of Barrett esophagus. **Goblet cells**, which have distinct mucous vacuoles that stain pale blue by H&E and impart the shape of a wine goblet to the remaining cytoplasm, define intestinal metaplasia and are a feature of Barrett esophagus (Fig. 14–10, *C*). Dysplasia is classified as low-grade or high-grade on the basis of morphologic criteria. Intramucosal carcinoma is characterized by invasion of neoplastic epithelial cells into the lamina propria.

### Clinical Features

Diagnosis of Barrett esophagus requires endoscopy and biopsy, usually prompted by GERD symptoms. The best course of management is a matter of debate. While many investigators agree that periodic endoscopy with biopsy, for detection of dysplasia, is reasonable, uncertainties about the frequency with which dysplasia occurs and whether it can regress spontaneously complicate clinical decision making. By contrast, intramucosal carcinoma requires therapeutic intervention. Treatment options include surgical resection (*esophagectomy*), and newer modalities such as photodynamic therapy, laser ablation, and endoscopic mucosectomy. Multifocal high-grade dysplasia, which carries a significant risk of progression to intramucosal or invasive carcinoma, may be treated in a fashion similar to intramucosal carcinoma.

## ESOPHAGEAL TUMORS

Two morphologic variants account for a majority of esophageal cancers: adenocarcinoma and squamous cell carcinoma. Worldwide, squamous cell carcinoma is more common, but in the United States and other Western countries adenocarcinoma is on the rise. Other rare tumors occur but are not discussed here.

### Adenocarcinoma

Esophageal adenocarcinoma typically arises in a background of Barrett esophagus and long-standing GERD. Risk of adenocarcinoma is greater in patients with documented dysplasia and is further increased by tobacco use, obesity, and previous radiation therapy. Conversely, reduced adenocarcinoma risk is associated with diets rich in fresh fruits and vegetables.

Esophageal adenocarcinoma occurs most frequently in whites and shows a strong gender bias, being seven times more common in men than in women. However, the incidence varies by a factor of 60 worldwide, with rates being highest in developed Western countries, including the United States, the United Kingdom, Canada, Australia, and the Netherlands, and lowest in Korea, Thailand, Japan, and Ecuador. In countries where esophageal adenocarcinoma is more common, the incidence has increased markedly since 1970, more rapidly than for almost any other cancer. As a result, esophageal adenocarcinoma, which represented less than 5% of esophageal cancers before 1970, now accounts for half of all esophageal cancers in the United States.

#### PATHOGENESIS

Molecular studies suggest that the progression of Barrett esophagus to adenocarcinoma occurs over an extended period through the stepwise acquisition of genetic and epigenetic changes. This model is supported by the observation that epithelial clones identified in nondysplastic Barrett metaplasia persist and accumulate mutations during progression to dysplasia and invasive carcinoma. Chromosomal abnormalities and *TP53* mutation are often present at early stages of esophageal adenocarcinoma. Additional genetic changes and inflammation also are thought to contribute to neoplastic progression.

#### MORPHOLOGY

Esophageal adenocarcinoma usually occurs in the distal third of the esophagus and may invade the adjacent gastric cardia (Fig. 14–11, *A*). While early lesions may appear as flat or raised patches in otherwise intact mucosa, tumors may form large exophytic masses, infiltrate diffusely, or ulcerate and invade deeply. On microscopic examination, Barrett esophagus frequently is present adjacent to the tumor. Tumors typically produce mucin and form glands (Fig. 14–11, *B*).

### Clinical Features

Although esophageal adenocarcinomas are occasionally discovered during evaluation of GERD or surveillance of Barrett esophagus, they more commonly manifest with

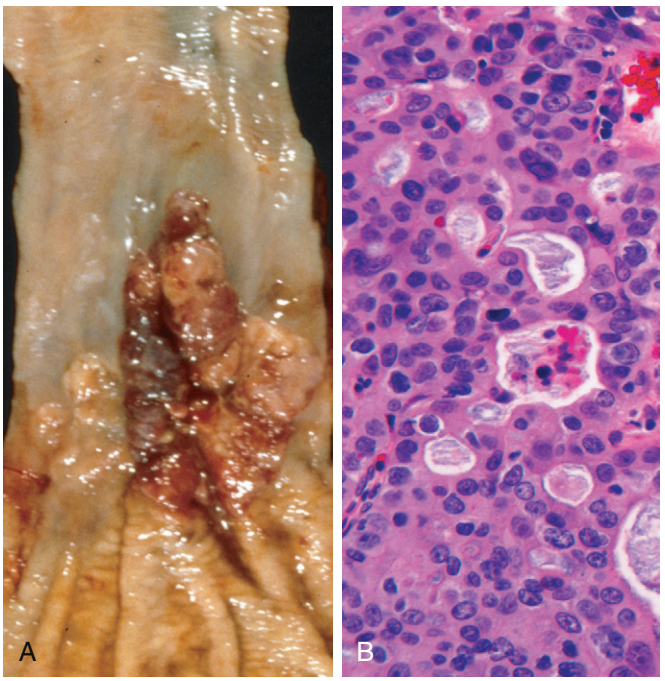

**Figure 14–11** Esophageal adenocarcinoma. **A,** Adenocarcinoma usually occurs distally and, as in this case, often involves the gastric cardia. **B,** Esophageal adenocarcinoma growing as back-to-back glands.

pain or difficulty in swallowing, progressive weight loss, chest pain, or vomiting. By the time symptoms and signs appear, the tumor usually has spread to submucosal lymphatic vessels. As a result of the advanced stage at diagnosis, the overall 5-year survival rate is less than 25%. By contrast, 5-year survival approximates 80% in the few patients with adenocarcinoma limited to the mucosa or submucosa.

## Squamous Cell Carcinoma

In the United States, esophageal squamous cell carcinoma typically occurs in adults older than 45 years of age and affects males four times more frequently than females. Risk factors include alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, Plummer-Vinson syndrome, frequent consumption of very hot beverages, and previous radiation therapy to the mediastinum. It is nearly 6 times more common in African Americans than in whites—a striking risk disparity that cannot be accounted for by differences in rates of alcohol and tobacco use. The incidence of esophageal squamous cell carcinoma can vary by more than 100-fold between and within countries, being more common in rural and underdeveloped areas. The countries with highest incidences are Iran, central China, Hong Kong, Argentina, Brazil, and South Africa.

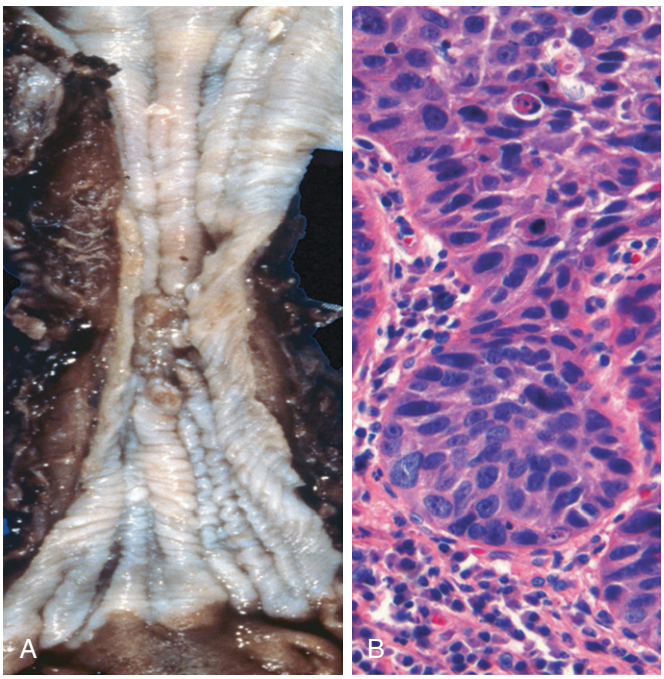

**Figure 14–12** Esophageal squamous cell carcinoma. **A,** Squamous cell carcinoma most frequently is found in the midesophagus, where it commonly causes strictures. **B,** Squamous cell carcinoma composed of nests of malignant cells that partially recapitulate the stratified organization of squamous epithelium.

### PATHOGENESIS

A majority of esophageal squamous cell carcinomas in Europe and the United States are at least partially attributable to the use of alcohol and tobacco, the effects of which synergize to increase risk. However, esophageal squamous cell carcinoma also is common in some regions where alcohol and tobacco use is uncommon. Thus, nutritional deficiencies, as well as polycyclic hydrocarbons, nitrosamines, and other mutagenic compounds, such as those found in fungus-contaminated foods, have been considered as possible risk factors. HPV infection also has been implicated in esophageal squamous cell carcinoma in high-risk but not in low-risk regions. The molecular pathogenesis of esophageal squamous cell carcinoma remains incompletely defined.

### MORPHOLOGY

In contrast to the distal location of most adenocarcinomas, half of squamous cell carcinomas occur in the middle third of the esophagus (Fig. 14–12, *A*). Squamous cell carcinoma begins as an in situ lesion in the form of **squamous dysplasia.** Early lesions appear as small, gray-white plaquelike thickenings. Over months to years they grow into tumor masses that may be polypoid and protrude into and obstruct the lumen. Other tumors are either ulcerated or diffusely infiltrative lesions that spread within the esophageal wall, where they cause thickening, rigidity, and luminal narrowing. These cancers may invade surrounding structures including the respiratory tree, causing pneumonia; the aorta, causing catastrophic exsanguination; or the mediastinum and pericardium.

Most squamous cell carcinomas are moderately to well differentiated (Fig. 14–12, *B*). Less common histologic variants include verrucous squamous cell carcinoma, spindle cell carcinoma, and basaloid squamous cell carcinoma. Regardless of histologic type, symptomatic tumors are generally very large at diagnosis and have already invaded the esophageal wall. The rich submucosal lymphatic network promotes circumferential and longitudinal spread, and intramural tumor nodules may be present several centimeters away from the principal mass. The sites of lymph node metastases vary with tumor location: Cancers in the upper third of the esophagus favor cervical lymph nodes; those in the middle third favor mediastinal, paratracheal, and tracheobronchial nodes; and those in the lower third spread to gastric and celiac nodes.

### Clinical Features

Clinical manifestations of squamous cell carcinoma of the esophagus begin insidiously and include dysphagia, odynophagia (pain on swallowing), and obstruction. As with other forms of esophageal obstruction, patients may unwittingly adjust to the progressively increasing obstruction by altering their diet from solid to liquid foods. Extreme weight loss and debilitation result from both impaired nutrition and effects of the tumor itself. Hemorrhage and sepsis may accompany tumor ulceration. Occasionally, the first symptoms are caused by aspiration of food through a tracheoesophageal fistula.

Increased use of endoscopic screening has led to earlier detection of esophageal squamous cell carcinoma. The

timing is critical, because 5-year survival rates are 75% for patients with superficial esophageal carcinoma but much lower for patients with more advanced tumors. Lymph node metastases, which are common, are associated with poor prognosis. The overall 5-year survival rate remains a dismal 9%.

### SUMMARY

#### Diseases of the Esophagus

- *Esophageal obstruction* may occur as a result of mechanical or functional anomalies. Mechanical causes include developmental defects, fibrotic strictures, and tumors.
- *Achalasia,* characterized by incomplete LES relaxation, increased LES tone, and esophageal aperistalsis, is a common form of *functional esophageal obstruction.*
- *Esophagitis* can result from chemical or infectious mucosal injury. Infections are most frequent in immunocompromised persons.
- The most common cause of esophagitis is *gastroesophageal reflux disease* (GERD), which must be differentiated from *eosinophilic esophagitis.*
- *Barrett esophagus,* which may develop in patients with chronic GERD, is associated with increased risk of esophageal adenocarcinoma.
- *Esophageal squamous cell carcinoma* is associated with alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, tylosis, and Plummer-Vinson syndrome.

## STOMACH

Disorders of the stomach are a frequent cause of clinical disease, with inflammatory and neoplastic lesions being particularly common. In the United States, symptoms related to gastric acid account for nearly one third of all health care spending on gastrointestinal disease. In addition, despite a decreasing incidence in certain locales, including the United States, gastric cancer remains a leading cause of death worldwide.

The stomach is divided into four major anatomic regions: the cardia, fundus, body, and antrum. The cardia is lined mainly by mucin-secreting *foveolar cells* that form shallow glands. The antral glands are similar but also contain endocrine cells, such as *G cells,* that release gastrin to stimulate luminal acid secretion by *parietal cells* within the gastric fundus and body. The well-developed glands of the body and fundus also contain *chief cells* that produce and secrete digestive enzymes such as pepsin.

## INFLAMMATORY DISEASE OF THE STOMACH

### Acute Gastritis

Acute gastritis is a transient mucosal inflammatory process that may be asymptomatic or cause variable degrees of epigastric pain, nausea, and vomiting. In more severe cases there may be mucosal erosion, ulceration, hemorrhage, hematemesis, melena, or, rarely, massive blood loss.

### PATHOGENESIS

The gastric lumen is strongly acidic, with a pH close to one—more than a million times more acidic than the blood. This harsh environment contributes to digestion but also has the potential to damage the mucosa. Multiple mechanisms have evolved to protect the gastric mucosa (Fig. 14–13). Mucin secreted by surface **foveolar cells** forms a thin layer of mucus that prevents large food particles from directly touching the epithelium. The mucus layer also promotes formation of an "unstirred" layer of fluid over the epithelium that protects the mucosa and has a neutral pH as a result of bicarbonate ion secretion by surface epithelial cells. Finally, the rich vascular supply to the gastric mucosa delivers oxygen, bicarbonate, and nutrients while washing away acid that has back-diffused into the lamina propria. Acute or chronic gastritis can occur after disruption of any of these protective mechanisms. For example, reduced mucin synthesis in elderly persons is suggested to be one factor that explains their increased susceptibility to gastritis. Nonsteroidal anti-inflammatory drugs (NSAIDs) may interfere with cytoprotection normally provided by prostaglandins or reduce bicarbonate secretion, both of which increase the susceptibility of the gastric mucosa to injury. Ingestion of harsh chemicals, particularly acids or bases, either accidentally or as a suicide attempt, also results in severe gastric injury, predominantly as a consequence of direct damage to mucosal epithelial and stromal cells. Direct cellular injury also is implicated in gastritis due to excessive alcohol consumption, NSAIDs, radiation therapy, and chemotherapy.

### MORPHOLOGY

On histologic examination, mild acute gastritis may be difficult to recognize, since the lamina propria shows only moderate edema and slight vascular congestion. The **surface epithelium is intact,** although scattered neutrophils may be present. Lamina propria lymphocytes and plasma cells are not prominent. The presence of neutrophils above the basement membrane—specifically, in direct contact with epithelial cells—is abnormal in all parts of the gastrointestinal tract and signifies **active inflammation.** With more severe mucosal damage, *erosion,* or loss of the superficial epithelium, may occur, leading to formation of mucosal neutrophilic infiltrates and purulent exudates. Hemorrhage also may occur, manifesting as dark puncta in an otherwise hyperemic mucosa. Concurrent presence of erosion and hemorrhage is termed **acute erosive hemorrhagic gastritis.**

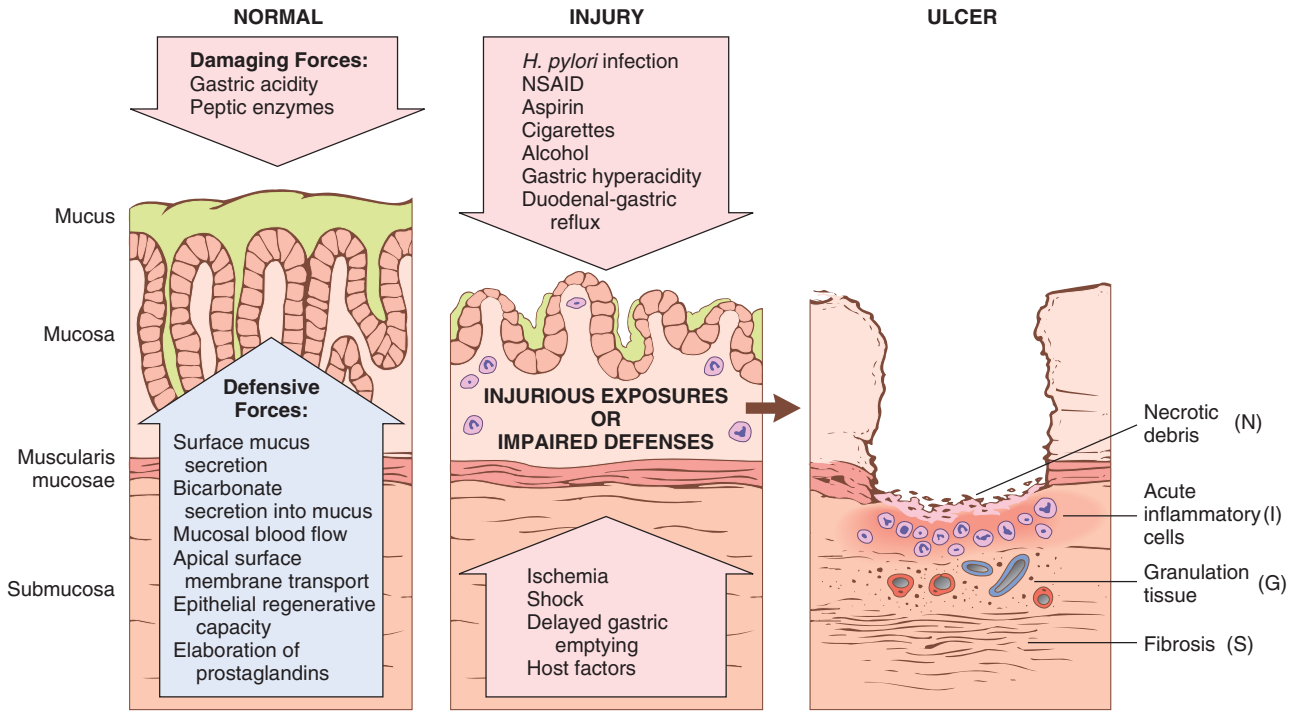

**Figure 14–13** Mechanisms of gastric injury and protection. This diagram illustrates the progression from more mild forms of injury to ulceration that may occur with acute or chronic gastritis. Ulcers include layers of necrotic debris *(N)*, inflammation *(I)*, and granulation tissue *(G)*; a fibrotic scar *(S)*, which develops over time, is present only in chronic lesions.

## Acute Peptic Ulceration

Focal, acute peptic injury is a well-known complication of therapy with NSAIDs as well as severe physiologic stress. Such lesions include

- *Stress ulcers,* most commonly affecting critically ill patients with shock, sepsis, or severe trauma
- *Curling ulcers,* occurring in the proximal duodenum and associated with severe burns or trauma
- *Cushing ulcers,* arising in the stomach, duodenum, or esophagus of persons with intracranial disease, have a high incidence of perforation

### PATHOGENESIS

The pathogenesis of acute ulceration is complex and incompletely understood. NSAID-induced ulcers are caused by direct chemical irritation as well as cyclooxygenase inhibition, which prevents prostaglandin synthesis. This eliminates the protective effects of prostaglandins, which include enhanced bicarbonate secretion and increased vascular perfusion. Lesions associated with intracranial injury are thought to be caused by direct stimulation of vagal nuclei, which causes gastric acid hypersecretion. Systemic acidosis, a frequent finding in critically ill patients, also may contribute to mucosal injury by lowering the intracellular pH of mucosal cells. Hypoxia and reduced blood flow caused by stress-induced splanchnic vasoconstriction also contribute to acute ulcer pathogenesis.

### MORPHOLOGY

Lesions described as acute gastric ulcers range in depth from shallow erosions caused by superficial epithelial damage to deeper lesions that penetrate the mucosa. Acute ulcers are rounded and typically are less than 1 cm in diameter. The ulcer base frequently is stained brown to black by acid-digested extravasated red cells, in some cases associated with transmural inflammation and local serositis. While these lesions may occur singly, more often multiple ulcers are present within the stomach and duodenum. Acute stress ulcers are sharply demarcated, with essentially normal adjacent mucosa, although there may be suffusion of blood into the mucosa and submucosa and some inflammatory reaction. The scarring and thickening of blood vessels that characterize chronic peptic ulcers are absent. Healing with complete reepithelialization occurs days or weeks after the injurious factors are removed.

### Clinical Features

Symptoms of gastric ulcers include nausea, vomiting, and coffee-ground hematemesis. Bleeding from superficial gastric erosions or ulcers that may require transfusion develops in 1% to 4% of these patients. Other complications, including perforation, can also occur. Proton pump inhibitors, or the less frequently used histamine $H_2$ receptor antagonists, may blunt the impact of stress ulceration, but the most important determinant of outcome is the severity of the underlying condition.

## Chronic Gastritis

The symptoms and signs associated with chronic gastritis typically are less severe but more persistent than those of acute gastritis. Nausea and upper abdominal discomfort may occur, sometimes with vomiting, but hematemesis is uncommon. *The most common cause of chronic gastritis is infection with the bacillus* Helicobacter pylori. *Autoimmune gastritis,* the most common cause of *atrophic gastritis,* represents less than 10% of cases of chronic gastritis and is the most common form of chronic gastritis in patients without *H. pylori* infection. Less common causes include radiation injury and chronic bile reflux.

### Helicobacter pylori *Gastritis*

The discovery of the association of *H. pylori* with peptic ulcer disease revolutionized the understanding of chronic gastritis. These spiral-shaped or curved bacilli are present in gastric biopsy specimens from almost all patients with duodenal ulcers and a majority of those with gastric ulcers or chronic gastritis. Acute *H. pylori* infection does not produce sufficient symptoms to require medical attention in most cases; rather the chronic gastritis ultimately causes the afflicted person to seek treatment. *H. pylori* organisms are present in 90% of patients with chronic gastritis affecting the antrum. In addition, the increased acid secretion that occurs in *H. pylori* gastritis may result in peptic ulcer disease of the stomach or duodenum; *H. pylori* infection also confers increased risk of gastric cancer.

#### Epidemiology

In the United States, *H. pylori* infection is associated with poverty, household crowding, limited education, African American or Mexican American ethnicity, residence in areas with poor sanitation, and birth outside of the United States. Colonization rates exceed 70% in some groups and range from less than 10% to more than 80% worldwide. In high-prevalence areas, infection often is acquired in childhood and then persists for decades. Thus, the incidence of *H. pylori* infection correlates most closely with sanitation and hygiene during an individual's childhood.

## PATHOGENESIS

*H. pylori* infection most often manifests as a **predominantly antral gastritis with high acid production, despite hypogastrinemia.** The risk of duodenal ulcer is increased in these patients, and in most cases, gastritis is limited to the antrum.

*H. pylori* organisms have adapted to the ecologic niche provided by gastric mucus. Although *H. pylori* may invade the gastric mucosa, the contribution of invasion to disease pathogenesis is not known. Four features are linked to *H. pylori* virulence:

- **Flagella,** which allow the bacteria to be motile in viscous mucus
- **Urease,** which generates ammonia from endogenous urea, thereby elevating local gastric pH around the organisms and protecting the bacteria from the acidic pH of the stomach
- **Adhesins,** which enhance bacterial adherence to surface foveolar cells
- **Toxins,** such as that encoded by cytotoxin-associated gene A (*CagA*), that may be involved in ulcer or cancer development by poorly defined mechanisms

These factors allow *H. pylori* to create an imbalance between gastroduodenal mucosal defenses and damaging forces that overcome those defenses. Over time, chronic antral *H. pylori* gastritis may progress to **pangastritis,** resulting in **multifocal atrophic gastritis,** reduced acid secretion, intestinal metaplasia, and increased risk of gastric adenocarcinoma in a subset of patients. The underlying mechanisms contributing to this progression are not clear, but interactions between the host immune system and the bacterium seem to be critical.

## MORPHOLOGY

Gastric biopsy specimens generally demonstrate *H. pylori* in infected persons (Fig. 14–14, *A*). The organism is concentrated within the superficial mucus overlying epithelial cells in

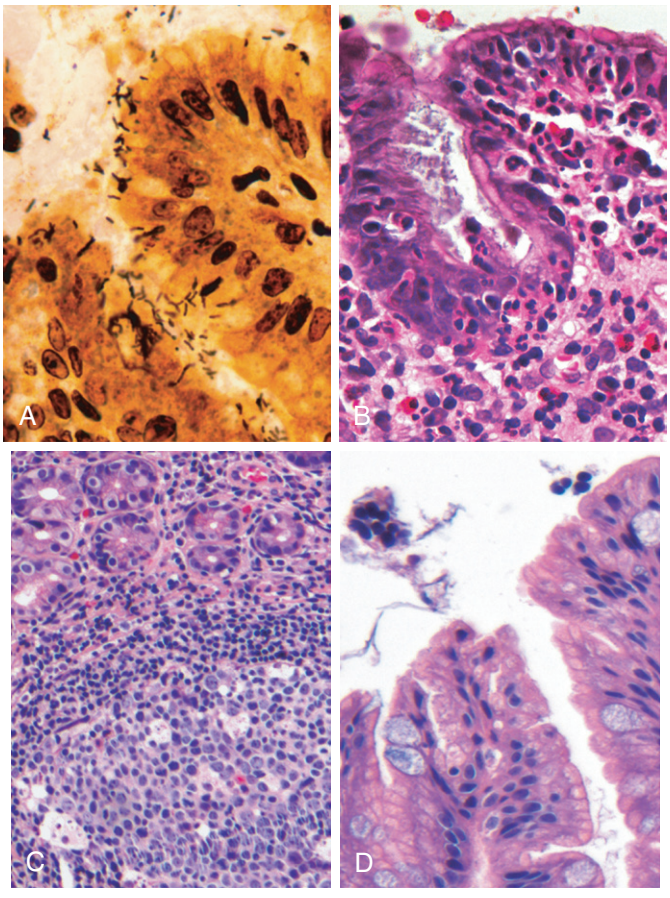

**Figure 14–14** Chronic gastritis. **A,** Spiral-shaped *Helicobacter pylori* bacilli are highlighted in this Warthin-Starry silver stain. Organisms are abundant within surface mucus. **B,** Intraepithelial and lamina propria neutrophils are prominent. **C,** Lymphoid aggregates with germinal centers and abundant subepithelial plasma cells within the superficial lamina propria are characteristic of *H. pylori* gastritis. **D,** Intestinal metaplasia, recognizable as the presence of goblet cells admixed with gastric foveolar epithelium, can develop and is a risk factor for development of gastric adenocarcinoma.

the surface and neck regions. The inflammatory reaction includes a variable number of neutrophils within the lamina propria, including some that cross the basement membrane to assume an intraepithelial location (Fig. 14–14, *B*) and accumulate in the lumen of gastric pits to create pit abscesses. The superficial lamina propria includes large numbers of plasma cells, often in clusters or sheets, as well as increased numbers of lymphocytes and macrophages. When intense, inflammatory infiltrates may create thickened rugal folds, mimicking infiltrative lesions. Lymphoid aggregates, some with germinal centers, frequently are present (Fig. 14–14, *C*) and represent an induced form of **mucosa-associated lymphoid tissue** (MALT) that has the potential to transform into lymphoma. **Intestinal metaplasia,** characterized by the presence of goblet cells and columnar absorptive cells (Fig. 14–14, *D*), also may be present and is associated with increased risk of gastric adenocarcinoma. *H. pylori* shows tropism for gastric foveolar epitheleum and generally is not found in areas of intestinal metaplasia, acid-producing mucosa of the gastric body, or duodenal epithelium. Thus, an antral biopsy is preferred for evaluation of *H. pylori* gastritis.

Clinical Features

In addition to histologic identification of the organism, several diagnostic tests have been developed including a noninvasive serologic test for anti–*H. pylori* antibodies, fecal bacterial detection, and the urea breath test based on the generation of ammonia by bacterial urease. Gastric biopsy specimens also can be analyzed by the rapid urease test, bacterial culture, or polymerase chain reaction (PCR) assay for bacterial DNA. Effective treatments include combinations of antibiotics and proton pump inhibitors. Patients with *H. pylori* gastritis usually improve after treatment, although relapses can follow incomplete eradication or reinfection.

### *Autoimmune Gastritis*

*Autoimmune gastritis* accounts for less than 10% of cases of chronic gastritis. In contrast with that caused by *H. pylori,* autoimmune gastritis typically spares the antrum and induces *hypergastrinemia* (Table 14–2). Autoimmune gastritis is characterized by

- Antibodies to parietal cells and intrinsic factor that can be detected in serum and gastric secretions
- Reduced serum pepsinogen I levels
- Antral endocrine cell hyperplasia
- Vitamin $B_{12}$ deficiency
- Defective gastric acid secretion (*achlorhydria*)

## PATHOGENESIS

Autoimmune gastritis is associated with loss of parietal cells, which secrete acid and intrinsic factor. Deficient acid production stimulates gastrin release, resulting in hypergastrinemia and hyperplasia of antral gastrin-producing G cells. Lack of intrinsic factor disables ileal vitamin $B_{12}$ absorption, leading to $B_{12}$ deficiency and megaloblastic anemia **(pernicious anemia);** reduced serum concentration of pepsinogen I reflects chief cell loss. Although *H. pylori* can cause hypochlorhydria, it is not associated with achlorhydria or pernicious anemia, because the parietal and chief cell damage is not as severe as in autoimmune gastritis.

## MORPHOLOGY

Autoimmune gastritis is characterized by diffuse **damage of the oxyntic** (acid-producing) **mucosa** within the body and fundus. Damage to the antrum and cardia typically is absent or mild. With **diffuse atrophy,** the oxyntic mucosa of the body and fundus appears markedly thinned, and rugal folds are lost. Neutrophils may be present, but the inflammatory infiltrate more commonly is composed of lymphocytes, macrophages, and plasma cells; in contrast with ***H. pylori* gastritis,** the inflammatory reaction most often is deep and centered on the gastric glands. **Parietal and chief cell loss** can be extensive, and **intestinal metaplasia** may develop.

Clinical Features

Antibodies to parietal cells and intrinsic factor are present early in disease, but pernicious anemia develops in only a minority of patients. The median age at diagnosis is 60 years, and there is a slight female predominance. Autoimmune gastritis often is associated with other autoimmune diseases but is not linked to specific human leukocyte antigen (HLA) alleles.

**Table 14–2** Characteristics of *Helicobacter pylori*–Associated and Autoimmune Gastritis

| Feature | Location | |
|---|---|---|
| | *H. pylori*–Associated: Antrum | Autoimmune: Body |
| Inflammatory infiltrate | Neutrophils, subepithelial plasma cells | Lymphocytes, macrophages |
| Acid production | Increased to slightly decreased | Decreased |
| Gastrin | Normal to decreased | Increased |
| Other lesions | Hyperplastic/inflammatory polyps | Neuroendocrine hyperplasia |
| Serology | Antibodies to *H. pylori* | Antibodies to parietal cells ($H^+$,$K^+$-ATPase, intrinsic factor) |
| Sequelae | Peptic ulcer, adenocarcinoma, lymphoma | Atrophy, pernicious anemia, adenocarcinoma, carcinoid tumor |
| Associations | Low socioeconomic status, poverty, residence in rural areas | Autoimmune disease; thyroiditis, diabetes mellitus, Graves disease |

## Peptic Ulcer Disease

*Peptic ulcer disease* (PUD) most often is associated with *H. pylori* infection or NSAID use. In the US, the latter is becoming the most common cause of gastric ulcers as *H. pylori* infection rates fall and low-dose aspirin use in the aging population increases. PUD may occur in any portion of the gastrointestinal tract exposed to acidic gastric juices but is most common in the gastric antrum and first portion of the duodenum. PUD also may occur in the esophagus as a result of GERD or acid secretion by ectopic gastric mucosa, and in the small intestine secondary to gastric heteropia within a Meckel diverticulum.

### Epidemiology

PUD is common and is a frequent cause of physician visits worldwide. It leads to treatment of over 3 million people, 190,000 hospitalizations, and 5000 deaths in the United States each year. The lifetime risk of developing an ulcer is approximately 10% for males and 4% for females.

### PATHOGENESIS

*H. pylori* infection and NSAID use are the primary underlying causes of PUD. **The imbalances of mucosal defenses and damaging forces that cause chronic gastritis (Fig. 14–13) are also responsible for PUD.** Thus, PUD generally develops on a background of chronic gastritis. Although more than 70% of PUD cases are associated with *H. pylori* infection, only 5% to 10% of *H. pylori*–infected persons develop ulcers. It is probable that host factors as well as variation among *H. pylori* strains determine the clinical outcomes.

Gastric hyperacidity is fundamental to the pathogenesis of PUD. The acidity that drives PUD may be caused by *H. pylori* infection, parietal cell hyperplasia, excessive secretory responses, or impaired inhibition of stimulatory mechanisms such as gastrin release. For example, **Zollinger-Ellison syndrome,** characterized by multiple peptic ulcerations in the stomach, duodenum, and even jejunum, is caused by uncontrolled release of gastrin by a tumor and the resulting massive acid production. Cofactors in peptic ulcerogenesis include chronic NSAID use, as noted; cigarette smoking, which impairs mucosal blood flow and healing; and high-dose corticosteroids, which suppress prostaglandin synthesis and impair healing. Peptic ulcers are more frequent in persons with alcoholic cirrhosis, chronic obstructive pulmonary disease, chronic renal failure, and hyperparathyroidism. In the latter two conditions, hypercalcemia stimulates gastrin production and therefore increases acid secretion. Finally, psychologic stress may increase gastric acid production and exacerbate PUD.

### MORPHOLOGY

Peptic ulcers are four times more common in the proximal duodenum than in the stomach. Duodenal ulcers usually occur within a few centimeters of the pyloric valve and involve the anterior duodenal wall. Gastric peptic ulcers are predominantly located near the interface of the body and antrum.

Peptic ulcers are solitary in more than 80% of patients. Lesions less than 0.3 cm in diameter tend to be shallow, whereas those over 0.6 cm are likely to be deeper. The classic peptic ulcer is a round to oval, **sharply punched-out defect** (Fig. 14–15, *A*). The base of peptic ulcers is smooth and clean as a result of peptic digestion of exudate and on histologic examination is composed of richly vascular granulation tissue (Fig. 14–15, *B*). Ongoing bleeding within the ulcer base may cause life-threatening hemorrhage. **Perforation** is a complication that demands emergent surgical intervention.

### Clinical Features

Peptic ulcers are chronic, recurring lesions that occur most often in middle-aged to older adults without obvious precipitating conditions, other than chronic gastritis. A majority of peptic ulcers come to clinical attention after patient complaints of *epigastric burning or aching pain,* although a significant fraction manifest with complications such as *iron deficiency anemia, frank hemorrhage,* or *perforation.* The pain tends to occur 1 to 3 hours after meals during the day, is worse at night, and is relieved by alkali or food. Nausea,

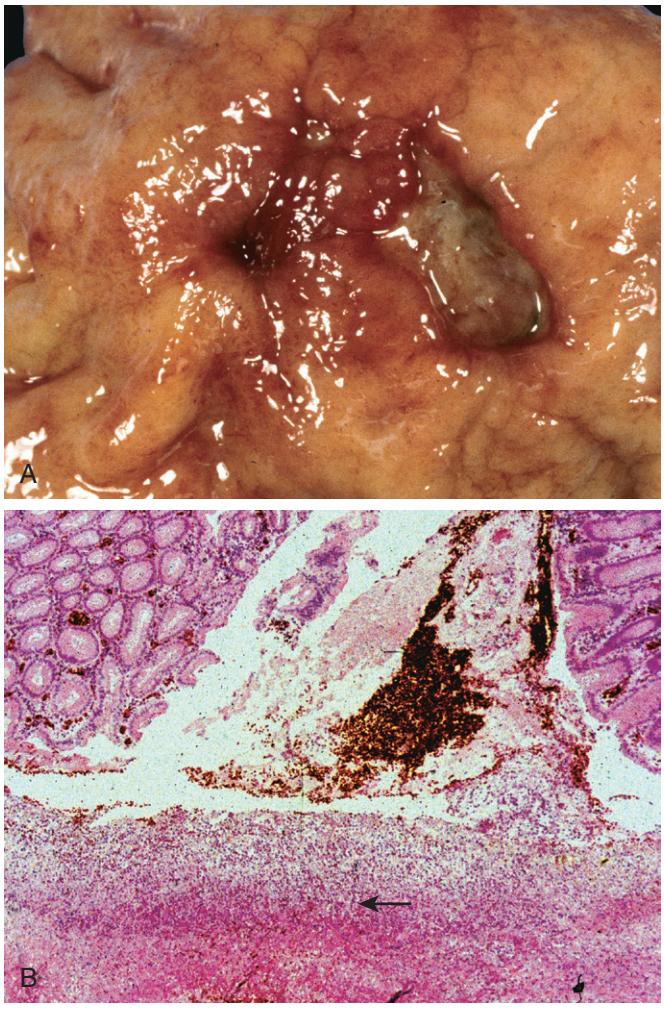

**Figure 14–15** Acute gastric perforation in a patient presenting with free air under the diaphragm. **A,** Mucosal defect with clean edges. **B,** The necrotic ulcer base *(arrow)* is composed of granulation tissue.

vomiting, bloating, and belching may be present. Healing may occur with or without therapy, but the tendency to develop ulcers later remains.

A variety of surgical approaches formerly were used to treat PUD, but current therapies are aimed at *H. pylori* eradication with antibiotics and neutralization of gastric acid, usually through use of proton pump inhibitors. These efforts have markedly reduced the need for surgical management, which is reserved primarily for treatment of bleeding or perforated ulcers. PUD causes much more morbidity than mortality.

## SUMMARY

### Acute and Chronic Gastritis

- The spectrum of *acute gastritis* ranges from asymptomatic disease to mild epigastric pain, nausea, and vomiting. Causative factors include any agent or disease that interferes with gastric mucosal protection. Acute gastritis can progress to *acute gastric ulceration.*
- The most common cause of chronic gastritis is *H. pylori infection*; most remaining cases are caused by *autoimmune gastritis*.
- *H. pylori* gastritis typically affects the antrum and is associated with increased gastric acid production. The induced mucosa-associated lymphoid tissue (MALT) can transform into lymphoma.
- *Autoimmune gastritis* causes atrophy of the gastric body oxyntic glands, which results in decreased gastric acid production, antral G cell hyperplasia, achlorhydria, and vitamin $B_{12}$ deficiency. Anti-parietal cell and anti–intrinsic factor antibodies typically are present.
- *Intestinal metaplasia* develops in both forms of chronic gastritis and is a risk factor for development of gastric adenocarcinoma.
- Peptic ulcer disease can be caused by *H. pylori* chronic gastritis and the resultant hyperchlorhydria or NSAID use. Ulcers can develop in the stomach or duodenum and usually heal after suppression of gastric acid production and, if present, eradication of the *H. pylori.*

# NEOPLASTIC DISEASE OF THE STOMACH

## Gastric Polyps

*Polyps,* nodules or masses that project above the level of the surrounding mucosa, are identified in up to 5% of upper gastrointestinal tract endoscopies. Polyps may develop as a result of epithelial or stromal cell hyperplasia, inflammation, ectopia, or neoplasia. Although many different types of polyps can occur in the stomach, only hyperplastic and inflammatory polyps, fundic gland polyps, and adenomas are considered here.

### *Inflammatory and Hyperplastic Polyps*

Approximately 75% of all gastric polyps are *inflammatory* or *hyperplastic polyps.* They most commonly affect persons between 50 and 60 years of age, usually arising in a background of chronic gastritis that initiates the injury and reactive hyperplasia that cause polyp growth. If associated with *H. pylori* gastritis, polyps may regress after bacterial eradication.

#### MORPHOLOGY

In the stomach, inflammatory and hyperplastic polyps are essentially the same entity, with the distinction based solely on the degree of inflammation. The polyps frequently are multiple and characteristically are ovoid in shape, less than 1 cm in diameter, and covered by a smooth surface. On microscopic examination, polyps have irregular, cystically dilated, and elongated foveolar glands. The lamina propria typically is edematous with variable degrees of acute and chronic inflammation, and surface erosions may be present.

The frequency with which **dysplasia,** a precancerous in situ lesion, develops in inflammatory or hyperplastic polyps correlates with size; there is a significant increase in risk in polyps larger than 1.5 cm.

### *Fundic Gland Polyps*

*Fundic gland polyps* occur sporadically and in persons with familial adenomatous polyposis (FAP) but do not have neoplastic potential. They are, however, worth mentioning here because their incidence has increased markedly as a result of the use of proton pump inhibitors. This likely results from increased gastrin secretion, in response to reduced acidity, and glandular hyperplasia driven by gastrin. Fundic gland polyps may be asymptomatic or associated with nausea, vomiting, or epigastric pain. These well-circumscribed polyps occur in the gastric body and fundus, often are multiple, and are composed of cystically dilated, irregular glands lined by flattened parietal and chief cells.

### *Gastric Adenoma*

Gastric adenomas represent as many as 10% of all gastric polyps. Their incidence increases with age and varies among different populations in parallel with that of gastric adenocarcinoma. Patients usually are between 50 and 60 years of age, and males are affected three times more often than females. Similar to other forms of gastric dysplasia, adenomas almost always occur on a background of chronic gastritis with atrophy and intestinal metaplasia. The risk for development of adenocarcinoma in gastric adenomas is related to the size of the lesion and is particularly elevated with lesions greater than 2 cm in diameter. Overall, carcinoma may be present in up to 30% of gastric adenomas.

#### MORPHOLOGY

Gastric adenomas are most commonly located in the antrum and typically are composed of intestinal-type columnar epithelium. By definition, all gastrointestinal adenomas exhibit epithelial dysplasia, which can be classified as low- or high-grade. Both grades may include enlargement, elongation, and hyperchromasia of epithelial cell nuclei, epithelial crowding, and pseudostratification. High-grade dysplasia is characterized by more severe cytologic atypia and irregular architecture, including glandular budding and gland-within-gland, or cribriform, structures.

## Gastric Adenocarcinoma

Adenocarcinoma is the most common malignancy of the stomach, comprising more than 90% of all gastric cancers. Early symptoms resemble those of chronic gastritis, including dyspepsia, dysphagia, and nausea. As a result, in low-incidence regions such as the United States, the cancer is often at advanced stages when clinical manifestations such as weight loss, anorexia, altered bowel habits, anemia, and hemorrhage trigger diagnostic evaluation.

### Epidemiology

Gastric cancer rates vary markedly with geography. The incidence is up to 20 times higher in Japan, Chile, Costa Rica, and Eastern Europe than in North America, northern Europe, Africa, and Southeast Asia. Mass endoscopic screening programs can be successful in regions of high incidence, such as Japan, where 35% of newly detected cases are *early gastric cancer,* or tumors limited to the mucosa and submucosa. Unfortunately, mass screening programs are not cost-effective in regions in which the incidence is low, and less than 20% of cases are detected at an early stage in North America and northern Europe.

Gastric cancer is more common in lower socioeconomic groups and in persons with *multifocal mucosal atrophy and intestinal metaplasia.* PUD does not impart an increased risk of gastric cancer, but patients who have had *partial gastrectomies* for PUD have a slightly higher risk of developing cancer in the residual gastric stump as a result of hypochlorhydria, bile reflux, and chronic gastritis.

In the United States, *gastric cancer rates dropped by more than 85% during the 20th century.* Similar declines have been reported in many other Western countries, reflecting the importance of environmental and dietary factors. Despite this decrease in overall gastric adenocarcinoma incidence, *cancer of the gastric cardia is on the rise.* This trend probably is related to increased rates of Barrett esophagus and may reflect the growing prevalence of chronic GERD and obesity.

### PATHOGENESIS

Gastric cancers are genetically heterogeneous but certain molecular alterations are common. We will consider these first to be followed by the role of *H. pylori*–induced chronic inflammation and the association of a subset of gastric cancers with EBV infection.

- **Mutations:** While the majority of gastric cancers are not hereditary, mutations identified in familial gastric cancer have provided important insights into mechanisms of carcinogenesis in sporadic cases. Germline mutations in *CDH1*, which encodes E-cadherin, a protein that contributes to epithelial intercellular adhesion, are associated with familial gastric cancers, usually of the diffuse type. Mutations in *CDH1* are present in about 50% of diffuse gastric tumors, while E-cadherin expression is drastically decreased in the rest, often by methylation of the *CDH1* promoter. **Thus, the loss of E-cadherin function seems to be a key step in the development of diffuse gastric cancer.**

  In contrast to *CDH1*, patients with familial adenomatous polyposis (FAP) who have germline mutations in **adenomatous polyposis coli (*APC*) genes** have an increased risk of intestinal-type gastric cancer. Sporadic intestinal-type gastric cancer is associated with several genetic abnormalities including acquired mutations of β-catenin, a protein that binds to both E-cadherin and APC protein; microsatellite instability; and hypermethylation of genes including *TGFβRII, BAX, IGFRII,* and *p16/INK4a*. *TP53* mutations are present in a majority of sporadic gastric cancers of both histologic types.
- ***H. pylori:*** Chronic gastritis, most commonly due to *H. pylori* infection, promotes the development and progression of cancers that may be induced by diverse genetic alterations (Chapter 5). As is the case with many forms of chronic inflammation, *H. pylori*–induced chronic gastritis is associated with increased production of proinflammatory proteins, such as interleukin-1β (IL-1β) and tumor necrosis factor (TNF). It is therefore not surprising that polymorphisms associated with enhanced production of these cytokines confer increased risk of chronic gastritis-associated intestinal-type gastric cancer in those with coexisting *H. pylori* infection.
- **EBV:** While *H. pylori* is most commonly associated with gastric cancer, approximately 10% of gastric adenocarcinomas are associated with Epstein-Barr virus (EBV) infection. Although the precise role of EBV in the development of gastric adenocarcinomas remains to be defined, it is notable that EBV episomes in these tumors frequently are clonal, suggesting that infection preceded neoplastic transformation. Further, *TP53* mutations are uncommon in the EBV-positive gastric tumors, suggesting that the molecular pathogenesis of these cancers is distinct from that of other gastric adenocarcinomas. Morphologically, EBV-positive tumors tend to occur in the proximal stomach and most commonly have a diffuse morphology with a marked lymphocytic infiltrate.

### MORPHOLOGY

Gastric adenocarcinomas are classified according to their location in the stomach as well as gross and histologic morphology. The **Lauren classification** that separates gastric cancers into **intestinal** and **diffuse** types correlates with distinct patterns of molecular alterations, as discussed above. Intestinal-type cancers tend to be bulky (Fig. 14–16, *A*) and are composed of glandular structures similar to esophageal and colonic adenocarcinoma. Intestinal-type adenocarcinomas typically grow along broad cohesive fronts to form either an exophytic mass or an ulcerated tumor. The neoplastic cells often contain apical mucin vacuoles, and abundant mucin may be present in gland lumina.

Diffuse gastric cancers display an infiltrative growth pattern (Fig. 14–16, *B*) and are composed of discohesive cells with large mucin vacuoles that expand the cytoplasm and push the nucleus to the periphery, creating a **signet ring cell** morphology (Fig. 14–16, *C*). These cells permeate the mucosa and stomach wall individually or in small clusters. A mass may be difficult to appreciate in diffuse gastric cancer, but these infiltrative tumors often evoke a **desmoplastic** reaction that stiffens the gastric wall and may cause diffuse rugal flattening and a rigid, thickened wall that imparts a "leather bottle" appearance termed **linitis plastica.**

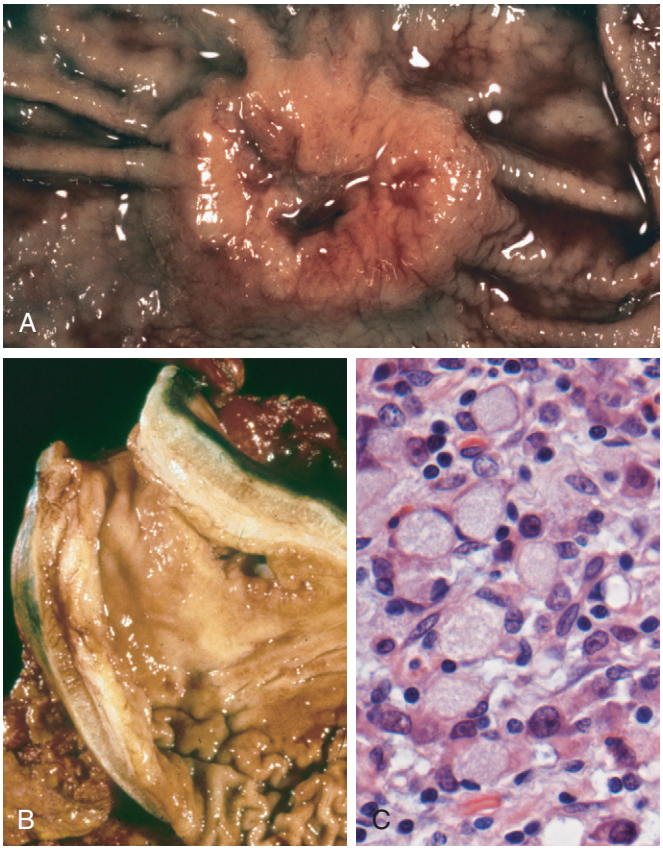

**Figure 14–16** Gastric adenocarcinoma. **A,** Intestinal-type adenocarcinoma consisting of an elevated mass with heaped-up borders and central ulceration. Compare with the peptic ulcer in Figure 14-15, A. **B,** Linitis plastica. The gastric wall is markedly thickened, and rugal folds are partially lost. **C,** Signet ring cells with large cytoplasmic mucin vacuoles and peripherally displaced, crescent-shaped nuclei.

### Clinical Features

Intestinal-type gastric cancer predominates in high-risk areas and develops from precursor lesions including flat dysplasia and adenomas. The mean age at presentation is 55 years, and the male-to-female ratio is 2:1. By contrast, the incidence of diffuse gastric cancer is relatively uniform across countries, there are no identified precursor lesions, and the disease occurs at similar frequencies in males and females. Of note, *the remarkable decrease in gastric cancer incidence applies only to the intestinal type,* which is most closely associated with atrophic gastritis and intestinal metaplasia. As a result, the incidences of intestinal and diffuse types of gastric cancers are now similar in some regions.

*The depth of invasion and the extent of nodal and distant metastasis at the time of diagnosis remain the most powerful prognostic indicators for gastric cancer.* Local invasion into the duodenum, pancreas, and retroperitoneum also is characteristic. When possible, surgical resection remains the preferred treatment for gastric adenocarcinoma. After surgical resection, the 5-year survival rate for early gastric cancer can exceed 90%, even if lymph node metastases are present. By contrast, the 5-year survival rate for advanced gastric cancer remains below 20%, in large part because current chemotherapy regimens are minimally effective. Because of the advanced stage at which most gastric cancers are discovered in the United States, the overall 5-year survival is less than 30%.

## Lymphoma

Although extranodal lymphomas can arise in virtually any tissue, they do so most commonly in the gastrointestinal tract, particularly the stomach. In allogeneic hematopoietic stem cell and organ transplant recipients, the bowel also is the most frequent site for Epstein-Barr virus–positive B cell lymphoproliferations. Nearly 5% of all gastric malignancies are primary lymphomas, the most common of which are indolent extranodal marginal zone B cell lymphomas. In the gut, these tumors often are referred to as lymphomas of *mucosa-associated lymphoid tissue* (MALT), or *MALTomas.* This entity and the second most common primary lymphoma of the gut, diffuse large B cell lymphoma, are discussed in Chapter 11.

## Carcinoid Tumor

Carcinoid tumors arise from neuroendocrine organs (e.g., the endocrine pancreas) and neuroendocrine-differentiated gastrointestinal epithelia (e.g., G-cells). A majority are found in the gastrointestinal tract, and more than 40% occur in the small intestine. The tracheobronchial tree and lungs are the next most commonly involved sites. Gastric carcinoids may be associated with endocrine cell hyperplasia, chronic atrophic gastritis, and Zollinger-Ellison syndrome. These tumors were called "carcinoid" because they are slower growing than carcinomas. The most current WHO classification describes these as low- or intermediate grade neuroendocrine tumors. The grade is based on mitotic activity and the fraction of cells immunohistochemcially positive for Ki67, a mitotic marker. However, it is important to recognize that site within the GI tract and extent of local invasion are also important prognostic indicators (see later). High-grade neuroendocrine tumors, termed *neuroendocrine carcinoma*, frequently display necrosis and, in the GI tract, are most common in the jejunum.

### MORPHOLOGY

Carcinoid tumors are intramural or submucosal masses that create small polypoid lesions (Fig. 14–17, *A*). The tumors are yellow or tan in appearance and elicit an intense desmoplastic reaction that may cause kinking of the bowel and obstruction. On histologic examination, carcinoid tumors are composed of islands, trabeculae, strands, glands, or sheets of uniform cells with scant, pink granular cytoplasm and a round to oval stippled nucleus (Fig. 14–17, *B*).

### Clinical Features

The peak incidence of carcinoid tumors is in the sixth decade, but they may appear at any age. Symptoms are determined by the hormones produced. For example, the *carcinoid syndrome* is caused by vasoactive substances secreted by the tumor that cause cutaneous flushing, sweating, bronchospasm, colicky abdominal pain, diarrhea, and right-sided cardiac valvular fibrosis. When tumors are

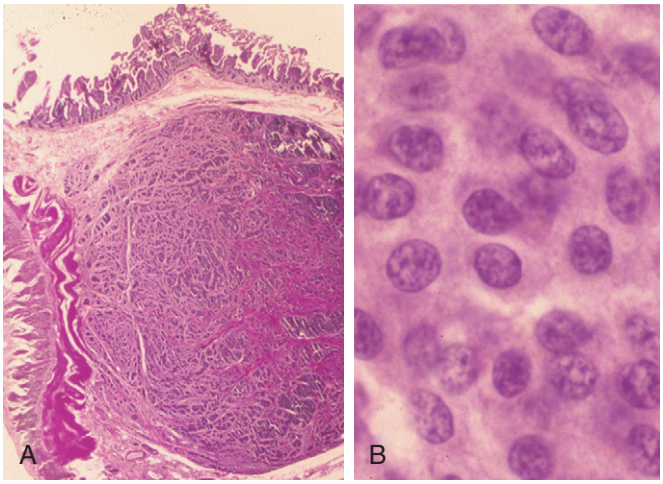

**Figure 14–17** Gastrointestinal carcinoid tumor (neuroendocrine tumor). **A,** Carcinoid tumors often form a submucosal nodule composed of tumor cells embedded in dense fibrous tissue. **B,** High magnification shows the bland cytology that typifies carcinoid tumors. The chromatin texture, with fine and coarse clumps, frequently assumes a "salt and pepper" pattern. Despite their innocuous appearance, carcinoids can be aggressive.

confined to the intestine, the vasoactive substances released are metabolized to inactive forms by the liver—a "first-pass" effect similar to that seen with oral drugs. Thus, carcinoid syndrome occurs in less than 10% of patients and is *strongly associated with metastatic disease.*

*The most important prognostic factor for gastrointestinal carcinoid tumors is location:*

- *Foregut carcinoid tumors,* those found within the stomach, duodenum proximal to the ligament of Treitz, and esophagus, rarely metastasize and generally are cured by resection. Although rare, duodenal gastrin-producing carcinoid tumors, *gastrinomas,* have been associated with proton pump inhibitor therapy.
- *Midgut carcinoid tumors* that arise in the jejunum and ileum often are multiple and tend to be aggressive. In these tumors, greater depth of local invasion, increased size, and presence of necrosis and mitosis are associated with poor outcome.
- *Hindgut carcinoids* arising in the appendix and colorectum typically are discovered incidentally. Those in the appendix occur at any age and are almost uniformly benign. Rectal carcinoid tumors tend to produce polypeptide hormones and may manifest with abdominal pain and weight loss; they only occasionally metastasize.

## Gastrointestinal Stromal Tumor

A wide variety of mesenchymal neoplasms may arise in the stomach. Many are named according to the cell type they most resemble; for example, smooth muscle tumors are called *leiomyomas* or *leiomyosarcomas,* nerve sheath tumors are termed *schwannomas,* and those resembling glomus bodies in the nail beds and at other sites are termed *glomus tumors.* These tumors are all rare and are not discussed here. *Gastrointestinal stromal tumor (GIST)* is the most common mesenchymal tumor of the abdomen, and more than half of these tumors occur in the stomach.

### Epidemiology

Overall, GISTs are slightly more common in males. The peak incidence of gastric GIST is around 60 years of age, with less than 10% occurring in persons younger than 40 years of age.

### PATHOGENESIS

Approximately **75% to 80% of all GISTs have oncogenic, gain-of-function mutations of the gene encoding the tyrosine kinase c-KIT,** which is the receptor for stem cell factor. Another 8% of GISTs have mutations that activate a related tyrosine kinase, platelet-derived growth factor receptor A (PDGFRA); thus activating mutations in tyrosine kinases are found in virtually all GISTs. However, either mutation is sufficient for tumorigenesis, and *c-KIT* and *PDGFRA* mutations are almost never found in a single tumor. GISTs appear to arise from, or share a common stem cell with, the interstitial cells of Cajal, which express c-KIT, are located in the muscularis propria, and serve as pacemaker cells for gut peristalsis.

### MORPHOLOGY

Primary gastric GISTs usually form a solitary, well-circumscribed, fleshy, submucosal mass. Metastases may form multiple small serosal nodules or fewer large nodules in the liver; spread outside of the abdomen is uncommon. GISTs can be composed of thin, elongated **spindle cells** or plumper **epithelioid cells.** The most useful diagnostic marker is c-KIT, consistent with the relationship between GISTs and interstitial cells of Cajal, which is immunohistochemically detectable in 95% of these tumors.

### Clinical Features

Symptoms of GISTs at presentation may be related to mass effects or mucosal ulceration. Complete surgical resection is the primary treatment for localized gastric GIST. The prognosis correlates with tumor size, mitotic index, and location, *with gastric GISTs being somewhat less aggressive than those arising in the small intestine.* Recurrence or metastasis is rare for gastric GISTs less than 5 cm across but common for mitotically active tumors larger than 10 cm. Patients with unresectable, recurrent, or metastatic disease often respond to *imatinib,* an inhibitor of the tyrosine kinase activity of c-KIT and PDGFRA that is also effective in suppressing BCR-ABL kinase activity in chronic myelogenous leukemia (Chapter 11). Unfortunately, GISTs eventually become resistant to imatinib, and other kinase inhibitors are now being evaluated in imatinib-resistant disease.

### SUMMARY

#### Gastric Polyps and Tumors

- *Inflammatory and hyperplastic gastric polyps* are reactive lesions associated with chronic gastritis. Risk of dysplasia increases with polyp size.

- *Gastric adenomas* develop in a background of chronic gastritis and are particularly associated with intestinal metaplasia and mucosal (glandular) atrophy. Adenocarcinoma frequently arises in gastric adenomas, which therefore require complete excision and surveillance to detect recurrence.
- Gastric adenocarcinoma incidence varies markedly with geography and also is more common in lower socioeconomic groups.
- Gastric adenocarcinomas are classified according to location and gross and histologic morphology. Those with an *intestinal* histologic pattern tend to form bulky tumors and may be ulcerated, whereas those composed of *signet ring cells* typically display a diffuse infiltrative growth pattern that may thicken the gastric wall (*linitis plastica*) without forming a discrete mass.
- *H. pylori* infection is the most common etiologic agent for gastric adenocarcinoma, but other associations, including chronic atrophic gastritis and EBV infection, suggest several pathways of neoplastic transformation are operative.
- *Primary gastric lymphomas* most often are derived from the mucosa-associated lymphoid tissue whose development is induced by chronic gastritis.
- *Carcinoid tumors* arise from the diffuse components of the endocrine system, and are most common in the gastrointestinal tract, particularly the small intestine. The single most important prognostic factor is location: Tumors of the small intestine tend to be most aggressive, while those of the appendix are almost always benign.
- *Gastrointestinal stromal tumor* (GIST) is the most common mesenchymal tumor of the abdomen, occurs most often in the stomach; it arises from benign pacemaker cells, also known as the interstitial cells of Cajal. A majority of tumors have activating mutations in either the c-KIT or the PDGFRA tyrosine kinases and respond to kinase inhibitors.

# SMALL AND LARGE INTESTINES

The small intestine and colon account for most of the length of the gastrointestinal tract and are the sites of a wide variety of diseases, many of which affect nutrient and water transport. Perturbation of these processes can cause malabsorption and diarrhea. The intestines are also the principal site where the immune system interfaces with a diverse array of antigens present in food and gut microbes. Indeed, intestinal bacteria outnumber eukaryotic cells in the human body by ten-fold. Thus, it is not surprising that the small intestine and colon frequently are involved by infectious and inflammatory processes. Finally, the colon is the most common site of gastrointestinal neoplasia in Western populations.

## INTESTINAL OBSTRUCTION

Obstruction of the gastrointestinal tract may occur at any level, but the small intestine is most often involved because of its relatively narrow lumen. Collectively, *hernias, intestinal adhesions, intussusception,* and *volvulus* account for 80% of mechanical obstructions (Fig. 14–18), while tumors and infarction account for most of the remainder. The clinical manifestations of intestinal obstruction include abdominal pain and distention, vomiting, and constipation. Surgical intervention usually is required in cases involving mechanical obstruction or severe infarction.

### Hirschsprung Disease

*Hirschsprung disease* occurs in approximately 1 of 5000 live births and stems from a congenital defect in colonic innervation. It may be isolated or occur in combination with other developmental abnormalities. It is more common in males but tends to be more severe in females. Siblings of patients have an increased risk of Hirschsprung disease.

Patients typically present as neonates with failure to pass meconium in the immediate postnatal period followed by obstructive constipation. The major threats to life

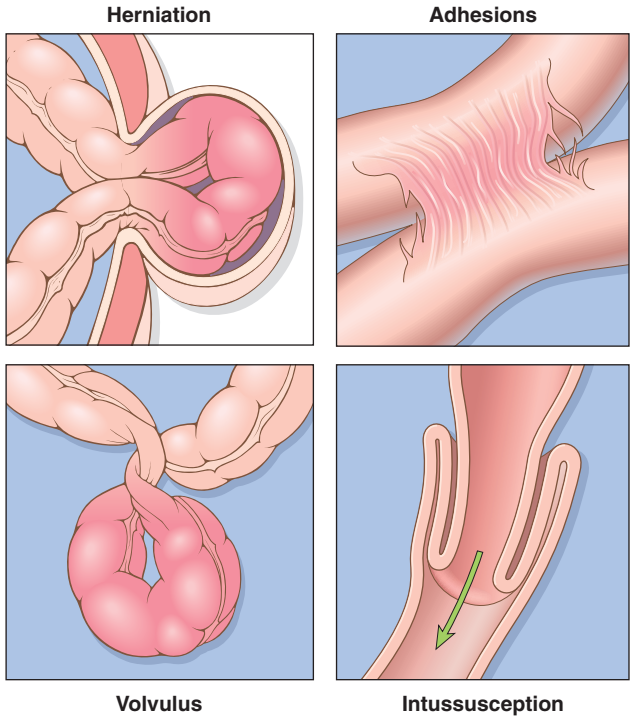

**Figure 14–18** Intestinal obstruction. The four major mechanical causes of intestinal obstruction are (1) herniation of a segment in the umbilical or inguinal regions, (2) adhesion between loops of intestine, (3) volvulus, and (4) intussusception.

are enterocolitis, fluid and electrolyte disturbances, perforation, and peritonitis. Surgical resection of the aganglionic segment with anastomosis of the normal colon to the rectum is effective, although it may take years for patients to attain normal bowel function and continence.

### PATHOGENESIS

The enteric neuronal plexus develops from neural crest cells that migrate into the bowel wall during embryogenesis. Hirschsprung disease, also known as **congenital aganglionic megacolon,** results when the normal migration of neural crest cells from cecum to rectum is disrupted. This produces a distal intestinal segment that lacks both the Meissner submucosal plexus and the Auerbach myenteric plexus ("aganglionosis"). Coordinated peristaltic contractions are absent and the subsequent functional obstruction results in dilation proximal to the affected segment. While the mechanisms underlying this defective neural crest cell migration are unknown, **heterozygous loss-of-function mutations in the receptor tyrosine kinase RET account for a majority of familial cases** and approximately 15% of sporadic cases. However, mutations also occur in other genes, only some of which have been identified, and modifying genes or environmental factors also play a role.

### MORPHOLOGY

Hirschsprung disease always affects the rectum, but the length of the additional involved segments varies. Most cases are limited to the rectum and sigmoid colon, but severe disease can involve the entire colon. The aganglionic region may have a grossly normal or contracted appearance, while the normally innervated proximal colon may undergo progressive dilation as a result of the distal obstruction (Fig. 14–19). Diagnosis of Hirschsprung disease requires demonstrating the absence of ganglion cells in the affected segment.

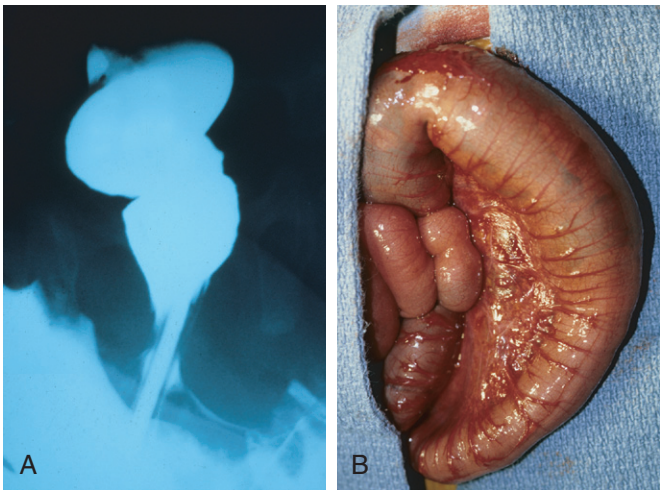

**Figure 14–19** Hirschsprung disease. **A,** Preoperative barium enema study showing constricted rectum (*bottom of the image*) and dilated sigmoid colon. Ganglion cells were absent in the rectum, but present in the sigmoid colon. **B,** Corresponding intraoperative appearance of the dilated sigmoid colon.
*(Courtesy of Dr. Aliya Husain, The University of Chicago, Chicago, Illinois.)*

## Abdominal Hernia

Any weakness or defect in the wall of the peritoneal cavity may permit protrusion of a serosa-lined pouch of peritoneum called a *hernia sac.* Acquired hernias most commonly occur anteriorly, through the inguinal and femoral canals or umbilicus, or at sites of surgical scars. These are of concern because of visceral protrusion (*external herniation*). This is particularly true of inguinal hernias, which tend to have narrow orifices and large sacs. Small bowel loops are herniated most often, but portions of omentum or large bowel also protrude, and any of these may become entrapped. Pressure at the neck of the pouch may impair venous drainage, leading to stasis and edema. These changes increase the bulk of the herniated loop, leading to permanent entrapment, or *incarceration,* and over time, arterial and venous compromise, or *strangulation,* can result in infarction.

### SUMMARY

#### Intestinal Obstruction

- *Hirschsprung disease* is the result of defective neural crest cell migration from cecum to rectum. It gives rise to functional obstruction.
- *Abdominal herniation* may occur through any weakness or defect in the wall of the peritoneal cavity, including inguinal and femoral canals, umbilicus, and sites of surgical scarring.

# VASCULAR DISORDERS OF BOWEL

The greater portion of the gastrointestinal tract is supplied by the celiac, superior mesenteric, and inferior mesenteric arteries. As they approach the intestinal wall, the superior and inferior mesenteric arteries fan out to form the mesenteric arcades. Interconnections between arcades, as well as collateral supplies from the proximal celiac and distal pudendal and iliac circulations, make it possible for the small intestine and colon to tolerate slowly progressive loss of the blood supply from one artery. By contrast, acute compromise of any major vessel can lead to infarction of several meters of intestine.

## Ischemic Bowel Disease

Ischemic damage to the bowel wall can range from *mucosal infarction,* extending no deeper than the muscularis mucosa; to *mural infarction* of mucosa and submucosa; to *transmural infarction* involving all three layers of the wall. While mucosal or mural infarctions often are secondary to acute or chronic *hypoperfusion,* transmural infarction is generally caused by acute vascular obstruction. Important causes of acute arterial obstruction include severe *atherosclerosis* (which is often prominent at the origin of mesenteric vessels), *aortic aneurysm, hypercoagulable states, oral contraceptive use,* and *embolization of cardiac vegetations or aortic atheromas.* Intestinal hypoperfusion can also be associated with *cardiac failure, shock, dehydration,* or *vasoconstrictive drugs.* Systemic *vasculitides,* such as polyarteritis nodosum, Henoch-Schönlein purpura, or Wegener granulomatosis,

also may damage intestinal arteries. Mesenteric venous thrombosis can also lead to ischemic disease, but is uncommon. Other causes include invasive neoplasms, cirrhosis, portal hypertension, trauma, or abdominal masses that compress the portal drainage.

## PATHOGENESIS

Intestinal responses to ischemia occur in two phases. The initial hypoxic injury occurs at the onset of vascular compromise and, although some damage occurs, intestinal epithelial cells are relatively resistant to transient hypoxia. The second phase, reperfusion injury, is initiated by restoration of the blood supply and associated with the greatest damage. In severe cases multiorgan failure may occur. While the underlying mechanisms of reperfusion injury are incompletely understood, they involve free radical production, neutrophil infiltration, and release of inflammatory mediators, such as complement proteins and cytokines (Chapter 10). **The severity of vascular compromise, time frame during which it develops, and vessels affected are the major variables that determine severity of ischemic bowel disease.** Two aspects of intestinal vascular anatomy also contribute to the distribution of ischemic damage:

- Intestinal segments at the end of their respective arterial supplies are particularly susceptible to ischemia. These **watershed zones** include the splenic flexure, where the superior and inferior mesenteric arterial circulations terminate, and, to a lesser extent, the sigmoid colon and rectum where inferior mesenteric, pudendal, and iliac arterial circulations end. Generalized hypotension or hypoxemia can therefore cause localized injury, and ischemic disease should be considered in the differential diagnosis for focal colitis of the splenic flexure or rectosigmoid colon.
- Intestinal capillaries run alongside the glands, from crypt to surface, before making a hairpin turn at the surface to empty into the postcapillary venules. This configuration allows oxygenated blood to supply crypts but leaves the surface epithelium vulnerable to ischemic injury. This anatomy protects the crypts, which contain the epithelial stem cells that are necessary to repopulate the surface. Thus, surface epithelial atrophy, or even necrosis with consequent sloughing, with normal or hyperproliferative crypts constitutes a morphologic signature of ischemic intestinal disease.

## MORPHOLOGY

Despite the increased susceptibility of watershed zones, **mucosal and mural infarction** may involve any level of the gut from stomach to anus. Disease frequently is segmental and patchy in distribution, and the mucosa is hemorrhagic and often ulcerated. The bowel wall is thickened by edema that may involve the mucosa or extend into the submucosa and muscularis propria. With severe disease, pathologic changes include extensive mucosal and submucosal hemorrhage and necrosis, but serosal hemorrhage and serositis generally are absent. Damage is more pronounced in acute arterial thrombosis and **transmural infarction.** Blood-tinged mucus or blood accumulates within the lumen. Coagulative necrosis of the muscularis propria occurs within 1 to 4 days and may be associated with purulent serositis and perforation.

In **mesenteric venous thrombosis,** arterial blood continues to flow for a time, resulting in a less abrupt transition from affected to normal bowel. However, propagation of the thrombus may lead to secondary involvement of the splanchnic bed. The ultimate result is similar to that produced by acute arterial obstruction, because impaired venous drainage eventually prevents entry of oxygenated arterial blood.

Microscopic examination of ischemic intestine demonstrates **atrophy or sloughing of surface epithelium** (Fig. 14–20, *A*). By contrast, crypts may be hyperproliferative. Inflammatory infiltrates initially are absent in acute ischemia, but neutrophils are recruited within hours of reperfusion. Chronic ischemia is accompanied by fibrous scarring of the lamina propria (Fig. 14–20, *B*) and, uncommonly, stricture formation. In acute phases of ischemic damage, bacterial superinfection and enterotoxin release may induce pseudomembrane formation that can resemble *Clostridium difficile*–associated pseudomembranous colitis (discussed later).

### Clinical Features

Ischemic bowel disease tends to occur in older persons with coexisting cardiac or vascular disease. Acute transmural infarction typically manifests with sudden, severe abdominal pain and tenderness, sometimes accompanied by nausea, vomiting, bloody diarrhea, or grossly melanotic stool. This presentation may progress to shock and vascular collapse within hours as a result of blood loss. Peristaltic sounds diminish or disappear, and muscular spasm creates boardlike rigidity of the abdominal wall. Because these physical signs overlap with those of other abdominal emergencies, including acute appendicitis, perforated ulcer, and acute cholecystitis, the diagnosis of intestinal infarction may be delayed or missed, with disastrous consequences. As the mucosal barrier breaks down, bacteria enter the circulation and sepsis can develop; the mortality rate may exceed 50%.

The overall progression of ischemic enteritis depends on the underlying cause and severity of injury:

- *Mucosal and mural infarctions* by themselves may not be fatal. However, these may progress to more extensive,

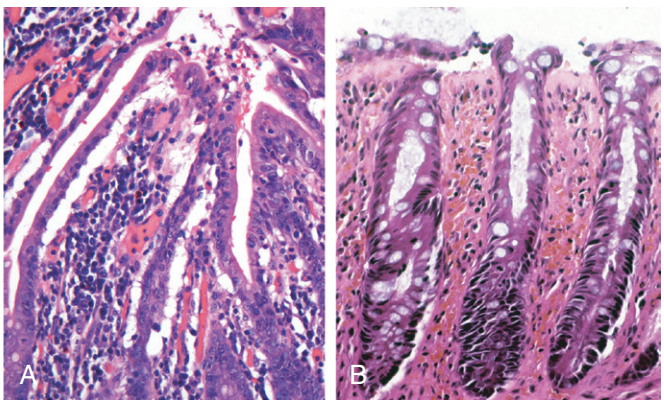

**Figure 14–20** Ischemia. **A,** Characteristic attenuated and partially detached villous epithelium in acute jejunal ischemia. Note the hyperchromatic nuclei of proliferating crypt cells. **B,** Chronic colonic ischemia with atrophic surface epithelium and fibrotic lamina propria.

transmural infarction if the vascular supply is not restored by correction of the insult or, in chronic disease, by development of adequate collateral supplies.

- *Chronic ischemia* may masquerade as inflammatory bowel disease, with episodes of bloody diarrhea interspersed with periods of healing.
- *CMV infection* causes ischemic gastrointestinal disease as a consequence of the viral tropism for and infection of endothelial cells. CMV infection can be a complication of immunosuppressive therapy (Chapter 8).
- *Radiation enterocolitis* occurs when the gastrointestinal tract is irradiated. In addition to epithelial damage, radiation-induced vascular injury may be significant and produce changes that are similar to ischemic disease. In addition to clinical history, the presence of bizarre "radiation fibroblasts" within the stroma may provide an important clue to the etiology. Acute radiation enteritis manifests as anorexia, abdominal cramps, and a malabsorptive diarrhea, while chronic radiation enteritis or colitis often is more indolent and may present as an inflammatory colitis.
- *Necrotizing enterocolitis* is an acute disorder of the small and large intestines that can result in transmural necrosis. It is the most common acquired gastrointestinal emergency of neonates, particularly those who are premature or of low birth weight, and occurs most often when oral feeding is initiated (Chapter 6). Ischemic injury generally is considered to contribute to its pathogenesis.
- *Angiodysplasia* is characterized by malformed submucosal and mucosal blood vessels. It occurs *most often in the cecum or right colon,* and usually presents after the sixth decade of life. Although the prevalence of angiodysplasia is less than 1% in the adult population, *it accounts for 20% of major episodes of lower intestinal bleeding; intestinal hemorrhage may be chronic and intermittent or acute and massive.* The pathogenesis is unknown.

## Hemorrhoids

*Hemorrhoids* affect about 5% of the general population. Simply put, hemorrhoids are dilated anal and perianal collateral vessels that connect the portal and caval venous systems to relieve elevated venous pressure within the hemorrhoid plexus. Thus, although hemorrhoids are both more common and less serious than esophageal varices, the pathogenesis of these lesions is similar. Common factors that predispose to hemorrhoids are constipation and associated straining, which increase intra-abdominal and venous pressures, venous stasis of pregnancy, and portal hypertension.

### MORPHOLOGY

Collateral vessels within the inferior hemorrhoidal plexus are located below the anorectal line and are termed **external hemorrhoids,** while those that result from dilation of the superior hemorrhoidal plexus within the distal rectum are referred to as **internal hemorrhoids.** On histologic examination, hemorrhoids consist of thin-walled, dilated, submucosal vessels that protrude beneath the anal or rectal mucosa. In their exposed position, they are subject to trauma and tend to become inflamed, thrombosed, and, in the course of time, recanalized. Superficial ulceration may occur.

### Clinical Features

Hemorrhoids often manifest with pain and rectal bleeding, particularly bright red blood seen on toilet tissue. Except in pregnant women, hemorrhoids are rarely encountered in persons younger than 30 years of age. Hemorrhoids also may develop as a result of portal hypertension, where the implications are more ominous. Hemorrhoidal bleeding generally is not a medical emergency; treatment options include sclerotherapy, rubber band ligation, and infrared coagulation. In severe cases, hemorrhoids may be removed surgically by *hemorrhoidectomy.*

### SUMMARY

#### Vascular Disorders of Bowel

- Intestinal ischemia can occur as a result of either *arterial or venous obstruction.*
- *Ischemic bowel disease* resulting from hypoperfusion is most common at the splenic flexure, sigmoid colon, and rectum; these are *watershed zones* where two arterial circulations terminate.
- *Systemic vasculitides and infectious diseases* (e.g., CMV infection) can cause vascular disease that is not confined to the gastrointestinal tract.
- *Angiodysplasia* is a common cause of major lower gastrointestinal bleeding in the elderly.
- *Hemorrhoids* are collateral vessels that form to allow resolution of venous hypertension.

# DIARRHEAL DISEASE

## Malabsorptive Diarrhea

Diarrhea is a common symptom of many intestinal diseases, including those due to infection, inflammation, ischemia, malabsorption, and nutritional deficiency. This section focuses primarily on *malabsorption,* which manifests most commonly as *chronic diarrhea* and is characterized by defective absorption of fats, fat- and water-soluble vitamins, proteins, carbohydrates, electrolytes and minerals, and water. Other disorders associated with *secretory* and *exudative* types of diarrhea (e.g., cholera and inflammatory bowel disease, respectively) are addressed in separate sections.

Chronic malabsorption causes weight loss, anorexia, abdominal distention, borborygmi, and muscle wasting. A hallmark of malabsorption is *steatorrhea,* characterized by excessive fecal fat and bulky, frothy, greasy, yellow or clay-colored stools. *The chronic malabsorptive disorders most commonly encountered in the United States are pancreatic insufficiency, celiac disease, and Crohn disease.* Intestinal graft-versus-host disease is an important cause of both

malabsorption and diarrhea after allogeneic hematopoietic stem cell transplantation. Environmental enteropathy (previously known as tropical sprue) is pervasive in some communities within developing countries.

*Diarrhea* is defined as an increase in stool mass, frequency, or fluidity, typically to volumes greater than 200 mL per day. In severe cases stool volume can exceed 14 L per day and, without fluid resuscitation, result in death. Painful, bloody, small-volume diarrhea is known as *dysentery.* Diarrhea can be classified into four major categories:

- *Secretory diarrhea* is characterized by isotonic stool and persists during fasting.
- *Osmotic diarrhea,* such as that occurring with lactase deficiency, is due to osmotic forces exerted by unabsorbed luminal solutes. The diarrheal fluid is more than 50 mOsm more concentrated than plasma, and the condition abates with fasting.
- *Malabsorptive diarrhea* caused by inadequate nutrient absorption is associated with steatorrhea and is relieved by fasting.
- *Exudative diarrhea* is due to inflammatory disease and characterized by purulent, bloody stools that continue during fasting.

Malabsorption results from disturbance in at least one of the four phases of nutrient absorption: (1) *intraluminal digestion,* in which proteins, carbohydrates, and fats are broken down into absorbable forms; (2) *terminal digestion,* which involves the hydrolysis of carbohydrates and peptides by disaccharidases and peptidases, respectively, in the brush border of the small intestinal mucosa; (3) *transepithelial transport,* in which nutrients, fluid, and electrolytes are transported across and processed within the small intestinal epithelium; and (4) *lymphatic transport* of absorbed lipids.

In many malabsorptive disorders, a defect in one of these processes predominates, but more than one usually contributes (Table 14–3). As a result, malabsorption syndromes resemble each other more than they differ. Symptoms and signs include *diarrhea* (from nutrient malabsorption and excessive intestinal secretion), *flatus, abdominal pain,* and *weight loss.* Inadequate absorption of vitamins and minerals can result in anemia and mucositis due to pyridoxine, folate, or vitamin $B_{12}$ deficiency; bleeding due to vitamin K deficiency; osteopenia and tetany due to calcium, magnesium, or vitamin D deficiency; or neuropathy due to vitamin A or $B_{12}$ deficiency. A variety of endocrine and skin disturbances also may occur.

### Cystic Fibrosis

Cystic fibrosis is discussed in greater detail elsewhere (Chapter 6). Only the malabsorption associated with cystic fibrosis is considered here. Owing to the absence of the epithelial cystic fibrosis transmembrane conductance regulator (CFTR), persons with cystic fibrosis have defects in intestinal and pancreatic ductal chloride ion secretion. This abnormality leads to interference with bicarbonate, sodium, and water secretion, ultimately resulting in defective luminal hydration. This failure of hydration can result in meconium ileus, which is present in up to 10% of newborns with cystic fibrosis. In the pancreas, intraductal concretions can begin to form in utero. This leads to obstruction, low-grade chronic autodigestion of the pancreas, and eventual *exocrine pancreatic insufficiency in more than 80% of patients.* The result is failure of the intraluminal phase of nutrient absorption, which can be effectively treated in most patients with oral enzyme supplementation.

### Celiac Disease

*Celiac disease,* also known as *celiac sprue* or *gluten-sensitive enteropathy,* is an immune-mediated enteropathy triggered by the ingestion of gluten-containing cereals, such as wheat, rye, or barley, in genetically predisposed persons. In countries whose populations consist predominantly of white people of European ancestry, celiac disease is a common disorder, with an estimated prevalence of 0.5%

**Table 14–3** Defects in Malabsorptive and Diarrheal Disease

| Disease | Intraluminal Digestion | Terminal Digestion | Transepithelial Transport | Lymphatic Transport |
|---|---|---|---|---|
| Celiac disease | | + | + | |
| Tropical sprue | | + | + | |
| Chronic pancreatitis | + | | | |
| Cystic fibrosis | + | | | |
| Primary bile acid malabsorption | + | | + | |
| Carcinoid syndrome | | | + | |
| Autoimmune enteropathy | | + | + | |
| Disaccharidase deficiency | | + | | |
| Whipple disease | | | | + |
| Abetalipoproteinemia | | | + | |

| Parasitic gastroenteritis | | + | + | |
| Inflammatory bowel disease | + | + | + | |

+ indicates that the process is abnormal in the disease indicated. Other processes are not affected.

to 1%. The primary treatment for celiac disease is a *gluten-free diet.* Despite the challenges of adhering to such a diet, it does result in symptomatic improvement for most patients.

## PATHOGENESIS

Celiac disease is an intestinal immune reaction to gluten, the major storage protein of wheat and similar grains. Gluten is digested by luminal and brush border enzymes into amino acids and peptides, including a 33–amino acid gliadin peptide that is resistant to degradation by gastric, pancreatic, and small intestinal proteases (Fig. 14–21). Gliadin is deamidated by tissue transglutaminase and is then able to interact with HLA-DQ2 or HLA-DQ8 on antigen-presenting cells and be presented to CD4+ T cells. These T cells produce cytokines that are likely to contribute to the tissue damage and characteristic mucosal histopathology. A characteristic B cell response follows: this includes production of anti-tissue transglutaminase, anti-deamidated gliadin, and, perhaps as a result of cross-reactive epitopes, anti-endomysial antibodies, which are diagnostically useful (see below). However, whether these antibodies contribute to celiac disease pathogenesis or are merely markers remains controversial. In addition to CD4+ cells, there is accumulation of CD8+ cells that are not specific for gliadin. These CD8+ cells may play an ancillary role in causing tissue damage. It is thought that deamidated gliadin peptides induce epithelial cells to produce the cytokine IL-15, which in turn triggers activation and proliferation of CD8+ intraepithelial lymphocytes that can express the MIC-A receptor NKG2D. These lymphocytes become cytotoxic and kill enterocytes that have been induced by various stressors to express surface MIC-A, an HLA class I–like protein that is recognized by NKG2D and, possibly, other epithelial proteins. The damage caused by these immune mechanisms may increase the movement of gliadin peptides across the epithelium, which are deamidated by tissue transglutaminase, thus perpetuating the cycle of disease.

While nearly all people eat grain and are exposed to gluten and gliadin, most do not develop celiac disease. Thus, host factors determine whether disease develops. Among these, HLA proteins seem to be critical, since almost all people with celiac disease carry the class II HLA-DQ2 or HLA-DQ8 alleles. However, the HLA locus accounts for less than half of the genetic component of celiac disease. Other genetic contributors are not fully defined. There is also an association of celiac disease with other immune diseases including type 1 diabetes, thyroiditis, and Sjögren syndrome.

## MORPHOLOGY

Biopsy specimens from the second portion of the duodenum or proximal jejunum, which are exposed to the highest concentrations of dietary gluten, generally are diagnostic in celiac disease. The histopathologic picture is characterized by increased numbers of intraepithelial CD8+ T lymphocytes, with **intraepithelial lymphocytosis, crypt hyperplasia, and villous atrophy** (Fig. 14–22). This loss of mucosal and brush border surface area probably accounts for the malabsorption. In addition, increased rates of epithelial turnover, reflected in increased crypt mitotic activity, may limit the ability of absorptive enterocytes to fully differentiate and contribute to defects in terminal digestion and transepithelial transport. Other features of fully developed celiac disease include increased numbers of plasma cells, mast cells, and eosinophils, especially within the upper part of the lamina propria. With increased serologic screening and early detection of disease-associated antibodies, it is now appreciated that an increase in the number of intraepithelial lymphocytes,

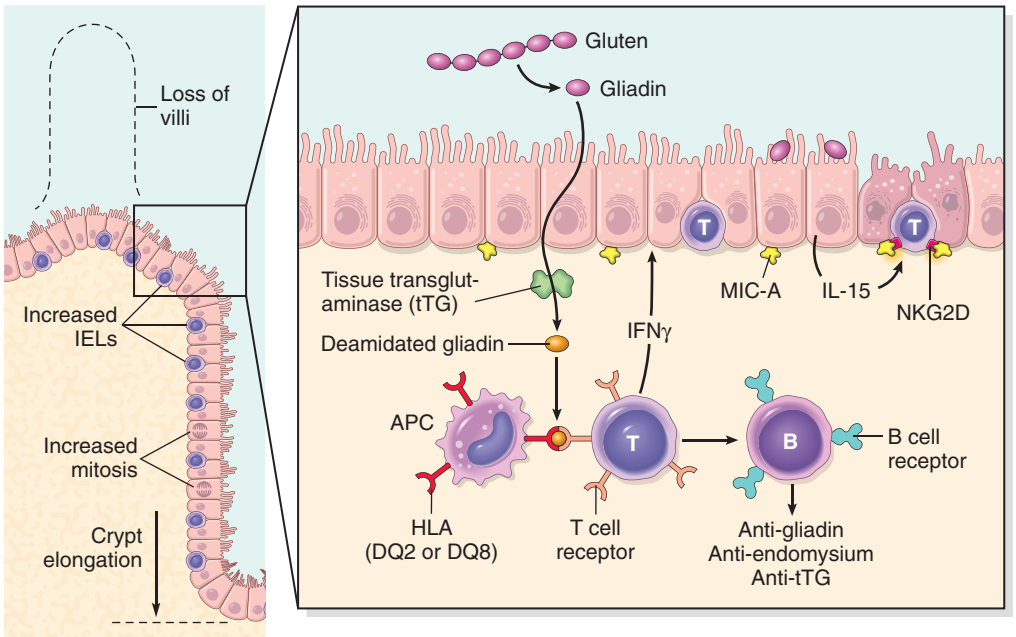

**Figure 14–21** *Left panel,* The morphologic alterations that may be present in celiac disease, including villous atrophy, increased numbers of intraepithelial lymphocytes (IELs), and epithelial proliferation with crypt elongation. *Right panel,* A model for the pathogenesis of celiac disease. Note that both innate and adaptive immune mechanisms are involved in the tissue responses to gliadin.

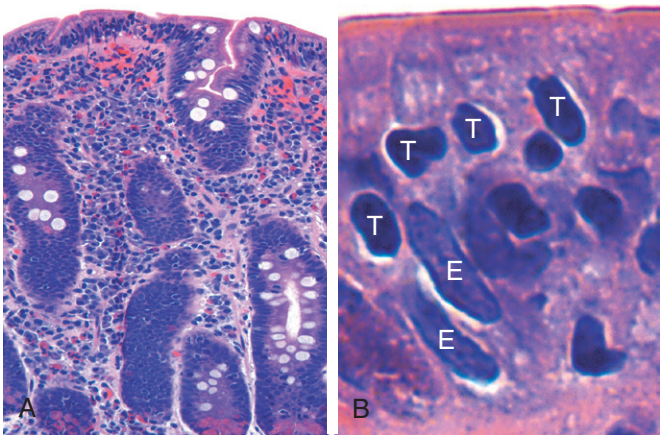

**Figure 14–22** Celiac disease. **A,** Advanced cases of celiac disease show complete loss of villi, or total villous atrophy. Note the dense plasma cell infiltrates in the lamina propria. **B,** Infiltration of the surface epithelium by T lymphocytes, which can be recognized by their densely stained nuclei (labeled *T*). Compare with elongated, pale-staining epithelial nuclei (labeled *E*).

particularly within the villus, is a marker of mild forms of celiac disease. Intraepithelial lymphocytosis and villous atrophy are not specific for celiac disease, however, and can be a feature of other disorders, including viral enteritis. The combination of histologic and serologic findings is most specific for diagnosis of celiac disease.

### Clinical Features

In adults, celiac disease manifests most commonly between the ages of 30 and 60. However, many cases escape clinical attention for extended periods because of atypical presentations. Some patients have *silent* celiac disease, defined as positive serology and villous atrophy without symptoms, or *latent* celiac disease, in which positive serology is not accompanied by villous atrophy. Symptomatic adult celiac disease is often associated with anemia (due to iron deficiency and, less commonly, $B_{12}$ and folate deficiency), diarrhea, bloating, and fatigue.

Pediatric celiac disease, which affects male and female children equally, may manifest with *classic symptoms,* typically between the ages of 6 and 24 months (after introduction of gluten to the diet) with irritability, abdominal distention, anorexia, diarrhea, failure to thrive, weight loss, or muscle wasting. Children with *nonclassic symptoms* tend to present at older ages with complaints of abdominal pain, nausea, vomiting, bloating, or constipation. A characteristic pruritic, blistering skin lesion, *dermatitis herpetiformis,* also is present in as many as 10% of patients, and the incidence of *lymphocytic gastritis* and *lymphocytic colitis* also is increased.

Noninvasive serologic tests generally are performed before biopsy. The most sensitive tests are the presence of IgA antibodies to tissue transglutaminase or IgA or IgG antibodies to deamidated gliadin. Antiendomysial antibodies are highly specific but less sensitive than other antibodies. The absence of HLA-DQ2 or HLA-DQ8 is useful for its high negative predictive value, but the presence of these common alleles is not helpful in confirming the diagnosis.

Patients with celiac disease exhibit a higher than normal rate of malignancy. The most common celiac disease–associated cancer is *enteropathy-associated T cell lymphoma,* an aggressive tumor of intraepithelial T lymphocytes. *Small intestinal adenocarcinoma* also is more frequent in persons with celiac disease. Thus, when symptoms such as abdominal pain, diarrhea, and weight loss develop despite a strict gluten-free diet, cancer or *refractory sprue,* in which the response to a gluten-free diet is lost, must be considered. It is, however, important to recognize that failure to adhere to a gluten-free diet is the most common cause of recurrent symptoms, and that most people with celiac disease do well with dietary restrictions and die of unrelated causes.

### *Environmental (Tropical) Enteropathy*

The term *environmental enteropathy* refers to a syndrome of stunted growth and impaired intestinal function that is common in developing countries, including many parts of sub-Saharan Africa, such as Gambia; aboriginal populations within northern Australia; and some groups within South America and Asia, such as residents of impoverished communities within Brazil, Guatemala, India, and Pakistan. The impact of environmental enteropathy, which was previously called *tropical enteropathy* or *tropical sprue,* cannot be overstated, as it is estimated to affect over 150 million children worldwide. Although malnutrition must contribute to the pathogenesis of this disorder, also referred to as *tropical enteropathy,* neither supplementary feeding nor vitamin and mineral supplementation are able to fully reverse the syndrome. Repeated bouts of diarrhea suffered within the first 2 or 3 years of life are most closely linked to environmental enteropathy. Many pathogens are endemic in these communities, but no single infectious agent has been linked to these diarrheal episodes. Intestinal biopsy specimens have been examined in only a small number of cases, and reported histologic features are more similar to those of severe celiac disease than to those of infectious enteritis. One hypothesis is that recurrent diarrhea establishes a cycle of mucosal injury, malnutrition, infection, and inflammation. However, this has not been established in part because accepted diagnostic criteria for environmental enteropathy are lacking, as the entity has been defined primarily by epidemiologic assessment of physical and cognitive growth and development.

### *Lactase (Disaccharidase) Deficiency*

The disaccharidases, including lactase, are located in the apical brush border membrane of the villous absorptive epithelial cells. Because the defect is biochemical, biopsies are generally unremarkable. Lactase deficiency is of two types:

- *Congenital lactase deficiency* is an autosomal recessive disorder caused by a mutation in the gene encoding lactase. The disease is rare and manifests as explosive diarrhea with watery, frothy stools and abdominal distention after milk ingestion. Symptoms abate when exposure to milk and milk products is terminated, thus removing the osmotically active but unabsorbable lactose from the lumen.
- *Acquired lactase deficiency* is caused by downregulation of lactase gene expression and is particularly common among Native Americans, African Americans, and

Chinese populations. Downregulation of lactase occurs in the gut after childhood, perhaps reflecting the fact that, before farming of dairy animals, lactase was unnecessary after children stopped drinking mother's milk. Onset of acquired lactase deficiency is sometimes associated with enteric viral or bacterial infections.

### *Abetalipoproteinemia*

*Abetalipoproteinemia* is an autosomal recessive disease characterized by an inability to secrete triglyceride-rich lipoproteins. Although it is rare, it is included here as an example of a transepithelial transport defect that leads to malabsorption. Mutation in the *microsomal triglyceride transfer protein* renders enterocytes unable to export lipoproteins and free fatty acids. As a result, monoglycerides and triglycerides accumulate within the epithelial cells. Lipid vacuoles in small intestinal epithelial cells are evident by light microscopy and can be highlighted by special stains, such as oil red O, particularly after a fatty meal. Abetalipoproteinemia manifests in infancy, and the clinical picture is dominated by failure to thrive, diarrhea, and steatorrhea. Failure to absorb essential fatty acids leads to deficiencies of fat-soluble vitamins, and lipid defects in plasma membranes often produce acanthocytic red cells (spur cells) in peripheral blood smears.

### *Irritable Bowel Syndrome*

*Irritable bowel syndrome* (IBS) is characterized by chronic and relapsing abdominal pain, bloating, and changes in bowel habits including diarrhea and constipation. The pathogenesis is poorly defined but involves psychologic stressors, diet, and abnormal gastrointestinal motility. Despite very real symptoms, no gross or microscopic abnormalities are found in most IBS patients. Thus, the diagnosis depends on clinical symptoms. IBS typically manifests between 20 and 40 years of age, and there is a significant female predominance. Variability in diagnostic criteria makes it difficult to establish the incidence, but *reported prevalence rates in developed countries typically are between 5% and 10%*. In patients with diarrhea, microscopic colitis, celiac disease, giardiasis, lactose intolerance, small bowel bacterial overgrowth, bile salt malabsorption, colon cancer, and inflammatory bowel disease must be excluded (although IBS is common in patients with inflammatory bowel disease). The prognosis for IBS is most closely related to symptom duration, with longer duration correlating with reduced likelihood of improvement.

### *Microscopic Colitis*

*Microscopic colitis* encompasses two entities, *collagenous colitis* and *lymphocytic colitis*. Both of these idiopathic diseases manifest with chronic, nonbloody, watery diarrhea without weight loss. Findings on radiologic and endoscopic studies typically are normal. Collagenous colitis, which occurs primarily in middle-aged and older women, is characterized by the presence of a dense subepithelial collagen layer, increased numbers of intraepithelial lymphocytes, and a mixed inflammatory infiltrate within the lamina propria. Lymphocytic colitis is histologically similar, but the subepithelial collagen layer is of normal thickness and the increase in intraepithelial lymphocytes may be greater, frequently exceeding one T lymphocyte per five colonocytes. Lymphocytic colitis is associated with celiac and autoimmune diseases, including thyroiditis, arthritis, and autoimmune or lymphocytic gastritis.

### *Graft-Versus-Host Disease*

Graft-versus-host disease occurs after allogeneic hematopoietic stem cell transplantation. The small bowel and colon are involved in most cases. Although graft-versus-host disease is secondary to the targeting of antigens on the recipient's epithelial cells by donor T cells, the lymphocytic infiltrate in the lamina propria is typically sparse. Epithelial apoptosis, particularly of crypt cells, is the most common histologic finding. Intestinal graft-versus-host disease often manifests as a watery diarrhea.

## SUMMARY

### Malabsorptive Diarrhea

- Diarrhea can be characterized as *secretory*, *osmotic*, *malabsorptive*, or *exudative*.
- The malabsorption associated with cystic fibrosis is the result of *pancreatic insufficiency* (i.e., inadequate pancreatic digestive enzymes) and *deficient luminal breakdown* of nutrients.
- *Celiac disease* is an immune-mediated enteropathy triggered by the ingestion of gluten-containing grains. The malabsorptive diarrhea in celiac disease is due to *loss of brush border surface area* and, possibly, deficient enterocyte maturation as a result of immune-mediated epithelial damage.
- *Lactase deficiency* causes an *osmotic diarrhea* owing to the inability to break down or absorb lactose.
- *Irritable bowel syndrome* (IBS) is characterized by chronic, relapsing abdominal pain, bloating, and changes in bowel habits. The pathogenesis is poorly defined.
- The two forms of microscopic colitis, *collagenous colitis* and *lymphocytic colitis*, both cause chronic watery diarrhea. The intestines are grossly normal, and the diseases are identified by their characteristic histologic features.

## Infectious Enterocolitis

Enterocolitis can manifest with a broad range of signs and symptoms including diarrhea, abdominal pain, urgency, perianal discomfort, incontinence, and hemorrhage. This global problem is responsible for more than 12,000 deaths per day among children in developing countries and half of all deaths before age 5 worldwide. Bacterial infections, such as enterotoxigenic *Escherichia coli*, frequently are responsible, but the most common pathogens vary with age, nutrition, and host immune status, as well as environmental influences (Table 14–4). For example, epidemics of cholera are common in areas with poor sanitation, as a result of inadequate public health measures, or as a consequence of natural disasters (e.g., the Haiti earthquake of 2010) or war. Pediatric infectious diarrhea, which may result in severe dehydration and metabolic acidosis, commonly is caused by enteric viruses. A summary of the epidemiology and clinical features of selected causes of bacterial enterocolitis is presented in

**Table 14–4** Features of Bacterial Enterocolitides

| Infection Type | Geography | Reservoir | Transmission | Epidemiology | Affected GI Sites | Symptoms | Complications |
|---|---|---|---|---|---|---|---|
| Cholera | India, Africa | Shellfish | Fecal-oral, water | Sporadic, endemic, epidemic | Small intestine | Severe watery diarrhea | Dehydration, electrolyte imbalances |
| *Campylobacter* spp. | Developed countries | Chickens, sheep, pigs, cattle | Poultry, milk, other foods | Sporadic; children, travelers | Colon | Watery or bloody diarrhea | Arthritis, Guillain-Barré syndrome |
| Shigellosis | Developing countries | Humans | Fecal-oral, food, water | Children | Left colon, ileum | Bloody diarrhea | Reactive arthritis hemolytic-uremic syndrome |
| Salmonellosis | Worldwide | Poultry, farm animals, reptiles | Meat, poultry, eggs, milk | Children, elderly | Colon and small intestine | Watery or bloody diarrhea | Sepsis |
| Enteric (typhoid) fever | India, Mexico, Philippines | Humans | Fecal-oral, water | Children. adolescents, travelers | Small intestine | Bloody diarrhea, fever | Chronic infection, carrier state, encephalopathy, myocarditis |
| *Yersinia* spp. | Northern and central Europe | Pigs | Pork, milk, water | Clustered cases | Ileum, appendix, right colon | Abdominal pain, fever, diarrhea | Autoimmune, e.g., reactive arthritis |
| *Escherichia coli* | | | | | | | |
| Enterotoxigenic (ETEC) | Developing countries | Unknown | Food, fecal-oral | Infants, adolescents, travelers | Small intestine | Severe watery diarrhea | Dehydration, electrolyte imbalances |
| Enterohemorrhagic (EHEC) | Worldwide | Widespread, includes cattle | Beef, milk, produce | Sporadic and epidemic | Colon | Bloody diarrhea | Hemolytic-uremic syndrome |
| Enteroinvasive (EIEC) | Developing countries | Unknown | Cheese, other foods, water | Young children | Colon | Bloody diarrhea | Unknown |
| Enteroaggregative (EAEC) | Worldwide | Unknown | Unknown | Children, adults, travelers | Colon | Nonbloody diarrhea, afebrile | Poorly defined |
| Pseudomembranous colitis (*C. difficile*) | Worldwide | Humans, hospitals | Antibiotics allow emergence | Immunosuppressed, antibiotic-treated | Colon | Watery diarrhea, fever | Relapse, toxic megacolon |
| Whipple disease | Rural > urban | Unknown | Unknown | Rare | Small intestine | Malabsorption | Arthritis, CNS disease |
| Mycobacterial infection | Worldwide | Unknown | Unknown | Immunosuppressed | Small intestine | Malabsorption, diarrhea, fever | Pneumonia, infection at other sites |

CNS, central nervous system; GI, gastrointestinal.

Table 14–4. Representative bacterial, viral, and parasitic enterocolitides are discussed below.

### *Cholera*

*Vibrio cholerae* organisms are comma-shaped, gram-negative bacteria that cause cholera, a disease that has been endemic in the Ganges Valley of India and Bangladesh for all of recorded history. *V. cholerae* is transmitted primarily by contaminated drinking water. However, it also can be present in food and causes rare cases of seafood-associated disease. There is a marked seasonal variation in most climates due to rapid growth of *Vibrio* bacteria at warm temperatures; the only animal reservoirs are shellfish and plankton. Relatively few *V. cholerae* serotypes are pathogenic, but other species of *Vibrio* also can cause disease.

#### PATHOGENESIS

Despite the severe diarrhea, *Vibrio* organisms are noninvasive and remain within the intestinal lumen. Flagellar proteins, which are involved in motility and attachment, are necessary for efficient bacterial colonization, and a secreted metalloproteinase that also has hemagglutinin activity is important for bacterial detachment and shedding in the stool. However, it is the **preformed enterotoxin,** cholera toxin, which causes disease. The toxin, which is composed of five B subunits that direct endocytosis and a single active A subunit, is delivered to the endoplasmic reticulum by **retrograde transport.** A fragment of the A subunit is transported from the endoplasmic reticulum lumen into the cytosol, where it interacts with cytosolic ADP ribosylation factors to ribosylate and activate the G protein $G_{s\alpha}$. This stimulates adenylate cyclase and the resulting increases in intracellular cyclic adenosine monophosphate (cAMP) open the cystic fibrosis transmembrane conductance regulator (CFTR), which releases chloride ions into the lumen. Sodium and bicarbonate absorption are also reduced. Accumulation of these ions creates an osmotic gradient that draws water into the lumen, leading to massive **secretory diarrhea.** Remarkably, mucosal biopsy specimens show only minimal morphologic alterations.

#### Clinical Features

Most exposed persons are asymptomatic or suffer only mild diarrhea. Those with severe disease have an abrupt onset of watery diarrhea and vomiting after an incubation period of 1 to 5 days. The rate of diarrheal stool production may reach 1 L per hour, leading to dehydration, hypotension, electrolyte imbalances, muscular cramping, anuria, shock, loss of consciousness, and death. Most deaths occur within the first 24 hours after presentation. Although the mortality rate for severe cholera is 50% to 70% without treatment, fluid replacement can save more than 99% of patients.

### Campylobacter *Enterocolitis*

*Campylobacter jejuni* is the most common bacterial enteric pathogen in developed countries and is an important cause of traveler's diarrhea. Most infections are associated with ingestion of improperly cooked chicken, but outbreaks also can be caused by unpasteurized milk or contaminated water.

#### PATHOGENESIS

The pathogenesis of *Campylobacter* infection remains poorly defined, but four major virulence properties contribute: motility, adherence, toxin production, and invasion. Flagella allow *Campylobacter* to be motile. This facilitates adherence and colonization, which are also necessary for mucosal invasion. Cytotoxins that cause epithelial damage and a cholera toxin–like enterotoxin are also released by some *C. jejuni* isolates. **Dysentery** generally is associated with invasion and only occurs with a small minority of *Campylobacter* strains. **Enteric fever** occurs when bacteria proliferate within the lamina propria and mesenteric lymph nodes.

*Campylobacter* infection can result in reactive arthritis, primarily in patients with HLA-B27. Other extraintestinal complications, including erythema nodosum and Guillain-Barré syndrome, a flaccid paralysis caused by autoimmune-induced inflammation of peripheral nerves, are not HLA-linked. Fortunately, Guillain-Barré syndrome develops in 0.1% or less of persons infected with *Campylobacter.*

#### MORPHOLOGY

***Campylobacter, Shigella, Salmonella,*** and many other bacterial infections, including ***Yersinia*** and ***E. coli,*** all induce a similar histopathology, termed **acute self-limited colitis,** and these pathogens cannot be reliably distinguished by tissue biopsy. Thus, specific diagnosis is primarily by stool culture. The histology of acute self-limited colitis includes prominent lamina propria and intraepithelial neutrophil infiltrates (Fig. 14–23, *A*); **cryptitis** (neutrophil infiltration of the crypts) and **crypt abscesses** (crypts with accumulations of luminal neutrophils) also may be present. The preservation of crypt architecture in most cases of acute self-limited colitis is helpful in distinguishing these infections from inflammatory bowel disease (Fig. 14–23, *B*).

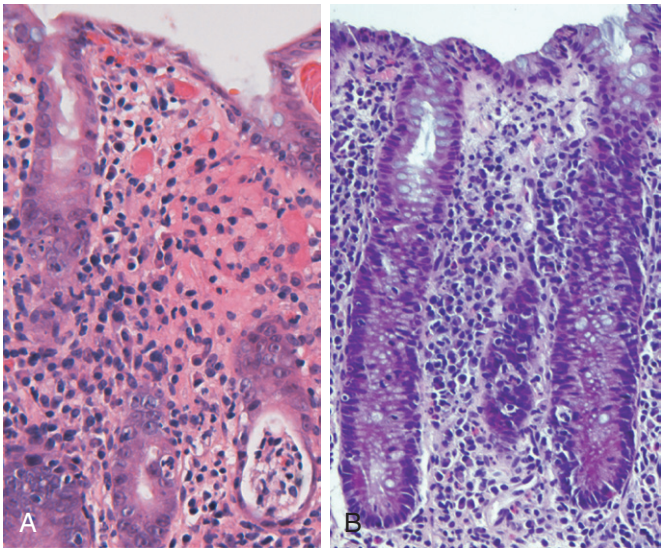

**Figure 14–23** Bacterial enterocolitis. **A,** *Campylobacter jejuni* infection produces acute, self-limited colitis. Neutrophils can be seen within surface and crypt epithelium and a crypt abscess is present at the *lower right.* **B,** Enteroinvasive *Escherichia coli* infection is similar to other acute, self-limited colitides. Note the maintenance of normal crypt architecture and spacing, despite abundant intraepithelial neutrophils.

### Clinical Features

Ingestion of as few as 500 *C. jejuni* organisms can cause disease after an incubation period of up to 8 days. Watery diarrhea, either acute or with onset after an influenza-like prodrome, is the primary manifestation, and dysentery develops in 15% to 50% of patients. Patients may shed bacteria for 1 month or more after clinical resolution. The disease is self limited and therefore antibiotic therapy generally is not required. Diagnosis is primarily by stool culture since the histologic changes are not specific for *Campylobacter* colitis.

## *Shigellosis*

*Shigella* organisms are gram-negative bacilli that are unencapsulated, nonmotile, facultative anaerobes. Although humans are the only known reservoir, *Shigella* remains one of the most common causes of bloody diarrhea. It is estimated that 165 million cases occur worldwide each year. Shigellae are highly transmissible by the fecal-oral route or through ingestion of contaminated water and food; the *infective dose is fewer than 100 organisms* and each gram of stool contains as many as $10^9$ organisms during acute phases of the disease.

In the United States and Europe, children in day care centers, migrant workers, travelers to developing countries, and residents of nursing homes are most commonly affected. Most *Shigella*-associated infections and deaths occur in children younger than 5 years of age; in countries in which *Shigella* is endemic, it is responsible for approximately 10% of all cases of pediatric diarrheal disease and as many as 75% of diarrheal deaths.

### PATHOGENESIS

*Shigella* organisms are resistant to the harsh acidic environment of the stomach, which partially explains the very low infective dose. Once in the intestine, organisms are taken up by M (microfold) epithelial cells, which are specialized for sampling and uptake of luminal antigens. After intracellular proliferation, the bacteria escape into the lamina propria. These bacteria then infect small intestinal and colonic epithelial cells through the basolateral membranes, which express bacterial receptors. Alternatively, luminal shigellae can directly modulate epithelial tight junctions to expose basolateral bacterial receptors. The latter is partly mediated by virulence proteins, some of which are directly injected into the host cytoplasm by a type III secretion system. Some *Shigella dysenteriae* serotypes also release the Shiga toxin Stx, which inhibits eukaryotic protein synthesis and causes host cell death.

### MORPHOLOGY

*Shigella* infections are most prominent in the left colon, but the ileum may also be involved, perhaps reflecting the abundance of M cells in the epithelium overlying the Peyer's patches. The histologic appearance in early cases is similar to that in other acute self-limited colitides. In more severe cases, the mucosa is hemorrhagic and ulcerated, and pseudomembranes may be present. Perhaps because of the tropism for M cells, aphthous-appearing ulcers similar to those seen in Crohn disease also may occur. The potential for confusion with chronic inflammatory bowel disease is substantial, particularly if there is distortion of crypt architecture. Confirmation of *Shigella* infection requires stool culture.

### Clinical Features

After an incubation period of 1 to 7 days, *Shigella* causes self-limited disease characterized by about 6 days of diarrhea, fever, and abdominal pain. The initially watery diarrhea progresses to a dysenteric phase in approximately 50% of patients, and constitutional symptoms can persist for as long as 1 month. A subacute presentation also can develop in a minority of adults. Antibiotic treatment shortens the clinical course and reduces the duration over which organisms are shed in the stool, but antidiarrheal medications are contraindicated because they can prolong symptoms by delaying bacterial clearance.

Complications of *Shigella* infection are uncommon and include *reactive arthritis,* a triad of sterile arthritis, urethritis, and conjunctivitis that preferentially affects HLA-B27–positive men between 20 and 40 years of age. Hemolytic uremic syndrome, which typically is associated with *enterohemorrhagic Escherichia coli* (EHEC), also may occur after infection with shigellae that secrete Shiga toxin.

## Escherichia coli

*Escherichia coli* are gram-negative bacilli that colonize the healthy GI tract; most are nonpathogenic, but a subset cause human disease. The latter are classified according to morphology, mechanism of pathogenesis, and in vitro behavior (Table 14–4). Here we summarize their pathogenic mechanisms:

- **Enterotoxigenic *E. coli* (ETEC) organisms** are the principal cause of traveler's diarrhea, and are spread by the fecal-oral route. They express a heat labile toxin (LT) that is similar to cholera toxin and a heat-stable toxin (ST) that increases intracellular cGMP with effects similar to the cAMP elevations caused by LT.
- **Enterohemorrhagic *E. coli* (EHEC) organisms** are categorized as O157:H7 and non-O157:H7 serotypes. Outbreaks of *E. coli* O157:H7 in developed countries have been associated with the consumption of inadequately cooked ground beef, milk, and vegetables. Both O157:H7 and non-O157:H7 serotypes produce Shiga-like toxins and can cause dysentery. They can also give rise to hemolytic-uremic syndrome (Chapter 13).
- **Enteroinvasive *E. coli* (EIEC) organisms** resemble *Shigella* bacteriologically but do not produce toxins. They invade the gut epithelial cells and produce a bloody diarrhea.
- **Enteroaggregative *E. coli* (EAEC) organisms** attach to enterocytes by adherence fimbriae. Although they produce LT and Shiga-like toxins, histologic damage is minimal.

## *Salmonellosis*

*Salmonella* species, which are members of the Enterobacteriaceae family of gram-negative bacilli, are divided into

*Salmonella typhi,* the causative agent of typhoid fever (discussed in the next section) and nontyphoid *Salmonella* strains that cause gastroenteritis. Nontyphoid *Salmonella* infection usually is due to *Salmonella enteritidis*; more than 1 million cases occur each year in the United States, which result in 2000 deaths; the prevalence is even greater in many other countries. Infection is most common in young children and elderly persons, with peak incidence in summer and fall. Transmission usually is through contaminated food, particularly raw or undercooked meat, poultry, eggs, and milk.

## PATHOGENESIS

Very few viable *Salmonella* organisms are necessary to cause infection, and the absence of gastric acid, as in persons with atrophic gastritis or those on acid-suppressive therapy, further reduces the required inoculum. Salmonellae possess **virulence genes that encode a type III secretion system** capable of transferring bacterial proteins into M cells and enterocytes. The transferred proteins activate host cell Rho GTPases, thereby triggering actin rearrangement and bacterial uptake into phagosomes where the bacteria can grow. Salmonellae also secrete a molecule that induces epithelial release of a chemoattractant eicosanoid that draws neutrophils into the lumen and potentiates mucosal damage. Stool cultures are essential for diagnosis.

### *Typhoid Fever*

Typhoid fever, also referred to as enteric fever, is caused by *Salmonella typhi* and *Salmonella paratyphi*. It affects up to 30 million individuals worldwide each year. Infection by *S. typhi* is more common in endemic areas, where children and adolescents are most often affected. By contrast, *S. paratyphi* predominates in travelers and those living in developed countries. Humans are the sole reservoir for *S. typhi* and *S. paratyphi* and transmission occurs from person to person or via contaminated food or water. Gallbladder colonization may be associated with gallstones and a chronic carrier state. Acute infection is associated with anorexia, abdominal pain, bloating, nausea, vomiting, and bloody diarrhea followed by a short asymptomatic phase that gives way to bacteremia and fever with flu-like symptoms. It is during this phase that detection of organisms by blood culture may prompt antibiotic treatment and prevent further disease progression. Without such treatment, the febrile phase is followed by up to 2 weeks of sustained high fevers with abdominal tenderness that may mimic appendicitis. *Rose spots*, small erythematous maculopapular lesions, are seen on the chest and abdomen. Systemic dissemination may cause *extraintestinal complications* including encephalopathy, meningitis, seizures, endocarditis, myocarditis, pneumonia, and cholecystitis. Patients with sickle cell disease are particularly susceptible to *Salmonella* osteomyelitis.

Like *S. enteritidis*, *S. typhi* and *S. paratyphi* are taken up by M cells and then engulfed by mononuclear cells in the underlying lymphoid tissue. Thus, infection causes Peyer's patches in the terminal ileum to enlarge into plateau-like elevations up to 8 cm in diameter. Mucosal shedding creates oval ulcers oriented along the long axis of the ileum. However, unlike *S. enteritidis*, *S. typhi* and *S. paratyphi* can disseminate via lymphatic and blood vessels. This causes reactive hyperplasia of draining lymph nodes, in which bacteria-containing phagocytes accumulate. In addition, the spleen is enlarged and soft with pale red pulp, obliterated follicular markings, and prominent phagocyte hyperplasia. Randomly scattered small foci of parenchymal necrosis with macrophage aggregates, termed *typhoid nodules*, are also present in the liver, bone marrow, and lymph nodes.

### *Pseudomembranous Colitis*

Pseudomembranous colitis, generally caused by *Clostridium difficile,* is also known as antibiotic-associated colitis or antibiotic-associated diarrhea. The latter terms apply to diarrhea developing during or after a course of antibiotic therapy and may be due to *C. difficile* as well as *Salmonella, C. perfringens* type A, or *S. aureus.* However, the latter two organisms produce enterotoxins and are common agents of food poisoning. They do not cause pseudomembranes. Disruption of the normal colonic microbiota by antibiotics allows *C. difficile* overgrowth. Toxins released by *C. difficile* cause the ribosylation of small GTPases, such as Rho, and lead to disruption of the epithelial cytoskeleton, tight junction barrier loss, cytokine release, and apoptosis.

## MORPHOLOGY

Fully developed *C. difficile*–associated colitis is accompanied by formation of **pseudomembranes** (Fig. 14–24, *A*), made up of an adherent layer of inflammatory cells and debris at sites of colonic mucosal injury. The surface epithelium is denuded, and the superficial lamina propria contains a dense infiltrate of neutrophils and occasional fibrin thrombi within capillaries. Damaged crypts are distended by a mucopurulent exudate that "erupts" to the surface in a fashion reminiscent of a volcano (Fig. 14–24, *B*).

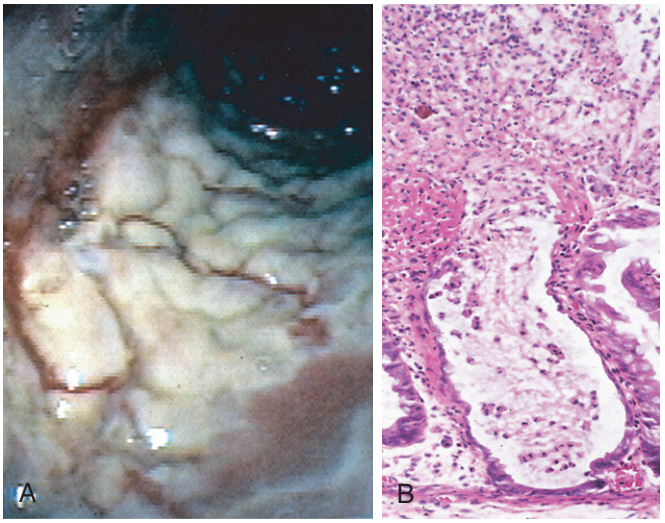

**Figure 14–24** *Clostridium difficile* colitis. **A,** The colon is coated by tan pseudomembranes composed of neutrophils, dead epithelial cells, and inflammatory debris (endoscopic view). **B,** Typical pattern of neutrophils emanating from a crypt is reminiscent of a volcanic eruption.

Clinical Features

In addition to antibiotic exposure, risk factors for *C. difficile*–associated colitis include advanced age, hospitalization, and immunosuppression. The organism is particularly prevalent in hospitals; as many as 20% of hospitalized adults are colonized with *C. difficile* (a rate 10 times higher than in the general population), but most colonized patients are free of disease. Persons with *C. difficile*–associated colitis present with fever, leukocytosis, abdominal pain, cramps, hypoalbuminemia, watery diarrhea, and dehydration. Fecal leukocytes and occult blood may be present, but grossly bloody diarrhea is rare. Diagnosis of *C. difficile*–associated colitis usually is accomplished by detection of *C. difficile* toxin, rather than culture, and is supported by the characteristic histopathologic findings. Regimens of metronidazole or vancomycin are generally effective treatments, but antibiotic-resistant and hypervirulent *C. difficile* strains are increasingly common, and the infection may recur in at-risk patients.

### *Norovirus*

Norovirus, previously known as Norwalk-like virus, is a common agent of nonbacterial infectious gastroenteritis. Norovirus causes approximately half of all gastroenteritis outbreaks worldwide and is a common cause of sporadic gastroenteritis in developed countries. Local outbreaks usually are related to contaminated food or water, but person-to-person transmission underlies most sporadic cases. Infections spread easily within schools, hospitals, and nursing homes and, most recently, on cruise ships. After a short incubation period, affected persons develop nausea, vomiting, watery diarrhea, and abdominal pain. Biopsy morphology is nonspecific. The disease is self-limited.

### *Rotavirus*

The encapsulated rotavirus infects 140 million people and causes 1 million deaths each year, making rotavirus *the most common cause of severe childhood diarrhea and diarrhea-related deaths worldwide.* Children between 6 and 24 months of age are most vulnerable. Protection in the first 6 months of life is probably due to the presence of antibodies to rotavirus in breast milk, while protection beyond 2 years is due to immunity that develops after the first infection. Outbreaks in hospitals and day care centers are common, and infection spreads easily; the estimated minimal infective inoculum is only 10 viral particles. *Rotavirus selectively infects and destroys mature (absorptive) enterocytes in the small intestine, and the villus surface is repopulated by immature secretory cells.* This change in functional capacity results in loss of absorptive function and net secretion of water and electrolytes that is compounded by an osmotic diarrhea from incompletely absorbed nutrients. Like norovirus, rotavirus produces clinically apparent infection after a short incubation period, manifested by vomiting and watery diarrhea for several days. Vaccines are now available, and their use is beginning to change the epidemiology of rotavirus infection. For unknown reasons, oral rotavirus vaccines have been less effective in developing countries where they are most needed.

### *Parasitic Disease*

Although viruses and bacteria are the predominant enteric pathogens in the United States, parasitic disease and protozoal infections affect over half of the world's population on a chronic or recurrent basis. The small intestine can harbor as many as 20 species of parasites, including nematodes, such as the roundworms *Ascaris* and *Strongyloides*; hookworms and pinworms; cestodes, including flatworms and tapeworms; trematodes, or flukes; and protozoa.

- *Ascaris lumbricoides.* This nematode infects more than 1 billion people worldwide as a result of human fecal-oral contamination. Ingested eggs hatch in the intestine and larvae penetrate the intestinal mucosa. From here the larvae migrate via the splanchnic circulation to the liver, creating hepatic abscesses, and then through the systemic circulation to the lung, where they can cause *Ascaris* pneumonitis. In the latter case, larvae migrate up the trachea, are swallowed, and arrive again in the intestine to mature into adult worms.
- *Strongyloides.* The larvae of *Strongyloides* live in fecally contaminated ground soil and can penetrate unbroken skin. They migrate through the lungs to the trachea from where they are swallowed and then mature into adult worms in the intestines. Unlike other intestinal worms, which require an ovum or larval stage outside the human, the eggs of *Strongyloides* can hatch within the intestine and release larvae that penetrate the mucosa, creating a vicious cycle referred to as autoinfection. Hence, *Strongyloides* infection can persist for life, and immunosuppressed individuals can develop overwhelming infections.
- *Necator americanus* and *Ancylostoma duodenale.* These hookworms infect 1 billion people worldwide and cause significant morbidity. Infection is initiated by larval penetration through the skin. After further development in the lungs, the larvae migrate up the trachea and are swallowed. Once in the duodenum, the larvae mature and the adult worms attach to the mucosa, suck blood, and reproduce. Hookworms are the leading cause of iron deficiency anemia in the developing world.
- *Giardia lamblia.* This flagellated protozoan, also referred to as *Giardia duodenalis* or *Giardia intestinalis*, is responsible for the *most common pathogenic parasitic infection in humans* and is spread by fecally contaminated water or food. Infection may occur after ingestion of as few as 10 cysts. Because cysts are resistant to chlorine, *Giardia* organisms are endemic in unfiltered public and rural water supplies. In the acid environment of the stomach excystation occurs and trophozoites are released. Secretory IgA and mucosal IL-6 responses are important for clearance of *Giardia* infections, and immunosuppressed, agammaglobulinemic, or malnourished persons often are severely affected. *Giardia* evade immune clearance through continuous modification of the major surface antigen, variant surface protein, and can persist for months or years while causing intermittent symptoms. *Giardia* infection decreases the expression of brush border enzymes, including lactase, and causes microvillous damage and apoptosis of small intestinal epithelial cells. *Giardia* trophozoites are noninvasive and can be identified in duodenal biopsy specimens by their

characteristic pear shape. Giardiasis is clinically characterized by acute or chronic diarrhea and can result in malabsorption.

## SUMMARY

### Infectious Enterocolitis

- *Vibrio cholerae* secretes a pre-formed toxin that causes massive chloride secretion. Water follows the resulting osmotic gradient, leading to *secretory diarrhea.*
- *Campylobacter jejuni* is the most common bacterial enteric pathogen in developed countries and also causes traveler's diarrhea. Most isolates are noninvasive. *Salmonella* and *Shigella* spp. are invasive and associated with exudative bloody diarrhea (dysentery). *Salmonella* infection is a common cause of food poisoning. *S. typhi* can cause systemic disease (typhoid fever).
- Pseudomembranous colitis is often triggered by antibiotic therapy that disrupts the normal microbiota and allows *C. difficile* to colonize and grow. The organism releases toxins that disrupt epithelial function. The associated inflammatory response includes characteristic volcano-like eruptions of neutrophils from colonic crypts that spread to form mucopurulent pseudomembranes.
- *Rotavirus* is the most common cause of severe childhood diarrhea and diarrheal mortality worldwide. The diarrhea is secondary to loss of mature enterocytes, resulting in malabsorption as well as secretion.
- *Parasitic* and *protozoal* infections affect over half of the world's population on a chronic or recurrent basis.

# INFLAMMATORY INTESTINAL DISEASE

## Sigmoid Diverticulitis

In general, diverticular disease refers to acquired pseudodiverticular outpouchings of the colonic mucosa and submucosa. Such *colonic diverticula* are rare in persons younger than 30 years of age, but the prevalence approaches 50% in Western adult populations beyond the age of 60. Diverticula generally are multiple, and the condition is referred to as *diverticulosis.* This disease is much less common in Japan and nonindustrialized countries, probably because of dietary differences.

### PATHOGENESIS

Colonic diverticula tend to develop under conditions of elevated intraluminal pressure in the sigmoid colon. This is facilitated by the unique structure of the colonic muscularis propria, where nerves, arterial vasa recta, and their connective tissue sheaths penetrate the inner circular muscle coat to create discontinuities in the muscle wall. In other parts of the intestine, these gaps are reinforced by the external longitudinal layer of the muscularis propria, but in the colon, this muscle layer is discontinuous, being gathered into the three bands termed **taeniae coli.** High luminal pressures may be generated by exaggerated peristaltic contractions, with spasmodic sequestration of bowel segments that may be exacerbated by diets low in fiber, which reduce stool bulk.

### MORPHOLOGY

Anatomically, colonic diverticula are small, flask-like outpouchings, usually 0.5 to 1 cm in diameter, that occur in a regular distribution in between the taeniae coli (Fig. 14–25, *A*). They are most common in the sigmoid colon, but other regions of the colon may be affected in severe cases. Because diverticula are compressible, easily emptied of fecal contents, and often surrounded by the fat-containing **epiploic appendices** on the surface of the colon, they may be missed on casual inspection. Colonic diverticula have a thin wall composed of a flattened or atrophic mucosa, compressed submucosa, and attenuated muscularis propria—often, this last component is totally absent (Fig. 14–30, *B* and *C*). Hypertrophy of the circular layer of the muscularis propria in the affected bowel segment is common. Obstruction of diverticula leads to inflammatory changes, producing **diverticulitis** and peridiverticulitis. Because the wall of the diverticulum is supported only by the muscularis mucosa and a thin layer of subserosal adipose tissue, inflammation and increased pressure within an obstructed diverticulum can lead to **perforation.** With or without perforation, recurrent diverticulitis may cause segmental colitis, fibrotic thickening in and around the colonic wall, or stricture formation. Perforation can lead to formation of pericolonic abscesses, development of sinus tracts, and, occasionally, peritonitis.

#### Clinical Features

Most persons with diverticular disease remain asymptomatic throughout their lives. About 20% of those affected develop complaints including intermittent cramping, continuous lower abdominal discomfort, constipation, and

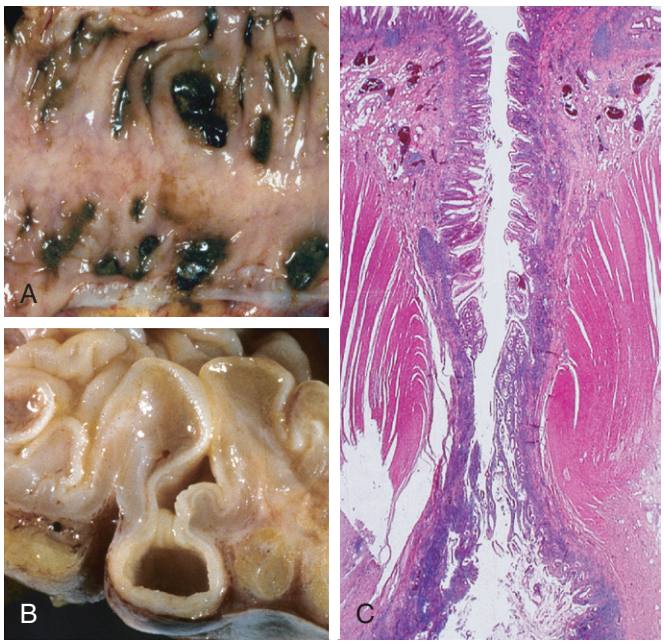

**Figure 14–25** Sigmoid diverticular disease. **A,** Stool-filled diverticula are regularly arranged. **B,** Cross-section showing the outpouching of mucosa beneath the muscularis propria. **C,** Low-power photomicrograph of a sigmoid diverticulum showing protrusion of the mucosa and submucosa through the muscularis propria.

diarrhea. Longitudinal studies have shown that while diverticula can regress early in their development they often become more numerous and larger over time. Whether a high-fiber diet prevents such progression or protects against diverticulitis is unclear. Even when diverticulitis occurs, it most often resolves spontaneously or after antibiotic treatment, and relatively few patients require surgical intervention.

## SUMMARY

### Sigmoid Diverticulitis

- *Diverticular disease* of the sigmoid colon is common in Western populations over the age of 60. Contributing etiologic factors include low-fiber diets, colonic spasm, and the unique anatomy of the colon. Inflammation of diverticula, *diverticulitis*, affects a minority of persons with *diverticulosis* but can cause perforation in its most severe form.

## Inflammatory Bowel Disease

*Inflammatory bowel disease* (IBD) is a chronic condition resulting from inappropriate mucosal immune activation. IBD encompasses two major entities, *Crohn disease* and *ulcerative colitis*. The distinction between ulcerative colitis and Crohn disease is based, in large part, on the distribution of affected sites and the morphologic expression of disease at those sites (Fig. 14–26; Table 14–5). *Ulcerative colitis is limited to the colon and rectum and extends only into the mucosa and submucosa.* By contrast, *Crohn disease, which also has been referred to as regional enteritis (because of frequent ileal involvement), may involve any area of the gastrointestinal tract and frequently is transmural.*

**Table 14–5** Features That Differ Between Crohn Disease and Ulcerative Colitis

| Feature | Crohn Disease | Ulcerative Colitis |
|---|---|---|
| **Macroscopic** | | |
| Bowel region affected | Ileum ± colon | Colon only |
| Rectal involvement | Sometimes | Always |
| Distribution | Skip lesions | Diffuse |
| Stricture | Yes | Rare |
| Bowel wall appearance | Thick | Thin |
| Inflammation | Transmural | Limited to mucosa and submucosa |
| Pseudopolyps | Moderate | Marked |
| Ulcers | Deep, knifelike | Superficial, broad-based |
| Lymphoid reaction | Marked | Moderate |
| Fibrosis | Marked | Mild to none |
| Serositis | Marked | No |
| Granulomas | Yes (~35%) | No |
| Fistulas/sinuses | Yes | No |
| **Clinical** | | |
| Perianal fistula | Yes (in colonic disease) | No |
| Fat/vitamin malabsorption | Yes | No |
| Malignant potential | With colonic involvement | Yes |
| Recurrence after surgery | Common | No |
| Toxic megacolon | No | Yes |

NOTE: Not all features may be present in a single case.

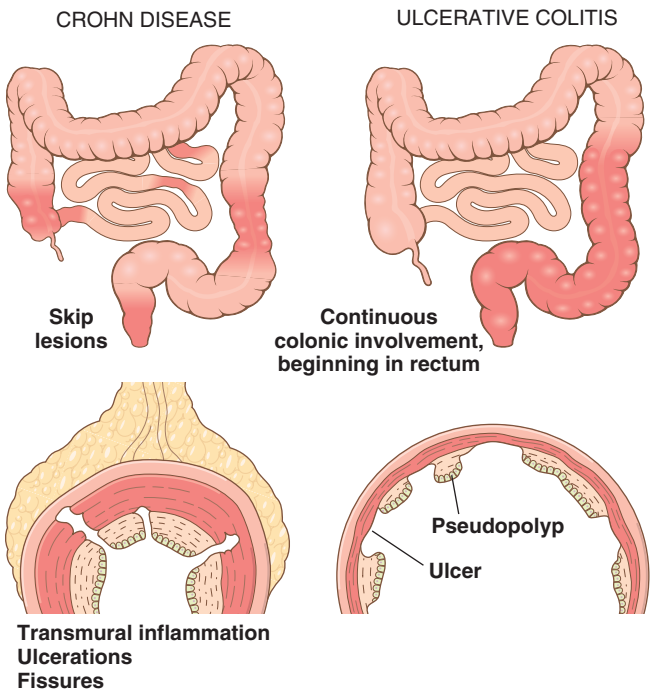

**Figure 14–26** Distribution of lesions in inflammatory bowel disease. The distinction between Crohn disease and ulcerative colitis is based primarily on morphology.

### Epidemiology

Both Crohn disease and ulcerative colitis are more common in females and frequently present during adolescence or in young adults. In Western industrialized nations, IBD is most common among whites and, in the United States, occurs 3 to 5 times more often among eastern European (Ashkenazi) Jews. This predilection is at least partly due to genetic factors, as discussed next under "Pathogenesis." The geographic distribution of IBD is highly variable, but it is most prevalent in North America, northern Europe, and Australia. IBD incidence worldwide is on the rise and is becoming more common in regions in which the prevalence was historically low. The *hygiene hypothesis* suggests that these changes in incidence are related to improved food storage conditions and decreased food contamination. Specifically, it proposes that a reduced frequency of enteric infections due to improved hygiene has resulted in inadequate development of regulatory processes that limit mucosal immune responses early in life. As a result, exposure of susceptible individuals to normally innocuous microbes later in life triggers inappropriate immune responses that may be self-sustaining due to loss of intestinal epithelial barrier function. Although many details are

lacking, some data, including some from animal models and the observation in humans that an episode of acute infectious gastroenteritis increases the risk of developing IBD, are consistent with the hygiene hypothesis.

## PATHOGENESIS

The cause(s) of IBD remains uncertain. However, **most investigators believe that IBD results from a combination of errant host interactions with intestinal microbiota, intestinal epithelial dysfunction, and aberrant mucosal immune responses.** This view is supported by epidemiologic, genetic, and clinical studies as well as data from laboratory models of IBD (Fig. 14–27).

- **Genetics.** Risk of disease is increased when there is an affected family member, and in Crohn disease, the concordance rate for monozygotic twins is approximately 50%. By contrast, concordance of monozygotic twins for ulcerative colitis is only 16%, suggesting that genetic factors are less dominant in this form of IBD.

  Molecular linkage analyses of affected families have identified *NOD2* (nucleotide oligomerization binding domain 2) as a susceptibility gene in Crohn disease. *NOD2* encodes a protein that binds to intracellular bacterial peptidoglycans and subsequently activates NF-κB. It has been postulated that disease-associated *NOD2* variants are less effective at recognizing and combating luminal microbes, which are then able to enter the lamina propria and trigger inflammatory reactions. Other data suggest that *NOD2* may regulate immune responses to prevent excessive activation by luminal microbes. Whatever the mechanism by which *NOD2* polymorphisms contribute to the pathogenesis of Crohn disease, it should be recognized that disease develops in less than 10% of persons carrying *NOD2* mutations, and *NOD2* mutations are uncommon in African and Asian patients with Crohn disease.

  In recent years, genome-wide association studies (GWAS) that assess single-nucleotide polymorphisms have been used to broaden the search for IBD-associated genes. The number of genes identified by GWAS is increasing rapidly (already numbering more than 30), but along with *NOD2*, two Crohn disease–related genes of particular interest are *ATG16L1* (autophagy-related 16–like-1), a part of the autophagosome pathway that is critical to host cell responses to intracellular bacteria, and *IRGM* (immunity-related GTPase M), which also is involved in autophagy and clearance of intracellular bacteria. *NOD2, ATG16L1,* and *IRGM* are expressed in multiple cell types, and their precise roles in the pathogenesis of Crohn disease have yet to be defined. Like *NOD2,* however, *ATG16L1* and *IRGM* are related to recognition and response to intracellular pathogens, supporting the hypothesis that inappropriate immune reactions to luminal bacteria are important in pathogenesis of IBD. None of these genes are associated with ulcerative colitis.
- **Mucosal immune responses.** Although the mechanisms by which mucosal immunity contributes to the pathogenesis of ulcerative colitis and Crohn disease are still being deciphered, immunosuppressive and immunomodulatory agents remain mainstays of IBD therapy. Polarization of helper T cells to the $T_H1$ type is well recognized in Crohn disease, and emerging data suggest that $T_H17$ T cells also contribute to disease pathogenesis. Consistent with this, certain polymorphisms of the IL-23 receptor confer protection from Crohn disease and ulcerative colitis (IL-23 is involved in the development and maintenance of $T_H17$ cells). The protection afforded by IL-23 receptor polymorphisms, together with the recognized effectiveness of anti-TNF therapy in some patients with ulcerative colitis, seems to support roles for $T_H1$ and $T_H17$ cells.

  Some data suggest that the pathogenic immune response in ulcerative colitis includes a significant $T_H2$ component. For example, mucosal IL-13 production is increased in ulcerative colitis, and, to a lesser degree, Crohn disease. However, the pathogenic role of $T_H2$ cells in IBD pathogenesis remains controversial. Polymorphisms of the *IL-10* gene as well as *IL-10R,* the IL10 receptor gene, have been linked to ulcerative colitis but not Crohn disease, further emphasizing the importance of immunoregulatory signals in IBD pathogenesis.

  Overall, it is likely that some combination of derangements that activate mucosal immunity and suppress immunoregulation contribute to the development of both ulcerative colitis and Crohn disease. The relative roles of the innate and adaptive arms of the immune system are the subject of ongoing intense scrutiny.
- **Epithelial defects.** A variety of epithelial defects have been described in Crohn disease, ulcerative colitis, or both. For example, defects in intestinal epithelial tight junction barrier function are present in patients with Crohn disease and a subset of their healthy first-degree relatives. This barrier dysfunction cosegregates with specific disease-associated *NOD2* polymorphisms, and experimental models demonstrate that barrier dysfunction can activate

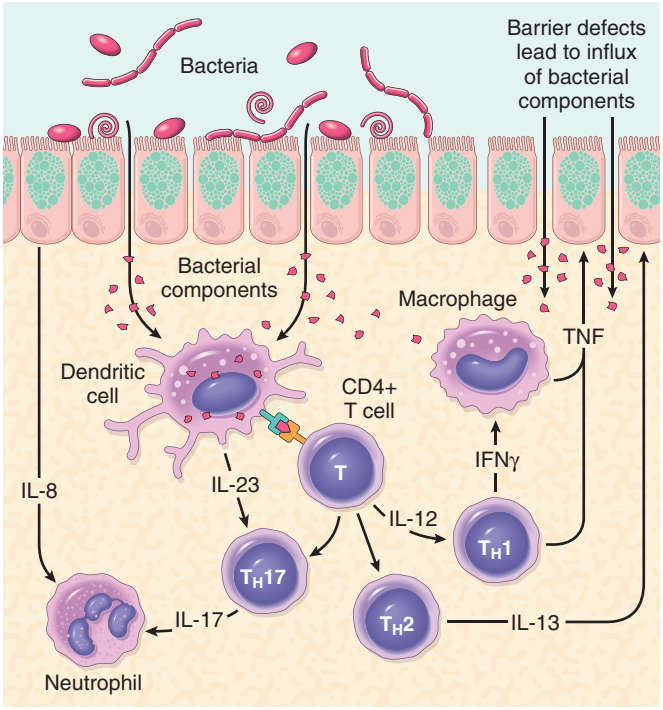

**Figure 14–27** A model of pathogenesis of inflammatory bowel disease (IBD). Aspects of both Crohn disease and ulcerative colitis are shown.

innate and adaptive mucosal immunity and sensitize subjects to disease. Interestingly, the Paneth cell granules, which contain antimicrobial peptides that can affect composition of the luminal microbiota, are abnormal in patients with Crohn disease carrying *ATG16L1* mutations, thus providing one potential mechanism where a defective feedback loop between the epithelium and microbiota could contribute to disease pathogenesis.

- **Microbiota.** The quantity of microbial organisms in the gastrointestinal lumen is enormous, amounting to as many as $10^{12}$ organisms/mL of fecal material in the colon (50% of fecal mass). This abundance means that, on a per cell level, we are only about 10% human. There is significant inter-individual variation in the composition of this microbial population, which is modified by diet and disease. Despite a growing body of data that suggest that intestinal microbiota contribute to IBD pathogenesis, their precise role remains to be defined. In keeping with this, some antibiotics, such as metronidazole, can be helpful in maintenance of remission in Crohn disease. Ongoing studies suggest that ill-defined mixtures containing probiotic, or beneficial, bacteria also may combat disease in experimental models, as well as in some patients with IBD, although the mechanisms responsible are not well understood.

One model that unifies the roles of intestinal microbiota, epithelial function, and mucosal immunity suggests a cycle by which transepithelial flux of luminal bacterial components activates innate and adaptive immune responses. In a genetically susceptible host, the subsequent release of TNF and other immune-mediated signals direct epithelia to increase tight junction permeability, which further increases the flux of luminal material. These events may establish a self-amplifying cycle in which a stimulus at any site may be sufficient to initiate IBD. Although this model is helpful in advancing the current understanding of IBD pathogenesis, a variety of factors are associated with disease for unknown reasons. For example, a single episode of appendicitis is associated with reduced risk of developing ulcerative colitis. Tobacco use also modifies the risk of IBD. Somewhat surprisingly, the risk of Crohn disease is increased by smoking, whereas that of ulcerative colitis is reduced.

### *Crohn Disease*

Crohn disease, also known as regional enteritis, may occur in any area of the gastrointestinal tract.

#### MORPHOLOGY

The most common sites involved by Crohn disease at presentation are the **terminal ileum, ileocecal valve,** and **cecum.** Disease is limited to the small intestine alone in about 40% of cases; the small intestine and the colon both are involved in 30% of patients; and the remainder of cases are characterized by colonic involvement only. The presence of multiple, separate, sharply delineated areas of disease, resulting in **skip lesions,** is characteristic of Crohn disease and may help in differentiation from ulcerative colitis. Strictures are common (Fig. 14–28, *A*).

The earliest lesion, the **aphthous ulcer,** may progress, and multiple lesions often coalesce into elongated, serpentine ulcers oriented along the axis of the bowel. Edema and loss of normal mucosal folds are common. Sparing of interspersed mucosa results in a coarsely textured, **cobblestone** appearance in which diseased tissue is depressed below the level of normal mucosa (Fig. 14–28, *B*). **Fissures** frequently develop between mucosal folds and may extend deeply to become sites of perforation or fistula tracts. The intestinal wall is thickened as a consequence of transmural edema, inflammation, submucosal fibrosis, and hypertrophy of the muscularis propria, all of which contribute to stricture formation. In cases with extensive transmural disease, mesenteric fat frequently extends around the serosal surface **(creeping fat)** (Fig. 14–28, *C*).

The microscopic features of active Crohn disease include abundant neutrophils that infiltrate and damage crypt epithelium. Clusters of neutrophils within a crypt are referred to as a **crypt abscess** and often are associated with crypt destruction. Ulceration is common in Crohn disease, and there may be an abrupt transition between ulcerated and normal mucosa. Repeated cycles of crypt destruction and regeneration lead to **distortion of mucosal architecture;** the normally straight and parallel crypts take on bizarre branching shapes and unusual orientations to one another (Fig. 14–29,

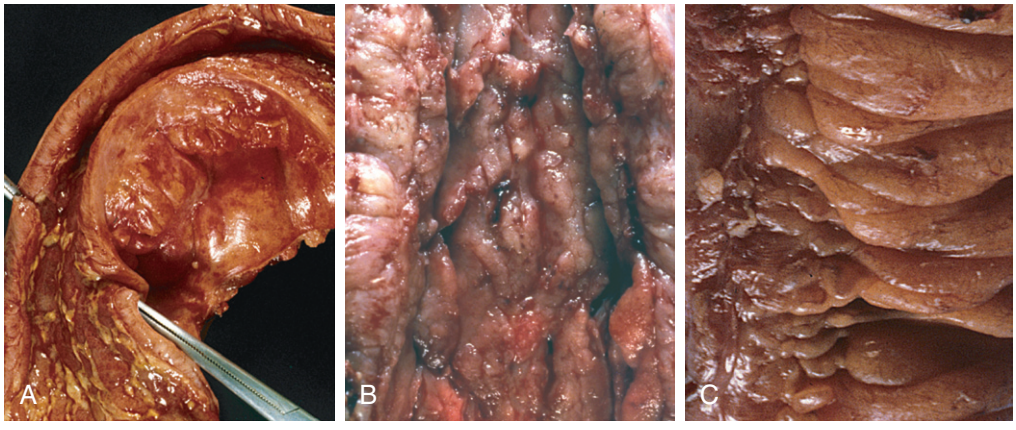

**Figure 14–28** Gross pathology of Crohn disease. **A,** Small intestinal stricture. **B,** Linear mucosal ulcers and thickened intestinal wall. **C,** Creeping fat.

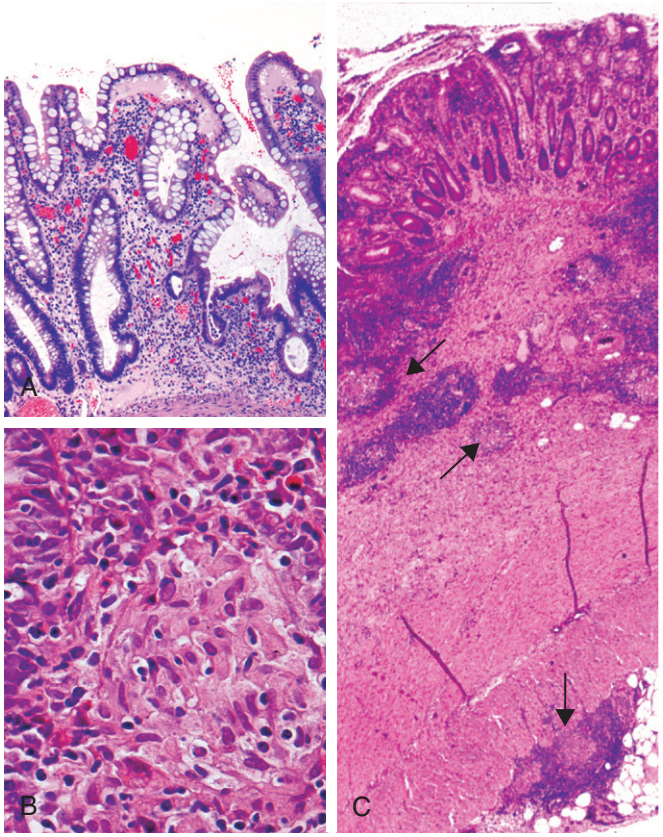

**Figure 14–29** Microscopic pathology of Crohn disease. **A,** Haphazard crypt organization results from repeated injury and regeneration. **B,** Noncaseating granuloma. **C,** Transmural Crohn disease with submucosal and serosal granulomas (*arrows*).

*A*). Epithelial metaplasia, another consequence of chronic relapsing injury, often takes the form of gastric antral-appearing glands (pseudopyloric metaplasia). **Paneth cell metaplasia** also may occur in the left colon, where Paneth cells normally are absent. These architectural and metaplastic changes may persist even when active inflammation has resolved. Mucosal atrophy, with loss of crypts, may result after years of disease. **Noncaseating granulomas** (Fig. 14–29, *B*), a hallmark of Crohn disease, are found in approximately 35% of cases and may arise in areas of active disease or uninvolved regions in any layer of the intestinal wall (Fig. 14–29, *C*). Granulomas also may be found in mesenteric lymph nodes. Cutaneous granulomas form nodules that are referred to (misleadingly) as **metastatic Crohn disease. The absence of granulomas does not preclude a diagnosis of Crohn disease.**

### Clinical Features

The clinical manifestations of Crohn disease are extremely variable. *In most patients, disease begins with intermittent attacks of relatively mild diarrhea, fever, and abdominal pain.* Approximately 20% of patients present acutely with right lower quadrant pain, fever, and bloody diarrhea that may mimic acute appendicitis or bowel perforation. Periods of active disease typically are interrupted by asymptomatic intervals that last for weeks to many months. Disease reactivation can be associated with a variety of external triggers, including physical or emotional stress, specific dietary items, and cigarette smoking.

Iron deficiency anemia may develop in persons with colonic disease, while extensive small bowel disease may result in serum protein loss and hypoalbuminemia, generalized nutrient malabsorption, or malabsorption of vitamin $B_{12}$ and bile salts. Fibrosing strictures, particularly of the terminal ileum, are common and require surgical resection. Disease often recurs at the site of anastomosis, and as many as 40% of patients require additional resections within 10 years. Fistulas develop between loops of bowel and may also involve the urinary bladder, vagina, and abdominal or perianal skin. Perforations and peritoneal abscesses are common.

Extraintestinal manifestations of Crohn disease include uveitis, migratory polyarthritis, sacroiliitis, ankylosing spondylitis, erythema nodosum, and clubbing of the fingertips, any of which may develop before intestinal disease is recognized. Pericholangitis and primary sclerosing cholangitis also occur in Crohn disease but are more common in ulcerative colitis. As discussed later on, risk of colonic adenocarcinoma is increased in patients with long-standing colonic Crohn disease.

## *Ulcerative Colitis*

Ulcerative colitis is closely related to Crohn disease. However, ulcerative colitis is limited to the colon and rectum. Some extraintestinal manifestations of ulcerative colitis overlap with those of Crohn disease, including migratory polyarthritis, sacroiliitis, ankylosing spondylitis, uveitis, skin lesions, pericholangitis, and primary sclerosing cholangitis.

### MORPHOLOGY

Ulcerative colitis always involves the rectum and extends proximally in a continuous fashion to involve part or all of the colon. Skip lesions are not seen (although focal appendiceal or cecal inflammation occasionally may be present). Disease of the entire colon is termed **pancolitis** (Fig. 14–30, *A*). Disease limited to the rectum or rectosigmoid may be referred to descriptively as **ulcerative proctitis** or **ulcerative proctosigmoiditis.** The small intestine is normal, although mild mucosal inflammation of the distal ileum, **backwash ileitis,** may be present in severe cases of pancolitis.

On gross evaluation, involved colonic mucosa may be slightly red and granular-appearing or exhibit extensive **broad-based ulcers.** The transition between diseased and uninvolved colon can be abrupt (Fig. 14–30, *B*). Ulcers are aligned along the long axis of the colon but typically do not replicate the serpentine ulcers of Crohn disease. Isolated islands of regenerating mucosa often bulge into the lumen to create small elevations, termed **pseudopolyps.** Chronic disease may lead to **mucosal atrophy** and a flat, smooth mucosal surface lacking normal folds. Unlike in Crohn disease, **mural thickening is absent, the serosal surface is normal, and strictures do not occur.** However, inflammation and inflammatory mediators can damage the muscularis propria and disturb neuromuscular function leading to

colonic dilation and **toxic megacolon,** which carries a significant risk of perforation.

Histologic features of mucosal disease in ulcerative colitis are similar to those in colonic Crohn disease and include inflammatory infiltrates, crypt abscesses, crypt distortion, and epithelial metaplasia. However, **skip lesions are absent and inflammation generally is limited to the mucosa and superficial submucosa** (Fig. 14–30, *C*). In severe cases, mucosal damage may be accompanied by ulcers that extend more deeply into the submucosa, but the muscularis propria is rarely involved. Submucosal fibrosis, mucosal atrophy, and distorted mucosal architecture remain as residua of healed disease, but the histologic pattern also may revert to near normal after prolonged remission. **Granulomas are not present.**

### Clinical Features

Ulcerative colitis is a relapsing disorder characterized by attacks of bloody diarrhea with expulsion of stringy, mucoid material and lower abdominal pain and cramps that are temporarily relieved by defecation. These symptoms may persist for days, weeks, or months before they subside, and occasionally the initial attack may be severe enough to constitute a medical or surgical emergency. More than half of the patients have mild disease, and almost all experience at least one relapse during a 10-year period. Colectomy cures intestinal disease, but extraintestinal manifestations may persist.

The factors that trigger ulcerative colitis are not known, but as noted previously, infectious enteritis precedes disease onset in some cases. In other cases the first attack is preceded by psychologic stress, which also may be linked to relapse during remission. The initial onset of symptoms also has been reported to occur shortly after smoking cessation in some patients, and smoking may partially relieve symptoms. Unfortunately, studies of nicotine as a therapeutic agent have been disappointing.

### *Indeterminate Colitis*

Histopathologic and clinical overlap between ulcerative colitis and Crohn disease is common, and it is not possible to make a distinction in up to 10% of patients with IBD. In such cases, termed *indeterminate colitis,* the small bowel is not involved, and the continuous pattern of colonic disease typically would indicate ulcerative colitis. However, patchy disease, fissures, a family history of Crohn disease, perianal lesions, onset after initiation of cigarette smoking, or findings that are not typical of ulcerative colitis may create uncertainty. Because of extensive overlap in medical management of ulcerative colitis and Crohn disease, patients carrying a diagnosis of indeterminate colitis can be treated effectively. Nevertheless, it is preferable, when possible, to definitively categorize patients, because evolving medical therapies and surgical management differ for ulcerative colitis and for Crohn disease.

### *Colitis-Associated Neoplasia*

*One of the most feared long-term complications of ulcerative colitis and colonic Crohn disease is the development of neoplasia.* This process begins as dysplasia, which, just as in Barrett esophagus and chronic gastritis, is a step along the road to full-blown carcinoma. The risk of dysplasia is related to several factors:

- Risk increases sharply 8 to 10 years after disease initiation.
- Patients with pancolitis are at greater risk than those with only left-sided disease.
- Greater frequency and severity of active inflammation (characterized by the presence of neutrophils) may increase risk. This is another example of the enabling effect of inflammation on carcinogenesis (Chapter 5).

To facilitate early detection of neoplasia, patients typically are enrolled in surveillance programs approximately 8 years after diagnosis of IBD. The primary exception to this approach is in patients with primary sclerosing cholangitis,

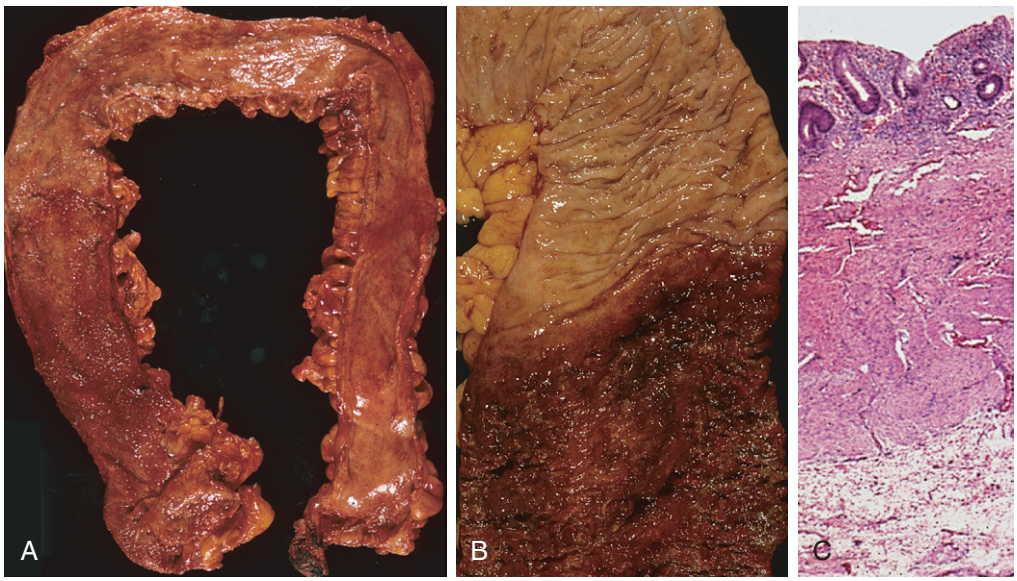

**Figure 14–30** Pathology of ulcerative colitis. **A,** Total colectomy with pancolitis showing active disease, with red, granular mucosa in the cecum (*left*) and smooth, atrophic mucosa distally (*right*). **B,** Sharp demarcation between active ulcerative colitis (*bottom*) and normal (*top*). **C,** This full-thickness histologic section shows that disease is limited to the mucosa. Compare with Figure 14–28, C.

who are at markedly greater risk for development of dysplasia and generally are enrolled for surveillance at the time of diagnosis. Surveillance requires regular and extensive mucosal biopsy, making it a costly practice. In many cases, dysplasia occurs in flat areas of mucosa that are not recognized as abnormal on gross evaluation. Thus, advanced endoscopic imaging techniques are beginning to be used experimentally to increase sensitivity of detection in normal-looking tissue.

IBD-associated dysplasia is classified histologically as low-grade or high-grade. High-grade dysplasia can be associated with invasive carcinoma at the same site or elsewhere in the colon and therefore often prompts colectomy, particularly when the changes are multifocal. Low-grade dysplasia may be treated with colectomy or monitored closely, depending on a variety of clinical factors. Colonic adenomas (discussed later on) also occur in patients with IBD, and in some cases these may be difficult to differentiate from a polypoid focus of IBD-associated dysplasia.

### SUMMARY

#### Inflammatory Bowel Disease

- Inflammatory bowel disease (IBD) is an umbrella term for Crohn disease and ulcerative colitis.
- Crohn disease most commonly affects the terminal ileum and cecum, but any site within the gastrointestinal tract can be involved; skip lesions and noncaseating granulomas are common.
- Ulcerative colitis is limited to the colon, is continuous from the rectum, and ranges in extent from only rectal disease to pancolitis; neither skip lesions nor granulomas are present.
- Both Crohn disease and ulcerative colitis can have extraintestinal manifestations.
- The risk of colonic epithelial dysplasia and adenocarcinoma is increased in patients who have had IBD for more than 8 to 10 years.

## COLONIC POLYPS AND NEOPLASTIC DISEASE

Polyps are most common in the colon but may occur in the esophagus, stomach, or small intestine. Those without stalks are referred to as *sessile.* As sessile polyps enlarge, proliferation of cells adjacent to the polyp and the effects of traction on the luminal protrusion, may combine to create a stalk. Polyps with stalks are termed *pedunculated.* In general, intestinal polyps can be classified as non-neoplastic or neoplastic. The most common neoplastic polyp is the adenoma, which has the potential to progress to cancer. Non-neoplastic colonic polyps can be further classified as inflammatory, hamartomatous, or hyperplastic.

### Inflammatory Polyps

The polyp that forms as part of the *solitary rectal ulcer syndrome* is an example of the purely inflammatory lesion. Patients present with the clinical triad of rectal bleeding, mucus discharge, and an inflammatory lesion of the anterior rectal wall. The underlying cause is impaired relaxation of the anorectal sphincter, creating a sharp angle at the anterior rectal shelf. This leads to recurrent abrasion and ulceration of the overlying rectal mucosa. Chronic cycles of injury and healing produce a polypoid mass made up of inflamed and reactive mucosal tissue.

### Hamartomatous Polyps

Hamartomatous polyps occur sporadically and as components of various genetically determined or acquired syndromes (Table 14–6). As described previously, hamartomas are disorganized, tumor-like growths composed of mature cell types normally present at the site at which the polyp develops. Hamartomatous polyposis syndromes are rare, but they are important to recognize because of associated intestinal and extraintestinal manifestations and the need to screen family members.

#### *Juvenile Polyps*

*Juvenile polyps* are the most common type of hamartomatous polyp. They may be *sporadic or syndromic.* In adults, the sporadic form sometimes is also referred to as an *inflammatory polyp,* particularly when dense inflammatory infiltrates are present. The vast majority of juvenile polyps occur in children younger than 5 years of age. *Juvenile polyps characteristically are located in the rectum,* and most manifest with rectal bleeding. In some cases, prolapse occurs and the polyp protrudes through the anal sphincter. Sporadic juvenile polyps are usually solitary but in persons with the autosomal dominant syndrome of juvenile polyposis the number varies from 3 to as many as 100. Colectomy may be required to limit the hemorrhage associated with polyp ulceration in juvenile polyposis. Dysplasia occurs in a small proportion of (mostly syndrome-associated) juvenile polyps, and the juvenile polyposis syndrome is associated with increased risk for the development of colonic adenocarcinoma.

### MORPHOLOGY

Individual sporadic and syndromic juvenile polyps often are indistinguishable. They typically are pedunculated, smooth-surfaced, reddish lesions that are less than 3 cm in diameter and display characteristic cystic spaces on cut sections. Microscopic examination shows the spaces to be dilated glands filled with mucin and inflammatory debris (Fig. 14–31, *A*). Some data suggest that mucosal hyperplasia is the initiating event in polyp development, and this mechanism is consistent with the discovery that mutations in pathways that regulate cellular growth, such as transforming growth factor-β (TGF-β) signaling, are associated with autosomal dominant juvenile polyposis.

#### *Peutz-Jeghers Syndrome*

Peutz-Jeghers syndrome is a rare autosomal dominant disorder defined by the presence of multiple gastrointestinal

**Table 14–6** Gastrointestinal (GI) Polyposis Syndromes

| Syndrome | Mean Age at Presentation (years) | Mutated Gene(s) | GI Lesions | Selected Extragastrointestinal Manifestations |
|---|---|---|---|---|
| Peutz-Jeghers syndrome | 10–15 | *LKB1/STK11* | Arborizing polyps—small intestine > colon > stomach; colonic adenocarcinoma | Mucocutaneous pigmentation; increased risk of thyroid, breast, lung, pancreas, gonadal, and bladder cancers |
| Juvenile polyposis | <5 | *SMAD4, BMPR1A* | Juvenile polyps; increased risk of gastric, small intestinal, colonic, and pancreatic adenocarcinoma | Pulmonary arteriovenous malformations, digital clubbing |
| Cowden syndrome, Bannayan-Ruvalcaba-Riley syndrome | <15 | *PTEN* | Hamartomatous polyps, lipomas, ganglioneuromas, inflammatory polyps; increased risk of colon cancer | Benign skin tumors, benign and malignant thyroid and breast lesions |
| Cronkhite-Canada syndrome | >50 | Nonhereditary | Hamartomatous colon polyps, crypt dilatation and edema in nonpolypoid mucosa | Nail atrophy, hair loss, abnormal skin pigmentation, cachexia, anemia |
| Tuberous sclerosis | Infancy to adulthood | *TSC1, TSC2* | Hamartomatous polyps (rectal) | Facial angiofibroma, cortical tubers, renal angiomyolipoma |
| Familial adenomatous polyposis (FAP) | | | | |
| Classic FAP | 10–15 | *APC, MUTYH* | Multiple adenomas | Congenital RPE hypertrophy |
| Attenuated FAP | 40–50 | *APC, MUTYH* | Multiple adenomas | |
| Gardner syndrome | 10–15 | *APC, MUTYH* | Multiple adenomas | Osteomas, desmoids, skin cysts |
| Turcot syndrome | 10–15 | *APC, MUTYH* | Multiple adenomas | CNS tumors, medulloblastoma |

CNS, central nervous system; RPE, retinal pigment epithelium.

hamartomatous polyps and mucocutaneous hyperpigmentation that carries an increased risk of several malignancies, including cancers of the colon, pancreas, breast, lung, ovaries, uterus, and testes, as well as other unusual neoplasms. Germ line heterozygous loss-of-function mutations in the gene *LKB1/STK11* are present in approximately half of the patients with the familial form of Peutz-Jeghers syndrome, as well as a subset of patients with the sporadic form. Intestinal polyps are most common in the small intestine, although they may also occur in the stomach and colon and, rarely, in the bladder and lungs. On gross evaluation, the polyps are large and pedunculated with a lobulated contour. Histologic examination demonstrates a characteristic arborizing network of connective tissue, smooth muscle, lamina propria, and glands lined by normal-appearing intestinal epithelium (Fig. 14–31, *B*).

## Hyperplastic Polyps

Colonic hyperplastic polyps are common epithelial proliferations that typically are discovered in the sixth and seventh decades of life. The pathogenesis of hyperplastic polyps is incompletely understood, but formation of these lesions is thought to result from decreased epithelial cell turnover and delayed shedding of surface epithelial cells, leading to a "pileup" of goblet cells.

Although these lesions have no malignant potential, they must be distinguished from sessile serrated adenomas, histologically similar lesions that have malignant potential, as described later.

### MORPHOLOGY

Hyperplastic polyps are most commonly found in the left colon and typically are less than 5 mm in diameter. They are smooth, nodular protrusions of the mucosa, often on the crests of mucosal folds. They may occur singly but more frequently are multiple, particularly in the sigmoid colon and rectum. Histologically, hyperplastic polyps are composed of mature goblet and absorptive cells. The delayed shedding of these cells leads to crowding that creates the serrated surface architecture that is the morphologic hallmark of these lesions (Fig. 14–32).

## Adenomas

Any neoplastic mass lesion in the gastrointestinal tract may produce a mucosal protrusion, or polyp. The most common and clinically important neoplastic polyps are *colonic adenomas, benign polyps that give rise to a majority of colorectal adenocarcinomas*. Most adenomas, however, do not progress to adenocarcinoma.

*Colorectal adenomas are characterized by the presence of epithelial dysplasia.* These growths range from small, often pedunculated polyps to large sessile lesions. There is no gender predilection, and they are present in nearly 50% of adults living in the Western world beginning age 50. Because these polyps are precursors to colorectal cancer, current recommendations are that all adults in the United States undergo surveillance colonoscopy starting at age 50. Because persons with a family history are at risk for

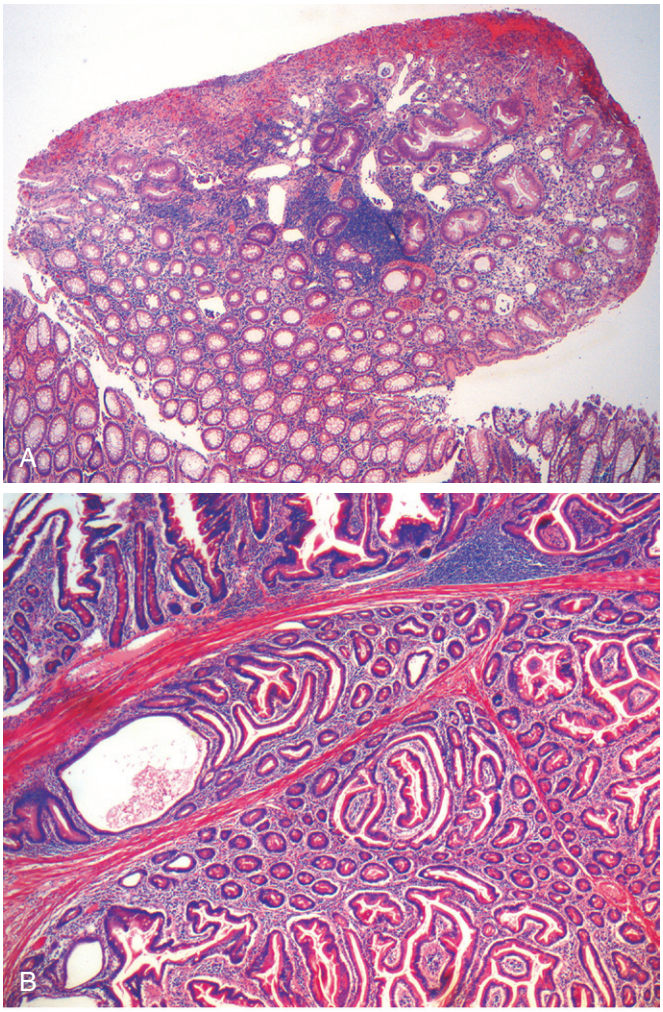

**Figure 14–31** Hamartomatous polyps. **A,** Juvenile polyp. Note the surface erosion and cystically dilated crypts filled with mucus, neutrophils, and debris. **B,** Peutz-Jeghers polyp. Complex glandular architecture and bundles of smooth muscle help to distinguish Peutz-Jeghers polyps from juvenile polyps.

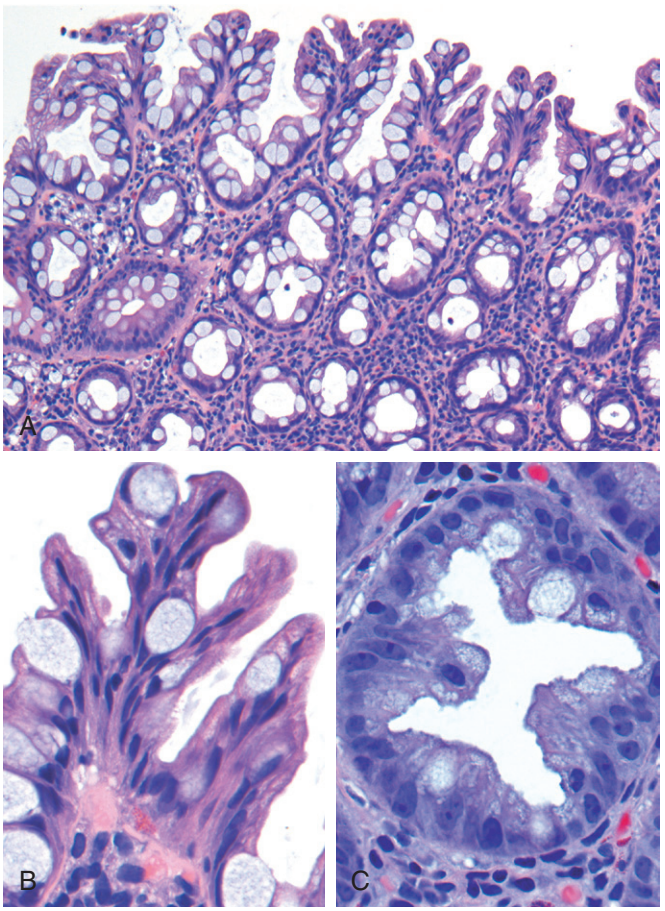

**Figure 14–32** Hyperplastic polyp. **A,** Polyp surface with irregular tufting of epithelial cells. **B,** Tufting results from epithelial overcrowding. **C,** Epithelial crowding produces a serrated architecture when glands are cut in cross-section.

developing colon cancer earlier in life, they typically are screened at least 10 years before the youngest age at which a relative was diagnosed. While adenomas are less common in Asia, their frequency has risen (in parallel with an increasing incidence of colorectal adenocarcinoma) as Western diets and lifestyles become more common.

## MORPHOLOGY

Typical adenomas range from 0.3 to 10 cm in diameter and can be **pedunculated** (Fig. 14–33, *A*) or **sessile,** with the surface of both types having a texture resembling velvet (Fig. 14–33, *B*) or a raspberry, due to the abnormal epithelial growth pattern. Histologically, the cytologic hallmark of **epithelial dysplasia** (Fig. 14–34, *C*) is nuclear hyperchromasia, elongation, and stratification. These changes are most easily appreciated at the surface of the adenoma, because the epithelium fails to mature as cells migrate out of the crypt. Pedunculated adenomas have slender fibromuscular stalks (Fig. 14–33, *C*) containing prominent blood vessels derived from the submucosa. The stalk usually is covered by non-neoplastic epithelium, but dysplastic epithelium is sometimes present.

Adenomas can be classified as **tubular, tubulovillous, or villous** on the basis of their architecture. These categories, however, have little clinical significance in isolation. Tubular adenomas tend to be small, pedunculated polyps composed of small, rounded or tubular glands (Fig. 14–34, *A*). By contrast, villous adenomas, which often are larger and sessile, are covered by slender villi (Fig. 14–34, *B*). Tubulovillous adenomas have a mixture of tubular and villous elements. Although foci of invasion are more frequent in villous adenomas than in tubular adenomas, villous architecture alone does not increase cancer risk when polyp size is considered.

The histologic features of **sessile serrated adenomas** overlap with those of hyperplastic polyps and the typical cytologic features of dysplasia are lacking (Fig. 14–34, *D*). However, these lesions, which are most common in the right colon, have a malignant potential similar to that of traditional adenomas. The most useful histologic feature that distinguishes sessile serrated adenomas and hyperplastic polyps is the presence of serrated architecture throughout the full length of the glands, including the crypt base, associated with crypt dilation and lateral growth, in the former (Fig. 14–34,

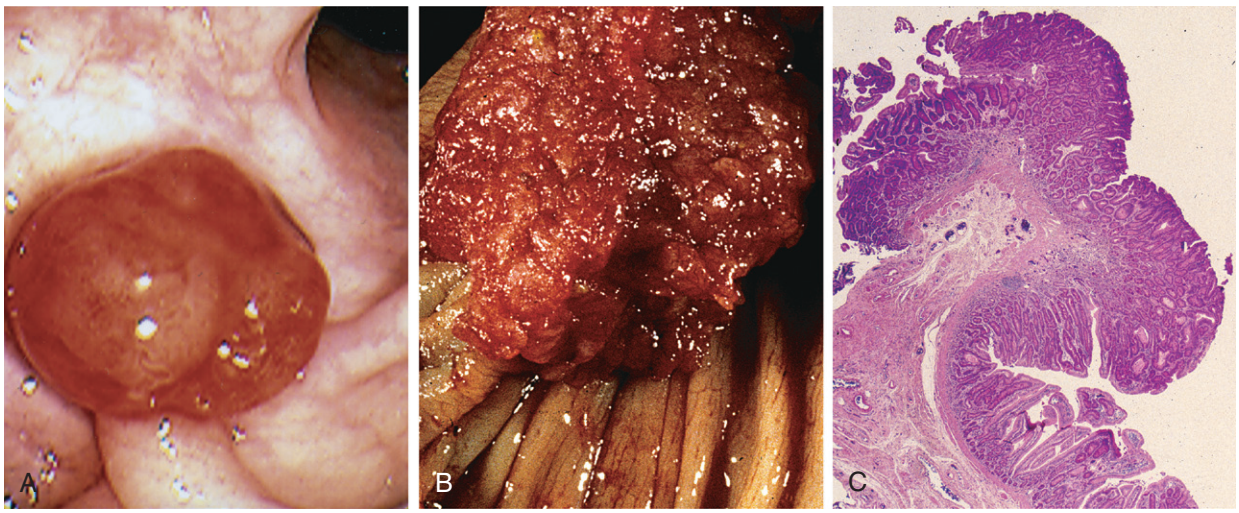

**Figure 14–33** Colonic adenomas. **A,** Pedunculated adenoma (endoscopic view). **B,** Adenoma with a velvety surface. **C,** Low-magnification photomicrograph of a pedunculated tubular adenoma.

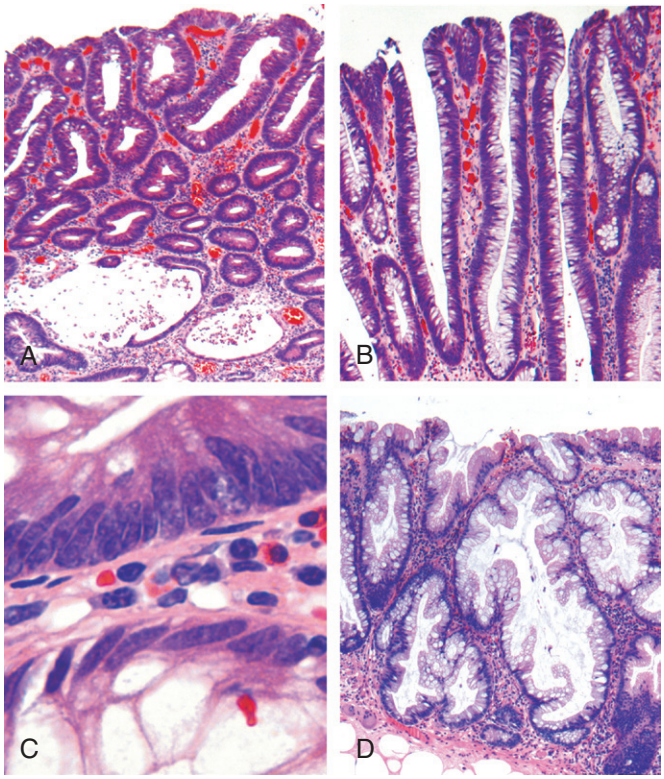

**Figure 14–34** Histologic appearance of colonic adenomas. **A,** Tubular adenoma with a smooth surface and rounded glands. In this case, crypt dilation and rupture, with associated reactive inflammation, can be seen at the bottom of the field. **B,** Villous adenoma with long, slender projections that are reminiscent of small intestinal villi. **C,** Dysplastic epithelial cells (*top*) with an increased nuclear-to-cytoplasmic ratio, hyperchromatic and elongated nuclei, and nuclear pseudostratification. Compare with the nondysplastic epithelium below. **D,** Sessile serrated adenoma lined by goblet cells without typical cytologic features of dysplasia. This lesion is distinguished from a hyperplastic polyp by involvement of the crypts. Compare with the hyperplastic polyp in Figure 14–32.

*D*). By contrast, serrated architecture typically is confined to the surface of hyperplastic polyps.

Although most colorectal adenomas are benign lesions, a small proportion may harbor invasive cancer at the time of detection. **Size is the most important characteristic that correlates with risk of malignancy.** For example, while cancer is extremely rare in adenomas less than 1 cm in diameter, some studies suggest that nearly 40% of lesions larger than 4 cm in diameter contain foci of cancer. In addition to size, high-grade dysplasia is a risk factor for cancer in an individual polyp (but not other polyps in the same patient).

## Familial Syndromes

Several syndromes associated with colonic polyps and increased rates of colon cancer have been described. The genetic basis of these disorders has been established and has greatly enhanced the current understanding of sporadic colon cancer (Table 14–7).

### *Familial Adenomatous Polyps*

Familial adenomatous polyposis (FAP) is an autosomal dominant disorder marked by the appearance of numerous colorectal adenomas by the teenage years. It is caused by mutations of the *adenomatous polyposis coli* gene (*APC*). *A count of at least 100 polyps is necessary for a diagnosis* of classic FAP, and as many as several thousand may be present (Fig. 14–35). Except for their remarkable numbers, these growths are *morphologically indistinguishable from sporadic adenomas*. Colorectal adenocarcinoma develops in 100% of patients with untreated FAP, often before age 30. As a result, prophylactic colectomy is standard therapy for persons carrying *APC* mutations. However, patients remain at risk for *extraintestinal manifestations,* including neoplasia at other sites. Specific *APC* mutations are also associated with the development of other manifestations of FAP and explain variants such as Gardner syndrome and Turcot syndrome. In addition to intestinal polyps, clinical features of *Gardner syndrome*, a variant of FAP, may include osteomas of

**Table 14–7** Common Patterns of Sporadic and Familial Colorectal Neoplasia

| Etiology | Molecular Defect | Target Gene(s) | Transmission | Predominant Site(s) | Histology |
|---|---|---|---|---|---|
| Familial adenomatous polyposis (70% of FAP) | APC/WNT pathway | *APC* | Autosomal dominant | None | Tubular, villous; typical adenocarcinoma |
| Familial adenomatous polyposis (<10% of FAP) | DNA mismatch repair | *MUTYH* | None, recessive | None | Sessile serrated adenoma; mucinous adenocarcinoma |
| Hereditary nonpolyposis colorectal cancer | DNA mismatch repair | *MSH2, MLH1* | Autosomal dominant | Right side | Sessile serrated adenoma; mucinous adenocarcinoma |
| Sporadic colon cancer (80%) | APC/WNT pathway | *APC* | None | Left side | Tubular, villous; typical adenocarcinoma |
| Sporadic colon cancer (10% to 15%) | DNA mismatch repair | *MSH2, MLH1* | None | Right side | Sessile serrated adenoma; mucinous adenocarcinoma |

mandible, skull, and long bones; epidermal cysts; desmoid and thyroid tumors; and dental abnormalities, including unerupted and supernumerary teeth. *Turcot syndrome* is rarer and is characterized by intestinal adenomas and tumors of the central nervous system. Two thirds of patients with Turcot syndrome have *APC* gene mutations and develop medulloblastomas. The remaining one third have mutations in one of several genes involved in DNA repair and develop glioblastomas. Some patients who have FAP without *APC* loss have mutations of the base excision repair gene *MUTYH*. The role of these genes in tumor development is discussed below.

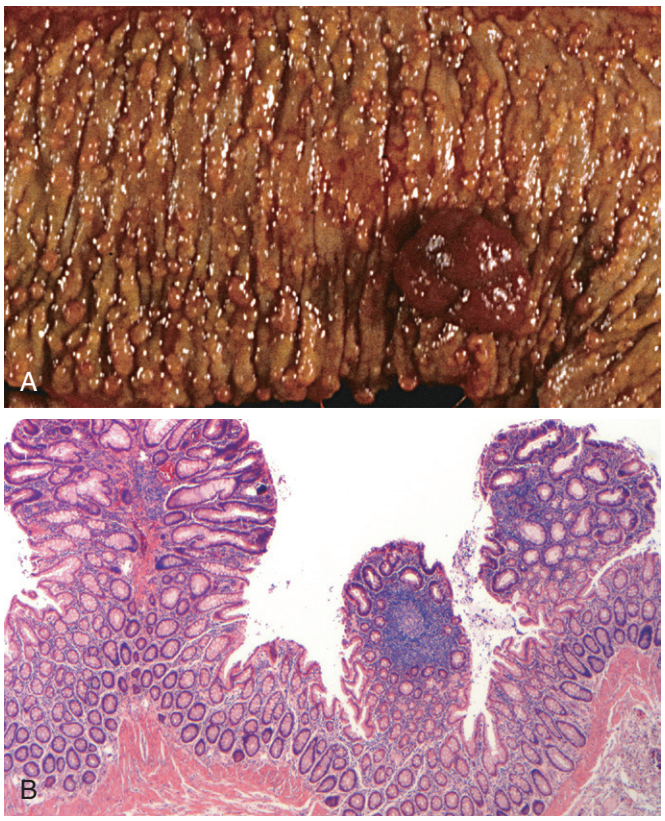

**Figure 14–35** Familial adenomatous polyposis. **A,** Hundreds of small colonic polyps are present along with a dominant polyp (*right*). **B,** Three tubular adenomas are present in this single microscopic field.

### *Hereditary Nonpolyposis Colorectal Cancer*

*Hereditary nonpolyposis colorectal cancer* (HNPCC), also known as Lynch syndrome, originally was described as familial clustering of cancers at several sites including the colorectum, endometrium, stomach, ovary, ureters, brain, small bowel, hepatobiliary tract, and skin. Colon cancers in patients with HNPCC tend to occur at *younger ages* than for sporadic colon cancers and often are located in the *right colon* (Table 14–7).

Just as identification of *APC* mutations in FAP has provided molecular insights into the pathogenesis of a majority of sporadic colon cancers, dissection of the defects in HNPCC has shed light on the mechanisms responsible for most of the remaining sporadic cases. HNPCC is caused by inherited germline mutations in genes that encode proteins responsible for the detection, excision, and repair of errors that occur during DNA replication. At least five such mismatch repair genes have been recognized, but a majority of HNPCC cases involve either *MSH2* or *MLH1.* Patients with HNPCC inherit one mutated DNA repair gene and one normal allele. When the second copy is lost through mutation or epigenetic silencing, defects in mismatch repair lead to the accumulation of mutations at rates up to 1000 times higher than normal, mostly in regions containing short repeating DNA sequences referred to as microsatellite DNA. The human genome contains approximately 50,000 to 100,000 microsatellites, which are prone to undergo expansion during DNA replication and represent the most frequent sites of mutations in HNPCC. The consequences of mismatch repair defects and the resulting *microsatellite instability* are discussed next in the context of colonic adenocarcinoma.

## Adenocarcinoma

Adenocarcinoma of the colon is the most common malignancy of the gastrointestinal tract and is a major contributor to morbidity and mortality worldwide. By contrast, the small intestine, which accounts for 75% of the overall length of the gastrointestinal tract, is an uncommon site for benign and malignant tumors. Among malignant small intestinal tumors, adenocarcinomas and carcinoid tumors have roughly equal rates of occurrence, followed by lymphomas and sarcomas.

### Epidemiology

Each year in the United States there are more than 130,000 new cases and 55,000 deaths from colorectal adenocarcinoma. This represents nearly 15% of all cancer-related deaths, second only to lung cancer. Colorectal cancer incidence peaks at 60 to 70 years of age, and less than 20% of cases occur before age 50. Males are affected slightly more often than females. Colorectal carcinoma is most prevalent in the United States, Canada, Australia, New Zealand, Denmark, Sweden, and other developed countries. The incidence of this cancer is as much as 30-fold lower in India, South America, and Africa. In Japan, where incidence was previously very low, rates have now risen to intermediate levels (similar to those in the United Kingdom), presumably as a result of changes in lifestyle and diet.

The dietary factors most closely associated with increased colorectal cancer rates are low intake of unabsorbable vegetable fiber and high intake of refined carbohydrates and fat.

In addition to dietary modification, pharmacologic chemoprevention has become an area of great interest. Several epidemiologic studies suggest that aspirin or other NSAIDs have a protective effect. This is consistent with studies showing that some NSAIDs cause polyp regression in patients with FAP in whom the rectum was left in place after colectomy. It is suspected that this effect is mediated by inhibition of the enzyme cyclooxygenase-2 (COX-2), which is highly expressed in 90% of colorectal carcinomas and 40% to 90% of adenomas and is known to promote epithelial proliferation, particularly in response to injury.

## PATHOGENESIS

Studies of colorectal carcinogenesis have provided fundamental insights into the general mechanisms of cancer evolution. The combination of molecular events that lead to colonic adenocarcinoma is heterogeneous and includes genetic and epigenetic abnormalities. At least two distinct genetic pathways APC/β-catenin pathway, have been described. In simplest terms, these are the disturbances of which lead to increased WNT signaling, and the microsatellite instability pathway, which is associated with defects in DNA mismatch repair (see Table 14–7). Both pathways involve the stepwise accumulation of multiple mutations, but the genes involved and the mechanisms by which the mutations accumulate differ. Epigenetic events, the most common of which is methylation-induced gene silencing, may enhance progression along both pathways.

- The **APC/β-catenin pathway.** The classic **adenoma-carcinoma sequence,** which accounts for as much as 80% of sporadic colon tumors, typically involves mutation of the *APC* tumor suppressor early in the neoplastic process (Fig. 14–36). Both copies of the *APC* gene must be functionally inactivated, either by mutation or epigenetic events, for adenomas to develop. **APC is a key negative regulator of β-catenin, a component of the WNT signaling pathway** (Chapter 5). The APC protein normally binds to and promotes degradation of β-catenin. With loss of APC function, β-catenin accumulates and translocates to the nucleus, where it activates the transcription of genes, such as those encoding MYC and cyclin D1, which promote proliferation. This is followed by additional mutations, including activating mutations in *KRAS*, which also promote growth and prevent apoptosis. The conclusion that mutation of *KRAS* is a late event is supported by the observation that mutations are present in fewer than 10% of adenomas less than 1 cm in diameter, in 50% of adenomas greater than 1 cm in diameter, and in 50% of invasive adenocarcinomas. Neoplastic progression also is associated with mutations in other

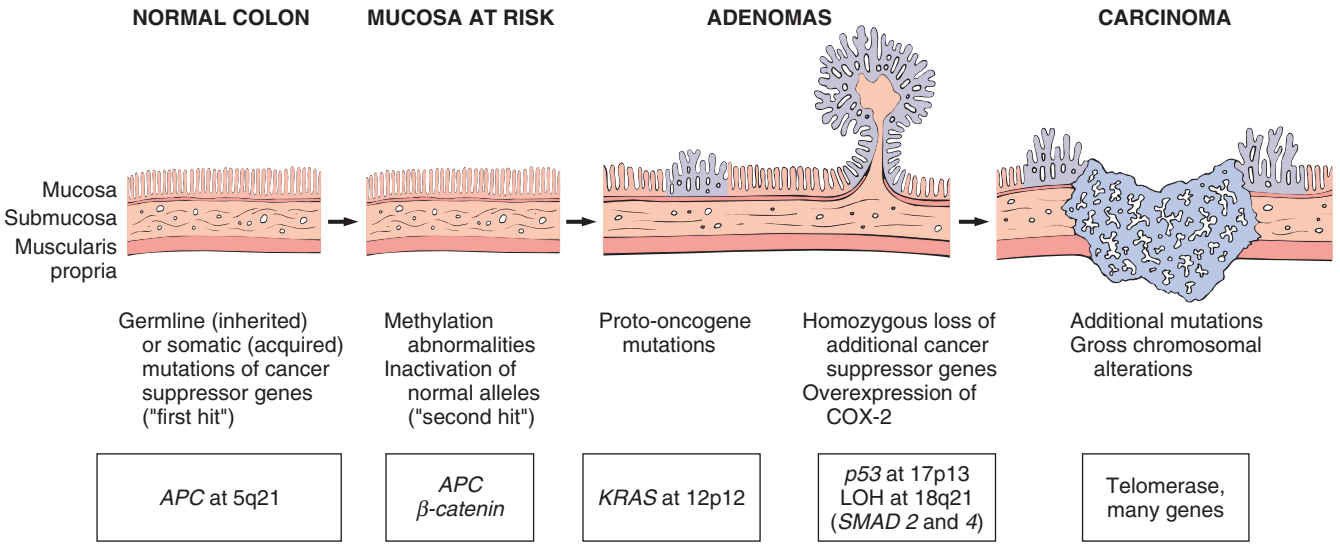

**Figure 14–36** Morphologic and molecular changes in the adenoma-carcinoma sequence. It is postulated that loss of one normal copy of the tumor suppressor gene *APC* occurs early. Persons may be born with one mutant allele, making them extremely prone to the development of colon cancer, or inactivation of *APC* may occur later in life. This is the "first hit" according to Knudson's hypothesis. The loss of the intact copy of *APC* follows ("second hit"). Other mutations involving *KRAS*, *SMAD2*, and *SMAD4*, and the tumor suppressor gene *TP53*, lead to the emergence of carcinoma, in which additional mutations occur. Although there may be a preferred temporal sequence for these changes, it is the aggregate effect of the mutations, rather than their order of occurrence, that appears most critical.

tumor suppressor genes such as those encoding SMAD2 and SMAD4, which are effectors of TGF-β signaling. Because TGF-β signaling normally inhibits the cell cycle, loss of these genes may allow unrestrained cell growth. The tumor suppressor gene *TP53* is mutated in 70% to 80% of colon cancers but is uncommonly affected in adenomas, suggesting that *TP53* mutations also occur at late stages of tumor progression. "Loss of function" of *TP53* and other tumor suppressor genes often is caused by chromosomal deletions, highlighting chromosomal instability as a hallmark of the APC/β-catenin pathway. Alternatively, tumor suppressor genes may be silenced by methylation of CpG islands, a 5′ region of some genes that frequently includes the promoter and transcriptional start site. Expression of telomerase also increases as lesions become more advanced.

- **The microsatellite instability pathway.** In patients with DNA mismatch repair deficiency (due to loss of mismatch repair genes, as discussed earlier) mutations accumulate in microsatellite repeats, a condition referred to as **microsatellite instability.** These mutations generally are silent, because microsatellites typically are located in noncoding regions, but other microsatellite sequences are located in the coding or promoter regions of genes involved in regulation of cell growth, such as those encoding the type II TGF-β receptor and the pro-apoptotic protein BAX (Fig. 14–37). Because TGF-β inhibits colonic epithelial cell proliferation, type II TGF-β receptor mutants can contribute to uncontrolled cell growth, while loss of *BAX* may enhance the survival of genetically abnormal clones. Mutations in the oncogene *BRAF* and silencing of distinct groups of genes due to CpG island hypermethylation also are common in cancers that develop through DNA mismatch repair defects. By contrast, *KRAS* and *TP53* typically are not mutated. Thus, the combination of microsatellite instability, *BRAF* mutation, and methylation of specific targets, such as *MLH1*, is the signature of this pathway of carcinogenesis.

## MORPHOLOGY

Overall, adenocarcinomas are distributed approximately equally over the entire length of the colon. **Tumors in the proximal colon often grow as polypoid, exophytic masses** that extend along one wall of the large-caliber cecum and ascending colon; these tumors rarely cause obstruction. By contrast, **carcinomas in the distal colon tend to be annular lesions that produce "napkin ring"** constrictions and luminal narrowing (Fig. 14–38), sometimes to the point of obstruction. Both forms grow into the bowel wall over time and may be palpable as firm masses. The general microscopic characteristics of right- and left-sided colonic adenocarcinomas are similar. Most tumors are composed of tall columnar cells that resemble dysplastic epithelium found in adenomas (Fig. 14–39, *A*). The invasive component of these tumors elicits a strong stromal desmoplastic response, which is responsible for their characteristic firm consistency. Some poorly differentiated tumors form few glands (Fig. 14–39, *B*). Others may produce abundant mucin that accumulates within the intestinal wall, and these carry a poor prognosis. Tumors also may be composed of signet ring cells that are similar to those in gastric cancer (Fig. 14–39, *C*).

### Clinical Features

The availability of endoscopic screening combined with the recognition that most carcinomas arise within adenomas presents a unique opportunity for cancer prevention. Unfortunately, colorectal cancers develop insidiously and may therefore go undetected for long periods. Cecal and other *right-sided colon cancers* most often are called to clinical attention by the appearance of *fatigue and weakness due to iron deficiency anemia.* Thus, it is a clinical maxim that the underlying cause of iron deficiency anemia in an older man or postmenopausal woman is gastrointestinal cancer until proven otherwise. *Left-sided colorectal adenocarcinomas* may produce *occult bleeding, changes in bowel habits, or cramping* left lower quadrant discomfort.

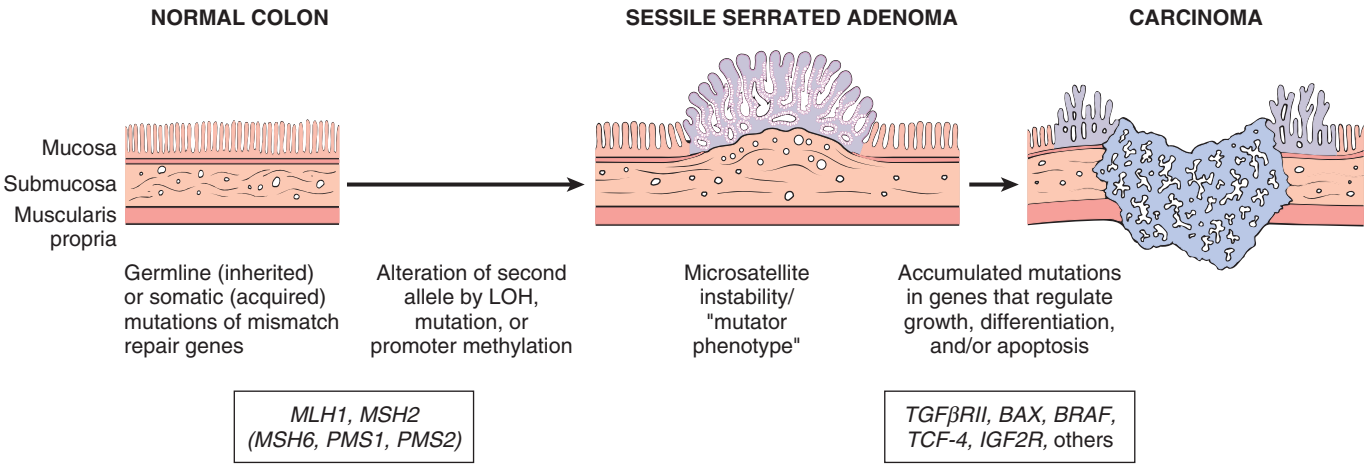

**Figure 14–37** Morphologic and molecular changes in the mismatch repair pathway of colon carcinogenesis. Defects in mismatch repair genes result in microsatellite instability and permit accumulation of mutations in numerous genes. If these mutations affect genes involved in cell survival and proliferation, cancer may develop. LOH, loss of heterozygosity.

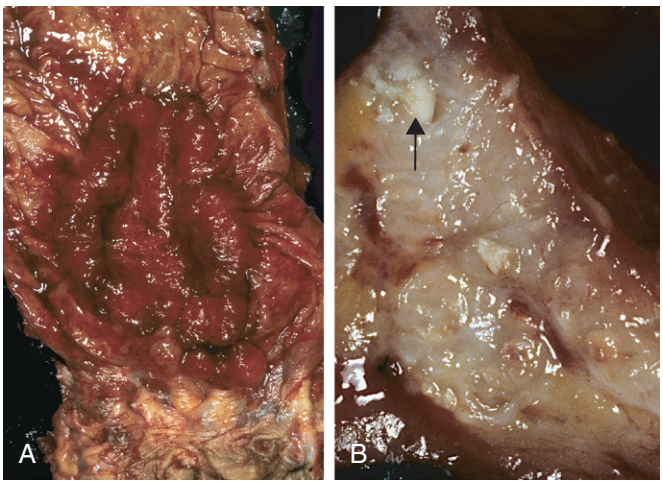

**Figure 14–38** Colorectal carcinoma. **A,** Circumferential, ulcerated rectal cancer. Note the anal mucosa at the bottom of the image. **B,** Cancer of the sigmoid colon that has invaded through the muscularis propria and is present within subserosal adipose tissue (*left*). Areas of chalky necrosis are present within the colon wall (*arrow*).

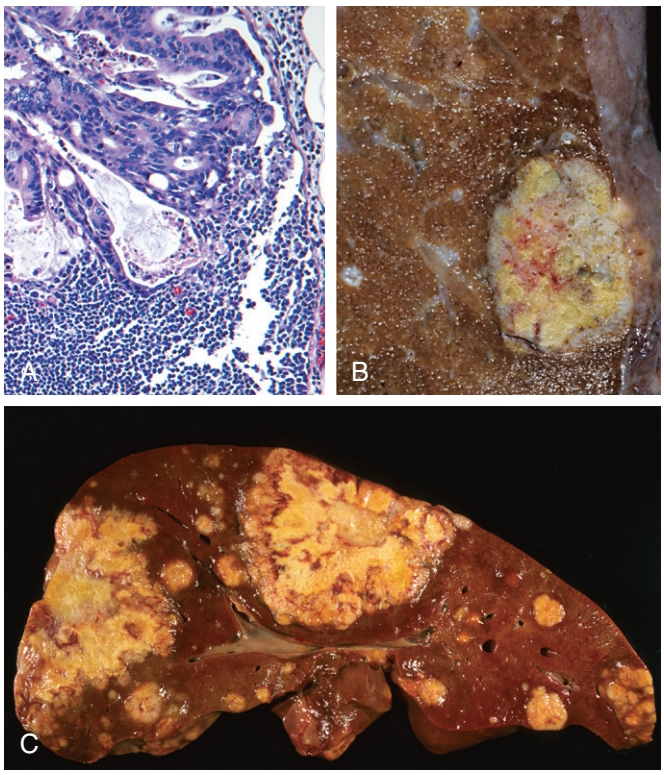

**Figure 14–40** Metastatic colorectal carcinoma. **A,** Lymph node metastasis. Note the glandular structures within the subcapsular sinus. **B,** Solitary subpleural nodule of colorectal carcinoma metastatic to the lung. **C,** Liver containing two large and many smaller metastases. Note the central necrosis within metastases.

Although poorly differentiated and mucinous histologic patterns are associated with poor prognosis, *the two most important prognostic factors are depth of invasion and the presence or absence of lymph node metastases.* Invasion into the muscularis propria imparts significantly reduced survival that is decreased further by the presence of lymph node metastases (Fig. 14–40, *A*). These factors were originally recognized by Dukes and Kirklin and form the core of the TNM (tumor-node-metastasis) classification (Table 14–8) and staging system (Table 14–9) from the American Joint Committee on Cancer. Regardless of stage, however, some patients with small numbers of metastases do well for years after resection of distant tumor nodules. This observation once again emphasizes the clinical and molecular heterogeneity of colorectal carcinomas. Metastases may involve regional lymph nodes, lungs (Fig. 14–40, *B*), and bones, but because of the portal drainage, the liver is the most common site of metastatic lesions (Fig. 14–40, *C*). The rectum does not drain by way of the portal circulation, and metastases from carcinomas of the anal region often circumvent the liver.

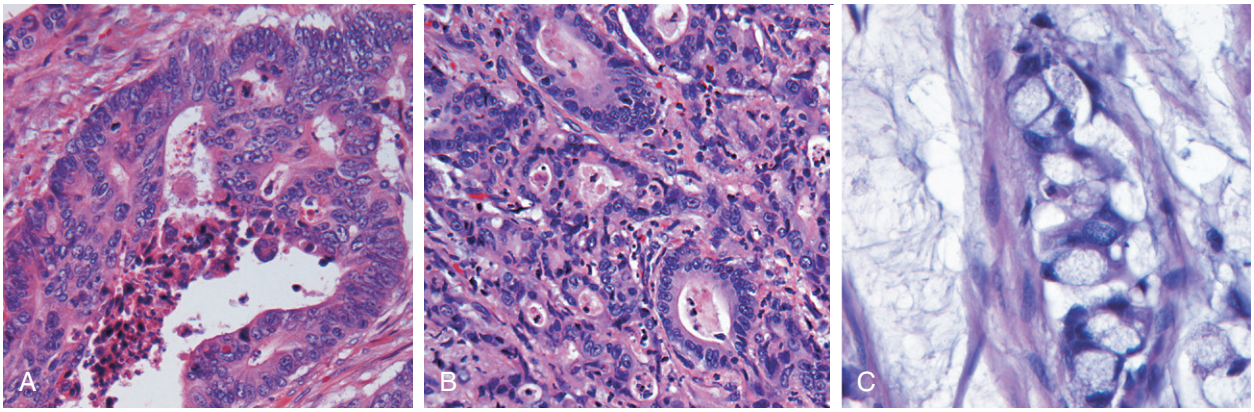

**Figure 14–39** Histologic appearance of colorectal carcinoma. **A,** Well-differentiated adenocarcinoma. Note the elongated, hyperchromatic nuclei. Necrotic debris, present in the gland lumen, is typical. **B,** Poorly differentiated adenocarcinoma forms a few glands but is largely composed of infiltrating nests of tumor cells. **C,** Mucinous adenocarcinoma with signet ring cells and extracellular mucin pools.

**Table 14–8** AJCC Tumor-Node-Metastasis (TNM) Classification of Colorectal Carcinoma

| Designation | Description |
|---|---|
| **Tumor** | |
| Tis | In situ dysplasia or intramucosal carcinoma |
| T1 | Tumor invades submucosa |
| T2 | Tumor invades into, but not through, muscularis propria |
| T3 | Tumor invades through muscularis propria |
| T4 | Tumor invades adjacent organs or visceral peritoneum |
| **Regional Lymph Nodes** | |
| NX | Lymph nodes cannot be assessed |
| N0 | No regional lymph node metastasis |
| N1 | Metastasis in one to three regional lymph nodes |
| N2 | Metastasis in four or more regional lymph nodes |
| **Distant Metastasis** | |
| MX | Distant metastasis cannot be assessed |
| M0 | No distant metastasis |
| M1 | Distant metastasis or seeding of abdominal organs |

AJCC, American Joint Committee on Cancer.

**Table 14–9** AJCC Colorectal Cancer Staging and Survival

| Stage* | Tumor-Node-Metastasis (TNM) Criteria | | | 5-Year Survival (%) |
|---|---|---|---|---|
| | T | N | M | |
| I | T1, T2 | N0 | M0 | 74 |
| II | | | | |
| IIA | T3 | N0 | M0 | 67 |
| IIB | T4 | N0 | M0 | 59 |
| III | | | | |
| IIIA | T1, T2 | N1 | M0 | 73 |
| IIIB | T3, T4 | N1 | M0 | 46 |
| IIIC | Any T | N2 | M0 | 28 |
| IV | Any T | Any N | M1 | 6 |

*Colorectal cancer staging is based on the TNM classification (Table 14–8). For example, a T3 tumor without nodal or distant metastases is classified as stage IIA and is associated with a 5-year survival rate of 67%.
AJCC, American Joint Committee on Cancer.

## SUMMARY

### Colonic Polyps, Adenomas, and Adenocarcinomas

- *Intestinal polyps* can be classified as non-neoplastic or neoplastic. The non-neoplastic polyps can be further defined as inflammatory, hamartomatous, or hyperplastic.
- *Inflammatory polyps* form as a result of chronic cycles of injury and healing.
- *Hamartomatous polyps* occur sporadically or as a part of genetic diseases. In the latter case, they often are associated with increased risk of malignancy.
- Hyperplastic polyps are benign epithelial proliferations most commonly found in the left colon and rectum. They are not reactive in origin, in contrast with gastric hyperplastic polyps; have no malignant potential; and must be distinguished from *sessile serrated adenomas*.
- Benign epithelial neoplastic polyps of the intestines are termed *adenomas*. The hallmark feature of these lesions, which are the precursors of colonic adenocarcinomas, is cytologic dysplasia.
- In contrast with traditional adenomas, *sessile serrated adenomas* lack cytologic dysplasia and share morphologic features with hyperplastic polyps.
- *Familial adenomatous polyposis* (FAP) and *hereditary nonpolyposis colorectal cancer* (HNPCC) are the most common forms of familial colon cancer. FAP is caused by *APC* mutations, and patients typically have over 100 adenomas and develop colon cancer before the age of 30.
- HNPCC is caused by mutations in DNA mismatch repair genes. Patients with HNPCC have far fewer polyps and develop cancer at an older age than that typical for patients with FAP but at a younger age than in patients with sporadic colon cancer.
- FAP and HNPCC are examples of two distinct pathways of neoplastic transformation, both of which contribute to sporadic colon cancer.
- The vast majority of colonic cancers are adenocarcinomas. The two most important prognostic factors are *depth of invasion* and the presence or absence of *lymph node metastases*.

# APPENDIX

The appendix is a normal true diverticulum of the cecum. Like any diverticulum, it is prone to acute and chronic inflammation, and acute appendicitis is a relatively common entity. Other lesions, including tumors, can also occur in the appendix but are far less common.

## ACUTE APPENDICITIS

Acute appendicitis is most common in adolescents and young adults but may occur in any age group. The lifetime risk for appendicitis is 7%; males are affected slightly more often than females. Despite the prevalence of acute appendicitis, the diagnosis can be difficult to confirm preoperatively, and the condition may be confused with mesenteric lymphadenitis (often secondary to unrecognized *Yersinia* infection or viral enterocolitis), acute salpingitis, ectopic pregnancy, mittelschmerz (pain associated with ovulation), and Meckel diverticulitis.

### PATHOGENESIS

Acute appendicitis is thought to be initiated by progressive increases in intraluminal pressure that compromises venous outflow. In 50% to 80% of cases, acute appendicitis is associated with overt luminal obstruction, usually by a small, stone-like mass of stool, or **fecalith,** or, less commonly, a gallstone,

tumor, or mass of worms. Ischemic injury and stasis of luminal contents, which favor bacterial proliferation, trigger inflammatory responses including tissue edema and neutrophilic infiltration of the lumen, muscular wall, and periappendiceal soft tissues.

## MORPHOLOGY

In early acute appendicitis, subserosal vessels are congested, and a modest perivascular neutrophilic infiltrate is present within all layers of the wall. The inflammatory reaction transforms the normal glistening serosa into a dull, granular-appearing, erythematous surface. Although mucosal neutrophils and focal superficial ulceration often are present, these findings are not specific, and diagnosis of acute appendicitis requires neutrophilic infiltration of the muscularis propria. In more severe cases, focal abscesses may form within the wall **(acute suppurative appendicitis),** and these may even progress to large areas of hemorrhagic ulceration and gangrenous necrosis that extend to the serosa, creating **acute gangrenous appendicitis,** which often is followed by rupture and suppurative peritonitis.

### Clinical Features

Typically, early acute appendicitis produces periumbilical pain that ultimately localizes to the right lower quadrant, followed by nausea, vomiting, low-grade fever, and a mildly elevated peripheral white cell count. A classic physical finding is *McBurney's sign,* deep tenderness noted at a location two thirds of the distance from the umbilicus to the right anterior superior iliac spine (McBurney's point). These signs and symptoms often are absent, however, creating difficulty in clinical diagnosis.

# TUMORS OF THE APPENDIX

The most common tumor of the appendix is the *carcinoid.* It usually is discovered incidentally at the time of surgery or on examination of a resected appendix. This neoplasm most frequently involves the distal tip of the appendix, where it produces a solid bulbous swelling up to 2 to 3 cm in diameter. Although intramural and transmural extension may be evident, nodal metastases are very infrequent, and distant spread is exceptionally rare. Conventional *adenomas* or *non–mucin-producing adenocarcinomas* also occur in the appendix and may cause obstruction and enlargement that mimics the changes of acute appendicitis. *Mucocele,* a dilated appendix filled with mucin, may simply stem from an obstructed appendix containing inspissated mucin or may be a consequence of *mucinous cystadenoma* or *mucinous cystadenocarcinoma.* In the latter instance, invasion through the appendiceal wall can lead to intraperitoneal seeding and spread. In women, the resulting peritoneal implants may be mistaken for mucinous ovarian tumors. In the most advanced cases, the abdomen fills with tenacious, semisolid mucin, a condition called *pseudomyxoma peritonei.* This disseminated intraperitoneal disease may be held in check for years by repeated debulking but in most instances is ultimately fatal.

## SUMMARY

### Appendix

- *Acute appendicitis* is most common in children and adolescents. It is thought to be initiated by increased intraluminal pressure consequent to obstruction of the appendiceal lumen, which compromises venous outflow.
- The most common tumor of the appendix is the *carcinoid.*
- The clinical presentation with *appendiceal adenocarcinoma* can be indistinguishable from that with acute appendicitis.

## THE LIVER

The liver and its companion biliary tree and gallbladder are considered together because of their anatomic proximity and interrelated functions and the overlapping features of some diseases that affect these organs. This chapter focuses primarily on the liver, because it has by far the greater role in normal physiology and is the site of a wide variety of diseases.

Residing at the crossroads between the digestive tract and the rest of the body, the liver has the enormous task of maintaining the body's metabolic homeostasis. This task includes the processing of dietary amino acids, carbohydrates, lipids, and vitamins; synthesis of serum proteins; and detoxification and excretion into bile of endogenous waste products and xenobiotics. Thus, it is not surprising that the liver is vulnerable to a wide variety of metabolic, toxic, microbial, and circulatory insults. In some instances the disease process is primary to the liver. In others the hepatic involvement is secondary, often to some of the most common diseases in humans, such as heart failure, diabetes, and extrahepatic infections.

The liver has enormous functional reserve, and regeneration occurs in all but the most fulminant of hepatic diseases. Surgical removal of 60% of the liver in a normal person is followed by minimal and transient hepatic impairment, with restoration of most of its mass by regeneration within 4 to 6 weeks. In persons who have sustained massive hepatic necrosis, almost perfect restoration may occur if the patient can survive the metabolic insult of liver failure. The functional reserve and the regenerative capacity of the liver mask to some extent the clinical impact of early liver damage. However, with progression of diffuse disease or disruption of the circulation or bile flow, the consequences of deranged liver function become severe and even life-threatening.

*Contributions of Drs. Jim Crawford and Nelson Fausto to this chapter in earlier editions are gratefully acknowledged.*

| Hepatopulmonary syndrome |

# CLINICAL SYNDROMES

The major clinical syndromes of liver disease are hepatic failure, cirrhosis, portal hypertension, and cholestasis. These conditions have characteristic clinical manifestations (Table 15–1), and a battery of laboratory tests for their evaluation (Table 15–2), with liver biopsy representing the gold standard for diagnosis.

**Table 15–2** Laboratory Evaluation of Liver Disease

| Test Category | Serum Measurement* |

## Hepatic Failure

The most severe clinical consequence of liver disease is hepatic failure. It generally develops as the end point of progressive damage to the liver, either through insidious piecemeal destruction of hepatocytes or by repetitive waves of symptomatic parenchymal damage. Less commonly, hepatic failure is the result of sudden, massive destruction. Whatever the sequence, 80% to 90% of hepatic function must be lost before hepatic failure ensues. In many cases, the balance is tipped toward decompensation by intercurrent conditions or events that place demands on the liver. These include systemic infections, electrolyte disturbances, major surgery, heart failure, and gastrointestinal bleeding.

The patterns of injury that cause liver failure fall into three categories:

- *Acute liver failure with massive hepatic necrosis.* Most often caused by *drugs* or *viral hepatitis*, acute liver failure denotes clinical hepatic insufficiency that progresses from onset of symptoms to hepatic encephalopathy within 2 to 3 weeks. A course extending as long as 3 months is called subacute failure. *The histologic correlate of acute liver failure is massive hepatic necrosis,* whatever the underlying cause. It is an uncommon but life-threatening condition that often necessitates liver transplantation.
- *Chronic liver disease.* This is the most common route to hepatic failure and is the end point of relentless chronic liver damage. While all structural components of the liver are involved in end-stage chronic liver disease, the processes that initiate and drive chronic damage to the liver can usually be classified as either primarily hepatocytic (or *parenchymal*), biliary, or vascular. Regardless of the initiating factors, chronic damage to the liver often ends in cirrhosis, as described later.
- *Hepatic dysfunction without overt necrosis.* Less commonly than the forms described above, hepatocytes may be viable but unable to perform their normal metabolic function. Settings where this is seen most often are mitochondrial injury in Reye syndrome, acute fatty liver of pregnancy, and some drug- or toxin-mediated injuries.

### Clinical Features

The clinical manifestations of hepatic failure from chronic liver disease are much the same regardless of the cause of the disease. *Jaundice* is an almost invariable finding. Impaired hepatic synthesis and secretion of albumin lead to *hypoalbuminemia,* which predisposes to peripheral edema. *Hyperammonemia* is attributable to defective hepatic urea cycle function. Signs and symptoms of chronic disease include *palmar erythema* (a reflection of local vasodilatation) and *spider angiomas* of the skin. Each angioma is a central, pulsating, dilated arteriole from which small vessels radiate. There may also be impaired estrogen metabolism and consequent hyperestrogenemia, which leads to *hypogonadism* and *gynecomastia* in men. Acute liver failure may manifest as jaundice or encephalopathy, but notably absent on physical examination are the other stigmata of chronic liver disease.

Hepatic failure is life-threatening for several reasons. The accumulation of toxic metabolites may have

widespread effects and patients are highly susceptible to failure of multiple organ systems. Thus, respiratory failure with pneumonia and sepsis can give rise to renal failure and thus claim the lives of many individuals with hepatic failure. A *coagulopathy* develops, attributable to impaired hepatic synthesis of blood clotting factors. The resultant bleeding tendency may lead to massive gastrointestinal hemorrhage as well as bleeding elsewhere. Intestinal absorption of blood places a metabolic load on the liver that worsens the severity of hepatic failure.

The outlook with full-blown hepatic failure is particularly grave for persons with chronic liver disease. A rapid downhill course is usual, with death occurring within weeks to a few months in about 80% of cases. About 40% of patients with acute liver failure may recover spontaneously. Liver transplantation in acute or chronic liver failure can be curative, however. Conditions contributing to the extraordinary morbidity and eventual mortality associated with severe liver disease are discussed next.

## Jaundice and Cholestasis

Jaundice results from the retention of bile. Hepatic bile formation serves two major functions. First, bile constitutes the primary pathway for the elimination of bilirubin, excess cholesterol, and xenobiotics that are insufficiently water-soluble to be excreted in the urine. Second, secreted bile salts and phospholipid molecules promote emulsification of dietary fat in the lumen of the gut. Bile formation is a complex process and is readily disrupted by a variety of hepatic insults. Thus, *jaundice,* a yellow discoloration of skin and sclerae (*icterus*), occurs when systemic retention of bilirubin produces serum levels above 2.0 mg/dL (the normal level in adults is below 1.2 mg/dL). *Cholestasis* is defined as systemic retention of not only bilirubin but also other solutes eliminated in bile (particularly bile salts and cholesterol).

### *Bilirubin and Bile Acids*

Bilirubin is the end product of heme degradation (Fig. 15–1). Most of the daily production (0.2 to 0.3 g) is derived from breakdown of senescent red cells within mononuclear phagocytes, with the remainder derived primarily from the turnover of hepatic hemoproteins. Excessive destruction of erythroid progenitors in the bone marrow due to intramedullary apoptosis (ineffective erythropoiesis) is an important cause of jaundice in hematologic disorders (Chapter 11). Whatever the source, heme oxygenase oxidizes heme to biliverdin, which is then reduced to bilirubin by biliverdin reductase. Bilirubin thus formed outside the liver in cells of the mononuclear phagocyte system (including the spleen) is released and bound to serum albumin. Hepatocellular processing of bilirubin involves the following sequence:

1. Carrier-mediated uptake at the sinusoidal membrane
2. Cytosolic protein binding and delivery to the endoplasmic reticulum
3. Conjugation with one or two molecules of glucuronic acid by bilirubin uridine diphosphate–glucuronosyltransferase
4. Excretion of the water-soluble, nontoxic bilirubin glucuronides into bile. Most bilirubin glucuronides are deconjugated by gut bacterial β-glucuronidases and degraded to colorless urobilinogens. The urobilinogens and the residue of intact pigment are largely excreted in feces. Approximately 20% of the urobilinogens are reabsorbed in the ileum and colon, returned to the liver, and promptly reexcreted into bile. Conjugated and unconjugated bile acids also are reabsorbed in the ileum and returned to the liver by the *enterohepatic circulation.*

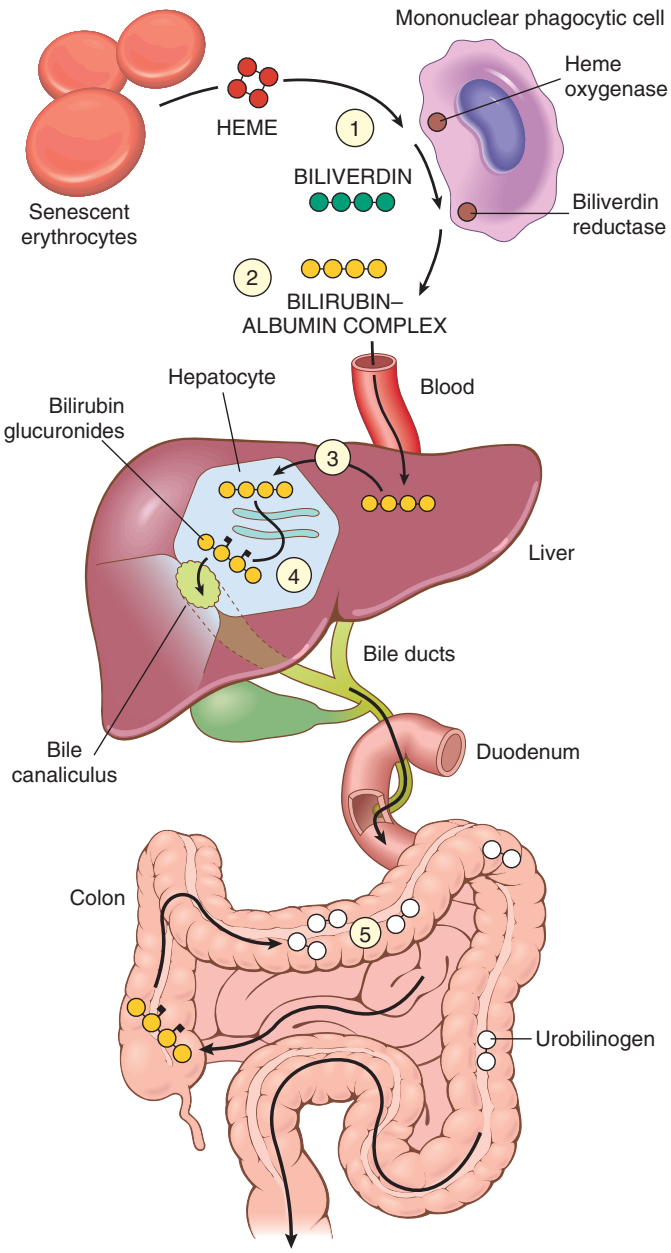

**Figure 15–1** Bilirubin metabolism and elimination. *1*, Normal bilirubin production (0.2 to 0.3 g/day) is derived primarily from the breakdown of senescent circulating red cells, with a minor contribution from degradation of tissue heme-containing proteins. *2*, Extrahepatic bilirubin is bound to serum albumin and delivered to the liver. *3* and *4*, Hepatocellular uptake (*3*) and glucuronidation (*4*) by glucuronosyltransferase in the hepatocytes generate bilirubin monoglucuronides and diglucuronides, which are water-soluble and readily excreted into bile. *5*, Gut bacteria deconjugate the bilirubin and degrade it to colorless urobilinogens. The urobilinogens and the residue of intact pigments are excreted in the feces, with some reabsorption and reexcretion into bile.

## PATHOGENESIS

In the normal adult, the rate of systemic bilirubin production is equal to the rates of hepatic uptake, conjugation, and biliary excretion. Jaundice occurs when the equilibrium between bilirubin production and clearance is disrupted; the major responsible disorders are listed in Table 15–3. More than one mechanism may operate to cause jaundice, especially in hepatitis, when both unconjugated and conjugated bilirubin may be produced in excess. In severe disease, bilirubin levels may reach 30 to 40 mg/dL.

Of these various causes of jaundice, the most common are hepatitis, obstruction to the flow of bile (discussed later in this chapter), and hemolytic anemia (Chapter 11). Because the hepatic machinery for conjugating and excreting bilirubin does not fully mature until about 2 weeks of age, almost every newborn develops transient and mild unconjugated hyperbilirubinemia, termed **neonatal jaundice** or physiologic jaundice of the newborn.

Jaundice also may result from inborn errors of metabolism, including

- **Gilbert syndrome,** a relatively common (7% of the population), benign, somewhat heterogeneous inherited condition manifesting as mild, fluctuating unconjugated hyperbilirubinemia. The primary cause is decreased hepatic levels of glucuronosyltransferase attributed to a mutation in the encoding gene; polymorphisms in the gene may play a role in the variable expression of this disease. **The hyperbilirubinemia is not associated with any morbidity.**
- **Dubin-Johnson syndrome** results from an autosomal recessive defect in the transport protein responsible for hepatocellular excretion of bilirubin glucuronides across the canalicular membrane. Affected persons exhibit conjugated hyperbilirubinemia. Other than having a darkly pigmented liver (from polymerized epinephrine metabolites, not bilirubin) and hepatomegaly, patients are otherwise without functional problems.

**Table 15–3** Main Causes of Jaundice

| |
|---|
| **Predominantly Unconjugated Hyperbilirubinemia** |
| Excess Production of Bilirubin |
| Hemolytic anemias<br>Resorption of blood from internal hemorrhage (e.g., alimentary tract bleeding, hematomas)<br>Ineffective erythropoiesis syndromes (e.g., pernicious anemia, thalassemia) |
| Reduced Hepatic Uptake |
| Drug interference with membrane carrier systems<br>Diffuse hepatocellular disease (e.g., viral or drug-induced hepatitis, cirrhosis) |
| Impaired Bilirubin Conjugation |
| Physiologic jaundice of the newborn |
| **Predominantly Conjugated Hyperbilirubinemia** |
| Decreased Hepatocellular Excretion |
| Deficiency in canalicular membrane transporters<br>Drug-induced canalicular membrane dysfunction (e.g., oral contraceptives, cyclosporine)<br>Hepatocellular damage or toxicity (e.g., viral or drug-induced hepatitis, total parenteral nutrition, systemic infection) |
| Impaired Intra- or Extrahepatic Bile Flow |
| Inflammatory destruction of intrahepatic bile ducts (e.g., primary biliary cirrhosis, primary sclerosing cholangitis, graft-versus-host disease, liver transplantation); gall stones, carcinoma of the pancreas |

Cholestasis, which results from impaired bile flow due to hepatocellular dysfunction or intrahepatic or extrahepatic biliary obstruction, also may manifest as jaundice. However, sometimes *pruritus* is the presenting symptom, the pathogenesis of which remains obscure. *Skin xanthomas* (focal accumulations of cholesterol) sometimes appear, the result of hyperlipidemia and impaired excretion of cholesterol. A *characteristic laboratory finding is elevated serum alkaline phosphatase,* an enzyme present in bile duct epithelium and in the canalicular membrane of hepatocytes. A different alkaline phosphatase isozyme normally is expressed in many other tissues such as bone, and so hepatic origin must be verified. Reduced bile flow also causes intestinal malabsorption including inadequate absorption of the fat-soluble vitamins A, D, and K.

Extrahepatic biliary obstruction frequently is amenable to surgical correction. By contrast, cholestasis caused by diseases of the intrahepatic biliary tree or hepatocellular secretory failure (collectively termed *intrahepatic cholestasis*) cannot be treated surgically (short of transplantation), and the patient's condition may be worsened by an operative procedure. Thus, *there is some urgency in identifying the cause of jaundice and cholestasis.*

## SUMMARY

### Jaundice and Cholestasis

- Jaundice occurs when retention of bilirubin leads to serum levels above 2.0 mg/dL.
- Hepatitis and intra- or extrahepatic obstruction of bile flow are the most common causes of jaundice involving the accumulation of conjugated bilirubin.
- Hemolytic anemias are the most common cause of jaundice involving the accumulation of unconjugated bilirubin.
- Cholestasis is the impairment of bile flow resulting in the retention of bilirubin, bile acids, and cholesterol.
- Serum alkaline phosphatase usually is elevated in cholestatic conditions.

## Hepatic Encephalopathy

Hepatic encephalopathy may develop rapidly in acute liver failure or insidiously with gradually evolving chronic liver failure from cirrhosis. In either setting, patients with hepatic encephalopathy show a spectrum of brain dysfunction ranging from subtle behavioral abnormalities to

marked confusion and stupor, to deep coma and death. These changes may progress over hours or days as, for example, in fulminant hepatic failure or gradually in a person with marginal hepatic function from chronic liver disease. Associated fluctuating neurologic signs include rigidity, hyperreflexia, nonspecific electroencephalographic changes, and, rarely, seizures. Particularly characteristic is *asterixis* (also called flapping tremor), which is a pattern of nonrhythmic, rapid extension-flexion movements of the head and extremities, best seen when the arms are held in extension with dorsiflexed wrists.

In most instances there are only minor morphologic changes in the brain, such as edema and an astrocytic reaction. Two factors seem to be important in the genesis of this disorder:

- Severe loss of hepatocellular function
- Shunting of blood from portal to systemic circulation around the chronically diseased liver

In the acute setting, an elevation in blood ammonia, which impairs neuronal function and promotes generalized brain edema, seems to be key. In the chronic setting, deranged neurotransmitter production, particularly in monoaminergic, opioidergic, γ-aminobutyric acid (GABA)-ergic, and endocannabanoid systems, leads to neuronal dysfunction.

## Cirrhosis

Cirrhosis is among the top 10 causes of death in the Western world. Its major causes include chronic viral infections, alcoholic or nonalcoholic steatohepatitis (NASH), autoimmune diseases affecting hepatocytes and/or bile ducts, and iron overload. *Cirrhosis* is defined as a *diffuse process characterized by fibrosis and the conversion of normal liver architecture into structurally abnormal nodules.* Its main characteristics by definition are not focal but rather involve most (if not all) of the diseased liver and include

- *Fibrous septa* in the form of delicate bands or broad scars around multiple adjacent lobules. Long-standing fibrosis generally is irreversible so long as disease persists or if disease-associated vascular shunts are widespread, although regression is possible if the underlying cause of liver disease is reversed.
- *Parenchymal nodules,* ranging in size from very small (less than 3 mm in diameter—micronodules) to large (over 1 cm—macronodules), encircled by these fibrous bands. Hepatocytes in these nodules derive from two sources: (1) preexistent, long-lived hepatocytes that, by the time cirrhosis is established, display features of replicative senescence; and (2) newly formed hepatocytes capable of replication that are derived from stem/progenitor cells found adjacent to the canals of Hering and small bile ductules—the hepatobiliary stem cell niche. These stem/progenitor cells also give rise to the *ductular reactions* found at the periphery of most cirrhotic nodules, where parenchyma meets stromal scar, and are accompanied by proliferating endothelial cells, myofibroblasts, and inflammatory cells.

There is no satisfactory classification of cirrhosis save for specification of the presumed underlying etiology. After all known causes have been excluded, about 10% of cases remain, referred to as cryptogenic cirrhosis, although in recent years most of these are recognized as probable "burned-out" NASH. General principles are presented next; the distinguishing features of each form of cirrhosis are discussed subsequently in the relevant disease overview.

### PATHOGENESIS

**Three processes are central to the pathogenesis of cirrhosis: death of hepatocytes, extracellular matrix deposition, and vascular reorganization.**

Changes in the connective tissue and extracellular matrix (ECM) are common to all forms of cirrhosis. In the normal liver, ECM consisting of interstitial collagens (fibril-forming collagen types I, III, V, and XI) is present only in the liver capsule, in portal tracts, and around central veins. The hepatocytes have no true basement membrane; instead, a delicate framework containing type IV collagen and other proteins lies in the space between sinusoidal endothelial cells and hepatocytes (the space of Disse). By contrast, in cirrhosis, types I and III collagen and other ECM components are deposited in the space of Disse (Fig. 15–2).

The major source of excess collagen in cirrhosis are the perisinusoidal stellate cells (formerly known as Ito cells), which lie in the space of Disse. Although they normally function as storage cells for vitamin A, during the development of fibrosis they activate and transform into myofibroblasts. The stimuli for the activation of stellate cells and production of collagen are believed to include reactive oxygen species, growth factors, and cytokines such as tumor necrosis factor (TNF), interleukin-1 (IL-1), and lymphotoxins, which can be produced by damaged hepatocytes or by stimulated Kupffer cells and sinusoidal endothelial cells. Activated stellate cells themselves produce growth factors, cytokines, and chemokines that cause their further proliferation and collagen synthesis—in particular, transforming growth factor-β (TGF-β). Portal fibroblasts probably also participate in some forms of cirrhosis. During the course of chronic liver disease, fibrosis is a dynamic process that involves the synthesis, deposition, and resorption of ECM components, modulated by changing balances between metalloproteases and tissue inhibitors of metalloproteases (Chapter 2). Thus, even in late-stage disease, if the disease process is halted or eliminated, significant remodeling and even restoration of liver function **(cirrhotic regression)** is possible.

Vascular injuries and changes also play significant roles in remodeling of the liver into a cirrhotic state. Inflammation and thrombosis of portal veins, hepatic arteries, and/or central veins may lead to alternating zones of parenchymal hypoperfusion, with resulting parenchymal atrophy, and hyperperfusion, with overcompensating regeneration. The major vascular lesions that contribute to defects in liver function are loss of sinusoidal endothelial cell fenestrations (Fig. 15–2) and the development of portal vein–hepatic vein and hepatic artery–portal vein vascular shunts. While normal sinusoids have fenestrated endothelial cells that allow free exchange of solutes between plasma and hepatocytes, loss of fenestrations and increased basement membrane

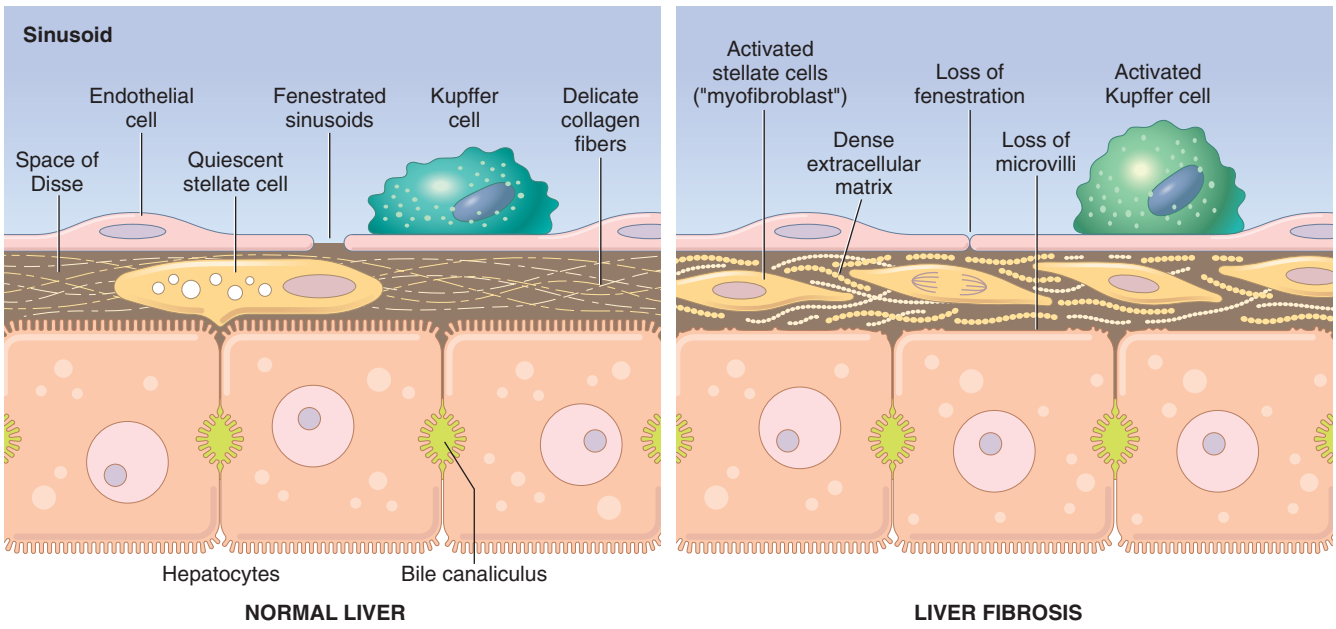

**Figure 15–2** Liver fibrosis. In the normal liver, the perisinusoidal space (space of Disse) contains a delicate framework of extracellular matrix components. In liver fibrosis, stellate cells are activated to produce a dense layer of matrix material that is deposited in the perisinusoidal space. Collagen deposition blocks the endothelial fenestrations and prevents the free exchange of materials from the blood. Kupffer cells also are activated and produce cytokines that are involved in fibrosis. Note that this illustration is not to scale; the space of Disse is actually much narrower than shown.

formation convert thin-walled sinusoids into higher pressure, fast-flowing vascular channels without such solute exchange. In particular, the movement of proteins (e.g., albumin, clotting factors, lipoproteins) between hepatocytes and the plasma is markedly impaired. These functional changes are aggravated by the loss of microvilli from the hepatocyte surface, further diminishing its transport capacity. Vascular shunts mentioned earlier lead to abnormal vascular pressures in the liver and contribute to hepatic dysfunction and portal hypertension, described later.

The causes of liver cell injury that give rise to cirrhosis are varied and depend on the etiology (viral, alcoholic, drugs). As described earlier, the normal liver cells are replaced by parenchymal nodules derived from long-lived surviving hepatocytes and new cells generated from stem cells. The regenerating liver cells form spherical nodules confined by fibrous septa.

## SUMMARY

### Cirrhosis

- The three main characteristics of cirrhosis are (1) involvement of most or all of the liver, (2) bridging fibrous septa, and (3) parenchymal nodules containing a mix of senescent and replicating (often stem/progenitor cell-derived) hepatocytes.
- Cirrhosis usually is an end-stage process that may have multiple causes. The most frequent are chronic hepatitis B and C and alcoholic and nonalcoholic steatohepatitis. Less frequent causes are autoimmune and biliary diseases and metabolic conditions such as hemochromatosis.
- The main complications of cirrhosis are related to decreased liver function, portal hypertension, and increased risk for development of hepatocellular carcinoma.

### Clinical Features

All forms of cirrhosis may be clinically silent. When symptoms appear, they typically are nonspecific and include anorexia, weight loss, weakness, and, in advanced disease, frank debilitation. Incipient or overt hepatic failure may develop, usually precipitated by imposition of a metabolic load on the liver, as from systemic infection or a gastrointestinal hemorrhage. Most cases of ultimately fatal cirrhosis involve one of the following mechanisms:

- Progressive liver failure
- A complication related to portal hypertension
- The development of hepatocellular carcinoma

## Portal Hypertension

Increased resistance to portal blood flow may develop from prehepatic, intrahepatic, and posthepatic causes (described later). *The dominant intrahepatic cause is cirrhosis, accounting for most cases of portal hypertension.* Far less frequent are instances of *noncirrhotic portal hypertension*, such as from schistosomiasis, massive fatty change, diffuse granulomatous diseases (e.g., sarcoidosis, miliary tuberculosis), and diseases affecting the portal microcirculation, exemplified by *nodular regenerative hyperplasia.*

Portal hypertension in cirrhosis results from increased resistance to portal flow at the level of the sinusoids and

compression of central veins by perivenular fibrosis and expanded parenchymal nodules. Anastomoses between the arterial and portal systems in the fibrous bands also contribute to portal hypertension by imposing arterial pressure on the normally low-pressure portal venous system. Another major factor in the causation of portal hypertension is an increase in portal venous blood flow resulting from a hyperdynamic circulation. This is caused by arterial vasodilation in the splanchnic circulation, resulting primarily from increased production of nitric oxide (NO) in the vascular bed. This occurs in response to reduced clearance of bacterial DNA absorbed from the gut that bypasses the Kupffer cells due to intrahepatic shunting of blood from portal to systemic circulation. Bacterial DNA causes increased production of NO. The major clinical consequences are discussed next (Fig. 15–3).

### *Ascites*

*Ascites* refers to the collection of excess fluid in the peritoneal cavity. It usually becomes clinically detectable when at least 500 mL have accumulated, but many liters may collect, causing massive abdominal distention. Ascites generally is a serous fluid containing as much as 3 g/dL of protein (largely albumin). More importantly, the serum to ascites albumin gradient is ≥1.1 g/dL. The fluid may contain a scant number of mesothelial cells and mononuclear leukocytes. Influx of neutrophils suggests secondary infection, whereas presence of red cells points to possible disseminated intraabdominal cancer. With long-standing ascites, seepage of peritoneal fluid through transdiaphragmatic lymphatics may produce hydrothorax, more often on the right side.

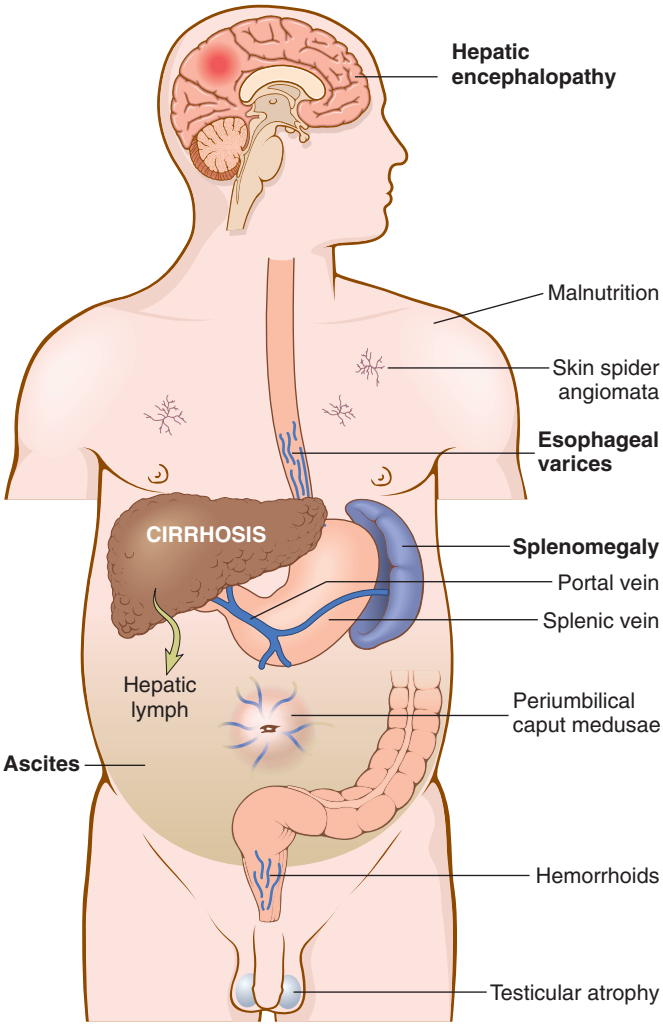

**Figure 15–3** Some clinical consequences of portal hypertension in the setting of cirrhosis. The most important manifestations are in **bold** type.

## PATHOGENESIS

The pathogenesis of ascites is complex, involving one or more of the following mechanisms:

- Increased movement of intravascular fluid into the extravascular space of Disse, caused by sinusoidal hypertension and hypoalbuminemia.
- Leakage of fluid from the hepatic interstitium into the peritoneal cavity. Normal thoracic duct lymph flow is 800 to 1000 mL/day. With cirrhosis, hepatic lymphatic flow may approach 20 L/day, exceeding thoracic duct capacity. Hepatic lymph is rich in proteins and low in triglycerides, as reflected in the protein-rich ascitic fluid.
- Renal retention of sodium and water due to secondary hyperaldosteronism (Chapter 3), despite a total body sodium mass greater than normal.

## Portosystemic Shunt

With the rise in portal venous pressure, shunts develop wherever the systemic and portal circulations share capillary beds. Principal sites are veins around and within the rectum (manifest as hemorrhoids), the cardioesophageal junction (producing esophagogastric varices), the retroperitoneum, and the falciform ligament of the liver (involving periumbilical and abdominal wall collaterals). Although hemorrhoidal bleeding may occur, it is rarely massive or life-threatening. Much more important are the *esophagogastric varices* that appear in about 65% of persons with advanced cirrhosis of the liver, causing massive hematemesis and death in some instances (Chapter 14). Rarely, abdominal wall collaterals appear as dilated subcutaneous veins extending outward from the umbilicus (*caput medusae*).

### *Splenomegaly*

Long-standing congestion may cause congestive splenomegaly. The degree of enlargement varies widely (usually 1000 g or less) and is not necessarily correlated with other features of portal hypertension. Massive splenomegaly may secondarily induce a variety of hematologic abnormalities attributable to hypersplenism (Chapter 11).

### *Hepatorenal Syndrome*

Hepatorenal syndrome generally appears only with severe liver disease and is marked by the development of renal failure without primary abnormalities of the kidneys themselves. Excluded by this definition are concomitant toxic damage to both the liver and the kidney, as may occur in carbon tetrachloride and mushroom poisoning and the copper toxicity of Wilson disease. Also excluded are instances of advanced hepatic failure in which circulatory collapse leads to acute tubular necrosis and renal failure. Kidney function promptly improves if hepatic failure is reversed. Although the exact cause is unknown, evidence points to splanchnic vasodilatation and systemic vasoconstriction, leading to a severe reduction in renal blood flow, particularly to the cortex.

The syndrome is heralded by a drop in urine output and rising blood urea nitrogen and creatinine values. The ability to concentrate urine is retained, producing a hyperosmolar urine devoid of proteins and abnormal sediment that is surprisingly low in sodium (unlike renal tubular necrosis). Renal dialysis or other treatments are at best bridges to the only cure, liver transplantation; however, transplantation recipients with hepatorenal syndrome have a high mortality in the months after the operation.

### *Portopulmonary Hypertension and Hepatopulmonary Syndrome*

Pulmonary dysfunction in chronic liver disease is common and may be life-threatening. Causes of liver injury also may damage the lungs (e.g., $\alpha_1$-antitrypsin deficiency leading to both cirrhosis and emphysema). Ascites, pressing upward on the diaphragm, and pleural effusions associated with portal hypertension can compromise lung capacity. Finally, changes in pulmonary blood flow occurring secondary to hepatic failure may lead to *portopulmonary hypertension* or *hepatopulmonary syndrome*.

Portopulmonary hypertension is defined as pulmonary arterial hypertension associated with liver disease or portal hypertension. Although the mechanisms underlying this condition remain obscure, they seem to involve portal hypertension of any cause (cirrhotic or non-cirrhotic) and excessive pulmonary vasoconstriction and vascular remodeling, which eventually lead to right-sided heart failure; *the most common clinical manifestations are dyspnea on exertion* and clubbing of the fingers, followed by palpitations and chest pain.

Hepatopulmonary syndrome is associated with abnormal intrapulmonary vascular dilatation in combination with increased pulmonary blood flow. Shunting of blood through such dilatations leads to ventilation-perfusion mismatch and reduced oxygen diffusion, thus giving rise to *severe arterial hypoxemia with dyspnea and cyanosis*. Oxygen supplementation can alleviate these problems early on, though the most severe intrapulmonary vascular dilatation or formation of arteriovenous malformations causes right-to-left shunting that is only partially correctable. Platypnea (easier breathing while lying down as compared to when sitting or standing) and orthodeoxia (fall of arterial blood oxygen with upright posture) are pathognomonic of hepatopulmonary syndrome.

Selected patients with portopulmonary hypertension experience some degree of reversal of disturbed pulmonary function with liver transplantation.

## DRUG- OR TOXIN-INDUCED LIVER DISEASE

As the major drug metabolizing and detoxifying organ in the body, the liver is subject to injury from an enormous array of therapeutic and environmental chemicals. Injury may result from direct toxicity, through hepatic conversion of a xenobiotic to an active toxin, or by immune mechanisms, such as by a drug or a metabolite acting as a hapten to convert a cellular protein into an immunogen.

A diagnosis of drug- or toxin-induced liver disease may be made on the basis of a temporal association of liver damage with drug or toxin exposure and, it is hoped, recovery on removal of the compound(s), combined with exclusion of other potential causes. *Exposure to a toxin or therapeutic agent should always be included in the differential diagnosis of any form of liver disease.* By far the most important agent that produces toxic liver injury is alcohol; its characteristic histologic (but not clinical) features are shared with nonalcoholic fatty liver disease (NAFLD) and therefore it is discussed in that section.

Drug-induced liver disease is a common condition that may manifest as a mild reaction or, much more seriously, as acute liver failure or chronic liver disease. A large number of drugs and chemicals can produce liver injury (Table 15–4). It is important to keep in mind that compounds other than those normally thought of as drugs or medicines may be to blame; often careful, persistent history taking will uncover exposure to other potential toxins such as herbal remedies, dietary supplements, topical applications (e.g., ointments, perfumes, shampoo), and environmental exposures (e.g., cleaning solvents, pesticides, fertilizers).

Principles of drug and toxic injury are discussed in Chapter 7. Here it suffices to note that drug reactions may be classified as *predictable* or *unpredictable* (idiosyncratic). Predictable drug or toxin reactions affect all people in a dose-dependent fashion. Unpredictable reactions depend on individual host variations, particularly the propensity to mount an immune response to drug-related antigen or the rate at which the agent is metabolized. Both classes of injury may be immediate or take weeks to months to develop.

A classic predictable hepatotoxin is acetaminophen, now the most common cause of acute liver failure necessitating transplantation in the United States. The toxic agent is not acetaminophen itself but rather toxic metabolites produced by the cytochrome P-450 system in acinus zone 3 hepatocytes (Fig. 15–4). As these cells die, the zone 2 hepatocytes take over this metabolic function, in turn becoming injured. In severe overdoses the zone of injury extends to the periportal hepatocytes, resulting in fulminant hepatic failure (Fig. 15–5, *A* and *B*). While intentional suicidal overdoses are common, so are accidental overdoses. This is because the cytotoxicity is dependent on the activity of the cytochrome P-450 system, which may be

**Table 15–4** Different Forms of Drug- or Toxin-Induced Hepatic Injury

| Pattern of Injury | Morphologic Findings | Examples of Associated Agents |
|---|---|---|
| Cholestatic | Bland hepatocellular cholestasis, without inflammation | Contraceptive and anabolic steroids; estrogen replacement therapy |
| Cholestatic hepatitis | Cholestasis with lobular inflammation and necrosis; may show bile duct destruction | Numerous antibiotics; phenothiazines |
| Hepatocellular necrosis | Spotty hepatocyte necrosis<br>Submassive necrosis, zone 3<br>Massive necrosis | Methyldopa, phenytoin<br>Acetaminophen, halothane<br>Isoniazid, phenytoin |
| Steatosis | Macrovesicular | Ethanol, methotrexate, corticosteroids, total parenteral nutrition |
| Steatohepatitis | Microvesicular, Mallory bodies | Amiodarone, ethanol |
| Fibrosis and cirrhosis | Periportal and pericellular fibrosis | Methotrexate, isoniazid, enalapril |
| Granulomas | Noncaseating epithelioid granulomas | Sulfonamides, numerous other agents |
| Vascular lesions | Sinusoidal obstruction syndrome (venoocclusive disease): obliteration of central veins<br>Budd-Chiari syndrome<br>Sinusoidal dilatation<br>Peliosis hepatis: blood-filled cavities, not lined by endothelial cells | High-dose chemotherapy, bush teas<br>Oral contraceptives<br>Oral contraceptives, numerous other agents<br>Anabolic steroids, tamoxifen |
| Neoplasms | Hepatic adenoma<br>Hepatocellular carcinoma<br>Cholangiocarcinoma<br>Angiosarcoma | Oral contraceptives, anabolic steroids<br>Thorotrast<br>Thorotrast<br>Thorotrast, vinyl chloride |

From Washington K: Metabolic and toxic conditions of the liver. In Iacobuzio-Donahue CA, Montgomery EA (eds): Gastrointestinal and Liver Pathology. Philadelphia, Churchill Livingstone, 2005.

upregulated by other agents taken in combination with acetaminophen, such as alcohol (beware acetaminophen as a hangover prophylactic) or codeine in acetaminophen compound tablets.

Examples of drugs that can cause idiosyncratic reactions are chlorpromazine (an agent that causes cholestasis in individuals who metabolize it slowly), halothane (which can cause a fatal immune-mediated hepatitis in some persons exposed to this anesthetic on several occasions), and other drugs such as sulfonamides, α-methyldopa, and allopurinol. Often, idiosyncratic drug or toxin reactions involve a variable combination of direct cytotoxicity and immune-mediated hepatocyte or bile duct destruction. Examples of hepatotoxins are given in each disease-specific category described later.

## SUMMARY

### Drug- or Toxin-Induced Liver Disease

- Drug- and toxin-induced liver disease may be predictable (intrinsic) or unpredictable (idiosyncratic).
- Predictable hepatotoxins affect most individuals in a dose-dependent fashion.
- Unpredictable hepatotoxins affect rare persons in an idiosyncratic way, often involving a combination of direct cytotoxicity and immune-mediated injury.
- Every pattern of liver injury can be caused by some toxin or drug; therefore, exposures involving these agents must always be considered in the differential diagnosis.
- In addition to prescription and over-the-counter medications, herbal remedies, dietary supplements, topical applications, and environmental exposures may be responsible for hepatotoxicity.

# ACUTE AND CHRONIC HEPATITIS

The terminology of acute and chronic hepatitis can be confusing, since the term *hepatitis* is applied to a number of different diseases and different forms of liver injury. For example, *hepatitis* is a descriptor for specific histopathologic patterns of hepatocyte injury associated with inflammation and, when chronic, with scarring. Acute and chronic forms of hepatitis are distinguished in part by duration and in part by the pattern of cell injury. Viral hepatitides are also classified on the basis of the causative hepatotropic virus such as hepatitis types A, B, C, D, and E. Because all forms of hepatitis, including those due to the hepatitis viruses as well as autoimmune and drug- and toxin-induced hepatitides, share the same patterns of injury, the general descriptions are presented first, followed by clinicopathologic correlations specific to each cause.

## MORPHOLOGY

On gross inspection, liver involved by mild acute hepatitis appears normal or slightly mottled. At the other end of the spectrum, in massive hepatic necrosis the liver may shrink to 500 to 700 g and become transformed into a limp, red organ covered by a wrinkled, baggy capsule. The distribution of liver destruction is extremely capricious: **The entire liver may be involved, or only patchy areas affected.** On sectioning (Fig. 15–5, *A*), necrotic areas have a muddy-red, mushy appearance with blotchy bile staining.

If patients survive for more than a week, surviving hepatocytes begin to regenerate (Chapter 2). If the parenchymal framework is preserved, regeneration is orderly and liver architecture is restored. With more massive destruction,

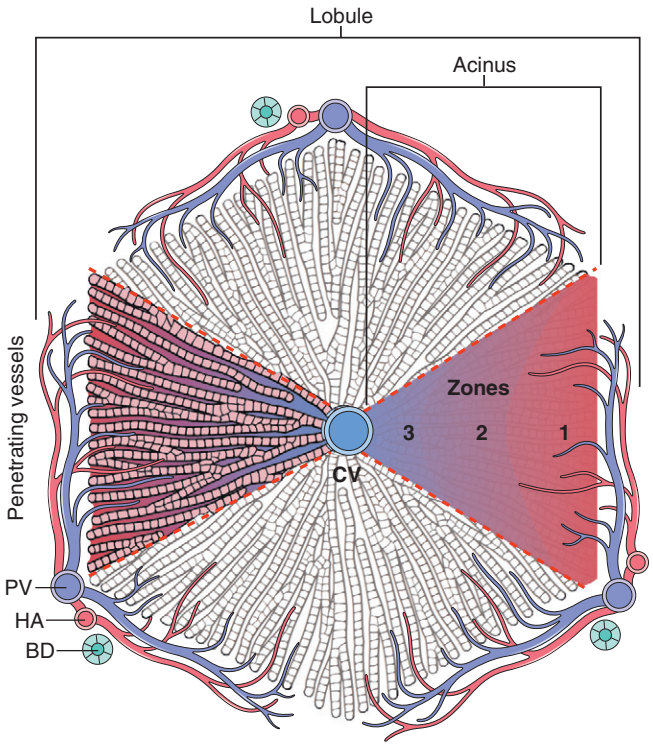

**Figure 15–4** Microscopic architecture of the liver parenchyma. Both a lobule and an acinus are represented. The idealized classic lobule is represented as hexagonal centered on a central vein (CV), also known as terminal hepatic venule, and has portal tracts at three of its apices. The portal tracts contain branches of the portal vein (PV), hepatic artery (HA), and the bile duct (BD) system. Regions of the lobule generally are referred to as *periportal, midzonal,* and *centrilobular,* according to their proximity to portal spaces and central vein. Another useful way to subdivide the liver architecture is to use the blood supply as a point of reference. Using this approach, triangular acini can be recognized. Acini have at their base branches of portal vessels that penetrate the parenchyma ("penetrating vessels"). On the basis of the distance from the blood supply, the acinus is divided into zones 1 (closest to blood source), 2, and 3 (farthest from blood source).

regeneration is disorderly, yielding nodular masses of liver cells separated by granulation tissue and, eventually, scar, particularly in patients with a protracted course of submassive necrosis.

The gross appearance of the liver in chronic hepatitis may be normal or include grossly evident focal scarring or, as cirrhosis develops, may feature widespread nodularity surrounded by extensive scarring.

The general microscopic features of acute and chronic hepatitis of all causes are listed in Table 15–5. Unlike most other organ systems in which the distinction between acute and chronic inflammation depends on the predominant type of inflammatory cell—neutrophilic in acute injury, mononuclear in chronic phases—mononuclear infiltrates predominate in all phases of most hepatitic diseases because they all invoke T cell–mediated immunity. Thus, **the distinction between acute and chronic hepatitis is based on the pattern of cell injury and severity of inflammation, with acute hepatitis often showing less inflammation and more hepatocyte death than chronic hepatitis.**

Both hepatocyte injury and inflammation, while related, can be highly variable depending on etiology and host factors. The hepatocyte injury takes two forms. The first is swelling **(ballooning degeneration),** producing cells with empty-appearing pale cytoplasm that subsequently rupture and undergo **necrosis (cytolysis).** The necrotic cells appear to have **dropped out,** leaving collapsing sinusoidal collagen reticulin framework behind; scavenger macrophages mark sites of dropout. The second pattern of cell death is **apoptosis,** in which hepatocytes shrink, become intensely eosinophilic, and have fragmented nuclei; effector T cells may be present in the immediate vicinity. When located in the parenchyma away from portal tracts, these features are called **lobular hepatitis** (Fig. 15–6).

In severe cases, confluent necrosis of hepatocytes is seen around central veins (Fig. 15–5, *B*). In these areas there may be cellular debris, collapsed reticulin fibers, congestion/hemorrhage, and variable inflammation. With increasing severity, **central-portal bridging necrosis** develops, followed by, even worse, **parenchymal collapse.** When the injury is overwhelming, massive hepatic necrosis and fulminant liver failure ensue. In occasional cases, the injury is not

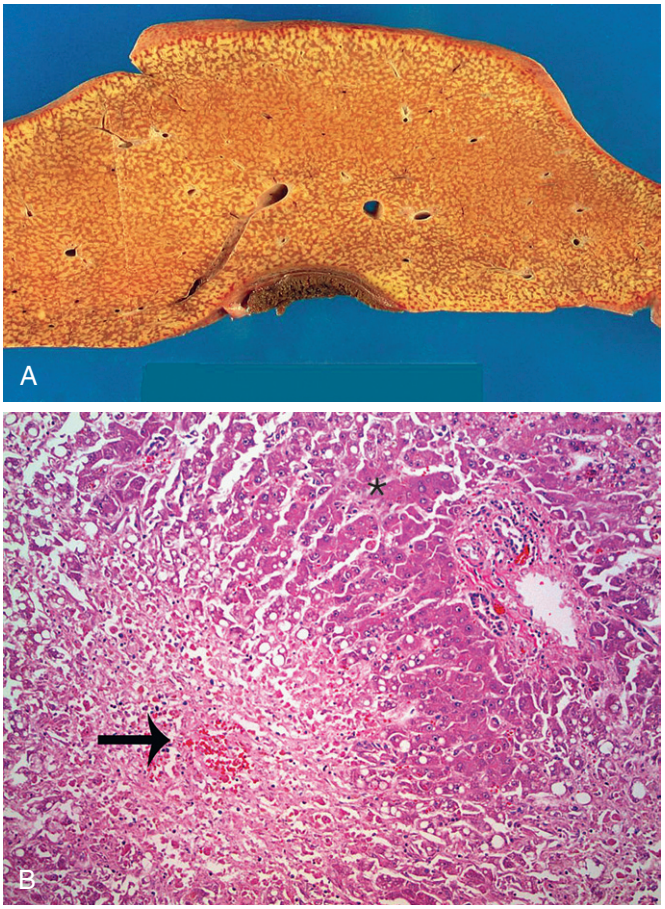

**Figure 15–5 A,** Massive necrosis, cut section of liver. The liver is small (700 g), bile-stained, soft, and congested. **B,** Hepatocellular necrosis caused by acetaminophen overdose. Confluent necrosis is seen in the perivenular region (zone 3) (*large arrow*). There is little inflammation. The residual normal tissue is indicated by the *asterisk*.

The prominent lymphoid infiltrate is typical of the cause of disease in this biopsy: chronic hepatitis C.

severe enough to cause death (or necessitate transplantation), and the liver survives, although with abundant scarring that replaces areas of confluent necrosis. In such cases, some patients rapidly develop **posthepatitic cirrhosis.**

Portal inflammation in acute hepatitis is minimal or absent; dense **mononuclear portal infiltrates** of variable prominence are the defining lesion of **chronic hepatitis** (Fig. 15–7). There is often **interface hepatitis** as well, distinguished from lobular hepatitis by its location at the interface between hepatocellular parenchyma and portal stroma (or scars, when present). The hallmark of severe chronic liver damage is scarring. At first, only portal tracts exhibit fibrosis, but in some patients, with time, **fibrous septa**—bands of dense scar—will extend between portal tracts. In the most severe cases, continued scarring and nodule formation leads to the development of **cirrhosis** (Fig 15–8).

Clinical assessment of chronic hepatitis often requires liver biopsy in addition to clinical and serologic data. Liver biopsy is helpful in confirming the clinical diagnosis, excluding common concomitant conditions (e.g., fatty liver disease, hemochromatosis), assessing histologic features associated

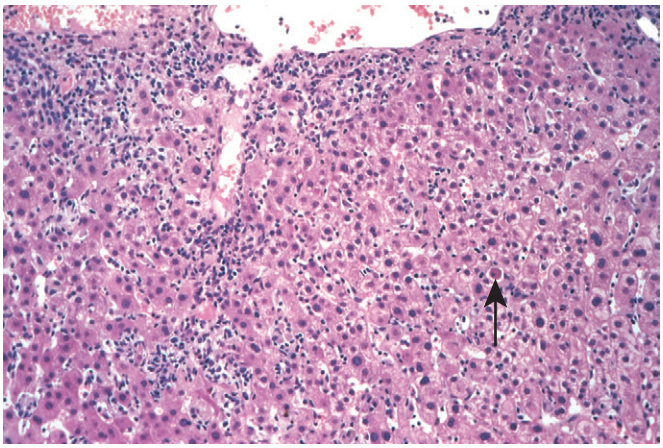

**Figure 15–6** Acute viral hepatitis showing disruption of lobular architecture, inflammatory cells in sinusoids, and apoptotic cells (*arrow*).

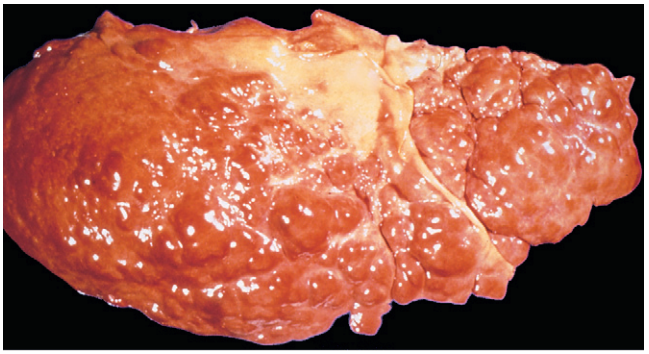

**Figure 15–8** Cirrhosis resulting from chronic viral hepatitis. Note the irregular nodularity of the liver surface.

with an increased risk of malignancy (e.g., small and large cell change, described later), **grading the extent of hepatocyte injury and inflammation, and staging the progression of scarring.** Such grading and staging are useful for assessing prognosis and therapeutic options.

## Viral Hepatitis

Viral hepatitis is caused mainly by hepatitis viruses A (HAV), B (HBV), C (HCV), D (HDV), and E (HEV). These viruses and their infections have distinct features, which are summarized in Table 15–6.

### *Hepatitis A Virus*

Hepatitis A usually is a benign, self-limited disease with an incubation period of 2 to 6 weeks (average 28 days). HAV does not cause chronic hepatitis or a carrier state. Rarely there is fulminant hepatitis; fatalities occur at a rate of only 0.1%. HAV occurs throughout the world and is endemic in countries with poor hygiene and sanitation, so that most natives of such countries have detectable antibodies to HAV by the age of 10 years. Epidemics are not unusual. The disease tends to be mild or asymptomatic in children, with severe HAV infections occurring mainly in adults.

HAV is spread by ingestion of contaminated water and foods and is shed in the stool for 2 to 3 weeks before and 1 week after the onset of jaundice. HAV is not shed in any significant quantities in saliva, urine, or semen. Close personal contact with an infected person during the period of fecal shedding, with fecal-oral contamination, accounts for most cases and explains the outbreaks in institutional settings such as schools and nurseries. *Because HAV viremia is transient, blood-borne transmission of HAV occurs only rarely; therefore, donated blood is not routinely screened for this virus.* Waterborne epidemics may occur in developing countries where people live in overcrowded, unsanitary conditions. Among developed countries, sporadic infections may be contracted by the consumption of raw or steamed shellfish (oysters, mussels, clams), which concentrate the virus from seawater contaminated with human sewage.

HAV is a small, nonenveloped, single-stranded RNA picornavirus. It reaches the liver from the intestinal tract after ingestion, replicates in hepatocytes, and is shed in the bile and feces. The virus itself does not seem to be toxic to hepatocytes, and hence the liver injury seems to result from T cell–mediated damage of infected hepatocytes. As depicted in Figure 15–9, immunoglobulin M (IgM) antibodies against HAV appear in blood at the onset of symptoms. Detection of anti-HAV IgM antibody is the best diagnostic marker for the disease; IgG antibody persists beyond convalescence and is the primary defense against reinfection. In the United States, the prevalence of seropositivity increases gradually with age, reaching 40% by the age of 50 years.

Measures for the prevention and management of hepatitis A include (1) hygienic practices focused on the disposal of human wastes and personal hygiene; (2) passive immunization with immune serum globulin for persons at high risk for infection (very young, very old, or immunocompromised) after exposure to the virus; and (3) administration of inactivated-virus vaccine given either before exposure (e.g., before travel to endemic areas) or very early after exposure.

### *Hepatitis B Virus*

HBV can produce various clinical syndromes:

- Acute hepatitis with recovery and clearance of the virus
- Fulminant hepatitis with massive liver necrosis
- Nonprogressive chronic hepatitis
- Progressive chronic disease sometimes ending in cirrhosis
- An asymptomatic carrier state

**Table 15–6** The Hepatitis Viruses

| Virus | Hepatitis A | Hepatitis B | Hepatitis C | Hepatitis D | Hepatitis E |
|---|---|---|---|---|---|
| Type of virus | ssRNA | Partially dsDNA | ssRNA | Circular defective ssRNA | ssRNA |
| Viral family | Hepatovirus; related to picornavirus | Hepadnavirus | Flaviridae | Subviral particle in Deltaviridae family | Hepevirus |
| Route of transmission | Fecal-oral (contaminated food or water) | Parenteral, sexual contact, perinatal | Parenteral; intranasal cocaine use is a risk factor | Parenteral | Fecal-oral |
| Incubation period | 2–6 weeks | 4–26 weeks | 2–26 weeks | Same as for HBV | 2–8 weeks |
| Frequency of chronic liver disease | Never | 10% | ~80% | 5% (coinfection); ≤70% for superinfection | Never |
| Laboratory diagnosis | Detection of serum IgM antibodies | Detection of HBsAg or antibody to HBcAg | PCR assay for HCV RNA; 3rd-generation ELISA for antibody detection | Detection of IgM and IgG antibodies; HDV RNA serum; HDAg in liver | PCR assay for HEV RNA; detection of serum IgM and IgG antibodies |

dsDNA, double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDAg, hepatitis D antigen; HDV, hepatitis D virus; HEV, hepatitis E virus; IgG, IgM, immunoglobulins G and M; PCR, polymerase chain reaction; ssRNA, single-stranded RNA.

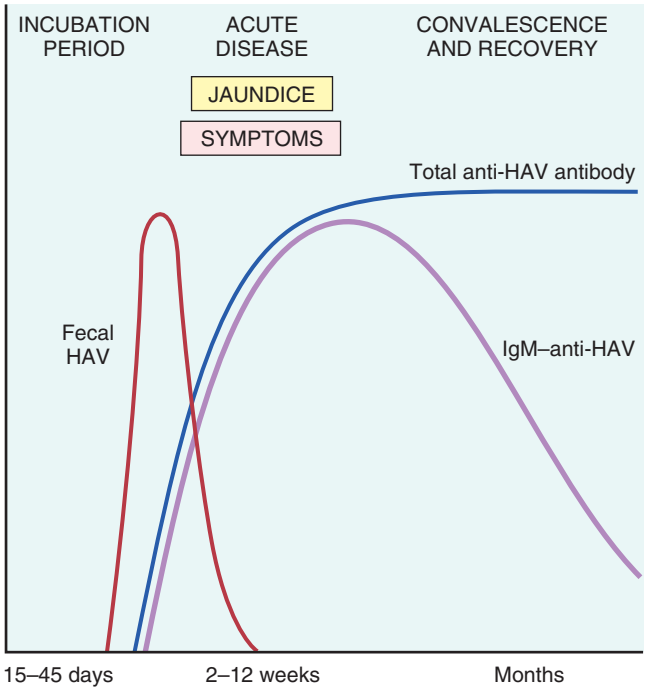

**Figure 15–9** The sequence of serologic markers in acute hepatitis A infection. HAV, hepatitis A virus. There are no routinely available tests for IgG anti-HAV; therefore the presence of this antibody is inferred from the difference between total and IgM-HAV.

HBV-induced chronic liver disease is an important precursor for the development of hepatocellular carcinoma. Figure 15–10 depicts the approximate frequencies of these outcomes.

***Epidemiology and Transmission.*** Globally, liver disease caused by HBV is an enormous problem, with an estimated 400 million people who are carriers of the virus. It is estimated that HBV will infect more than 2 billion people alive today at some point in their lives. About 80% of all chronic carriers live in Asia and the Western Pacific Rim region, where the prevalence of chronic hepatitis B is more than 10%. In the United States there are approximately 185,000 new infections per year. HBV is found in the blood during the last stages of a prolonged incubation period (4 to 26 weeks) and during active episodes of acute and chronic hepatitis. It also is present in all physiologic and pathologic body fluids, with the exception of stool. HBV is a hardy virus and can withstand extremes of temperature and humidity. Thus, whereas blood and body fluids are the primary vehicles of transmission, virus also may be spread by contact with body secretions such as semen, saliva, sweat, tears, breast milk, and pathologic effusions. In endemic regions, vertical transmission from mother to child during birth constitutes the main mode of transmission. In areas of low prevalence, horizontal transmission via transfusion, blood products, dialysis, needlestick accidents among health care workers, sharing of needles in intravenous drug use, and sexual transmission (homosexual or heterosexual) constitute the primary mechanisms for HBV infection. In one third of patients, the source of infection is unknown. Most HBV infections in adults are cleared, but vertical transmission produces a high rate of persistent infection since infants cannot readily clear the infection. Chronically infected persons are at significantly increased risk for development of hepatocellular carcinoma, explaining the high rate of that malignancy in Asia and Pacific Rim nations.

***HBV Structure and Genome.*** HBV is a member of the Hepadnaviridae, a group of DNA-containing viruses that cause hepatitis in many animal species. HBV replication does not involve the integration of the virus in the DNA of the host cell, but integrated HBV frequently is found in cells. The integrated viruses generally have large deletions and rearrangements and usually become inactive. The genome of HBV is a partially double-stranded circular DNA molecule of 3200 nucleotides that encodes

- The precore/core region of a nucleocapsid "core" protein, the *hepatitis B core antigen (HBcAg)*, and a precore

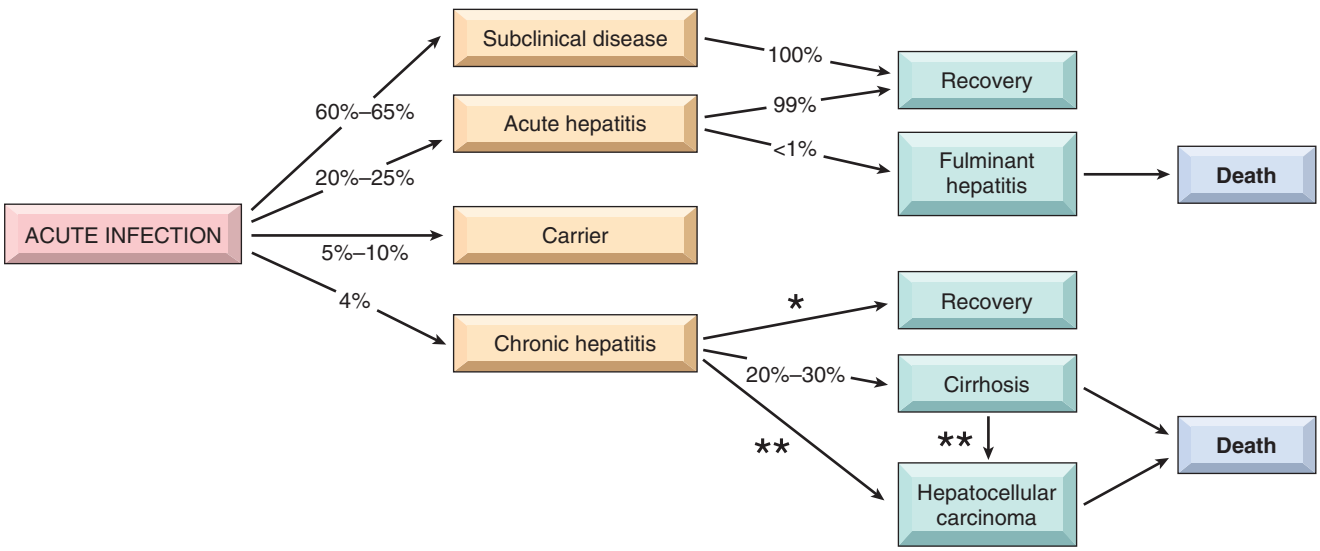

**Figure 15–10** The potential outcomes with hepatitis B infection in adults, with their approximate annual frequencies in the United States. *Estimated rate of recovery from chronic hepatitis is 0.5% to 1% per year. **The risk of hepatocellular carcinoma is 0.02% per year for chronic hepatitis B and 2.5% per year when cirrhosis has developed.

protein designated hepatitis Be antigen (HBeAg). HBcAg is retained in the infected hepatocyte; HBeAg is secreted into blood and is essential for the establishment of persistent infection.

- Envelope glycoprotein, the *hepatitis B surface antigen (HBsAg),* which may be produced and secreted into the blood in massive amounts. Blood HBsAg is immunogenic.
- A *DNA polymerase* with an error-prone reverse transcriptase activity that generates mutations in the genomes of replicating virus at a high rate.
- *HBV-X* protein, which acts as a transcriptional transactivator for many viral and host genes through interaction with various transcription factors. HBV-X is required for viral infectivity and may have a role in the development of hepatocellular carcinoma by regulating p53 degradation and expression (Chapter 6).

### Clinical Course

After exposure to the virus, there is a long, asymptomatic incubation period, which may be followed by acute disease (described later) lasting many weeks to months. The natural course of acute disease can be tracked using serum markers (Fig. 15–11):

- HBsAg appears before the onset of symptoms, peaks during overt disease, and then declines to undetectable levels in 3 to 6 months.
- Anti-HBs antibody does not rise until the acute disease is over and usually is not detectable for a few weeks to several months after the disappearance of HBsAg. Anti-HBs may persist for life, conferring immunity; this is the basis for current vaccination strategies using noninfectious HBsAg.
- HBeAg, HBV-DNA, and DNA polymerase appear in serum soon after HBsAg, and all signify active viral replication. Persistence of HBeAg is an important indicator of continued viral replication, infectivity, and probable progression to chronic hepatitis. The appearance of anti-HBe antibodies implies that an acute infection has peaked and is on the wane.
- IgM anti-HBc becomes detectable in serum shortly before the onset of symptoms, concurrent with elevation of serum aminotransferase levels (indicative of hepatocyte destruction). Over a period of months the IgM anti-HBc antibody is replaced by IgG anti-HBc. As in the case of anti-HAV, there is no specific assay for IgG anti-HBc, but its presence is inferred from decline of IgM anti-HBc in the face of rising levels of total anti-HBc.

Occasionally, mutated strains of HBV emerge that do not produce HBeAg, but are replication-competent and express HBcAg (more than 30% in the Mediterranean, up to 20% in the United States). In patients infected with such mutated strains, the HBeAg may be low or undetectable despite the presence of HBV viral load. A second ominous development is the emergence of viruses that are resistant to vaccine-induced immunity. For instance, replacement of arginine at amino acid 145 of HBsAg with glycine significantly alters recognition of HBsAg by anti-HBsAg antibodies.

Innate immunity protects the host during the initial phases of the infection, and a strong response by virus-specific CD4+ and CD8+ interferon γ–producing cells is associated with the resolution of acute infection. Current evidence suggests that HBV does not cause direct hepatocyte injury, and hepatocyte damage results from killing of the virus-infected cells by CD8+ cytotoxic T cells.

Hepatitis B can largely be prevented by vaccination and by the screening of donor blood, organs, and tissues. The vaccine is prepared from purified HBsAg produced in yeast. Vaccination induces a protective anti-HBs antibody response in 95% of infants, children, and adolescents. Universal vaccination has been a notable success in countries such as Taiwan and Gambia but unfortunately has not been adopted worldwide.

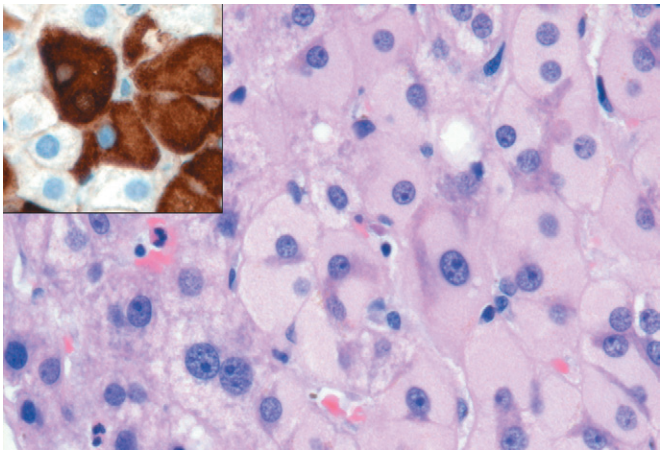

**Figure 15-12** Ground-glass hepatocytes in chronic hepatitis B, caused by accumulation of HBsAg in cytoplasm, have large, pale, finely granular, pink cytoplasmic inclusions on hematoxylin-eosin staining; immunostaining (*inset*) confirms that the endoplasmic reticulum is ballooned with surface antigen (*brown*). HBsAg, hepatitis B surface antigen.

## MORPHOLOGY

Microscopically, hepatitis B can produce all of the histologic features of acute and chronic hepatitis described earlier, but some liver biopsy specimens also display a particular morphologic feature that is nearly diagnostic, the **ground glass cell** (Fig. 15–12). In chronic HBV infection, some hepatocytes may have viral genomes integrated into the host genome. If, by chance, the surface antigen gene integrates into a host genomic site adjacent to an active promoter, then the cell is converted into a factory for surface antigen production. Usually in such cells full viral replication does not take place. Since surface antigen can only exit the cell as part of intact viral particles, the antigen just accumulates in these cells, creating a large cytoplasmic inclusion consisting of endoplasmic reticulum stuffed with surface antigen that has a fine, smoothly granular appearance similar to that of ground glass.

### *Hepatitis C Virus*

***Epidemiology and Transmission.*** HCV also is a major cause of liver disease. The worldwide carrier rate is estimated at 175 million persons (a 3% prevalence rate, ranging widely from 0.1% to 12%, depending on the country). Persistent chronic infection exists in 3 to 4 million persons in the United States, where the number of newly acquired HCV infections per year dropped from 180,000 in the mid-1980s to about 19,000 in 2006. This welcome change resulted from the marked reduction in transfusion-associated hepatitis C (as a result of screening procedures) and a decline of infections in intravenous drug abusers (related to practices motivated by fear of human immunodeficiency virus infection). However, the death rate from HCV will continue to climb for 20 to 25 years, because of the decades-long lag time between acute infection and liver failure. *The major route of transmission is through blood inoculation, with intravenous drug use accounting for at least 60% of cases in the United States.* Transmission by blood products is now fortunately rare, accounting for only 4% of all acute HCV infections. Occupational exposure among health care workers accounts for another 4% of cases. The rates of sexual transmission and vertical transmission are low. Infections of unknown origin account for 9% to 27% of cases. *HCV infection has a much higher rate than HBV of progression* to *chronic disease and eventual cirrhosis* (Fig. 15–13). In fact, hepatitis C is the condition that most frequently necessitates liver transplantation in the United States.

***Viral Structure and Genome.*** HCV is a positive-sense single-stranded RNA virus belonging to the family Flaviviridae. It contains highly conserved 5′- and 3′-terminal regions that flank a single open reading frame of nearly 9500 nucleotides that encode structural and nonstructural proteins. HCV is subclassified into six genotypes, based on the genetic sequence. Moreover, because of the poor fidelity of RNA replication, an infected person may carry many HCV variants, called *quasispecies.* The relationships between quasispecies and disease progression are being investigated, but it seems that high multiplicity of quasispecies is associated with worse prognosis. In addition, this variability seriously hampers efforts to develop an HCV vaccine.

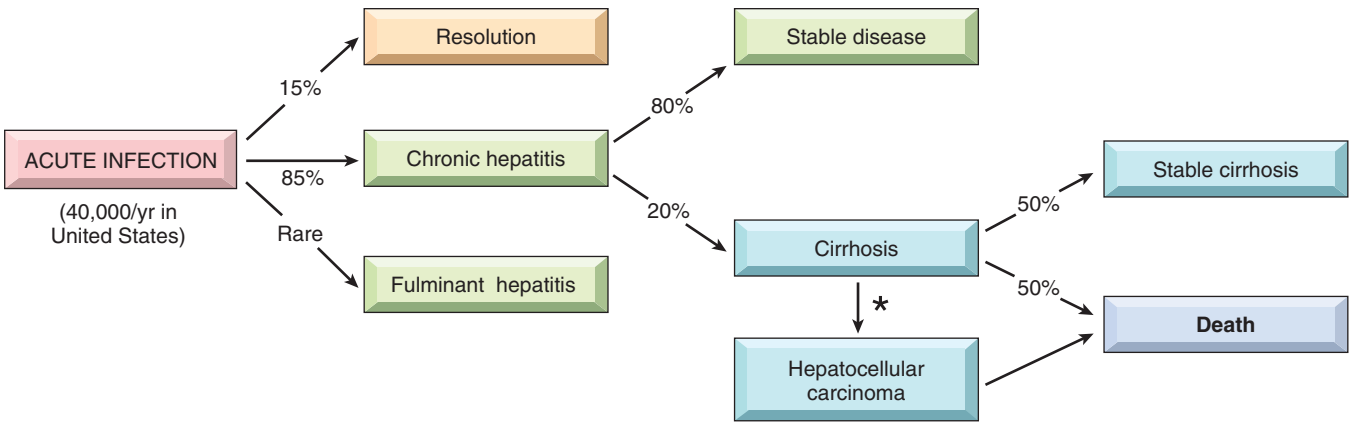

**Figure 15–13** The potential outcomes of hepatitis C infection in adults, with their approximate annual frequencies in the United States. The population estimates are for newly detected infection; because of the decades-long lag time for progression from acute infection to cirrhosis, the actual annual death rate from hepatitis C is about 10,000 per year and exceeded 22,000 deaths per year by 2008. *The risk of hepatocellular carcinoma is 1% to 4% per year.

### Clinical Course

The incubation period for hepatitis C ranges from 2 to 26 weeks, with a mean of 6 to 12 weeks. *Acute hepatitis C is asymptomatic in 75% of affected persons and is easily missed.* Thus, not much is known about this phase of the disease. HCV RNA can be detected in blood within days to 8 weeks depending on the inoculum size. Elevations of serum aminotransferases occur in 2 to 12 weeks. Although neutralizing anti-HCV antibodies develop within weeks to a few months, they *do not confer effective immunity* (Fig. 15–14). Strong immune responses involving CD4+ and CD8+ cells are associated with self-limited HCV infections, but it is not known why only a minority of persons are capable of clearing HCV infection.

In persistent infection, circulating HCV-RNA is detectable, and aminotransferases show episodic elevations, or continuous elevation with fluctuating levels. In a small percentage of affected persons, aminotransferase levels are normal even though abnormal liver histology persists. Increased enzyme activity may occur in the absence of clinical symptoms, presumably reflecting recurrent bouts of hepatocyte necrosis. *Persistent infection is the hallmark of HCV infection, occurring in 80% to 85% of patients with subclinical or asymptomatic acute infection* (Fig. 15–13). Cirrhosis develops in 20% of persistently infected persons: It can be present at the time of diagnosis or may take up to 20 years to develop. Alternatively, patients may have documented chronic HCV infection for decades, without progressing to cirrhosis. Fulminant hepatitis is rare. *Hepatitis C confers a significantly increased risk for hepatocellular carcinoma.*

### MORPHOLOGY

Microscopically, chronic hepatitis C displays the typical features of chronic hepatitis described above, but has some distinctive, common associated findings: (1) **fatty change,** resulting either from altered lipid metabolism in infected hepatocytes, or insulin resistance and the so-called metabolic syndrome (described later); (2) **lymphoid infiltrates** in portal tracts, sometimes with fully formed lymphoid follicles (Fig. 15–7); and (3) **bile duct injury,** which may be related to direct infection of cholangiocytes by the virus.

### *Hepatitis D Virus*

Also called *delta hepatitis virus,* HDV is a unique RNA virus that is replication-defective, causing infection only when it is encapsulated by HBsAg. Thus, *although taxonomically distinct from HBV, HDV is absolutely dependent on HBV coinfection for multiplication.* Delta hepatitis arises in two settings: (1) acute coinfection after exposure to serum containing both HDV and HBV and (2) superinfection of a chronic carrier of HBV with a new inoculum of HDV. In coinfections, HBV infection must first be established before HBsAg is made in sufficient amounts for production of HDV virions. Most coinfected persons clear the viruses and recover completely. By contrast, in most superinfected persons there is an acceleration of hepatitis, progressing to more severe chronic hepatitis 4 to 7 weeks later.

Infection by HDV is worldwide, with prevalence rates ranging from 8% among HBsAg carriers in southern Italy to as high as 40% in Africa and the Middle East. Surprisingly, HDV infection is uncommon in Southeast Asia and China, areas in which HBV infection is endemic. Periodic epidemic outbreaks have occurred in subtropical areas of Peru, Colombia, and Venezuela. In the United States, HDV infection is largely restricted to drug addicts and persons receiving multiple transfusions (e.g., hemophiliacs), who have prevalence rates of 1% to 10%.

HDV RNA and the HDV antigen (HDV Ag) are detectable in the blood and liver just before and in the early days of acute symptomatic disease. *IgM anti-HDV antibody is the most reliable indicator of recent HDV exposure,* as it is present at high titers only transiently in the immediate post-infection period. Acute coinfection by HDV and HBV

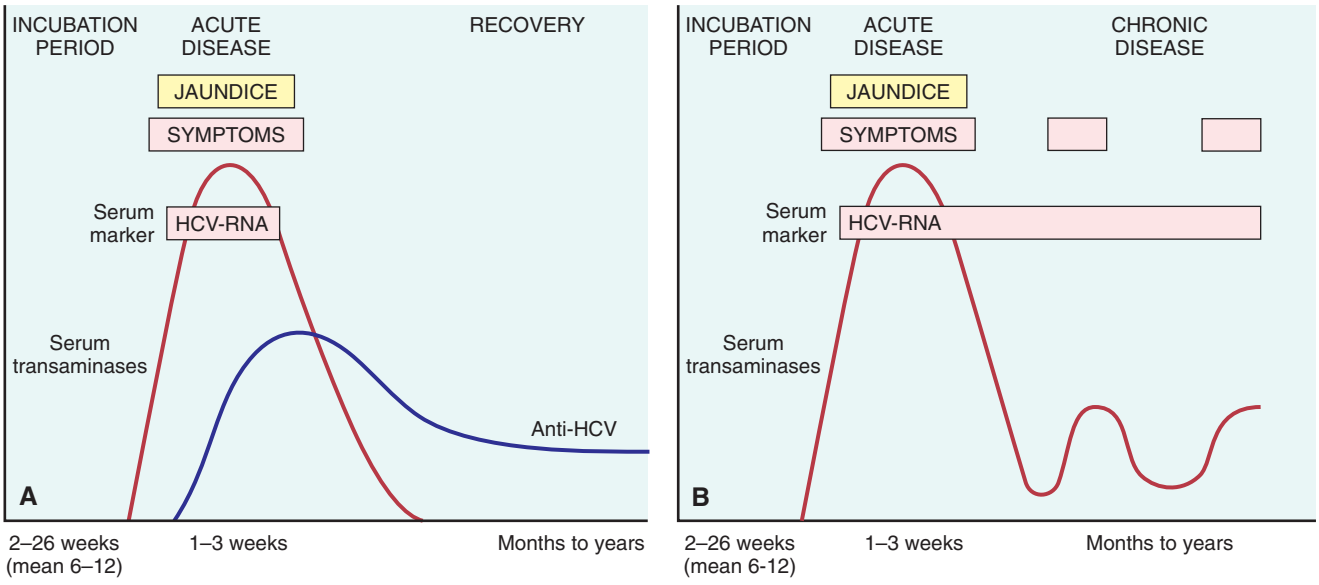

**Figure 15–14** Sequence of serologic markers for hepatitis C. **A,** Acute infection with resolution. **B,** Progression to chronic infection. See text for abbreviations.

is best indicated by detection of IgM against both HDV Ag and HBcAg (denoting new infection with HBV). With chronic delta hepatitis arising from HDV superinfection, HBsAg is present in serum, and anti-HDV antibodies (IgM and IgG) persist in low titer for months or longer.

### *Hepatitis E Virus*

HEV hepatitis is an enterically transmitted, waterborne infection occurring primarily beyond the years of infancy. HEV is endemic in India where it is caused by fecal contamination of drinking water. Prevalence rates of anti-HEV IgG antibodies approach 40% in the Indian population. Epidemics have been reported from Asia, sub-Saharan Africa, and Mexico. Sporadic infection seems to be uncommon; it is seen mainly in travelers and accounts for more than 50% of cases of sporadic acute viral hepatitis in India. *In most cases, the disease is self-limited; HEV is not associated with chronic liver disease or persistent viremia. A characteristic feature of the infection is the high mortality rate among pregnant women, approaching 20%.* The average incubation period after exposure is 6 weeks (range, 2 to 8 weeks).

HEV is a nonenveloped, single-stranded RNA hepevirus. A specific antigen, HEV Ag, can be identified in the cytoplasm of hepatocytes during active infection. Virus can be detected in stools, and anti-HEV IgG and IgM antibodies are detectable in serum.

### *Clinical Features and Outcomes for Viral Hepatitis*

A number of clinical syndromes may develop after exposure to hepatitis viruses:

- *Asymptomatic acute infection*: serologic evidence only
- *Acute hepatitis*: anicteric or icteric
- *Fulminant hepatitis*: submassive to massive hepatic necrosis with acute liver failure
- *Chronic hepatitis*: with or without progression to cirrhosis
- *Chronic carrier state*: asymptomatic without apparent disease

Not all of the hepatotropic viruses provoke each of these clinical syndromes (Table 15–6). As already mentioned, viral persistence and development of chronic disease are much more common after HCV infection than for HBV infection. *Because other infectious or noninfectious causes, particularly drugs and toxins, can lead to essentially identical syndromes, serologic studies are critical for the diagnosis of viral hepatitis and identification of virus types.*

Presented next are brief summaries of clinical outcomes with viral hepatitis.

***Asymptomatic Infection.*** Not surprisingly, patients with asymptomatic infection are identified only incidentally on the basis of minimally elevated serum aminotransferases or after the fact by the presence of antiviral antibodies.

***Acute Viral Hepatitis.*** Any one of the hepatotropic viruses can cause acute viral hepatitis. Acute infections are easily detected for HBV infections but are only rarely diagnosed for HCV. Although the following description is based mostly on HBV infections, *acute viral hepatitis, whatever the agent, can be divided into four phases:* (1) *incubation period,* (2) *symptomatic preicteric phase,* (3) *symptomatic icteric phase (with jaundice and scleral icterus),* and (4) *convalescence.*

Peak infectivity, attributed to the presence of circulating infectious viral particles, occurs during the last asymptomatic days of the incubation period and the early days of acute symptoms. The preicteric phase is marked by nonspecific, constitutional symptoms. Malaise is followed in a few days by general fatigability, nausea, and loss of appetite. Weight loss, low-grade fever, headaches, muscle and joint aches, vomiting, and diarrhea are inconstant symptoms. About 10% of patients with acute hepatitis B develop a serum sickness–like syndrome consisting of fever, rash, and arthralgias, attributed to circulating immune complexes. The hepatitis-related origin of all of these symptoms is suggested by elevated serum aminotransferase levels. Physical examination reveals a mildly enlarged, tender liver. In some patients the nonspecific symptoms are more severe, with higher fever, shaking chills, and headache, sometimes accompanied by right upper quadrant pain and tender liver enlargement. Surprisingly, as jaundice appears and these patients enter the icteric phase, other symptoms abate. The jaundice is caused predominantly by conjugated hyperbilirubinemia, which produces dark-colored urine. With hepatocellular damage and consequent defect in bilirubin conjugation, unconjugated hyperbilirubinemia also can occur. The stools may become light-colored, and the retention of bile salts may cause pruritus. An icteric phase is usual in adults (but not children) infected with HAV, present in about half of the cases involving HBV, and absent in most cases of HCV infection. In a few weeks to perhaps several months, the jaundice and most of the other systemic symptoms clear as convalescence begins.

***Fulminant Hepatitis.*** In a very small proportion of patients with acute hepatitis A, B, D, or E, acute liver failure may result from massive hepatic necrosis. (With the exception of immunosuppressed individuals, HCV almost never causes acute liver failure). Cases with a more protracted course of several weeks or months usually are referred to as "subacute hepatic necrosis"; the liver shows both massive necrosis and regenerative hyperplasia. As discussed later, drugs and chemicals also may cause massive hepatic necrosis.

***Chronic Hepatitis.*** *Chronic hepatitis* is defined by the presence of symptomatic, biochemical, or serologic evidence of continuing or relapsing hepatic disease for more than 6 months, with histologically documented inflammation and necrosis. Although the hepatitis viruses are responsible for most cases, there are many causes of chronic hepatitis (described later), such as autoimmunity, drugs and toxins, Wilson disease, and $\alpha_1$-antitrypsin (AAT) deficiency.

Etiology rather than the histologic pattern is the most important determinant of the probability of developing progressive chronic hepatitis. In particular, HCV is notorious for causing a chronic hepatitis evolving to cirrhosis (Fig. 15–13), regardless of histologic features at the time of initial evaluation.

The clinical features of chronic hepatitis are highly variable and are not predictive of outcome. In some patients, the only signs of chronic disease are persistent elevations of serum aminotransferase levels. The most common overt symptoms are fatigue and, less commonly, malaise, loss of appetite, and bouts of mild jaundice. Physical findings are few, the most common being spider angiomas, palmar erythema, mild hepatomegaly, and hepatic tenderness.

Laboratory studies may reveal prolongation of the prothrombin time and, in some instances, hypergammaglobulinemia, hyperbilirubinemia, and mildly elevated alkaline phosphatase levels. Occasionally in cases of HBV and HCV infection, circulating antibody-antigen complexes produce immune-complex disease in the form of vasculitis (subcutaneous or visceral) (Chapter 9) and glomerulonephritis (Chapter 13). Cryoglobulinemia is found in as many as 50% of patients with hepatitis C.

The clinical course is highly variable. Persons with hepatitis C may experience spontaneous remission or may have indolent disease without progression for years. Conversely, some patients have rapidly progressive disease and develop cirrhosis within a few years. The major causes of death in patients with chronic hepatitis relate to cirrhosis—namely, liver failure, hepatic encephalopathy, massive hematemesis from esophageal varices, and hepatocellular carcinoma.

***The Carrier State.*** A *carrier* is an asymptomatic person who harbors and therefore can transmit an organism. With hepatotropic viruses, carriers are those who

- Harbor one of the viruses but are free of symptoms or of significant histologic hepatitis on liver biopsy
- Have liver damage evident on biopsy (e.g., only mild necroinflammatory activity and scarring that remains in the early, noncirrhotic stages) but are essentially free of symptoms or disability

Both types of carriers constitute reservoirs of infection. HBV infection early in life, particularly through vertical transmission during childbirth, produces a carrier state 90% to 95% of the time. By contrast, only 1% to 10% of HBV infections acquired in adulthood yield a carrier state. Persons with impaired immunity are particularly likely to become carriers. The situation is less clear with HDV, although there is a well-defined low risk of posttransfusion hepatitis D, indicative of a carrier state in conjunction with HBV infection. From 0.2% to 0.6% of the general U.S. population is estimated to carry HCV.

## Other Viral Infections of the Liver

- *Epstein-Barr virus (EBV) infection* may cause a mild hepatitis during the acute phase of infectious mononucleosis.
- *Cytomegalovirus infection,* particularly in the newborn or immunocompromised, can cause the typical cytomegalic changes of that virus in almost any cell of the liver, including hepatocytes, cholangiocytes, and endothelial cells.
- *Herpes simplex* may infect hepatocytes in newborns or the immunosuppressed, leading to the appearance of the characteristic cytopathic changes and hepatic necrosis.
- *Yellow fever,* which has been a major and serious cause of hepatitis in tropical countries, causes hepatocyte apoptosis, which can be extensive. The apoptotic hepatocytes are intensely eosinophilic and are referred to as *Councilman bodies* after the pathologist who first described them. Infrequently, in children and immunosuppressed persons, hepatitis may be caused by rubella virus, adenovirus, or enterovirus infections.

### SUMMARY

#### Viral Hepatitis

- In the alphabet of hepatotropic viruses, some easy mnemonic devices may be useful:
  - The vowels (hepatitis A and E) never cause chronic hepatitis, only acute hepatitis.
  - Only the consonants (hepatitis B, C, D) have the potential to cause chronic disease (C for consonant and for chronic).
  - Hepatitis B can be transmitted by blood, birthing, and "bonking" (as they say in the United Kingdom).
  - Hepatitis C is the single virus that is more often chronic than not (almost never detected acutely; 85% or more of patients develop chronic hepatitis, 20% of whom will develop cirrhosis).
  - Hepatitis D, the delta agent, is a defective virus, requiring hepatitis B coinfection for its own capacity to infect and replicate.
  - Hepatitis E is endemic in equatorial regions and frequently epidemic.
- The inflammatory cells in both acute and chronic viral hepatitis are mainly T cells; it is the pattern of injury that is different, not the nature of the infiltrate.
- Biopsy assessment in chronic viral hepatitis is most important for grading and staging of disease, which are used to decide whether a patient undergoes often arduous antiviral treatments.
- Patients with long-standing HBV or HCV infections are at increased risk for the development of hepatocellular carcinomas, even in the absence of established cirrhosis.

## Autoimmune Hepatitis

Autoimmune hepatitis is a chronic disorder associated with histologic features that may be indistinguishable from chronic viral hepatitis. This disease may run an indolent or a severe course and typically responds dramatically to immunosuppressive therapy. Salient features include

- Female predominance (70%)
- Absence of serologic evidence of viral infection
- Elevated serum IgG (levels greater than 2.5 g/dL)
- High titers of autoantibodies in 80% of cases
- The presence of other forms of autoimmune diseases, seen in up to 60% of patients, including rheumatoid arthritis, thyroiditis, Sjögren syndrome, and ulcerative colitis

Autoimmune hepatitis can be divided into subtypes on the basis of the autoantibodies produced, but the relevance of this classification to clinical management is unclear. Most patients are found to have circulating antinuclear antibodies, anti–smooth muscle antibodies, liver/kidney microsomal antibody, and/or anti–soluble liver/pancreas antigen. These antibodies can be detected by immunofluorescence or enzyme-linked immunosorbent assays. The main effectors of cell damage in autoimmune hepatitis are believed to be CD4+ helper cells. Autoimmune hepatitis may manifest as mild to severe chronic hepatitis. Response to immunosuppressive therapy usually is

dramatic, although a full remission of disease is unusual. The overall risk of cirrhosis, the main cause of death, is 5%.

### MORPHOLOGY

Although autoimmune hepatitis shares patterns of injury with acute or chronic viral hepatitis, the time course of histologic progression differs. In viral hepatitis, fibrosis typically follows years or decades of slowly accumulating parenchymal injury, whereas in autoimmune hepatitis, there appears to be an early phase of severe cell injury and inflammation followed by rapid scarring. Of interest, and for unclear reasons, this early wave of hepatocyte damage and necrosis usually is subclinical. Clinical evolution correlates with a limited number of histologic patterns:

- Very severe hepatocyte injury associated with widespread **confluent necrosis**
- Marked inflammation concurrent with advanced scarring
- **Burned-out cirrhosis,** associated with little ongoing cell injury or inflammation. This last category was once the most common finding at diagnosis, but heightened clinical awareness of autoimmune hepatitis specifically has led to increasingly earlier diagnosis. Of note, the mononuclear infiltrate in autoimmune hepatitis frequently has **abundant plasma cells.**

## Drug/Toxin-Mediated Injury Mimicking Hepatitis

Many drugs have effects that can mimic the features of acute or chronic viral or autoimmune hepatitis.

- As already described, *acetaminophen toxicity* is one of the leading causes of acute failure leading to liver transplantation. The histologic features may be indistinguishable from those of fulminant acute hepatitis A or hepatitis B.
- *Isoniazid* is an example of an idiosyncratic hepatotoxin that can cause a chronic hepatitis precisely mimicking chronic viral hepatitis that may or may not resolve on removal of the instigating agent.
- Other drugs (e.g., minocyclin and nitrofurantoin) or toxins can induce an autoimmune hepatitis with all of the clinical and histologic features typical of that disease: autoantibodies, elevated IgG, and plasma cell–rich hepatic infiltrates. Such cases sometimes respond to treatment with immunosuppression but occasionally do not, progressing to cirrhosis despite withdrawal of the inciting agent.

# ALCOHOLIC AND NONALCOHOLIC FATTY LIVER DISEASE

Alcohol is a well-known cause of fatty liver disease in adults, and can manifest histologically as steatosis, steatohepatitis, and cirrhosis. In recent years it has become evident that another entity, the so-called nonalcoholic fatty liver disease (NAFLD), can mimic the entire spectrum of hepatic changes typically associated with alcohol abuse. NAFLD (described in more detail later) is associated with insulin resistance, obesity, diabetes mellitus, hypertension, and dyslipidemias, collectively called the metabolic syndrome. Since the morphologic changes of alcoholic and nonalcoholic fatty liver disease are indistinguishable, they are described together, followed by the distinctive clinical features of each of the entities.

### MORPHOLOGY

Three categories of liver alterations are observed in fatty liver disease. They can be present in any combination: steatosis (fatty change), hepatitis (alcoholic or steatohepatitis), and fibrosis.

**Hepatocellular Steatosis.** Hepatocellular fat accumulation typically begins in centrilobular hepatocytes. The lipid droplets range from small (microvesicular) to large (macrovesicular), the largest filling and expanding the cell and displacing the nucleus. As steatosis becomes more extensive, the lipid accumulation spreads outward from the central vein to hepatocytes in the midlobule and then the periportal regions (Fig. 15–15). Macroscopically, the fatty liver with widespread steatosis is large (weighing 4 to 6 kg or more), soft, yellow, and greasy.

**Steatohepatitis.** These changes typically are more pronounced with alcohol use than in NAFLD, but can be seen with variable degrees of prominence in fatty liver disease of any cause:

- **Hepatocyte ballooning.** Single or scattered foci of cells undergo swelling and necrosis; as with steatosis, these features are most prominent in the centrilobular regions.
- **Mallory-Denk bodies.** These consist of tangled skeins of intermediate filaments (including ubiquitinated keratins 8 and 18) and are visible as eosinophilic cytoplasmic inclusions in degenerating hepatocytes (Fig. 15–16).
- **Neutrophil infiltration.** Predominantly neutrophilic infiltration may permeate the lobule and accumulate around degenerating hepatocytes, particularly those containing Mallory-Denk bodies. Lymphocytes and macrophages also may be seen in portal tracts or parenchyma (Fig. 15–16, *A* and *B*).

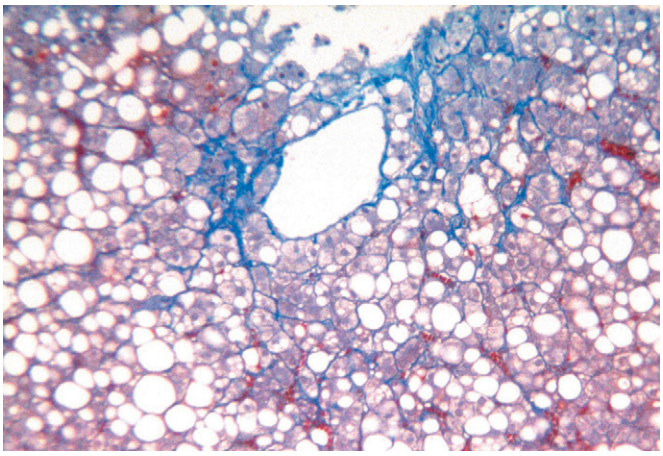

**Figure 15–15** Fatty liver disease. Macrovesicular steatosis is most prominent around the central vein and extends outward to the portal tracts with increasing severity. The intracytoplasmic fat is seen as clear vacuoles. Some fibrosis (stained *blue*) is present in a characteristic perisinusoidal "chicken wire fence" pattern. (Masson trichrome stain.)
*(Courtesy of Dr. Elizabeth Brunt, Washington University in St. Louis, St. Louis, Missouri.)*

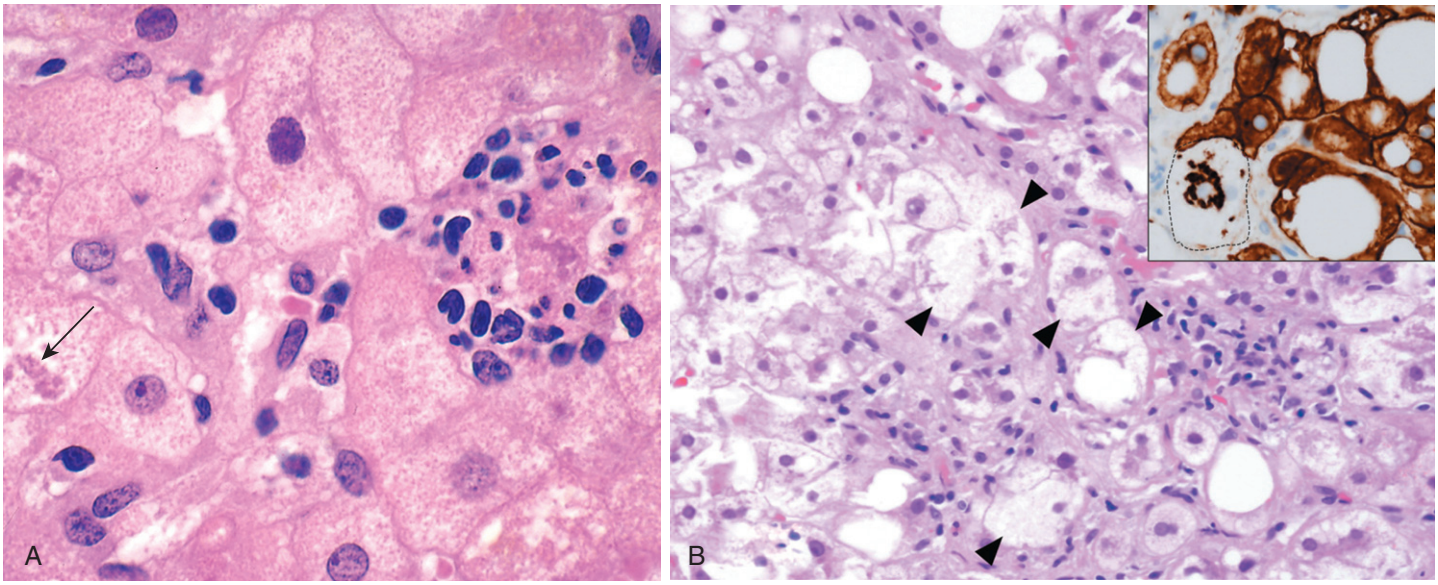

**Figure 15-16 A,** Alcoholic hepatitis with clustered inflammatory cells marking the site of a necrotic hepatocyte. A Mallory-Denk body is present in another hepatocyte (*arrow*). **B,** Steatohepatitis with many ballooned hepatocytes (*arrowheads*) containing prominent Mallory-Denk bodies; clusters of inflammatory cells are also seen; *inset* shows immunostaining for keratins 8 and 18 (*brown*), with most hepatocytes, including those with fat vacuoles, showing normal cytoplasmic staining, but in the ballooned cell (*dotted line*), the keratins are collapsed into the Mallory-Denk body, leaving the cytoplasm "empty."

*(Courtesy of Dr. Elizabeth Brunt, Washington University in St. Louis, St. Louis, Missouri.)*

**Steatohepatitis with fibrosis.** Fatty liver disease of all kinds has a distinctive pattern of scarring. Like the other changes, fibrosis appears first in the centrilobular region as **central vein sclerosis.** Perisinusoidal scar appears next in the space of Disse of the centrilobular region and then spreads outward, encircling individual or small clusters of hepatocytes in a **chicken wire fence pattern** (Fig. 15–15). These tendrils of fibrosis eventually link to portal tracts and then begin to condense to create **central-portal fibrous septa.** As these become more prominent, the liver takes on a nodular, cirrhotic appearance. Because in most cases of fatty liver disease the underlying cause persists, the continual subdivision of established nodules by new, perisinusoidal scarring leads to a classic **micronodular** or **Laennec cirrhosis.** Early in the course, the liver is yellow-tan, fatty, and enlarged. However, with persistent damage, over the course of years the liver is transformed into a brown, shrunken, nonfatty organ composed of cirrhotic nodules that are usually less than 0.3 cm in diameter—smaller than is typical for most chronic viral hepatitis (Fig. 15–17). The end-stage cirrhotic liver may enter into a "burned-out" phase devoid of fatty change and other typical features (Fig. 15–18). A majority of cases of **cryptogenic cirrhosis,** without clear etiology, are now recognized as "burned-out" NASH.

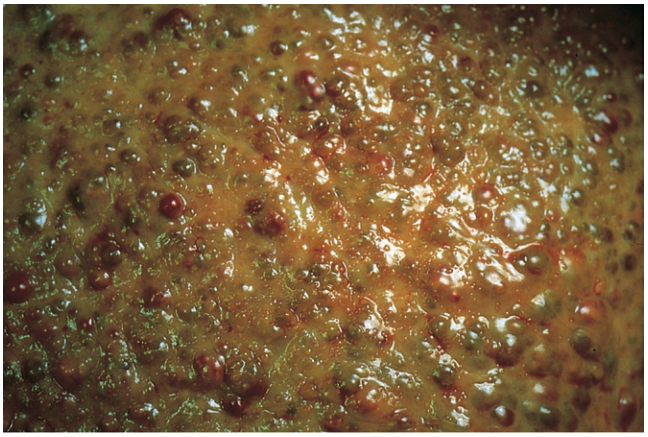

**Figure 15–17** Alcoholic cirrhosis. The characteristic diffuse nodularity of the surface is induced by the underlying fibrous scarring. The average nodule size is 3 mm in this close-up view. The *greenish* tint is caused by bile stasis.

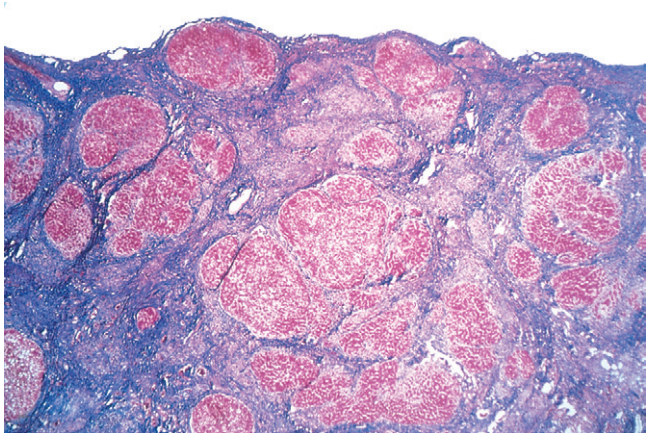

**Figure 15–18** Steatohepatitis leading to cirrhosis. Small nodules are entrapped in *blue*-staining fibrous tissue; fatty accumulation is no longer seen in this "burned-out" stage. (Masson trichrome stain.)

## Alcoholic Liver Disease

Excessive ethanol consumption causes more than 60% of chronic liver disease in Western countries and accounts for 40% to 50% of deaths due to cirrhosis. The following statistics attest to the magnitude of the problem in the United States:

- More than 10 million Americans are alcoholics.
- Alcohol abuse is the fifth leading cause of death, being responsible for 80,000 to 85,000 deaths annually. Of these deaths, 20,000 are attributable directly to end-stage cirrhosis; another 10,000 to 12,000 are the result of automobile accidents.
- From 25% to 30% of hospitalized patients have problems related to alcohol abuse.

Chronic alcohol consumption has many adverse effects (Chapter 7). Among the most important are the distinctive, overlapping forms of alcohol-related fatty liver disease already described: (1) hepatic steatosis, (2) alcoholic hepatitis, and (3) fibrosis and cirrhosis, collectively referred to as *alcoholic liver disease* (Fig. 15–19).

From 90% to 100% of heavy drinkers develop fatty liver (i.e., hepatic steatosis), and of those, 10% to 35% develop alcoholic hepatitis, whereas only 8% to 20% of chronic alcoholics develop cirrhosis. Steatosis, alcoholic hepatitis, and fibrosis may develop independently, so they do not necessarily represent a continuum of changes. Hepatocellular carcinoma arises in 10% to 20% of patients with alcoholic cirrhosis.

### PATHOGENESIS

Short-term ingestion of as much as 80 g of ethanol per day (5–6 beers or 8–9 ounces of 80-proof liquor) generally produces mild, reversible hepatic changes, such as fatty liver. Chronic intake of 40 to 80 g/day is considered a borderline risk factor for severe injury. For reasons that may relate to decreased gastric metabolism of ethanol and differences in body composition, women are more susceptible than men to hepatic injury. It seems that how often and what one drinks may affect the risk of liver disease development. For example, binge drinking causes more liver injury than that associated with steady, lower level consumption. Individual, possibly genetic risk factors must exist, but no reliable markers of susceptibility are known. In the absence of a clear understanding of the factors that influence liver damage, no **safe** upper limit for alcohol consumption can be proposed.

The metabolism of ethanol by the alcohol dehydrogenase and microsomal ethanol-oxidizing system is discussed in Chapter 7. As mentioned, the induction of cytochrome P-450 by chronic alcohol use leads to augmented transformation of other drugs to toxic metabolites. In particular, this effect can accelerate the metabolism of acetaminophen into highly toxic metabolites and increase the risk of liver injury even with therapeutic doses. Discussed next are the detrimental effects of alcohol and its byproducts on hepatocellular function.

**Hepatocellular steatosis** results from several mechanisms: (1) shunting of substrates away from catabolism and

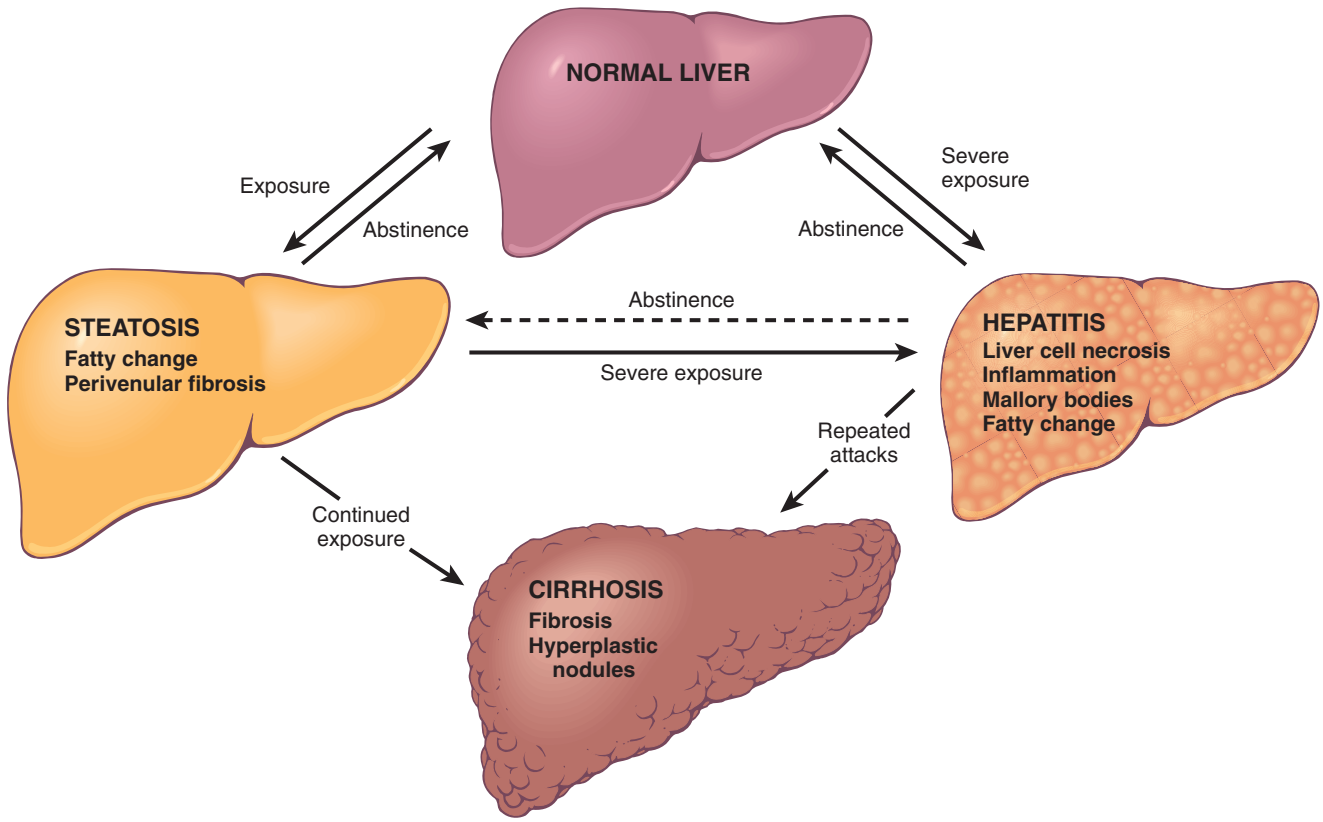

**Figure 15–19** Alcoholic liver disease. The interrelationships among hepatic steatosis, alcoholic hepatitis, and alcoholic cirrhosis are shown, along with a depiction of key morphologic features at the microscopic level. As stated in the text, it should be noted that steatosis, alcoholic hepatitis, and cirrhosis may also develop independently and not along a continuum.

toward lipid biosynthesis, because of the generation of excess reduced nicotinamide-adenine dinucleotide resulting from metabolism of ethanol by alcohol dehydrogenase and acetaldehyde dehydrogenase; (2) impaired assembly and secretion of lipoproteins; and (3) increased peripheral catabolism of fat.

The causes of **alcoholic hepatitis** are uncertain, but it may stem from one or more of the following toxic by products of ethanol and its metabolites:

- **Acetaldehyde** (a major metabolite of ethanol) induces lipid peroxidation and acetaldehyde-protein adduct formation, which may disrupt cytoskeleton and membrane function.
- **Alcohol** directly affects cytoskeleton organization (as illustrated by Mallory-Denk bodies), mitochondrial function, and membrane fluidity.
- **Reactive oxygen species** generated during oxidation of ethanol by the microsomal ethanol oxidizing system react with and damage membranes and proteins. Reactive oxygen species also are produced by neutrophils, which infiltrate areas of hepatocyte necrosis.
- **Cytokine-mediated inflammation** and cell injury is a major feature of alcoholic hepatitis and alcoholic liver disease in general. TNF is considered to be the main effector of injury; IL-1, IL-6, and IL-8 may also contribute. The main stimuli for the production of cytokines in alcoholic liver disease are the reactive oxygen species, mentioned earlier, and microbial products (e.g., endotoxin) derived from gut bacteria.

Because generation of acetaldehyde and free radicals is maximal in the centrilobular region, this region is most susceptible to toxic injury. Pericellular fibrosis and sinusoidal fibrosis develop in this area of the lobule. Concurrent viral hepatitis, particularly hepatitis C, is a major accelerator of liver disease in alcoholics. The prevalence of hepatitis C among persons with alcoholic disease is about 30% (and vice versa).

For unknown reasons, **cirrhosis** develops in only a small fraction of chronic alcoholics. With complete abstinence, some regression of scar can be seen in all cases, and the micronodular liver transforms, with regeneration, into a macronodular cirrhotic organ; rarely, there is regression of cirrhosis altogether.

### Clinical Features

*Hepatic steatosis* may be innocuous or give rise to hepatomegaly with mild elevations of serum bilirubin and alkaline phosphatase. Severe hepatic compromise is unusual. Alcohol withdrawal and the provision of an adequate diet are sufficient treatment.

It is estimated that 15 to 20 years of excessive drinking are necessary to develop *alcoholic cirrhosis,* but *alcoholic hepatitis* can occur after just weeks or months of consistent use. The onset is typically acute and often follows a bout of particularly heavy drinking. Symptoms and laboratory abnormalities may range from minimal to severe. Most patients present with malaise, anorexia, weight loss, upper abdominal discomfort, tender hepatomegaly, and fever. Typical laboratory findings include hyperbilirubinemia, elevated alkaline phosphatase, and neutrophilic leukocytosis. Serum alanine aminotransferase and aspartate aminotransferase are elevated but usually remain below 500 U/mL. The outlook is unpredictable; each bout of hepatitis carries about a 10% to 20% risk of death. With repeated bouts, cirrhosis appears in about one third of patients within a few years; alcoholic hepatitis also may be superimposed on cirrhosis.

The manifestations of alcoholic cirrhosis are similar to those of other forms of cirrhosis, presented earlier. Commonly, the first signs of cirrhosis relate to complications of portal hypertension. The stigmata of cirrhosis (e.g., an abdomen grossly distended with ascites, wasted extremities, caput medusae) may be the presenting features. Alternatively, a patient may first present with life-threatening variceal hemorrhage or hepatic encephalopathy. In other cases, insidious onset of malaise, weakness, weight loss, and loss of appetite precede the appearance of jaundice, ascites, and peripheral edema. Laboratory findings reflect the developing hepatic disease, with elevated serum aminotransferase, hyperbilirubinemia, variable elevation of alkaline phosphatase, hypoproteinemia (globulins, albumin, and clotting factors), and anemia. Finally, cirrhosis may be clinically silent, discovered only at autopsy or when stress such as infection or trauma tips the balance toward hepatic insufficiency. In chronic alcoholics, alcohol may become a major caloric source in the diet, displacing other nutrients and leading to malnutrition and vitamin deficiencies (e.g., thiamine, vitamin $B_{12}$). Compounding these effects is impaired digestive function, primarily related to chronic gastric and intestinal mucosal damage and pancreatitis.

The long-term outlook for alcoholic patients with liver disease is variable. The most important aspect of treatment is abstinence from alcohol. The 5-year survival rate approaches 90% in abstainers who are free of jaundice, ascites, or hematemesis but drops to 50% to 60% in persons who continue to imbibe. Among those with end-stage alcoholic liver disease, the immediate causes of death are

- Hepatic failure
- Massive gastrointestinal hemorrhage
- Intercurrent infection (to which affected persons are predisposed)
- Hepatorenal syndrome
- Hepatocellular carcinoma in 3% to 6% of cases

## SUMMARY

### Alcoholic Liver Disease

- Alcoholic liver disease has three main manifestations: hepatic steatosis, alcoholic hepatitis, and cirrhosis, which may occur alone or in combination.
- Consumption of 50 to 60 g/day of alcohol is considered to be the threshold for the development of alcoholic liver disease.
- Cirrhosis typically develops after 10 to 15 years of drinking or more, but only occurs in a small proportion of chronic alcoholics; alcoholic cirrhosis has the same morphologic and clinical features as cirrhosis caused by viral hepatitis.
- The multiple pathologic effects of alcohol include changes in lipid metabolism, decreased export of lipoproteins, and cell injury caused by reactive oxygen species and cytokines.

## Nonalcoholic Fatty Liver Disease (NAFLD)

NAFLD is a common condition in which fatty liver disease develops in persons who do not drink alcohol. The liver can show any of the three types of changes described earlier (steatosis, steatohepatitis, and cirrhosis). The term nonalcoholic steatohepatitis (NASH) is used to describe overt clinical features of liver injury, such as elevated transaminases and histologic features of hepatitis already described. NAFLD is consistently associated with insulin resistance and the metabolic syndrome (described below). Other commonly associated abnormalities are:

- Type 2 diabetes (or family history of the condition)
- Obesity, primarily central obesity (body mass index greater than 30 $kg/m^2$ in whites and greater than 25 $kg/m^2$ in Asians)
- Dyslipidemia (hypertriglyceridemia, low high-density lipoprotein cholesterol, high low-density lipoprotein cholesterol)
- Hypertension

### PATHOGENESIS

Metabolic syndrome is defined as having at least two of the following: obesity, insulin resistance, dyslipidemia, and hypertension. In patients with metabolic syndrome, the presence of type 2 diabetes and obesity is the best predictor of severe fibrosis and disease progression. Insulin resistance results in the accumulation of triglycerides in hepatocytes by at least three mechanisms:

- Impaired oxidation of fatty acids
- Increased synthesis and uptake of fatty acids
- Decreased hepatic secretion of very-low-density lipoprotein cholesterol

Fat-laden hepatocytes are highly sensitive to lipid peroxidation products generated by oxidative stress, which can damage mitochondrial and plasma membranes, causing apoptosis. Either as a consequence of oxidative stress or through release from visceral adipose tissue, levels of TNF, IL-6, and of the MCP-1 chemokine increase, contributing to liver damage and inflammation. Important roles are emerging for adiponectin and leptin in regulating these processes as well.

NAFLD is the most common cause of incidental elevation of serum transaminases. Most persons with steatosis are asymptomatic; patients with active steatohepatitis or fibrosis may also be asymptomatic, but some may have fatigue, malaise, right upper quadrant discomfort, or more severe symptoms of chronic liver disease. Liver biopsy is required for diagnosis. Fortunately, the frequency of progression from steatosis to active steatohepatitis and then from active steatohepatitis to cirrhosis seems to be low. Nevertheless, NAFLD is considered to be a significant contributor to the pathogenesis of "cryptogenic" cirrhosis.

Because they share common features, the incidence of coronary artery disease is increased in patients with NAFLD. Current therapy of NAFLD is directed toward obesity reduction and decrease in insulin resistance. Clinical trials of pioglitazone, a stimulator of the transcription factor PPAR-γ, which modulates the expression of insulin-sensitive genes, in nondiabetic patients with biopsy-proven steatohepatitis demonstrated a significant benefit as evidenced by reversal of NAFLD histologic changes. Lifestyle modifications (diet and exercise) appear to be the most effective form of treatment.

Pediatric NAFLD is becoming an increasing problem as metabolic syndrome and NAFLD approach epidemic proportions. *In children, the appearance of the histologic injuries is somewhat different: Inflammation and scarring tend to be more prominent in the portal tracts and periportal regions, and mononuclear infiltrates rather than neutrophilic infiltrates predominate.*

### SUMMARY

#### Nonalcoholic Fatty Liver Disease

- Nonalcoholic fatty liver disease (NAFLD) is associated with the metabolic syndrome, obesity, type 2 diabetes, and dyslipidemia and/or hypertension.
- NAFLD may show all the changes associated with alcoholic liver disease: steatosis, steatohepatitis (NASH), and cirrhosis, although the features of steatohepatitis (such as hepatocyte ballooning, Mallory-Denk bodies, and neutrophilic infiltration) often are less prominent than they are in alcohol-related injury.
- Pediatric NAFLD is increasingly being recognized as the obesity epidemic spreads to pediatric age groups, although its histologic pattern differs somewhat from that seen in adults.

## Drug/Toxin-Mediated Injury with Steatosis

Steatosis has a wide array of causes, including alcohol abuse, total parenteral nutrition, amiodarone, and methotrexate. A special category meriting emphasis involves mitochondrial injury leading to diffuse, hepatocellular *microvesicular steatosis,* usually associated with severe and potentially fatal acute liver dysfunction. The classic example is *Reye syndrome,* a rare disease that primarily affects children younger than 4 years of age who have a viral illness. The onset is heralded by pernicious vomiting and accompanied by irritability or lethargy and hepatomegaly. Serum bilirubin, ammonia, and aminotransferase levels are essentially normal at presentation. Although most patients recover, about 25% progress to coma, accompanied by elevations in the serum levels of bilirubin, aminotransferases, and particularly ammonia. Death occurs from progressive neurologic deterioration or liver failure. Survivors of more serious illness may be left with permanent neurologic impairments.

Reye syndrome has been associated with aspirin administration during viral illnesses; while there is no definitive evidence that salicylates play a causal role in this disorder, as a precaution aspirin is contraindicated in children and teenagers with febrile illnesses. Agents that are known to cause similar mitochondrial dysfunction include tetracycline and valproate, as well as toxins in unripe ackee fruit, popular in Jamaica. Highly active antiretroviral therapy (HAART) regimens used for HIV disease also may cause the same histologic injuries, but, for unclear reasons, these patients are spared significant morbidity.

### MORPHOLOGY

The key pathologic finding is **hepatocellular microvesicular steatosis.** Electron microscopy of hepatocellular mitochondria reveals pleomorphic enlargement and electron lucency of the matrices, with disruption of cristae and loss of dense bodies. Specifically with Reye syndrome, **cerebral edema** usually is present. Astrocytes are swollen and mitochondrial changes similar to those seen in the liver may develop. Inflammation is notably absent, as is any evidence of viral infection. **Skeletal muscles, kidneys,** and **heart** also may reveal microvesicular fatty change and mitochondrial alterations, although these changes are more subtle than those in the liver.

## CHOLESTATIC LIVER DISEASES

Cholestatic liver diseases include entities that lead to primary hepatocellular dysfunction (e.g. neonatal cholestasis, drug cholestasis, sepsis) or to bile duct injuries, including some that are mechanical (e.g., obstruction of large ducts by stones or tumor) or inflammatory (such as autoimmune diseases). To be clear, however, bile duct diseases cannot be neatly divided into intrahepatic or extrahepatic, because diseases may affect both intra- and extrahepatic segments, and exclusively extrahepatic biliary disorders may still cause secondary changes within the liver. We will first discuss the important cholestatic liver diseases, a heterogeneous group of disorders that have as their hallmark clinical signs and symptoms of cholestasis; biliary obstruction is considered under diseases of the extrahepatic biliary tree.

### Neonatal Cholestasis

As mentioned earlier, mild transient elevations in serum unconjugated bilirubin are common in normal newborns. Prolonged conjugated hyperbilirubinemia that lasts beyond the first 14 days of life is termed *neonatal cholestasis*. The major causes are extrahepatic biliary atresia, discussed later, and a variety of other disorders collectively referred to as *neonatal hepatitis.* Neonatal hepatitis is not a specific entity, nor are the disorders necessarily inflammatory. Instead, the finding of *neonatal cholestasis* should evoke a diligent search for recognizable toxic, metabolic, and infectious liver diseases. With greater awareness of etiology and better diagnostic tools, *idiopathic neonatal hepatitis* constitutes only 10% to 15% of cases of neonatal hepatitis.

Clinical presentation of infants with any form of neonatal cholestasis is fairly typical, with jaundice, dark urine, light or acholic stools, and hepatomegaly. Variable degrees of hepatic synthetic defects, such as hypoprothrombinemia, may be present. Differentiation between the two most common causes of neonatal cholestasis—extrahepatic atresia and idiopathic hepatitis—assumes great importance, because definitive treatment of biliary atresia requires surgical intervention, whereas surgery may adversely affect the clinical course in a child with idiopathic neonatal hepatitis. Fortunately, discrimination between these diseases can be made in about 90% of cases using clinical data and liver biopsy.

### Cholestasis of Sepsis

Sepsis may affect the liver in many ways. These include direct effects of intrahepatic bacterial infection (e.g., abscess formation or bacterial cholangitis) and ischemia caused by septic shock (particularly when the liver is cirrhotic) or in response to circulating microbial products. The latter is most likely to lead to the cholestasis of sepsis, particularly when the systemic infection is due to gram-negative organisms.

The most common alteration is *canalicular cholestasis,* with bile plugs within predominantly centrilobular canaliculi (Fig. 15–20, *A*). Histologic findings include prominent activated Kupffer cells and mild portal inflammation, but hepatocyte necrosis is scant or absent. *Ductular cholestasis* is a more ominous finding, wherein canals of Hering and

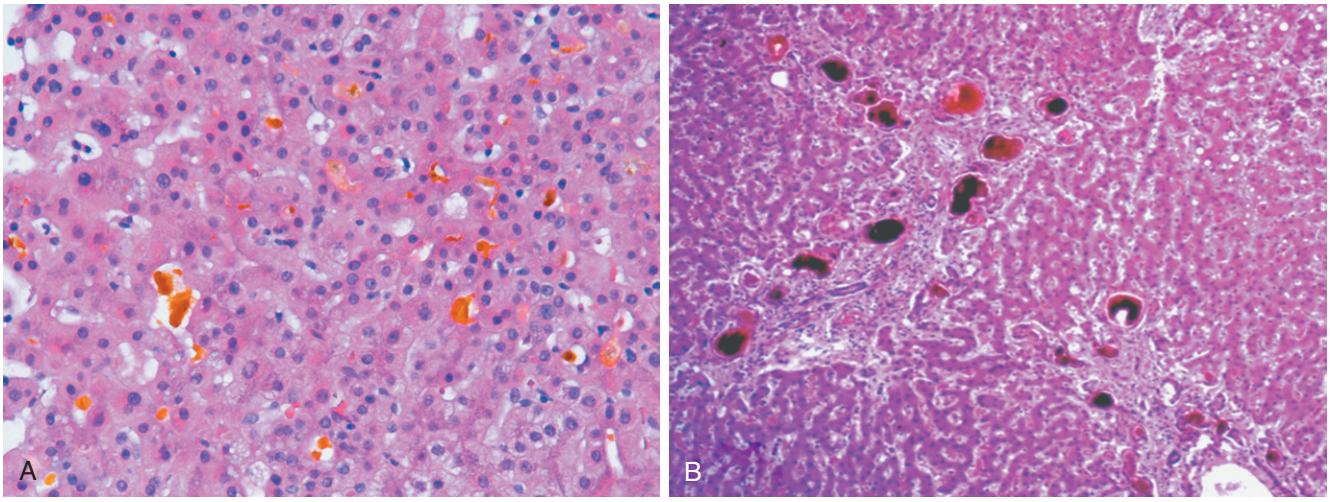

**Figure 15–20 A,** Cholestasis of sepsis. Prominent bile plugs are present in dilated canaliculi in the centrilobular region. **B,** Ductular cholestasis. Large, dark bile concretions within markedly dilated canals of Hering and ductules at the portal-parenchymal interface. This feature, indicative of current or impending severe sepsis, is related to endotoxemia.

**Table 15–7** Main Features of Primary Biliary Cirrhosis and Primary Sclerosing Cholangitis

| Parameter | Primary Biliary Cirrhosis | Primary Sclerosing Cholangitis |
|---|---|---|
| Age | Median age 50 years (30–70) | Median age 30 years |
| Gender | 90% female | 70% male |
| Clinical course | Progressive | Unpredictable but progressive |
| Associated conditions | Sjögren syndrome (70%)<br>Scleroderma (5%)<br>Thyroid disease (20%) | Inflammatory bowel disease (70%)<br>Pancreatitis (≤25%)<br>Idiopathic fibrosing diseases (retroperitoneal fibrosis) |
| Serology | 95% AMA-positive<br>20% ANA-positive<br>40% ANCA-positive | 0–5% AMA-positive (low titer)<br>6% ANA-positive<br>65% ANCA-positive |
| Radiology | Normal | Strictures and beading of large bile ducts; pruning of smaller ducts |
| Duct lesion | Florid duct lesions and loss of small ducts only | Inflammatory destruction of extrahepatic and large intrahepatic ducts; fibrotic obliteration of medium and small intrahepatic ducts |

AMA, antimitochondrial antibody; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody.

bile ductules at the interface of portal tracts and parenchyma become dilated and contain prominent bile plugs (Fig. 15–20, *B*). This change, which is not a typical feature of biliary obstruction, often accompanies or even precedes the development of septic shock.

## Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic, progressive, and sometimes fatal cholestatic liver disease characterized by destruction of intrahepatic bile ducts, portal inflammation and scarring, and the development of cirrhosis and liver failure over years to decades (Table 15–7). *The cardinal feature of PBC is a nonsuppurative destruction of small and medium-sized intrahepatic bile ducts.* PBC is primarily a disease of middle-aged women, with peak incidence between the ages of 40 and 50 years. The name is a bit of a misnomer, because end-stage PBC is not always cirrhotic. Some patients may die or undergo transplantation because of severe portal hypertension in the absence of fully established cirrhosis, although others, usually displaying severe intractable cholestasis, are fully cirrhotic.

### PATHOGENESIS

More than 90% of persons with PBC demonstrate high titers of autoantibodies directed against several mitochondrial acid dehydrogenases. It is still unclear why the immune response is focused on these enzymes and why intrahepatic bile ducts are the targets of the immune attack. Recent evidence suggests that exposure to certain xenobiotics may modify mitochondrial proteins, providing one possible trigger for the immune response.

### Clinical Course

The onset of PBC is insidious, but the disease often comes to attention while the patient is still asymptomatic through discovery of an elevated serum alkaline phosphatase in routine laboratory tests. The diagnosis is usually made by demonstration of antimitochondrial antibodies and typical biopsy findings. Patients often present with pruritus and usually prove to have advanced disease.

Untreated patients progress to hepatic decompensation associated with portal hypertension, with variceal bleeding and hepatic encephalopathy, over a period of 2 or more decades. However, *early treatment with oral ursodeoxycholic acid dramatically improves the disease course, greatly slowing progression. Its mechanisms of action remain unclear, although they appear to include inhibition of apoptosis of biliary epithelium and inhibition of immune responses.* Hyperbilirubinemia is a late feature and usually signifies incipient hepatic decompensation. Associated extrahepatic conditions include the Sjögren syndrome of dry eyes and dry mouth, scleroderma, thyroiditis, rheumatoid arthritis, Raynaud phenomenon, and celiac disease.

### MORPHOLOGY

The morphology of PBC is most revealing in the precirrhotic stage. Interlobular bile ducts are actively destroyed by lymphocytic or plasmacytic inflammation with or without granulomas (the **florid duct lesion**) (Fig. 15–21). Some biopsy specimens, however, do not have active destructive lesions and show only portal tracts lacking bile ducts. Portal tracts upstream from the damaged bile ducts show bile ductular proliferation, and inflammation and necrosis of the adjacent periportal parenchyma. This leads to the development of

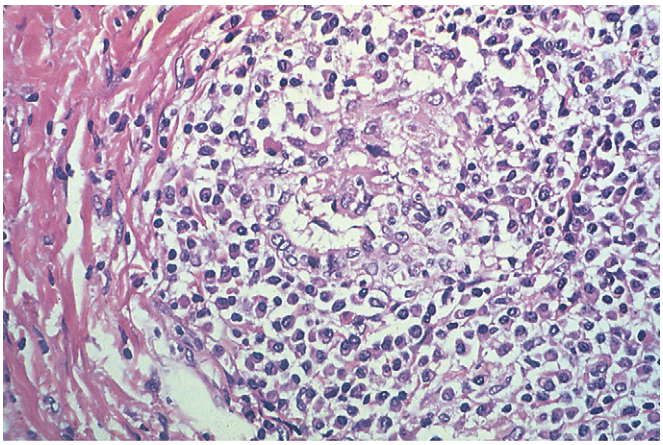

**Figure 15–21** Primary biliary cirrhosis. A portal tract is markedly expanded by an infiltrate of lymphocytes and plasma cells. Note the granulomatous reaction to a bile duct undergoing destruction (florid duct lesion).

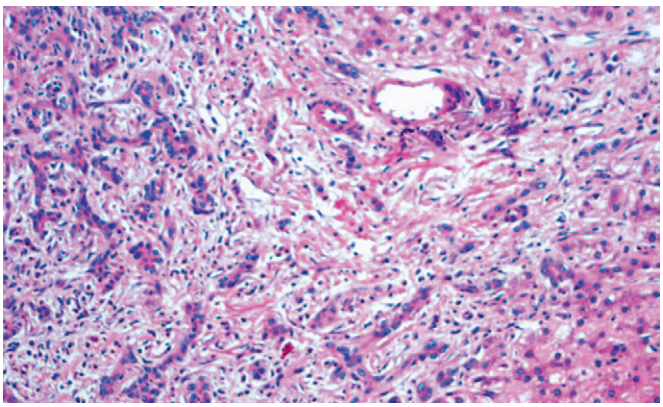

**Figure 15–22** An example of ductular reaction in a fibrotic septum. *(Courtesy of Dr. Matthew Yeh, University of Washington, Seattle, Washington.)*

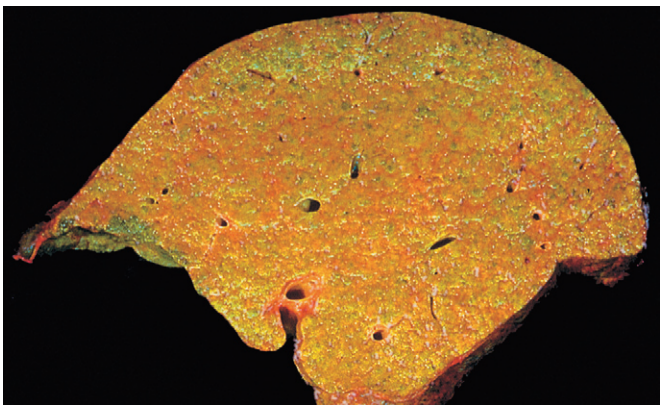

**Figure 15–23** Primary biliary cirrhosis, end stage. This sagittal section demonstrates liver enlargement, nodularity indicative of cirrhosis, and green discoloration due to cholestasis.

portal-portal septal fibrosis (Fig. 15–22). Mild interface and lobular hepatitis also may be present. The features sometimes overlap with those of autoimmune hepatitis; this overlap syndrome is diagnosed only when the hepatitic component is very prominent and there are serologic findings typical for autoimmune hepatitis.

Two paths to end-stage liver disease are recognized, both taking years or decades to evolve. Some patients develop prominent portal hypertension; on histologic examination these livers may display widespread nodularity without the surrounding scar tissue seen in cirrhosis—a feature called **nodular regenerative hyperplasia.** Such livers often are larger than normal and may show a vague nodularity that differs from the obvious nodules of cirrhosis. Why these hepatocytic changes occur in a disease that appears to be primarily biliary in nature is not understood.

Other patients follow a classical path with increasingly widespread duct loss leading to cirrhosis and profound cholestasis. The bile accumulation in such **chronic cholestasis** is not centrilobular, as in drug-induced or sepsis-associated cholestatic syndromes, but is periportal/periseptal and associated with **feathery degeneration** marked by ballooned, bile-stained hepatocytes, often with prominent Mallory-Denk bodies. These cells, while morphologically similar to those seen in alcoholic hepatitis, differ by their periportal rather than centrilobular location. Such end-stage livers show cirrhosis and vivid green discoloration, matching the patient's general icteric state (Fig. 15–23). Because there is little hepatocyte loss, the regenerative nodular hyperplasia often leads to hepatomegaly early in the disease course, a point of distinction from the shrunken livers of chronic hepatitis or alcoholism.

## Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic disorder, characterized by progressive fibrosis and destruction of extrahepatic and intrahepatic bile ducts of all sizes (Table 15–7). Because the changes in the ducts are patchy, cholangiography, performed endoscopically or with the aid of magnetic resonance imaging (MRI), shows a characteristic *beading* in the affected segments of the biliary tree due to narrow strictures alternating with normal sized or dilated ducts. PSC commonly is seen in association with inflammatory bowel disease (Chapter 15), particularly ulcerative colitis, which coexists in approximately 70% of affected patients. Conversely, the prevalence of PSC among persons with ulcerative colitis is about 4%. The disorder tends to occur in the third through fifth decades of life, most often after development of inflammatory bowel disease. Males are affected more often than females, in a ratio of 2:1.

The cause of PSC is unknown. The association with ulcerative colitis, linkage with certain *HLA-DR* alleles, and presence of antinuclear cytoplasmic antibodies with a perinuclear localization (Chapter 10) in 80% of cases all suggest that this is an immunologically mediated disease.

### MORPHOLOGY

The characteristic features of PSC are different in the extrahepatic and large intrahepatic ducts than in the smaller ducts. The largest ducts have chronic inflammation with superimposed acute inflammation, very similar to the mucosal lesions of ulcerative colitis. These inflamed areas lead to narrowing of the larger ducts either because edema and inflammation narrows the lumen or because of subsequent scarring. The smaller ducts, however, often have little in the way of inflammation and show a striking **circumferential fibrosis** often referred to as **onion skinning** around an increasingly atrophic duct lumen (Fig. 15–24). Eventually the lumen disappears altogether, leaving just a dense button of scar tissue, the virtually diagnostic **tombstone scar.** Because the likelihood of sampling such smaller duct lesions on a random needle biopsy is minuscule, diagnosis depends not on biopsy but on radiologic imaging of the extrahepatic and largest intrahepatic ducts.

In response to duct loss, as in PBC, bile ductular proliferation, portal-portal septal fibrosis, and cirrhosis follow. The end-stage liver is therefore usually cirrhotic and green. **Biliary intraepithelial neoplasia** may appear and be a harbinger of **cholangiocarcinoma,** a fatal complication seen in a minority of patients.

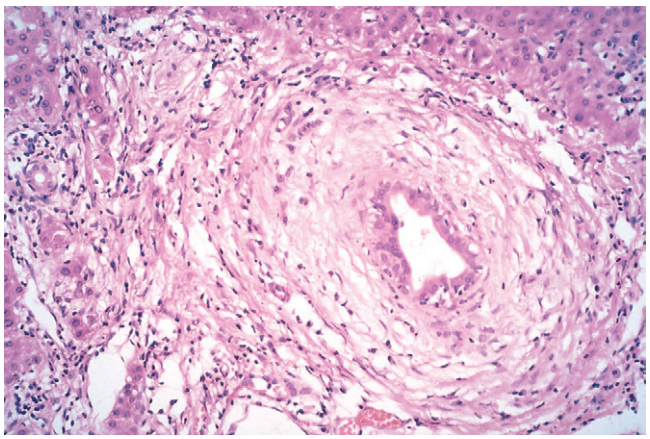

**Figure 15–24** Primary sclerosing cholangitis. A bile duct undergoing degeneration is entrapped in a dense, "onion-skin" concentric scar.

### Clinical Course

Asymptomatic patients may come to attention due to persistently elevated levels of serum alkaline phosphatase. Other patients present acutely with symptoms related to acute cholangitis—infection complicating previously asymptomatic biliary strictures—such as fever, right upper quadrant tenderness, and sometimes acute jaundice. Patients who present at later stages may have progressive fatigue, pruritus, and chronic jaundice. PSC generally has a protracted course over many years. Cholangiocarcinoma develops in 10% to 15% of patients with PSC, with a median time from diagnosis to malignant transformation of 5 years.

## Drug/Toxin-Induced Cholestasis

Cholestasis is a common feature of drug- or toxin-induced hepatic injury and may be seen alone or in combination with hepatitic features. When hepatocyte injury is minimal it is referred to as *bland* cholestasis, which is characterized by canalicular bile plugs and/or mid-centrilobular hepatocyte swelling and cytoplasmic bile pigment accumulation. *Cholestatic hepatitis,* in which features of cholestasis (elevated serum bilirubin and alkaline phosphatase, canalicular and hepatocellular cholestasis) and of hepatitis (elevated serum transaminases, lobular and interface hepatitis) coexist, is a particularly telling indication of drug- or toxin-induced injury. Common or well-known causes of such injury include C17 alkylated anabolic or contraceptive steroids, total parenteral nutrition, and antibiotics. Mimics of PBC and PSC, associated with not only cholestasis but actual loss of bile ducts, include liver injuries caused by chlorpromazine, amitryptyline, and organic arsenicals.

# INHERITED METABOLIC DISEASES

Although there are a relatively large number of inherited metabolic liver diseases, in this section only some common and selected conditions are discussed: hemochromatosis, Wilson disease, and AAT deficiency.

## Hemochromatosis

*Hereditary hemochromatosis* refers to genetic disorders characterized by excessive accumulation of body iron, most of which is deposited in the liver, pancreas, and heart. *At least four genetic variants of hereditary hemochromatosis are recognized. The most common form is an autosomal recessive disease of adult onset caused by mutations in the HFE gene.* Acquired forms of iron accumulation from known sources of excess iron are called *secondary iron overload.* Among the most important are multiple transfusions, ineffective erythropoiesis (as in β-thalassemia and myelodysplastic syndromes), and increased iron intake.

As discussed in Chapter 11, the total body iron pool ranges from 2 to 6 gm in normal adults; about 0.5 gm is stored in the liver, 98% of which is in hepatocytes. In hereditary hemochromatosis, iron accumulates over the lifetime of the affected person from excessive intestinal absorption. Total iron accumulation may exceed 50 gm, over one third of which is found in the liver. *Fully developed cases show (1) cirrhosis (seen in all patients), (2) diabetes mellitus (in 75% to 80% of patients), and (3) skin pigmentation (in 75% to 80%).*

### PATHOGENESIS

The total body content of iron is tightly regulated, such that the limited daily losses of iron are matched by gastrointestinal absorption since there is no excretory pathway for excess absorbed iron. **In hereditary hemochromatosis there is a defect in the regulation of intestinal absorption of dietary iron, leading to net iron accumulation of 0.5 to 1.0 g/year.** The hereditary hemochromatosis gene, responsible for the most common form of this disorder, is called *HFE*. It is located on the short arm of chromosome 6. It encodes a protein that is similar in structure to MHC class I proteins. The role of HFE in regulating iron uptake is complex and not fully understood. Expression of the mutated HFE protein on small intestinal enterocytes leads to inappropriately upregulated absorption of iron and its binding **to transferrin,** the major iron carrying molecule in blood. But HFE is not the whole story, and its interactions with other proteins, particularly **hepcidin,** produced by the liver, form a web of iron metabolic control networks that are only recently becoming elucidated.

It appears that *HFE* and the other genes involved in less common forms of hereditary hemochromatosis all regulate the levels of hepcidin, the iron hormone produced by the liver. Hepcidin normally down-regulates the efflux of iron from the intestines and macrophages into the plasma and inhibits iron absorption. When hepcidin levels are reduced there is increased iron absorption. Mice in whom the hepcidin gene is deleted develop iron overload resembling hemochromatosis, and mice that overexpress hepcidin develop severe iron deficiency, thus establishing the central role of hepcidin in regulating iron absorption. As might be expected, hepcidin levels are reduced in all currently known genetic forms of hemochromatosis, including the most common form caused by mutations in the HFE gene. The interconnections between the functions of these various genes and hepcidin synthesis are still being elucidated.

Hereditary hemochromatosis manifests typically after 20 gm of storage iron has accumulated. Regardless of source, excessive iron seems to be directly toxic to tissues by the following mechanisms:

- Lipid peroxidation by iron-catalyzed free radical reactions
- Stimulation of collagen formation
- Direct interactions of iron with DNA

## MORPHOLOGY

The morphologic changes in hereditary hemochromatosis are all responses to the **deposition of hemosiderin** in the following organs (in decreasing order of severity): liver, pancreas, myocardium, pituitary, adrenal, thyroid and parathyroid glands, joints, and skin. In the liver, iron becomes evident first as golden-yellow hemosiderin granules in the cytoplasm of periportal hepatocytes, which stain blue with the Prussian blue stain (Fig. 15–25). With increasing iron load, there is progressive involvement of the rest of the lobule, along with bile duct epithelium and Kupffer cells. Iron is a direct hepatotoxin, and inflammation is characteristically absent. At this stage, the liver typically is slightly larger than normal, dense, and chocolate brown. Fibrous septa develop slowly, linking portal tracts to each other and leading ultimately to **cirrhosis** in an intensely pigmented (very dark brown to black) liver.

In normal persons the iron content of unfixed liver tissue is less than 1000 μg/g dry weight. Adult patients with clinically evident iron overload of hereditary hemochromatosis exhibit greater than 10,000 μg/g dry weight of iron; hepatic iron concentrations in excess of 22,000 μg/g dry weight are associated with the development of fibrosis and cirrhosis.

The **pancreas** becomes intensely pigmented, acquires diffuse interstitial fibrosis, and may show some parenchymal atrophy. Hemosiderin is found in the acinar and the islet cells and sometimes in the interstitial fibrous stroma. The **heart** often is enlarged, with hemosiderin granules within the myocardial fibers. The pigmentation may induce a striking brown coloration of the myocardium. A delicate interstitial fibrosis may appear. Although **skin** pigmentation is partially attributable to hemosiderin deposition in dermal macrophages and fibroblasts, most of the coloration results from increased epidermal melanin production. The combination of these pigments renders the skin slate-gray. With hemosiderin deposition in the **joint synovial linings,** an acute synovitis may develop. There is also excessive deposition of calcium pyrophosphate, which damages the articular cartilage and sometimes produces disabling polyarthritis, referred to as pseudogout. The **testes** may be small and atrophic but usually are not discolored.

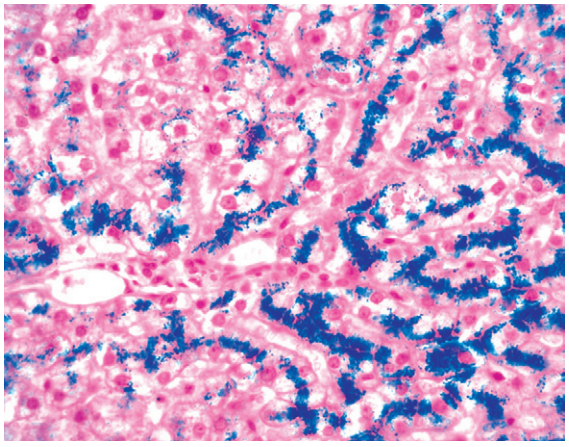

**Figure 15–25** Hereditary hemochromatosis. In this Prussian blue–stained histologic section, hepatocellular iron appears *blue*. The parenchymal architecture is normal.

### Clinical Features

Males predominate (in a ratio of 5 to 7:1), with slightly earlier clinical presentation, partly because physiologic iron loss (with menstruation or pregnancy) retards iron accumulation in women. In the most common forms, caused by *HFE* mutations, symptoms usually first appear in the fifth and sixth decades of life in men and later in women. With population screening it has become clear that even homozygous carriers of the most common *HFE* mutation (C282Y) have variable penetrance, so that disease progression is unpredictable.

The principal manifestations include hepatomegaly, skin pigmentation (particularly in sun-exposed areas), deranged glucose homeostasis or frank diabetes mellitus from destruction of pancreatic islets, cardiac dysfunction (arrhythmias, cardiomyopathy), and atypical arthritis. In some patients the presenting complaint is loss of libido and impotence. *The classic clinical triad of cirrhosis with hepatomegaly, skin pigmentation, and diabetes mellitus* may not develop until late in the course of the disease. Death may result from cirrhosis, hepatocellular carcinoma, or cardiac disease. Treatment of iron overload does not remove the risk for development of hepatocellular carcinoma, because of the cumulative, irreversible oxidative damage to DNA produced by iron. The risk for hepatocellular carcinoma development in patients with hemochromatosis is 200 times higher than in normal populations.

Fortunately, hereditary hemochromatosis can be diagnosed long before irreversible tissue damage has occurred. Screening involves demonstration of very high levels of serum iron and ferritin, exclusion of secondary causes of iron overload, and liver biopsy if indicated. Also important is screening of relatives of probands for the causative mutations. The natural course of the disease can be substantially altered by a variety of interventions, mainly phlebotomy and the use of iron chelators to decrease total body iron. Patients diagnosed in the subclinical, precirrhotic stage and treated by regular phlebotomy have a normal life expectancy. Heterozygotes may show a mild increase in iron absorption and accumulation.

## Wilson Disease

This autosomal recessive disorder is marked by the accumulation of toxic levels of copper in many tissues and organs, principally the liver, brain, and eye. The cause is loss-of-function mutations in the *ATP7B* gene, more than 300 of which have been identified. This gene, located on chromosome 13, encodes an ATPase metal ion transporter that localizes to the Golgi region of hepatocytes. About

1 in 100 people are asymptomatic carriers, and the incidence of the disease is approximately 1 per 30,000 population; thus, it is much less common than hereditary hemochromatosis.

## PATHOGENESIS

Normal copper physiology involves the following sequence:

1. Absorption of ingested copper (2 to 5 mg/day)
2. Plasma transport in complex with albumin
3. Hepatocellular uptake, followed by binding to an $\alpha_2$-globulin (apoceruloplasmin) to form ceruloplasmin
4. Secretion of ceruloplasmin-bound copper into plasma, where it accounts for 90% to 95% of plasma copper
5. Hepatic uptake of desialylated, senescent ceruloplasmin from the plasma, followed by lysosomal degradation and secretion of free copper into bile

In Wilson disease, the initial steps of copper absorption and transport to the liver are normal. However, without ATP7B activity, copper cannot be passed on to apoceruloplasmin and therefore cannot be excreted into bile, the **primary route for copper elimination from the body.** Copper thus accumulates progressively in hepatocytes, apparently causing toxic injury by a three-step mechanism: (1) promoting the formation of free radicals, (2) binding to sulfhydryl groups of cellular proteins, and (3) displacing other metals in hepatic metalloenzymes.

Usually by the age of 5 years, copper begins to escape from the overloaded, damaged hepatocytes into the circulation. Free copper generates oxidants that can lead to red cell hemolysis. It also is deposited in many other tissues, such as the brain, cornea, kidneys, bones, joints, and parathyroid glands, where it also produces damage through the same mechanisms that injure hepatocytes. Concomitantly, urinary excretion of copper increases markedly.

## MORPHOLOGY

The liver often bears the brunt of injury in Wilson disease, with protean hepatic changes ranging from relatively minor to massive damage and mimicking many other diseases. Thus, Wilson disease may mimic **fatty liver disease,** with mild to moderate steatosis, steatohepatitis, and even similar patterns of scarring. Patterns of **acute hepatitis** and **chronic hepatitis** simulate those of viral hepatitis. The acute hepatitis–like injury, in its most severe form, may manifest as fulminant hepatic failure. The chronic hepatitis–like picture may coexist with features of fatty liver disease, including the mononuclear infiltrates and lobular-interface hepatitis of the former, with the steatosis, hepatocyte ballooning, and Mallory-Denk bodies of the latter. With progression of chronic hepatitis, **cirrhosis** develops. Excess copper deposition can often be demonstrated by special stains (e.g., rhodanine stain for copper, orcein stain for copper-associated protein). Because copper also accumulates in chronic obstructive cholestasis, and because histologic analysis cannot reliably distinguish Wilson disease from other causes of liver disease, demonstration of hepatic copper content in excess of 250 μg/g dry weight is most helpful for making a diagnosis.

In the **brain,** toxic injury primarily affects the basal ganglia, particularly the putamen, which demonstrates atrophy and even cavitation. Nearly all patients with neurologic involvement develop **eye lesions** called **Kayser-Fleischer rings** (green to brown deposits of copper in Descemet membrane in the limbus of the cornea)—hence the alternative designation of this condition as hepatolenticular degeneration.

### Clinical Features

The age at onset and the clinical presentation of Wilson disease are extremely variable, but the disorder rarely manifests before the age of 6 years or in elderly persons. The most common presentation is acute or chronic liver disease. Neuropsychiatric manifestations, including mild behavioral changes, frank psychosis, or a Parkinson disease–like syndrome, are the initial features in most of the remaining cases. Unlike nearly all other forms of cirrhosis, hepatocellular carcinoma is quite uncommon in Wilson disease. Demonstration of Kayser-Fleischer rings or of markedly elevated hepatic copper levels in a person with low serum ceruloplasmin strongly favors the diagnosis. Early recognition and long-term therapy with copper chelators (such as D-penicillamine) and zinc salts (which lower copper uptake from the gut) have dramatically altered the usual progressive downhill course.

## $\alpha_1$-Antitrypsin Deficiency

$\alpha_1$-Antitrypsin (AAT) deficiency is an autosomal recessive disorder marked by abnormally low serum levels of this protease inhibitor. The major function of AAT is the inhibition of proteases, particularly neutrophil elastase released at sites of inflammation. AAT deficiency leads to pulmonary emphysema, because a relative lack of this protein permits the unrestrained activity of tissue-destructive proteases (Chapter 12). Hepatic disease results from retention of mutant AAT in the liver.

## PATHOGENESIS

AAT is a small (394–amino acid) plasma glycoprotein synthesized predominantly by hepatocytes. The *AAT* gene, located on human chromosome 14, is very polymorphic, and at least 75 forms have been identified. Most allelic variants produce normal or mildly reduced levels of serum AAT. However, homozygotes for the Z allele (*PiZZ* genotype) have circulating AAT levels that are only 10% of normal levels. *AAT* alleles are autosomal codominant, and consequently *PiMZ* heterozygotes have intermediate plasma levels of AAT. The PiZ polypeptide contains a single amino acid substitution that results in misfolding of the nascent polypeptide in the hepatocyte endoplasmic reticulum. Because the mutant protein cannot be secreted by the hepatocyte, it accumulates in the endoplasmic reticulum and triggers the so-called unfolded protein response, which can lead to induction of apoptosis (Chapter 1). Curiously, all persons with the *PiZZ* genotype accumulate AAT in the liver, but only 8% to 20% develop significant liver damage. This manifestation may be related to a genetic tendency in which susceptible persons are less able to degrade accumulated AAT protein within hepatocytes.

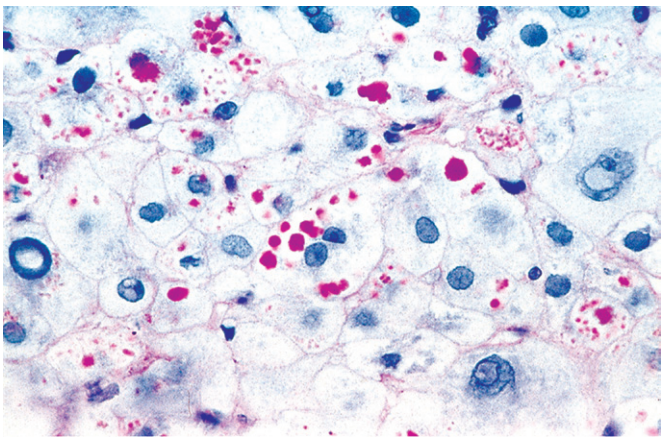

**Figure 15–26** $\alpha_1$-Antitrypsin deficiency. Periodic acid–Schiff stained histologic section of liver, highlighting the characteristic magenta cytoplasmic granules.
*(Courtesy of Dr. I. Wanless, Toronto General Hospital, Toronto, Ontario, Canada.)*

## MORPHOLOGY

Hepatocytes in AAT deficiency contain round to oval **cytoplasmic globules** composed of retained AAT, a glycoprotein that is strongly positive in a periodic acid–Schiff stain (Fig. 15–26). By electron microscopy they lie within smooth, and sometimes rough, endoplasmic reticulum. Hepatic injury associated with PiZZ homozygosity may range from marked **cholestasis** with **hepatocyte necrosis** in newborns, to **childhood cirrhosis,** to a smoldering chronic hepatitis or cirrhosis that becomes apparent only late in life.

### Clinical Course

Of all newborns with AAT deficiency, 10% to 20% exhibit cholestasis. In older children, adolescents, and adults, presenting symptoms may be related to chronic hepatitis, cirrhosis, or pulmonary disease. The disease may remain silent until cirrhosis appears in middle to later life. Hepatocellular carcinoma develops in 2% to 3% of adults with *PiZZ* genotype, usually but not always in the setting of cirrhosis. The treatment and cure for the severe hepatic disease are orthotopic liver transplantation.

## SUMMARY

### Inherited Metabolic Diseases

- Hemochromatosis is characterized by accumulation of iron in liver, pancreas, heart, pituitary gland, joints and other tissues. It is usually caused by mutations in the *HFE* gene, which encodes a protein that influences intestinal iron uptake.
- Wilson disease is the result of accumulation of copper in the liver, brain, and eyes; it is caused by a mutation in the metal ion transporter *ATP7B*.
- $\alpha_1$-Antitrypsin (AAT) deficiency in persons of *PiZZ* genotype causes pulmonary emphysema (due to increased elastase activity) and liver injury (caused by the accumulation of misfolded AAT).

# CIRCULATORY DISORDERS

In view of the enormous flow of blood through the liver, it is not surprising that circulatory disturbances have considerable impact on the liver. These disorders can be grouped according to whether blood flow into, through, or from the liver is impaired (Fig. 15–27).

## Impaired Blood Flow into the Liver

### *Hepatic Artery Inflow*

*Liver infarcts* are rare, thanks to the double blood supply to the liver. Interruption of the main hepatic artery does not always produce ischemic necrosis of the organ, because retrograde arterial flow through accessory vessels and the portal venous supply may sustain the liver parenchyma. The one exception is hepatic artery thrombosis in the transplanted liver, which generally leads to loss of the organ. Thrombosis or compression of an intrahepatic branch of the hepatic artery by polyarteritis nodosa (Chapter 9), embolism, neoplasia, or sepsis may result in a localized parenchymal infarct.

### *Portal Vein Obstruction and Thrombosis*

Extrahepatic blockage of the portal vein may be slow in developing and well tolerated or may be a catastrophic and potentially lethal event; most cases fall somewhere in between. Occlusion of the portal vein or its major branches typically produces abdominal pain and, in most instances, ascites and other manifestations of portal hypertension like esophageal varices prone to rupture. Acute impairment of visceral blood flow leads to profound congestion and bowel infarction. Extrahepatic portal vein obstruction may arise from the following:

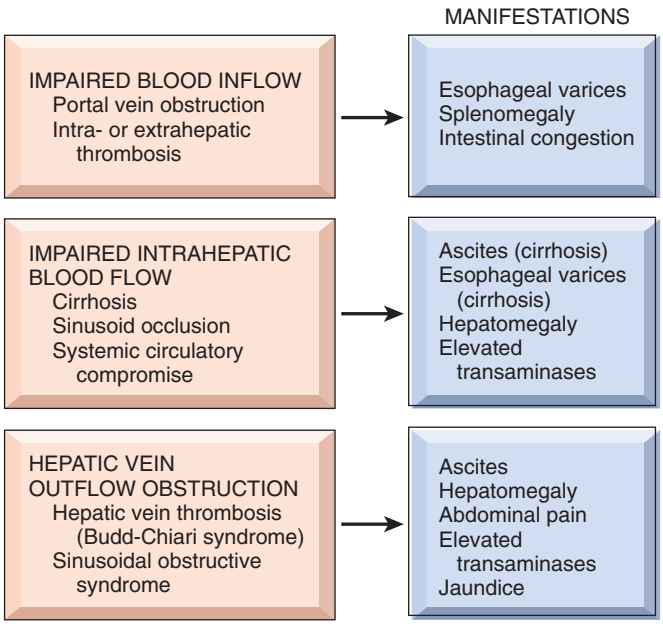

**Figure 15–27** Hepatic circulatory disorders. The forms and clinical manifestations of compromised blood flow are contrasted.

- Peritoneal sepsis (e.g., acute diverticulitis or appendicitis leading to pylephlebitis in the splanchnic circulation)
- Pancreatitis initiating splenic vein thrombosis that propagates into the portal vein
- Thrombogenic diseases and postsurgical thromboses
- Vascular invasion by primary or secondary cancer in the liver that progressively occludes portal inflow to the liver (extensions of hepatocellular carcinoma can even occlude the main portal vein)
- Banti syndrome, in which subclinical thrombosis of the portal vein (as from neonatal omphalitis or umbilical vein catheterization) produces a fibrotic, partially recanalized vascular channel presenting as splenomegaly or esophageal varices years after the occlusive event
- Cirrhosis, although not an extrahepatic cause of obstruction, reduces the flow of blood in the portal veins and hence provides a substratum for extrahepatic portal vein thrombosis.

Intrahepatic thrombosis of a portal vein radicle, when acute, does not cause ischemic infarction but instead results in a sharply demarcated area of red-blue discoloration (so-called *infarct of Zahn*). There is no necrosis; the only morphologic changes are hepatocellular atrophy and marked congestion of distended sinusoids. *Hepatoportal sclerosis* is a chronic, usually idiopathic (perhaps autoimmune), generally bland condition of progressive portal tract sclerosis leading to impaired portal vein inflow. Identified causes include myeloproliferative disorders associated with hypercoagulability, peritonitis, or exposure to arsenicals.

## Impaired Blood Flow Through the Liver

The most common intrahepatic cause of portal blood flow obstruction is cirrhosis, as described earlier. In addition, physical occlusion of the sinusoids occurs in a small but important group of diseases. In sickle cell disease, the hepatic sinusoids may become obstructed by sickled red cells, leading to panlobular parenchymal necrosis. *Disseminated intravascular coagulation* may cause occlusion of sinusoids. This blockage usually is inconsequential except in eclampsia, in which periportal sinusoidal occlusion and parenchymal necrosis may occur. Subsequent suffusion of blood under the capsule may precipitate a fatal intra-abdominal hemorrhage.

### *Passive Congestion and Centrilobular Necrosis*

Passive congestion and centrilobular necrosis are hepatic manifestations of systemic circulatory disorders that constitute a morphologic continuum. Right-sided cardiac decompensation leads to passive congestion of the liver and, if persistent, can cause centrilobular necrosis and perivenular fibrosis in the areas of necrosis. In most instances, the only clinical evidence of centrilobular necrosis is a small elevation in serum aminotransferase levels, although some patients have hyperbilirubinemia and elevated alkaline phosphatase.

#### MORPHOLOGY

In right-sided cardiac failure, the liver is slightly enlarged, tense, and cyanotic, with rounded edges. Microscopic examination reveals **congestion of centrilobular sinusoids.** Over time, centrilobular hepatocytes become atrophic, resulting in markedly attenuated liver cell cords. An uncommon complication of sustained, chronic, severe congestive heart failure is so-called **cardiac sclerosis.** The pattern of liver fibrosis is distinctive, inasmuch as it is mostly centrilobular. Rarely bridging fibrous septa and cirrhosis develop.

Left-sided cardiac failure or shock may lead to hepatic hypoperfusion and hypoxia. In this instance, the two areas most dependent on arterial flow (receiving little in the way of portal vein nutrients)—namely, centrilobular hepatocytes and bile ducts—undergo ischemic necrosis. The combination of left-sided hypoperfusion and right-sided retrograde congestion acts synergistically to generate a distinctive lesion, centrilobular hemorrhagic necrosis (Fig. 15–28). The liver takes on a variegated mottled appearance, reflecting hemorrhage and necrosis in the centrilobular regions, alternating with pale midzonal areas, known traditionally as the **nutmeg liver** because of its similarity to the cut surface of a nutmeg.

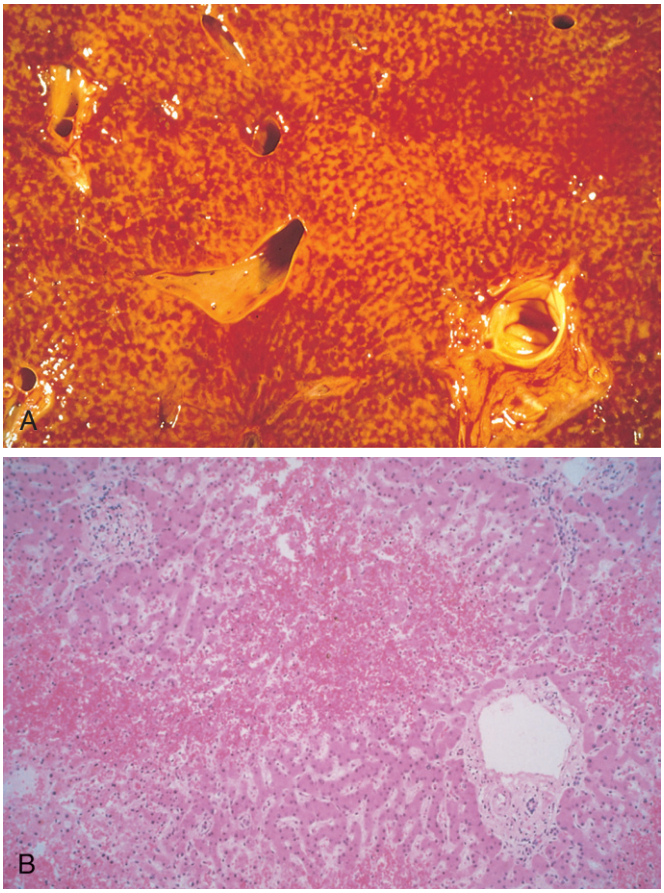

**Figure 15–28** Centrilobular hemorrhagic necrosis (nutmeg liver). **A,** The cut liver section, in which major blood vessels are visible, is notable for a variegated mottled red appearance, representing hemorrhage in the centrilobular regions of the parenchyma. **B,** On microscopic examination, the centrilobular region is suffused with red blood cells, and hepatocytes are not readily visible. Portal tracts and the periportal parenchyma are intact.

## Hepatic Vein Outflow Obstruction

### *Hepatic Vein Thrombosis (Budd-Chiari Syndrome)*

The Budd-Chiari syndrome results from the *thrombosis one or more major hepatic veins* and is characterized by hepatomegaly, ascites, and abdominal pain. Hepatic vein thrombosis is associated with myeloproliferative disorders (especially polycythemia vera), pregnancy, the postpartum state, the use of oral contraceptives, paroxysmal nocturnal hemoglobinuria, and intra-abdominal cancers, particularly hepatocellular carcinoma. All of these conditions produce thrombotic tendencies or, in the case of liver cancers, sluggish blood flow. Some cases are caused by mechanical obstruction to blood outflow, as by a massive intrahepatic abscess or parasitic cyst, or by obstruction of the inferior vena cava at the level of the hepatic veins by thrombus or tumor. About 10% of cases are idiopathic.

#### MORPHOLOGY

With acutely developing thrombosis of the major hepatic veins or inferior vena cava, the liver is swollen and red-purple, with a tense capsule (Fig. 15–29). On microscopic examination, severe centrilobular congestion and necrosis are apparent in affected hepatic parenchyma. In instances in which the thrombosis develops more slowly, centrilobular fibrosis is seen. The major veins may contain completely or incompletely occlusive fresh thrombi or, in chronic cases, organized adherent thrombi.

Mortality attributable to untreated acute Budd-Chiari syndrome is high. Prompt surgical creation of a portosystemic venous shunt permits reverse flow through the portal vein and improves the prognosis considerably; direct dilation of caval obstruction may be possible during angiography. The chronic form of the syndrome is far less grave, and more than two thirds of the patients are alive after 5 years.

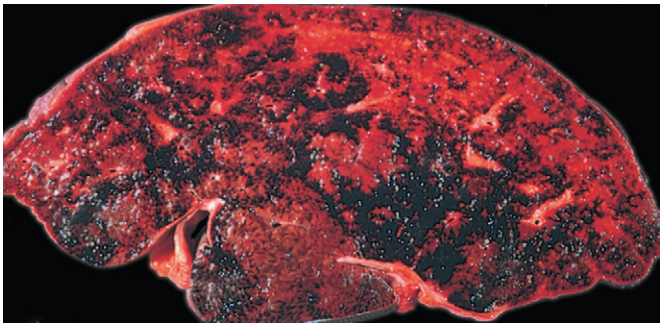

**Figure 15–29** Budd-Chiari syndrome. Thrombosis of the major hepatic veins has caused profound hepatic congestion.

### *Sinusoidal Obstruction Syndrome*

Originally described in Jamaican drinkers of "bush tea" containing pyrrolizidine alkaloid, *sinusoidal obstruction syndrome* formerly was known as *venoocclusive disease*. The new designation more specifically indicates that the condition is caused by toxic injury to sinusoidal endothelium. Damaged endothelial cells slough, leading to formation of thrombi that block sinusoidal flow. Endothelial damage allows red cells to spill into the space of Disse, and also causes proliferation of stellate cells and fibrosis of terminal branches of the hepatic vein (Fig. 15–30). Sinusoidal obstruction syndrome now occurs primarily in the first 20 to 30 days after bone marrow transplantation, affecting 20% of recipients. The sinusoidal injury is believed to be caused by chemotherapeutic agents such as cyclophosphamide, actinomycin D, and mithramycin, and by total body radiation, used in pre- or posttransplantation regimens. The clinical presentation resembles the Budd-Chiari syndrome and varies, ranging from mild to severe. Severe sinusoidal obstruction syndrome that does not resolve after 3 months of treatment can be fatal.

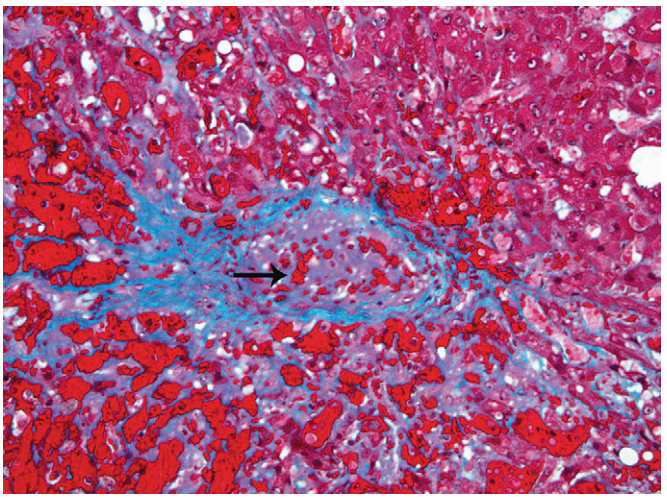

**Figure 15–30** Sinusoidal obstruction syndrome (formerly known as venoocclusive disease). A central vein is occluded by cells and newly formed collagen (*arrow*). There is also fibrosis in the sinusoidal spaces. Fibrous tissue is stained *blue* by the Masson trichrome stain.

#### SUMMARY

##### Circulatory Disorders

- Circulatory disorders of the liver can be caused by impaired blood inflow, defects in intrahepatic blood flow, and obstruction of blood outflow.
- Portal vein obstruction by intra- or extrahepatic thrombosis may cause portal hypertension, esophageal varices, and ascites.
- The most common cause of impaired intrahepatic blood flow is cirrhosis.
- Conditions of obstruction of blood outflow include hepatic vein thrombosis (Budd-Chiari syndrome) and sinusoidal obstruction syndrome, previously known as venoocclusive disease.

# OTHER INFLAMMATORY AND INFECTIOUS DISEASES

## Liver Abscesses

In developing countries liver abscesses are common; most result from parasitic infections, such as amebic and (less commonly) other protozoal and helminthic organisms. In developed countries parasitic liver abscesses are more rare. In the Western world, bacterial abscesses are more common, representing a complication of an infection elsewhere. The organisms reach the liver through one of the following pathways:

- Ascending infection in the biliary tract (ascending cholangitis)
- Vascular seeding, either portal or arterial, predominantly from the gastrointestinal tract
- Direct invasion of the liver from a nearby source
- A penetrating injury

Debilitating disease with immune deficiency is a common setting—for example, extreme old age, immunosuppression, or cancer chemotherapy with marrow failure.

Pyogenic (bacterial) hepatic abscesses may occur as solitary or multiple lesions, ranging in size from millimeters to massive lesions many centimeters in diameter. Many pathogens can cause pyogenic liver abscess and often more than one organism is involved. The most common bacterial agents are *E. coli, Klebsiella pneumoniiae*, *Proteus* spp., pseudomonas, and *Streptococcus milleri.* Increasingly *Candida* spp. are also being isolated. Because of the polymicrobial nature of the abscesses, identification of the organisms is important. Gross and microscopic features are those of any pyogenic abscess: liquefactive necrosis with abundant neutrophils.

Liver abscesses are associated with fever and, in many instances, with right upper quadrant pain and tender hepatomegaly. Jaundice may result if there is biliary obstruction. Antibiotic therapy along with percutaneous or surgical drainage is often necessary. If the treatment is delayed, particularly in persons with serious coexistent disease, the mortality rate with large liver abscesses ranges from 30% to 90%. With early recognition and appropriate management, as many as 90% of patients may survive.

## Granulomatous Disease

Granulomas are common in the liver, being present in as many as 10% of liver biopsy specimens. They may reflect systemic disease or be specific to the liver. Granulomatous disease may be classified into four etiologic categories:

- "See the cause," in which infectious agents can be visualized with special stains, such as fungal or acid-fast organisms
- "Know the cause," in which organisms are not seen but a previous diagnosis (e.g., known tuberculosis, systemic sarcoidosis, duct destructive lesions in known primary biliary cirrhosis) explains the lesions
- "Suspect the cause," in which the appearance of the granulomas or clinicopathologic correlation points to a likely underlying disorder, such as caseous necrosis, strongly suggestive of infection, or eosinophilia, which points to parasites or drug- or toxin-induced injury
- "Don't know the cause," accounting for approximately 10% of hepatic granulomas, most of which are incidental findings of no clinical import

Because of their infiltrative nature, granulomatous diseases of the liver give rise to intrahepatic cholestasis with elevations of alkaline phosphatase and γ-glutamyl transpeptidase.

# TUMORS AND HEPATIC NODULES

The liver and lungs share the dubious distinction of being the visceral organs most often involved by metastatic cancers. Indeed, *the most common hepatic neoplasms are metastatic carcinomas,* with colon, lung, and breast heading the list of the primary sites. *Primary hepatic malignancies* are almost all *hepatocellular carcinomas,* which show a dramatic geographic variation in incidence throughout the world, as discussed later. Two other types of primary liver cancers, hepatoblastoma (a childhood hepatocellular tumor) and angiosarcoma (a tumor of blood vessels associated with exposure to vinyl chloride and arsenic), are too rare to merit further discussion here.

Hepatic masses come to attention for a variety of reasons. They may generate epigastric fullness and discomfort or be detected by routine physical examination. Radiographic studies for other indications may pick up incidental liver masses.

## Benign Tumors

The most common benign lesions of the liver are *cavernous hemangiomas,* which are identical to those occurring in other parts of the body (Chapter 9). These well-circumscribed lesions consist of endothelial cell–lined vascular channels and intervening stroma. They appear as discrete red-blue, soft nodules, usually less than 2 cm in diameter, often directly beneath the capsule. Their chief clinical significance lies in the importance of not mistaking them for metastatic tumors; blind percutaneous needle biopsy may cause severe intra-abdominal bleeding.

*Von Meyenburg complexes* are another quite common benign finding in the liver. These are presumed to be congenital bile duct hamartomas and are usually isolated or present in small numbers. They are composed of bile duct–like structures separated by bland, densely collagenized stroma. These lesions have no malignant potential, but when multiple may indicate the presence of *fibropolycystic disease of the liver,* which may occur in association with certain forms of polycystic kidney disease (Chapter 13).

### *Focal Nodular Hyperplasia*

*Focal nodular hyperplasia* (FNH) is found most often in otherwise normal livers. It is a localized, well-demarcated, but poorly encapsulated lesion, consisting of hyperplastic hepatocyte nodules with a central, stellate fibrous scar. It is not a true neoplasm but rather represents a response to abnormal vascular flow through a congenital or acquired vascular anomaly that gives rise to alternating areas of

parenchymal regeneration and atrophy. FNH may range in size from 1 cm to many centimeters across. It usually is an incidental finding, most commonly in women of reproductive age, in whom it may grow in response to estrogens, including those found in contraceptive pills. These lesions carry no risk for malignancy but may cause symptoms by pressing on the liver capsule.

### *Hepatic Adenoma*

Hepatic adenoma is a benign hepatocellular neoplasm that usually occurs in women of child-bearing age who have used oral contraceptive pills, and it may regress on discontinuance of hormone use. These lesions usually are well-demarcated but unencapsulated tumors that may be pale, yellow-tan, or bile-stained and up to 30 cm in diameter (Fig. 15–31). On histologic examination, hepatic adenomas are composed of sheets and cords of cells that may resemble normal hepatocytes or have minimal variation in cell and nuclear size. Portal tracts are absent; instead, prominent arterial vessels and draining veins are distributed throughout. Liver cell adenomas are significant for three reasons: (1) when they manifest as an intrahepatic mass, they may be mistaken for the more ominous hepatocellular carcinoma; (2) subcapsular adenomas are at risk for rupture, particularly during pregnancy (under estrogenic stimulation), causing life-threatening intraabdominal hemorrhage; and (3) although malignant transformation is unusual, adenomas harboring β-catenin mutations carry a risk of developing into hepatocellular carcinoma.

Molecular studies now classify these lesions into three somewhat discrete types:

- 35% to 40% of adenomas have biallelic inactivation through somatic (90%) or germline (10%) mutations of either the *HNF1A* gene (encoding a hepatocyte transcription factor) or the *CYP1B1* gene (encoding cytochrome P-450). These adenomas are most common in women, sometimes associated with oral contraceptive use, and are often yellow from marked steatosis. They carry little risk for malignant transformation.
- 10% to 15% of adenomas have activating mutations of β-catenin. These have a high risk for malignant transformation, are most common in men and may be related to anabolic steroid use and possibly nonalcoholic fatty liver disease.
- More than 50% of adenomas are *inflammatory,* being associated with increased expression of acute phase reactant proteins such as serum amyloid A and C-reactive protein in the tumor and sometimes in the serum. About 10% of these tumors also have activating mutations of β-catenin and may undergo malignant transformation. This type is most common in women and is often associated with obesity and fatty liver disease. Morphologically, this subgroup may be identical to FNH, and the distinction may be made by demonstrating an inflammatory phenotype (such as by expression of serum amyloid A protein, SAA).

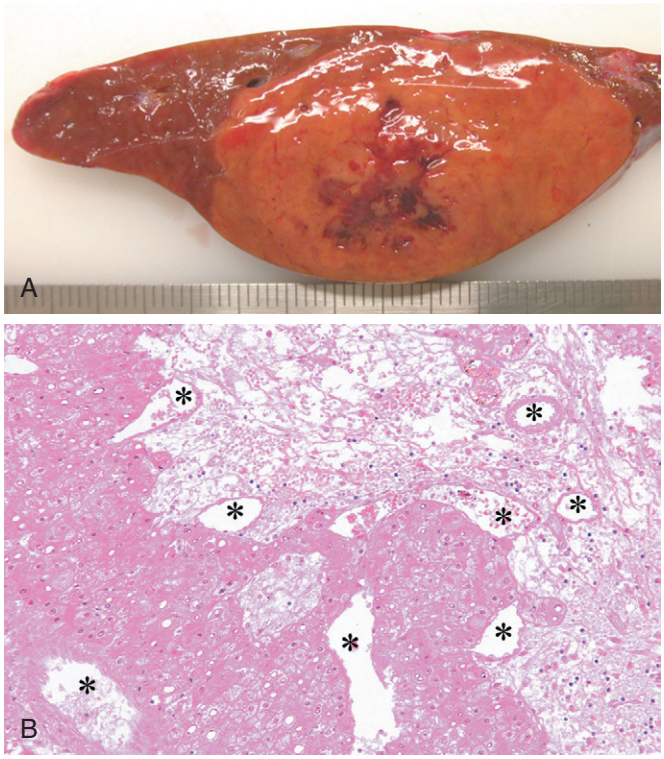

**Figure 15–31** Hepatic adenoma. **A,** Surgically resected specimen showing a discrete mass underneath the liver capsule with hemorrhagic necrosis (*dark red areas*). **B,** Photomicrograph showing adenoma, with cords of normal-appearing hepatocytes, absence of portal tracts, and prominent neovascularization (*asterisks*). A large zone of infarcted tumor is present.

## Precursor Lesions of Hepatocellular Carcinoma

While hepatocellular adenomas sometimes can be premalignant, they represent a rare pathway to hepatocellular malignancy. Far more common precursors are cellular changes and nodular lesions that are found in the setting of chronic liver disease, particularly chronic viral hepatitis, alcoholic liver disease, and metabolic diseases such as AAT deficiency and hereditary hemochromatosis. Usually they are found in late-stage disease, in particular when cirrhosis is already established. However, while it has often been said that cirrhosis itself is premalignant, this is imprecise: The processes that lead to cirrhosis and to malignant transformation usually take years to decades and run parallel to each other, rather than in sequence.

### *Cellular Dysplasia*

Two forms of hepatocellular dysplasia are recognized, both of which are most common in the setting of chronic viral hepatitis. *Large cell change* consists of scattered hepatocytes, usually in periportal or periseptal regions, that are larger than normal hepatocytes and have pleomorphic, often multiple nuclei (Fig. 15–32, *A*). Although morphologically atypical, these cells are not believed to be on the pathway to malignant transformation but rather are considered a marker of molecular changes stemming from chronic injury that predispose other morphologically normal hepatocytes to undergo malignant transformation. *Small cell change* is characterized by smaller-than-normal hepatocytes with normal-sized, often hyperchromatic, oval or angulated nuclei. Small cell change may appear anywhere in the

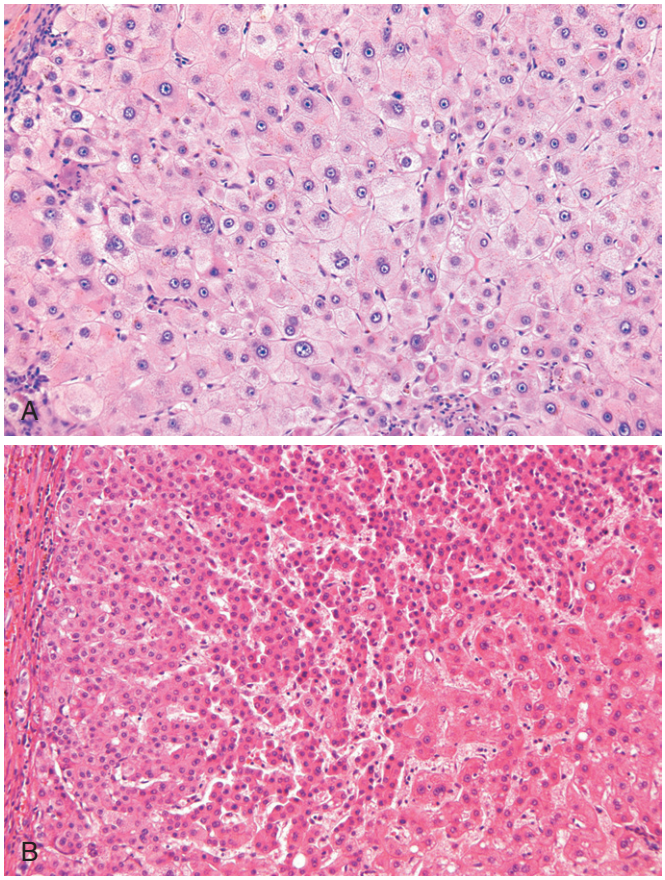

**Figure 15–32 A,** Large cell change. Very large hepatocytes with very large, often atypical nuclei are scattered among normal-size hepatocytes with round, typical nuclei. **B,** Small cell change (SCC). Normal-appearing hepatocytes are in the *lower right corner.* SCC is indicated by smaller than normal hepatocytes with thickened liver cell plates, and high nuclear : cytoplasmic ratio.
*(A and B, Courtesy of Dr. Young Nyun Park, Yonsei Medical College, Seoul, South Korea.)*

hepatic lobule, often with formation of vaguely nodular clusters. This form of dysplasia is considered to be directly premalignant (Fig. 15–32, *B*).

### *Dysplastic Nodules*

Dysplastic nodules probably represent the major pathway to hepatocellular carcinoma in chronic liver disease. In cirrhotic livers, dysplastic nodules are distinguished by their larger size: Most cirrhotic nodules range from 0.3 to 0.8 cm, but dysplastic nodules often are 1 to 2 cm across (Fig. 15–33, *A*). These are neoplastic growths that encompass many adjacent hepatic lobules, without displacing all of the portal tracts. These lesions are at high risk for malignant transformation and in fact sometimes contain overtly malignant subnodules (Fig. 15–33, *B*).

## Hepatocellular Carcinomas

### Epidemiology

Worldwide, hepatocellular carcinoma, HCC (also known erroneously as hepatoma) accounts for approximately 5.4% of all cancers, but its incidence varies widely in different parts of the world. More than 85% of cases occur in countries with high rates of chronic HBV infection. The highest incidences of HCC are found in Asian countries (southeast China, Korea, Taiwan) and sub-Saharan African countries in which HBV is transmitted vertically, and, as already discussed, the carrier state starts in infancy. Moreover, many of these populations are exposed to aflatoxin, which when combined with HBV infection increases the risk of hepatocellular carcinoma dramatically over that in noninfected, nonexposed populations; depending on the study, the estimated increase in HCC ranges from 23-fold to 216-fold.The peak incidence of hepatocellular carcinoma in these areas is between 20 and 40 years of age, and in almost 50% of cases, the tumor appears in the absence of cirrhosis. In Western countries the incidence of hepatocellular carcinoma is rapidly increasing, largely owing to the

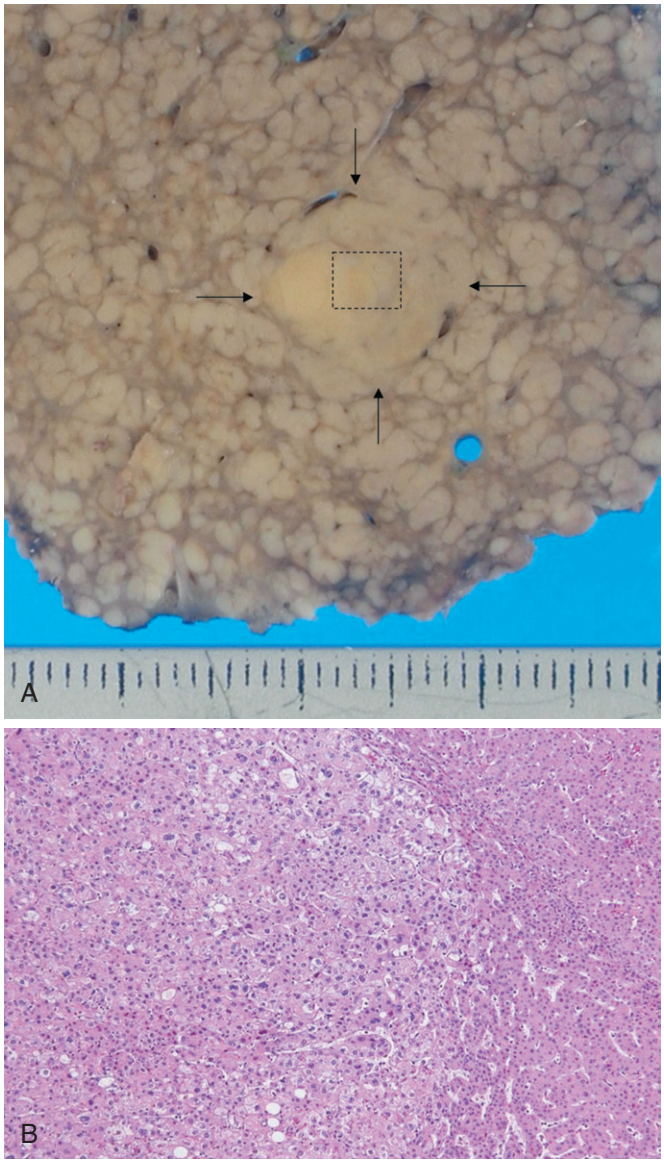

**Figure 15–33 A,** Hepatitis C–related cirrhosis with a distinctively large nodule (*arrows*). Nodule-in-nodule growth in this dysplastic nodule suggests a high grade lesion. **B,** Histologically the region within the box in **A** shows a well-differentiated hepatocellular carcinoma (HCC) (*right side*) and a subnodule of moderately differentiated HCC within it (*center, left*).
*(A and B, Courtesy of Dr. Masamichi Kojiro, Kurume University, Kurume, Japan.)*

hepatitis C epidemic. It tripled in the United States in recent decades, but it is still 8-fold to 30-fold lower than the incidence in some Asian countries. In Western populations, hepatocellular carcinoma rarely manifests before the age of 60, and in almost 90% of cases, tumors develop in the setting of cirrhosis. There is a pronounced male preponderance throughout the world, about 3:1 in low-incidence areas and as high as 8:1 in high-incidence areas.

## PATHOGENESIS

Several general factors relevant to the pathogenesis of HCC are discussed in Chapter 5. Only a few points merit emphasis here.

- Three major etiologic associations have been established: infection with HBV or HCV, alcoholic cirrhosis, and aflatoxin exposure. In the U.S., NAFLD is increasingly becoming an important risk factor for hepatocellular cancer. Other associated conditions include hemochromatosis, $\alpha_1$-antitrypsin deficiency, and tyrosinemia.
- Many variables, including age, gender, chemicals, viruses, hormones, alcohol, and nutrition, interact in the development of HCC. For example, the disease most likely to give rise to this tumor is hereditary tyrosinemia, a rare disorder in which almost 40% of patients develop this tumor.
- In many parts of the world, including Japan and Central Europe, chronic HCV infection is the most important risk factor in the development of liver cancer.
- In certain regions of the world, such as China and southern Africa, especially Mozambique, where HBV is endemic, high-level exposure to dietary aflatoxins derived from the fungus *Aspergillus flavus* is common. These carcinogenic toxins are found in "moldy" grains and peanuts. Aflatoxin can bind covalently with cellular DNA, resulting in mutations in genes such as *TP53*.

Despite the detailed knowledge about the etiologic agents of HCC, the pathogenesis of the tumor is still uncertain. **In most cases, it develops from small-cell, high-grade dysplastic nodules in cirrhotic livers.** In keeping with this, these nodules may be monoclonal and may contain chromosomal aberrations similar to those seen in HCCs. The cell of origin of HCC has been the subject of considerable debate. It seems that **the tumors may arise from both mature hepatocytes and progenitor cells (known as ductular cells or oval cells).** Distinguishing high-grade dysplastic nodules from early HCC is difficult even in biopsies, because there are no molecular markers specific for these stages. An important criterion is nodule vascularization, visualized by imaging, which is almost always a clear indication of malignancy.

**An almost universal feature of hepatocellular carcinoma is the presence of structural and numeric chromosomal abnormalities indicative of genomic instability.** The precise origin of genomic instability in this tumor is not known, but several factors seem to be most important:

- Inflammation and regeneration, seen in all forms of chronic hepatitis, are believed to be main contributors to acquired mutations in genomic DNA.
- Acquired mutations in specific oncogenes (such as *β-catenin*) and tumor suppressors (such as *TP53*) contribute to dysregulated growth and further increases in genomic instability.
- Acquired defects in DNA repair, particularly those in repair systems for double-stranded DNA breaks, also perpetuate DNA damage and may cause chromosomal defects.

Neither HBV nor HCV contains oncogenes. The already mentioned *HBV-X* gene may have some oncogenic potential (Chapter 5). The tumorigenic capacity of these viruses probably relates primarily to their capacity to cause chronic inflammation and increased cell turnover.

## MORPHOLOGY

HCC may appear grossly as (1) a **unifocal,** usually massive tumor; (2) a **multifocal tumor** made of nodules of variable size; or (3) a **diffusely infiltrative** cancer, permeating widely and sometimes involving the entire liver, blending imperceptibly into the cirrhotic background. Particularly in the latter two patterns, it may be difficult to radiologically distinguish regenerative cirrhotic nodules from neoplasms of similar size. Discrete tumor masses usually are yellow-white, punctuated sometimes by bile staining and areas of hemorrhage or necrosis. **HCC has a strong propensity for vascular invasion.** Extensive intrahepatic metastases are characteristic, and occasionally snakelike masses of tumor invade the portal vein (with occlusion of the portal circulation) or inferior vena cava, extending even into the right side of the heart.

On histologic examination, HCCs range from well-differentiated lesions that reproduce hepatocytes arranged in cords, trabeculae or glandular patterns (Fig. 15–34), to poorly differentiated lesions, often composed of large, multinucleate anaplastic giant cells. **In the better-differentiated variants, globules of bile may be found within the cytoplasm of cells and in pseudocanaliculi** between cells. Acidophilic hyaline inclusions within the cytoplasm may be present, resembling Mallory bodies. There is little stroma in most hepatocellular carcinomas, explaining their soft consistency.

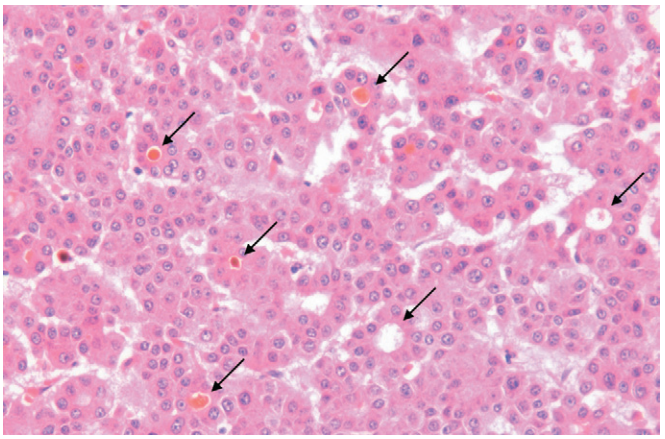

**Figure 15–34** Well-differentiated hepatocellular carcinoma has distortions of normal structures: Liver cell plates are markedly widened, and frequent "pseudoacinar" structures (*arrows*)—abnormal bile canaliculi—often contain bile.

A distinctive clinicopathologic variant of HCC is the **fibrolamellar carcinoma.** It occurs in young male and female adults (20 to 40 years of age) with equal incidence and has no association with cirrhosis or other risk factors. It usually consists of a single tumor with fibrous bands coursing through it, superficially resembling focal nodular hyperplasia. The fibrolamellar variant has a better prognosis than that of the other, more common variants.

Clinical Features

Although HCC may manifest with silent hepatomegaly, it is more often encountered in persons with symptomatic cirrhosis of the liver. In these persons, *a rapid increase in liver size, sudden worsening of ascites, or the appearance of bloody ascites, fever, and pain call attention to the development of a tumor.* There are no good serologic screening tests for hepatocellular carcinoma. The most commonly used marker is serum alpha-fetoprotein level, but it rises only with advanced tumors and only in 50% of patients. Furthermore, false-positive results are obtained in yolk-sac tumors, and many non-neoplastic conditions such as cirrhosis, chronic hepatitis, normal pregnancy, and massive liver necrosis. Hence the test is neither specific nor sensitive. *Radiologic screening of patients with cirrhosis at 6-month intervals, looking for dysplastic nodules or early, small hepatocellular carcinomas, is the current clinical frontier.*

The overall prognosis with advanced HCC is grim. Resection or ablation may be curative for a single small lesion (most often those with the uncommon fibrolamellar variant), but does not prevent de novo emergence of new HCCs in a chronically diseased liver. Transplantation can be curative, however. Without resection, median survival is 7 months. Recent clinical trials have shown that treatment with sorafenib, a broad-spectrum tyrosine kinase inhibitor, provides some benefit to those with advanced disease. In some countries such as Taiwan, HBV immunization programs have lowered the incidence of HCC substantially, proving that preventive measures can alleviate the terrible toll taken by this disease in endemic regions.

### SUMMARY

#### Liver Tumors

- The most common malignant tumors of the liver are metastatic carcinomas, most often from colon, lung, and breast.
- The main primary malignancy is hepatocellular carcinoma. It is common in regions of Asia and Africa, and its incidence is increasing in the United States.
- The main etiologic agents for hepatocellular carcinoma are hepatitis B and C, alcoholic cirrhosis, hemochromatosis, and, more rarely, tyrosinemia and $\alpha_1$-antitrypsin (AAT) deficiency.
- In the Western population, about 90% of hepatocellular carcinomas develop in cirrhotic livers; in Asia, almost 50% of cases develop in noncirrhotic livers.
- The chronic inflammation and cellular regeneration associated with viral hepatitis may be predisposing factors for the development of carcinomas.
- Hepatocellular carcinomas may be unifocal or multifocal, tend to invade blood vessels, and recapitulate normal liver architecture to varying degrees.

# DISORDERS OF THE GALLBLADDER AND THE EXTRAHEPATIC BILIARY TRACT

Disorders of the gallbladder and biliary tract affect a large proportion of the world's population. *Cholelithiasis* (*gallstones*) accounts for more than 95% of these diseases. About 2% of the United States federal health budget is spent on cholelithiasis and its complications. In this section, gallbladder diseases (cholelithiasis and cholecystitis) are discussed first, followed by consideration of some disorders of the extrahepatic bile ducts. It should be kept in mind that lesions of the extrahepatic biliary tract may extend to intrahepatic bile ducts, and that tumors of the biliary tract (cholangiocarcinomas, described later) may have intra- or extrahepatic locations.

## GALLBLADDER DISEASES

### Cholelithiasis (Gallstones)

Gallstones afflict 10% to 20% of adults residing in Western countries in the Northern Hemisphere, 20% to 40% in Latin American countries, and only 3% to 4% in Asian countries. In the United States, about 1 million new cases of gallstones are diagnosed annually, and two thirds of persons so affected undergo surgery, with retrieval of as much as 25 to 50 million tons of stones! There are two main types of gallstones: *cholesterol stones,* containing crystalline cholesterol monohydrate (80% of stones in the West), and *pigment stones,* made of bilirubin calcium salts.

### PATHOGENESIS

Bile formation is the only significant pathway for elimination of excess cholesterol from the body, either as free cholesterol or as bile salts. Cholesterol is rendered water-soluble by aggregation with bile salts and lecithins. When cholesterol concentrations exceed the solubilizing capacity of bile (supersaturation), cholesterol can no longer remain dispersed and crystallizes out of solution. Cholesterol gallstone formation is enhanced by **hypomobility of the gallbladder** (stasis), which promotes nucleation, and by **mucus hypersecretion,** with consequent trapping of the crystals, thereby enhancing their aggregation into stones.

Formation of pigment stones is more likely in the presence of unconjugated bilirubin in the biliary tree, as occurs in

**Table 15–8** Risk Factors for Gallstones

| |
|---|
| **Cholesterol Stones** |
| Demography: Northern Europeans, North and South Americans, Native Americans, Mexican Americans |
| Advancing age |
| Female sex hormones |
| Female gender |
| Oral contraceptives |
| Pregnancy |
| Obesity and insulin resistance |
| Rapid weight reduction |
| Gallbladder stasis |
| Inborn disorders of bile acid metabolism |
| Dyslipidemia syndromes |
| **Pigment Stones** |
| Demography: Asian more than Western, rural more than urban |
| Chronic hemolysis (e.g., sickle cell anemia, hereditary spherocytosis) |
| Biliary infection |
| Gastrointestinal disorders: ileal disease (e.g., Crohn disease), ileal resection or bypass, cystic fibrosis with pancreatic insufficiency |

hemolytic anemias and infections of the biliary tract. The precipitates are primarily insoluble calcium bilirubinate salts.

The major risk factors for gallstones are listed in Table 15–8. Up to 80% of people with gallstones, however, have no identifiable risk factors other than age and gender. Some elaboration on these risk factors follows:

- **Age and gender.** The prevalence of gallstones increases throughout life. In the United States, less than 5% to 6% of the population younger than age 40 has stones, in contrast with 25% to 30% of those older than 80 years. The prevalence in women of all ages is about twice as high as in men.
- **Ethnic and geographic.** Cholesterol gallstone prevalence approaches 50% to 75% in certain Native American populations—the Pima, Hopi, and Navajos—whereas pigment stones are rare; the prevalence seems to be related to biliary cholesterol hypersecretion.
- **Heredity.** In addition to ethnicity, a positive family history imparts increased risk, as do a variety of inborn errors of metabolism such as those associated with impaired bile salt synthesis and secretion.
- **Environment.** Estrogenic influences, including oral contraceptives and pregnancy, increase hepatic cholesterol uptake and synthesis, leading to excess biliary secretion of cholesterol. Obesity, rapid weight loss, and treatment with the hypocholesterolemic agent clofibrate also are strongly associated with increased biliary cholesterol secretion.
- **Acquired disorders.** Any condition in which gallbladder motility is reduced predisposes to gallstones, such as pregnancy, rapid weight loss, and spinal cord injury. In most cases, however, gallbladder hypomotility is present without obvious cause.

## MORPHOLOGY

**Cholesterol stones** arise exclusively in the gallbladder and consist of 50% to 100% cholesterol. **Pure cholesterol stones** are pale yellow; increasing proportions of calcium carbonate, phosphates, and bilirubin impart gray-white to black discoloration (Fig. 15–35). They are ovoid and firm; they can occur singly, but most often there are several, with faceted surfaces resulting from their apposition. **Most cholesterol stones are radiolucent, although as many as 20% may have sufficient calcium carbonate to be radiopaque.**

**Figure 15–35** Cholesterol gallstones. Mechanical manipulation during laparoscopic cholecystectomy has caused fragmentation of several cholesterol gallstones, revealing interiors that are pigmented because of entrapped bile pigments. The gallbladder mucosa is reddened and irregular as a result of coexistent acute and chronic cholecystitis.

**Pigment stones** may arise anywhere in the biliary tree and are classified into black and brown stones. In general, black pigment stones are found in sterile gallbladder bile, while brown stones are found in infected intrahepatic or extrahepatic ducts. The stones contain calcium salts of unconjugated bilirubin and lesser amounts of other calcium salts, mucin glycoproteins, and cholesterol. Black stones are usually small in size, fragile to the touch, and numerous (Fig. 15–36). Brown stones tend to be single or few in number and to have a soft, greasy, soaplike consistency that results from the presence of retained fatty acid salts released by the action of bacterial phospholipases on biliary lecithins. Because of calcium carbonates and phosphates, **50% to 75% of black stones are radiopaque.** Brown stones, which contain calcium soaps, are radiolucent.

**Figure 15–36** Pigmented gallstones. Several faceted black gallstones are present in this otherwise unremarkable gallbladder removed from a patient who had a mechanical mitral valve prosthesis, leading to chronic intravascular hemolysis.

### Clinical Features

70% to 80% of individuals with gallstones remain asymptomatic throughout life, with the risk of symptoms diminishing over time. In the unfortunate minority, however, the symptoms are striking. There is usually pain, often excruciating, which typically localizes to the right upper quadrant or epigastric region and can be constant or, less commonly, spasmodic. Such "biliary" pain is caused by gallbladder or biliary tree obstruction, or by inflammation of the gallbladder itself. More severe complications include empyema, perforation, fistulas, inflammation of the biliary tree, and obstructive cholestasis or pancreatitis. The larger the calculi, the less likely they are to enter the cystic or common ducts to produce obstruction; it is the very small stones, or "gravel," that are more dangerous. Occasionally a large stone may erode directly into an adjacent loop of small bowel, generating intestinal obstruction (*gallstone ileus*).

## Cholecystitis

Inflammation of the gallbladder may be acute, chronic, or acute superimposed on chronic, and almost always occurs in association with gallstones. In the United States, cholecystitis is one of the most common indications for abdominal surgery. Its epidemiologic distribution closely parallels that of gallstones.

### MORPHOLOGY

In **acute cholecystitis,** the gallbladder usually is enlarged and tense, and it assumes a bright red or blotchy, violaceous color, the latter imparted by subserosal hemorrhages. The serosa frequently is covered by a fibrinous, or in severe cases, fibrinopurulent exudate. In 90% of cases, stones are present, often obstructing the neck of the gallbladder or the cystic duct. The gallbladder lumen is filled with cloudy or turbid bile that may contain fibrin, blood, and frank pus. When the contained exudate is mostly pus, the condition is referred to as **empyema of the gallbladder.** In mild cases the gallbladder wall is thickened, edematous, and hyperemic. In more severe cases the gallbladder is transformed into a green-black necrotic organ—a condition termed **gangrenous cholecystitis.** On histologic examination, the inflammatory reactions are not distinctive and consist of the usual patterns of acute inflammation (i.e., edema, leukocytic infiltration, vascular congestion, frank abscess formation, or gangrenous necrosis).

The morphologic changes in **chronic cholecystitis** are extremely variable and sometimes subtle. The mere presence of stones within the gallbladder, even in the absence of acute inflammation, often is taken as sufficient justification for the diagnosis. The gallbladder may be contracted, of normal size, or enlarged. Mucosal ulcerations are infrequent; the submucosa and subserosa often are thickened from fibrosis. In the absence of superimposed acute cholecystitis, mural lymphocytes are the only signs of inflammation.

### *Acute Calculous Cholecystitis*

Acute inflammation of a gallbladder that contains stones is termed *acute calculous cholecystitis* and is precipitated by obstruction of the gallbladder neck or cystic duct. *It is the most common major complication of gallstones and the most common reason for emergency cholecystectomy.* Manifestations of obstruction may appear with remarkable suddenness and constitute a surgical emergency. In some cases, however, symptoms may be mild and resolve without medical intervention.

Acute calculous cholecystitis is initially the result of chemical irritation and inflammation of the gallbladder wall in the setting of obstruction to bile outflow. The action of phospholipases derived from the mucosa hydrolyzes biliary lecithin to lysolecithin, which is toxic to the mucosa. The normally protective glycoprotein mucous layer is disrupted, exposing the mucosal epithelium to the direct detergent action of bile salts. Prostaglandins released within the wall of the distended gallbladder contribute to mucosal and mural inflammation. Distention and increased intraluminal pressure also may compromise blood flow to the mucosa. These events occur in the absence of bacterial infection; only later may bacterial contamination develop.

### *Acute Acalculous Cholecystitis*

Between 5% and 12% of gallbladders removed for acute cholecystitis contain no gallstones. Most cases occur in seriously ill patients. Some of the most common predisposing insults are

- Major, nonbiliary surgery
- Severe trauma (e.g., from motor vehicle crashes)
- Severe burns
- Sepsis

Other contributing factors include dehydration, gallbladder stasis and sludging, vascular compromise, and, ultimately, bacterial contamination.

### *Chronic Cholecystitis*

Chronic cholecystitis may be the sequel to repeated bouts of acute cholecystitis, but in most instances it develops without any history of acute attacks. Like acute cholecystitis it is almost always associated with gallstones. However, gallstones do not seem to have a direct role in the initiation of inflammation or the development of pain, because chronic acalculous cholecystitis causes symptoms and morphologic alterations similar to those seen in the calculous form. Rather, supersaturation of bile predisposes the patient to both chronic inflammation and, in most instances, stone formation. Microorganisms, usually *E. coli* and enterococci, can be cultured from the bile in only about one third of cases. Unlike acute calculous cholecystitis, stone obstruction of gallbladder outflow in chronic cholecystitis is not a requisite. Most gallbladders removed at elective surgery for gallstones show features of chronic cholecystitis, making it likely that biliary symptoms emerge after long-term coexistence of gallstones and low-grade inflammation.

### Clinical Features

*Acute calculous cholecystitis* presents with biliary pain that lasts for more than 6 hours. The pain is severe, usually steady, upper abdominal in location, and often radiates to the right shoulder. Fever, nausea, leukocytosis, and prostration are classic; the presence of conjugated

hyperbilirubinemia suggests obstruction of the common bile duct. The right subcostal region is markedly tender and rigid as a result of spasm of the abdominal muscles; occasionally a tender, distended gallbladder can be palpated. Mild attacks usually subside spontaneously over 1 to 10 days; however, recurrence is common. Approximately 25% of symptomatic patients are sufficiently ill to require surgical intervention.

Symptoms arising from *acute acalculous cholecystitis* usually are obscured by the generally severe clinical condition of the patient. The diagnosis therefore rests on keeping this possibility in mind.

*Chronic cholecystitis* does not have the striking manifestations of the acute forms and is usually characterized by recurrent attacks of steady epigastric or right upper quadrant pain. Nausea, vomiting, and intolerance for fatty foods are frequent accompaniments.

The diagnosis of acute cholecystitis usually is based on the detection of gallstones by ultrasonography, typically accompanied by evidence of a thickened gallbladder wall. Chronic cholecystitis, on the other hand, is a pathologic diagnosis based on the examination of the resected gallbladder. Attention to this disorder is important because of the potential for the following serious complications:

- Bacterial superinfection with cholangitis or sepsis
- Gallbladder perforation and local abscess formation
- Gallbladder rupture with diffuse peritonitis
- Biliary enteric (cholecystenteric) fistula, with drainage of bile into adjacent organs, entry of air and bacteria into the biliary tree, and potentially gallstone-induced intestinal obstruction (ileus)
- Aggravation of preexisting medical illness, with cardiac, pulmonary, renal, or liver decompensation

# DISORDERS OF EXTRAHEPATIC BILE DUCTS

## Choledocholithiasis and Cholangitis

Choledocholithiasis and cholangitis are considered together because these conditions frequently go hand in hand. *Choledocholithiasis* is the presence of stones within the biliary tree. In Western nations, almost all stones are derived from the gallbladder; in Asia, there is a much higher incidence of primary ductal and intrahepatic, usually pigmented, stone formation. Choledocholithiasis may not immediately obstruct major bile ducts; asymptomatic stones are found in about 10% of patients at the time of surgical cholecystectomy. Symptoms may develop because of (1) biliary obstruction, (2) cholangitis, (3) hepatic abscess, (4) chronic liver disease with secondary biliary cirrhosis, or (5) acute calculous cholecystitis.

*Cholangitis* is the term used for acute inflammation of the wall of bile ducts, almost always caused by bacterial infection of the normally sterile lumen. It can result from any lesion obstructing bile flow, most commonly choledocholithiasis, and also from surgery involving the biliary tree. Other causes include tumors, indwelling stents or catheters, acute pancreatitis, and benign strictures. Bacteria most likely enter the biliary tract through the sphincter of Oddi, rather than by the hematogenous route. *Ascending cholangitis* refers to the propensity of bacteria, once within the biliary tree, to infect intrahepatic biliary ducts. The usual pathogens are *E. coli, Klebsiella, Enterococci, Clostridium,* and *Bacteroides*. Two or more organisms are found in half of the cases. In some world populations, parasitic cholangitis is a significant problem. Causative organisms include *Fasciola hepatica* or schistosomiasis in Latin America and the Near East, *Clonorchis sinensis* or *Opisthorchis viverrini* in the Far East, and cryptosporidiosis in persons with acquired immunodeficiency syndrome.

Bacterial cholangitis usually produces fever, chills, abdominal pain, and jaundice. The most severe form of cholangitis is suppurative cholangitis, in which purulent bile fills and distends bile ducts, with an attendant risk of liver abscess formation. Because sepsis rather than cholestasis is the predominant risk in cholangitic patients, prompt diagnosis and intervention are imperative.

## Secondary Biliary Cirrhosis

Prolonged obstruction of the extrahepatic biliary tree results in profound damage to the liver itself. The most common cause of obstruction is extrahepatic cholelithiasis. Other obstructive conditions include biliary atresia (discussed later on), malignancies of the biliary tree and head of the pancreas, and strictures resulting from previous surgical procedures. The initial morphologic features of cholestasis were described earlier and are entirely reversible with correction of the obstruction. However, secondary inflammation resulting from biliary obstruction initiates periportal fibrogenesis, which eventually leads to scarring and nodule formation, generating secondary biliary cirrhosis.

## Biliary Atresia

Biliary atresia is a major cause of neonatal cholestasis, accounting for one third of the cases of cholestasis in infants and occurring in approximately 1 in 10,000 live births. *Biliary atresia is defined as a complete obstruction of bile flow caused by destruction or absence of all or part of the extrahepatic bile ducts.* It is the most frequent cause of death from liver disease in early childhood and accounts for more than half of the referrals of children for liver transplantation.

The salient features of biliary atresia include

- Inflammation and fibrosing stricture of the hepatic or common bile ducts
- Inflammation of major intrahepatic bile ducts, with progressive destruction of the intrahepatic biliary tree
- Florid features of biliary obstruction on liver biopsy (i.e., ductular reaction, portal tract edema and fibrosis, and parenchymal cholestasis)
- Periportal fibrosis and cirrhosis within 3 to 6 months of birth

### Clinical Course

Infants with biliary atresia present with neonatal cholestasis; there is a slight female predominance. Affected infants have normal birth weights and postnatal weight gain. Stools become acholic as the disease evolves. Laboratory

findings do not distinguish between biliary atresia and intrahepatic cholestasis, but a liver biopsy provides evidence of bile duct obstruction in 90% of cases of biliary atresia. Liver transplantation is the definitive treatment. Without surgical intervention, death usually occurs within 2 years of birth.

## SUMMARY

### Diseases of the Gallbladder and Extrahepatic Bile Ducts

- Gallbladder diseases include cholelithiasis and acute and chronic cholecystitis.
- Gallstone formation is a common condition in Western countries. The great majority of the gallstones are cholesterol stones. Pigmented stones containing bilirubin and calcium are most common in Asian countries.
- Risk factors for the development of cholesterol stones are advancing age, female gender, estrogen use, obesity, and heredity.
- Cholecystitis almost always occurs in association with cholelithiasis, although in about 10% of cases it occurs in the absence of gallstones.
- Acute calculous cholecystitis is the most common reason for emergency cholecystectomy.
- Obstructive lesions of the extrahepatic bile ducts in adults can give rise to ascending infection (cholangitis) and secondary biliary cirrhosis.
- Infants born with congenital biliary atresia present with neonatal cholestasis and require liver transplantation for cure.

# TUMORS

## Carcinoma of the Gallbladder

Although uncommon, carcinoma of the gallbladder is the most frequent malignant tumor of the biliary tract. It is 2 to 6 times more common in women and occurs most frequently in the seventh decade of life. Carcinoma of the gallbladder is more frequent in the populations of Mexico and Chile, presumably due to the higher incidence of gallstone disease in these regions. In the United States the incidence is highest in Hispanics and Native Americans. Only rarely is it discovered at a resectable stage, and the mean 5-year survival rate is a dismal 5%. Gallstones are present in 60% to 90% of cases. In Asia, where pyogenic and parasitic diseases of the biliary tree are more common, gallstones are less important. Presumably, gallbladders containing stones or infectious agents develop cancer as a result of recurrent trauma and chronic inflammation. The role of carcinogenic derivatives of bile acids is unclear.

### MORPHOLOGY

Cancers of the gallbladder may exhibit **exophytic** or **infiltrating** growth patterns. The infiltrating pattern is more common and usually appears as a poorly defined area of diffuse thickening and induration of the gallbladder wall that may cover several square centimeters or involve the entire gallbladder. These tumors are scirrhous and very firm. The exophytic pattern grows into the lumen as an irregular, cauliflower-like mass but at the same time also invades the underlying wall (Fig. 15–37). **Most are adenocarcinomas,** which may be papillary or poorly differentiated. About 5% are squamous cell carcinomas or demonstrate adenosquamous differentiation, and rare neuroendocrine tumors also occur. By the time gallbladder cancers are discovered, most have invaded the liver or have spread to the bile ducts or to the portal hepatic lymph nodes.

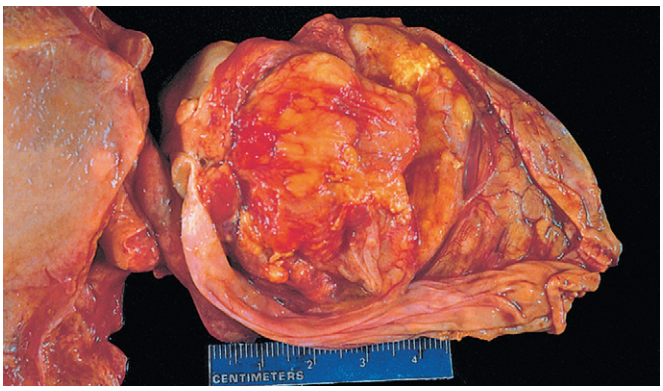

**Figure 15–37** Adenocarcinoma of the gallbladder. The opened gallbladder contains a large, exophytic tumor that virtually fills the lumen.

#### Clinical Features

Preoperative diagnosis of carcinoma of the gallbladder is the exception, being reported in less than 20% of patients. Onset of symptoms is insidious, and presenting manifestations typically are indistinguishable from those associated with cholelithiasis: abdominal pain, jaundice, anorexia, and nausea and vomiting. The fortunate person develops early obstruction and acute cholecystitis or undergoes cholecystectomy for coexistent symptomatic gallstones before the tumor spreads to other sites.

## Cholangiocarcinomas

Cholangiocarcinomas are adenocarcinomas that arise from cholangiocytes lining the intrahepatic and extrahepatic biliary ducts. Extrahepatic cholangiocarcinomas constitute approximately two thirds of these tumors and may develop at the hilum (known as Klatskin tumors) or more distally in the biliary tree. Cholangiocarcinomas occur mostly in persons of 50 to 70 years of age. Because both intra- and extrahepatic cholangiocarcinomas generally are asymptomatic until they reach an advanced stage, the prognosis is poor, and most patients have unresectable tumors. Risk factors include primary sclerosing cholangitis, fibropolycystic diseases of the biliary tree, and infestation by *Clonorchis sinensis* or *Opisthorchis viverrini.*

All risk factors for cholangiocarcinomas cause chronic cholestasis and inflammation, which presumably promote the occurrence of somatic mutations in cholangiocytes.

Several consistent genetic changes have been noted in these tumors, including activating mutations in the *KRAS* and *BRAF* oncogenes and loss-of-function mutations in the *TP53* tumor suppressor gene.

## MORPHOLOGY

**Cholangiocarcinomas** are typical adenocarcinomas with more or less well-formed glands often accompanied by abundant fibrous stroma (desmoplasia) yielding a firm, gritty consistency (Fig. 15–38). Bile pigment and hyaline inclusions are absent from the tumor cells, while intracellular mucin may be prominent.

Because partial or complete obstruction of bile ducts rapidly leads to jaundice, extrahepatic biliary tumors tend to be relatively small at the time of diagnosis, whereas intrahepatic tumors may cause symptoms only when much of the liver is replaced by tumor. Cholangiocarcinomas may spread to extrahepatic sites such as regional lymph nodes, lungs, bones, and adrenal glands. Invasion along peribiliary nerves is another route of spread to the abdomen. Cholangiocarcinoma has a greater propensity for extrahepatic spread than does hepatocellular carcinoma.

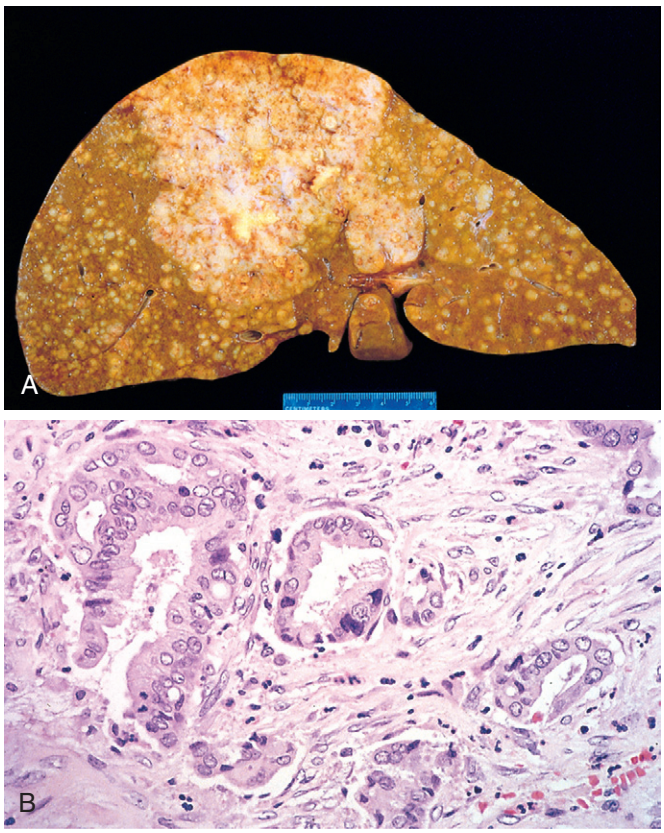

**Figure 15–38** Cholangiocarcinoma. **A,** Massive neoplasm in the right lobe and widespread intrahepatic metastases. **B,** Tumor cells forming glandular structures surrounded by dense sclerotic stroma.

### Clinical Features

*Intrahepatic* cholangiocarcinoma may be manifested by the presence of a liver mass and nonspecific signs and symptoms such as weight loss, pain, anorexia, and ascites. Symptoms and signs arising from *extrahepatic* cholangiocarcinomas (jaundice, acholic stools, nausea and vomiting, and weight loss) result from biliary obstruction. Commonly associated findings include elevated serum levels of alkaline phosphatase and aminotransferases. Surgical resection is the only treatment available, but in a large majority of cases is not curative. Transplantation is contraindicated. Mean survival times range from 6 to 18 months, regardless of whether aggressive resection or palliative surgery is performed.

CHAPTER 16

# Pancreas

CHAPTER CONTENTS

**Congenital Anomalies 646**
Agenesis 646
Pancreas Divisum 646
Annular Pancreas 646
Ectopic Pancreas 646
Congenital Cysts 646
**Pancreatitis 646**
Acute Pancreatitis 646
Chronic Pancreatitis 649
**Pancreatic Neoplasms 651**
Cystic Neoplasms 651
Pancreatic Carcinoma 652

The pancreas has critical endocrine functions, and the exocrine portion of the pancreas is a major source of potent enzymes that are essential for digestion. Diseases affecting the pancreas can be the source of significant morbidity and mortality. Unfortunately, despite its physiologic importance, the retroperitoneal location of the pancreas and the generally vague nature of signs and symptoms associated with its injury or dysfunction allow many pancreatic diseases to progress undiagnosed for extended periods of time; thus, recognition of pancreatic disorders often requires a high degree of suspicion.

The pancreas is a transversely oriented retroperitoneal organ extending from the so-called C loop of the duodenum to the hilum of the spleen. Although the pancreas does not have well-defined anatomic subdivisions, adjacent vessels and ligaments serve to demarcate the organ into a head, body, and tail.

The pancreas gets its name from the Greek *pankreas,* meaning "all flesh," and is a complex lobulated organ with distinct endocrine and exocrine elements. The endocrine portion constitutes only 1% to 2% of the pancreas and is composed of about 1 million cell clusters, the islets of Langerhans; these cells secrete insulin, glucagon, and somatostatin. The most significant disorders of the *endocrine pancreas* are diabetes mellitus and neoplasms; these are described in detail in Chapter 19 and are not discussed further here.

The *exocrine pancreas* is composed of *acinar cells* that produce the digestive enzymes, and the ductules and ducts that convey them to the duodenum. The acinar cells are responsible for the synthesis of digestive enzymes, which are mostly made as inactive pro-enzymes that are stored in *zymogen granules.* When acinar cells are stimulated to secrete, the granules fuse with the apical plasma membrane and release their contents into the central acinar lumen. These secretions are transported to the duodenum through a series of anastomosing ducts.

The epithelial cells lining the ducts also are active participants in pancreatic secretion: The cuboidal cells lining the smaller ductules secrete bicarbonate-rich fluid, while the columnar cells lining the larger ducts produce mucin. The epithelial cells of the larger ducts also express the *cystic fibrosis transmembrane conductance regulator* (CFTR); aberrant function of this membrane protein affects the viscosity of the pancreatic secretions and has a fundamental role in the pathophysiology of pancreatic disease in persons with cystic fibrosis (Chapter 6).

As described later, autodigestion of the pancreas (e.g., in pancreatitis) can be a catastrophic event. A number of "fail-safe" mechanisms have evolved to minimize the risk of occurrence of this phenomenon:

- A majority of pancreatic enzymes are synthesized as inactive proenzymes and sequestered in membrane-bound zymogen granules, as mentioned above.
- Activation of proenzymes requires conversion of trypsinogen to trypsin by duodenal enteropeptidase (also called enterokinase).
- Trypsin inhibitors (e.g., SPINK1, also known as pancreatic secretory trypsin inhibitor) also are secreted by acinar and ductal cells.
- Trypsin cleaves and inactivates itself, a negative feedback mechanism that normally puts a limit on local levels of activated trypsin.
- Acinar cells are remarkably resistant to the action of activated enzymes such as trypsin, chymotrypsin, and phospholipase $A_2$.

Diseases of the exocrine pancreas include cystic fibrosis, congenital anomalies, acute and chronic pancreatitis, and neoplasms. Cystic fibrosis is discussed in detail in Chapter 6; the other pathologic processes are discussed in the remainder of this chapter.

*The contributions of those who authored this chapter in previous editions of this book are gratefully acknowledged.*

# CONGENITAL ANOMALIES

Pancreatic development is a complex process involving fusion of dorsal and ventral primordia; subtle deviations in this process frequently give rise to congenital variations in pancreatic anatomy. While most of these do not cause disease per se, variants (especially in ductal anatomy) can present challenges to the endoscopist and the surgeon. For example, failure to recognize idiosyncratic anatomy could result in inadvertent severing of a pancreatic duct during surgery, resulting in pancreatitis.

## Agenesis

Very rarely, the pancreas may be totally absent, a condition usually (but not invariably) associated with additional severe malformations that are incompatible with life. *Pancreatic duodenal homeobox 1* is a homeodomain transcription factor critical for normal pancreatic development, and mutations of the *PDX1* gene, located on chromosomal locus 13q12.1, have been associated with pancreatic agenesis.

## Pancreas Divisum

*Pancreas divisum* is the most common clinically significant congenital pancreatic anomaly, with an incidence of 3% to 10% in autopsy series. It occurs when the duct systems of the fetal pancreatic primordia fail to fuse. As a result, the main pancreatic duct drains only a small portion of the head of the gland, while the bulk of the pancreas (from the dorsal pancreatic primordium) drains through the minor sphincter, which has a narrow opening. As a result of this defect in drainage, persons with pancreas divisum have elevated intraductal pressures throughout most of the pancreas and are at increased risk for chronic pancreatitis.

## Annular Pancreas

*Annular pancreas* is a relatively uncommon variant of pancreatic fusion in which a ring of pancreatic tissue completely encircles the duodenum. It can manifest with signs and symptoms of duodenal obstruction such as gastric distention and vomiting.

## Ectopic Pancreas

Aberrantly situated, or *ectopic,* pancreatic tissue occurs in about 2% of the population; favored sites are the stomach and duodenum, followed by the jejunum, Meckel diverticulum, and ileum. These embryologic rests typically are small (ranging from millimeters to centimeters in diameter) and are located in the submucosa; they are composed of normal pancreatic acini with occasional islets. Though usually incidental and asymptomatic, ectopic pancreas can cause pain from localized inflammation, or—rarely—can cause mucosal bleeding. Approximately 2% of pancreatic neuroendocrine tumors (Chapter 19) arise in ectopic pancreatic tissue.

## Congenital Cysts

*Congenital cysts* probably result from anomalous development of the pancreatic ducts. In *polycystic disease,* the kidneys, liver, and pancreas can all contain cysts (Chapter 13). Congenital cysts generally are unilocular and range from microscopic to 5 cm in diameter. They are lined by either uniform cuboidal or flattened epithelium and are enclosed in a thin, fibrous capsule. These benign cysts contain clear serous fluid—an important point of distinction from pancreatic cystic neoplasms, which often are mucinous (see further on).

# PANCREATITIS

Inflammatory disorders of the pancreas range in severity from mild, self-limited disease to life-threatening, widely destructive process, and are accordingly associated with deficits that may be trivial and transient or serious and permanent. In *acute pancreatitis,* function can return to normal if the underlying cause of inflammation is removed. By contrast, *chronic pancreatitis* is defined by irreversible destruction of exocrine pancreatic parenchyma.

## Acute Pancreatitis

Acute pancreatitis is a reversible inflammatory disorder that varies in severity, ranging from focal edema and fat necrosis to widespread hemorrhagic parenchymal necrosis. Acute pancreatitis is relatively common, with an annual incidence of 10 to 20 per 100,000 people in the Western world. *Approximately 80% of cases are attributable to either biliary tract disease or alcoholism* (Table 16–1). Roughly 5% of patients with gallstones develop acute pancreatitis, and gallstones are implicated in 35% to 60% of cases overall.

**Table 16–1** Etiologic Factors in Acute Pancreatitis

| |
|---|
| **Metabolic** |
| Alcoholism* |
| Hyperlipoproteinemia |
| Hypercalcemia |
| Drugs (e.g., azathioprine) |
| **Genetic** |
| Mutations in the cationic trypsinogen (*PRSS1*) and trypsin inhibitor (*SPINK1*) genes |
| **Mechanical** |
| Gallstones* |
| Trauma |
| Iatrogenic injury |
| Perioperative injury |
| Endoscopic procedures with dye injection |
| **Vascular** |
| Shock |
| Atheroembolism |
| Polyarteritis nodosa |
| **Infectious** |
| Mumps |
| Coxsackievirus |

*Most common causes in the United States.

Excessive alcohol intake has been reported as a cause of acute pancreatitis at variable rates, from 65% of cases in the United States to 5% or less in the United Kingdom.

Other causes of acute pancreatitis include

- Non–gallstone-related obstruction of the pancreatic ducts (e.g., due to periampullary neoplasms such as pancreatic cancer, pancreas divisum, biliary "sludge," or parasites, particularly *Ascaris lumbricoides* and *Clonorchis sinensis*)
- Medications including anticonvulsants, cancer chemotherapeutic agents, thiazide diuretics, estrogens, and more than 85 others in clinical use
- Infections with mumps virus or coxsackievirus
- Metabolic disorders, including hypertriglyceridemia, hyperparathyroidism, and other hypercalcemic states
- Ischemia due to vascular thrombosis, embolism, vasculitis, or shock
- Trauma, both blunt force and iatrogenic during surgery or endoscopy
- Inherited mutations in genes encoding pancreatic enzymes or their inhibitors (e.g., *SPINK1*). For example, *hereditary pancreatitis* is an autosomal dominant disease with 80% penetrance that is characterized by recurrent attacks of severe pancreatitis, usually beginning in childhood. It is caused by mutations in the gene *PRSS1*, which encodes trypsinogen, the proenzyme of pancreatic trypsin. The pathogenic mutations alter the site through which trypsin cleaves and inactivates itself, abrogating an important negative feedback mechanism. This defect leads not only to the hyperactivation of trypsin, but also to the hyperactivation of many other digestive enzymes that require trypsin cleavage for their activation. As a result of this unbridled protease activity, the pancreas is prone to autodigestion and injury.

Of note, 10% to 20% of cases of acute pancreatitis have no identifiable cause (*idiopathic pancreatitis*), although a growing body of evidence suggests that many may have an underlying genetic basis.

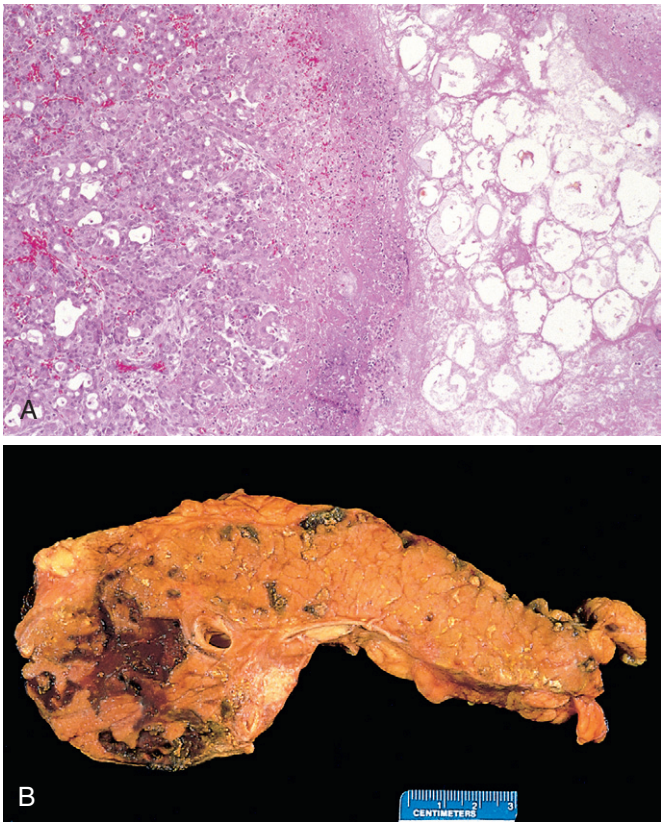

**Figure 16–1** Acute pancreatitis. **A,** The microscopic field shows a region of fat necrosis (*right*) and focal pancreatic parenchymal necrosis (*center*). **B,** The pancreas has been sectioned longitudinally to reveal dark areas of hemorrhage in the pancreatic substance and a focal area of pale fat necrosis in the peripancreatic fat (*upper left*).

## MORPHOLOGY

The basic alterations in acute pancreatitis are **(1) microvascular leakage causing edema, (2) necrosis of fat by lipases, (3) an acute inflammatory reaction, (4) proteolytic destruction of pancreatic parenchyma, and (5) destruction of blood vessels leading to interstitial hemorrhage.**

In milder forms, histologic alterations include interstitial edema and focal areas of fat necrosis in the pancreatic substance and peripancreatic fat (Fig. 16–1, *A*). Fat necrosis results from enzymatic destruction of fat cells; the released fatty acids combine with calcium to form insoluble salts that precipitate in situ.

In more severe forms, such as **acute necrotizing pancreatitis,** necrosis of pancreatic tissue affects acinar and ductal tissues as well as the islets of Langerhans; vascular damage causes hemorrhage into the parenchyma of the pancreas. Macroscopically, the pancreas exhibits red-black hemorrhagic areas interspersed with foci of yellow-white, chalky fat necrosis (Fig. 16–1, *B*). Fat necrosis also can occur in extrapancreatic fat, including the omentum and bowel mesentery, and even outside the abdominal cavity (e.g., in subcutaneous fat). In most cases the peritoneum contains a serous, slightly turbid, brown-tinged fluid with globules of fat (derived from enzymatically digested adipose tissue). In the most severe form, **hemorrhagic pancreatitis,** extensive parenchymal necrosis is accompanied by diffuse hemorrhage within the substance of the gland.

## PATHOGENESIS

The histologic changes seen in acute pancreatitis strongly suggest **autodigestion of the pancreatic substance by inappropriately activated pancreatic enzymes.** As described previously, the zymogen forms of pancreatic enzymes must be enzymatically cleaved to be activated; trypsin is central in this process, so **activation of trypsin is a critical triggering event in acute pancreatitis.** If trypsin is inappropriately generated from its proenzyme trypsinogen, it can activate itself as well as other proenzymes (e.g., phospholipases and elastases) that can then take part in the process of autodigestion. Trypsin also converts prekallikrein to its activated form, thus sparking the kinin system, and, by activation of factor XII (Hageman factor), also sets in motion the clotting and complement systems (Chapter 2).

Three pathways can incite the initial enzyme activation that may lead to acute pancreatitis (Fig. 16–2):

- **Pancreatic duct obstruction.** Impaction of a gallstone or biliary sludge, or extrinsic compression of the ductal system by a mass blocks ductal flow, increases intraductal pressure, and allows accumulation of an enzyme-rich interstitial fluid. Since lipase is secreted in an active form, local fat necrosis may result. Injured tissues, periacinar myofibroblasts, and leukocytes then release pro-inflammatory cytokines that promote local inflammation and interstitial edema through a leaky microvasculature. Edema further compromises local blood flow, causing vascular insufficiency and ischemic injury to acinar cells.
- **Primary acinar cell injury.** This pathogenic mechanism comes into play in acute pancreatitis caused by ischemia, viral infections (e.g., mumps), drugs, and direct trauma to the pancreas.
- **Defective intracellular transport of proenzymes within acinar cells.** In normal acinar cells, digestive enzymes intended for zymogen granules (and eventually extracellular release) and hydrolytic enzymes destined for lysosomes are transported in discrete pathways after synthesis in the endoplasmic reticulum. However, at least in some animal models of metabolic injury, pancreatic proenzymes and lysosomal hydrolases become packaged together. This results in proenzyme activation, lysosomal rupture (action of phospholipases), and local release of activated enzymes. The role of this mechanism in human acute pancreatitis is not clear.

**Alcohol consumption may cause pancreatitis by several mechanisms.** Alcohol transiently increases pancreatic exocrine secretion and contraction of the sphincter of Oddi (the muscle regulating the tone at the ampulla of Vater). Alcohol also has direct toxic effects on acinar cells, including induction of oxidative stress in acinar cells, which leads to membrane damage (see below). Finally, chronic alcohol ingestion results in the secretion of protein-rich pancreatic fluid, which leads to the deposition of inspissated protein plugs and obstruction of small pancreatic ducts.

### Clinical Features

*Abdominal pain* is the cardinal manifestation of acute pancreatitis. Its severity varies from mild and uncomfortable to severe and incapacitating. Suspected acute pancreatitis is diagnosed primarily by the presence of elevated plasma

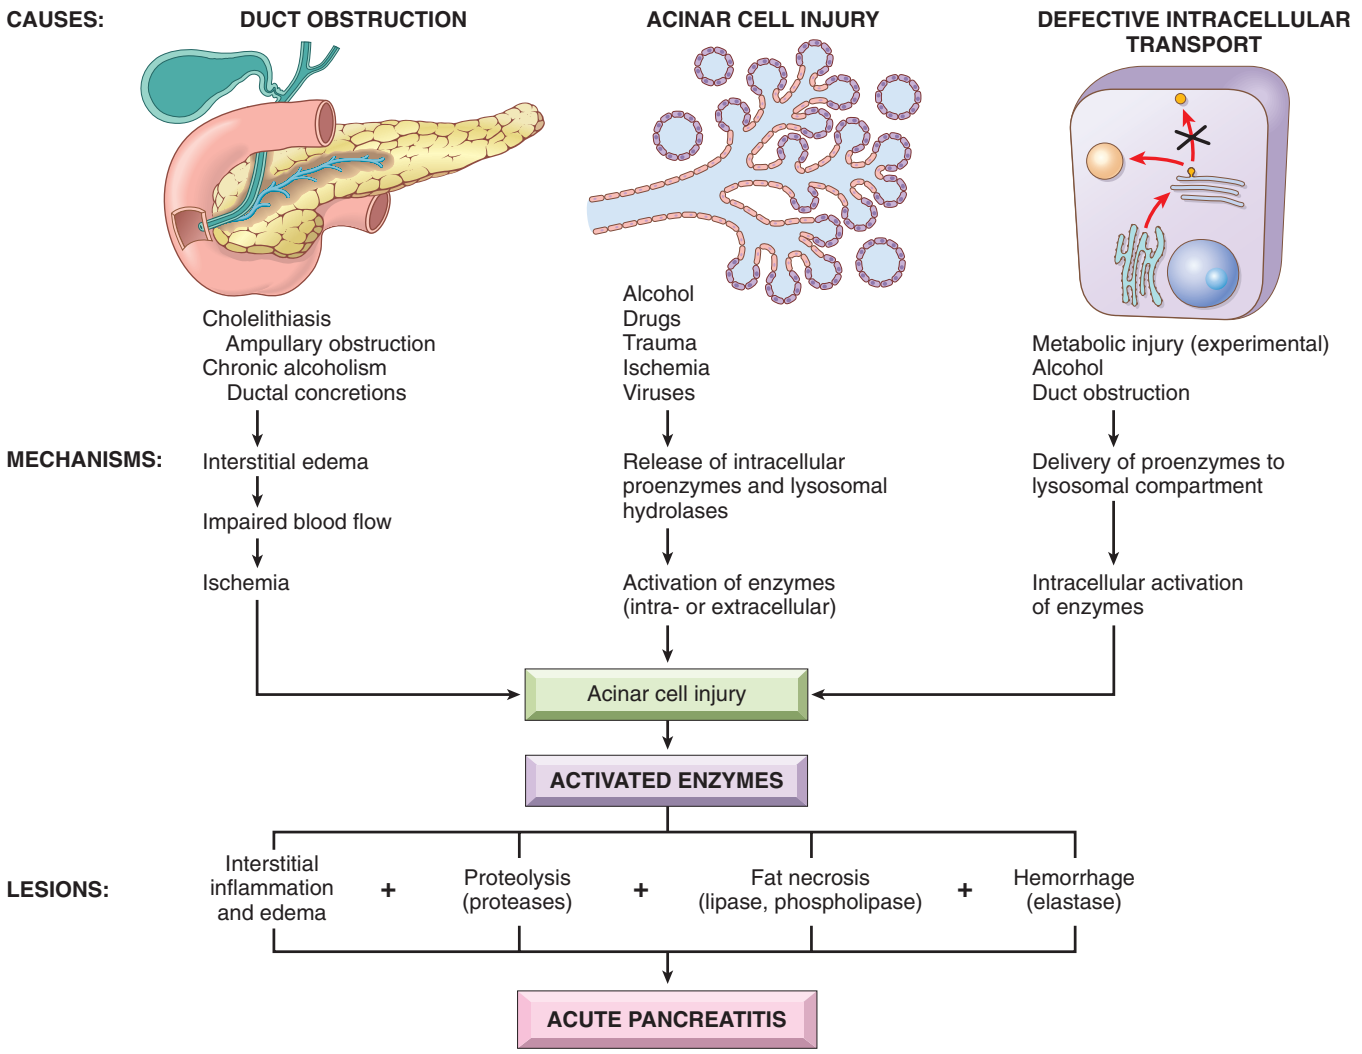

**Figure 16–2** Proposed pathogenesis of acute pancreatitis.

levels of amylase and lipase and the exclusion of other causes of abdominal pain. In 80% of cases acute pancreatitis is mild and self limiting; the remaining 20% develop severe disease.

*Full-blown acute pancreatitis constitutes a medical emergency of the first magnitude.* Affected persons usually experience the sudden calamitous onset of an "acute abdomen" with pain, abdominal guarding, and the ominous absence of bowel sounds. Characteristically, the pain is constant and intense and often is referred to the upper back; it must be differentiated from pain of other causes such as perforated peptic ulcer, biliary colic, acute cholecystitis with rupture, and occlusion of mesenteric vessels with infarction of the bowel.

The manifestations of severe acute pancreatitis are attributable to systemic release of digestive enzymes and explosive activation of the inflammatory response. The initial clinical evaluation may reveal leukocytosis, disseminated intravascular coagulation (Chapter 11), acute respiratory distress syndrome (due to alveolar capillary injury) (Chapter 12), and diffuse fat necrosis. Peripheral vascular collapse (shock) can rapidly ensue as a result of increased microvascular permeability and resultant hypovolemia, compounded by endotoxemia (from breakdown of the barriers between gastrointestinal flora and the bloodstream), and renal failure due to acute tubular necrosis (Chapter 13).

*Laboratory findings* include markedly elevated serum amylase during the first 24 hours, followed (within 72 to 96 hours) by rising serum lipase levels. Hypocalcemia can result from precipitation of calcium in areas of fat necrosis; if persistent, it is a poor prognostic sign. The enlarged inflamed pancreas can be visualized by computed tomography (CT) or magnetic resonance imaging (MRI).

The crux of the management of acute pancreatitis is supportive therapy (e.g., maintaining blood pressure and alleviating pain) and "resting" the pancreas by total restriction of food and fluids. In 40% to 60% of cases of acute necrotizing pancreatitis, the necrotic debris becomes infected, usually by gram-negative organisms from the alimentary tract, further complicating the clinical course. Although most persons with acute pancreatitis eventually recover, some 5% die from shock during the first week of illness; acute respiratory distress syndrome and acute renal failure are ominous complications. In surviving patients, sequelae include sterile or infected *pancreatic "abscesses"* or *pancreatic pseudocysts.*

### *Pancreatic Pseudocysts*

A common sequela of acute pancreatitis (and in particular, alcoholic pancreatitis) is a *pancreatic pseudocyst.* Liquefied areas of necrotic pancreatic tissue become walled off by fibrous tissue to form a cystic space, lacking an epithelial lining (hence the designation *pseudo*). The cyst contents are rich in pancreatic enzymes, and a laboratory assessment of the cyst aspirate can be diagnostic. Pseudocysts account for approximately 75% of all pancreatic cysts. While many pseudocysts spontaneously resolve, they can become secondarily infected, and larger pseudocysts can compress or even perforate into adjacent structures.

#### MORPHOLOGY

Pseudocysts usually are solitary; they commonly are attached to the surface of the gland and involve peripancreatic tissues such as the lesser omental sac or the retroperitoneum between the stomach and transverse colon or liver (Fig. 16–3, *A*). They can range in diameter from 2 cm to 30 cm. Since pseudocysts form by walling off areas of hemorrhagic fat necrosis, they typically are composed of necrotic debris encased by fibrous walls of granulation tissue lacking an epithelial lining (Fig. 16–3, *B*).

## Chronic Pancreatitis

Chronic pancreatitis is characterized by long-standing inflammation, fibrosis, and destruction of the exocrine pancreas; in its late stages, the endocrine parenchyma also is lost. Although chronic pancreatitis can result from recurrent bouts of acute pancreatitis, *the chief distinction between acute and chronic pancreatitis is the irreversible impairment in pancreatic function in the latter.* The prevalence of chronic pancreatitis is difficult to determine but probably ranges between 0.04% and 5% of the U.S. population. By far *the most common cause of chronic pancreatitis is long-term alcohol abuse*; middle-aged men constitute the bulk of patients in

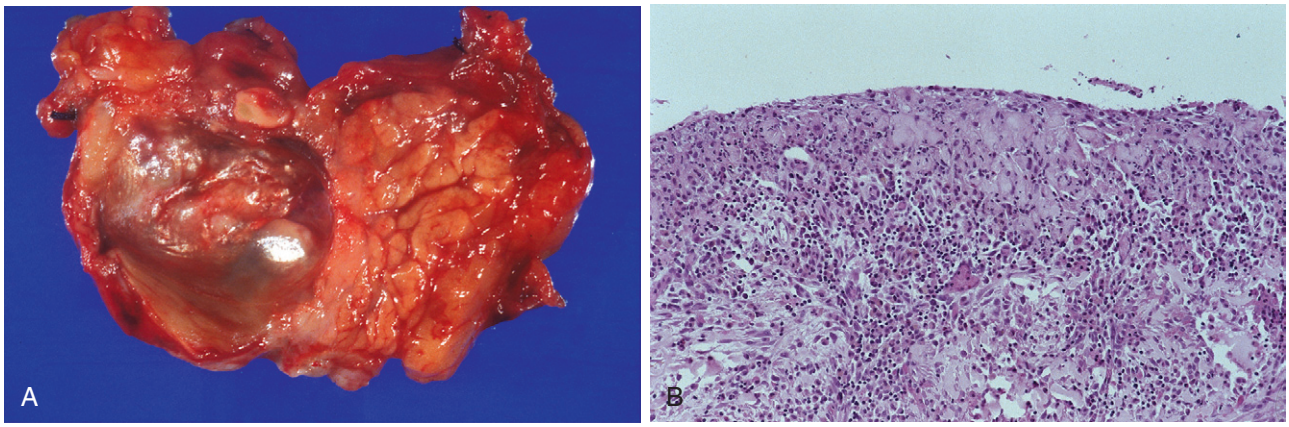

**Figure 16–3** Pancreatic pseudocyst. **A,** Cross-section revealing a poorly defined cyst with a necrotic brownish wall. **B,** Histologically, the cyst lacks a true epithelial lining and instead is lined by fibrin and granulation tissue, with typical changes of chronic inflammation.

this etiologic group. Less common causes of chronic pancreatitis include

- Long-standing pancreatic duct *obstruction* (e.g., by pseudocysts, calculi, neoplasms, or pancreas divisum)
- *Tropical pancreatitis,* a poorly characterized heterogeneous disorder seen in Africa and Asia, with a subset of cases having a genetic basis
- *Hereditary pancreatitis* due to mutations in the pancreatic trypsinogen gene (*PRRS1*) (see Table 16–1 earlier), or the *SPINK1* gene encoding a trypsin inhibitor
- *Chronic pancreatitis associated with CFTR mutations.* As discussed in detail in Chapter 6, cystic fibrosis is caused by mutations in the *CFTR* gene; the CFTR protein also is expressed in pancreatic ductal epithelium, and *CFTR* mutations decrease bicarbonate secretion and increase the viscosity of the secretions, thereby promoting protein plugging.

As many as 40% of persons with chronic pancreatitis have no recognizable predisposing factors. As with acute pancreatitis, however, a growing number of these "idiopathic" cases are associated with inherited mutations in genes important for normal pancreatic exocrine function. For example, genetic testing reveals that 25% to 30% of patients with "idiopathic" pancreatitis harbor germline mutations in the *CFTR* gene, albeit distinct from the ones that lead to classic multisystem cystic fibrosis (Chapter 6).

## MORPHOLOGY

Chronic pancreatitis is characterized by **parenchymal fibrosis, reduced number and size of acini, and variable dilation of the pancreatic ducts;** there is a relative sparing of the islets of Langerhans (Fig. 16–4, *A*). **Acinar loss** is a constant feature, usually with a chronic inflammatory infiltrate around remaining lobules and ducts. The ductal epithelium may be atrophied or hyperplastic or exhibit squamous metaplasia, and ductal concretions may be noted (Fig. 16–4, *B*). The remaining islets of Langerhans become embedded in the sclerotic tissue and may fuse and appear enlarged; eventually they also disappear. On gross evaluation, the gland is hard, sometimes with extremely dilated ducts and visible calcified concretions.

Autoimmune pancreatitis (AIP) is a distinct form of chronic pancreatitis that is characterized by one of two morphologic patterns: (1) striking infiltration of the pancreas by lymphoplasmacytic cells, many of which are positive for IgG4, accompanied by a "swirling" fibrosis and venulitis **(lymphoplasmacytic sclerosing pancreatitis),** or (2) a duct-centric mixed infiltrate composed of neutrophils, lymphocytes and plasma cells, often obliterating the ductal epithelium **(idiopathic duct centric pancreatitis).** IgG4-related autoimmune pancreatitis is a multisystem disease and may be one manifestation of IgG4-associated fibrosing disorders (Chapter 4). Recognition of autoimmune pancreatitis in both its forms is important, because it can mimic pancreatic cancer and also because it responds to steroid therapy.

## PATHOGENESIS

Although the pathogenesis of chronic pancreatitis is not well defined, several hypotheses are proposed:

- **Ductal obstruction by concretions.** Many of the inciting agents in chronic pancreatitis (e.g., alcohol) increase the protein concentration of pancreatic secretions, and these proteins can form ductal plugs.
- **Toxic-metabolic.** Toxins, including alcohol and its metabolites, can exert a direct toxic effect on acinar cells, leading to lipid accumulation, acinar cell loss, and eventually parenchymal fibrosis.
- **Oxidative stress.** Alcohol-induced oxidative stress may generate free radicals in acinar cells, leading to membrane damage (Chapter 1), and subsequent expression of chemokines like interleukin-8 (IL-8), which recruits mononuclear inflammatory cells. Oxidative stress also promotes the fusion of lysosomes and zymogen granules with resulting acinar cell necrosis, inflammation, and fibrosis.

In contrast with acute pancreatitis, a variety of profibrogenic cytokines, such as transforming growth factor-β (TGF-β), connective tissue growth factor, and platelet-derived growth factor, are secreted in chronic pancreatitis. These cytokines induce the activation and proliferation of periacinar myofibroblasts ("pancreatic stellate cells"), which deposit collagen and are instrumental in the pathogenesis of fibrosis.

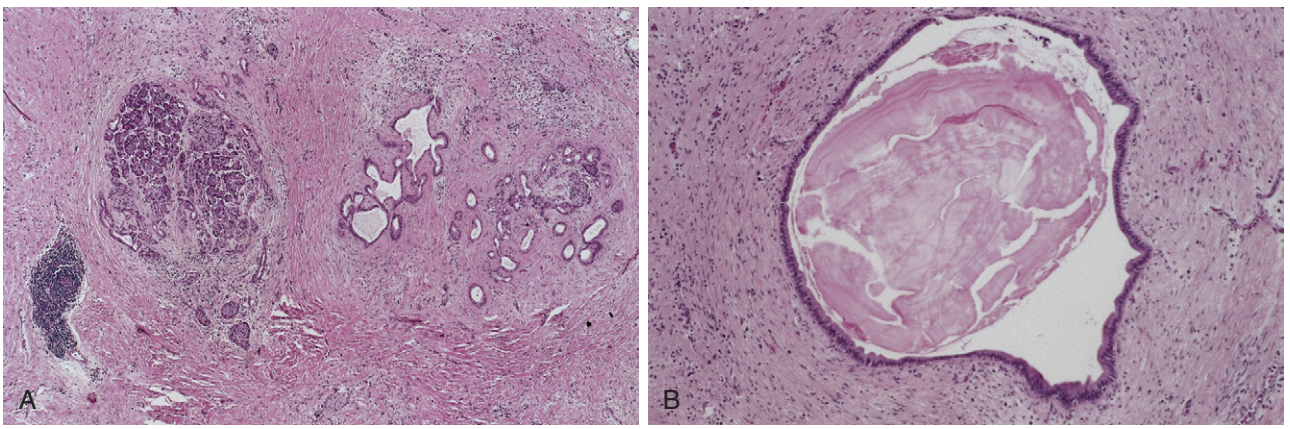

**Figure 16–4** Chronic pancreatitis. **A,** Extensive fibrosis and atrophy has left only residual islets (*left*) and ducts (*right*), with a sprinkling of chronic inflammatory cells and acinar tissue. **B,** A higher-power view demonstrating dilated ducts with inspissated eosinophilic concretions in a patient with alcoholic chronic pancreatitis.

### Clinical Features

Chronic pancreatitis manifests in several different ways. It may announce itself with repeated bouts of jaundice, vague indigestion, or persistent or recurrent abdominal and back pain, or it may be entirely silent until pancreatic insufficiency and diabetes mellitus develop (the latter as a consequence of islet destruction). Attacks can be precipitated by alcohol abuse, overeating (increases demand on pancreatic secretions), or opiates or other drugs that increase the muscle tone of the sphincter of Oddi.

*The diagnosis of chronic pancreatitis requires a high degree of clinical suspicion.* During an attack of abdominal pain, there may be mild fever and modest elevations of serum amylase. In end-stage disease, however, acinar destruction may be so advanced that enzyme elevations are absent. Gallstone-induced obstruction may manifest as jaundice or elevated levels of serum alkaline phosphatase. A very helpful finding is visualization of calcifications within the pancreas by CT or ultrasonography. Weight loss and hypoalbuminemic edema from malabsorption caused by pancreatic exocrine insufficiency also can point to the disease.

Although chronic pancreatitis is usually not acutely life-threatening, the long-term outlook is poor, with a 50% mortality rate over 20 to 25 years. Severe *pancreatic exocrine insufficiency* and chronic malabsorption may develop, as can *diabetes mellitus.* In other patients, *severe chronic pain* may dominate the clinical picture. *Pancreatic pseudocysts* (described earlier) develop in about 10% of patients. Persons with hereditary pancreatitis have a 40% lifetime risk of developing pancreatic cancer. The degree to which other forms of chronic pancreatitis contribute to cancer development is unclear.

#### SUMMARY

**Pancreatitis**

- *Acute pancreatitis* is characterized by inflammation and reversible parenchymal damage that ranges from focal edema and fat necrosis to widespread parenchymal necrosis and hemorrhage; the clinical presentation varies widely, from mild abdominal pain to rapidly fatal vascular collapse.
- *Chronic pancreatitis* is characterized by irreversible parenchymal damage and scar formation; clinical presentations include chronic malabsorption (due to pancreatic exocrine insufficiency) and diabetes mellitus (due to islet cell loss).
- Both entities share similar pathogenic mechanisms, and indeed recurrent acute pancreatitis can result in chronic pancreatitis. *Ductal obstruction* and *long-term alcohol abuse* are the most common causes in both forms. Inappropriate activation of pancreatic digestive enzymes (due to mutations in genes encoding trypsinogen or trypsin inhibitors) and primary acinar injury (due to toxins, infections, ischemia, or trauma) also cause pancreatitis.

## PANCREATIC NEOPLASMS

Pancreatic exocrine neoplasms can be cystic or solid. Some tumors are benign, while others are among the most lethal of all malignancies.

### Cystic Neoplasms

Only 5% to 15% of all pancreatic cysts are neoplastic; these constitute less than 5% of all pancreatic neoplasms. Some of these are entirely benign (e.g., serous cystadenoma); others, such as mucinous cystic neoplasms, can be benign or malignant.

#### *Serous Cystadenomas*

*Serous cystadenomas* account for approximately 25% of all pancreatic cystic neoplasms; they are composed of glycogen-rich cuboidal cells surrounding small cysts containing clear, straw-colored fluid (Fig. 16–5). The tumors typically manifest in the seventh decade of life with nonspecific symptoms such as abdominal pain; the female-to-male ratio is 2:1. These tumors are almost uniformly benign, and surgical resection is curative in the vast majority of patients. Most serous cystadenomas carry somatic mutations of the von Hippel-Lindau (*VHL*) tumor suppressor gene, the product of which binds to hypoxia-inducible factor 1 alpha (HIF1alpha) and results in its degradation (Chapter 5).

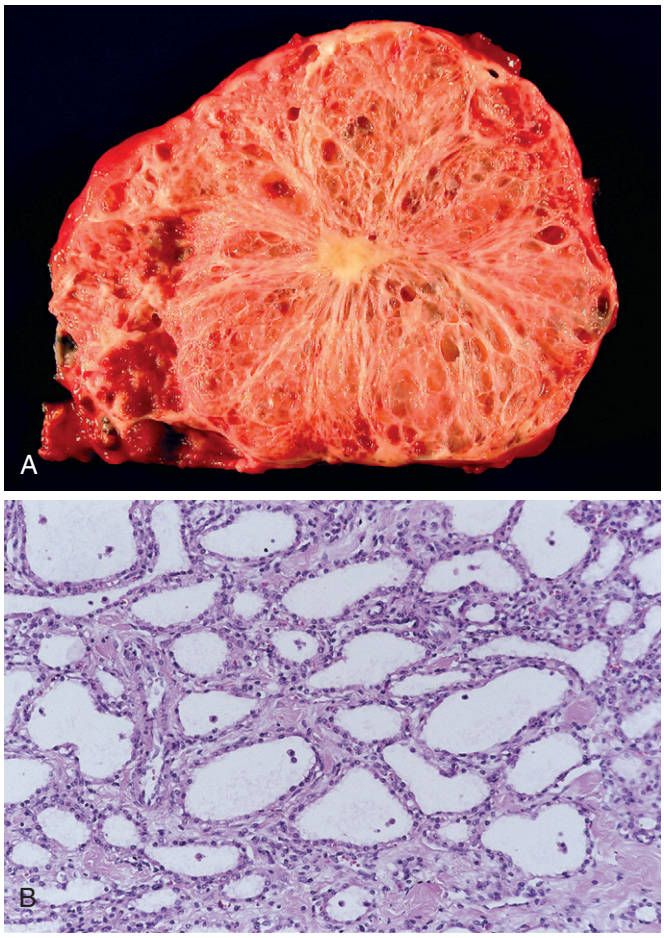

**Figure 16–5** Serous cystadenoma. **A,** Cross-section through a serous cystadenoma. Only a thin rim of normal pancreatic parenchyma remains. The cysts are relatively small and contain clear, straw-colored fluid. **B,** The cysts are lined by cuboidal epithelium without atypia.

### *Mucinous Cystic Neoplasms*

*Close to 95% of mucinous cystic neoplasms* arise in women, usually in the body or tail of the pancreas, and manifest as painless, slow-growing masses. The cystic spaces are filled with thick, tenacious mucin, and the cysts are lined by a columnar mucinous epithelium with an associated densely cellular stroma resembling that of the ovary (Fig. 16–6). Based on the degree of cytologic and architectural atypia in the lining epithelium, noninvasive mucinous cystic neoplasms are classified as harboring *low-grade, moderate,* or *severe* dysplasia. Up to one third of these cysts can be associated with an invasive adenocarcinoma. Distal pancreatectomy for noninvasive cysts typically is curative, even in the setting of severe dysplasia.

### *Intraductal Papillary Mucinous Neoplasms*

*Intraductal papillary mucinous neoplasms* (IPMNs) are mucin-producing intraductal neoplasms. In contrast with mucinous cystic neoplasms, IPMNs occur more frequently in men than in women and more frequently involve the head of the pancreas. IPMNs arise in the main pancreatic ducts, or one of its major branch ducts, and lack the cellular stroma seen in mucinous cystic neoplasms (Fig. 16–7). As with mucinous cystic neoplasms, the epithelia of noninvasive IPMNs harbor various grades of dysplasia, and a subset of lesions is associated with an invasive adenocarcinoma component. Notably, up to two thirds of IPMNs harbor oncogenic mutations of *GNAS* on chromosome 20q13, which encodes the alpha subunit of a stimulatory G-protein, $G_s$ (Chapter 19). Constitutive activation of this G-protein is predicted to result in an intracellular cascade that promotes cell proliferation.

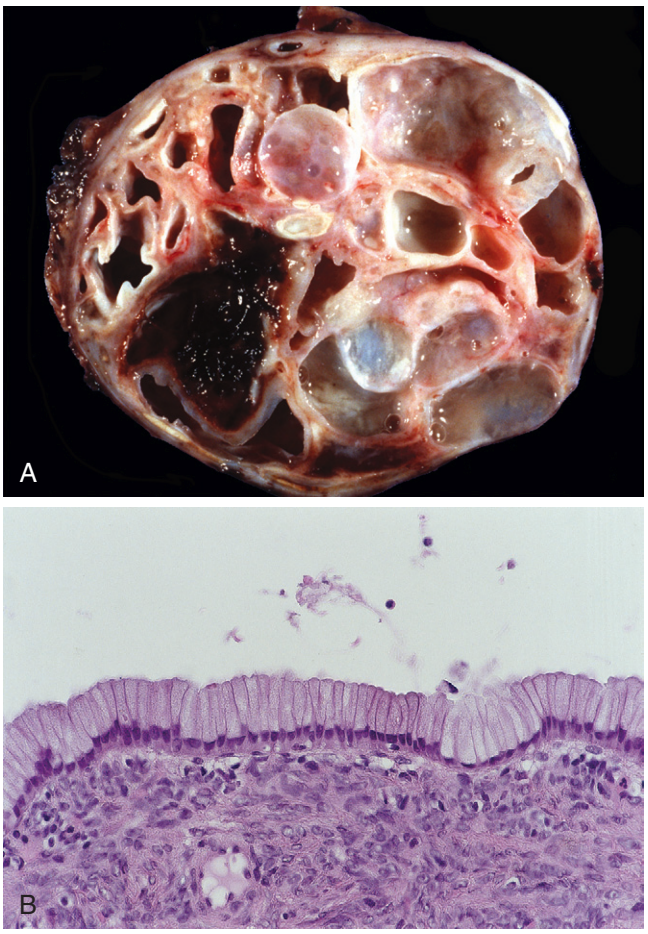

**Figure 16–6** Mucinous cystic neoplasm. **A,** Cross-section through a mucinous multiloculated cyst in the tail of the pancreas. The cysts are large and filled with tenacious mucin. **B,** The cysts are lined by columnar mucinous epithelium, with a densely cellular "ovarian" stroma.

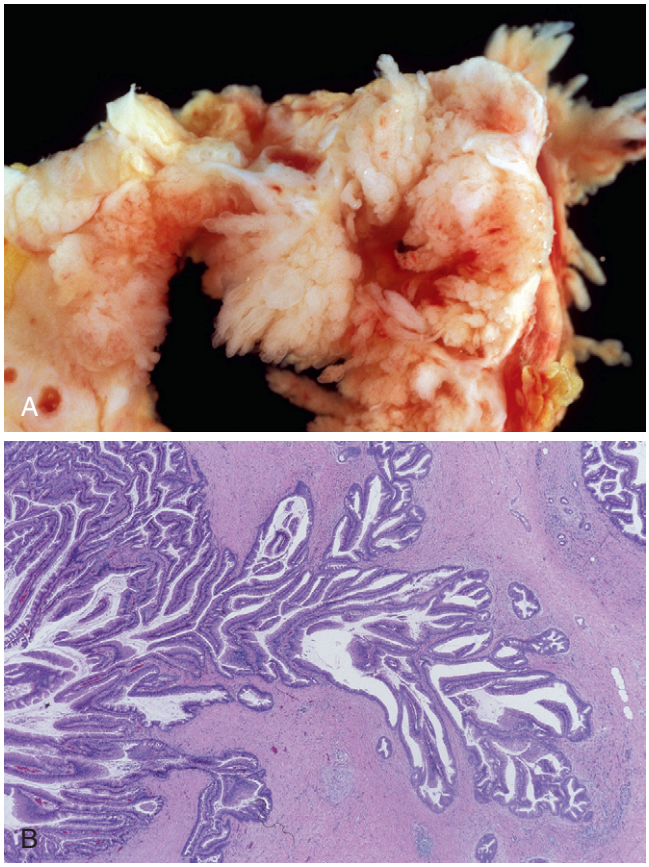

**Figure 16–7** Intraductal papillary mucinous neoplasm. **A,** Cross-section through the head of the pancreas showing a prominent papillary neoplasm distending the main pancreatic duct. **B,** The papillary mucinous neoplasm involved the main pancreatic duct (*left*) and is extending down into the smaller ducts and ductules (*right*).

## Pancreatic Carcinoma

Infiltrating ductal adenocarcinoma of the pancreas (more commonly referred to as "pancreatic cancer") is the fourth leading cause of cancer death in the United States, preceded only by lung, colon, and breast cancers. Although it is substantially less common than the other three malignancies, pancreatic carcinoma is near the top of the list of killers because it carries one of the highest mortality rates. Over 44,000 Americans were diagnosed with pancreatic cancer in 2010, and virtually all will die of it; the 5-year survival rate is dismal—less than 5%. Sadly, Ralph Steinman, one of the 2011 Nobel Laureates in physiology or medicine died of pancreatic cancer, three days before the announcement of his award.

## PATHOGENESIS

Like all cancers, pancreatic cancer arises as a consequence of inherited and acquired mutations in cancer-associated genes. In a pattern analogous to that seen in the multistep progression of colon cancer (Chapter 5), there is a progressive accumulation of genetic changes in pancreatic epithelium as it proceeds from non-neoplastic, to noninvasive precursor lesions, to invasive carcinoma (Fig. 16–8). While both intraductal papillary mucinous neoplasms and mucinous cystic neoplasms can progress to invasive adenocarcinoma and are thus considered bona fide precursors of cancer (as noted earlier), the most common antecedent lesions of pancreatic cancer arise in small ducts and ductules, and are called **pancreatic intraepithelial neoplasias (PanINs).** Evidence in favor of the precursor relationship of PanINs to frank malignancy includes the fact that these microscopic lesions often are found adjacent to infiltrating carcinomas and the two share a number of genetic alterations. Moreover, the epithelial cells in PanINs show dramatic telomere shortening, potentially predisposing these lesions to accumulating additional chromosomal abnormalities on their way to becoming invasive carcinoma.

The recent sequencing of the pancreatic cancer genome has confirmed that four genes are most commonly affected by somatic mutations in this neoplasm: *KRAS, CDKNA2A/p16, SMAD4,* and *TP53*:

- *KRAS* is the most frequently altered oncogene in pancreatic cancer; it is activated by a point mutation in 80% to 90% of cases. These mutations impair the intrinsic GTPase activity of the Kras protein so that it is constitutively active. In turn, Kras activates a number of intracellular signaling pathways ("Kras effectors") that promote carcinogenesis (Chapter 5).
- The *p16 (CDKN2A)* gene is the most frequently inactivated tumor suppressor gene in pancreatic cancer, being turned off in 95% of cases. The p16 protein has a critical role in cell cycle control; inactivation removes an important checkpoint.
- The *SMAD4* tumor suppressor gene is inactivated in 55% of pancreatic cancers and only rarely in other tumors; it codes for a protein that plays an important role in signal transduction downstream of the transforming growth factor-β receptor.
- Inactivation of the *TP53* tumor suppressor gene occurs in 50% to 70% of pancreatic cancers. Its gene product, p53, acts both to enforce cell cycle checkpoints and as an inducer of apoptosis or senescence (Chapter 5).
- Mutations of *VHL* or *GNAS,* found in aforementioned pancreatic cysts, have not been described in ductal adenocarcinomas, and provide a likely basis for the widely different histopathology and natural history of these lesions.

What causes these molecular changes is unknown. Pancreatic cancer is primarily a disease of the elderly population, with 80% of cases occurring between the ages of 60 and 80. The strongest environmental influence is **smoking,** which doubles the risk. Chronic pancreatitis and diabetes mellitus are also both associated with an increased risk of pancreatic cancer. It is difficult to sort out whether chronic pancreatitis is the cause of pancreatic cancer or an effect of the disease, since small pancreatic cancers can block the pancreatic duct and thereby produce chronic pancreatitis. On the other hand, as discussed in Chapter 5, chronic inflammation is now considered an enabler of malignancy. Likewise, the basis of the association of diabetes mellitus with pancreatic cancer is also unclear, since diabetes can occur as a consequence of pancreatic cancer, and in fact, new-onset diabetes in an elderly patient may be the first sign of this malignancy. Familial clustering of pancreatic cancer has been reported, and a growing number of inherited genetic defects are now recognized that increase pancreatic cancer risk. For example, germline mutations of the familial breast/ovarian cancer gene *BRCA2* are seen in approximately 10% of cases arising in persons of Ashkenazi Jewish heritage.

## MORPHOLOGY

Approximately 60% of pancreatic cancers arise in the head of the gland, 15% in the body, and 5% in the tail; in the remaining 20%, the neoplasm diffusely involves the entire

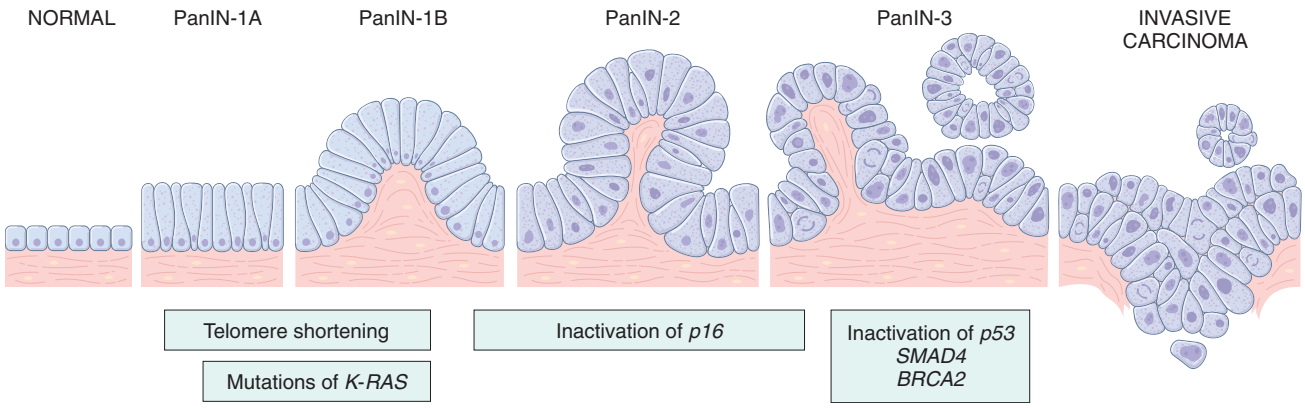

**Figure 16–8** Progression model for the development of pancreatic cancer. It is postulated that telomere shortening and mutations of the oncogene *K-RAS* occur at early stages, inactivation of the *p16* tumor suppressor gene occurs at intermediate stages, and the inactivation of the *TP53, SMAD4,* and *BRCA2* tumor suppressor genes occurs at late stages. Note that while there is a general temporal sequence of changes, the accumulation of multiple mutations is more important than their occurrence in a specific order. PanIN, pancreatic intraepithelial neoplasm. The numbers following the labels on the top refer to stages in the development of PanINs.

*(Modified from Maitra A, Hruban RH: Pancreatic cancer. Annu Rev Pathol Mech Dis 3:157, 2008.)*

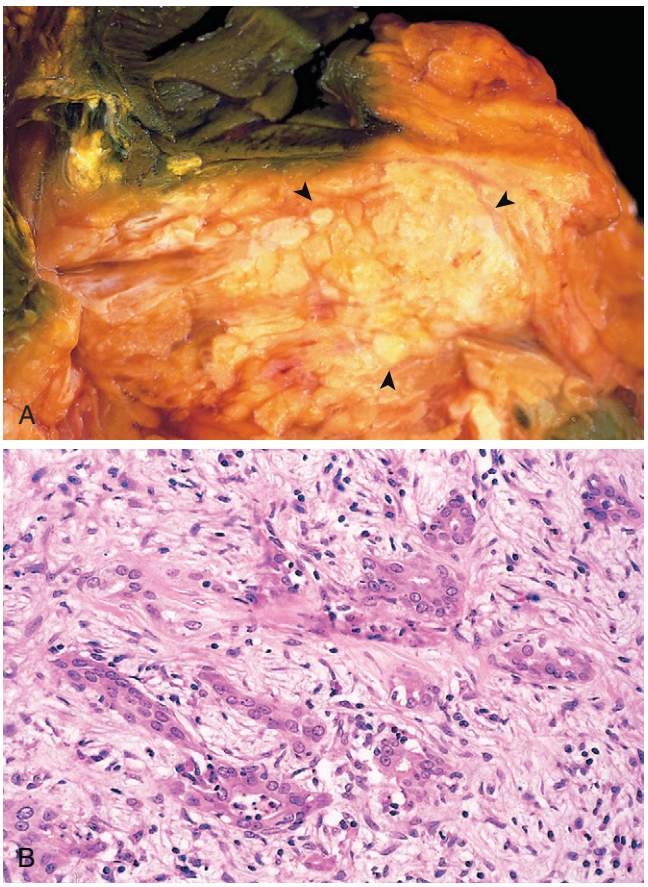

**Figure 16–9** Carcinoma of the pancreas. **A,** A cross-section through the head of the pancreas and adjacent common bile duct showing both an ill-defined mass in the pancreatic substance (*arrowheads*) and the green discoloration of the duct resulting from total obstruction of bile flow. **B,** Poorly formed glands are present in a densely fibrotic (desmoplastic) stroma within the pancreatic substance.

organ. Carcinomas of the pancreas usually are hard, gray-white, stellate, poorly defined masses (Fig. 16–9, *A*).

The vast majority of carcinomas are **ductal adenocarcinomas,** recapitulating to some degree the normal duct epithelium by forming glands and secreting mucin. Two features are characteristic of pancreatic cancer: It is highly invasive (even "early" invasive pancreatic cancers invade peripancreatic tissues extensively), and it elicits an intense non-neoplastic host reaction composed of fibroblasts, lymphocytes, and extracellular matrix **(desmoplastic response).**

**Most carcinomas of the head of the pancreas obstruct the distal common bile duct** as it courses through the head of the pancreas. In 50% of such cases, there is marked distention of the biliary tree, and patients typically exhibit jaundice. In marked contrast, **carcinomas of the body and tail of the pancreas do not impinge on the biliary tract and hence remain silent for some time. They may be quite large and widely disseminated by the time they are discovered.** Pancreatic cancers often extend through the retroperitoneal space, entrapping adjacent nerves (thus, accounting for the pain), and occasionally invade the spleen, adrenals, vertebral column, transverse colon, and stomach. Peripancreatic, gastric, mesenteric, omental, and portahepatic lymph nodes frequently are involved, and the liver often is enlarged as a consequence of metastatic deposits. Distant metastases may occur, principally to the lungs and bones.

On microscopic examination, pancreatic carcinoma usually is a moderately to poorly differentiated adenocarcinoma forming abortive tubular structures or cell clusters and exhibiting an aggressive, deeply infiltrative growth pattern (Fig. 16–9, *B*). Dense stromal fibrosis accompanies tumor invasion, and there is a proclivity for perineural invasion within and beyond the organ. Lymphatic invasion also is commonly seen.

Less common variants of pancreatic cancer include **adenosquamous carcinomas** with focal squamous differentiation in addition to glandular differentiation; and **undifferentiated carcinomas with osteoclast-like giant cells** of monocytic lineage intermixed within the neoplasm.

### Clinical Features

*Carcinomas of the pancreas typically remain silent until their extension impinges on some other structure.* Pain usually is the first symptom, but by that point these cancers are often beyond cure. *Obstructive jaundice* can be associated with carcinoma in the head of the pancreas, but it rarely draws attention to the cancer soon enough for timely intervention. Weight loss, anorexia, and generalized malaise and weakness are manifestations of advanced disease. *Migratory thrombophlebitis* (*Trousseau syndrome*) occurs in about 10% of patients and is attributable to the elaboration of platelet-aggregating factors and pro-coagulants from the tumor or its necrotic products (Chapter 3).

The clinical course of pancreatic carcinoma is rapidly progressive and distressingly brief. Less than 20% of pancreatic cancers are resectable at the time of diagnosis. It has long been recognized that there is a profound need for biomarkers capable of detecting early, potentially curable, pancreatic cancers. Although serum levels of many enzymes and antigens (e.g., carcinoembryonic and CA19-9 antigens) are elevated, these markers are neither specific nor sensitive enough to be useful for screening. Several imaging techniques, such as endoscopic ultrasonography and high-resolution CT scans, are helpful for investigation in cases of suspected cancer but are not useful as screening tests.

## SUMMARY

### Pancreatic Neoplasms

- Pancreatic cancer probably arises from noninvasive precursor lesions (most commonly, PanINs), developing by progressive accumulation of characteristic mutations of oncogenes (e.g., *KRAS*) and tumor suppressor genes (e.g., *CDKN2A/p16, TP53,* and *SMAD4*).
- Typically, these neoplasms are ductal adenocarcinomas that produce an intense desmoplastic response.
- Most pancreatic cancers are diagnosed at an advanced stage, accounting for the high mortality rate.
- Obstructive jaundice is a feature of carcinoma of the head of the pancreas; many patients also experience debilitating pain.

## PENIS

### Malformations

The most common malformations of the penis include abnormalities in the location of the distal urethral orifice, termed *hypospadias* and *epispadias*. In *hypospadias,* the more common of the two conditions, the abnormal opening of the urethra is on the ventral aspect of the penis anywhere along the shaft. This anomalous urethral orifice is sometimes constricted, resulting in urinary tract obstruction and an increased risk for urinary tract infections. The abnormality occurs in 1 in 300 live male births and may be associated with other congenital anomalies, such as inguinal hernia and undescended testis. In *epispadias,* the abnormal urethral orifice is on the dorsal aspect of the penis.

### Inflammatory Lesions

*Balanitis* and *balanoposthitis* refer to local inflammation of the glans penis and of the overlying prepuce, respectively. Among the more common agents are *Candida albicans,* anaerobic bacteria, *Gardnerella,* and pyogenic bacteria. Most cases occur as a consequence of poor local hygiene in uncircumcised males, with accumulations of desquamated epithelial cells, sweat, and debris, termed *smegma,* acting as a local irritant. *Phimosis* represents a condition in which the prepuce cannot be retracted easily over the glans penis. Although phimosis may occur as a congenital anomaly, most cases are acquired from scarring of the prepuce secondary to previous episodes of balanoposthitis.

### Neoplasms

More than 95% of penile neoplasms arise on squamous epithelium. In the United States, squamous cell carcinomas of the penis are relatively uncommon, accounting for about 0.4% of all cancers in males. In developing countries, however, penile carcinoma occurs at much higher rates. Most cases occur in uncircumcised patients older than 40 years of age. Several factors have been implicated in the pathogenesis of squamous cell carcinoma of the penis, including poor hygiene (with resultant exposure to potential carcinogens in smegma), smoking, and infection with human papillomavirus (HPV), particularly types 16 and 18.

*Squamous cell carcinoma in situ* of the penis (*Bowen disease*) occurs in older uncircumcised males and appears grossly as a solitary plaque on the shaft of the penis. Histologic examination reveals morphologically malignant cells throughout the epidermis with no invasion of the underlying stroma (Fig. 17–1). It gives rise to infiltrating squamous cell carcinoma in approximately 10% of patients.

*Invasive squamous cell carcinoma* of the penis appears as a gray, crusted, papular lesion, most commonly on the glans penis or prepuce. In many cases, infiltration of the underlying connective tissue produces an indurated, ulcerated lesion with irregular margins (Fig. 17–2). Histologically, it is a typical keratinizing squamous cell carcinoma. The prognosis is related to the stage of the tumor. With localized lesions, the 5-year survival rate is 66%, whereas metastasis to inguinal lymph nodes carries a grim 27% 5-year survival rate. *Verrucous carcinoma* is a variant of squamous cell carcinoma characterized by a papillary

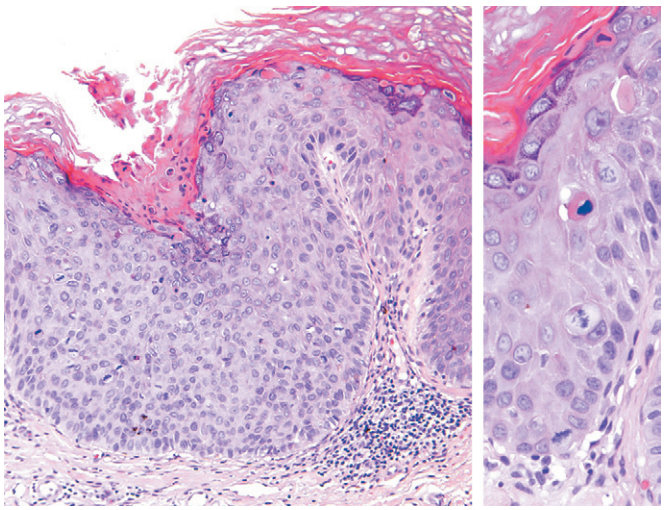

**Figure 17–1** Carcinoma in situ (Bowen disease) of the penis. The epithelium above the intact basement membrane shows delayed maturation and disorganization *(left)*. Higher magnification *(right)* shows several mitotic figures, some above the basal layer, a dyskeratotic cell, and nuclear pleomorphism.

architecture, virtually no cytologic atypia, and rounded, pushing deep margins. Verrucous carcinomas are locally invasive but do not metastasize.

## SUMMARY

### Lesions of the Penis

- Squamous cell carcinoma and its precursor lesions are the most important penile lesions. Many are associated with HPV infection.
- Squamous cell carcinoma occurs on the glans or shaft of the penis as an ulcerated infiltrative lesion that may spread to inguinal nodes and infrequently to distant sites. Most cases occur in uncircumcised males.
- Other important penile disorders include congenital abnormalities involving the position of the urethra (epispadias, hypospadias) and inflammatory disorders (balanitis, phimosis).

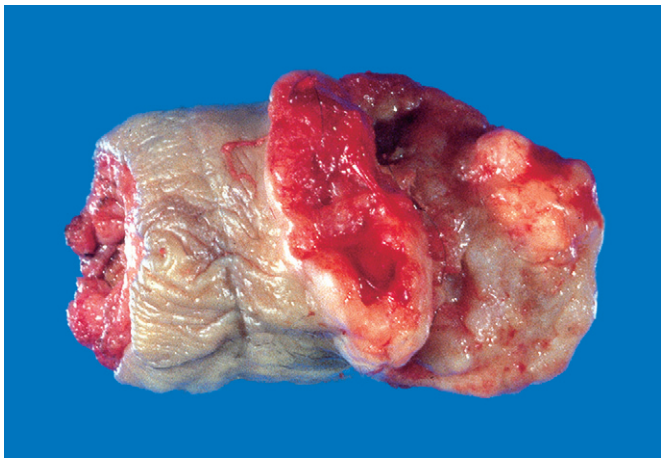

**Figure 17–2** Carcinoma of the penis. The glans penis is deformed by an ulcerated, infiltrative mass.

# SCROTUM, TESTIS, AND EPIDIDYMIS

The skin of the scrotum may be affected by several inflammatory processes, including local fungal infections and systemic dermatoses. Neoplasms of the scrotal sac are unusual. *Squamous cell carcinoma,* the most common of these, is of historical interest in that it represents the first human malignancy associated with environmental influences, dating from Sir Percival Pott's observation of a high incidence of the disease in chimney sweeps. The subsequent edict by the Chimney Sweeps Guild that its members must bathe daily remains one of the most successful public health measures for cancer prevention. Several disorders unrelated to the testes and epididymis may also present as scrotal enlargement. *Hydrocele,* the most common cause of scrotal enlargement, is caused by an accumulation of serous fluid within the tunica vaginalis. It may arise in response to neighboring infections or tumors, or it may be idiopathic. It is readily distinguished from collections of pus, lymph, and blood by allowing a beam of light to pass through (transluminescence). Accumulation of blood or lymphatic fluid within the tunica vaginalis, termed *hematoceles* and *chyloceles,* respectively, also may cause testicular enlargement. In extreme cases of lymphatic obstruction, caused, for example, by filariasis, the scrotum and the lower extremities may enlarge to grotesque sizes—a condition termed *elephantiasis.*

## Cryptorchidism and Testicular Atrophy

Cryptorchidism represents a *failure of testicular descent* into the scrotum. Normally, the testes descend from the abdominal cavity into the pelvis by the third month of gestation and then through the inguinal canals into the scrotum during the last 2 months of intrauterine life. The diagnosis of cryptorchidism is only established with certainty after the age of 1 year, particularly in premature infants, because testicular descent into the scrotum is not always complete at birth. By 1 year of age, cryptorchidism affects 1% of the male population. The condition is bilateral in approximately 10% of affected patients. In the vast majority of cases, the cause of the cryptorchidism is unknown. Because undescended testes become atrophic, bilateral cryptorchidism causes sterility. However, even unilateral cryptorchidism may be associated with atrophy of the contralateral descended gonad and therefore may also lead to sterility. In addition to infertility, failure of descent is associated with a 3- to 5-fold increased risk of *testicular cancer.* Patients with unilateral cryptorchidism are also at increased risk for the development of cancer in the contralateral, normally descended testis, suggesting that some intrinsic abnormality, rather than simple failure of descent, is responsible for the increased cancer risk. Surgical placement of the undescended testis into the scrotum (orchiopexy) before puberty decreases the likelihood of testicular atrophy and reduces but does not eliminate the risk of cancer and infertility.

The cryptorchid testis may be of normal size early in life, but some degree of atrophy usually is present by the onset of puberty. Microscopic evidence of tubular atrophy is evident by the age of 5 to 6 years, and hyalinization is present by the time of puberty. Foci of *intratubular germ cell neoplasia* (discussed later), may be present in cryptorchid

testes and are likely precursors of subsequent germ cell tumors. Atrophic changes similar to those in cryptorchid testes may be caused by several other insults, including chronic ischemia, trauma, irradiation, and antineoplastic chemotherapy, as well as conditions associated with chronically elevated estrogen levels (e.g., cirrhosis). Intratubular germ cell neoplasia is not a feature of these conditions, however.

## SUMMARY

### Cryptorchidism

- Cryptorchidism refers to incomplete descent of the testis from the abdomen to the scrotum and is present in about 1% of 1-year-old male infants.
- Bilateral or, in some cases, even unilateral cryptorchidism is associated with tubular atrophy and sterility.
- The cryptorchid testis carries a 3- to 5-fold higher risk for testicular cancer, which arises from foci of intratubular germ cell neoplasia within the atrophic tubules. Orchiopexy reduces the risk of sterility and cancer.

## Inflammatory Lesions

Inflammatory lesions of the testis are more common in the epididymis than in the testis proper. Some of the more important inflammatory disorders are sexually transmitted and are discussed later in the chapter. Other causes of testicular inflammation include nonspecific epididymitis and orchitis, mumps, and tuberculosis. *Nonspecific epididymitis* and *orchitis* usually begin as a primary urinary tract infection that then spreads to the testis through the vas deferens or the lymphatics of the spermatic cord. The involved testis typically is swollen and tender, and histologic examination reveals a predominantly neutrophilic inflammatory infiltrate. Orchitis complicates *mumps infection* in roughly 20% of infected adult males but rarely occurs in children. Affected testes are edematous and congested, and contain a predominantly lymphoplasmacytic inflammatory infiltrate. Severe mumps orchitis may lead to extensive necrosis, loss of seminiferous epithelium, tubular atrophy, fibrosis, and sterility. Several conditions, including infections and autoimmune injury, may elicit granulomatous inflammation in the testis. Of these, *tuberculosis* is the most common. Testicular tuberculosis generally begins as an epididymitis, with secondary involvement of the testis. Histologically, there is granulomatous inflammation and caseous necrosis identical to that seen in active tuberculosis in other sites.

## Vascular Disturbances

*Torsion,* or twisting of the spermatic cord, typically results in obstruction of testicular venous drainage while leaving the thick-walled and more resilient arteries patent, so that intense vascular engorgement and venous infarction follow unless the torsion is relieved. There are two types of testicular torsion. *Neonatal torsion* occurs either in utero or shortly after birth. It lacks any associated anatomic defect to account for its occurrence. *Adult torsion* typically is seen in adolescence and manifests with sudden onset of testicular pain. In contrast with neonatal torsion, adult torsion results from a bilateral anatomic defect whereby the testis has increased mobility, giving rise to the so-called bell clapper abnormality. It often occurs without any inciting injury; sudden pain heralding the torsion may even awaken the patient from sleep.

Torsion constitutes one of the few urologic emergencies. If the testis is explored surgically and the cord can be manually untwisted within approximately 6 hours, there is a good chance that the testis will remain viable. To prevent the catastrophic occurrence of torsion in the contralateral testis, the unaffected testis typically is surgically fixed within the scrotum (orchiopexy).

## Testicular Neoplasms

Testicular neoplasms occur in roughly 6 per 100,000 males. In the 15- to 34-year-old age group, when these neoplasms peak in incidence, they are the most common tumors of men. Tumors of the testis are a heterogeneous group of neoplasms that include germ cell tumors and sex cord–stromal tumors. *In postpubertal males, 95% of testicular tumors arise from germ cells, and all are malignant.* By contrast, neoplasms derived from Sertoli or Leydig cells (sex cord–stromal tumors) are uncommon and usually benign. The focus of the remainder of this discussion is on testicular germ cell tumors.

The cause of testicular neoplasms remains unknown. Testicular tumors are more common in whites than in blacks, and the incidence has increased in white populations over recent decades. As noted previously, *cryptorchidism is associated with a three- to five-fold increase in the risk of cancer* in the undescended testis, as well as an increased risk of cancer in the contralateral descended testis. A history of cryptorchidism is present in approximately 10% of cases of testicular cancer. Intersex syndromes, including androgen insensitivity syndrome and gonadal dysgenesis, also are associated with an increased frequency of testicular cancer. Family history is important, because brothers of males with germ cell tumors have an 8- to 10-fold increased risk over that of the population at large, presumably owing to inherited risk factors. The development of cancer in one testis is associated with a markedly increased risk of neoplasia in the contralateral testis. An isochromosome of the short arm of chromosome 12, i(12p), is found in virtually all germ cell tumors, regardless of their histologic type. The gene(s) that are dysregulated by this chromosomal abnormality, as well as the other mutations that contribute to the molecular pathogenesis of germ cell tumors, are an area of ongoing research.

Most testicular tumors in postpubertal males arise from the in situ lesion *intratubular germ cell neoplasia.* This lesion is present in conditions associated with a high risk of developing germ cell tumors (e.g., cryptorchidism, dysgenetic gonads). These in situ lesions can be found in grossly "normal" testicular tissue adjacent to germ cell tumors in virtually all cases.

Testicular germ cell tumors are subclassified into seminomas and nonseminomatous germ cell tumors (Table 17–1). Seminomas, sometimes referred to as "classic" seminomas to distinguish them from the less common spermatocytic seminoma (discussed further on), account for about 50% of testicular germ cell neoplasms. They are

**Table 17–1** Summary of Testicular Tumors

| Tumor | Peak Patient Age (yr) | Morphology | Tumor Marker(s) |
|---|---|---|---|
| Seminoma | 40–50 | Sheets of uniform polygonal cells with cleared cytoplasm; lymphocytes in the stroma | 10% of patients have elevated hCG |
| Embryonal carcinoma | 20–30 | Poorly differentiated, pleomorphic cells in cords, sheets, or papillary formation; most contain some yolk sac and choriocarcinoma cells | Negative (pure embryonal carcinoma) |
| Yolk sac tumor | 3 | Poorly differentiated endothelium-like, cuboidal, or columnar cells | 90% of patients have elevated AFP |
| Choriocarcinoma | 20–30 | Cytotrophoblast and syncytiotrophoblast without villus formation | 100% of patients have elevated hCG |
| Teratoma | All ages | Tissues from all three germ cell layers with varying degrees of differentiation | Negative (pure teratoma) |
| Mixed tumor | 15–30 | Variable, depending on mixture; commonly teratoma and embryonal carcinoma | 90% of patients have elevated hCG and AFP |

AFP, alpha fetoprotein; hCG, human chorionic gonadotropin.

histologically identical to ovarian dysgerminomas and to germinomas occurring in the central nervous system and other extragonadal sites.

## MORPHOLOGY

The histologic appearances of germ cell tumors may be **pure** (i.e., composed of a single histologic type) or **mixed** (seen in 40% of cases). **Seminomas** are soft, well-demarcated, gray-white tumors that bulge from the cut surface of the affected testis (Fig. 17–3). Large tumors may contain foci of coagulation necrosis, usually without hemorrhage. Microscopically, seminomas are composed of **large, uniform cells with distinct cell borders, clear, glycogen-rich cytoplasm, and round nuclei with conspicuous nucleoli** (Fig. 17–4). The cells often are arrayed in small lobules with intervening fibrous septa. A lymphocytic infiltrate usually is present and may, on occasion, overshadow the neoplastic cells. Seminomas may also be accompanied by an ill-defined granulomatous reaction. In approximately 15% of cases, syncytiotrophoblasts are present that are the source of the minimally elevated serum hCG concentrations encountered in some males with pure seminoma. Their presence has no bearing on prognosis.

Although related by name to seminoma, **spermatocytic seminoma** is a distinct clinical and histologic entity. This is an uncommon tumor. It occurs in much older individuals than other testicular tumors; affected patients generally are older than 65 years of age. In contrast with classic seminomas, spermatocytic seminomas lack lymphocytic infiltrates, granulomas, and syncytiotrophoblasts; are not admixed with other germ cell tumor histologies; are not associated with intratubular germ cell neoplasia; and do not metastasize. The tumor usually comprises polygonal cells of variable size that are arranged in nodules or sheets.

**Embryonal carcinomas** are ill-defined, invasive masses containing foci of hemorrhage and necrosis (Fig. 17–5). The primary lesions may be small, even in patients with systemic metastases. The tumor cells are **large and primitive-looking, with basophilic cytoplasm, indistinct cell borders, and large nuclei with prominent nucleoli.** The neoplastic cells may be arrayed in undifferentiated, solid sheets or may contain primitive glandular structures and irregular papillae (Fig. 17–6). In most cases, cells characteristic of other germ cell tumors (e.g., yolk sac tumor, teratoma, choriocarcinoma) are admixed with the embryonal areas. Pure embryonal carcinomas account for only 2% to 3% of all testicular germ cell tumors.

**Figure 17–3** Seminoma of the testis appearing as a well-circumscribed, pale, fleshy, homogeneous mass.

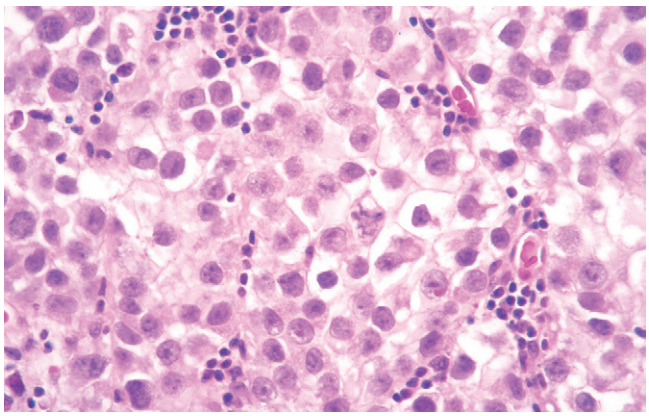

**Figure 17–4** Seminoma of the testis. Microscopic examination reveals large cells with distinct cell borders, pale nuclei, prominent nucleoli, and a sparse lymphocytic infiltrate.

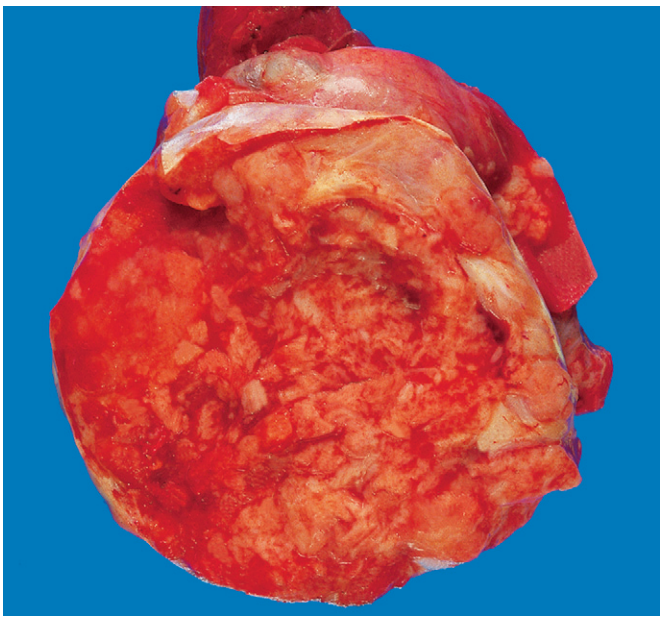

**Figure 17–5** Embryonal carcinoma. In contrast with the seminoma illustrated in Figure 17–3, this tumor is a hemorrhagic mass.

**Yolk sac tumors** are the most common primary testicular neoplasm in children younger than 3 years of age; in this age group it has a very good prognosis. In adults, yolk sac tumors most often are seen admixed with embryonal carcinoma. On gross inspection, these tumors often are large and may be well demarcated. Histologic examination discloses low cuboidal to columnar epithelial cells forming microcysts, lacelike (reticular) patterns, sheets, glands, and papillae (Fig. 17–7). A distinctive feature is the presence of structures resembling primitive glomeruli, the so-called **Schiller-Duvall** bodies. Tumors often have eosinophilic hyaline globules in which $\alpha_1$-antitrypsin and alpha fetoprotein (AFP) can be demonstrated by immunohistochemical techniques. As mentioned later, AFP can also be detected in the serum.

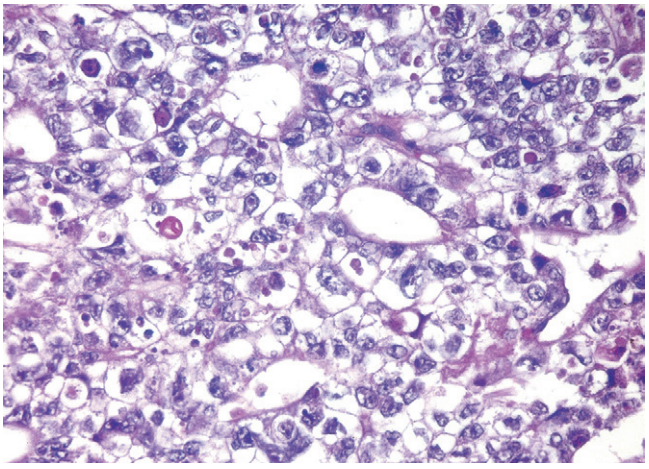

**Figure 17–6** Embryonal carcinoma. Note the sheets of undifferentiated cells and primitive gland-like structures. The nuclei are large and hyperchromatic.

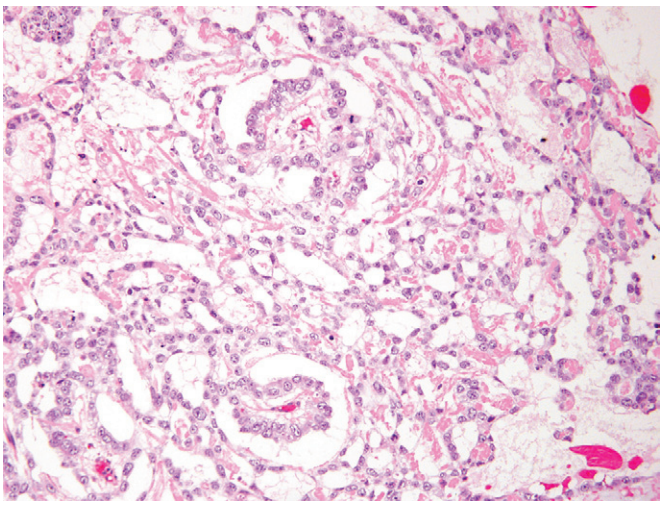

**Figure 17–7** Yolk sac tumor demonstrating areas of loosely textured, microcystic tissue and papillary structures resembling a developing glomerulus (Schiller-Duval bodies).

**Choriocarcinomas** are tumors in which the pluripotential neoplastic germ cells differentiate along **trophoblastic** lines. Grossly, the primary tumors often are small, nonpalpable lesions, even those with extensive systemic metastases. Microscopic examination reveals that choriocarcinomas are composed of sheets of small cuboidal cells irregularly intermingled with or capped by large, eosinophilic syncytial cells containing multiple dark, pleomorphic nuclei; these represent **cytotrophoblastic** and **syncytiotrophoblastic** differentiation, respectively (Fig. 17–8). HCG within syncytiotrophoblasts can be identified by immunohistochemical staining and is elevated in the serum.

**Teratomas** are tumors in which the neoplastic germ cells differentiate along somatic cell lines. These tumors form firm masses that on cut surface often contain cysts and recognizable areas of cartilage. They may occur at any age from infancy to adult life. Pure forms of teratoma are fairly common in infants and children, being second in frequency only to yolk

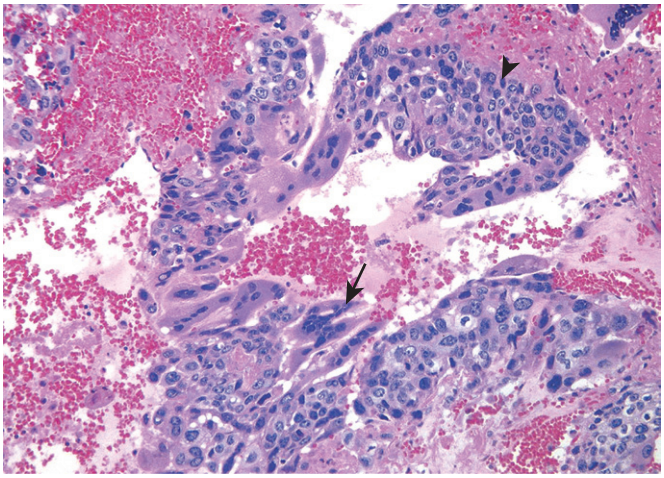

**Figure 17–8** Choriocarcinoma. Both cytotrophoblastic cells with central nuclei (*arrowhead, upper right*) and syncytiotrophoblastic cells with multiple dark nuclei embedded in eosinophilic cytoplasm (*arrow, middle*) are present. Hemorrhage and necrosis are prominent.

sac tumors. In adults, pure teratomas are rare, constituting 2% to 3% of germ cell tumors, and as with embryonal carcinomas, most are seen in combination with other histologic types. Teratomas are composed of a heterogeneous, helter-skelter collection of differentiated cells or organoid structures, such as neural tissue, muscle bundles, islands of cartilage, clusters of squamous epithelium, structures reminiscent of thyroid gland, bronchial epithelium, and bits of intestinal wall or brain substance, all embedded in a fibrous or myxoid stroma (Fig. 17–9). Elements may be mature (resembling various tissues within the adult) or immature (sharing histologic features with fetal or embryonal tissues). In prepubertal males, teratomas are typically benign, whereas teratomas in postpubertal males are malignant, being capable of metastasis regardless of whether they are composed of mature or immature elements.

Dermoid cysts and epidermoid cysts, common in the ovary (Chapter 18), are rare in the testis. These tumors should not be considered teratomas since they are uniformly benign regardless of the patient's age.

Rarely, non–germ cell tumors may arise in teratoma—a phenomenon referred to as "teratoma with malignant transformation." These neoplasms may take the form of a focus of squamous cell carcinoma, mucin-secreting adenocarcinoma, or sarcoma. The importance of non–germ cell malignancies arising in a teratoma is that when the non–germ cell component spreads outside of the testis it does not respond to chemotherapy; thus, the only hope for cure resides in the local resectability of the metastases.

### Clinical Features

Patients with testicular germ cell neoplasms present most frequently with a *painless testicular mass* that (unlike enlargements caused by hydroceles) is non-translucent. Biopsy of a testicular neoplasm is associated with a risk of tumor spillage, which would necessitate excision of the scrotal skin in addition to orchiectomy. Consequently, the standard management of a solid testicular mass is radical orchiectomy, based on the presumption of malignancy. Some tumors, especially nonseminomatous germ cell neoplasms, may have metastasized widely by the time of diagnosis in the absence of a palpable testicular lesion.

Seminomas and nonseminomatous tumors differ in their behavior and clinical course. *Seminomas often remain confined to the testis* for long intervals and may reach considerable size before diagnosis. Metastases most commonly are encountered in the iliac and paraaortic lymph nodes, particularly in the upper lumbar region. Hematogenous metastases occur late in the course of the disease.

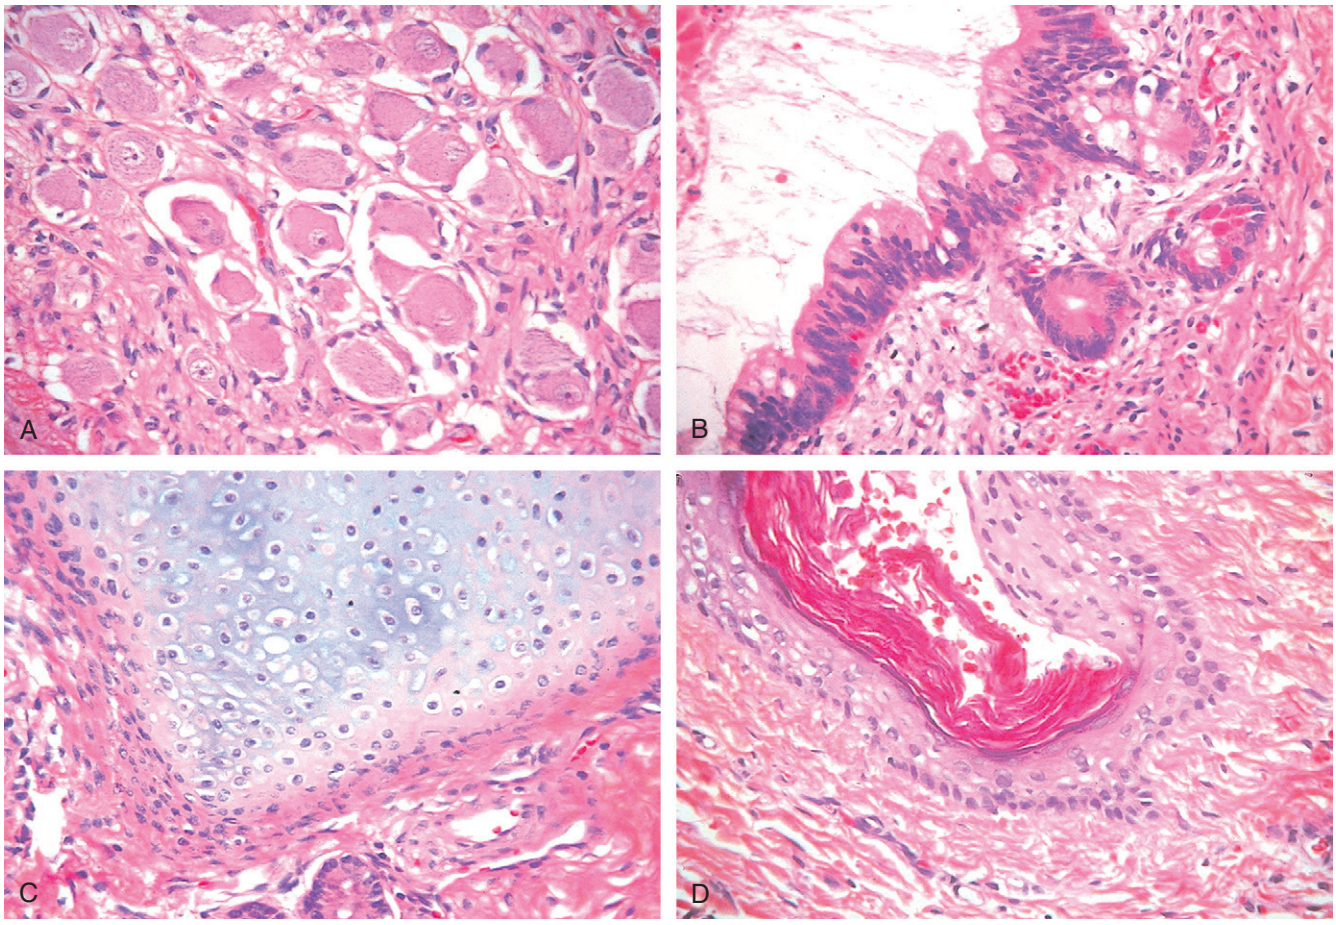

**Figure 17–9** Teratoma. Testicular teratomas contain mature cells from endodermal, mesodermal, and ectodermal lines. **A–D,** Four different fields from the same tumor specimen contain neural (ectodermal) **(A),** glandular (endodermal) **(B),** cartilaginous (mesodermal) **(C),** and squamous epithelial **(D)** elements.

By contrast, *nonseminomatous germ cell neoplasms tend to metastasize earlier,* by lymphatic as well as hematogenous routes. Hematogenous metastases are most common in the liver and lungs. Metastatic lesions may be identical to the primary testicular tumor or may contain elements of other germ cell tumors.

Assay of *tumor markers* secreted by germ cell tumors is important in two ways; these markers (summarized in Table 17–1 along with some salient clinical and morphologic features) are helpful diagnostically, but have an even more valuable role in following the response of tumors to therapy after the diagnosis is established. Human chorionic gonadotropin (hCG) is always elevated in patients with choriocarcinoma and, as noted, can be minimally elevated in persons with other germ cell tumors containing syncytiotrophoblastic cells without cytotrophoblasts. Increased alpha fetoprotein (AFP) in the setting of a testicular neoplasm indicates a yolk sac tumor component. The levels of lactate dehydrogenase (LDH) correlate with the tumor burden.

The treatment of testicular germ cell neoplasms is a remarkable cancer therapy success story. Although roughly 8000 new cases of testicular cancer occur in the United States yearly, fewer than 400 men are expected to die of the disease. In fact, after being treated for widely metastatic testicular cancer, Lance Armstrong won the grueling Tour de France bicycle race a record seven times! Seminoma, which is extremely radiosensitive and tends to remain localized for long periods, has the best prognosis. More than 95% of patients with early-stage disease can be cured. Among nonseminomatous germ cell tumors, the histologic subtype does not influence the prognosis significantly, and hence these are treated as a group. Approximately 90% of the patients achieve complete remission with aggressive chemotherapy, and most are cured. Pure choriocarcinoma carries a dismal prognosis. However, when it is a minor component of a mixed germ cell tumor, the prognosis is not so adversely affected. With all testicular tumors, recurrences, typically in the form of distant metastases, usually occur within the first 2 years after treatment.

## SUMMARY

### Testicular Tumors

- Testicular tumors are the most common cause of painless testicular enlargement. They occur with increased frequency in association with undescended testis and with testicular dysgenesis.
- Germ cells are the source of 95% of testicular tumors, and the remainder arise from Sertoli or Leydig cells. Germ cell tumors may be composed of a single histologic pattern (60% of cases) or mixed patterns (40%).
- The most common "pure" histologic patterns of germ cell tumors are seminoma, embryonal carcinoma, yolk sac tumors, choriocarcinoma, and teratoma. Mixed tumors contain more than one element, most commonly embryonal carcinoma, teratoma, and yolk sac tumor.
- Clinically, testicular germ cell tumors can be divided into two groups: seminomas and nonseminomatous tumors. Seminomas remain confined to the testis for a long time and spread mainly to paraaortic nodes—distant spread is rare. Nonseminomatous tumors tend to spread earlier, by both lymphatics and blood vessels.
- HCG is produced by syncytiotrophoblasts and is always elevated in patients with choriocarcinomas and those with seminomas containing syncytiotrophoblasts. AFP is elevated when there is a yolk sac tumor component.

# PROSTATE

The prostate can be divided into several biologically distinct regions, the most important of which are the peripheral and transition zones (Fig. 17–10). The types of proliferative lesions are different in each region. For example, most *hyperplastic lesions* arise in the inner transition zone, while most *carcinomas* (70% to 80%) arise in the peripheral zones. The normal prostate contains glands with two cell layers, a flat basal cell layer and an overlying columnar secretory cell layer. Surrounding prostatic stroma contains a mixture of smooth muscle and fibrous tissue. It is involved by infectious, inflammatory, hyperplastic, and neoplastic disorders, of which prostate cancer is by far the most important clinically.

## Prostatitis

Prostatitis is divided into four categories: (1) *acute bacterial prostatitis* (2% to 5% of cases), caused by the same

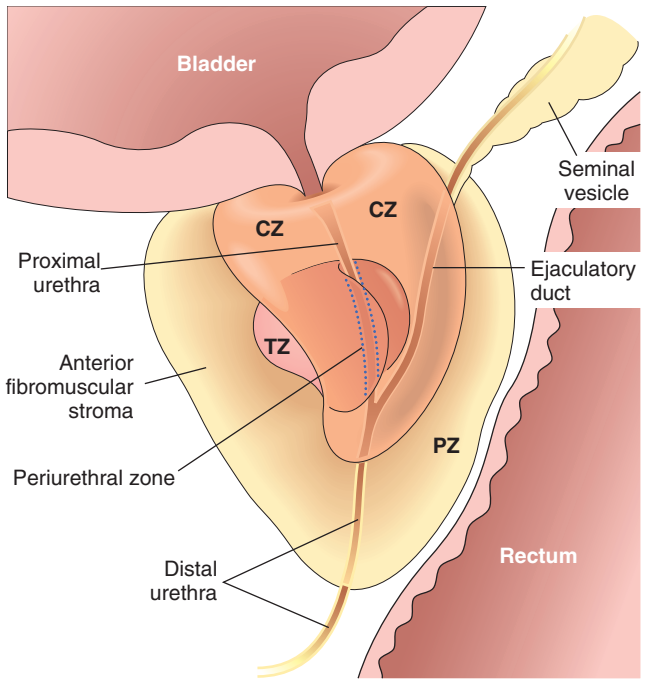

**Figure 17–10** Adult prostate. The normal prostate contains several distinct regions, including a central zone (CZ), a peripheral zone (PZ), a transitional zone (TZ), and a periurethral zone. Most carcinomas arise from the peripheral glands of the organ and often are palpable during digital examination of the rectum. Nodular hyperplasia, by contrast, arises from more centrally situated glands and is more likely than carcinoma to produce urinary obstruction early in its course.

organisms associated with other acute urinary tract infections; (2) *chronic bacterial prostatitis* (2% to 5% of cases), also caused by common uropathogens; (3) *chronic nonbacterial prostatitis, or chronic pelvic pain syndrome* (90% to 95% of cases), in which no uropathogen is identified despite the presence of local symptoms; and (4) *asymptomatic inflammatory prostatitis* (incidence unknown), associated with incidental identification of leukocytes in prostatic secretions without uropathogens.

The prostate is usually not biopsied in men with symptoms of acute or chronic prostatitis, since the findings are usually non-specific and are not helpful in managing patients. The exception is in patients with granulomatous prostatitis, in which a specific etiology may be established. In the United States, the most common cause is instillation of bacille Calmette-Guérin (BCG) within the bladder for treatment of superficial bladder cancer. BCG is an attenuated tuberculosis strain that produces a histologic picture in the prostate indistinguishable from tuberculosis. Disseminated prostatic tuberculosis is rare in the Western world. Fungal granulomatous prostatitis is typically seen only in immunocompromised hosts. Nonspecific granulomatous prostatitis is relatively common and represents a reaction to secretions from ruptured prostatic ducts and acini. Postsurgical prostatic granulomas also may be seen.

### Clinical Features

Clinically, *acute bacterial prostatitis* is associated with fever, chills, and dysuria; it may be complicated by sepsis. On rectal examination, the prostate is exquisitely tender and boggy. *Chronic bacterial prostatitis* usually is associated with recurrent urinary tract infections bracketed by asymptomatic periods. Presenting manifestations may include with low back pain, dysuria, and perineal and suprapubic discomfort. Both acute and chronic bacterial prostatitis are treated with antibiotics. The diagnosis of *chronic nonbacterial prostatitis* (chronic pelvic pain syndrome) is difficult. It requires completion of the NIH Chronic Prostatitis Symptom Index survey by the patient, digital rectal examination, urinalysis, and sequential collection of urine and prostatic fluid specimens, before, during, and after prostatic massage. This technique of collecting samples prevents contamination from the bladder and urethra and is used to document prostatic inflammation (by presence of leukocytes) in the absence of infection. There are no proven therapies for chronic pelvic pain syndrome.

## SUMMARY

### Prostatitis

- Bacterial prostatitis may be acute or chronic; the responsible organism usually is *E. coli* or another gram-negative rod.
- Chronic nonbacterial prostatitis (also known as chronic pelvic pain syndrome), despite sharing symptomatology with chronic bacterial prostatitis, is of unknown etiology and does not respond to antibiotics.
- Granulomatous prostatitis has a multifactorial etiology, with both infectious and noninfectious elements.

## Benign Prostatic Hyperplasia (Nodular Hyperplasia)

*Benign prostatic hyperplasia* (BPH) is an extremely common abnormality. It is present in a significant number of men by the age of 40, and its frequency rises progressively with age, reaching 90% by the eighth decade of life. BPH is characterized by proliferation of both stromal and epithelial elements, with resultant enlargement of the gland and, in some cases, urinary obstruction. Although the cause of BPH remains incompletely understood, it is clear that *excessive androgen-dependent growth of stromal and glandular elements has a central role.* BPH does not occur in males castrated before the onset of puberty or in men with genetic diseases that block androgen activity. Dihydrotestosterone (DHT), the ultimate mediator of prostatic growth, is synthesized in the prostate from circulating testosterone by the action of the enzyme 5α-reductase, type 2. DHT binds to nuclear androgen receptors, which regulate the expression of genes that support the growth and survival of prostatic epithelium and stromal cells. Although testosterone can also bind to androgen receptors and stimulate growth, DHT is 10 times more potent. Clinical symptoms of lower urinary tract obstruction caused by prostatic enlargement may also be exacerbated by contraction of prostatic smooth muscle mediated by $\alpha_1$-adrenergic receptors.

## MORPHOLOGY

BPH virtually always occurs in the inner, transitional zone of the prostate. The affected prostate is enlarged, typically weighing between 60 and 100 g, and contains many well-circumscribed nodules that bulge from the cut surface (Fig. 17–11). The nodules may appear solid or contain cystic spaces, the latter corresponding to dilated glandular elements. The urethra is usually compressed by the hyperplastic nodules, often to a narrow slit. In some cases, hyperplastic glandular and stromal elements lying just under the epithelium of the proximal prostatic urethra may project into the bladder lumen as a pedunculated mass, producing a ball-valve type of urethral obstruction.

Microscopically the hyperplastic nodules are composed of variable proportions of proliferating glandular elements and fibromuscular stroma. The hyperplastic glands are lined by tall, columnar epithelial cells and a peripheral layer of flattened basal cells (Fig. 17–12). The glandular lumina often contain inspissated, proteinaceous secretory material known as **corpora amylacea.**

### Clinical Features

Clinical manifestations of prostatic hyperplasia occur in only about 10% of men with pathologic evidence of BPH. Because BPH preferentially involves the inner portions of the prostate, the most common manifestations are related to *lower urinary tract obstruction*, often in the form of difficulty in starting the stream of urine (hesitancy) and intermittent interruption of the urinary stream while voiding. These symptoms frequently are accompanied by urinary urgency, frequency, and nocturia, all indicative of bladder irritation. Similar symptoms also may arise from urethral stricture or as a consequence of impaired bladder detrusor

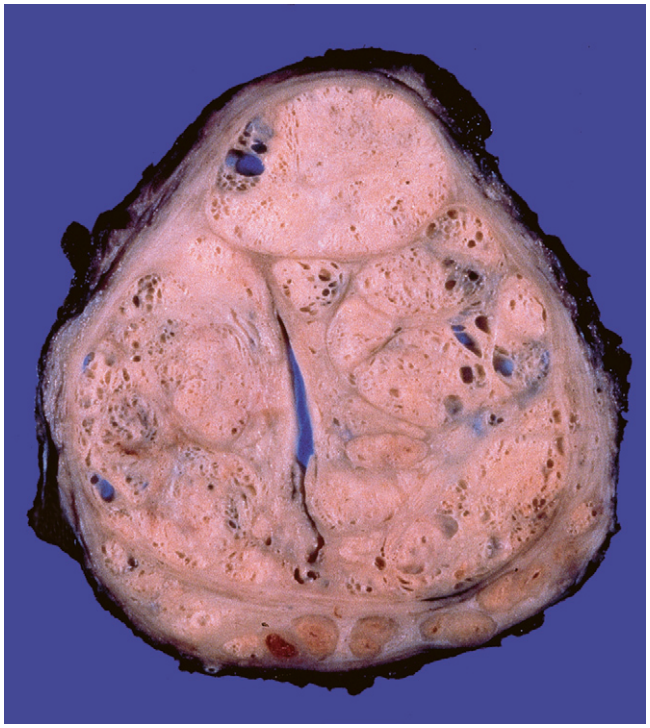

**Figure 17–11** Nodular prostatic hyperplasia. Well-defined nodules compress the urethra into a slitlike lumen.

muscle contractility in both men and women. The presence of residual urine in the bladder due to chronic obstruction increases the risk of urinary tract infections. In some affected men, BPH leads to complete urinary obstruction, with resultant painful distention of the bladder and, in the absence of appropriate treatment, hydronephrosis (Chapter 13). Initial treatment is pharmacologic, using targeted therapeutic agents that inhibit DHT formation (Finestride) or that relax smooth muscle by blocking alpha adrenergic blockers (Flomax). Various surgical techniques are reserved for severely symptomatic cases recalcitrant to medical therapy.

## SUMMARY

### Benign Prostatic Hyperplasia

- BPH is characterized by proliferation of benign stromal and glandular elements. DHT, an androgen derived from testosterone, is the major hormonal stimulus for proliferation.
- BPH most commonly affects the inner periuretheral zone of the prostate, producing nodules that compress the prostatic urethra. On microscopic examination, the nodules exhibit variable proportions of stroma and glands. Hyperplastic glands are lined by two cell layers: an inner columnar layer and an outer layer composed of flattened basal cells.
- Clinical symptoms and signs are reported by 10% of affected patients and include hesitancy, urgency, nocturia, and poor urinary stream. Chronic obstruction predisposes to recurrent urinary tract infections. Acute urinary obstruction may occur.

## Carcinoma of the Prostate

Adenocarcinoma of the prostate occurs mainly in men older than 50 years of age. It is the most common form of cancer in men, accounting for 25% of cancer in men in the United States in 2009. However, prostate cancer causes only 9% of cancer deaths in the United States, less than that for cancers of the lung and equal to that for colorectal cancer. Furthermore, over the past several decades, there has been a significant drop in prostate cancer mortality.

This relatively favorable outcome is related in part to increased detection of the disease through screening (described later), but how effective screening is at saving lives is controversial. This seeming paradox is related to wide variation in the natural history of prostate cancer, from aggressive and rapidly fatal to indolent disease of no clinical significance. Indeed, prostate carcinoma commonly is found incidentally at autopsy in men dying of other

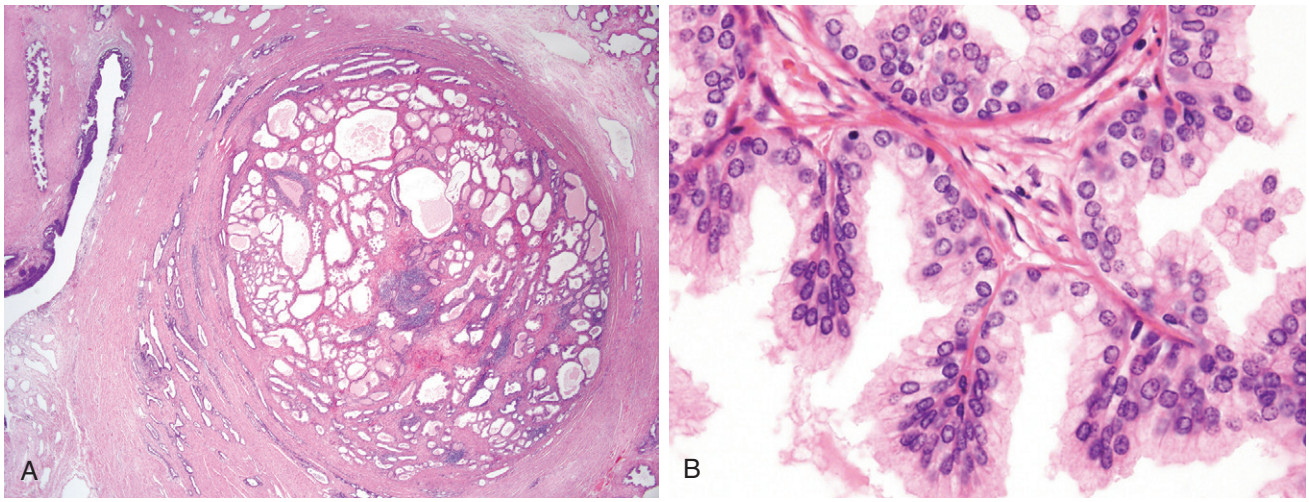

**Figure 17–12** Nodular hyperplasia of the prostate. **A,** Low-power photomicrograph demonstrates a well-demarcated nodule at the *right* of the field, with a portion of urethra seen to the *left*. In other cases of nodular hyperplasia, the nodularity is caused predominantly by stromal, rather than glandular, proliferation. **B,** Higher-power photomicrograph demonstrates the morphology of the hyperplastic glands, which are large, with papillary infolding.

causes, and many more men die with prostate cancer than of prostate cancer. It is not currently possible to identify the tumors that will be "bad actors" with certainty; thus, while some men are no doubt saved by early detection and treatment of their prostate cancers, it is equally certain that others are being "cured" of clinically inconsequential tumors.

## PATHOGENESIS

Clinical and experimental observations suggest that androgens, heredity, environmental factors, and acquired somatic mutations have roles in the pathogenesis of prostate cancer.

- **Androgens** are of central importance. Cancer of the prostate does not develop in males castrated before puberty, indicating that androgens somehow provide the "soil," the cellular context, within which prostate cancer develops. This dependence on androgens extends to established cancers, which often regress for a time in response to surgical or chemical castration. Notably, **tumors resistant to anti-androgen therapy often acquire mutations that permit androgen receptors to activate the expression of their target genes even in the absence of the hormones**. Thus, tumors that recur in the face of anti-androgen therapies still depend on gene products regulated by androgen receptors for their growth and survival. However, while prostate cancer, like normal prostate, is dependent on androgens for its survival, there is no evidence that androgens initiate carcinogenesis.
- **Heredity** also contributes, as there is an increased risk among first-degree relatives of patients with prostate cancer. Incidence of prostatic cancer is uncommon in Asians and highest among blacks and is also high in Scandinavian countries. Genome-wide association studies have identified a number of genetic variants that are associated with increased risk, including a variant near the *MYC* oncogene on chromosome 8q24 that appears to account for some of the increased incidence of prostate cancer in males of African descent. Similarly, in white American men, the development of prostate cancer has been linked to a susceptibility locus on chromosome 1q24-q25.
- **Environment** also plays a role, as evidenced by the fact that in Japanese immigrants to the United States the incidence of the disease rises (although not to the level seen in native-born Americans). Also, as the diet in Asia becomes more Westernized, the incidence of clinical prostate cancer in this region of the world appears to be increasing. However, the relationship between specific dietary components and prostate cancer risk is unclear.
- **Acquired somatic mutations,** as in other cancers, are the actual drivers of cellular transformation. One important class of somatic mutations is gene rearrangements that create fusion genes consisting of the androgen-regulated promoter of the *TMPRSS2* gene and the coding sequence of ETS family transcription factors (the most common being ERG). ***TMPRSS2-ETS* fusion genes** occur in approximately 40% to 50% of prostate cancers; it is possible that unregulated increased expression of ETS transcription factors interfere with prostatic epithelial cell differentiation. Other mutations commonly lead to activation of the oncogenic PI3K/AKT signaling pathway; of these, the most common are **mutations that inactivate the tumor suppressor gene *PTEN*,** which acts as a brake on PI3K activity.

## MORPHOLOGY

Most carcinomas detected clinically are not visible grossly. More advanced lesions appear as firm, gray-white lesions with ill-defined margins that infiltrate the adjacent gland (Fig. 17–13).

On histologic examination, most lesions are moderately differentiated adenocarcinomas that produce well-defined glands. The glands typically are smaller than benign glands and are lined by a single uniform layer of cuboidal or low columnar epithelium, lacking the basal cell layer seen in benign glands. In further contrast with benign glands, malignant glands are crowded together and characteristically lack branching and papillary infolding. The cytoplasm of the tumor cells ranges from pale-clear (as in benign glands) to a distinctive amphophilic (dark purple) appearance. Nuclei are enlarged and often contain one or more prominent nucleoli (Fig. 17–14). Some variation in nuclear size and shape is usual, but in general, pleomorphism is not marked. Mitotic figures are uncommon. With increasing grade, irregular or ragged glandular structures, cribriform glands, sheets of cells, or infiltrating individual cells are present. In approximately 80% of cases, prostatic tissue removed for carcinoma also harbors presumptive precursor lesions, referred to as high-grade prostatic intraepithelial neoplasia (HGPIN).

Prostate cancer is graded by the Gleason system, created in 1967 and updated in 2005. According to this system, prostate cancers are stratified into five grades on the basis of glandular patterns of differentiation. Grade 1 represents the most well-differentiated tumors and grade 5 tumors show no glandular differentiation. Since most tumors contain more than one pattern, a primary grade is assigned to the dominant pattern and a secondary grade to the next most frequent pattern. The two numerical grades are then added to obtain

**Figure 17–13** Adenocarcinoma of the prostate. Carcinomatous tissue is seen on the posterior aspect (*lower left*). Note the solid whiter tissue of cancer, in contrast with the spongy appearance of the benign peripheral zone on the contralateral side.

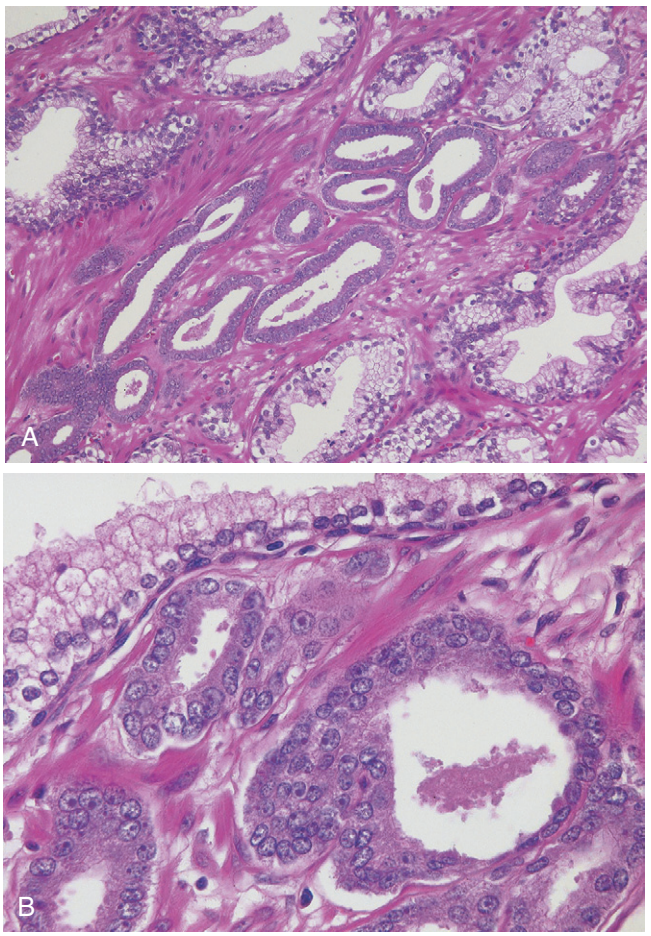

**Figure 17–14 A,** Adenocarcinoma of the prostate demonstrating small glands crowded in between larger benign glands. **B,** Higher magnification shows several small malignant glands with enlarged nuclei, prominent nucleoli, and dark cytoplasm, as compared with the larger, benign gland (*top*).

a combined Gleason score. Tumors with only one pattern are treated as if their primary and secondary grades are the same, and, hence, the number is doubled. Thus the most differentiated tumors have a Gleason score of 2 (1 + 1) and the least differentiated tumors merit a score of 10 (5 + 5).

### Clinical Features

A minority of carcinomas are discovered unexpectedly during histologic examination of prostate tissue removed by transurethral resection for BPH. Some *70% to 80% of prostate cancers arise in the outer (peripheral) glands* and hence may be palpable as irregular hard nodules on digital rectal examination. However, most prostate cancers are small, nonpalpable, asymptomatic lesions discovered on needle biopsy performed to investigate an elevated serum prostate-specific antigen (PSA) level (discussed later). Because of the peripheral location, prostate cancer is less likely than BPH to cause urethral obstruction in its initial stages. Locally advanced cancers often infiltrate the seminal vesicles and periurethral zones of the prostate and may invade the adjacent soft tissues, the wall of the urinary bladder, or (less commonly) the rectum. Bone metastases, particularly to the axial skeleton, are frequent late in the disease and typically cause osteoblastic (bone-producing) lesions that can be detected on *radionuclide bone scans.* The poor sensitivity and specificity of prostate imaging studies limit their diagnostic utility for the detection of early prostate cancer.

The PSA assay is the most important test used in the diagnosis and management of prostate cancer but, as will be discussed, suffers from a number of limitations. PSA is a product of prostatic epithelium and is normally secreted in the semen. It is a serine protease whose function is to cleave and liquefy the seminal coagulum formed after ejaculation. *In most laboratories, a serum PSA level of 4 ng/mL is the cutoff between normal and abnormal, although some guidelines designate values above 2.5 ng/mL as abnormal.* Although PSA screening can detect prostate cancers early in their course, many prostate cancers are slow-growing and clinically insignificant, requiring no treatment. In addition, prostate cancer treatments often cause significant complications, particularly erectile dysfunction and incontinence.

*One limitation of PSA is that while it is organ-specific, it is not cancer-specific.* BPH, prostatitis, prostatic infarcts, instrumentation of the prostate, and ejaculation also increase serum PSA levels. *Conversely, 20 to 40% of patients with organ-confined prostate cancer have a PSA value of 4.0 ng/mL or less.* In recognition of these problems, several refinements in the estimation and interpretation of PSA values have been proposed that aim to enhance the specificity and sensitivity of the test. One approach is to correct the PSA for estimated prostate size, to account for elevations in PSA that are associated with enlarged prostates (e.g., those involved by BPH). A second is to use a sliding scale that takes the rise in PSA that occurs with age into account. A third is to focus on changes in PSA levels in serial measurements over time. Men with prostate cancer demonstrate an increased rate of rise in PSA as compared with men who do not have prostate cancer. A significant rise in serum PSA levels, even if the PSA is within the "normal" range, should prompt a workup. Finally, PSA present in the serum is mostly bound to plasma proteins but also includes a minor free fraction. The *percentage of free PSA (the ratio of free PSA to total PSA) is lower in men with prostate cancer than in men with benign prostatic diseases.*

Once cancer is diagnosed, *serial measurements of PSA are of great value in assessing the response to therapy.* For example, a rising PSA level after radical prostatectomy or radiotherapy for localized disease is indicative of recurrent or disseminated disease.

The most common treatments for clinically localized prostate cancer are radical prostatectomy and radiotherapy. The prognosis after radical prostatectomy is based on the pathologic stage, margin status, and Gleason grade. The Gleason grade, clinical stage, and serum PSA values are important predictors of outcome after radiotherapy. Because many prostate cancers follow an indolent course, active surveillance ("watchful waiting") is an appropriate approach for older men, patients with significant comorbidity, or even some younger men with low serum PSA values and small, low-grade cancers. Advanced metastatic carcinoma is treated by androgen deprivation, effected either by orchiectomy or by administration of synthetic agonists of luteinizing hormone–releasing hormone (LHRH), which in effect achieve a pharmacologic

orchiectomy. Although antiandrogen therapy induces remissions, androgen-independent clones eventually emerge, leading to rapid disease progression and death. As mentioned earlier, these mutant clones continue to express many genes that in normal prostate are androgen-dependent.

### SUMMARY

#### Carcinoma of the Prostate

- Carcinoma of the prostate is a common cancer of older men between 65 and 75 years of age. Aggressive, clinical significant disease is more common in American blacks than in whites, while clinically insignificant occult lesions appear to occur at equal frequencies in these two races.
- Prostate carcinomas range from indolent lesions that will never cause patient harm to aggressive fatal tumors.
- The most common acquired mutations in prostatic carcinomas are *TPRSS2-ETS* fusion genes and mutations that activate the PI3K/AKT signaling pathway.
- Carcinomas of the prostate arise most commonly in the outer, peripheral gland and may be palpable by rectal examination, although currently many are nonpalpable.
- Microscopically, they are adenocarcinomas with variable differentiation. Neoplastic glands are lined by a single layer of cells.
- Grading of prostate cancer by the Gleason system correlates with pathologic stage and prognosis.
- Most localized cancers are clinically silent and are detected by routine monitoring of PSA concentrations in older men. Bone metastases, often osteoblastic, typify advanced prostate cancer.
- Serum PSA measurement is a useful but imperfect cancer screening test, with significant rates of false-negative and false-positive results. Evaluation of PSA concentrations after treatment has great value in monitoring progressive or recurrent disease.

## URETER, BLADDER, AND URETHRA

The renal pelves, ureters, bladder, and urethra are lined by urothelium. Beneath the mucosa are the lamina propria and, deeper yet, the muscularis propria (detrusor muscle), which makes up the bladder wall.

### Ureter

*Ureteropelvic junction (UPJ) obstruction,* a congenital disorder, results in hydronephrosis. It usually manifests in infancy or childhood, much more commonly in boys. It is the most frequent cause of hydronephrosis in infants and children (Chapter 13).

Primary *malignant tumors* of the ureter follow patterns similar to those arising in the renal pelvis, calyces, and bladder, and a majority are urothelial carcinomas.

*Retroperitoneal fibrosis* is an uncommon cause of ureteral narrowing or obstruction characterized by a *fibrous proliferative inflammatory process encasing the retroperitoneal structures and causing hydronephrosis.* The disorder occurs in middle to old age. At least a proportion of these cases are related to the newly described entity in which elevations of serum IgG4 are associated with fibroinflammatory lesions that are rich in IgG4-secreting plasma cells (Chapter 4). The affected sites include the pancreas, retroperitoneum, and salivary glands, to mention a few. Other cases are associated with drug exposures (ergot derivatives, adrenergic blockers), or malignant disease (lymphomas, urinary tract carcinomas). The majority of cases, however, have no obvious cause and are considered primary, or idiopathic (Ormond disease).

### Urinary Bladder

#### *Non-neoplastic Conditions*

A bladder or vesical *diverticulum* consists of a pouchlike evagination of the bladder wall. Diverticula may be congenital but more commonly are acquired lesions that arise as a consequence of persistent urethral obstruction caused, for example, by benign prostatic hyperplasia. Although most diverticula are small and asymptomatic, they sometimes lead to urinary stasis and predispose to infection.

Cystitis takes many forms. Most cases stem from nonspecific acute or chronic inflammation of the bladder. The common etiologic agents of *bacterial cystitis* are coliform bacteria. Patients receiving *cytotoxic antitumor drugs,* such as cyclophosphamide, sometimes develop *hemorrhagic cystitis.* Adenovirus infection also causes a hemorrhagic cystitis. Several distinct variants of cystitis are defined by either morphologic appearance or causation.

- *Interstitial cystitis* (i.e., chronic pelvic pain syndrome) is a *persistent, painful form of chronic cystitis occurring most frequently in women.* It is characterized by intermittent, often severe suprapubic pain, urinary frequency, urgency, hematuria and dysuria without evidence of bacterial infection, and cystoscopic findings of fissures and punctate hemorrhages (glomerulations) in the bladder mucosa. The histologic findings are nonspecific. Late in the course, transmural fibrosis may ensue, leading to a contracted bladder.
- *Malakoplakia* most commonly occurs in the bladder and results from defects in phagocytic or degradative function of macrophages, such that phagosomes become overloaded with undigested bacterial products. The macrophages have abundant granular cytoplasm filled with phagosomes stuffed with particulate and membranous bacterial debris. In addition, laminated mineralized concretions resulting from deposition of calcium in enlarged lysosomes, known as *Michaelis-Gutmann bodies,* typically are present within the macrophages.
- *Polypoid cystitis* is an inflammatory condition resulting from irritation to the bladder mucosa in which the urothelium is thrown into broad bulbous polypoid projections as a result of marked submucosal edema. Polypoid cystitis may be confused with papillary urothelial carcinoma both clinically and histologically.

Various metaplastic lesions may occur in the bladder. Nests of urothelium (*Brunn nests*) may grow downward into the lamina propria, and their central epithelial cells may variously differentiate into a cuboidal or columnar epithelium lining (*cystitis glandularis*); cystic spaces filled

with clear fluid lined by flattened urothelium (*cystitis cystica*); or goblet cells resembling intestinal mucosa (*intestinal or colonic metaplasia*). As a response to injury, the urothelium often undergoes *squamous metaplasia,* which must be differentiated from normal glycogenated squamous epithelium, commonly found at the trigone in women.

### *Neoplasms*

Bladder cancer accounts for approximately 7% of cancers and 3% of cancer deaths in the United States. The vast majority of bladder cancers (90%) are urothelial carcinomas. Carcinoma of the bladder is more common in men than in women, in industrialized than in developing nations, and in urban than in rural dwellers. About 80% of patients are between the ages of 50 and 80 years. Squamous cell carcinomas represent about 3% to 7% of bladder cancers in the United States but are much more common in countries where urinary schistosomiasis is endemic. They typically show extensive keratinization and are nearly always associated with chronic bladder irritation and infection. Adenocarcinomas of the bladder are rare and are histologically identical to adenocarcinomas seen in the gastrointestinal tract. Some arise from urachal remnants in the dome of the bladder or in association with extensive intestinal metaplasia.

## PATHOGENESIS

Bladder cancer, with rare exceptions, is not familial. Some of the most common factors implicated in the causation of urothelial carcinoma include **cigarette smoking, various occupational carcinogens,** and *Schistosoma haematobium* infections in areas where it is endemic, such as Egypt. Cancers occurring in the setting of schistosoma infections arise in a background of chronic inflammation, which you will recall is linked to a number of different cancers (Chapter 5). A model for bladder carcinogenesis has been proposed in which the tumor is **initiated by deletions of tumor-suppressor** genes on 9p and 9q, leading to formation of superficial papillary tumors, a few of which may then acquire *TP53* mutations and progress to invasion. A second pathway, possibly initiated by *TP53* mutations, leads first to carcinoma in situ and then, with loss of chromosome 9, progresses to invasion. The underlying genetic alterations in superficial tumors include fibroblast growth factor receptor 3 (FGFR3) mutations and activation of the Ras pathway (indeed, bladder cancer was one of the first human neoplasms found to have activating mutations in the *Ras* oncogene), whereas less common muscle invasive tumors often have loss-of-function mutations involving *TP53* and *RB*, the retinoblastoma tumor suppressor gene.

## MORPHOLOGY

Two distinct precursor lesions to invasive urothelial carcinoma are recognized (Fig. 17–15). The most common is a noninvasive papillary tumor (Fig. 17–16). The other precursor is carcinoma in situ (CIS), described below. In about half of the patients with invasive bladder cancer, no precursor lesion is found; in such cases, it is presumed that the precursor lesion was overgrown by the high-grade invasive component.

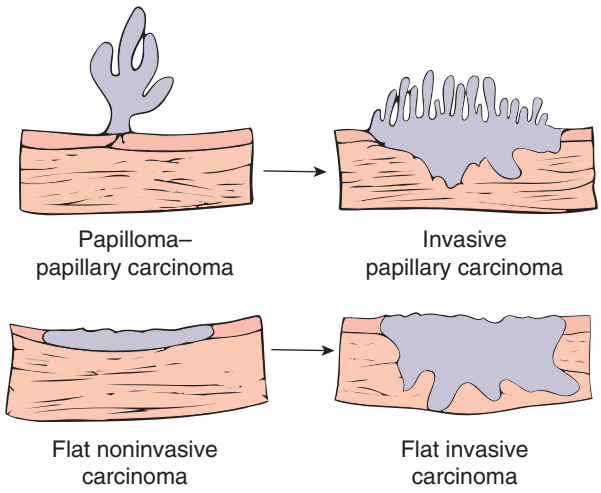

**Figure 17–15** Precursor lesions of invasive urothelial carcinoma.

Noninvasive papillary urothelial neoplasms demonstrate a range of atypia and are graded to reflect their biologic behavior (Table 17–2). The most common grading system classifies tumors as follows: (1) **papilloma**; (2) **papillary urothelial neoplasm of low malignant potential (PUNLMP)**; (3) **low-grade papillary urothelial carcinoma**; and (4) **high-grade papillary urothelial carcinoma** (Fig. 17–17). These exophytic papillary neoplasms are to be distinguished from **inverted urothelial papilloma,** which is entirely benign and not associated with an increased risk for subsequent carcinoma.

CIS is defined by the presence of cytologically malignant cells within a flat urothelium (Fig. 17–18). Like high-grade papillary urothelial carcinoma, CIS tumor cells lack cohesiveness. This leads to the shedding of malignant cells into the urine, where they can be detected by cytology. CIS

**Figure 17–16** Cystoscopic appearance of a papillary urothelial tumor, resembling coral, within the bladder.

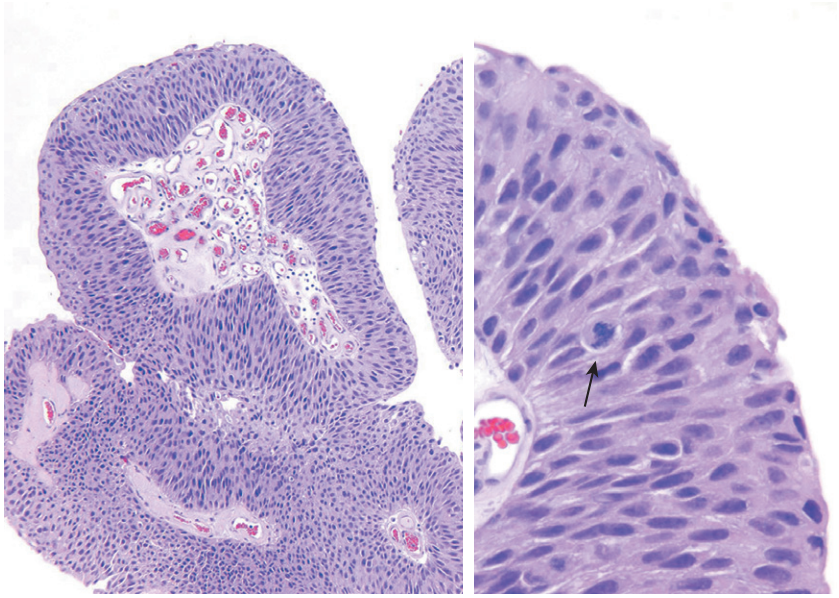

**Figure 17–17** Noninvasive low-grade papillary urothelial carcinoma. Higher magnification (*right*) shows slightly irregular nuclei with scattered mitotic figures (*arrow*).

commonly is multifocal and sometimes involves most of the bladder surface or extends into the ureters and urethra. Without treatment, 50% to 75% of CIS cases progress to muscle-invasive cancer.

**Invasive urothelial cancer** associated with papillary urothelial cancer (usually of high grade) or CIS may superficially invade the lamina propria or extend more deeply into underlying muscle. Underestimation of the extent of invasion in biopsy specimens is a significant problem. **The extent of invasion and spread (staging) at the time of initial diagnosis is the most important prognostic factor.** Almost all infiltrating urothelial carcinomas are of high grade.

### Clinical Features

Bladder tumors most commonly present with *painless hematuria.* Patients with urothelial tumors, whatever their grade, have a tendency to develop new tumors after excision, and recurrences may exhibit a higher grade. The risk of recurrence is related to several factors, including tumor size, stage, grade, multifocality, mitotic index, and associated dysplasia and/or CIS in the surrounding mucosa. Most recurrent tumors arise at sites different than that of the original lesion, yet share the same clonal abnormalities as those of the initial tumor; thus, these are true recurrences that stem from shedding and implantation of the original tumor cells at new sites. Whereas high-grade papillary urothelial carcinomas frequently are associated with either concurrent or subsequent invasive urothelial carcinoma, lower-grade papillary urothelial neoplasms often recur but infrequently invade (Table 17–2).

The treatment for bladder cancer depends on tumor grade and stage and on whether the lesion is flat or papillary. For small localized papillary tumors that are not high-grade, the initial transurethral resection is both diagnostic and therapeutically sufficient. Patients with tumors that are at high risk for recurrence or progression typically receive topical immunotherapy consisting of intravesical instillation of an attenuated strain of the tuberculosis bacillus called bacille Calmette-Guérin (BCG). BCG elicits a typical granulomatous reaction, and in doing so also triggers an effective local antitumor immune response. Patients are

**Table 17–2** Noninvasive Papillary Urothelial Neoplasms

| Neoplasm | Recurrences | Coexistent Invasion | Progression | Death |
|---|---|---|---|---|
| Papilloma | Rare | None | Rare* | None |
| PUNLMP | 30% | None | 2% | None |
| LGUC | 45% | <10% | 8–10% | 2–3% |
| HGUC | 45% | Up to 80% | 30% | 20% |

HGUC, high-grade papillary urothelial carcinoma; LGUC, low-grade papillary urothelial carcinoma; PUNLMP, papillary urothelial neoplasia of uncertain malignant potential.
*Rare cases of progression have occurred in immunocompromised patients.

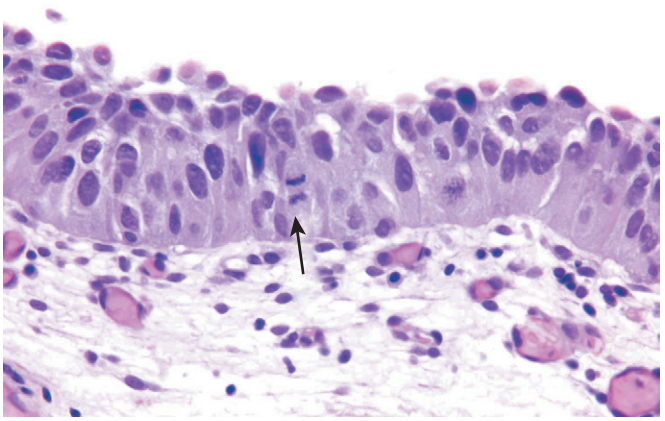

**Figure 17–18** Carcinoma in situ (CIS) with enlarged hyperchromatic nuclei and a mitotic figure (*arrow*).

closely monitored for tumor recurrence with periodic cystoscopy and urine cytologic studies for the rest of their lives. Radical cystectomy typically is reserved for (1) tumor invading the muscularis propria; (2) CIS or high-grade papillary cancer refractory to BCG; and (3) CIS extending into the prostatic urethra and down the prostatic ducts, where BCG cannot contact the neoplastic cells. Advanced bladder cancer is treated using chemotherapy, which can palliate but is not curative.

## SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases (STDs) have complicated human existence for centuries. Globally, approximately 15 million new cases of STD occur every year; of these, 4 million affect 15- to 19-year-olds, and 6 million affect 20- to 24-year-olds. Of the 10 leading infectious diseases that require notification of the Centers for Disease Control and Prevention (CDC) in the United States, five—chlamydial infection, gonorrhea, acquired immunodeficiency syndrome (AIDS), syphilis, and hepatitis B—are STDs (Table 17–3). In the United States, the two most common STDs are genital herpes and genital HPV infection, but these do not require CDC notification. Several of these entities, such as human immunodeficiency virus (HIV) infection, HPV infection, hepatitis B, and infection with *E. histolytica,* are discussed in other chapters.

### Syphilis

Syphilis, or lues, is a chronic venereal infection caused by the spirochete *Treponema pallidum.* First recognized in epidemic form in 16th-century Europe as the Great Pox, syphilis is an endemic infection in all parts of the world. In the United States, approximately 6000 cases are reported every year, but this number has been rising since 2000. For example, primary and secondary syphilis among females 10 years of age and older rose from 0.8 per 100,000 in 2004 to 1.5 per 100,000 in 2009. A strong racial disparity is evident: African Americans are affected 30 times more often than whites.

*T. pallidum* is a fastidious organism whose only natural host is man. The usual source of infection is contact with a cutaneous or mucosal lesion in a sexual partner in the early (primary or secondary) stages of syphilis. The organism is transmitted from such lesions during sexual activity through minute breaks in the skin or mucous membranes of the uninfected partner. In congenital cases, *T. pallidum* is

**Table 17–3** Classification of Important Sexually Transmitted Diseases

| Pathogen | Associated Disease(s)—Distribution by Gender | | |
|---|---|---|---|
| | Males | Both | Females |
| **Viruses** | | | |
| Herpes simplex virus | | Primary and recurrent herpes, neonatal herpes | |
| Hepatitis B virus | | Hepatitis | |
| Human papillomavirus | Cancer of penis (some cases) | Condyloma acuminatum | Cervical dysplasia and cancer, vulvar cancer |
| Human immunodeficiency virus | | Acquired immunodeficiency syndrome | |
| **Chlamydiae** | | | |
| *Chlamydia trachomatis* | Urethritis, epididymitis, proctitis | Lymphogranuloma venereum | Urethral syndrome, cervicitis, bartholinitis, salpingitis, and sequelae |
| **Mycoplasmas** | | | |
| *Ureaplasma urealyticum* | Urethritis | | Cervicitis |
| **Bacteria** | | | |
| *Neisseria gonorrhoeae* | Epididymitis, prostatitis, urethral stricture | Urethritis, proctitis, pharyngitis, disseminated gonococcal infection | Cervicitis, endometritis, bartholinitis, salpingitis and sequelae (infertility, ectopic pregnancy, recurrent salpingitis) |
| *Treponema pallidum* | | Syphilis | |
| *Haemophilus ducreyi* | | Chancroid | |
| *Calymmatobacterium granulomatis* | | Granuloma inguinale (donovanosis) | |

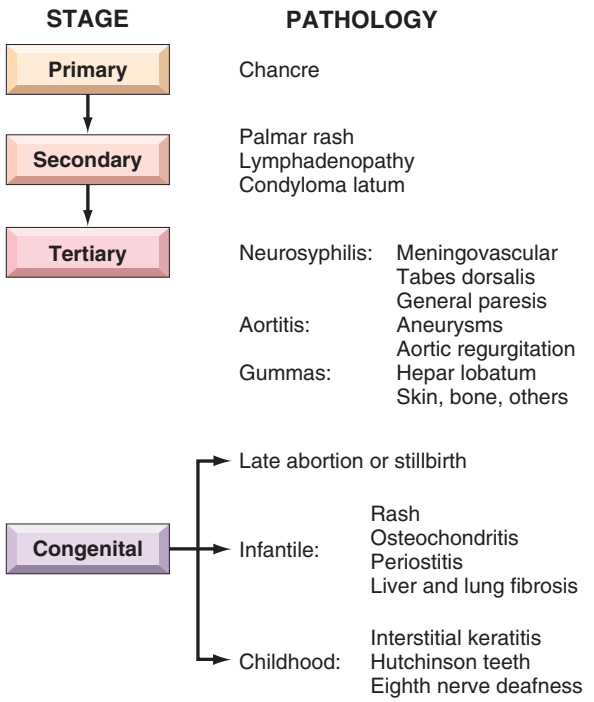

**Figure 17–19** Protean manifestations of syphilis.

transmitted across the placenta from mother to fetus, particularly during the early stages of maternal infection.

Once introduced into the body, the organisms rapidly disseminate to distant sites through lymphatics and the blood, even before the appearance of lesions at the primary inoculation site. This widespread dissemination accounts for the protean manifestations of the disease (Fig. 17–19), which can be divided into primary, secondary, and tertiary stages in adults. Between 9 and 90 days (mean, 21 days) after infection, a primary lesion, termed a *chancre,* appears at the point of spirochete entry. Systemic dissemination of organisms continues during this period, while the host mounts an immune response. Two types of antibodies are formed: antibodies that cross-react with host constituents (nontreponemal antibodies) and antibodies to specific treponemal antigens. This humoral response, however, fails to eradicate the organisms.

The chancre of *primary syphilis* resolves spontaneously over a period of 4 to 6 weeks and is followed in approximately 25% of untreated patients by the development of *secondary syphilis.* The manifestations of secondary syphilis, discussed in greater detail later on, include generalized lymphadenopathy and variable mucocutaneous lesions. *The mucocutaneous lesions of both primary and secondary syphilis are teeming with spirochetes and are highly infectious.* Like the chancre, the lesions of secondary syphilis resolve without any specific antimicrobial therapy, at which point patients are said to be in *early latent phase syphilis.* The U.S. Public Health Service restricts the definition of early latent syphilis to the 1-year period after infection. Mucocutaneous lesions may recur during this phase of the disease.

Patients with untreated syphilis next enter an asymptomatic, *late latent* phase of the illness. In about one third of cases, new symptoms develop over the next 5 to 20 years. This late symptomatic phase, or *tertiary syphilis,* is marked by the development of lesions in the cardiovascular system, central nervous system, or, less frequently, other organs. Spirochetes are much more difficult to demonstrate during the later stages of disease, and patients are accordingly much less likely to be infectious than are those in the primary or secondary stage of disease. Syphilis is common in HIV-infected patients. Like all other ulcerative genital diseases, syphilis promotes the transmission of HIV, and HIV stimulates the progression of syphilis.

## MORPHOLOGY

The pathognomonic microscopic lesion of syphilis is a **proliferative endarteritis** with an accompanying **inflammatory infiltrate rich in plasma cells.** Endarteritis has a central role in tissue injury at all sites involved by syphilis, but its pathogenesis is not understood; there is no evidence that the spirochetes cause any damage to host tissues directly. Instead, it is thought that the host immune response is responsible for the endothelial cell activation and proliferation that is the hallmark of the endarteritis, which eventually leads to perivascular fibrosis and luminal narrowing. Spirochetes are readily demonstrable in histologic sections of early lesions with the use of standard silver stains (e.g., Warthin-Starry stains). Large areas of parenchymal damage in tertiary syphilis result in the formation of a **gumma,** an irregular, firm mass of necrotic tissue surrounded by resilient connective tissue. On microscopic examination, the gumma contains a central zone of coagulative necrosis surrounded by a mixed inflammatory infiltrate composed of lymphocytes, plasma cells, activated macrophages (epithelioid cells), occasional giant cells, and a peripheral zone of dense fibrous tissue.

### *Primary Syphilis*

The chancre of syphilis is characteristically indurated and has been referred to as a "hard chancre," to distinguish it from the "soft chancre" of chancroid caused by *Haemophilus ducreyi* (discussed later). The primary chancre in males usually is on the penis. In females, multiple chancres may be present, usually in the vagina or on the uterine cervix. The chancre begins as a small, firm papule, which gradually enlarges to produce a painless ulcer with well-defined, indurated margins and a "clean," moist base (Fig. 17–20). Regional lymph nodes often are slightly enlarged and firm but painless. Histologic examination of the ulcer reveals the usual lymphocytic and plasmacytic inflammatory infiltrate and proliferative vascular changes, as described previously. Even without therapy, the primary chancre resolves over a period of several weeks to form a subtle scar.

### *Secondary Syphilis*

Within approximately 2 months of resolution of the chancre, the lesions of secondary syphilis appear. The manifestations of secondary syphilis are varied but typically include a combination of *generalized lymph node enlargement* and a variety of *mucocutaneous lesions.* Skin lesions usually are symmetrically distributed and may be maculopapular, scaly, or pustular. *Involvement of the palms of the hands and soles of the feet is common.* In moist skin areas, such as the

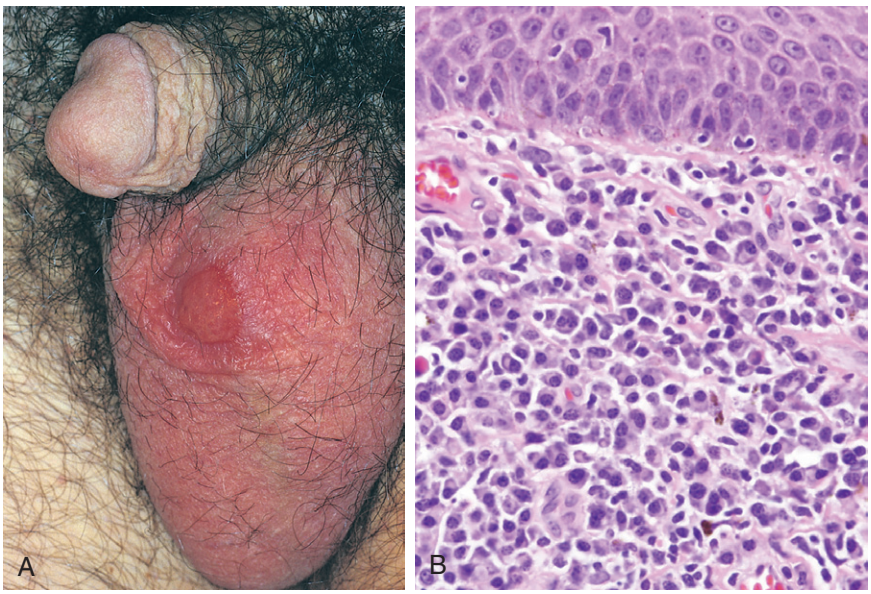

**Figure 17–20 A,** Syphilitic chancre of the scrotum. Such lesions typically are painless despite the presence of ulceration, and they heal spontaneously. **B,** Histologic features of the chancre include a diffuse plasma cell infiltrate beneath squamous epithelium of skin.

anogenital region, inner thighs, and axillae, broad-based, elevated lesions termed *condylomata lata* may appear (not to be confused with condyloma acuminata caused by HPV (Chapters 18 and 23). Superficial mucosal lesions resembling condylomata lata can occur anywhere but are particularly common in the oral cavity and pharynx and on the external genitalia.

Histologic examination of mucocutaneous lesions during the secondary phase of the disease reveals the characteristic *proliferative endarteritis,* accompanied by a *lymphoplasmacytic inflammatory infiltrate.* Spirochetes are present and often abundant within these mucocutaneous lesions; they are therefore contagious. Lymph node enlargement is most common in the neck and inguinal areas. Histologic examination of enlarged nodes demonstrates hyperplasia of germinal centers accompanied by increased numbers of plasma cells or, less commonly, granulomas or neutrophils.

Less common manifestations of secondary syphilis include hepatitis, renal disease, eye disease (iritis), and gastrointestinal abnormalities. The mucocutaneous lesions of secondary syphilis resolve over several weeks, at which point the disease enters its early latent phase, which lasts approximately 1 year. Lesions may recur at any time during this latent period, and these lesions are also highly infectious.

### *Tertiary Syphilis*

Tertiary syphilis develops in approximately one third of untreated patients, usually after a latent period of 5 years or more. Complications related to this phase of syphilis are divided into three major categories, cardiovascular syphilis, neurosyphilis, and so-called benign tertiary syphilis, which may occur singly or in combination. Cardiovascular syphilis takes the form of *syphilitic aortitis* and accounts for more than 80% of cases of tertiary disease; it is much more common in men than in women. The morphologic and clinical features of syphilitic aortitis are discussed in greater detail in Chapter 9. *Neurosyphilis* accounts for 10% of cases of tertiary syphilis overall but occurs at increased frequency in those with concomitant HIV infection; it is discussed in detail in Chapter 22. "Benign" tertiary syphilis is an uncommon form marked by the development of gummas in various sites. Emergence of these lesions probably is related to the development of delayed hypersensitivity. *Gummas occur most commonly in bone, skin, and the mucous membranes of the upper airway and mouth,* but any organ may be affected. *Spirochetes are rarely demonstrable within gummas.* Once common, gummas have become exceedingly rare thanks to the development of effective antibiotics such as penicillin. They are reported now mostly in patients with AIDS.

### *Congenital Syphilis*

*T. pallidum* may be transmitted across the placenta from an infected mother to the fetus at any time during pregnancy. *The likelihood of transmission is greatest during the early (primary and secondary) stages of disease, when spirochetes are most numerous.* Because the manifestations of maternal disease may be subtle, routine serologic testing for syphilis is mandatory in all pregnancies. The stigmata of congenital syphilis typically do not develop until after the fourth month of pregnancy. In the absence of treatment, as many as 40% of infected infants die in utero, typically after the fourth month. The incidence of congenital syphilis increased 23% in the United States from 2003 to 2008.

Manifestations of *congenital syphilis* include stillbirth, infantile syphilis, and late (tardive) congenital syphilis. Among infants who are stillborn, the most common manifestations are *hepatomegaly, bone abnormalities, pancreatic fibrosis,* and *pneumonitis.* The liver often shows extramedullary hematopoiesis and portal tract inflammation. Changes in the bones include inflammation and disruption of the osteochondral junction in long bones and, on occasion, bone resorption and fibrosis of the flat bones of the skull. The lungs may be firm and pale as a result of the presence of inflammatory cells and fibrosis in the alveolar septa (pneumonia alba). Spirochetes are readily demonstrable in tissue sections. In cases of congenital syphilis, the placenta is enlarged, pale, and edematous. Microscopy reveals

proliferative endarteritis involving the fetal vessels, a mononuclear inflammatory reaction (villitis), and villous immaturity.

*Infantile syphilis* refers to congenital syphilis in liveborn infants that is clinically manifest at birth or within the first few months of life. Affected infants present with chronic rhinitis (snuffles) and mucocutaneous lesions similar to those seen in secondary syphilis in adults. Visceral and skeletal changes resembling those seen in stillborn infants also may be present.

*Late, or tardive, congenital syphilis* refers to cases of untreated congenital syphilis of more than 2 years' duration. Classic manifestations include the Hutchinson triad: notched central incisors, interstitial keratitis with blindness, and deafness from eighth cranial nerve injury. Other changes include a so-called saber shin deformity caused by chronic inflammation of the periosteum of the tibia, deformed molar teeth ("mulberry molars"), chronic meningitis, chorioretinitis, and gummas of the nasal bone and cartilage with a resultant "saddlenose" deformity.

### *Serologic Tests for Syphilis*

Although polymerase chain reaction (PCR)–based testing for syphilis has been developed, serology remains the mainstay of diagnosis. Serologic tests for syphilis include nontreponemal antibody tests and antitreponemal antibody tests. Nontreponemal tests measure antibody to cardiolipin, an antigen that is present in both host tissues and the treponemal cell wall. These antibodies are detected by the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests. Nontreponemal antibody tests are usually positive by 4 to 6 weeks of infection and are strongly positive in the secondary phase of infection. *However, nontreponemal antibody test results may revert to negative during the tertiary phase* or, conversely, may on occasion be persistently positive in some patients after successful treatment. Two additional points regarding nontreponemal antibody tests deserve emphasis:

- *Nontreponemal antibody test results often are negative during the early stages of disease,* even in the presence of a primary chancre. Hence, during this period, direct visualization of the spirochetes by darkfield or immunofluorescence microscopy may be the only way to confirm the diagnosis.
- *As many as 15% of positive VDRL test results are unrelated to syphilis.* These false-positive results, which may be acute (transient) or chronic (persistent), increase in frequency with age and are associated with a variety of conditions, including the antiphospholipid antibody syndrome (Chapter 3).

Treponemal antibody tests also become positive within 4 to 6 weeks after an infection, but, unlike those for nontreponemal antibody tests, they usually remain positive indefinitely, even after successful treatment. *These tests give strongly positive results in virtually all cases of secondary syphilis.* They are not recommended as screening tests, however, because they remain positive after treatment and have a high false-positive test rate (approximately 2%) in the general population.

Serologic response may be delayed, exaggerated (false-positive results), or absent in patients with syphilis and coexistent HIV infection. In most cases, however, these tests remain useful in the diagnosis and management of syphilis in patients with AIDS.

## SUMMARY

### Syphilis

- Syphilis is caused by *T. pallidum* and has three stages. In primary syphilis a painless lesion called chancre develops on the external genitalia along with regional lymph node enlargement. Secondary syphilis manifests with generalized lymphadenopathy and mucocutaneous lesions that may be maculopapular or take the form of flat raised lesions called condylomata lata. Tertiary syphilis may cause proximal aortitis and aortic insufficiency; may involve the brain, meninges, and the spinal cord; or may cause focal granulomatous lesions called gummas in multiple organs.
- Congenital syphilis is caused by maternal transmission of the spirochetes, mostly during primary and secondary stages of disease in the mother. It may lead to stillbirth or cause widespread tissue injury in liver, spleen, lung, bones, and pancreas.
- On histologic examination, most syphilitic lesions demonstrate proliferative endarteritis and a plasma cell–rich inflammatory infiltrate. Gummas have a central area of necrosis surrounded by lymphoplasmacytic infiltrates and epithelioid cells.
- The diagnostic mainstay is serologic testing. Nontreponemal antibody tests (VDRL and RPR) are usually positive in early disease, but may be negative in advanced disease. Treponeme-specific antibody test results become positive later and remain positive indefinitely. Treponemes can also be identified by microscopic examination of primary and secondary lesions.

## Gonorrhea

Gonorrhea is a sexually transmitted infection of the lower genitourinary tract caused by *Neisseria gonorrhoeae.* Gonorrhea is second only to chlamydial infection of the genitourinary tract (discussed later) among reportable communicable diseases in the United States. With an estimated 650,000 cases each year in the United States, it remains a major public health problem. The gravity of gonococcal infections has increased with the emergence of strains of *N. gonorrhoeae* that are resistant to multiple antibiotics.

Humans are the only natural reservoir for *N. gonorrhoeae.* The organism is highly fastidious, and spread of infection requires direct contact with the mucosa of an infected person, usually during sexual activity. The bacteria initially attach to mucosal epithelium, particularly of the columnar or transitional type, using a variety of membrane-associated adhesion molecules and structures termed *pili* (Chapter 8). Such attachment prevents the organism from being unceremoniously flushed away by body fluids such as urine or endocervical mucus. The organism then penetrates through the epithelial cells to invade the deeper tissues of the host.

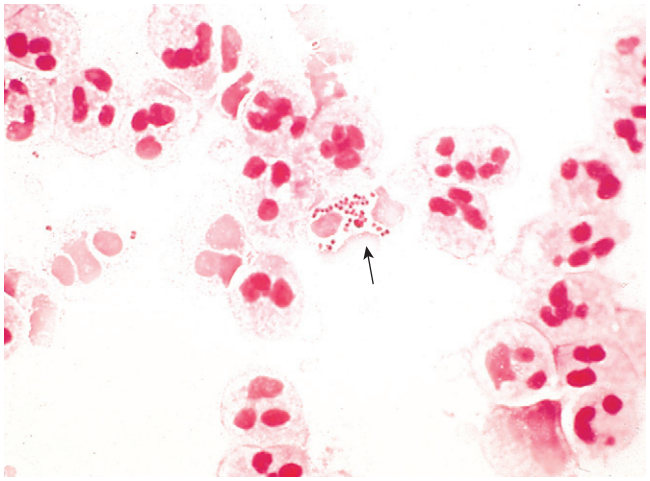

**Figure 17–21** *Neisseria gonorrhoeae.* Gram stain of urethral discharge demonstrates characteristic gram-negative, intracellular diplococci (*arrow*).

*(Courtesy of Dr. Rita Gander, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

## MORPHOLOGY

***N. gonorrhoeae*** provokes an intense, suppurative inflammatory reaction. In males this manifests most often as a **purulent urethral discharge,** associated with an edematous, congested urethral meatus. Gram-negative diplococci, many within the cytoplasm of neutrophils, are readily identified in Gram stains of the purulent exudate (Fig. 17–21). Ascending infection may result in the development of **acute prostatitis, epididymitis** (Fig. 17–22), or **orchitis.** Abscesses may complicate severe cases. Urethral and endocervical exudates tend to be less conspicuous in females, although acute inflammation of adjacent structures, such as the Bartholin glands, is fairly common. Ascending infection involving the uterus, fallopian tubes, and ovaries results in **acute salpingitis,** sometimes complicated by tuboovarian abscesses. The acute inflammatory process is followed by the development of granulation tissue and scarring, with resultant strictures and other permanent deformities of the involved structures, giving rise to **pelvic inflammatory disease** (Chapter 18).

**Figure 17–22** Acute epididymitis caused by gonococcal infection. The epididymis is involved by an abscess. Normal testis is seen on the *right.*

### Clinical Features

In most infected males, gonorrhea is manifested by the presence of *dysuria, urinary frequency, and a mucopurulent urethral exudate* within 2 to 7 days of the time of initial infection. Treatment with appropriate antimicrobial therapy results in eradication of the organism and prompt resolution of symptoms. Untreated infections may ascend to involve the prostate, seminal vesicles, epididymis, and testis. Neglected cases may be complicated by chronic urethral stricture and, in more advanced cases, by permanent sterility. Untreated men also may become chronic carriers of *N. gonorrhoeae.*

Among female patients, acute infections acquired by vaginal intercourse may be asymptomatic or associated with *dysuria, lower pelvic pain, and vaginal discharge.* Untreated cases may be complicated by ascending infection, leading to acute inflammation of the fallopian tubes (salpingitis) and ovaries. Scarring of the fallopian tubes may occur, with resultant infertility and an increased risk of ectopic pregnancy. Gonococcal infection of the upper genital tract may spread to the peritoneal cavity, where the exudate may extend up the right paracolic gutter to the dome of the liver, resulting in gonococcal perihepatitis. Depending on sexual practices, other sites of primary infection in both males and females include the oropharynx and the anorectal area, with resultant acute pharyngitis and proctitis, respectively.

*Disseminated infection* is much less common than local infection, occurring in 0.5% to 3% of cases of gonorrhea. It is more common in females than in males. Manifestations include, most commonly, tenosynovitis, arthritis, and pustular or hemorrhagic skin lesions. Endocarditis and meningitis are rare presentations. Strains that cause disseminated infection usually are resistant to the lytic action of complement, but rare patients with inherited complement deficiencies are susceptible to systemic spread regardless of the infecting strain.

*Gonococcal infection may be transmitted to infants* during passage through the birth canal. The affected neonate may develop purulent infection of the eyes (ophthalmia neonatorum), an important cause of blindness in the past. The routine application of antibiotic ointment to the eyes of newborns has markedly reduced this disorder.

Both culture and a variety of tests that detect organism-specific nucleic acids can be used to diagnose gonococcal infections. The advantage of culture is that it permits determination of antibiotic sensitivity. Nucleic acid–based tests are more rapid and somewhat more sensitive than culture, and are being used increasingly.

## SUMMARY

### Gonorrhea

- Gonorrhea is a common STD affecting the genitourinary tract. Control of dissemination requires an effective complement-mediated immune response.
- In males there is a severe, symptomatic urethritis that can spread to the prostate, epididymis, and testis. In females the initial lesions on the cervix and urethra are less prominent than corresponding lesions in males, but ascending infection to fallopian tubes and ovaries can cause scarring and deformity with resultant sterility.
- Pregnant women can transmit gonorrhea to newborns during passage through the birth canal.
- Diagnosis can be made by culture of the exudates as well as by nucleic acid amplification techniques.

## Nongonococcal Urethritis and Cervicitis

Nongonococcal urethritis (NGU) and cervicitis are the most common forms of STD. A variety of organisms has been implicated in the pathogenesis of NGU and cervicitis, including *C. trachomatis, Trichomonas vaginalis, U. urealyticum,* and *Mycoplasma genitalium. Most cases are apparently caused by C. trachomatis, and this organism is believed to be the most common bacterial cause of STD in the United States. U. urealyticum* is the next most common cause of NGU. Gonorrhea infection frequently is accompanied by chlamydial infection.

*C. trachomatis* is a small gram-negative bacterium that is an obligate intracellular pathogen. It exists in two forms. The infectious form, the *elementary body,* is capable of at least limited survival in the extracellular environment. The elementary body is taken up by host cells, primarily through a process of receptor-mediated endocytosis. Once inside the cell, the elementary body differentiates into a metabolically active form, termed the *reticulate body.* Using energy sources from the host cell, the reticulate body replicates and ultimately forms new elementary bodies capable of infecting additional cells. They preferentially infect columnar epithelial cells.

*C. trachomatis* infections may be associated with a wide range of clinical features that are virtually indistinguishable from those caused by *N. gonorrhoeae.* Thus, patients may develop epididymitis, prostatitis, pelvic inflammatory disease, pharyngitis, conjunctivitis, perihepatic inflammation, and, among persons engaging in anal sex, proctitis. *C. trachomatis* also causes lymphogranuloma venereum (LGV), discussed in the next section.

The morphologic and clinical features of chlamydial infection, with the exception of lymphogranuloma venereum, are virtually identical to those of gonorrhea. The primary infection is characterized by a *mucopurulent discharge containing a predominance of neutrophils.* Organisms are not visible in Gram-stained sections. In contrast with the gonococcus, *C. trachomatis* cannot be isolated with the use of conventional culture media. The diagnosis is best made by nucleic acid amplification tests on voided urine. Although culture can be done from genital swabs, it is not possible from urine. Molecular tests also are more sensitive than culture. Another important manifestation of chlamydial infection is *reactive arthritis* (formerly known as Reiter syndrome), predominantly in patients who are HLA-B27–positive. This condition typically manifests as a combination of urethritis, conjunctivitis, arthritis, and generalized mucocutaneous lesions.

## SUMMARY

### Nongonococcal Urethritis and Cervicitis

- NGU and cervicitis are the most common forms of STD. A majority of the cases are caused by *C. trachomatis,* and the rest by *T. vaginalis, U. urealyticum,* and *M. genitalium.*
- *C. trachomatis* is a gram-negative intracellular bacterium that causes a disease that is clinically indistinguishable from gonorrhea in both men and in women. Diagnosis requires detection of the bacteria by molecular methods. Culture from genital swabs is possible but requires special methods.
- In patients who are HLA-B27–positive, *C. trachomatis* infection can cause reactive arthritis along with conjunctivitis, and generalized mucocutaneous lesions.

## Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a chronic, ulcerative disease caused by certain strains of *C. trachomatis,* which are distinct from those causing the more common NGU or cervicitis discussed earlier. It is a sporadic disease in the United States and western Europe but is endemic in parts of Asia, Africa, the Caribbean region, and South America. As in the case of granuloma inguinale (discussed later), sporadic cases of LGV are seen most often among persons with multiple sexual partners.

## MORPHOLOGY

LGV may present as nonspecific urethritis, papular or ulcerative lesions involving the lower genitalia, tender inguinal and/or femoral lymphadenopathy that typically is unilateral, or proctocolitis. The lesions contain a **mixed granulomatous and neutrophilic inflammatory response;** variable numbers of chlamydial inclusions may be seen in the cytoplasm of epithelial cells or inflammatory cells with special staining methods. Regional lymphadenopathy is common, usually appearing within 30 days of the time of infection. Lymph node involvement is characterized by a granulomatous inflammatory reaction associated with irregularly shaped foci of necrosis and neutrophilic infiltration **(stellate abscesses).** With time, the inflammatory reaction gives rise to extensive fibrosis that can cause local lymphatic obstruction and strictures, producing **lymphedema.** Rectal strictures also occur, particularly in women. In active lesions, the diagnosis of LGV may be made by demonstration of the organism in biopsy sections or smears of exudate. In more chronic cases, the diagnosis rests on the demonstration of antibodies to the appropriate chlamydial serotypes in the patient's serum. Nucleic acid amplification tests have also been developed.

## Chancroid (Soft Chancre)

Chancroid, sometimes called the "third" venereal disease (after syphilis and gonorrhea), is an acute, ulcerative infection caused by *Haemophilus ducreyi,* a small, gram-negative coccobacillus. The disease is most common in tropical and subtropical areas and is more prevalent in lower socioeconomic groups, particularly among men who have regular contact with prostitutes. *Chancroid is one of the most common causes of genital ulcers in Africa and Southeast Asia,* where it serves as an important cofactor in the transmission of HIV infection. Chancroid probably is underdiagnosed in the United States, because most STD clinics do not have facilities for isolating *H. ducreyi* and PCR-based tests are not widely available.

### MORPHOLOGY

At 4 to 7 days after inoculation, a tender, **erythematous papule** develops on the external genitalia. In male patients, the primary lesion is usually on the penis; in female patients, most lesions occur in the vagina or periurethral area. Over the course of several days the surface of the primary lesion erodes to produce an **irregular ulcer,** which is more likely to be painful in males than in females. In contrast with the primary chancre of syphilis, the ulcer of chancroid is not indurated, and multiple lesions may be present. The base of the ulcer is covered by shaggy, yellow-gray exudate. The regional **lymph nodes,** particularly in the inguinal region, become enlarged and tender in about 50% of cases within 1 to 2 weeks of the primary inoculation. In untreated cases, the inflamed and enlarged nodes (buboes) may erode the overlying skin to produce chronic, draining ulcers.

On microscopic examination, the ulcer of chancroid contains a superficial zone of neutrophilic debris and fibrin, with an underlying zone of granulation tissue containing areas of necrosis and thrombosed vessels. A dense, lymphoplasmacytic inflammatory infiltrate is present beneath the layer of granulation tissue. Coccobacillary organisms sometimes are demonstrable in Gram- or silver-stained preparations, but they often are obscured by the mixed bacterial growth frequently present at the ulcer base. A definitive diagnosis of chancroid requires the identification of *H. ducreyi* on special culture media that are not widely available from commercial sources; even when such media are used, sensitivity is less than 80%. Therefore, the diagnosis often is based on clinical grounds alone.

## Granuloma Inguinale

Granuloma inguinale is a chronic inflammatory disease caused by *Calymmatobacterium granulomatis,* a minute, encapsulated coccobacillus related to the *Klebsiella* genus. This disease is uncommon in the United States and western Europe but is endemic in rural areas in certain tropical and subtropical regions. When it occurs in urban settings, transmission of *C. granulomatis* typically is associated with a history of multiple sexual partners. Untreated cases are characterized by extensive scarring, often associated with lymphatic obstruction and lymphedema (elephantiasis) of the external genitalia. Culture of the organism is difficult, and PCR-based assays are not widely available.

### MORPHOLOGY

Granuloma inguinale begins as a raised, papular lesion involving the moist, stratified squamous epithelium of the genitalia. The lesion eventually undergoes ulceration, accompanied by the development of abundant granulation tissue, which takes the form of a protuberant, soft, painless mass. As the lesion enlarges, its borders become raised and indurated. Disfiguring scars may develop in untreated cases, sometimes associated with formation of urethral, vulvar, or anal strictures. Regional lymph nodes typically are spared or show only nonspecific reactive changes, in contrast with chancroid.

Microscopic examination of active lesions reveals marked epithelial hyperplasia at the borders of the ulcer, sometimes mimicking carcinoma **(pseudoepitheliomatous hyperplasia).** A mixture of neutrophils and mononuclear inflammatory cells is present at the base of the ulcer and beneath the surrounding epithelium. The organisms are demonstrable in Giemsa-stained smears of the exudate as minute coccobacilli within vacuoles in macrophages (Donovan bodies). Silver stains (e.g., the Warthin-Starry stain) also may be used to demonstrate the organism.

### SUMMARY

#### Lymphogranuloma Venereum, Chancroid, and Granuloma Inguinale

- LGV is caused by *C. trachomatis* serotypes that are distinct from those that cause NGU. LGV is associated with urethritis, ulcerative genital lesions, lymphadenopathy, and involvement of the rectum. The lesions show both acute and chronic inflammation; they progress to fibrosis, with consequent lymphedema and formation of rectal strictures.
- *H. ducreyi* infection causes an acute painful ulcerative genital infection called *chancroid.* Inguinal node involvement occurs in many cases and leads to their enlargement and ulceration. Ulcers show a superficial area of acute inflammation and necrosis, with an underlying zone of granulation tissue and mononuclear infiltrate. Diagnosis is possible by culture of the organism.
- *Granuloma inguinale* is a chronic fibrosing STD caused by *C. granulomatis.* The initial papular lesion on the genitalia expands and ulcerates, with formation of urethral, vulvar, or anal strictures in some cases. Microscopic examination reveals granulation tissue and intense epithelial hyperplasia that can mimic the histologic pattern in squamous cell carcinoma. Organisms are visible as small intracellular coccobacilli within vacuolated macrophages (Donovan bodies).

## Trichomoniasis

*T. vaginalis* is a sexually transmitted protozoan that is a frequent cause of vaginitis. The trophozoite form adheres to the mucosa, where it causes superficial lesions. In females, *T. vaginalis* infection often is associated with loss

of acid-producing Döderlein bacilli. It may be asymptomatic or be associated with pruritus and a profuse, frothy, yellow vaginal discharge. Urethral colonization may cause urinary frequency and dysuria. *T. vaginalis* infection typically is asymptomatic in males but in some cases may manifest as NGU. The organism usually is demonstrable in smears of vaginal scrapings.

## Genital Herpes Simplex

Genital herpes infection, or herpes genitalis, is a common STD that affects an estimated 50 million people in the United States. Although both herpes simplex virus 1 (HSV-1) and HSV-2 can cause anogenital or oral infections, most cases of anogenital herpes are caused by HSV-2. However, *recent years have seen a rise in the number of genital infections caused by HSV-1, in part due to the increasing practice of oral sex.* Genital HSV infection may occur in any sexually active population. As with other STDs, the risk of infection is directly related to the number of sexual contacts. Up to 95% of HIV-positive men who have sex with men are seropositive for HSV-1 and/or HSV-2. HSV is transmitted when the virus comes into contact with a mucosal surface or broken skin of a susceptible host. Such transmission requires direct contact with an infected person, because the virus is readily inactivated at room temperature, particularly if dried.

### MORPHOLOGY

The initial lesions of genital HSV infection are **painful, erythematous vesicles** on the mucosa or skin of the lower genitalia and adjacent extragenital sites. The anorectal area is a particularly common site of primary infection among men who have sex with men. Histologic changes include the presence of **intraepithelial vesicles** accompanied by necrotic cellular debris, neutrophils, and cells harboring characteristic intranuclear viral inclusions. The classic **Cowdry type A inclusion** appears as a light purple, homogeneous intranuclear structure surrounded by a clear halo. Infected cells commonly fuse to form multinucleate syncytia. The inclusions readily stain with antibodies to HSV, permitting a rapid, specific diagnosis of HSV infection in histologic sections or smears. Immunohistochemical tests have largely replaced detection of HSV infection by cytologic examination, which is less sensitive and prone to false-positive results.

### Clinical Features

As mentioned earlier, both HSV-1 and HSV-2 can cause genital or oral infection, and both can produce primary or recurrent mucocutaneous lesions that are clinically indistinguishable. The manifestations of HSV infection vary considerably, depending on whether the infection is primary or recurrent. Primary infection with HSV-2 often is mildly symptomatic. In persons experiencing their first episode, locally painful vesicular lesions are often accompanied by dysuria, urethral discharge, local lymph node enlargement and tenderness, and systemic manifestations, such as fever, muscle aches, and headache. HSV is actively shed during this period and continues to be shed until the mucosal lesions have completely healed. Signs and symptoms may last for several weeks during the primary phase of disease. Recurrences are much more common with HSV-1 than with HSV-2 and typically are milder and of shorter duration than in the primary episode. As with primary infection, HSV is shed while active lesions are present.

In immunocompetent adults, herpes genitalis generally is not life-threatening. However, HSV does pose a major threat to immunosuppressed patients, in whom fatal, disseminated disease may develop. Also life-threatening is *neonatal herpes infection,* which occurs in about half of infants delivered vaginally of mothers suffering from either primary or recurrent genital HSV infection. The viral infection is acquired during passage through the birth canal. Its incidence has risen in parallel with the rise in genital HSV infection. *The manifestations of neonatal herpes, which typically develop during the second week of life, include rash, encephalitis, pneumonitis, and hepatic necrosis.* Approximately 60% of affected infants die of the disease, with significant morbidity occurring in about half of the survivors. The laboratory diagnosis of genital herpes relies on viral culture. Of note, however, the sensitivity of culture is low, especially for recurrent lesions, and declines rapidly as lesions begin to heal. Molecular diagnostic tests also are available but are used mostly in diagnosis of extragenital herpes, particularly with central nervous system infections.

## Human Papillomavirus Infection

HPV causes a number of squamous proliferations in the genital tract, including condyloma acuminatum, as well as several precancerous lesions that commonly undergo transformation to carcinomas; these most commonly involve the cervix (Chapter 18), but also occur in the penis, vulva, and oropharyngeal tonsils. *Condylomata acuminata,* also known as venereal warts, are caused by HPV types 6 and 11. These lesions occur on the penis as well as on the female genitalia. They should not be confused with the condylomata lata of secondary syphilis. Genital HPV infection may be transmitted to neonates during vaginal delivery. Recurrent and potentially life-threatening papillomas of the upper respiratory tract may develop subsequently in affected infants.

### MORPHOLOGY

In males, condylomata acuminata usually occur on the coronal sulcus or inner surface of the prepuce, where they range in size from small, sessile lesions to large, papillary proliferations measuring several centimeters in diameter. In females, they commonly occur on the vulva. Examples of the microscopic appearance of these lesions are presented in Chapter 18.

### SUMMARY

#### Herpes Simplex Virus and Human Papillomavirus Infections

- HSV-2 and, less commonly, HSV-1 can cause genital infections. Initial (primary) infection causes painful, erythematous, intraepithelial vesicles on the mucosa and skin of external genitalia, along with regional lymph node

enlargement. Recurrent lesions are more common with HSV-1 than with HSV-2 infection, and in general are less painful and less extensive than primary lesions.

- On histologic examination the vesicles of HSV infection contain necrotic cells and fused multinucleate giant cells with intranuclear inclusions (Cowdry type A) that stain with antibodies to the virus.
- Neonatal herpes can be life-threatening and occurs in children born to mothers with genital herpes. Affected infants have generalized herpes, often associated with encephalitis and consequent high mortality.
- HPV causes many proliferative lesions of the genital mucosa, including condyloma acuminatum, precancerous lesions, and invasive cancers.

## VULVA

The *vulva* is the external female genitalia and includes the moist hair-bearing skin and mucosa in that region. Disorders of the vulva most frequently are inflammatory, rendering them more uncomfortable than serious. Malignant tumors of the vulva, although life-threatening, are rare.

### VULVITIS

One of the most common causes of vulvitis is reactive inflammation in response to an exogenous stimulus, whether an irritant (contact irritant dermatitis) or an allergen (contact allergic dermatitis). Scratching-induced trauma secondary to associated intense "itching" (pruritus) often exacerbates the primary condition.

Contact irritant eczymatous dermatitis manifests as well-defined erythematous weeping and crusting papules and plaques (Chapter 23) and may be a reaction to urine, soaps, detergents, antiseptics, deodorants, or alcohol. Allergic dermatitis has a similar clinical appearance and may result from allergy to perfumes; additives in creams, lotions, and soaps; chemical treatments on clothing; and other antigens.

Vulvitis also may be caused by infections, which in this setting often are sexually transmitted (Chapter 17). The most important of these infectious agents in North America are human papillomavirus (HPV), the causative agent of condyloma acuminatum and vulvar intraepithelial neoplasia (VIN) (discussed later); herpes simplex virus (HSV-1 or -2), the agent of genital herpes with its characteristic

*The contributions of Drs. Susan Lester (Diseases of Breast) and Anthony Montag (Diseases of Female Genital System) are gratefully acknowledged.*

vesicular eruption; *N. gonorrhoeae*, a cause of suppurative infection of the vulvovaginal glands; *Treponema pallidum,* the syphilis pathogen, in association with the primary chancre at a vulvar site of inoculation; and *Candida,* also a potential cause of vulvitis.

An important complication of vulvitis is obstruction of the excretory ducts of Bartholin glands. This blockage may result in painful dilation of the glands (a Bartholin cyst) and abscess formation.

## NON-NEOPLASTIC EPITHELIAL DISORDERS

The epithelium of the vulvar mucosa may undergo both atrophic thinning and hyperplastic thickening, often in the form of lichen sclerosus and lichen simplex chronicus, respectively.

### Lichen Sclerosus

Lichen sclerosus is characterized by thinning of the epidermis, disappearance of rete pegs, hydropic degeneration of the basal cells, dermal fibrosis, and a scant perivascular, mononuclear inflammatory cell infiltrate (Fig. 18–1). It appears as smooth, white plaques (termed *leukoplakia*) or papules that in time may extend and coalesce. When the entire vulva is affected, the labia become somewhat atrophic and stiffened, and the vaginal orifice is constricted. Lichen sclerosus occurs in all age groups but most commonly affects postmenopausal women. The pathogenesis is uncertain, but the presence of activated T cells in the subepithelial inflammatory infiltrate and the increased frequency of autoimmune disorders in affected women suggest an autoimmune etiology. Lichen sclerosus is benign; however, a small percentage of women (1% to 5%) with symptomatic lichen sclerosus develop squamous cell carcinoma of the vulva.

### Lichen Simplex Chronicus

Lichen simplex chronicus is marked by epithelial thickening (particularly of the stratum granulosum) and hyperkeratosis. Increased mitotic activity is seen in the basal and suprabasal layers; however, there is no epithelial atypia (Fig. 18–1). Leukocytic infiltration of the dermis is sometimes pronounced. These nonspecific changes are a consequence of chronic irritation, often caused by pruritus related to an underlying inflammatory dermatosis. Lichen simplex chronicus appears as an area of leukoplakia. With isolated lesions, no increased predisposition to cancer has been found, but lichen simplex chronicus often is present at the margins of established vulvar cancer, raising the possibility of an association with neoplastic disease.

Lichen sclerosus and lichen simplex chronicus may coexist in different areas of the body in the same person, and both lesions may take the form of leukoplakia. Similar white patches or plaques also are seen in a variety of other benign dermatoses, such as psoriasis and lichen planus (Chapter 23), as well as in malignant lesions of the vulva, such as squamous cell carcinoma in situ and invasive squamous cell carcinoma. Thus, biopsy and microscopic examination are needed to differentiate these clinically similar-appearing lesions.

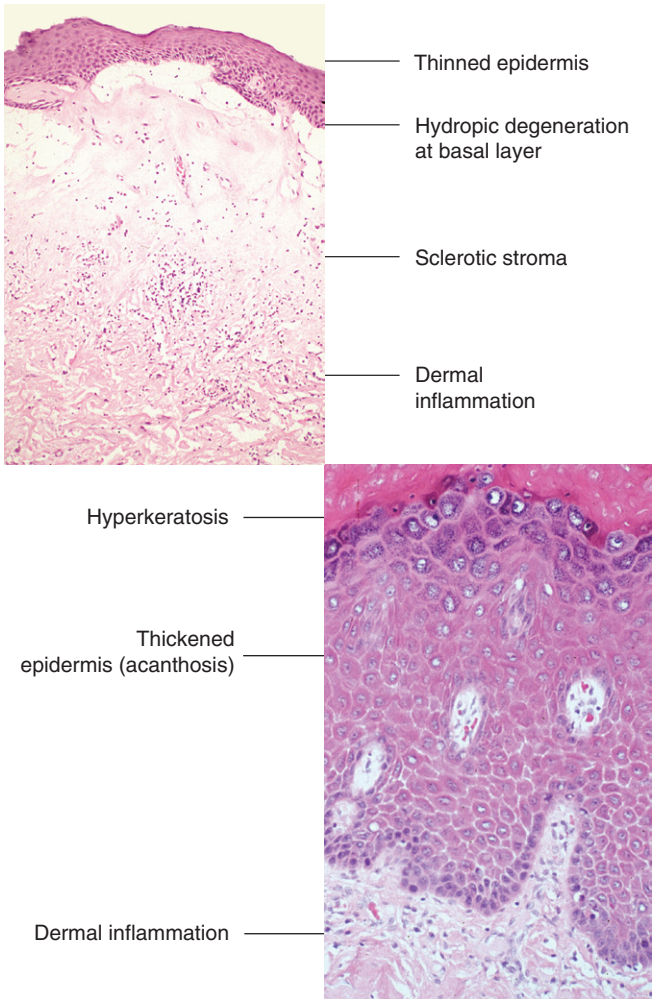

**Figure 18–1** *Upper panel*, Lichen sclerosus. *Lower panel*, Lichen simplex chronicus. The main features of the lesions are labeled.

### SUMMARY

#### Non-neoplastic Epithelial Disorders

- Lichen sclerosus is characterized by atrophic epithelium, usually with dermal fibrosis.
- Lichen sclerosus carries a slightly increased risk for development of squamous cell carcinoma.
- Lichen simplex chronicus is characterized by thickened epithelium (hyperplasia), usually with an inflammatory infiltrate.
- The lesions of lichen sclerosus and lichen simplex chronicus must be biopsied to definitively distinguish them from other causes of leukoplakia, such as squamous cell carcinoma of the vulva.

# TUMORS

## Condylomas

*Condyloma* is the name given to any warty lesion of the vulva. Most such lesions can be assigned to one of two distinctive forms. *Condylomata lata,* not commonly seen today, are flat, moist, minimally elevated lesions that occur in secondary syphilis (Chapter 17). The more common *condylomata acuminata* may be papillary and distinctly elevated or somewhat flat and rugose. They can occur anywhere on the anogenital surface, sometimes as single but more often as multiple lesions. When located on the vulva, they range from a few millimeters to many centimeters in diameter and are red-pink to pink-brown (Fig. 18–2). On histologic examination, the characteristic cellular feature is koilocytosis, a cytopathic change characterized by perinuclear cytoplasmic vacuolization and wrinkled nuclear contours that is a hallmark of HPV infection (Fig. 18–2; see also Chapter 17). Indeed, condylomata acuminata are strongly associated with HPV subtypes 6 and 11. HPV can be transmitted venereally, and identical lesions occur in men on the penis and around the anus. HPV 6 and 11 infections carry a low risk of malignant transformation, and hence, vulvar condylomas do not commonly progress to cancer.

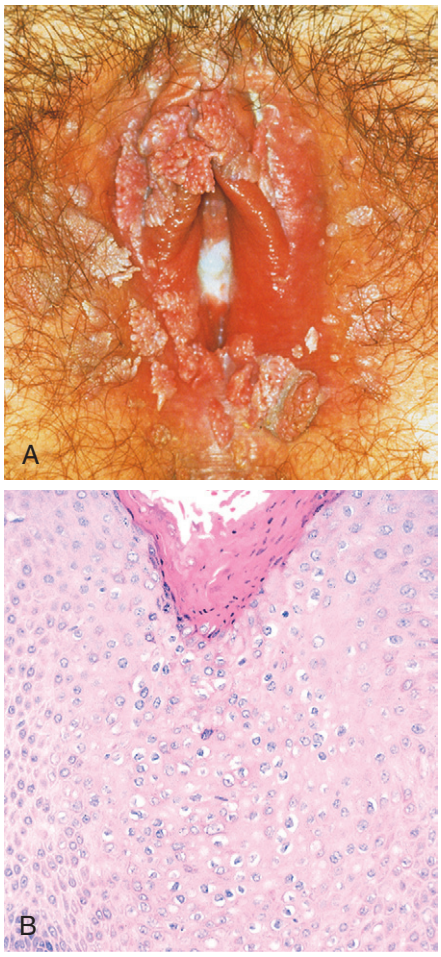

**Figure 18–2 A,** Numerous condylomas of the vulva. **B,** Histopathologic features of condyloma acuminatum include acanthosis, hyperkeratosis, and cytoplasmic vacuolation (koilocytosis, *center*).
*(A, Courtesy of Dr. Alex Ferenczy, McGill University, Montreal, Quebec, Canada.)*

## Carcinoma of the Vulva

Carcinoma of the vulva represents about 3% of all female genital tract cancers, occurring mostly in women older than age 60. Approximately 90% of carcinomas are squamous cell carcinomas; the other tumors are mainly adenocarcinomas or basal cell carcinomas.

There appear to be two distinct forms of vulvar squamous cell carcinoma. The less common form is related to high-risk HPV strains (especially HPV subtypes 16 and 18) and occurs in middle-aged women, particularly cigarette smokers. In this form, the onset of carcinoma often is preceded by precancerous changes in the epithelium termed *vulvar intraepithelial neoplasia* (VIN). VIN progresses in most patients to greater degrees of atypia and eventually undergoes transformation to carcinoma in situ; however, progression to invasive carcinoma is not inevitable and often occurs after many years. Environmental factors such as cigarette smoking and immunodeficiency appear to increase the risk of such progression.

A second form of vulvar carcinoma occurs in older women. It is not associated with HPV but often is preceded by years of reactive epithelial changes, principally lichen sclerosus. The overlying epithelium frequently lacks the typical cytologic changes of VIN, but it may display subtle atypia of the basal layer and basal keratinization. Invasive tumors of this form tend to be well differentiated and highly keratinizing.

### MORPHOLOGY

VIN and early vulvar carcinomas manifest as areas of **leukoplakia** in the form of whitish patches of epithelial thickening. In about one fourth of the cases, the lesions are pigmented owing to the presence of melanin. Over time, these areas are transformed into overt **exophytic** or ulcerative **endophytic tumors.** HPV-positive tumors often are multifocal and warty and tend to be poorly differentiated **squamous cell carcinomas,** whereas HPV-negative tumors usually are unifocal and typically manifest as well-differentiated keratinizing squamous cell carcinomas.

Both forms of vulvar carcinoma tend to remain confined to their site of origin for a few years but ultimately invade and spread, usually first to regional nodes. The risk of metastasis correlates with the size of the tumor and the depth of invasion. Women with tumors less than 2 cm in diameter have about a 90% 5-year survival rate after radical excision, whereas only 20% of those with advanced-stage lesions survive for 10 years.

## Extramammary Paget Disease

Paget disease is an intraepidermal proliferation of malignant epithelial cells that can occur in the skin of the vulva or nipple of the breast. However, unlike in the breast, where Paget disease is virtually always associated with an

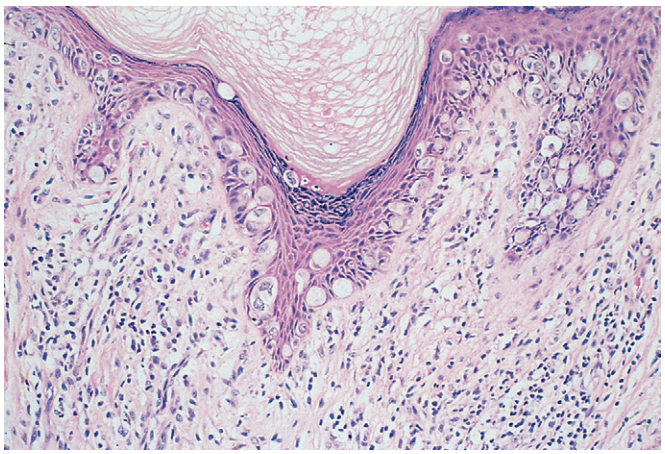

**Figure 18–3** Paget disease of the vulva, with large tumor cells with abundant clear cytoplasm scattered throughout the epidermis.

underlying carcinoma, a majority of cases of vulvar (extramammary) Paget disease have no demonstrable underlying tumor. Instead, vulvar Paget cells most commonly appear to arise from epidermal progenitor cells. Only occasionally, Paget disease in this location is accompanied by a subepithelial or submucosal tumor arising in an adnexal structure, typically sweat glands.

Paget disease manifests as a red, scaly, crusted plaque that may mimic the appearance of an inflammatory dermatitis. On histologic examination, large epithelioid cells with abundant pale, finely granular cytoplasm and occasional cytoplasmic vacuoles infiltrate the epidermis, singly and in groups (Fig. 18–3). The presence of mucin, as detected by periodic acid–Schiff (PAS) staining, is useful in distinguishing Paget disease from vulvar melanoma, which lacks mucin.

Intraepidermal Paget disease may persist for years or even decades without evidence of invasion. However, when there is an associated tumor involving skin appendages, the Paget cells may invade locally, and ultimately metastasize. Once metastasis occurs, the prognosis is poor.

### SUMMARY

#### Squamous Cell Carcinoma of the Vulva

- HPV-related vulvar squamous cell carcinomas usually are poorly differentiated lesions and sometimes are multifocal. They often evolve from vulvar intraepithelial neoplasia (VIN).
- Non–HPV-related vulvar squamous cell carcinomas occur in older women, usually are well differentiated and unifocal, and often are associated with lichen sclerosus or other inflammatory conditions.

#### Paget Disease of the Vulva

- Vulvar Paget disease is characterized by a red, scaly plaque caused by proliferation of malignant epithelial cells within the epidermis; usually, there is no underlying carcinoma, unlike Paget disease of nipple.
- Positive staining for PAS distinguishes Paget disease cells from melanoma.

## VAGINA

In adult fernales, the vagina is seldom a site of primary disease. More often, it is involved secondarily by cancer or infections arising in adjacent organs (e.g., cervix, vulva, bladder, rectum).

Congenital anomalies of the vagina fortunately are uncommon and include entities such as total absence of the vagina, a septate or double vagina (usually associated with a septate cervix and, sometimes, septate uterus), and congenital, lateral Gartner duct cysts arising from persistent wolffian duct rests.

### VAGINITIS

Vaginitis is a relatively common condition that is usually transient and of no clinical consequence. It is associated with production of a vaginal discharge (leukorrhea). A large variety of organisms have been implicated, including bacteria, fungi, and parasites. Many are normal commensals that become pathogenic only in the setting of diabetes, systemic antibiotic therapy (which causes disruption of normal microbial flora), immunodeficiency, pregnancy, or recent abortion. In adults, primary gonorrheal infection of the vagina is uncommon. The only other organisms worthy of mention, because they are frequent offenders, are *Candida albicans* and *Trichomonas vaginalis.* Candidal (monilial) vaginitis is characterized by a curdy white discharge. This organism is part of the normal vaginal flora in about 5% of women, so the appearance of symptomatic infection almost always involves one of the predisposing influences cited above or superinfection by a new, more aggressive strain. *T. vaginalis* produces a watery, copious gray-green discharge in which parasites can be identified by microscopy. *Trichomonas* also can be identified in about 10% of asymptomatic women; thus, active infection usually stems from sexual transmission of a new strain.

### MALIGNANT NEOPLASMS

#### Squamous Cell Carcinoma

Squamous cell carcinoma of the vagina is an extremely uncommon cancer that usually occurs in women older than 60 years of age in the setting of risk factors similar to those associated with carcinoma of the cervix (discussed later). Vaginal intraepithelial neoplasia is a precursor lesion that is nearly always associated with HPV infection. Invasive squamous cell carcinoma of the vagina is associated with the presence of HPV DNA in more than half of the cases, presumably derived from HPV-positive VIN.

### Clear Cell Adenocarcinoma

In 1970, clear cell adenocarcinoma, a very rare tumor, was identified in a cluster of young women whose mothers took diethylstilbestrol during pregnancy to prevent threatened abortion. Follow-up studies determined that the incidence of this tumor in persons exposed to diethylstilbestrol in utero was low (less than 1 per 1000, albeit about 40 times greater than in the unexposed population). However, since this agent was in wide use at the time it appears to be associated with a persistently elevated risk of cancer in those exposed. In about one third of exposed women, small glandular or microcystic inclusions appear in the vaginal mucosa. These benign lesions are seen as red, granular-appearing foci that on histologic examination are lined by mucus-secreting or ciliated columnar cells. This clinical condition is called *vaginal adenosis*, and it is from such precursor lesions that clear cell adenocarcinoma arises.

### Sarcoma Botryoides

Sarcoma botryoides (embryonal rhabdomyosarcoma) is a rare form of primary vaginal cancer that manifests as soft polypoid masses. It usually is encountered in infants and children younger than 5 years of age. It also may occur in other sites, such as the urinary bladder and bile ducts. These lesions are described in further detail in Chapter 20.

## CERVIX

Most cervical lesions are relatively banal inflammations (cervicitis), but the cervix also is the site of one of the most common cancers in women worldwide.

## CERVICITIS

Inflammatory conditions of the cervix are extremely common and are associated with a purulent vaginal discharge. Cervicitis can be subclassified as infectious or noninfectious, although differentiation is difficult owing to the presence of normal vaginal flora including incidental vaginal aerobes and anaerobes, streptococci, staphylococci, enterococci, and *Escherichia coli*.

Much more important are *Chlamydia trachomatis, Ureaplasma urealyticum, T. vaginalis, Candida* spp., *Neisseria gonorrhoeae,* HSV-2 (the agent of herpes genitalis), and certain types of HPV, all of which are often sexually transmitted. *C. trachomatis* is by far the most common of these pathogens, accounting for as many as 40% of cases of cervicitis encountered in sexually transmitted disease (STD) clinics. Although less common, herpetic infections are noteworthy because maternal-infant transmission during childbirth may result in serious, sometimes fatal systemic herpetic infection in the newborn.

### MORPHOLOGY

Nonspecific cervicitis may be either **acute** or **chronic.** The relatively uncommon **acute form** is limited to women in the postpartum period and usually is caused by staphylococci or streptococci. Chronic cervicitis consists of inflammation and epithelial regeneration, some degree of which is common in all women of reproductive age. The cervical epithelium may show hyperplasia and reactive changes in both squamous and columnar mucosae. Eventually, the columnar epithelium undergoes squamous metaplasia.

Cervicitis commonly comes to attention on routine examination or because of leukorrhea. Culture of the discharge must be interpreted cautiously, because (as mentioned previously) commensal organisms are virtually always present. Only the identification of known pathogens is helpful.

## NEOPLASIA OF THE CERVIX

*Most tumors of the cervix are of epithelial origin and are caused by oncogenic strains of human papillomavirus (HPV).* During development, the columnar, mucus-secreting epithelium of the endocervix is joined to the squamous epithelial covering of the exocervix at the cervical os. With the onset of puberty, the squamocolumnar junction undergoes eversion, causing columnar epithelium to become visible on the exocervix. The exposed columnar cells, however, eventually undergo squamous metaplasia, forming a region called the *transformation zone* (Fig. 18–4).

### PATHOGENESIS

HPV, the causative agent of cervical neoplasia, has a tropism for the immature squamous cells of the transformation zone. Most HPV infections are transient and are eliminated within months by an acute and chronic inflammatory response. A subset of infections persists, however, and some of these progress to cervical intraepithelial neoplasia (CIN), a

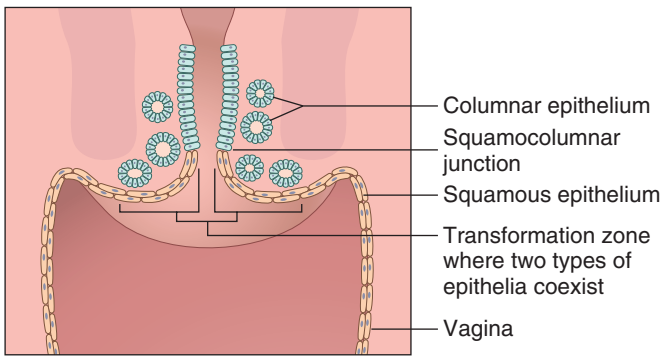

**Figure 18–4** Development of the cervical transformation zone.

precursor lesion from which most invasive cervical carcinomas develop.

HPV is detectable by molecular methods in nearly all cases of CIN and cervical carcinoma. Important risk factors for the development of CIN and invasive carcinoma thus are directly related to HPV exposure and include

- Early age at first intercourse
- Multiple sexual partners
- Male partner with multiple previous sexual partners
- Persistent infection by high-risk strains of papillomavirus

Although HPV infection occurs in the most immature squamous cells of the basal layer, replication of HPV DNA takes place in more differentiated overlying squamous cells. Squamous cells at this stage of maturation do not normally replicate DNA, but HPV-infected squamous cells do, as a consequence of expression of two potent oncoproteins encoded in the HPV genome called E6 and E7. The E6 and E7 proteins bind and inactivate two critical tumor suppressors, p53 and Rb, respectively (Chapter 5), and in doing so promote growth and increased susceptibility to additional mutations that may eventually lead to carcinogenesis.

Recognized serotypes of HPV can be classified as high-risk or low-risk types based on their propensity to induce carcinogenesis. High-risk HPV infection is the most important risk factor for the development of CIN and carcinoma. Two high-risk HPV strains, types 16 and 18, account for approximately 70% of cases of CIN and cervical carcinoma. In general, infections with high-risk HPV serotypes are more likely to persist, which is a risk factor for progression to carcinoma. These HPV subtypes also show a propensity to integrate into the host cell genome, an event that is linked to progression. Low-risk HPV strains (e.g., types 6 and 11), on the other hand, are associated with development of condylomas of the lower genital tract (Fig. 18–5) and do not integrate into the host genome, remaining instead as free episomal viral DNA. Despite the strong association of HPV infection with cancer of the cervix, HPV is not sufficient to drive the neoplastic process. As mentioned below, several HPV-infected high-grade precursor lesions do not progress to invasive cancer. The progression of cervical dysplasias to cervical cancers has been attributed to diverse factors such as immune and hormonal status, or co-infection with other sexually transmitted agents. More recently, somatically acquired mutations in the tumor suppressor gene *LKB1* were identified in more than 20% of cervical cancers. *LKB1* was first identified as the gene mutated in Peutz-Jeghers syndrome, an autosomal dominant condition characterized by hamartomatous polyps of the GI tract (Chapter 14) and a significantly elevated risk of epithelial malignancies at a variety of anatomic sites including the cervix. *LKB1* is also frequently inactivated in lung cancer. The LKB1 protein is a serine-threonine kinase that phosphorylates and activates AMPK, a metabolic sensor. AMPK in turn regulates cell growth through the mTOR complex.

## Cervical Intraepithelial Neoplasia (CIN)

HPV-related carcinogenesis begins with the precancerous epithelial change termed CIN, which usually precedes the development of an overt cancer by many years, sometimes decades. In keeping with this idea, CIN peaks in incidence at about 30 years of age, whereas invasive carcinoma peaks at about 45 years of age.

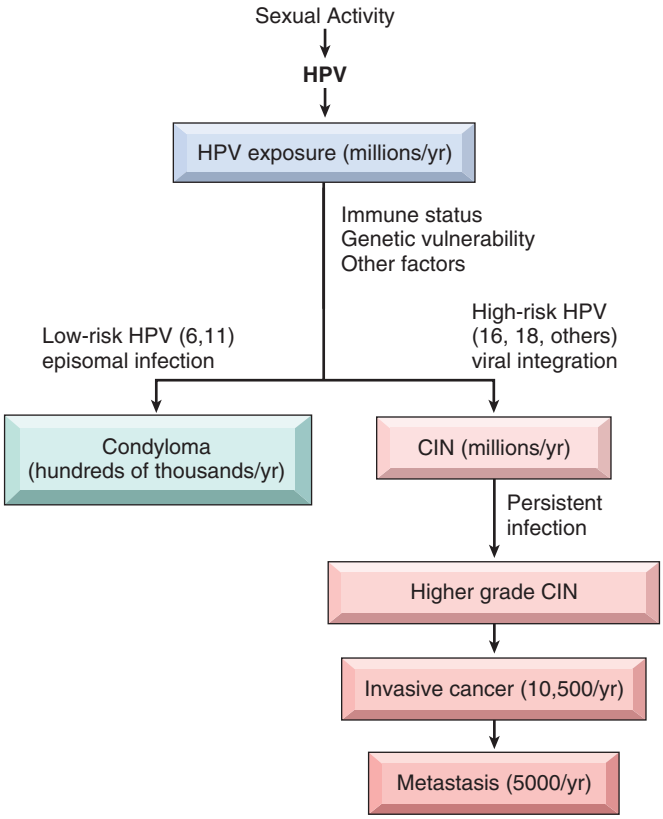

**Figure 18–5** Possible consequences of human papillomavirus (HPV) infection. Progression is associated with integration of virus and acquisition of additional mutations as discussed in the text. CIN, cervical intraepithelial neoplasia.

CIN usually starts as low-grade dysplasia (CIN I) and progresses to moderate (CIN II) and then severe dysplasia (CIN III) over time; exceptions have been reported, however, and some patients already have CIN III when the condition is first diagnosed. Generally speaking, the higher the grade of CIN, the greater the likelihood of progression; of note, however, in many cases, even high-grade lesions fail to progress to cancer and may even regress. Because decisions about patient management are two-tiered (i.e., observation versus surgical treatment), this three-tiered grading system has recently been simplified to a two-tiered system, with CIN I renamed **low-grade squamous intraepithelial lesion** (LSIL) and CIN II and CIN III combined into one category referred to as **high-grade squamous intraepithelial lesion** (HSIL). As shown in Table 18–1, the decision to treat HSIL and to observe LSIL is based on differences in the natural histories of these two groups of lesions.

**Table 18–1** Natural History of Squamous Intraepithelial Lesions (SILs)

| Lesion | Regress | Persist | Progress |
|---|---|---|---|
| LSIL (CIN I) | 60% | 30% | 10% (to HSIL) |
| HSIL (CIN II, III) | 30% | 60% | 10% (to carcinoma)* |

LSIL, low-grade SIL; HSIL, high-grade SIL.
*Progression within 10 years.

Cervical precancerous lesions are associated with abnormalities in cytologic preparations (Pap smears) that can be detected long before any abnormality is visible on gross inspection. Early detection of dysplastic changes is the rationale for the Papanicolaou (Pap) test, in which cells are scraped from the transformation zone and examined microscopically. To date, the Pap smear remains the most successful cancer screening test ever developed. In the United States, Pap screening has dramatically lowered the incidence of invasive cervical tumors to about 12,000 cases annually with a mortality of about 4000 per year; in fact, cervical cancer no longer ranks among the top 10 causes of cancer deaths in U.S. women. Paradoxically, the incidence of CIN has increased to its present level of more than 50,000 cases annually. Increased detection has certainly contributed to this.

The recently introduced quadrivalent HPV vaccine for types 6, 11, 16, and 18 is very effective in preventing HPV infections, which is expected to greatly lower the frequency of genital warts and cervical cancers associated with these HPV serotypes. Despite its efficacy, the vaccine does not supplant the need for routine cervical cancer screening—many at-risk women are already infected, and the vaccine protects against only some of the many oncogenic HPV serotypes.

### MORPHOLOGY

Figure 18–6 illustrates the three stages of CIN. **CIN I** is characterized by dyplastic changes in the lower third of the squamous epithelium and koilocytotic change in the superficial layers of the epithelium. In **CIN II,** dysplasia extends to the middle third of the epithelium and takes the form of delayed keratinocyte maturation. It also is associated with some variation in cell and nuclear size, heterogeneity of nuclear chromatin, and presence of mitoses above the basal layer extending into the middle third of the epithelium. The superficial layer of cells shows some differentiation and occasionally demonstrates the koilocytotic changes described. The next stage, **CIN III,** is marked by almost complete loss of maturation, even greater variation in cell and nuclear size, chromatin heterogeneity, disorderly orientation of the cells, and normal or abnormal mitoses; these changes affect virtually all layers of the epithelium. Koilocytotic change usually is absent. These histologic features correlate with the cytologic appearances shown in Figure 18–7. As mentioned previously, for clinical purposes CIN is divided into LSIL (CIN I) and HSIL (CIN II and CIN III).

CIN is asymptomatic and comes to clinical attention through an abnormal Pap smear result. These cases are followed up by colposcopy, during which acetic acid is used to highlight the location of lesions and the areas to be biopsied. Women with biopsy-documented LSIL are managed conservatively with careful observation, whereas HSILs are treated with surgical excision (cone biopsy). Follow-up smears and clinical examination are mandated for life in patients with HSIL, as these women remain at risk for HPV-associated cervical, vulvar, and vaginal cancers.

## Invasive Carcinoma of the Cervix

The most common cervical carcinomas are squamous cell carcinomas (75%), followed by adenocarcinomas and mixed adenosquamous carcinomas (20%) and small cell neuroendocrine carcinomas (less than 5%). All of these types of carcinomas are caused by HPV. Of interest, the relative proportion of adenocarcinomas has been increasing in recent decades owing to the decreasing incidence of invasive squamous carcinoma and suboptimal detection of glandular lesions by Pap smear.

Squamous cell carcinoma has a peak incidence at the age of about 45 years, some 10 to 15 years after detection of precursor CIN. As already discussed, progression of CIN to invasive carcinoma is variable and unpredictable and requires HPV infection as well as mutations in genes such as *LKB*. Risk factors for progression include cigarette smoking and human immunodeficiency virus

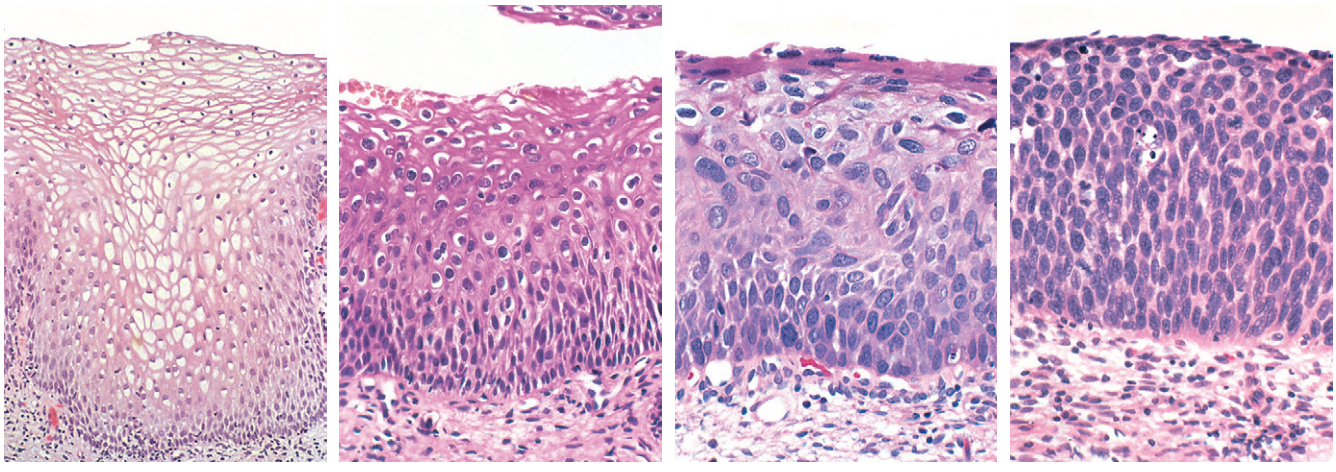

**Figure 18–6** Spectrum of cervical intraepithelial neoplasia (CIN), with normal squamous epithelium for comparison: CIN I with koilocytotic atypia; CIN II with progressive atypia in all layers of the epithelium; and CIN III (carcinoma in situ) with diffuse atypia and loss of maturation.

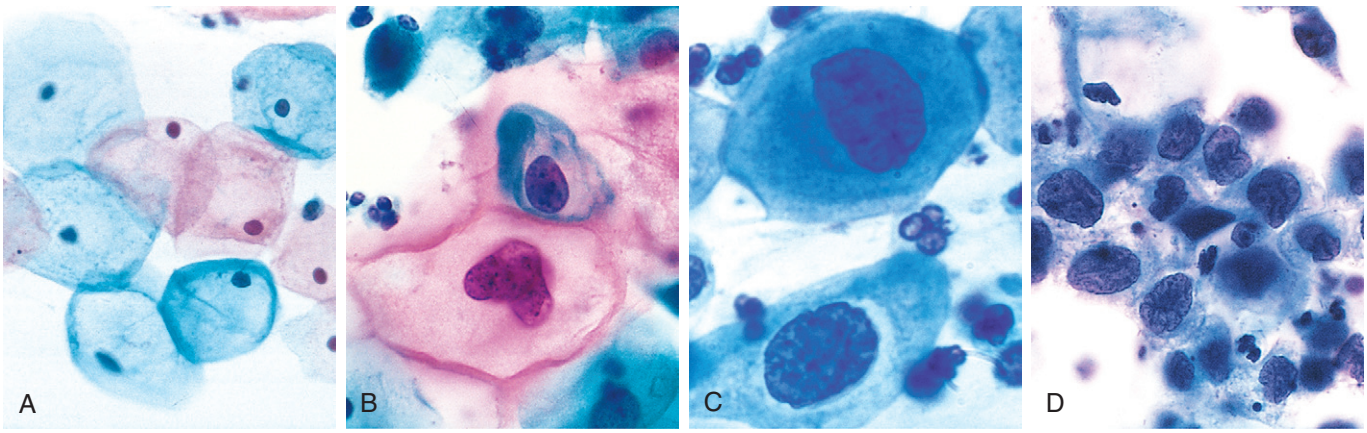

**Figure 18–7** Cytologic features of cervical intraepithelial neoplasia (CIN) in a Papanicolaou smear. Superficial squamous cells may stain either red or blue. **A,** Normal exfoliated superficial squamous epithelial cells. **B,** CIN I—low-grade squamous intraepithelial lesion (LSIL). **C** and **D,** CIN II and CIN III, respectively—both high-grade squamous intraepithelial lesions (HSILs). Note the reduction in cytoplasm and the increase in the nucleus-to-cytoplasm ratio as the grade of the lesion increases. This observation reflects the progressive loss of cellular differentiation on the surface of the cervical lesions from which these cells are exfoliated (Figure 18–6).
*(Courtesy of Dr. Edmund S. Cibas, Brigham and Women's Hospital, Boston, Massachusetts.)*

(HIV) infection, the latter finding suggesting that immune surveillance has a role in holding CIN in check. Although risk factors may help stratify patients who are likely to progress from CIN to carcinoma, the only reliable way to monitor the disease course is with frequent physical examinations coupled with biopsy of suspicious lesions.

## MORPHOLOGY

Invasive carcinomas of the cervix develop in the **transformation zone** and range from microscopic foci of stromal invasion to grossly conspicuous exophytic tumors (Fig. 18–8). Tumors encircling the cervix and penetrating into the underlying stroma produce a **barrel cervix,** which can be identified by direct palpation. Extension into the parametrial soft tissues can affix the uterus to the surrounding pelvic structures. The likelihood of spread to pelvic lymph nodes correlates with the depth of tumor invasion and the presence of tumor cells in vascular spaces. The risk of metastasis increases from less than 1% for tumors under 3 mm in depth to over 10% once invasion exceeds 3 mm. With the exception of unusual tumors exhibiting neuroendocrine differentiation, which are uniformly aggressive in their behavior, cervical carcinomas are graded based on their degree of squamous differentiation.

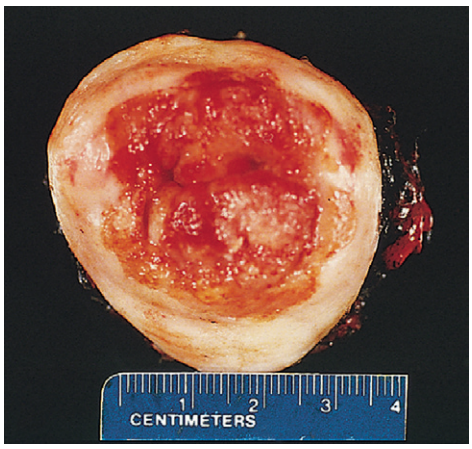

**Figure 18–8** Cervical os with surrounding, invasive, exophytic cervical carcinoma.

### Clinical Course

Invasive cervical cancer most often is seen in women who have never had a Pap smear or who have not been screened for many years. In such cases, cervical cancer often is symptomatic, with patients coming to medical attention for unexpected vaginal bleeding, leukorrhea, painful coitus (dyspareunia), or dysuria. Treatment is surgical by hysterectomy and lymph node dissection; small microinvasive carcinomas may be treated with cone biopsy. Mortality is most strongly related to tumor stage and, in the case of neuroendocrine carcinomas, to cell type. Most patients with advanced disease die as a result of local invasion rather than distant metastasis. In particular, renal failure stemming from obstruction of the urinary bladder and ureters is a common cause of death.

## SUMMARY

### Cervical Neoplasia

- Risk factors for cervical carcinoma are related to HPV exposure, such as early age at first intercourse, multiple sexual partners, and other factors including cigarette smoking and immunodeficiency.
- Nearly all cervical carcinomas are caused by HPV infections, particularly high-risk HPV types 16, 18, 31, and 33; the HPV vaccine is effective in preventing infection due to HPV types 16 and 18.
- HPV expresses E6 and E7 proteins that inactivate the p53 and Rb tumor suppressors, respectively, resulting in increased cell proliferation and suppression of DNA

damage–induced apoptosis. Loss of *LKB1* gene is also involved.
- In high-grade cervical dysplasias (CIN II and III), HPV is incorporated into the genome of the host cell.
- Not all HPV infections progress to CIN III or to invasive carcinoma. The time course from infection to invasive disease is usually 10 years or more. In general, the risk of progression is proportional to the degree of dysplasia.
- The Pap smear is a highly effective screening tool for the detection of cervical dysplasia and carcinoma and has significantly reduced the incidence of cervical carcinoma.

### Endocervical Polyp

Endocervical polyps are benign polypoid masses seen protruding from the endocervical mucosa (sometimes through the exocervix). They can be as large as a few centimeters, are soft and yielding to palpation, and have a smooth, glistening surface with underlying cystically dilated spaces filled with mucinous secretions. The surface epithelium and lining of the underlying cysts are composed of the same mucus-secreting columnar cells that line the endocervical canal. The stroma is edematous and may contain scattered mononuclear cells. Superimposed chronic inflammation may lead to squamous metaplasia of the overlying epithelium and ulcerations. These lesions may bleed, thereby arousing concern, but they have no malignant potential.

## BODY OF UTERUS

The uterine corpus is composed of endometrial mucosa and the underlying smooth muscle myometrium. The more frequent and significant disorders of the uterus are considered here.

## ENDOMETRITIS

Inflammation of the endometrium is classified as acute or chronic depending on whether a neutrophilic or a lymphoplasmacytic response predominates, respectively. The diagnosis of chronic endometritis generally requires the presence of plasma cells, as lymphocytes normally are seen in the endometrium.

Endometritis often is a consequence of pelvic inflammatory disease and is frequently due to *N. gonorrhoeae* or *C. trachomatis.* Histologic examination reveals a neutrophilic infiltrate in the superficial endometrium and glands coexisting with a stromal lymphoplasmacytic infiltrate. Prominent lymphoid follicles are more commonly seen in chlamydial infection. Tuberculosis causes granulomatous endometritis, frequently with associated tuberculous salpingitis and peritonitis. Although seen in the United States mainly in immunocompromised persons, tuberculous endometritis is common in countries where tuberculosis is endemic and should be included in the differential diagnosis for pelvic inflammatory disease in women who have recently emigrated from endemic areas.

Endometritis also may be due to retained products of conception, subsequent to miscarriage or delivery, or to presence of a foreign body such as an intrauterine device. Retained tissue or foreign bodies act as a nidus for ascending infection by vaginal or intestinal tract flora. Removal of the offending tissue or foreign body typically results in resolution.

Clinically, all forms of endometritis may manifest with fever, abdominal pain, and menstrual abnormalities. In addition, there is an increased risk of infertility and ectopic pregnancy as a consequence of damage and scarring of the fallopian tubes.

## ADENOMYOSIS

*Adenomyosis* refers to the growth of the basal layer of the endometrium down into the myometrium. Nests of endometrial stroma, glands, or both, are found deep in the myometrium interposed between the muscle bundles. The aberrant presence of endometrial tissue induces reactive hypertrophy of the myometrium, resulting in an enlarged, globular uterus, often with a thickened uterine wall. Because the glands in adenomyosis derive from the stratum basalis of the endometrium, they do not undergo cyclic bleeding. Nevertheless, marked adenomyosis may produce menorrhagia, dysmenorrhea, and pelvic pain before the onset of menstruation.

## ENDOMETRIOSIS

*Endometriosis* is defined by the presence of endometrial glands and stroma in a location outside the endomyometrium. It occurs in as many as 10% of women in their reproductive years and in nearly half of women with infertility. It frequently is multifocal and often involves pelvic structures (ovaries, pouch of Douglas, uterine ligaments, tubes, and rectovaginal septum). Less frequently, distant areas of the peritoneal cavity or periumbilical tissues are involved. Uncommonly, distant sites such as lymph nodes, lungs, and even heart, skeletal muscle, or bone are affected.

Three hypotheses have been put forth to explain the origin of these dispersed lesions (Fig. 18–9). The *regurgitation theory,* which is currently favored, proposes that menstrual backflow through the fallopian tubes leads to implantation. The *metaplastic theory*, on the other hand, posits endometrial differentiation of coelomic epithelium (from which endometrium originates) as the source. These two theories cannot, however, explain lesions in the lymph nodes, skeletal muscle, or lungs. Hence, the *vascular* or *lymphatic dissemination theory* has been invoked to explain

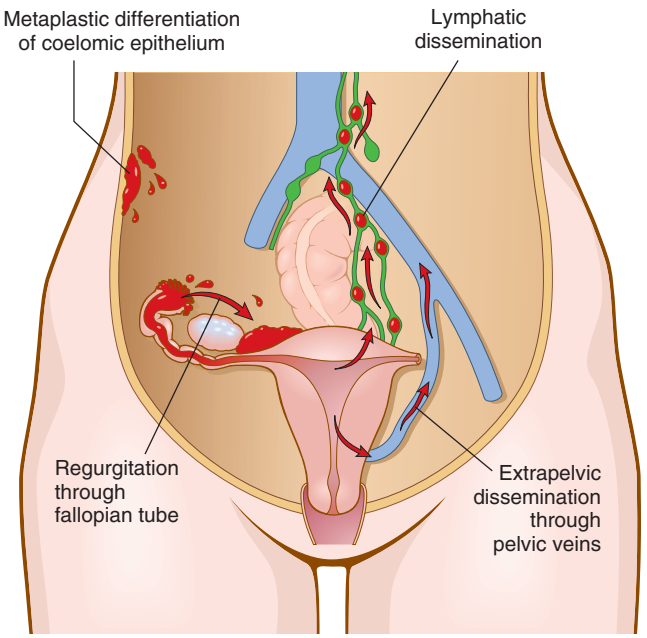

**Figure 18–9** Proposed origins of endometriosis.

extrapelvic or intranodal implants. Conceivably, all pathways could be valid in individual instances.

Recent studies suggest that the *endometriotic tissue is not just misplaced but is also abnormal.* As compared to normal endometrium, endometriotic tissue exhibits increased levels of inflammatory mediators, particularly prostaglandin E2, and increased estrogen production due to high aromatase activity of stromal cells. These changes enhance the survival and persistence of the endometriotic tissue within a foreign location (a key feature in the pathogenesis of endometriosis) and help to explain the beneficial effects of COX-2 inhibitors and aromatase inhibitors in the treatment of endometriosis.

## MORPHOLOGY

In contrast with adenomyosis, **endometriosis** almost always contains **functioning endometrium,** which undergoes cyclic bleeding. Because blood collects in these aberrant foci, they usually appear grossly as red-brown nodules or implants. They range in size from microscopic to 1 to 2 cm in diameter and lie on or just under the affected serosal surface. Often, individual lesions coalesce to form larger masses. When the ovaries are involved, the lesions may form large, blood-filled cysts that turn brown **(chocolate cysts)** as the blood ages (Fig. 18–10). With seepage and organization of the blood, widespread fibrosis occurs, leading to adhesions among pelvic structures, sealing of the tubal fimbriated ends, and distortion of the oviducts and ovaries. The histologic diagnosis at all sites depends on finding two of the following three features within the lesions: endometrial glands, endometrial stroma, and hemosiderin pigment.

### Clinical Features

The clinical manifestations of endometriosis depend on the distribution of the lesions. Extensive scarring of the oviducts and ovaries often produces discomfort in the lower abdominal quadrants and eventual sterility. Rectal wall involvement may produce pain on defecation, while involvement of the uterine or bladder serosa can cause dyspareunia (painful intercourse) and dysuria, respectively. Almost all cases feature severe dysmenorrhea and pelvic pain resulting from intrapelvic bleeding and periuterine adhesions.

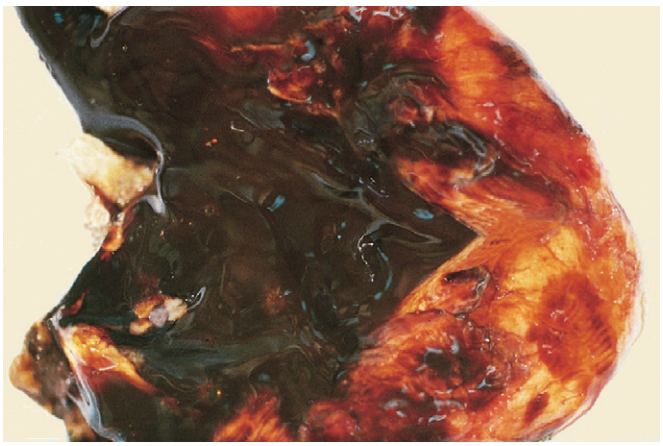

**Figure 18–10** Ovarian endometriosis. Sectioning of ovary reveals a large endometriotic cyst with degenerated blood ("chocolate cyst").

## ABNORMAL UTERINE BLEEDING

Women commonly seek medical attention for some type of abnormal uterine bleeding such as *menorrhagia* (profuse or prolonged bleeding at the time of the period), *metrorrhagia* (irregular bleeding between the periods), or postmenopausal bleeding. Common causes include endometrial polyps, leiomyomas, endometrial hyperplasia, endometrial carcinoma, and endometritis.

The probable cause of uterine bleeding in any given case depends somewhat on the age of the patient (Table 18–2). Abnormal bleeding from the uterus in the absence of an organic uterine lesion is called *dysfunctional uterine bleeding.* The various causes of abnormal uterine bleeding, both dysfunctional and that which is secondary to an organic lesion, can be segregated into four groups:

**Table 18–2** Causes of Abnormal Uterine Bleeding by Age Group

| Age Group | Cause(s) |
|---|---|
| Prepuberty | Precocious puberty (hypothalamic, pituitary, or ovarian origin) |
| Adolescence | Anovulatory cycle |
| Reproductive age | Complications of pregnancy (abortion, trophoblastic disease, ectopic pregnancy)<br>Proliferations (leiomyoma, adenomyosis, polyps, endometrial hyperplasia, carcinoma)<br>Anovulatory cycle<br>Ovulatory dysfunctional bleeding (e.g., inadequate luteal phase) |
| Perimenopause | Anovulatory cycle<br>Irregular shedding<br>Proliferations (carcinoma, hyperplasia, polyps) |
| Postmenopause | Proliferations (carcinoma, hyperplasia, polyps)<br>Endometrial atrophy |

- *Failure of ovulation.* Anovulatory cycles are very common at both ends of reproductive life, due to (1) hypothalamic-pituitary axis, adrenal, or thyroid dysfunction; (2) functional ovarian lesions producing excess estrogen; (3) malnutrition, obesity, or debilitating disease; and (4) severe physical or emotional stress. Regardless of the cause, ovulatory failure results in an excess of estrogen relative to progesterone. Thus, the endometrium goes through a proliferative phase that is not followed by the normal secretory phase. The endometrial glands may develop mild cystic changes or appear disorderly (Fig. 18–11, *A*), while the endometrial stroma, which requires progesterone for growth, may be scarce. This combination of abnormalities makes the endometrium prone to breakdown and abnormal bleeding.
- *Inadequate luteal phase.* The corpus luteum may fail to mature normally or may regress prematurely leading to a relative lack of progesterone. The endometrium under these circumstances fails to show the expected secretory changes.
- *Contraceptive-induced bleeding.* Older oral contraceptives containing synthetic estrogens and progestin induced a variety of endometrial responses, including a lush, decidua-like stroma and inactive, nonsecretory glands. The pills in current use no longer cause these abnormalities.
- *Endomyometrial disorders,* including chronic endometritis, endometrial polyps, and submucosal leiomyomas

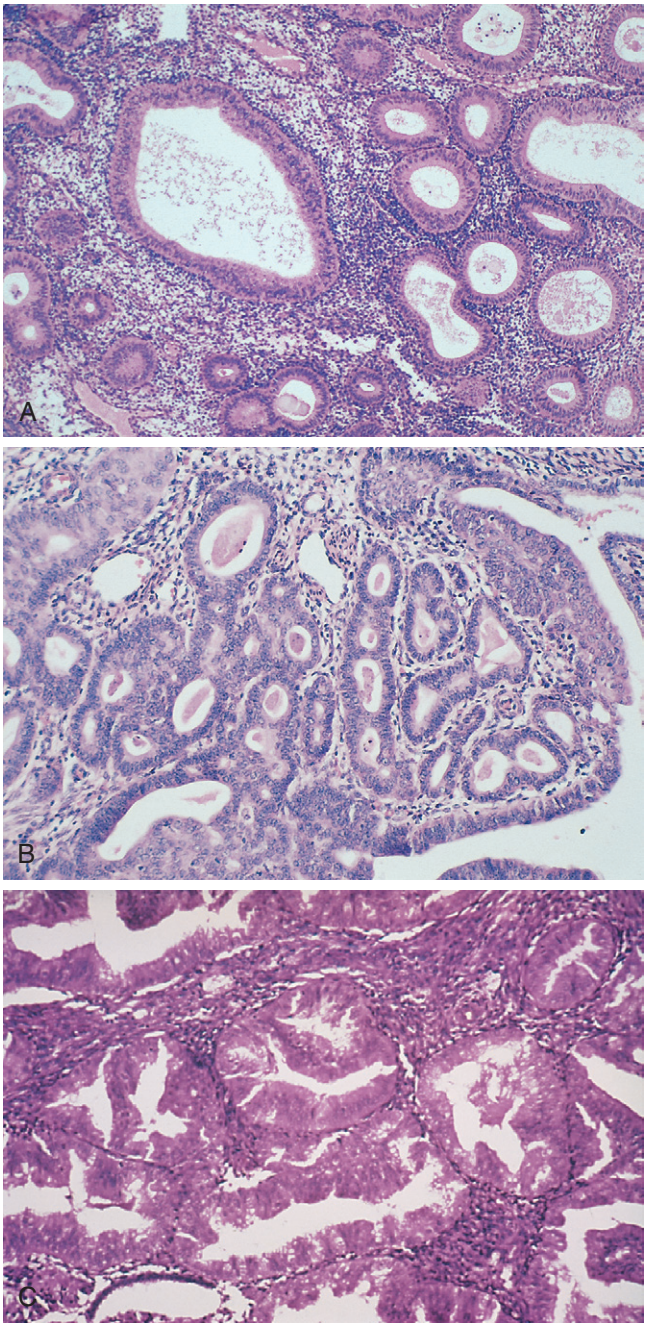

**Figure 18–11** Endometrial hyperplasia. **A,** Anovulatory or "disordered" endometrium containing dilated glands. **B,** Complex hyperplasia without atypia, characterized by nests of closely packed glands. **C,** Complex hyperplasia with atypia, seen as glandular crowding and cellular atypia.

### SUMMARY

#### Non-neoplastic Disorders of Endometrium

- Endometriosis refers to endometrial glands and stroma located outside the uterus and may involve the pelvic or abdominal peritoneum. Rarely, distant sites like the lymph nodes and the lungs also are involved.
- The ectopic endometrium in endometriosis undergoes cyclic bleeding, and the condition is a common cause of dysmenorrhea and pelvic pain.
- Adenomyosis refers to growth of endometrium into the myometrium with uterine enlargement. Unlike with endometriosis, there is no cyclic bleeding.

## PROLIFERATIVE LESIONS OF THE ENDOMETRIUM AND MYOMETRIUM

The most common proliferative lesions of the uterine corpus are endometrial hyperplasia, endometrial carcinomas, endometrial polyps, and smooth muscle tumors. All tend to produce abnormal uterine bleeding as their earliest manifestation.

### Endometrial Hyperplasia

An excess of estrogen relative to progestin, if sufficiently prolonged or marked, can induce exaggerated endometrial proliferation (hyperplasia), which is an important precursor of endometrial carcinoma. Potential causes of estrogen excess include failure of ovulation (such as is seen in perimenopause), prolonged administration of estrogenic steroids without counterbalancing progestin, and estrogen-producing ovarian lesions (such as polycystic ovary disease and granulosa-theca cell tumors of the ovary). A common cause of estrogen excess is obesity, as adipose tissue converts steroid precursors into estrogens.

The severity of hyperplasia is correlated with the level and duration of estrogen excess, and is classified based on architectural crowding (simple versus complex) and the

presence or absence of cytologic atypia (Fig. 18–11, *B* and *C*). The risk of developing carcinoma is related to the presence of cellular atypia. Complex hyperplasia without cellular atypia carries a low risk (less than 5%) for progression to endometrial carcinoma, while complex hyperplasia with cellular atypia is associated with a much higher risk (20% to 50%). When hyperplasia with atypia is discovered, it must be carefully evaluated for the presence of cancer and must be monitored by serial endometrial biopsies.

In time, the hyperplasia may proliferate autonomously, no longer requiring estrogen, and eventually may give rise to carcinoma. In a significant number of cases, the hyperplasia is associated with inactivating mutations in the *PTEN* tumor suppressor gene, an important brake on signaling through the PI-3-kinase/AKT signaling pathway. Acquisition of *PTEN* mutations is believed to be one of several key steps in the transformation of hyperplasias to endometrial carcinomas, which also often harbor *PTEN* mutations.

## Endometrial Carcinoma

In the United States and many other Western countries, endometrial carcinoma is the most frequent cancer occurring in the female genital tract. It generally appears between the ages of 55 and 65 years and is uncommon before age 40. Endometrial carcinomas comprise two distinct kinds of cancer: *endometrioid* and *serous carcinoma of the endometrium*. These two types are histologically and pathogenetically distinct. Endometrioid cancers arise in association with estrogen excess and endometrial hyperplasia in perimenopausal women, whereas serous cancers arise in the setting of endometrial atrophy in older postmenopausal women.

### PATHOGENESIS

The endometrioid type accounts for 80% of cases of endometrial carcinomas. These tumors are designated **endometrioid** because of their histologic similarity to normal endometrial glands. Risk factors for this type of carcinoma include (1) obesity, (2) diabetes, (3) hypertension, (4) infertility, and (5) exposure to unopposed estrogen. Many of these risk factors result in increased estrogenic stimulation of the endometrium and are associated with endometrial hyperplasia. In fact, it is well recognized that prolonged estrogen replacement therapy and estrogen-secreting ovarian tumors increase the risk of endometrioid type of endometrial carcinoma. Additionally, breast carcinoma (which also is estrogen-dependent) occurs in women with endometrial cancer (and vice versa) more frequently than by chance alone. **Mutations in mismatch repair genes and the tumor suppressor gene PTEN are early events in the stepwise development of endometrioid carcinoma.** Women with germline mutations in *PTEN* (Cowden syndrome) are at high risk for this cancer. *TP53* mutations occur but are relatively uncommon and are believed to be late events in the genesis of this tumor type.

The **serous type** of endometrial carcinoma is much less common, accounting for roughly 15% of tumors. Nearly all cases have mutations in the *TP53* tumor suppressor gene, whereas mutations in DNA mismatch repair genes and *PTEN* are rare.

### MORPHOLOGY

**Endometrioid carcinomas** closely resemble normal endometrium and may be exophytic or infiltrative (Fig. 18–12, *A* and *B*). They include a range of histologic types, including those showing mucinous, tubal (ciliated), and squamous (occasionally adenosquamous) differentiation. Tumors originate in the mucosa and may infiltrate the myometrium and enter vascular spaces. They may also metastasize to regional lymph nodes. Endometrioid carcinomas are graded I to III, based on the degree of differentiation. **Serous carcinomas,** on the other hand, form small tufts and papillae, rather than the glands seen in endometrioid carcinoma, and exhibit much greater cytologic atypia. They behave aggressively and thus are by definition high-grade. Immunohistochemistry often reveals high levels of p53 in serous carcinoma (Fig. 18–12, *C* and *D*), a finding that correlates with the presence of *TP53* mutations (mutant p53 accumulates and hence is more easily detected by staining).

### Clinical Course

Endometrial carcinomas usually manifest with leukorrhea and irregular bleeding, often in postmenopausal women. With progression, the uterus enlarges and may become affixed to surrounding structures as the cancer infiltrates surrounding tissues. These tumors usually are slow to metastasize, but if left untreated, eventually disseminate to regional nodes and more distant sites. With therapy, the 5-year survival rate for early-stage carcinoma is 90%, but survival drops precipitously in higher-stage tumors. The prognosis with serous carcinomas is strongly dependent on operative staging and cytologic screening of peritoneal washings; the latter is imperative, because very small or superficial serous tumors may nonetheless spread by way of the fallopian tube to the peritoneal cavity.

### SUMMARY

#### Endometrial Hyperplasia and Endometrial Carcinoma

- Endometrial hyperplasia results from excess endogenous or exogenous estrogen.
- Risk factors for developing endometrial hyperplasia include anovulatory cycles, polycystic ovary syndrome, estrogen-producing ovarian tumor, obesity, and estrogen therapy without counterbalancing progestin.
- The severity of hyperplasia is graded on the basis of architectural (simple versus complex) and cytologic (normal versus atypical) criteria. The risk of developing carcinoma is predominantly related to cytologic atypia.
- On the basis of clinical and molecular data, two major types of endometrial carcinoma are recognized:
  - *Endometrioid carcinoma* is associated with estrogen excess and endometrial hyperplasia. Early molecular changes include inactivation of DNA mismatch repair genes and the *PTEN* gene.
  - *Serous carcinoma* of the endometrium arises in older women and usually is associated with endometrial atrophy. Mutations in the *TP53* gene are an early event.

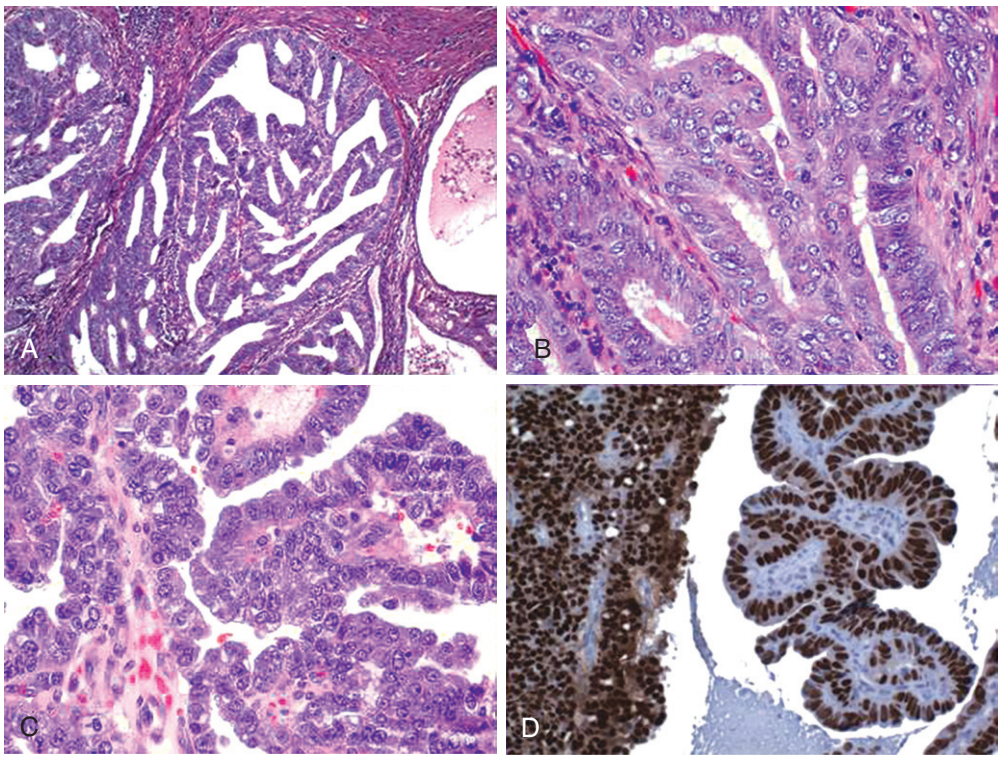

**Figure 18–12** Endometrial carcinoma. **A,** Endometrioid type, infiltrating myometrium and growing in a cribriform pattern. **B,** Higher magnification reveals loss of polarity and nuclear atypia. **C,** Serous carcinoma of the endometrium, with papilla formation and marked cytologic atypia. **D,** Immunohistochemical staining reveals accumulation of p53, a finding associated with *TP53* mutation.

- Stage is the major determinant of survival in both types. Serous tumors tend to manifest more frequently with extrauterine extension and therefore have a worse prognosis than endometrioid carcinomas.

## Endometrial Polyps

These sessile, usually hemispheric lesions range from 0.5 to 3 cm in diameter. Larger polyps may project from the endometrial mucosa into the uterine cavity. On histologic examination, they are composed of endometrium resembling the basalis, frequently with small muscular arteries. Some glands have a normal endometrial architecture, but more often they are cystically dilated. The stromal cells are monoclonal, often with a rearrangement of chromosomal region 6p21, and thus constitute the neoplastic component of the polyp.

Although endometrial polyps may occur at any age, they most commonly are detected around the time of menopause. Their clinical significance lies in abnormal uterine bleeding and, more important, in the risk (however rare) of giving rise to a cancer.

## Leiomyoma

Benign tumors that arise from the smooth muscle cells in the myometrium are properly termed *leiomyomas.* Because of their firmness, however, they often are referred to clinically as *fibroids.* Leiomyomas are the most common benign tumor in females, affecting 30% to 50% of women of reproductive age, and are considerably more frequent in blacks than in whites. These tumors are monoclonal and are associated with several different recurrent chromosomal abnormalities, including rearrangements of chromosomes 6 and 12 that also are found in a variety of other benign neoplasms, such as endometrial polyps and lipomas. Estrogens and possibly oral contraceptives stimulate the growth of leiomyomas; conversely, these tumors shrink postmenopausally.

### MORPHOLOGY

Leiomyomas are typically **sharply circumscribed,** firm gray-white masses with a characteristic **whorled cut surface.** They may occur singly, but more often **multiple tumors** are scattered within the uterus, ranging from small nodules to large tumors (Fig. 18–13) that may dwarf the uterus. Some are embedded within the myometrium (intramural), whereas others may lie directly beneath the endometrium (submucosal) or directly beneath the serosa (subserosal). In the latter location, tumors may extend out on attenuated stalks and even become attached to surrounding organs, from which they may develop a blood supply (**parasitic** leiomyomas). On histologic examination, the tumors are characterized by **bundles of smooth muscle cells** mimicking the appearance of normal myometrium. Foci of fibrosis, calcification, and degenerative softening may be present.

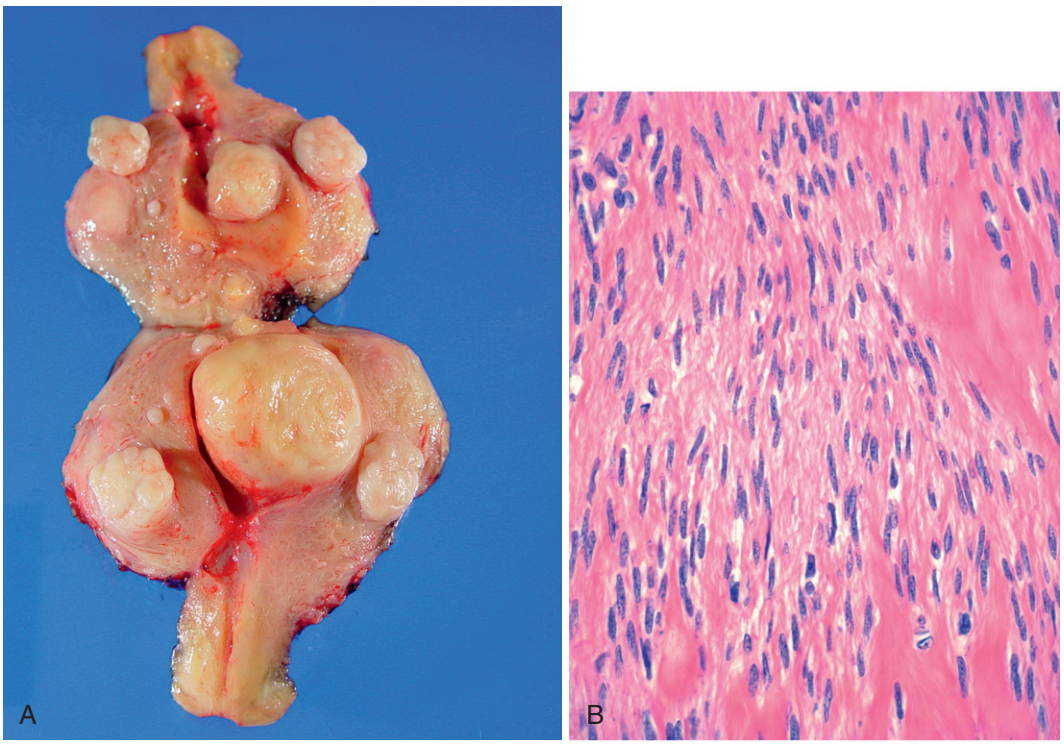

**Figure 18–13** Uterine leiomyomas. **A,** The uterus is opened to reveal multiple submucosal, myometrial, and subserosal gray-white tumors, each with a characteristic whorled appearance on cut section **B.** Microscopic appearance of leiomyoma reveals bundles of normal-looking smooth muscle cells.

*Leiomyomas* of the uterus often are asymptomatic, being discovered incidentally on routine pelvic examination. The most frequent presenting sign is menorrhagia, with or without metrorrhagia. Large leiomyomas may be palpated by the affected woman or may produce a dragging sensation. Leiomyomas almost never transform into sarcomas, and the presence of multiple lesions does not increase the risk of malignancy.

## Leiomyosarcoma

*Leiomyosarcomas* arise de novo from the mesenchymal cells of the myometrium, not from preexisting leiomyomas. They are almost always solitary and most often occur in postmenopausal women, in contradistinction to leiomyomas, which frequently are multiple and usually arise premenopausally.

### MORPHOLOGY

Leiomyosarcomas typically take the form of **soft, hemorrhagic, necrotic masses.** The histologic appearance varies widely, from tumors that closely resemble leiomyoma to wildly anaplastic neoplasms. Those well-differentiated tumors that lie at the interface between leiomyoma and leiomyosarcoma are sometimes designated smooth muscle tumors of uncertain malignant potential; in such cases, only time will tell if the tumor's behavior is benign or malignant. The diagnostic features of overt leiomyosarcoma include **tumor necrosis, cytologic atypia, and mitotic activity.** Since increased mitotic activity is sometimes seen in benign smooth muscle tumors, particularly in young women, an assessment of all three features is necessary to make a diagnosis of malignancy.

Recurrence after removal is common with these cancers, and many metastasize, typically to the lungs, yielding a 5-year survival rate of about 40%. The outlook with anaplastic tumors is less favorable than with well-differentiated tumors.

### SUMMARY

#### Uterine Smooth Muscle Neoplasms

- Benign smooth muscle tumors, called leiomyomas, are common and frequently multiple; they may manifest with menorrhagia or as a pelvic mass or may be detected as a cause of infertility.
- Malignant smooth muscle tumors, called leiomyosarcomas, arise de novo, not from leiomyomas.
- Criteria of malignancy include necrosis, cytologic atypia, and mitotic activity.

# FALLOPIAN TUBES

The most common disorder of the fallopian tubes is inflammation (salpingitis), almost invariably occurring as a component of pelvic inflammatory disease. Less common abnormalities are ectopic (tubal) pregnancy, endometriosis, and, rarely, primary tumors.

*Inflammations of the tube* are almost always microbial in origin. With the declining incidence of gonorrhea, nongonococcal organisms, such as *Chlamydia, Mycoplasma hominis,* coliforms, and (in the postpartum setting) streptococci and staphylococci, are now the major offenders. The morphologic changes produced by gonococci are similar to those in the male genital tract (Chapter 17). Nongonococcal infections can penetrate the wall of the tubes, giving rise to blood-borne infections, with seeding of the meninges, joint spaces, and sometimes even the heart valves. Tuberculous salpingitis is far less common and is almost always encountered in combination with tuberculous endometritis. All forms of salpingitis may produce fever, lower abdominal or pelvic pain, and pelvic masses, which are the result of distention of the tubes with either exudate or inflammatory debris (Fig. 18–14). Adherence of the inflamed tube to the ovary and adjacent ligamentous tissues may result in a *tuboovarian abscess,* referred to as a tuboovarian complex when infection subsides. Even more serious are adhesions of the tubal plicae, which are associated with increased risk of tubal ectopic pregnancy (discussed later). Damage to or obstruction of the tubal lumina may produce permanent sterility.

*Primary adenocarcinomas* of the fallopian tubes may be of serous or endometrioid histologic type. Although less common than ovarian tumors, serous fallopian tube carcinomas seem to be increased in women with *BRCA* mutations. In studies of prophylactic oophorectomies in such women, 10% had occult foci of malignancy, equally divided between the ovary and the fallopian tube, where they usually occurred in the fimbria. This has led to the suggestion that sporadic "ovarian" serous carcinomas (discussed later) may also originate in the fallopian tube, an idea that remains controversial. Because the fallopian tube provides access to the peritoneal cavity, fallopian tube carcinomas frequently involve the omentum and peritoneal cavity at presentation.

## SUMMARY

### Fallopian Tube Disease

- Salpingitis is usually a component of pelvic inflammatory disease; it results in scarring of the fallopian tube lining, increasing the risk of tubal ectopic pregnancy.
- Fallopian tube carcinomas usually manifest at an advanced stage, with involvement of the peritoneal cavity.

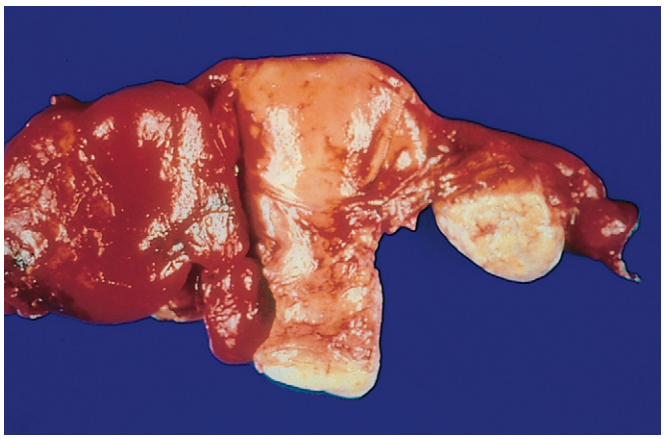

**Figure 18–14** Pelvic inflammatory disease, bilateral and asymmetric. The tube and ovary to the left of the uterus is totally obscured by a hemorrhagic inflammatory mass. The tube is adherent to the adjacent ovary on the other side.

# OVARIES

## FOLLICLE AND LUTEAL CYSTS

Follicle and luteal cysts in the ovaries are so commonplace that they may be considered variants of normal physiology. These innocuous lesions originate from unruptured graafian follicles or from follicles that have ruptured and then become immediately sealed. Such cysts often are multiple and develop subjacent to the serosal covering of the ovary. They typically are small (1 to 1.5 cm in diameter) and are filled with clear serous fluid. Occasionally, they become sufficiently large (4 to 5 cm) to produce palpable masses and pelvic pain. When small, they are lined by granulosa lining cells or luteal cells, but as fluid accumulates, pressure may cause atrophy of these cells. Sometimes these cysts rupture, producing intraperitoneal bleeding and peritoneal symptoms (acute abdomen).

## POLYCYSTIC OVARIAN DISEASE

*Polycystic ovarian disease* (formerly called *Stein-Leventhal syndrome*) is a disorder in which multiple cystic follicles in the ovaries produce excess androgens and estrogens. It usually comes to attention after menarche in teenage girls or young adults who present with oligomenorrhea, hirsutism, infertility, and sometimes obesity.

The ovaries are usually twice the normal size, gray-white with a smooth outer cortex, and studded with subcortical cysts 0.5 to 1.5 cm in diameter. Histologic examination reveals a thickened, fibrotic ovarian capsule overlying innumerable cystic follicles lined by granulosa cells with a hyperplastic luteinized theca interna. There is a conspicuous absence of corpora lutea in the ovary.

In most patients, the principal biochemical abnormalities are excessive production of androgens, high concentrations of luteinizing hormone, and low concentrations of follicle-stimulating hormone. The origins of these changes are poorly understood, but it is proposed that the ovaries elaborate excess androgens, which are converted to estrogenic hormones in peripheral fatty depots, which inhibit the secretion of follicle-stimulating hormone by the pituitary through the hypothalamus.

## TUMORS OF THE OVARY

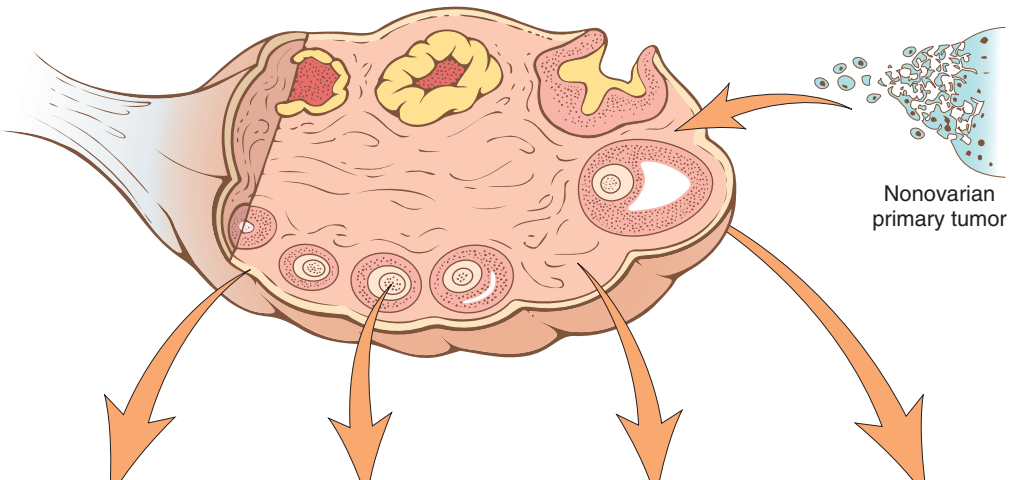
With more than 20,000 new cases diagnosed annually, ovarian cancer is the eighth most common cancer in U.S. women. It also is the fifth leading contributor to cancer mortality in women, with an estimated 14,000 deaths in 2010. Tumors of the ovary are amazingly varied. This diversity is attributable to the presence of three cell types in the normal ovary: the multipotent surface (coelomic) epithelium, the totipotent germ cells, and the sex cord–stromal cells, each of which gives rise to a number of different tumors (Fig. 18–15).

Neoplasms of surface epithelial origin account for the great majority of primary ovarian tumors and, in their malignant forms, account for almost 90% of ovarian cancers. Germ cell and sex cord–stromal cell tumors are much less frequent; although they constitute 20% to 30% of ovarian tumors, they are collectively responsible for less than 10% of malignant tumors of the ovary.

### Surface Epithelial Tumors

The vast majority of ovarian neoplasms is derived from the coelomic epithelium that covers the surface of the ovary. With repeated ovulation and scarring, surface epithelium becomes entrapped in the cortex of the ovary, forming small epithelial cysts. These can become metaplastic or undergo neoplastic transformation to give rise to a number of different epithelial tumors. Benign lesions usually are cystic (cystadenoma) and may have an accompanying stromal component (cystadenofibroma). Malignant tumors may also be cystic (cystadenocarcinoma) or solid (carcinoma). Some ovarian epithelial tumors fall into an intermediate, borderline category currently referred to as *tumors of low malignant potential*. These are best considered low-grade cancers with limited invasive potential and understandably carry a better prognosis than that for overtly malignant ovarian carcinomas.

Important risk factors for ovarian cancer include nulliparity, family history, and germline mutations in certain tumor suppressor genes. There is a higher incidence of carcinoma in unmarried women and married women with low parity. Of interest, prolonged use of oral contraceptives



| ORIGIN | SURFACE EPITHELIAL CELLS (Surface epithelial–stromal cell tumors) | GERM CELL | SEX CORD–STROMA | METASTASIS TO OVARIES |
|---|---|---|---|---|
| Overall frequency | 65%–70% | 15%–20% | 5%–10% | 5% |
| Proportion of malignant ovarian tumors | 90% | 3%–5% | 2%–3% | 5% |
| Age group affected | 20+ years | 0–25+ years | All ages | Variable |
| Types | • Serous tumor<br>• Mucinous tumor<br>• Endometrioid tumor<br>• Clear cell tumor<br>• Brenner tumor<br>• Cystadenofibroma | • Teratoma<br>• Dysgerminoma<br>• Endodermal sinus tumor<br>• Choriocarcinoma | • Fibroma<br>• Granulosa-theca cell tumor<br>• Sertoli-Leydig cell tumor | |

**Figure 18–15** Derivation, frequency, and age distribution for various ovarian neoplasms.

somewhat reduces the risk. Around 5% to 10% of ovarian cancers are familial, and most of these are associated with mutations in *BRCA1* and *BRCA2* tumor suppressor genes. As will be discussed later, mutations in *BRCA1* and *BRCA2* are also associated with hereditary breast cancer. The average lifetime risk for ovarian cancer approximates 30% in *BRCA1* carriers; the risk in *BRCA2* carriers is somewhat lower. In contrast with familial ovarian cancer, mutations in *BRCA1* and *BRCA2* are found in only 8% to 10% of sporadic ovarian cancers, which appear to arise through alternative molecular mechanisms.

## Serous Tumors

Serous tumors are the most common of the ovarian epithelial tumors. About 60% are benign, 15% are of low malignant potential, and 25% are malignant. Benign lesions are usually encountered in patients between 30 and 40 years of age, and malignant serous tumors are more commonly seen between 45 and 65 years of age. Taken together, borderline and malignant serous tumors are the most common ovarian malignancies, accounting for about 60% of all ovarian cancers.

Emerging evidence indicates that there are two types of serous carcinomas: low-grade and high-grade. The former arise from benign or borderline lesions and progress slowly in a stepwise manner to become invasive carcinoma. These low-grade tumors are associated with *KRAS*, *BRAF*, or *ERBB2* mutations. The high-grade serous tumors develop rapidly. As already mentioned, at least some of these high-grade lesions develop from tubal intraepithelial carcinoma, rather than ovarian coelomic epithelium. Recent "deep sequencing" of high-grade serous carcinomas has confirmed that 96% of tumors have mutations in *TP53*. Mutations affecting the Notch signaling pathway and FOXM1, a transcription factor previously implicated in the pathogenesis of ovarian carcinoma, were also detected in a sizable minority of tumors.

### MORPHOLOGY

Most serous tumors are large, spherical to ovoid, cystic structures up to 30 to 40 cm in diameter. **About 25% of the benign tumors are bilateral.** In the benign tumors, the serosal covering is smooth and glistening. By contrast, the surface of the cystadenocarcinoma has nodular irregularities representing areas in which the tumor has penetrated into the serosa. On cut section, small cystic tumors may have a single cavity, but larger ones frequently are divided by multiple septa into multiloculated masses. The cystic spaces usually are filled with a clear serous fluid. Protruding into the cystic cavities are papillary projections, which are more prominent in malignant tumors (Fig. 18–16).

On histologic examination, benign tumors contain a single layer of **tall columnar epithelial cells** that line the cyst or cysts. The cells often are ciliated. **Psammoma bodies** (concentrically laminated calcified concretions) are common in the tips of papillae. When frank carcinoma develops, anaplasia of the lining cells appears, as does invasion of the stroma. In carcinoma, papillary formations are complex and multilayered, and nests or undifferentiated sheets of malignant cells invade the axial fibrous tissue. Between clearly benign and obviously malignant forms lie **tumors of low malignant potential,** which exhibit less cytologic atypia and, typically, little or no stromal invasion. Tumors of low malignant potential may seed the peritoneum, but fortunately the tumor implants usually are "noninvasive." In general, malignant serous tumors spread to regional lymph nodes, including periaortic lymph nodes; distant lymphatic and hematogenous metastases are infrequent.

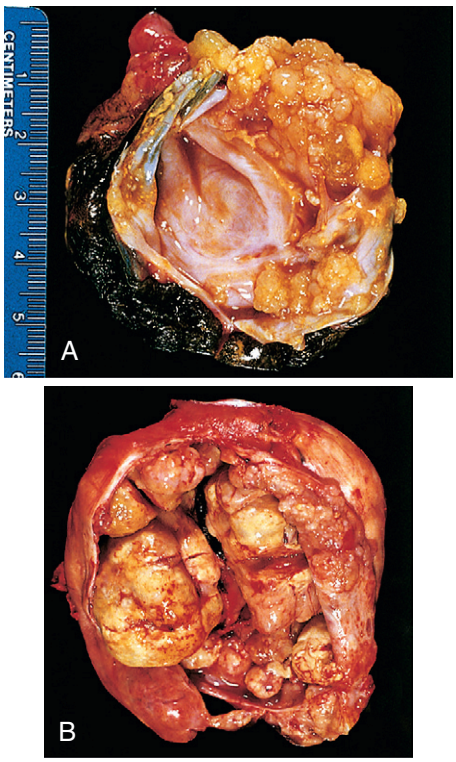


**Figure 18–16** Ovarian serous tumors. **A,** Borderline serous cystadenoma opened to display a cyst cavity lined by delicate papillary tumor growths. **B,** Cystadenocarcinoma. The cyst is opened to reveal a large, bulky tumor mass.
*(Courtesy of Dr. Christopher Crum, Brigham and Women's Hospital, Boston, Massachusetts.)*

The prognosis for patients with invasive serous cystadenocarcinoma is poor, even after surgery, irradiation, and chemotherapy, and depends heavily on the disease stage at diagnosis. If the tumor appears confined to the ovary, frank carcinomas have a 5-year survival rate of about 70%, whereas tumors of low malignant potential are associated with nearly 100% survival. With cancers that have penetrated the capsule, the 10-year survival rate is less than 15%.

## Mucinous Tumors

Mucinous tumors are, in most respects, similar to serous tumors, the essential difference being that the neoplastic epithelium consists of mucin-secreting cells. These tumors occur in women in the same age range as for those with serous tumors but are considerably less likely to be malignant. Overall, only 10% of mucinous tumors are malignant; another 10% are of low malignant potential, and 80% are benign.

### MORPHOLOGY

On gross examination, mucinous tumors produce cystic masses that may be indistinguishable from serous tumors except by the mucinous nature of the cystic contents. However, **they are more likely to be larger and multicystic** (Fig. 18–17, *A*)**. Serosal penetration and solid areas of growth are suggestive of malignancy.** On histologic examination, the cysts are lined by mucin-producing epithelial cells (Fig. 18–17, *B*). Malignant tumors are characterized by the presence of architectural complexity, including solid areas of growth, cellular stratification, cytologic atypia, and stromal invasion.

Compared with serous tumors, mucinous tumors are much less likely to be bilateral. This feature is sometimes useful in differentiating mucinous tumors of the ovary from metastatic mucinous adenocarcinoma from a gastrointestinal tract primary (the so-called **Krukenberg tumor**), which more often produces bilateral ovarian masses.

Ruptured ovarian mucinous tumors may seed the peritoneum; however, these deposits typically are transient and fail to establish long-term growth in the peritoneum. Implantation of mucinous tumor cells in the peritoneum with production of copious amounts of mucin is called **pseudomyxoma peritonei;** in most cases, this disorder is caused by metastasis from the gastrointestinal tract, primarily the appendix (Chapter 14).

The prognosis of mucinous cystadenocarcinoma is somewhat better than with its serous counterpart, although stage rather than histologic type (serous versus mucinous) is the major determinant of outcome.

### Endometrioid Tumors

These tumors may be solid or cystic; they sometimes develop in association with endometriosis. On microscopic examination, they are distinguished by the formation of tubular glands, similar to those of the endometrium, within the lining of cystic spaces. Although benign and borderline forms exist, endometrioid tumors usually are malignant. They are bilateral in about 30% of cases, and 15% to 30% of women with these ovarian tumors have a concomitant endometrial carcinoma. Similar to endometrioid-type carcinoma of the endometrium, endometrioid carcinomas of the ovary have mutations in the *PTEN* tumor suppressor gene.

### Brenner Tumor

The Brenner tumor is an uncommon, solid, usually unilateral ovarian tumor consisting of abundant stroma containing nests of transitional-type epithelium resembling that of the urinary tract. Occasionally, the nests are cystic and are lined by columnar mucus-secreting cells. Brenner tumors generally are smoothly encapsulated and gray-white on cut section, ranging from a few centimeters to 20 cm in diameter. These tumors may arise from the surface epithelium or from urogenital epithelium trapped within the germinal ridge. Although most are benign, both malignant and borderline tumors have been described.

## OTHER OVARIAN TUMORS

Many other types of tumors of germ cell and sex cord–stromal origin also arise in the ovary, but only the teratomas of germ cell origin are sufficiently common to merit description. Table 18–3 presents some salient features of other neoplasms of germ cell and sex cord origin.

### Teratomas

Teratomas constitute 15% to 20% of ovarian tumors. A distressing feature of these germ cell tumors is their predilection to arise in the first 2 decades of life; to make matters worse, the younger the person, the greater the likelihood of malignancy. More than 90% of these germ cell neoplasms, however, are benign mature cystic teratomas; the immature, malignant variant is rare.

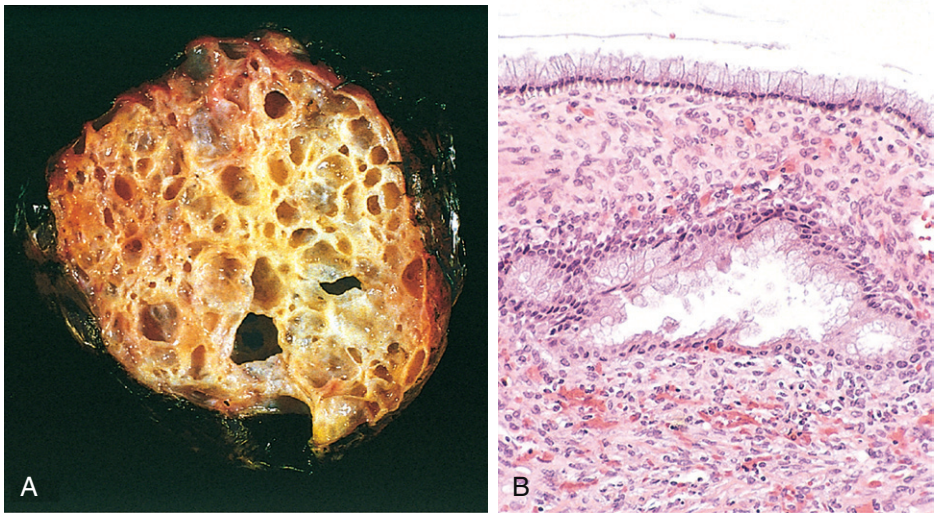

**Figure 18–17** Ovarian mucinous cystadenoma. **A,** Mucinous cystadenoma with multicystic appearance and delicate septa. Note the presence of glistening mucin within the cysts. **B,** Columnar cell lining of mucinous cystadenoma.

**Table 18–3** Salient Features of Ovarian Germ Cell and Sex Cord Neoplasms

| Neoplasm | Peak Incidence | Usual Location | Morphologic Features | Behavior |
|---|---|---|---|---|
| **Germ Cell Origin** | | | | |
| Dysgerminoma | Second to third decade of life<br>Occur with gonadal dysgenesis | Unilateral in 80–90% | Counterpart of testicular seminoma<br>Solid large to small gray masses<br>Sheets or cords of large clear cells separated by scant fibrous strands<br>Stroma may contain lymphocytes and occasional granulomas | All malignant but only one third aggressive and spread; all radiosensitive; 80% cure rate |
| Choriocarcinoma | First 3 decades of life | Unilateral | Identical to placental tumor<br>Often small, hemorrhagic focus with two types of epithelium: cytotrophoblast and syncytiotrophoblast | Metastasizes early and widely.<br>Primary focus may degenerate, leaving only metastases<br>In contrast with gestational tumors, ovarian primaries are resistant to chemotherapy |
| **Sex Cord Tumors** | | | | |
| Granulosa-theca cell | Most postmenopausal, but may occur at any age | Unilateral | May be tiny or large, gray to yellow (with cystic spaces)<br>Composed of mixture of cuboidal granulosa cells in cords, sheets, or strands and spindled or plump lipid-laden theca cells<br>Granulosa elements may recapitulate ovarian follicle as Call-Exner bodies | May elaborate large amounts of estrogen (from thecal elements) and so may promote endometrial or breast carcinoma<br>Granulosa element may be malignant (5% to 25%) |
| Thecoma-fibroma | Any age | Unilateral | Solid gray fibrous cells to yellow (lipid-laden) plump thecal cells | Most hormonally inactive<br>A few elaborate estrogens<br>About 40%, for obscure reasons, produce ascites and hydrothorax (Meigs syndrome)<br>Rarely malignant |
| Sertoli-Leydig cell | All ages | Unilateral | Usually small, gray to yellow-brown, and solid<br>Recapitulates development of testis with tubules or cords and plump pink Sertoli cells | Many masculinizing or defeminizing<br>Rarely malignant |
| **Metastases to Ovary** | | | | |
| | Older ages | Mostly bilateral | Usually solid gray-white masses as large as 20 cm in diameter<br>Anaplastic tumor cells, cords, glands, dispersed through fibrous background<br>Cells may be "signet ring" mucin-secreting | Primaries are gastrointestinal tract (Krukenberg tumors), breast, and lung |

### *Benign (Mature) Cystic Teratomas*

Almost all benign (mature) cystic teratomas are marked by the presence of mature tissues derived from all three germ cell layers: ectoderm, endoderm, and mesoderm. Usually these tumors contain cysts lined by epidermis replete with adnexal appendages—hence the common designation *dermoid cysts*. Most are discovered in young women as ovarian masses or are found incidentally on abdominal radiographs or scans because they contain foci of calcification produced by tooth-like structures contained within the tumor. About 90% are unilateral, with the right side more commonly affected. Rarely do these cystic masses exceed 10 cm in diameter. On cut section, they often are filled with sebaceous secretion and matted hair that, when removed, reveal a hair-bearing epidermal lining (Fig. 18–18). Sometimes there is a nodular projection from which teeth protrude. Occasionally, foci of bone and cartilage, nests of bronchial or gastrointestinal epithelium, and other tissues also are present.

For unknown reasons, these neoplasms sometimes produce infertility and are prone to undergo torsion (in 10% to 15% of cases), which constitutes an acute surgical emergency. A rare, but fascinating, paraneoplastic complication is limbic encephalitis, which may develop in women with teratomas containing mature neural tissue and often remits with tumor resection. In about 1% of cases, malignant transformation, usually to a squamous cell carcinoma, is seen.

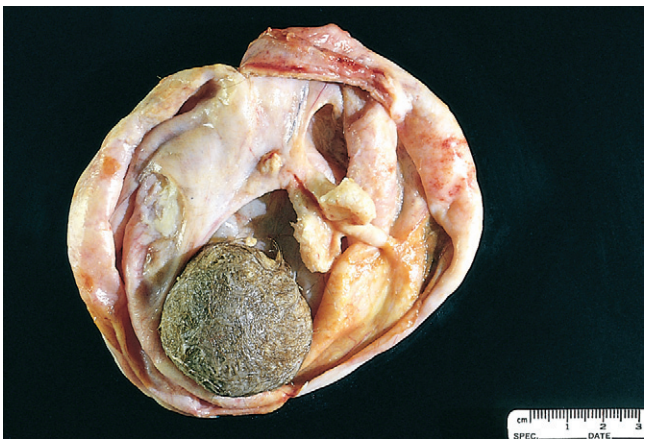

**Figure 18–18** Mature cystic teratoma (dermoid cyst) of the ovary. A ball of hair (*bottom*) and a mixture of tissues are evident.
*(Courtesy of Dr. Christopher Crum, Brigham and Women's Hospital, Boston, Massachusetts.)*

### *Immature Malignant Teratomas*

Malignant (immature) teratomas are found early in life, the mean age at clinical detection being 18 years. They differ strikingly from benign mature teratomas insofar as they often are bulky, predominantly solid on cut section, and punctuated by areas of necrosis; uncommonly, cystic foci are present that contain sebaceous secretion, hair, and other features similar to those of mature teratomas. On microscopic examination, the distinguishing feature is presence of immature elements or minimally differentiated cartilage, bone, muscle, nerve, or other tissues. Particularly ominous are foci of neuroepithelial differentiation, in view of the propensity of such foci to be aggressive and metastasize widely. Immature teratomas are both graded and staged in an effort to predict their behavior. Grade I, stage I tumors often can be cured with appropriate therapy, whereas those of higher grade and stage are associated with a more guarded outlook.

### *Specialized Teratomas*

A rare subtype of teratoma is composed entirely of specialized tissue. The most common example is struma ovarii, which is composed entirely of mature thyroid tissue that may actually produce hyperthyroidism. These tumors appear as small, solid, unilateral brown ovarian masses. Other specialized teratomas may take the form of ovarian carcinoid, which in rare instances produces carcinoid syndrome.

### Clinical Correlations

With all ovarian neoplasms, management poses a formidable clinical challenge, because symptoms or signs usually appear only when tumors are well advanced. The clinical presentation is remarkably similar, except with functioning neoplasms that exert hormonal effects. Ovarian tumors of surface epithelial origin usually are asymptomatic until they become large enough to cause local pressure symptoms (e.g., pain, gastrointestinal complaints, urinary frequency). Indeed, about 30% of all ovarian neoplasms are discovered incidentally on routine gynecologic examination. Larger masses, particularly the common epithelial tumors, may cause an increase in abdominal girth. Smaller masses, particularly dermoid cysts, sometimes twist on their pedicles (torsion), producing severe abdominal pain that mimics an acute abdomen. Metastatic seeding of malignant serous tumors often causes ascites, whereas functioning ovarian tumors often come to attention because of the endocrinopathies they produce.

Unfortunately, treatment of ovarian tumors remains unsatisfactory; only a modest increase in survival has been achieved since the mid-1970s. Screening methods that detect early tumors are badly needed, but those evaluated to date are of limited value. One such marker, the protein CA-125, is elevated in the sera of 75% to 90% of women with epithelial ovarian cancer. However, CA-125 is undetectable in up to 50% of women with cancer limited to the ovary; conversely, it often is elevated in a variety of benign conditions and nonovarian cancers. Hence, its usefulness as a screening test in asymptomatic postmenopausal women is limited. Currently, CA-125 measurements are of greatest value in monitoring response to therapy.

## SUMMARY

### Ovarian Tumors

- Tumors may arise from epithelium, sex cord–stromal cells, or germ cells.
- Epithelial tumors are the most common malignant ovarian tumors and are more common in women older than 40 years of age.
- The major types of epithelial tumors are serous, mucinous, and endometrioid. Each has a benign, malignant, and borderline (low malignant potential) counterpart.
- Sex cord–stromal tumors may display differentiation toward granulosa, Sertoli, Leydig, or ovarian stromal cell type. Depending on differentiation, they may produce estrogens or androgens.
- Germ cell tumors (mostly cystic teratomas) are the most common ovarian tumor in young women; a majority are benign.
- Germ cell tumors may differentiate toward oogonia (dysgerminoma), primitive embryonal tissue (embryonal), yolk sac (endodermal sinus tumor), placental tissue (choriocarcinoma), or multiple fetal tissues (teratoma).

# DISEASES OF PREGNANCY

Diseases of pregnancy and pathologic conditions of the placenta are important contributors to morbidity and mortality for both mother and child. Discussed in this section are a limited number of disorders in which knowledge of the morphologic lesions contributes to an understanding of clinical disease.

## PLACENTAL INFLAMMATIONS AND INFECTIONS

Infections may reach the placenta by either of two paths: (1) ascension through the birth canal or (2) hematogenous (transplacental) spread.

*Ascending infections* are by far the more common; in most instances, they are bacterial and are associated with premature rupture of the fetal membranes. On microscopic examination, the chorioamnion shows neutrophilic infiltration associated with edema and congestion (acute chorioamnionitis). With extension beyond the membranes, the infection may involve the umbilical cord and placental villi, resulting in acute vasculitis of the cord (funisitis). Ascending infections are caused by *Mycoplasma, Candida,* and the numerous bacteria of the vaginal flora.

Uncommonly, placental infections may arise by *hematogenous spread* of bacteria and other organisms; on histologic examination, placental villi are the most frequently affected structures (villitis). Syphilis, tuberculosis, listeriosis, toxoplasmosis, and various viruses (rubella, cytomegalovirus, herpes simplex virus) all can cause placental villitis. Transplacental infections can affect the fetus and give rise to the so-called TORCH (*t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus infection, *h*erpes) complex (Chapter 6).

## ECTOPIC PREGNANCY

Ectopic pregnancy is defined as implantation of a fertilized ovum in any site other than the uterus. As many as 1% of pregnancies are ectopic. In more than 90% of these cases, implantation occurs in the oviducts (tubal pregnancy); other sites include the ovaries and the abdominal cavity. Any factor that retards passage of the ovum through the oviducts predisposes to ectopic pregnancy. In about half of the cases, slowed passage is attributable to chronic inflammation and scarring in the oviduct; intrauterine tumors and endometriosis may also hamper passage of the ovum. In the other 50% of tubal pregnancies, no anatomic cause is evident. Ovarian pregnancies probably result from rare instances in which the ovum is fertilized just as the follicle ruptures. Gestation within the abdominal cavity occurs when the fertilized egg drops out of the fimbriated end of the oviduct and implants on the peritoneum.

### MORPHOLOGY

In all sites, early development of ectopic pregnancies proceeds normally, with formation of placental tissue, the amniotic sac, and decidual changes. With tubal pregnancies, the invading placenta eventually burrows through the wall of the oviduct, causing **intratubal hematoma (hematosalpinx), intraperitoneal hemorrhage,** or both. The tube is usually distended by freshly clotted blood containing bits of gray placental tissue and fetal parts. The histologic diagnosis depends on visualization of placental villi or, rarely, of the embryo.

Until rupture occurs, an ectopic pregnancy may be indistinguishable from a normal pregnancy, with cessation of menstruation and elevation of serum and urinary placental hormones. Under the influence of these hormones, the endometrium (in approximately 50% of cases) undergoes the characteristic hypersecretory and decidual changes of pregnancy. The absence of elevated gonadotropin levels does not exclude the diagnosis, however, because poor attachment and necrosis of the ectopic placenta are common. Rupture of an ectopic pregnancy may be catastrophic, with the sudden onset of intense abdominal pain and signs of an acute abdomen, often followed by shock. Prompt surgical intervention is necessary.

### SUMMARY

#### Ectopic Pregnancy

- Ectopic pregnancy is defined as implantation of the fertilized ovum outside of the uterine corpus. Approximately 1% of pregnancies implant ectopically; the most common site is the fallopian tube.
- Chronic salpingitis with scarring is a major risk factor for tubal ectopic pregnancy.
- Rupture of an ectopic pregnancy is a medical emergency that, if left untreated, may result in exsanguination and death.

## GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic tumors have been divided on histopathologic grounds into three overlapping morphologic categories: *hydatidiform mole, invasive mole,* and *choriocarcinoma.* These demonstrate a range of aggressiveness from benign hydatidiform moles to highly malignant choriocarcinomas. All elaborate human chorionic gonadotropin (hCG), which can be detected in the blood and urine at levels considerably higher than those found during normal pregnancy. In addition to aiding diagnosis, the rise or fall of hormone levels in the blood or urine can be used to monitor treatment efficacy. Clinicians prefer the umbrella term *gestational trophoblastic disease* because the response to therapy, as judged by the hormone levels, is significantly more important than pathologic subtyping of lesions. However, the genetics, pathology, and natural history of these disorders are sufficiently distinct to merit discussion of each.

### Hydatidiform Mole: Complete and Partial

The typical hydatidiform mole is a voluminous mass of swollen, sometimes cystically dilated, chorionic villi, appearing grossly as grapelike structures. The swollen villi are covered by varying amounts of normal to highly atypical chorionic epithelium. There are two distinctive subtypes of hydatidiform moles: *complete* and *partial.* Complete hydatidiform moles are not compatible with embryogenesis and never contain fetal parts. All of the chorionic villi are abnormal, and the chorionic epithelial cells are diploid (46,XX or, uncommonly, 46,XY). The partial hydatidiform mole is compatible with early embryo formation

**Table 18–4** Features of Complete and Partial Hydatidiform Mole

| Feature | Complete Mole | Partial Mole |
|---|---|---|
| Karyotype | 46,XX (46,XY) | Triploid (69,XXY) |
| Villous edema | All villi | Some villi |
| Trophoblast proliferation | Diffuse; circumferential | Focal; slight |
| Serum hCG | Elevated | Less elevated |
| Tissue hCG | ++++ | + |
| Risk of subsequent choriocarcinoma | 2% | Rare |

hCG, human chorionic gonadotropin.

and therefore may contain fetal parts, has some normal chorionic villi, and is almost always triploid (e.g., 69,XXY) (Table 18–4). Both types result from abnormal fertilization. In a complete mole the entire genetic content is supplied by two spermatozoa (or a diploid sperm), yielding diploid cells containing only paternal chromosomes, whereas in a partial mole a normal egg is fertilized by two spermatozoa (or a diploid sperm), resulting in a triploid karyotype with a preponderance of paternal genes.

The incidence of complete hydatidiform mole is about 1 to 1.5 per 2000 pregnancies in the United States and other Western countries. For unknown reasons, the incidence is much higher in Asian countries. Moles are most common before the age of 20 years and after the age of 40, and a history of the condition increases the risk for molar disease in subsequent pregnancies. Although molar disease formerly was discovered at 12 to 14 weeks of pregnancy during investigation for a gestation that was "too large for dates," early monitoring of pregnancies by ultrasound has lowered the gestational age at detection. In both complete and partial moles, elevation of hCG in the maternal blood and absence of fetal heart sounds are typical.

### MORPHOLOGY

The uterus may be of normal size in early moles, but in more advanced cases the uterine cavity is expanded by a delicate, friable mass of thin-walled, translucent cystic structures (Fig. 18–19). Fetal parts are rarely seen in complete moles but are common in partial moles. On microscopic examination, the **complete mole** shows hydropic swelling of poorly vascularized chorionic villi with a loose, myxomatous, edematous stroma. The chorionic epithelium almost always shows some degree of proliferation of both cytotrophoblasts and syncytiotrophoblasts (Fig. 18–20). Histologic grading to predict the clinical outcome of moles has been supplanted by careful monitoring of hCG levels. In **partial moles,** villous edema involves only some of the villi, and the trophoblastic proliferation is focal and slight. The villi of partial moles have a characteristic irregular, scalloped margin. In most cases of partial mole, some fetal cells are present, ranging from fetal red blood cells in placental villi to, in rare cases, a fully formed fetus.

Overall, 80% to 90% of moles do not recur after thorough curettage; 10% of complete moles are invasive. No more than 2% to 3% give rise to choriocarcinoma.

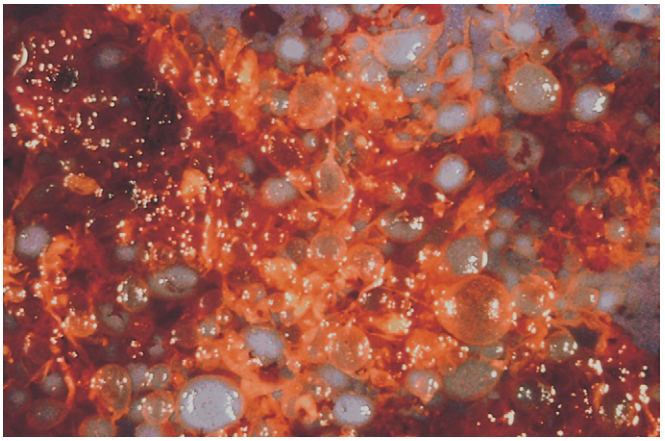

**Figure 18–19** Complete hydatidiform mole, consisting of numerous swollen (hydropic) villi.

## Invasive Mole

Invasive moles are complete moles that are more invasive locally but do not have the aggressive metastatic potential of a choriocarcinoma. An invasive mole retains hydropic villi, which penetrate the uterine wall deeply, possibly causing rupture and sometimes life-threatening hemorrhage. On microscopic examination, the epithelium of the villi shows atypical changes, with proliferation of both trophoblastic and syncytial components.

Although the marked invasiveness of this lesion makes removal technically difficult, metastases do not occur. Hydropic villi may embolize to distant organs, such as lungs or brain, but these emboli do not constitute true metastases and may indeed regress spontaneously. Because of deeper invasion into the myometrium, an invasive mole is difficult to remove completely by curettage, so if serum β-hCG remains elevated, further treatment is

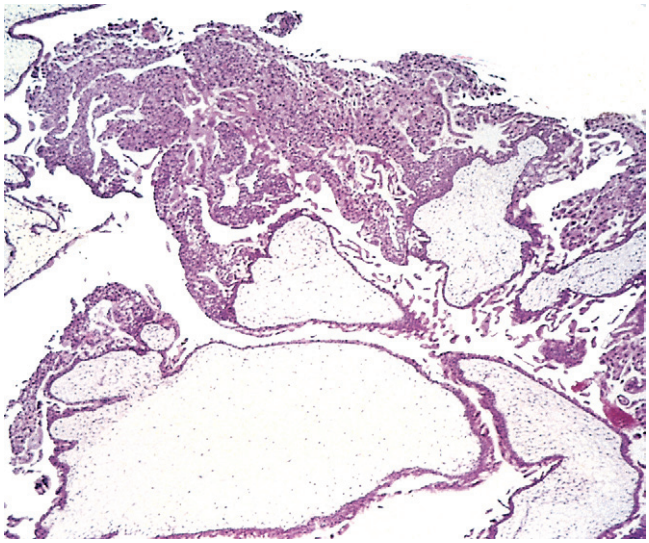

**Figure 18–20** Complete hydatidiform mole. In this microscopic image, distended hydropic villi (*below*) and proliferation of the chorionic epithelium (*above*) are evident.

*(Courtesy of Dr. Kyle Molberg, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

required. Fortunately, in most cases cure is possible with chemotherapy.

## Gestational Choriocarcinoma

Choriocarcinoma, a very aggressive malignant tumor, arises either from gestational chorionic epithelium or, less frequently, from totipotential cells within the gonads (as a germ cell tumor). These tumors are rare in the Western Hemisphere; in the United States, they occur in about 1 per 30,000 pregnancies but are much more common in Asian and African countries, reaching a frequency of 1 in 2000 pregnancies. Approximately 50% of choriocarcinomas arise from complete hydatidiform moles; about 25% arise after an abortion; the remainder manifest after what had been a normal pregnancy. Stated in another way, the more abnormal the conception, the greater the risk of developing gestational choriocarcinoma. In most cases, choriocarcinoma manifests with a bloody, brownish discharge accompanied by a rising titer of β-hCG in blood and urine, in the absence of marked uterine enlargement, such as would be anticipated with a mole. In general, the β-hCG titers are much higher than those associated with a mole.

### MORPHOLOGY

Choriocarcinomas usually appear as hemorrhagic, necrotic uterine masses. Sometimes the necrosis is so extensive that little viable tumor remains. Indeed, the primary lesion may "self-destruct," and only the metastases tell the story. Very early, the tumor insinuates itself into the myometrium and into vessels. **In contrast with hydatidiform moles and invasive moles, chorionic villi are not formed; instead, the tumor is composed of anaplastic cuboidal cytotrophoblasts and syncytiotrophoblasts** (Fig. 18–21).

By the time most choriocarcinomas are discovered, widespread vascular spread usually has occurred to the lungs (50%), vagina (30% to 40%), brain, liver, or kidneys. Lymphatic invasion is uncommon.

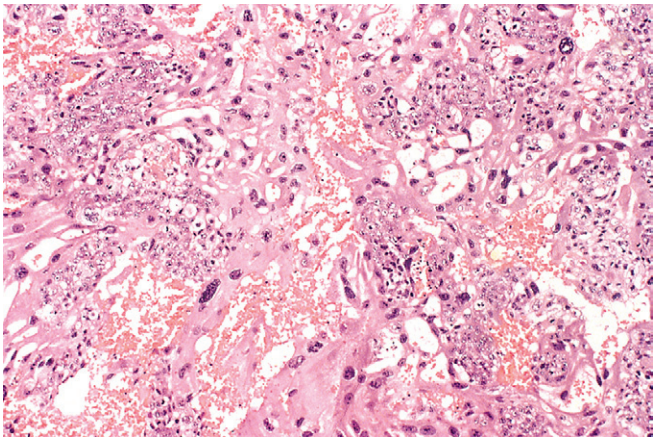

**Figure 18–21** Choriocarcinoma. This field contains both neoplastic cytotrophoblasts and multinucleate syncytiotrophoblasts.
*(Courtesy of Dr. David R. Genest, Brigham and Women's Hospital, Boston, Massachusetts.)*

Despite the extremely aggressive nature of placental choriocarcinoma, these tumors are remarkably sensitive to chemotherapy. Nearly 100% of affected patients are cured, even those with metastases at distant sites such as the lungs. By contrast, response to chemotherapy with choriocarcinomas that arise in the gonads (ovary or testis) is relatively poor. This striking difference in prognosis may be related to the presence of paternal antigens on placental choriocarcinomas that are lacking in gonadal lesions. Conceivably, a maternal immune response against the foreign (paternal) antigens helps clear the tumor by acting as an adjunct to chemotherapy.

## Placental Site Trophoblastic Tumor

Placental site trophoblastic tumors are derived from the placental site or intermediate trophoblast. These uncommon diploid tumors, often XX in karyotype, typically arise a few months after pregnancy. Because intermediate trophoblasts do not produce hCG in large amounts, hCG concentrations are only slightly elevated. More typically, these tumors produce human placental lactogen. An indolent clinical course is typical, with a generally favorable outcome if the tumor is confined to the endomyometrium. Of note, however, placental site trophoblastic tumors are not as sensitive to chemotherapy as are other trophoblastic tumors, and the prognosis is poor when spread has occurred beyond the uterus.

### SUMMARY

#### Gestational Trophoblastic Disease

- Molar disease is due to an abnormal contribution of paternal chromosomes in the gestation.
- Partial moles are triploid and have two sets of paternal chromosomes. They typically are accompanied by fetal tissue. There is a low rate of persistent disease.
- Complete moles are diploid, and all chromosomes are paternal. No embryonic or fetal tissues are associated with complete mole.
- Among complete moles, 10% to 15% are associated with persistent disease that usually takes the form of an invasive mole. Only 2% of complete moles progress to choriocarcinoma.
- Gestational choriocarcinoma is a highly invasive and frequently metastatic tumor that, in contrast with ovarian choriocarcinoma, is responsive to chemotherapy and curable in most cases.
- Placental site trophoblastic tumor is an indolent and usually early-stage tumor of intermediate trophoblast that produces human placental lactogen and does not respond well to chemotherapy.

# PREECLAMPSIA/ECLAMPSIA (TOXEMIA OF PREGNANCY)

The development of hypertension, accompanied by proteinuria and edema in the third trimester of pregnancy, is referred to as *preeclampsia*. This syndrome occurs in 5% to

10% of pregnancies, particularly with first pregnancies in women older than age 35 years. In those severely affected, seizures may occur, and the symptom complex is then termed *eclampsia.* By long-existing precedent, preeclampsia and eclampsia are still sometimes referred to as *toxemia of pregnancy.* No blood-borne toxin has ever been identified, and this historically sanctified term is a misnomer. Recognition and early treatment of preeclampsia have now made eclampsia, particularly fatal eclampsia, rare.

The exact triggering events initiating these syndromes are unknown, but a common feature underlying all cases is *insufficient maternal blood flow to the placenta secondary to inadequate remodeling of the spiral arteries of the uteroplacental vascular bed.* In normal pregnancy, the musculoelastic walls of the spiral arteries are invaded by trophoblasts, permitting them to dilate into wide vascular sinusoids. In preeclampsia and eclampsia, this vascular remodeling is impaired, the musculoelastic walls are retained, and the channels remain narrow. Decreased uteroplacental blood flow appears to result in placental hypoxia, placental dysfunction, and a shift to a systemic antiangiogenic state. Specifically, both increases in the circulating antiangiogenic factors soluble Flt1 (sFlt1) and soluble endoglin (sEng) and reductions in the level of proangiogenic factors, such as VEGF and PIGF, have been noted. These disturbances are hypothesized to result in *endothelial cell dysfunction, vascular hyperreactivity, and end-organ microangiopathy.* While the exact basis of preeclampsia remains to be further defined, several serious consequences have been associated with this condition:

- *Placental infarction,* stemming from the chronic hypoperfusion
- *Hypertension,* due to reduced endothelial production of the vasodilators prostacyclin (i.e., prostaglandin $I_2$) and prostaglandin $E_2$, and to increased production of the vasoconstrictor thromboxane $A_2$
- *Hypercoagulability,* due to endothelial dysfunction and release of tissue factor from the placenta
- *End-organ failure,* most notably of the kidney and the liver, which occurs in patients with full-blown eclampsia. Approximately 10% of the patients with severe preeclampsia develop the so-called HELLP syndrome, characterized by hemolysis, elevated liver enzymes, and low platelets.

### MORPHOLOGY

The morphologic changes of preeclampsia and eclampsia are variable and correlate to some degree with the severity of the disorder. **Placental abnormalities** include:

- **Infarcts,** which can be a feature of normal pregnancy, but are much more numerous with severe preeclampsia or eclampsia
- **Retroplacental hemorrhages**
- **Premature maturation of placental villi** associated with villous edema, hypovascularity, and increased production of syncytial epithelial knots
- **Fibrinoid necrosis** and focal accumulation of lipid-containing macrophages (acute atherosis) of decidual vessels

#### Clinical Features

Preeclampsia presents insidiously during weeks 24 and 25 of gestation, with edema, proteinuria, and rising blood pressure. Should the condition evolve into eclampsia, renal function is impaired, blood pressure rises further, and convulsions may occur. Prompt therapy early in the course aborts the associated organ changes, with all abnormalities resolving promptly after delivery or cesarean section.

### SUMMARY

#### Preeclampsia/Eclampsia

- Preeclampsia is due to abnormalities in maternal and placental blood flow, with resultant placental ischemia and infarction and abnormalities in production of vasodilators.
- Preeclampsia is characterized by edema, proteinuria, and hypertension in the second and third trimesters of pregnancy.
- Eclampsia is characterized, in addition, by seizures. It can be fatal when accompanied by multiorgan damage.

## BREAST

Lesions of the female breast are much more common than lesions of the male breast and usually take the form of palpable, sometimes painful nodules or masses. Fortunately, most are innocent, but as is well known, breast cancer is the most common cancer in women (excluding neoplasia of the skin) and is second only to lung cancer as a cause of cancer-related death. Hence, it is not uncommon for women to seek evaluation of even slightly suspicious *lumps* in the breast (Fig. 18–22).

We start our discussion of diseases of the breast with benign non-neoplastic lesions. Before considering the extremely common fibrocystic changes, several relatively minor lesions warrant brief mention. *Supernumerary nipples or breast tissue* may be found anywhere along the

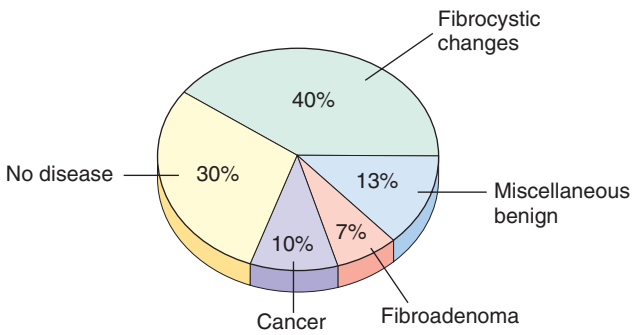

**Figure 18–22** Histopathologic findings in a series of women seeking evaluation of breast "lumps."

embryonic ridge (milk line). Besides being curiosities, these congenital anomalies are subject to the same diseases that affect the normal breast. *Congenital inversion of the nipple* is of clinical significance because similar changes may be produced by an underlying cancer. *Galactocele* arises during lactation from cystic dilation of an obstructed duct. Besides being painful "lumps," these cysts may rupture, inciting a local inflammatory reaction, with production of an indurated focus falsely suggestive of malignancy.

## FIBROCYSTIC CHANGES

The designation *fibrocystic* is applied to a miscellany of changes in the female breast that consist predominantly of cyst formation and fibrosis. In the past, these lesions were called *fibrocystic disease.* However, since most of these changes have little clinical significance beyond the need to distinguish them from cancer, the term *fibrocystic change* is preferred.

Overall, fibrocystic changes are the most common breast abnormality seen in premenopausal women. The changes tend to arise during reproductive age and are most likely a consequence of the *cyclic breast changes that occur normally in the menstrual cycle.* Estrogenic therapy and oral contraceptives do not seem to increase the incidence of these alterations, and oral contraceptives may, in fact, *decrease* the risk.

Fibrocystic changes can be subdivided into nonproliferative and proliferative patterns, as described next.

### Nonproliferative Changes

#### *Cysts and Fibrosis*

Nonproliferative changes are the most common type of fibrocystic lesions, characterized by an increase in fibrous stroma associated with dilation of ducts and formation of variably sized cysts.

#### MORPHOLOGY

A single, large cyst may form within one breast, but changes usually are multifocal and often bilateral. The involved areas appear as ill-defined, diffusely increased densities and discrete nodularities on mammography. The cysts range from less than 1 cm and up to 5 cm in diameter. Unopened, they are brown to blue **(blue dome cysts)** and are filled with watery, turbid fluid (Fig. 18–23). The secretions within the cysts may calcify, producing microcalcifications on mammograms. Histologic examination reveals an epithelial lining that in larger cysts may be flattened or even totally atrophic (Fig. 18–24). Frequently, the lining cells are large and polygonal with abundant granular, eosinophilic cytoplasm and small, round, deeply chromatic nuclei. Such morphology is called **apocrine metaplasia** and virtually always is benign.

The stroma surrounding all types of cysts usually consists of compressed fibrous tissue that has lost the delicate, myxomatous appearance of normal breast stroma. A stromal lymphocytic infiltrate is common in this and all other variants of fibrocystic change.

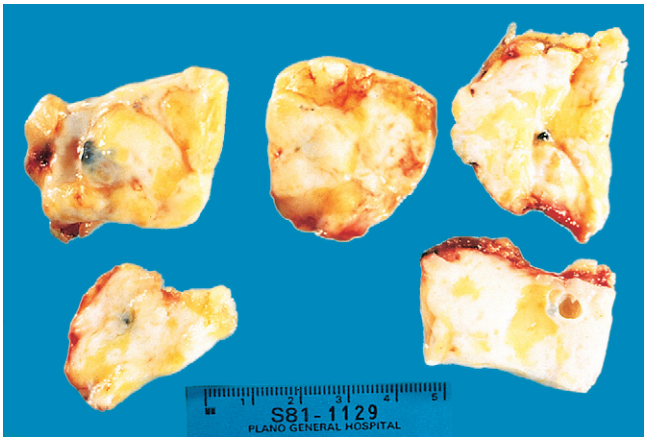

**Figure 18–23** Fibrocystic change seen in breast biopsy specimens. The scattered, poorly demarcated white areas represent foci of fibrosis. In the specimen at the *lower right*, a transected empty cyst is evident; in the two specimens on the *left*, unopened blue dome cysts are seen.
*(Courtesy of Dr. Kyle Molberg, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

### Proliferative Change

#### *Epithelial Hyperplasia*

Normal ducts and lobules of the breast are lined by two layers of cells—a layer of luminal cells overlying a second layer of myoepithelial cells. *Epithelial hyperplasia* is recognized by the presence of more than two cell layers. The spectrum of epithelial hyperplasia ranges from mild and orderly to atypical hyperplasias with features that resemble those of in situ carcinoma.

#### MORPHOLOGY

The gross appearance of epithelial hyperplasia is not distinctive and is dominated by coexisting fibrous or cystic changes. Histologic examination shows an almost infinite spectrum of proliferative alterations. The ducts, ductules, or lobules may be filled with orderly cuboidal cells within which small gland

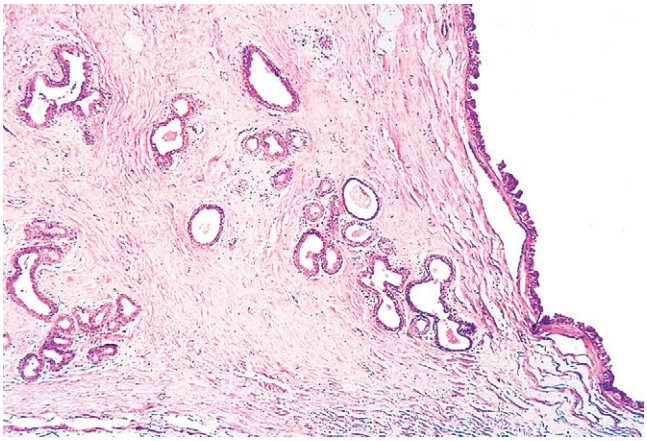

**Figure 18–24** Fibrocystic change of the nonproliferative type in a breast biopsy specimen. Visible in this field are dilated ducts, producing microcysts and, at *right*, the wall of a large cyst lined with epithelial cells.
*(Courtesy of Dr. Kyle Molberg, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Texas.)*

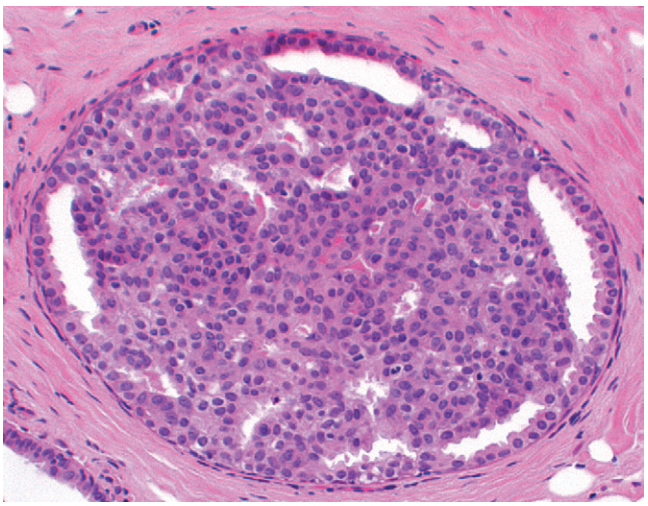

**Figure 18–25** Epithelial hyperplasia in a breast biopsy specimen. The duct lumen is filled with a heterogeneous population of cells of differing morphology. Irregular slitlike fenestrations are prominent at the periphery.

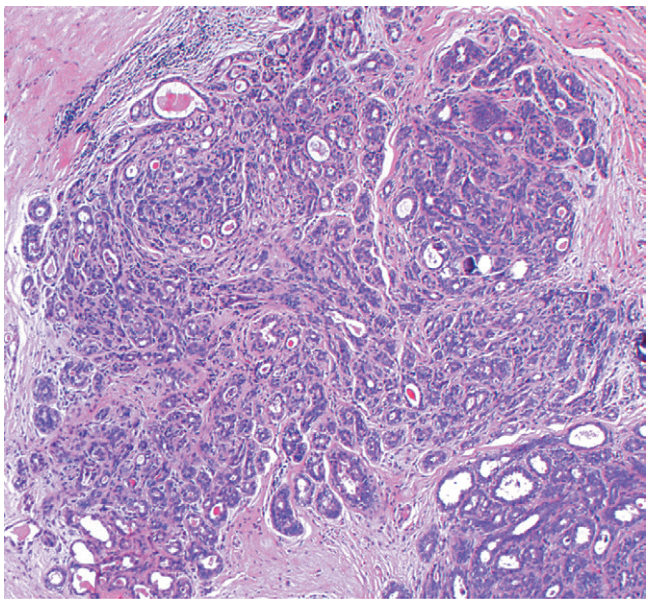

**Figure 18–26** Sclerosing adenosis, breast biopsy. The involved terminal duct lobular unit is enlarged, and the acini are compressed and distorted by surrounding dense stroma. Unlike in breast carcinoma, the acini are arranged in a swirling pattern, and the outer border is well circumscribed.

patterns (called **fenestrations**) can be discerned (Fig. 18–25). Sometimes, the proliferating epithelium projects as multiple small papillary excrescences into the ductal lumen **(ductal papillomatosis).** The degree of hyperplasia, judged in part by the number of layers of intraductal epithelium, can be mild, moderate, or marked. Occasionally, hyperplasia produces microcalcifications on mammography, raising concern for cancer.

In some instances the hyperplastic cells have features bearing some resemblance to ductal carcinoma in situ (described later). Such hyperplasia is called **atypical ductal hyperplasia. Atypical lobular hyperplasia** is used to describe hyperplasias that exhibit changes that approach but do not meet diagnostic criteria for lobular carcinoma in situ. Both atypical ductal and lobular hyperplasia are associated with an increased risk of invasive carcinoma.

### *Sclerosing Adenosis*

The type of fibrocystic change termed *sclerosing adenosis* is less common than cysts and hyperplasia but is significant because its clinical and morphologic features may mimic those of carcinoma. These lesions contain marked intralobular fibrosis and proliferation of small ductules and acini.

#### MORPHOLOGY

Grossly, the lesion has a hard, rubbery consistency, similar to that of breast cancer. Histologic examination shows a characteristic **proliferation of luminal spaces (adenosis) lined by epithelial cells and myoepithelial cells,** yielding masses of small glands within a fibrous stroma (Fig. 18–26). Aggregated glands may be virtually back to back, with single or multiple layers of cells in contact with one another. Marked stromal fibrosis, which may compress and distort the proliferating epithelium, is always associated with the adenosis—hence the designation **sclerosing adenosis.** This overgrowth of fibrous tissue may completely compress the lumina of the acini and ducts, so that they appear as solid cords of cells—a pattern that is difficult to distinguish histologically from invasive ductal carcinoma. The presence of double layers of epithelium and the identification of myoepithelial elements are helpful in arriving at the correct diagnosis.

## Relationship of Fibrocystic Changes to Breast Carcinoma

Certain clinical features of fibrocystic change tend to distinguish it from cancer, but the only certain way of making this distinction is through biopsy and histologic examination. Although fibrocystic changes are benign, some features may confer an increased risk for development of cancer:

- *Minimal or no increased risk of breast carcinoma*: fibrosis, cystic changes, apocrine metaplasia, mild hyperplasia
- *Slightly increased risk* (1.5- to 2-fold): moderate to florid hyperplasia (without atypia), ductal papillomatosis, sclerosing adenosis
- *Significantly increased risk* (5-fold): atypical hyperplasia, whether ductular or lobular

Proliferative fibrocystic changes usually are bilateral and multifocal and are associated with increased risk of subsequent carcinoma in both breasts.

## SUMMARY

### Fibrocystic Changes

- Fibrocystic changes may be classified as nonproliferative (cystic) or proliferative.
- Proliferative lesions include epithelial proliferations of ducts and lobules (with or without features of atypia) and adenosis (proliferation of terminal ducts), sometimes associated with fibrosis (sclerosing adenosis).
- Atypical hyperplasia (whether ductal or lobular) is associated with a five-fold increase in the risk of developing carcinoma.

## INFLAMMATORY PROCESSES

Inflammatory processes involving the breast are uncommon and are usually associated with pain and tenderness in the affected areas. Included in this category are several forms of mastitis and traumatic fat necrosis, none of which increase the risk of cancer.

Acute mastitis develops when bacteria, usually *Staphylococcus aureus,* gain access to the breast tissue through the ducts. The vast majority of cases arise during the early weeks of nursing, when the skin of the nipple is vulnerable to the development of fissures. Clinically, staphylococcal infections induce typical acute inflammatory changes, which can progress to form single or multiple abscesses.

*Mammary duct ectasia (plasma cell mastitis)* is a nonbacterial chronic inflammation of the breast associated with inspissation of breast secretions in the main excretory ducts. Ductal dilation and eventual rupture leads to reactive changes in the surrounding tissue that may present as a poorly defined periareolar mass with nipple retraction, mimicking the changes caused by some cancers. It is an uncommon condition usually encountered in parous women between 40 and 60 years of age.

### MORPHOLOGY

Usually the inflammatory changes are confined to an area drained by one or more of the major excretory ducts of the nipple. On histologic examination, the ducts are filled with granular debris, sometimes containing leukocytes and lipid-laden macrophages. The lining epithelium generally is destroyed. **The most distinguishing features consist of a prominent lymphoplasmacytic infiltrate and occasional granulomas in the periductal stroma.**

*Fat necrosis* is an uncommon, innocuous lesion that is significant only because it often produces a mass. Most women with this condition report some antecedent trauma to the breast.

### MORPHOLOGY

During the early stage of traumatic fat necrosis, the lesion is small, often tender, rarely more than 2 cm in diameter, and sharply localized. It consists of a central focus of necrotic fat cells surrounded by neutrophils and lipid-laden macrophages, sometimes with giant cells. This lesion later becomes enclosed by fibrous tissue and mononuclear leukocytes and eventually is replaced by scar tissue or a cyst consisting of necrotic debris. Calcifications may develop in either the scar or the cyst wall.

## TUMORS OF THE BREAST

Tumors are the most important lesions of the female breast. Although they may arise from connective tissue or epithelial structures, it is the latter that give rise to the common breast neoplasms.

### Fibroadenoma

Fibroadenoma is by far the most common benign neoplasm of the female breast. It is a biphasic tumor composed of fibroblastic stroma and epithelium-lined glands; however, only the stromal cells are clonal and truly neoplastic. Fibroadenomas typically appear in young women with a peak incidence in the third decade of life. They usually manifest as solitary, discrete, mobile masses. An absolute or relative increase in estrogen is thought to contribute to their development. In addition, fibroadenomas may enlarge late in the menstrual cycle and during pregnancy; after menopause, they may regress and calcify.

### MORPHOLOGY

The fibroadenomas form discrete masses, 1 cm to 10 cm in diameter and of firm consistency (Fig. 18–27). A cut section shows a uniform tan-white color, punctuated by softer yellow-pink specks representing the glandular areas. Histologic examination shows a loose fibroblastic stroma containing ductlike, epithelium-lined spaces of various shapes and sizes. As in normal breast tissue, these glandular spaces are lined by luminal and myoepithelial cells with a well-defined, intact basement membrane.

### Phyllodes Tumor

Like fibroadenomas, phyllodes tumors are biphasic, being composed of neoplastic stromal cells and epithelium-lined glands. However, the stromal element of these tumors is more cellular and abundant, often forming epithelium-lined leaflike projections (*phyllodes* is Greek for "leaflike"). These tumors are much less common than fibroadenomas and arise de novo, not from preexisting fibroadenomas. In the past, they had the tongue-tangling name *cystosarcoma phyllodes*—an unfortunate term because these tumors usually are benign. Ominous changes suggesting malignancy include increased stromal cellularity, anaplasia, high mitotic activity, rapid increase in size, and infiltrative margins. Fortunately, most phyllodes tumors remain localized and are cured by excision; malignant lesions may recur, but they also tend to remain localized. Only 15% of all cases are fully malignant, metastasizing to distant sites.

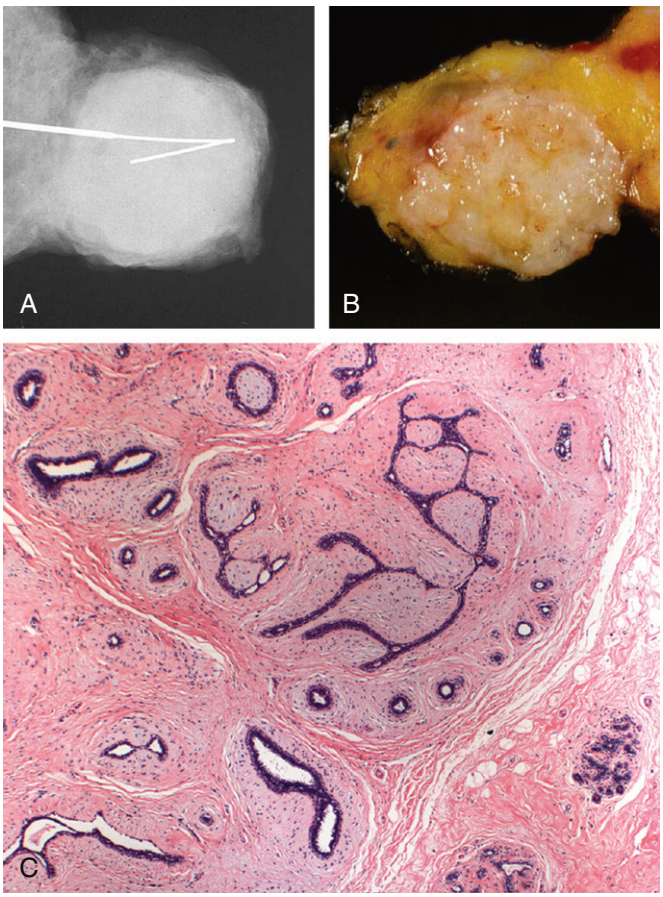

**Figure 18–27** Fibroadenoma. **A,** The radiograph shows a characteristic well-circumscribed mass. **B,** In this gross specimen, a rubbery well-circumscribed mass is clearly demarcated from the surrounding adipose tissue. **C,** In this micrograph, the proliferation of intralobular stroma can be seen to compress the entrapped glands, creating a "pushing" border that is sharply delineated from the surrounding normal tissue.

## Intraductal Papilloma

Intraductal papilloma is a benign neoplastic papillary growth. It is most often seen in premenopausal women. These lesions typically are solitary and found within the principal lactiferous ducts or sinuses. The clinical presentation may include

- Serous or bloody nipple discharge
- The presence of a *small subareolar tumor* a few millimeters in diameter
- *Nipple retraction,* in rare instances

### MORPHOLOGY

The tumors usually are solitary and less than 1 cm in diameter, consisting of delicate, branching growths within a dilated duct. On histologic examination, they are composed of multiple papillae, each having a connective tissue core covered by epithelial cells that are double-layered, with an outer luminal layer overlying a myoepithelial layer. The presence of a double-layered epithelium helps to distinguish intraductal papilloma from intraductal papillary carcinoma, which can present with clinical features similar to benign papilloma.

## Carcinoma

In 2010, more than 200,000 invasive breast cancers were diagnosed in women in the United States, and around 40,000 women died of this disease, making this scourge second only to lung cancer as a cause of cancer-related death in women. The lifetime risk of developing breast cancer is 1 in 8 for women in the United States. During the past 3 decades, the mortality rate among those diagnosed with breast cancer has dropped from 30% to 20%, mostly as a result of improved screening and treatment.

### *Epidemiology and Risk Factors*

A large number of risk factors for breast cancer have been identified. Table 18–5 divides these into well-established and less well-established groups and indicates, when possible, the relative risk posed by each. Some of the more important risk factors are summarized next.

***Age.*** Risk steadily increases throughout life, especially after menopause, peaking at roughly 80 years of age; 75% of women with breast cancer are older than 50 years of age, and only 5% are younger than 40.

***Geographic Variations.*** Surprising differences in the incidence and mortality rates of breast cancer have been reported for various countries. The risk for development of this disease is significantly higher in North America and northern Europe than in Asia and Africa. For example, the incidence and mortality rates are five times higher in the

**Table 18–5** Breast Cancer Risk Factors

| Factor | Relative Risk |
|---|---|
| **Well-Established Factors** | |
| Geography | Varies in different areas |
| Age | Increases after age 30 |
| Family history | |
| First-degree relative with breast cancer | 1.2–3.0 |
| Premenopausal | 3.1 |
| Premenopausal and bilateral | 8.5–9.0 |
| Postmenopausal | 1.5 |
| Postmenopausal and bilateral | 4.0–5.4 |
| Menstrual history | |
| Age at menarche <12 years | 1.3 |
| Age at menopause >55 years | 1.5–2.0 |
| Pregnancy | |
| First live birth from ages 25 to 29 years | 1.5 |
| First live birth after age 30 years | 1.9 |
| First live birth after age 35 years | 2.0–3.0 |
| Nulliparous | 3.0 |
| Benign breast disease | |
| Proliferative disease without atypia | 1.6 |
| Proliferative disease with atypical hyperplasia | >2.0 |
| Lobular carcinoma in situ | 6.9–12.0 |
| **Other Possible Factors** | |
| Exogenous estrogens | |
| Oral contraceptives | |
| Obesity | |
| High-fat diet | |
| Alcohol consumption | |
| Cigarette smoking | |

Data from Bilimoria MM, Morrow M: The women at increased risk for breast cancer: evaluation and management strategies. CA Cancer J Clin 46:263, 1995.

United States than in Japan. These differences seem to be environmental rather than genetic in origin, because migrants from low-incidence to high-incidence areas tend to acquire the rates of their adoptive countries, and vice versa. Diet, reproductive patterns, and nursing habits are thought to be involved.

***Race/Ethnicity.*** The highest rate of breast cancer is in non-Hispanic white women. However, Hispanic and African American women tend to develop cancer at a younger age and are more likely to develop aggressive tumors that present at an advanced stage. Such disparities between ethnicities are an area of intense study and currently are thought to be due to a combination of genetic differences and social factors, such as lifestyle choices and access to health care.

***Other Risk Factors.*** *Prolonged exposure to exogenous estrogens* postmenopausally, as occurs with hormone replacement therapy, has been proved to be useful for the prevention of osteoporosis. However, according to recent studies, relatively short-term use of combined estrogen plus progestin hormone therapy is associated with an increased risk of breast cancer, diagnosis at a more advanced stage of breast cancer, and higher incidence of abnormal mammograms. Because the 2002 Women's Health Initiative report suggested greater harm than benefit of combined estrogen plus a progestin, a precipitous decline has occurred in estrogen and progestin use, along with a serious reevaluation of perimenopausal hormone therapy.

*Oral contraceptives* have not been shown to affect the risk of breast cancer, even in women who have taken the pill for a long time or in women with a family history of breast cancer.

*Ionizing radiation* to the chest increases the risk of breast cancer. The magnitude of the risk depends on the radiation dose, the time since exposure, and age. Only women in whom irradiation occurred before age 30, during breast development, seem to be affected. For example, breast cancer develops in 20% to 30% of women who underwent irradiation for Hodgkin lymphoma in their teens and 20s, but the risk for women treated later in life is not elevated. Of import, the low doses of radiation associated with mammographic screening have no significant effect on the incidence of breast cancer.

*Many other, less well-established risk factors,* such as obesity, alcohol consumption, and a diet high in fat, have been implicated in the development of breast cancer by analysis of population studies. The risk associated with obesity probably is due to exposure of the breast to estrogen produced by adipose tissue.

## PATHOGENESIS

The causes of breast cancer remain incompletely understood. However, three sets of influences seem to be important: (1) genetic changes, (2) hormonal influences, and (3) environmental variables.

**Genetic Changes.** As with all cancers, mutations affecting proto-oncogenes and tumor suppressor genes in breast epithelium underlie oncogenesis. Among the best-characterized is **overexpression of the *HER2/NEU* proto-oncogene,** which undergoes amplification in up to 30% of invasive breast cancers. This gene is a member of the epidermal growth factor receptor family, and its overexpression is associated with a poor prognosis. **Amplification of *RAS* and *MYC* genes also has been reported in some human breast cancers.** Mutations of the well-known tumor suppressor genes *RB* and *TP53* also may be present. A large number of genes including the estrogen receptor gene may be inactivated by promoter hypermethylation. Undoubtedly, the transformation process involves multiple acquired genetic alterations, which can occur in various combinations, thereby giving rise to different subtypes of breast cancer. **Gene expression profiling can separate breast cancer into four molecular subtypes:** (1) luminal A (estrogen receptor–positive, *HER2/NEU*-negative); (2) luminal B (estrogen receptor–positive, *HER2/NEU* overexpressing); (3) *HER2/NEU* positive (*HER2/NEU* over expressing, estrogen receptor–negative); and (4) basal-like (estrogen receptor–negative and *HER2/NEU*-negative). These subtypes are associated with different outcomes and, in some instances, different therapies.

Approximately 10% of breast cancers are related to specific inherited mutations. Women who carry a breast cancer susceptibility gene are more likely to have bilateral cancer, to have other familial forms of cancer (e.g., ovarian cancer), to have a positive family history (i.e., multiple first-degree relatives affected before menopause), to develop breast cancer before menopause, and to belong to certain ethnic groups (e.g., people of Ashkenazi Jewish descent). **Roughly one third of women with hereditary breast cancer have mutations in *BRCA1* (at chromosomal locus 17q21.3) or *BRCA2* (located on chromosomal band 13q12-13).** These genes encode large, complex proteins that do not exhibit close homology to each other or other proteins. Although the molecular basis for their strong association with breast cancer risk is still being elucidated, both BRCA1 and BRCA2 are believed to function in a common DNA repair pathway (Chapter 5).

Genetically, *BRCA1* and *BRCA2* are classic tumor suppressor genes, in that cancer arises only when both alleles are inactivated or defective—the first genetic lesion caused by a germline mutation and the second by a subsequent somatic mutation. Genetic testing is available, but its utility is complicated by the existence of hundreds of different mutant alleles, only some of which confer cancer susceptibility. The degree of penetrance, age at cancer onset, and susceptibility to other types of cancers differ among the specific mutations. Most carriers, however, develop breast cancer by the age of 70 years, as compared with only 7% of women who do not carry a mutation. The role of these genes in nonhereditary sporadic breast cancer is less clear, as mutations affecting *BRCA1* and *BRCA2* are infrequent in sporadic tumors. Less common genetic diseases associated with breast cancer are the Li-Fraumeni syndrome (caused by germline mutations in *TP53*) (Chapter 5), Cowden syndrome (caused by germline mutations in *PTEN*—mentioned earlier under endometrial carcinoma) (see also Chapter 14), and the ataxia-telangiectasia gene carriers (Chapter 5).

**Hormonal Influences.** Endogenous estrogen excess, or more accurately, hormonal imbalance, clearly has a significant role. Many of the risk factors mentioned (long duration of

reproductive life, nulliparity, and late age at birth of first child) involve increased exposure to estrogen unopposed by progesterone (Table 18–5). Functioning ovarian tumors that elaborate estrogens are associated with breast cancer in postmenopausal women. Estrogens stimulate the production of growth factors, such as transforming growth factor-α, platelet-derived growth factor, and fibroblast growth factor and others, which may promote tumor development through paracrine and autocrine mechanisms.

**Environmental Variables.** Environmental influences are suggested by the variable incidence of breast cancer in genetically homogeneous groups and the geographic differences in prevalence, as discussed earlier.

## MORPHOLOGY

The most common location of tumors within the breast is in the upper outer quadrant (50%), followed by the central portion (20%). About 4% of women with breast cancer have bilateral primary tumors or sequential lesions in the same breast.

Breast cancers are classified according to whether they have or have not penetrated the limiting basement membrane: Those that remain within this boundary are termed in situ carcinomas, and those that have spread beyond it are designated invasive or infiltrating carcinomas. In this classification, the main forms of breast carcinoma are as follows:

A. Noninvasive
   1. Ductal carcinoma in situ (DCIS)
   2. Lobular carcinoma in situ (LCIS)
B. Invasive (infiltrating)
   1. Invasive ductal carcinoma ("not otherwise specified"), the most common subtype of invasive carcinoma
   2. Invasive lobular carcinoma
   3. Medullary carcinoma
   4. Colloid carcinoma (mucinous carcinoma)
   5. Tubular carcinoma
   6. Other types

### *Noninvasive (in situ) Carcinoma*

There are two types of noninvasive breast carcinoma: DCIS and LCIS. Morphologic studies have shown that both types usually arise from cells in the terminal duct lobular unit. DCIS tends to fill and distort ductlike spaces. By contrast, LCIS usually expands but does not alter the acini of lobules. Both are confined by a basement membrane and do not invade into stroma or lymphovascular channels.

**DCIS** has a wide variety of histologic appearances. Architectural patterns often are mixed and include solid, comedo, cribriform, papillary, micropapillary, and "clinging" types. Necrosis may be present in any of these types. Nuclear appearance tends to be uniform in a given case and ranges from bland and monotonous (low nuclear grade) to pleomorphic (high nuclear grade). The **comedo** subtype is distinctive and is characterized by cells with high-grade nuclei with extensive central necrosis (Fig. 18–28). The name derives from the toothpaste-like necrotic tissue that extrudes from transected ducts on application of gentle pressure. **Calcifications frequently are associated with DCIS,** originating as either calcified necrotic debris or calcified secretory material. The proportion of breast cancers that are diagnosed at the DCIS stage is only 5% in unscreened populations but up to 40% in screened populations, largely because of the ability of mammography to detect calcifications. DCIS only rarely manifests as a palpable or radiologically detectable mass. The prognosis with DCIS is excellent, with greater than 97% long-term survival after simple mastectomy. In some women, distant metastases develop without local recurrence; these patients usually are found to have extensive high-nuclear-grade DCIS, probably with small, undetected areas of invasion. At least one third of women with small areas of untreated DCIS of low nuclear grade will eventually develop invasive carcinoma. When invasive cancer does develop, it usually is in the same breast and quadrant as the earlier DCIS. Current treatment strategies attempt to eradicate the DCIS by surgery and irradiation. Treatment with antiestrogenic agents such as tamoxifen and aromatase also may decrease the risk of recurrence.

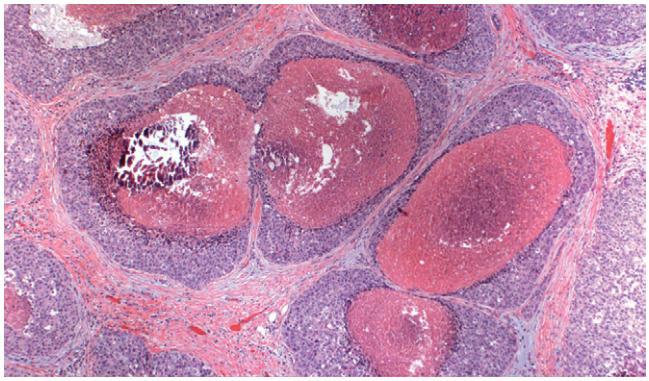

**Figure 18–28** Comedo ductal carcinoma in situ (DCIS). Several adjacent ducts are filled by tumor associated with large central zones of necrosis and calcified debris. This type of DCIS most frequently is detected as radiologic calcifications.

**Paget disease of the nipple** is caused by the extension of DCIS up the lactiferous ducts and into the contiguous skin of the nipple, producing a unilateral crusting exudate over the nipple and areolar skin. In almost all cases, an underlying carcinoma is present, and approximately 50% of the time this carcinoma is invasive. Prognosis is based on the underlying carcinoma and is not affected by the presence of Paget disease.

**LCIS** has a uniform appearance. The cells are monomorphic with bland, round nuclei and occur in loosely cohesive clusters within the lobules (Fig. 18–29). Intracellular mucin vacuoles (sometimes forming signet ring cells) are common. LCIS is virtually always an incidental finding, because unlike DCIS, it is only rarely associated with calcifications. Therefore, the incidence of LCIS has remained unchanged in mammographically screened populations. Approximately one third of women with LCIS will eventually develop invasive carcinoma. Unlike with DCIS, **subsequent invasive carcinomas may arise in either breast.** Most of these cancers are invasive lobular carcinomas; however, invasive ductal carcinomas also arise from LCIS. Thus, **LCIS is both a marker of an increased risk of carcinoma in both breasts and a direct precursor of some cancers.** Current treatment involves either chemoprevention with tamoxifen along with close clinical and radiologic follow-up evaluation or, less commonly, bilateral prophylactic mastectomy.

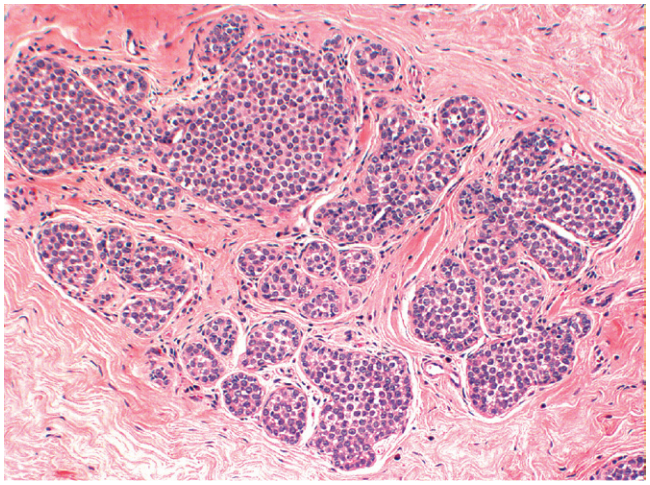

**Figure 18–29** Lobular carcinoma in situ. A monomorphic population of small, rounded, loosely cohesive cells fills and expands the acini of a lobule. The underlying lobular architecture is intact.

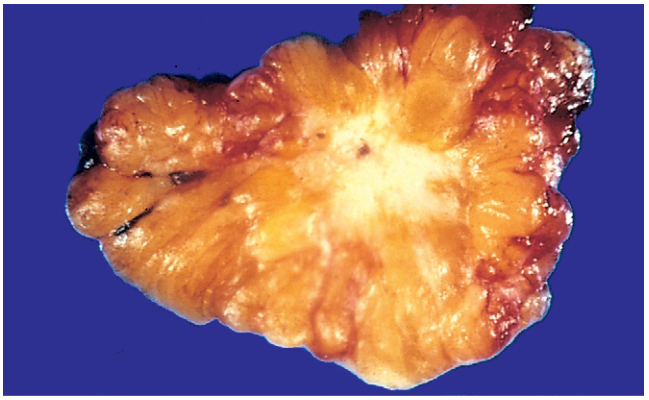

**Figure 18–30** Invasive ductal carcinoma is evident in this breast biopsy specimen. The hard, fibrotic lesion infiltrates the surrounding tissue, causing retraction.

***Invasive (Infiltrating) Carcinoma***

The distinctive histologic patterns of the subtypes of invasive carcinoma are described first, followed by the gross features common to all.

**Invasive ductal carcinoma** is a term used for all carcinomas that cannot be subclassified into one of the specialized types described below**.** A majority (70% to 80%) of cancers fall into this group. This type of cancer usually is associated with DCIS and, rarely, LCIS. Most ductal carcinomas produce a desmoplastic response, which replaces normal breast fat (resulting in a mammographic density) and forms a hard, palpable mass (Fig. 18–30). The microscopic appearance is quite heterogeneous, ranging from tumors with well-developed tubule formation and low-grade nuclei to tumors consisting of sheets of anaplastic cells (Fig. 18–31). The tumor margins typically are irregular. Invasion of lymphovascular spaces may be seen. About two thirds express estrogen or progesterone receptors, and about one third overexpress HER2/NEU.

**Invasive lobular carcinoma** consists of cells morphologically identical to the cells of LCIS. Two thirds of the cases are associated with adjacent LCIS. The cells invade individually into stroma and are often aligned in "single-file" strands or chains. This growth pattern correlates with the presence of mutations that abrogate the function of E-cadherin, a surface protein that contributes to the cohesion of normal breast epithelial cells. Although most manifest as palpable masses or mammographic densities, a significant subgroup may exhibit a diffusely invasive pattern without a desmoplastic response and may be clinically occult. Lobular carcinomas have a unique pattern of metastases among breast cancers;

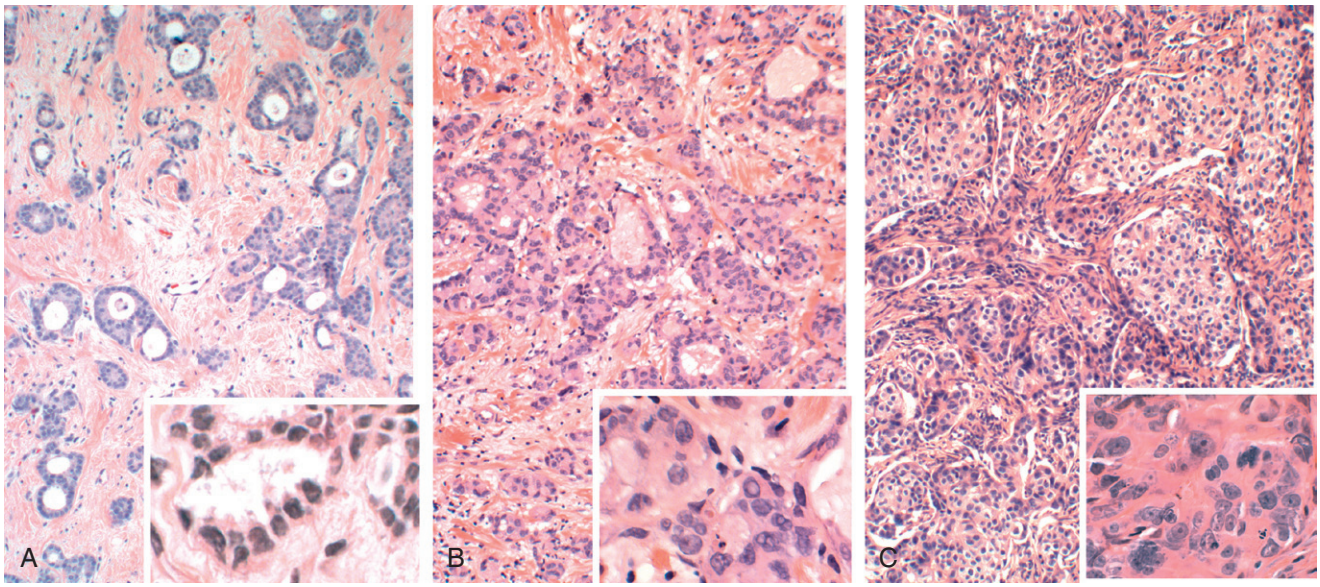

**Figure 18–31** Invasive breast carcinomas of no special type (*insets* show each tumor at higher magnification). **A,** Well-differentiated carcinoma consists of tubular or cribriform glands containing cells with small monomorphic nuclei within a desmoplastic response. **B,** Moderately differentiated carcinoma demonstrates less tubule formation and more solid nests of cells with pleomorphic nuclei. **C,** Poorly differentiated carcinoma infiltrates as ragged sheets of pleomorphic cells containing numerous mitotic figures and areas of tumor necrosis.

they more frequently spread to cerebrospinal fluid, serosal surfaces, gastrointestinal tract, ovary, uterus, and bone marrow. Lobular carcinomas also are more frequently multicentric and bilateral (in 10% to 20% of cases). Almost all of these carcinomas express hormone receptors, whereas HER2/NEU overexpression is rare. These tumors comprise fewer than 20% of all breast carcinomas.

**Inflammatory carcinoma** is defined by the clinical presentation of an enlarged, swollen, erythematous breast, usually without a palpable mass. The underlying carcinoma is generally poorly differentiated and diffusely infiltrative. Characteristically, carcinoma involves dermal lymphatic spaces. The resultant blockage of these channels leads to edema, resulting in the characteristic "inflamed" clinical appearance; true inflammation is minimal to absent. Many of these tumors metastasize to distant sites; the overall 5-year survival is under 50%, and understandably even lower in those with metastatic disease at diagnosis.

**Medullary carcinoma** is a rare subtype of carcinoma, accounting for less than 1% of breast cancers. These cancers consist of sheets of large anaplastic cells with well-circumscribed, "pushing" borders (Fig. 18–32, *A*). Clinically, they can be mistaken for fibroadenomas. There is invariably a pronounced lymphoplasmacytic infiltrate. DCIS usually is absent or minimal. Medullary carcinomas occur with increased frequency in women with *BRCA1* mutations, although most women with medullary carcinoma are not carriers. These carcinomas uniformly lack the estrogen and progesterone receptors and do not overexpress HER2/NEU (a combination that often is referred to as **triple-negative**).

**Colloid (mucinous) carcinoma** also is a rare subtype. The tumor cells produce abundant quantities of extracellular mucin, which dissects into the surrounding stroma (Fig. 18–32, *B*). Like medullary carcinomas, they often present as well-circumscribed masses and can be mistaken for fibroadenomas. On gross evaluation, the tumors usually are soft and gelatinous. Most express hormone receptors but do not overexpress HER2/NEU.

**Tubular carcinomas** rarely present as palpable masses but account for 10% of invasive carcinomas smaller than 1 cm found with mammographic screening. They usually are detected as irregular mammographic densities. On microscopic examination, the carcinomas consist of well-formed tubules with low-grade nuclei. Lymph node metastases are rare, and prognosis is excellent. Virtually all tubular carcinomas express hormone receptors and do not show HER2/NEU overexpression.

#### *Common Features of Invasive Cancers*

In all forms of breast cancer, local disease progression leads to similar physical findings. Invasive cancers tend to become adherent and fixed to the pectoral muscles or deep fascia of the chest wall and the overlying skin, with consequent retraction or dimpling of the skin or nipple. The latter is an important sign because it may be the first indication of malignancy. Involvement of the lymphatic pathways may result in localized lymphedema. In such cases, the skin becomes thickened around exaggerated hair follicles, giving an appearance known as peau d'orange ("orange peel").

### Clinical Course

Breast cancer often is discovered by the patient or her physician as a deceptively discrete, solitary, painless, and movable mass. At the time of clinical detection, the carcinoma typically is 2 to 3 cm in size, and involvement of the regional lymph nodes (most often axillary) is already present in about 50% of patients. With mammographic screening, carcinomas frequently are detected even before they become palpable. The average invasive carcinoma found by mammographic screening is around 1 cm in size, and only 15% of these have produced nodal metastases. In addition, DCIS often is detected before the development of invasive carcinoma during screening. As women age, fibrous breast tissue is replaced by fat, and screening becomes more sensitive as a result of the increased radiolucency of the breast and the increased incidence of malignancy. The current controversy over the best time to begin mammographic screening arises from efforts to balance the benefits of early cancer detection in some women with the

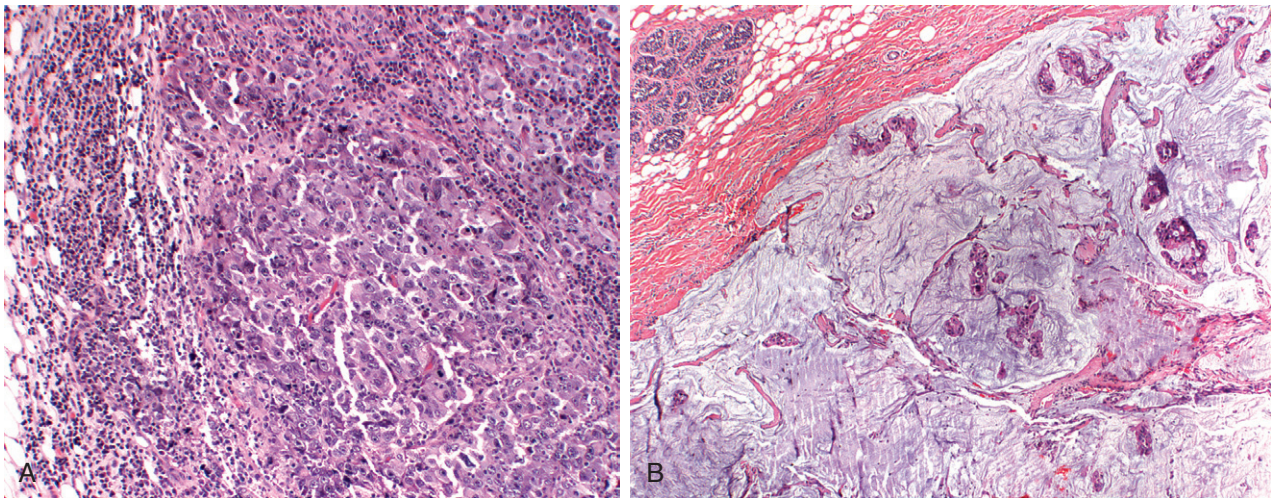

**Figure 18–32** Special types of breast carcinoma. **A,** Medullary carcinoma. The highly pleomorphic tumor cells grow in cohesive sheets and are associated with a prominent reactive infiltrate of lymphocytes and plasma cells. **B,** Mucinous (colloid) carcinoma. The tumor cells are present in small clusters within large pools of mucin. Note the characteristic well-circumscribed border, which mimics the appearance of benign masses.

risks of radiation exposure and the morbidity and expense associated with clinical workup of benign breast lesions (false positives). Magnetic resonance imaging is being studied as an adjunct to mammographic screening in high-risk, young patients with dense breasts that are difficult to image by mammography.

Breast cancer spread occurs through lymphatic and hematogenous channels. Outer quadrant and centrally located lesions typically spread first to the axillary nodes. Those in the medial inner quadrants often travel first to lymph nodes along the internal mammary arteries. More distant dissemination eventually ensues, and can involve virtually any organ or tissue in the body. Favored locations are the lungs, skeleton, liver, adrenals, and (less commonly) brain, but no site is exempt. *Metastases may come to clinical attention many years after apparent therapeutic control of the primary lesion, sometimes as long as 15 years later.* Nevertheless, with each passing year without disease recurrence, the likelihood of cure increases.

Prognosis of breast cancers is influenced by the following variables the first three of which are components of the tumor-node-metastasis (TNM) staging classification:

- *Tumor invasion and size.* In situ carcinomas carry an excellent prognosis (5-year survival rate greater than 90%), as do invasive carcinomas less than 2 cm in size (5-year survival rate of 87%).
- *Extent of lymph node involvement.* With no axillary node involvement, the 5-year survival rate is close to 80%. Survival is inversely related to the number of involved lymph nodes and is less than 50% with 16 or more involved nodes. Sentinel node biopsy is currently the mainstay for staging the axilla. This procedure identifies the primary lymph node(s) that drain the breast parenchyma using dye or a radioactive tracer (or sometimes both). Once identified, sentinel nodes are removed and examined microscopically. A sentinel lymph node that is free from carcinoma (a "negative node") is highly predictive of absence of metastatic carcinoma in the remaining lymph nodes. A "positive node," on the other hand, is an indication for a complete axillary dissection, which is used to stage the patient's disease.
- *Distant metastases.* Patients who develop hematogenous spread are rarely curable, although chemotherapy may prolong survival (the 5-year survival rate is approximately 15%).
- *Histologic grade.* The most common grading system for breast cancer evaluates tubule formation, nuclear grade, and mitotic rate. Well-differentiated carcinomas are associated with a significantly better prognosis than poorly differentiated carcinomas. Moderately differentiated carcinomas initially have a good prognosis, but survival at 20 years approaches that for poorly differentiated carcinomas.
- *The histologic type of carcinoma.* All specialized types of breast carcinoma (tubular, medullary, and mucinous) are associated with a somewhat better prognosis than carcinomas of no special type (*ductal carcinomas*). A major exception is inflammatory carcinoma, which has a poor prognosis.
- *The presence or absence of estrogen or progesterone receptors.* The presence of hormone receptors confers a slightly better prognosis. However, the practical reason for determining their presence is to predict the response to therapy. The highest rate of response (approximately 80%) to antiestrogen therapy (oophorectomy or tamoxifen) is seen in women whose tumor cells express both estrogen and progesterone receptors. Lower rates of response (25% to 45%) are seen if only estrogen receptor is present. If both are absent, very few patients (less than 10%) respond.
- *Overexpression of HER2/NEU.* Overexpression of this membrane-bound protein is almost always caused by gene amplification and can be determined by immunohistochemistry (which assesses protein levels) or by fluorescence in situ hybridization (which assesses the gene copy number). Overexpression is associated with a poorer prognosis. However, the clinical importance of evaluating HER2/NEU lies in predicting response to trastuzumab (Herceptin), a monoclonal antibody that binds and inhibits the function of HER2/NEU. This remains one of the best-characterized examples of an effective therapy directed against a tumor-specific molecular lesion.

Why some cancers recur after postoperative therapy while others do not remains a mystery. As mentioned earlier, gene expression profiling of breast cancers on microarrays (gene chips) (Chapter 5) has defined several molecular classes of breast cancer and also has been used to develop commercial tests that may predict the response of an individual patient's tumor to chemotherapy. At present there is insufficient data on the prognostic value of such tests.

## SUMMARY

### Breast Carcinoma

- The lifetime risk of developing breast cancer for an American woman is 1 in 8.
- A majority (75%) of breast cancers are diagnosed after the age of 50.
- Risk of developing breast cancer is related to estrogen exposure, genetic factors, long duration between menarche and menopause, atypical proliferative lesions, and family history of breast cancer in a first-degree relative, particularly if the disease was multifocal or in a premenopausal woman.
- About 10% of all breast cancers are caused by inherited mutations; *BRCA1* and *BRCA2* genes account for one third of the cases associated with single-gene mutations.
- Ductal carcinoma in situ (DCIS) is a precursor to invasive ductal carcinoma and typically is found on mammographic examination as calcifications. When carcinoma develops in a woman with a previous diagnosis of DCIS, it usually is an invasive ductal carcinoma in the same breast.
- Lobular carcinoma in situ (LCIS) frequently is an incidental finding and usually is not associated with calcifications. When carcinoma develops in a woman with a previous diagnosis of LCIS, it may occur in the affected or unaffected breast and usually is invasive lobular carcinoma but may be invasive ductal carcinoma.

- The natural history of breast carcinoma is long, with metastases sometimes appearing decades after the initial diagnosis.
- Prognosis is most dependent on tumor size, lymph node involvement, distant metastasis at presentation, tumor grade, and histologic type.
- Estrogen and progesterone receptor status and expression of HER2/NEU are used primarily to determine response to treatment. Estrogen receptor–expressing tumors are more likely to respond to tamoxifen. HER2/NEU-overexpressing tumors often are treated with trastuzumab.

## LESIONS OF THE MALE BREAST

The rudimentary male breast is relatively free of pathologic involvement. Only two disorders occur with sufficient frequency to be considered here: *gynecomastia* and *carcinoma.*

### Gynecomastia

As in females, male breasts are subject to hormonal influences, but they are considerably less sensitive in this regard than female breasts. Nonetheless, enlargement of the male breast, or gynecomastia, may occur in response to absolute or relative estrogen excesses. The most important cause of hyperestrinism in the male is cirrhosis and the consequent inability of the liver to metabolize estrogens. Other causes include Klinefelter syndrome, anabolic steroids, and some pharmacologic agents. Physiologic gynecomastia often occurs in puberty and in extreme old age.

The morphologic features of gynecomastia include an increase in connective tissue and epithelial hyperplasia of the ducts; lobule formation is rare. Clinically, a button-like, subareolar swelling develops, usually in both breasts but occasionally in only one.

### Carcinoma

Breast cancer is rare in men, with an incidence less than 1% of that reported for women. It typically is diagnosed in advanced age. Because of the scant amount of breast tissue in men, the tumor rapidly infiltrates the overlying skin and underlying thoracic wall. Both morphologically and biologically, these tumors resemble the invasive carcinomas seen in women. Unfortunately, almost half have spread to regional nodes or more distant sites by the time they are discovered.

The endocrine system is a highly integrated and widely distributed group of organs that orchestrate a state of metabolic equilibrium, or homeostasis, among the various tissues of the body. Signaling by extracellular secreted molecules can be classified as one of three types—autocrine, paracrine, or endocrine—according to the distance over which the signal acts (Chapter 2). In *endocrine* signaling, the secreted molecules, which frequently are called *hormones,* act on target cells distant from their site of synthesis. An endocrine hormone typically is carried by the blood from its site of release to its target. Increased activity of the target tissue often downregulates the activity of the gland that secretes the stimulating hormone, a process known as *feedback inhibition.*

Hormones can be classified into several broad categories, based on the nature of their receptors:

- *Hormones that trigger biochemical signals upon interacting with cell surface receptors*: This large class of compounds is composed of two groups: (1) peptide hormones, such as *growth hormone* and *insulin,* and (2) small molecules, such as *epinephrine.* Binding of these hormones to cell surface receptors leads to an increase in intracellular molecules, termed *second messengers,* such as cyclic adenosine monophosphate (cAMP); production of mediators from membrane phospholipids (e.g., inositol 1,4,5-trisphosphate); and shifts in intracellular levels of ionized calcium. Elevated levels of one or more of these compounds can change proliferation, differentiation, survival, and functional activity of cells, mainly by regulating the expression of specific genes.
- *Hormones that diffuse across the plasma membrane and interact with intracellular receptors*: Many lipid-soluble hormones pass through the plasma membrane by diffusion to interact with receptors in the cytosol or the nucleus. The resulting hormone-receptor complexes bind specifically to promoter and enhancer elements in DNA,

thereby affecting the expression of specific target genes. Hormones of this type include the *steroids* (e.g., estrogen, progesterone, glucocorticoids), the *retinoids* (vitamin A), and *thyroxine.*

Several processes may disturb the normal activity of the endocrine system, including impaired synthesis or release of hormones, abnormal interactions between hormones and their target tissues, and abnormal responses of target organs to their hormones. Endocrine diseases can be generally classified as (1) diseases of *underproduction or overproduction* of hormones, with associated biochemical and clinical consequences, or (2) diseases associated with the development of *mass lesions,* which may be nonfunctional or may be associated with overproduction or underproduction of hormones.

With the exception of mass lesions, study of endocrine diseases relies heavily on biochemical measurements of the levels of hormones, their regulators, and other metabolites.

## PITUITARY

The pituitary gland is a small, bean-shaped structure that lies at the base of the brain within the confines of the sella turcica. It is intimately related to the hypothalamus, with which it is connected by both a *stalk,* composed of axons extending from the hypothalamus, and a rich venous plexus constituting a portal circulation. Along with the hypothalamus, the pituitary has a central role in the regulation of most of the other endocrine glands. The pituitary is composed of two morphologically and functionally distinct components: the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis). Diseases of the pituitary, accordingly, can be divided into those that primarily affect the anterior lobe and those that primarily affect the posterior lobe.

The *anterior pituitary,* or *adenohypophysis,* is composed of epithelial cells derived embryologically from the developing oral cavity. In routine histologic sections, a colorful array of cells containing basophilic cytoplasm, eosinophilic cytoplasm, or poorly staining (*chromophobic*) cytoplasm is present (Fig. 19–1). Detailed studies using electron microscopy and immunocytochemical techniques have demonstrated that the staining properties of these cells are related to the presence of various trophic polypeptide hormones within their cytoplasm. The release of trophic hormones is in turn under the control of factors produced in the hypothalamus; while most hypothalamic factors are stimulatory and promote pituitary hormone release, others (e.g., somatostatin and dopamine) are inhibitory in their effects (Fig. 19–2). Rarely, signs and symptoms of pituitary disease may be caused by excess or lack of the hypothalamic factors, rather than by a primary pituitary abnormality.

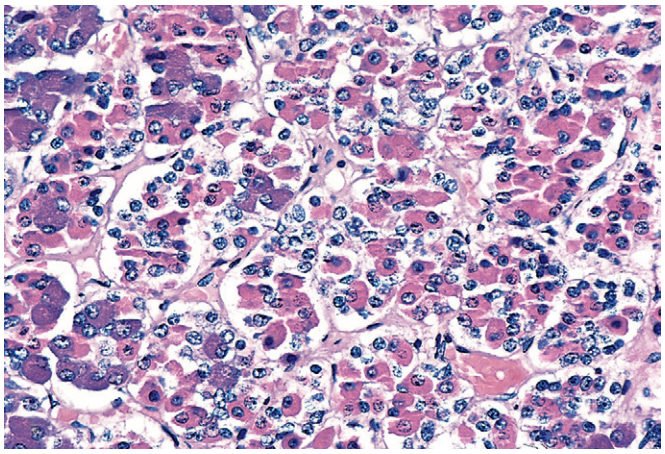

**Figure 19–1** Normal architecture of the anterior pituitary. The gland is populated by several distinct cell types containing a variety of stimulating (trophic) hormones. Each of the hormones has different staining characteristics, resulting in a mixture of cell types in routine histologic preparations. Note also the presence of a fine reticulin network.

Symptoms and signs of pituitary disease can be grouped as follows:

- *Hyperpituitarism*-related effects: Hyperpituitarism arises from excessive secretion of trophic hormones. It most often results from an *anterior pituitary adenoma* but also may be caused by other pituitary and extrapituitary lesions, as described subsequently. The symptoms and signs of hyperpituitarism are discussed in the context of individual tumors, later in the chapter.
- *Hypopituitarism*-related effects: Hypopituitarism is caused by deficiency of trophic hormones and results from a variety of destructive processes, including *ischemic injury, surgery or radiation,* and *inflammatory reactions.* In addition, *nonfunctional pituitary adenomas* may encroach upon and destroy adjacent normal anterior pituitary parenchyma, causing hypopituitarism.
- *Local mass effects*: Among the earliest changes referable to mass effect are *radiographic abnormalities of the sella turcica,* including sellar expansion, bony erosion, and disruption of the diaphragma sellae. Because of the close proximity of the optic nerves and chiasm to the sella, expanding pituitary lesions often compress decussating fibers in the optic chiasm. This altered neuroanatomy gives rise to *visual field abnormalities,* classically in the form of defects in the lateral (temporal) visual fields—a so-called *bitemporal hemianopsia.* As in the case of any expanding intracranial mass, pituitary adenomas may produce signs and symptoms of *elevated intracranial pressure,* including headache, nausea, and vomiting. Pituitary adenomas that extend beyond the sella turcica into the base of the brain (invasive pituitary adenoma) produce *seizures* or *obstructive hydrocephalus*; involvement of cranial nerves can result in *cranial nerve palsy.* On occasion, acute hemorrhage into an adenoma is associated with clinical evidence of rapid enlargement of the lesion and depression of consciousness, a situation appropriately termed *pituitary apoplexy.* Acute pituitary apoplexy constitutes a neurosurgical emergency, because it may be rapidly fatal.

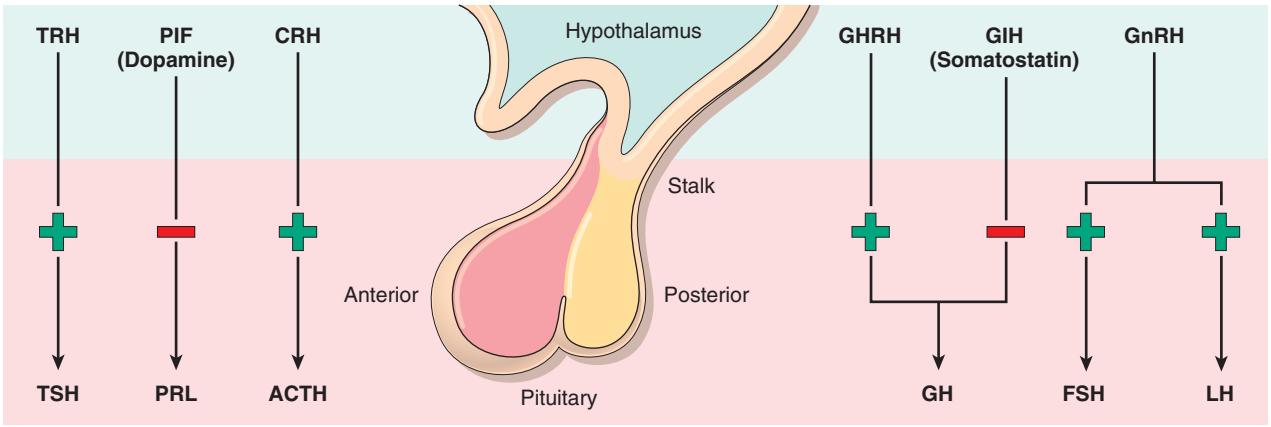

**Figure 19–2** The adenohypophysis (anterior pituitary) releases six hormones: adrenocorticotropic hormone (ACTH), or corticotropin; follicle-stimulating hormone (FSH); growth hormone (GH), or somatotropin; luteinizing hormone (LH); prolactin (PRL); and thyroid-stimulating hormone (TSH), or thyrotropin. These hormones are in turn under the control of various stimulatory and inhibitory hypothalamic releasing factors. The *stimulatory* releasing factors are corticotropin-releasing hormone (CRH), growth hormone–releasing hormone (GHRH), gonadotropin-releasing hormone (GnRH), and thyrotropin-releasing hormone (TRH). The *inhibitory* hypothalamic factors are growth hormone inhibitory hormone (GIH), or somatostatin, and prolactin inhibitory factor (PIF), which is the same as dopamine.

## HYPERPITUITARISM AND PITUITARY ADENOMAS

*The most common cause of hyperpituitarism is an adenoma arising in the anterior lobe.* Other, less common, causes include hyperplasia and carcinomas of the anterior pituitary, secretion of hormones by some extrapituitary tumors, and certain hypothalamic disorders. Some salient features of pituitary adenomas are as follows:

- *Pituitary adenomas are classified on the basis of hormone(s) produced by the neoplastic cells, which are detected by immunohistochemical stains performed on tissue sections* (Table 19–1).
- Pituitary adenomas can be *functional* (i.e., associated with hormone excess and clinical manifestations thereof) or *nonfunctioning* (i.e., demonstration of hormone production at the tissue level only, without clinical manifestations of hormone excess). Both functional and nonfunctioning pituitary adenomas usually are composed of a single cell type and produce a single predominant hormone, but there are some exceptions. Some pituitary adenomas can secrete two different hormones (growth hormone and prolactin being the most common combination); rarely, pituitary adenomas are plurihormonal. At the other end of the spectrum, pituitary adenomas also may be truly "*hormone negative,*" as indicated by absence of immunohistochemical reactivity or ultrastructural evidence of hormone production.
- Most pituitary adenomas occur as sporadic (i.e., nonfamilial) lesions. In about 5% of cases, however, adenomas occur as a result of an inherited predisposition (see later).
- Pituitary adenomas are designated, somewhat arbitrarily, as *microadenomas* if they are less than 1 cm in diameter and *macroadenomas* if they exceed 1 cm in diameter.
- Nonfunctioning and hormone-negative adenomas are likely to come to clinical attention at a later stage and are, therefore, more likely to be macroadenomas than

**Table 19–1** Classification of Pituitary Adenomas

| Pituitary Cell Type | Hormone | Tumor Type | Associated Syndrome* |
|---|---|---|---|
| Corticotroph | ACTH and other POMC-derived peptides | Densely granulated<br>Sparsely granulated | Cushing syndrome<br>Nelson syndrome |
| Somatotroph | GH | Densely granulated<br>Sparsely granulated | Gigantism (children)<br>Acromegaly (adults) |
| Lactotroph | Prolactin | Densely granulated<br>Sparsely granulated | Galactorrhea and amenorrhea (in females)<br>Sexual dysfunction, infertility |
| Mammosomatotroph | Prolactin, GH | Mammosomatotroph | Combined features of GH and prolactin excess |
| Thyrotroph | TSH | Thyrotroph | Hyperthyroidism |
| Gonadotroph | FSH, LH | Gonadotroph, "null cell," oncocytic adenomas | Hypogonadism, mass effects and hypopituitarism |

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; POMC, pro-opiomelanocortin; TSH, thyroid-stimulating hormone.
*Nonfunctioning adenomas in each category typically manifest with *mass effects* and often with *hypopituitarism*.
Data from Ezzat S, Asa SL: Mechanisms of disease: the pathogenesis of pituitary tumors. Nat Clin Pract Endocrinol Metab 2:220–230, 2006.

are lesions associated with endocrine abnormalities. In addition, nonfunctioning adenomas may cause *hypo*pituitarism as they encroach on and destroy adjacent anterior pituitary parenchyma.

## PATHOGENESIS

With recent advances in molecular techniques, substantial insight has been gained into the **genetic abnormalities associated with pituitary adenomas:**

- Guanine nucleotide–binding protein (G protein) mutations are the best-characterized molecular abnormalities in these neoplasms. G proteins have a critical role in signal transduction, transmitting signals from **cell surface receptors** (e.g., growth hormone–releasing hormone receptor) to **intracellular effectors** (e.g., adenyl cyclase), which then generate **second messengers** (e.g., cAMP). $G_s$ is a stimulatory G protein that has a pivotal role in signal transduction in several endocrine organs, including the pituitary. $G_s$ exists as an inactive protein, with guanosine diphosphate (GDP) bound to the guanine nucleotide–binding site of the alpha subunit of $G_s$, encoded by the *GNAS1* gene. On triggering of the hormone receptor, GDP dissociates, and guanosine triphosphate (GTP) binds to $G_s\alpha$, activating the G protein. GTP-bound $G_s\alpha$ directly interacts with and activates its effectors (such as adenyl cyclase), with a resultant increase in intracellular cAMP. The cAMP acts as a potent mitogenic stimulus for a variety of endocrine cell types, promoting cellular proliferation and hormone synthesis and secretion. The activation of $G_s\alpha$ and the resultant generation of cAMP are **transient** because of an intrinsic GTPase activity in the $\alpha$-subunit, which hydrolyzes GTP into GDP. **A mutation in the $\alpha$-subunit that interferes with its intrinsic GTPase activity therefore results in constitutive activation of $G_s\alpha$, persistent generation of cAMP, and unchecked cellular proliferation.** Approximately 40% of growth hormone–secreting somatotroph cell adenomas and a minority of adrenocorticotropic hormone (ACTH)–secreting corticotroph cell adenomas bear *GNAS1* mutations.
- As stated previously, approximately 5% of pituitary adenomas arise as a consequence of an inherited predisposition. **Four genes have been identified thus far as a cause of familial pituitary adenomas: *MEN1*, *CDKN1B*, *PRKAR1A*, and *AIP*.** Germline inactivating mutations of the *MEN1* gene are responsible for multiple endocrine neoplasia syndrome type 1 (MEN-1) (discussed in detail later on). The product of the *CDKN1B* gene is the cell cycle checkpoint regulator p27 or KIP1; germline mutations of *CDKN1B* are responsible for a subset of patients with a "MEN-1 like" syndrome who lack *MEN1* abnormalities. The gene encoding the **aryl hydrocarbon receptor–interacting protein (AIP)** is a recently described pituitary adenoma predisposition gene, and patients with *AIP* germline mutations often develop GH-secreting adenomas at a younger age (before 35 years) than that typical for sporadic GH adenoma patients.
- Mutations of *TP53* in pituitary adenomas are associated with a propensity for aggressive behavior, such as invasion and recurrence.

## MORPHOLOGY

The usual pituitary adenoma is a well-circumscribed, soft lesion that may, in the case of smaller tumors, be confined by the sella turcica. Larger lesions may compress the optic chiasm and adjacent structures (Fig. 19–3), erode the sella turcica and anterior clinoid processes, and extend locally into the cavernous and sphenoidal sinuses. In as many as 30% of cases, the adenomas are nonencapsulated and infiltrate adjacent bone, dura, and (uncommonly) brain. Foci of hemorrhage and/or necrosis are common in larger adenomas.

Pituitary adenomas are composed of relatively uniform, polygonal cells arrayed in sheets, cords, or papillae. Supporting connective tissue, or reticulin, is sparse, accounting for the soft, gelatinous consistency of many of these tumors. The nuclei of the neoplastic cells may be uniform or pleomorphic. Mitotic activity usually is scanty. The cytoplasm of the constituent cells may be acidophilic, basophilic, or chromophobic, depending on the type and amount of secretory product within the cell, but it is fairly uniform throughout the neoplasm. **This cellular monomorphism and the absence of a significant reticulin network distinguish pituitary adenomas from non-neoplastic anterior pituitary parenchyma** (Fig. 19–4). The functional status of the adenoma cannot be reliably predicted from its histologic appearance. Adenomas that harbor *TP53* mutations often demonstrate brisk mitotic activity and higher proliferation rates and are designated **atypical adenomas** to reinforce their potential for aggressive behavior.

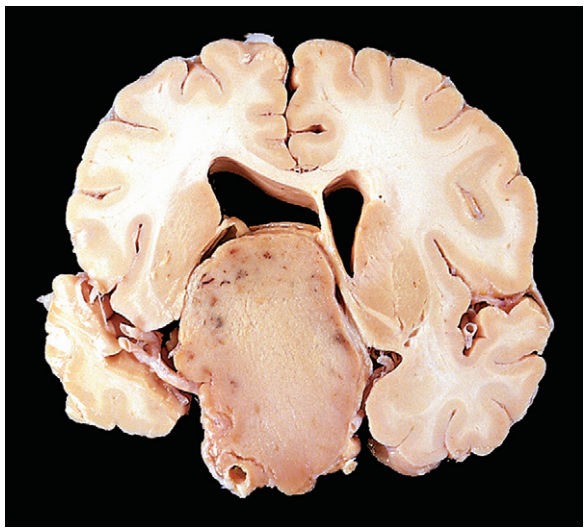

**Figure 19–3** Pituitary adenoma. This massive, nonfunctioning adenoma has grown far beyond the confines of the sella turcica and has distorted the overlying brain. Nonfunctioning adenomas tend to be larger at the time of diagnosis than those that secrete a hormone.

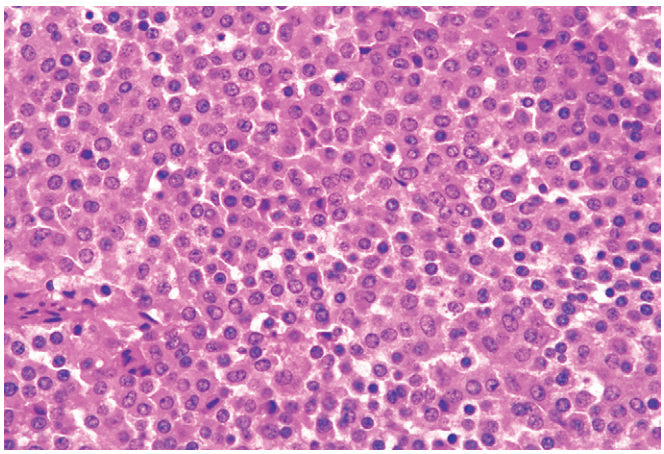

**Figure 19–4** Pituitary adenoma. The monomorphism of these cells contrasts markedly with the admixture of cells seen in the normal anterior pituitary in Figure 19–1. Note also the absence of reticulin network.

## SUMMARY

### Hyperpituitarism

- The most common cause of hyperpituitarism is an anterior lobe pituitary adenoma.
- Pituitary adenomas can be macroadenomas (greater than 1 cm in diameter) or microadenomas (less than 1 cm across), and on clinical evaluation, they can be functional or nonfunctioning.
- Macroadenomas may potentially lead to mass effects, including visual disturbances.
- Functioning adenomas are associated with distinct endocrine signs and symptoms.
- Mutation of the *GNAS1* gene, which results in constitutive activation of a stimulatory G protein, is one of the more common genetic alterations.
- The two distinctive morphologic features of most adenomas are their cellular monomorphism and absence of a reticulin network.

## Prolactinomas

*Prolactinomas are the most common type of hyperfunctioning pituitary adenoma.* They range in size from small microadenomas to large, expansile tumors associated with considerable mass effect. Prolactin is demonstrable within the cytoplasm of the neoplastic cells by immunohistochemical techniques.

*Hyperprolactinemia* causes amenorrhea, galactorrhea, loss of libido, and infertility. Because many of the manifestations of hyperprolactinemia (e.g., amenorrhea) are more obvious in premenopausal women than in men or postmenopausal women, prolactinomas usually are diagnosed at an earlier stage in women of reproductive age than in other persons so affected. By contrast, hormonal manifestations may be quite subtle in men and older women, in whom the tumor may reach considerable size before coming to clinical attention. Hyperprolactinemia may be caused by conditions or factors other than prolactin-secreting pituitary adenomas, including pregnancy, high-dose estrogen therapy, renal failure, hypothyroidism, hypothalamic lesions, and dopamine-inhibiting drugs (e.g., reserpine). In addition, any mass in the suprasellar compartment may disturb the normal inhibitory influence of hypothalamus on prolactin secretion, resulting in hyperprolactinemia—a mechanism known as the *stalk effect.* Thus, *mild* elevations of serum prolactin (less than 200 μg/L) in a patient with a pituitary adenoma do not necessarily indicate a prolactin-secreting neoplasm.

## Growth Hormone–Producing (Somatotroph Cell) Adenomas

Growth hormone–producing neoplasms (somatotroph cell adenomas), including those that produce a mixture of growth hormone and other hormones (e.g., prolactin), constitute the second most common type of functional pituitary adenoma. Because the clinical manifestations of excessive growth hormone may be subtle, somatotroph cell adenomas may be quite large by the time they come to clinical attention. On microscopic examination, growth hormone–producing adenomas are composed of densely or sparsely granulated cells, and immunohistochemical staining demonstrates growth hormone within the cytoplasm of the neoplastic cells. Small amounts of immunoreactive prolactin often are present as well.

*Persistent hypersecretion of growth hormone stimulates the hepatic secretion of insulin-like growth factor I (somatomedin C), which causes many of the clinical manifestations.* If a growth hormone–secreting adenoma occurs before the epiphyses close, as is the case in prepubertal children, excessive levels of growth hormone result in *gigantism.* This condition is characterized by a generalized increase in body size, with disproportionately long arms and legs. If elevated levels of growth hormone persist, or develop after closure of the epiphyses, affected persons develop *acromegaly,* in which growth is most conspicuous in soft tissues, skin, and viscera and in the bones of the face, hands, and feet. Enlargement of the jaw results in its protrusion (prognathism), with broadening of the lower face and separation of the teeth. The hands and feet are enlarged, with broad, sausage-like fingers. In clinical practice, the gigantism typically is accompanied by evidence of acromegaly.

Growth hormone excess also is associated with a number of other disturbances, including abnormal glucose tolerance and diabetes mellitus, generalized muscle weakness, hypertension, arthritis, osteoporosis, and congestive heart failure. Prolactin is demonstrable in a number of growth hormone–producing adenomas and in some cases may be released in sufficient quantities to produce signs and symptoms of hyperprolactinemia.

## Adrenocorticotropic Hormone–Producing (Corticotroph Cell) Adenomas

Most corticotroph cell adenomas are small (microadenomas) at the time of diagnosis. These adenomas stain positively with periodic acid–Schiff (PAS) stains, as a result of

the accumulation of glycosylated ACTH protein. As in the case of other pituitary hormones, the secretory granules can be detected by immunohistochemical methods. By electron microscopy they appear as membrane-bound, electron-dense granules averaging 300 nm in diameter.

Corticotroph cell adenomas may be clinically silent or may cause *hypercortisolism,* manifested clinically as *Cushing syndrome,* because of the stimulatory effect of ACTH on the adrenal cortex. Cushing syndrome, discussed in more detail later with diseases of the adrenal gland, may be caused by a wide variety of conditions in addition to ACTH-producing pituitary neoplasms. When the hypercortisolism is caused by excessive production of ACTH by the pituitary, the process is designated *Cushing disease,* because it is the pattern of hypercortisolism originally described by Dr. Harvey Cushing. Large, clinically aggressive corticotroph cell adenomas may develop after surgical removal of the adrenal glands for treatment of Cushing syndrome. In most instances, this condition, known as *Nelson syndrome,* results from loss of the inhibitory effect of adrenal corticosteroids on a preexisting corticotroph microadenoma. Because the adrenals are absent in persons with Nelson syndrome, hypercortisolism does not develop. Instead, patients present with the mass effects of the pituitary tumor. In addition, because ACTH is synthesized as part of a larger prohormone substance that includes melanocyte-stimulating hormone (MSH), hyperpigmentation also may be a feature.

### Other Anterior Pituitary Neoplasms

- *Gonadotroph (luteinizing hormone [LH]–producing and follicle-stimulating hormone [FSH]–producing)* adenomas can be difficult to recognize, because they secrete hormones inefficiently and variably, and the secretory products usually do not cause a recognizable clinical syndrome. They are typically detected when the tumors have become large enough to cause neurologic signs and symptoms, such as impaired vision, headaches, diplopia, or pituitary apoplexy. The neoplastic cells usually demonstrate immunoreactivity for the common gonadotropin α-subunit and the specific β-FSH and β-LH subunits; FSH usually is the predominant secreted hormone.
- *Thyrotroph (thyroid-stimulating hormone [TSH]–producing) adenomas* account for about 1% of all pituitary adenomas and constitute a rare cause of hyperthyroidism.
- *Nonfunctioning pituitary adenomas* comprise both clinically silent counterparts of the functioning adenomas just described (for example, a *silent gonadotroph adenoma*) and true *hormone-negative* (null cell) adenomas; the latter are quite infrequent, and as noted, many have been reclassified using improved diagnostic techniques. Nonfunctioning adenomas constitute approximately 25% of all pituitary tumors. Not surprisingly, the typical presentation with nonfunctioning adenomas is one characterized by mass effects. These lesions also may compromise the residual anterior pituitary sufficiently to produce hypopituitarism.
- *Pituitary carcinomas are exceedingly rare.* In addition to local extension beyond the sella turcica, these tumors virtually always demonstrate distant metastases.

## SUMMARY

### Clinical Manifestations of Pituitary Adenomas

- *Prolactinomas*: amenorrhea, galactorrhea, loss of libido, and infertility
- *Growth hormone (somatotroph cell) adenomas*: gigantism (children), acromegaly (adults), and impaired glucose tolerance and diabetes mellitus
- *Corticotroph cell adenomas*: Cushing syndrome, hyperpigmentation
- All pituitary adenomas, particularly nonfunctioning adenomas, may be associated with mass effects and hypopituitarism.

## HYPOPITUITARISM

Hypofunction of the anterior pituitary may occur with loss or absence of 75% or more of the anterior pituitary parenchyma. This may be *congenital* (exceedingly rare) or may result from a wide range of *acquired* abnormalities that are intrinsic to the pituitary. Less frequently, disorders that interfere with the delivery of pituitary hormone–releasing factors from the hypothalamus, such as hypothalamic tumors, also may cause hypofunction of the anterior pituitary. *Hypopituitarism accompanied by evidence of posterior pituitary dysfunction in the form of diabetes insipidus* (see later) *is almost always of hypothalamic origin.* Most cases of anterior pituitary hypofunction are caused by

- Nonfunctioning pituitary adenomas (discussed earlier)
- Ischemic necrosis of the anterior pituitary, an important cause of pituitary insufficiency. The anterior pituitary has substantial reserve capacity; as a result, destruction of large amounts of the anterior pituitary (75% or greater) must occur before signs and symptoms of hypopituitarism develop. *Sheehan syndrome,* or postpartum necrosis of the anterior pituitary, is the most common form of clinically significant ischemic necrosis of the anterior pituitary. During pregnancy, the anterior pituitary enlarges considerably, largely because of an increase in the size and number of prolactin-secreting cells. This physiologic enlargement of the gland, however, is not accompanied by an increase in blood supply from the low-pressure portal venous system. The enlarged gland is thus vulnerable to ischemic injury, especially in women who experience significant hemorrhage and hypotension during the peripartal period. The posterior pituitary, because it receives its blood directly from arterial branches, is much less susceptible to ischemic injury and therefore usually is not affected. Clinically significant pituitary necrosis also may be encountered in other conditions, including disseminated intravascular coagulation, sickle cell anemia, elevated intracranial pressure, traumatic injury, and shock of any origin. The residual gland is shrunken and scarred.
- Ablation of the pituitary by surgery or irradiation
- Other, less common causes of anterior pituitary hypofunction, including inflammatory lesions such as

sarcoidosis or tuberculosis, trauma, and metastatic neoplasms involving the pituitary.

The clinical manifestations of anterior pituitary hypofunction depend on the specific hormones that are lacking. In children, growth failure (*pituitary dwarfism*) may occur as a result of growth hormone deficiency. Gonadotropin or gonadotropin-releasing hormone (GnRH) deficiency leads to amenorrhea and infertility in women and to decreased libido, impotence, and loss of pubic and axillary hair in men. TSH and ACTH deficiencies result in symptoms of hypothyroidism and hypoadrenalism, respectively, and are discussed later in the chapter. Prolactin deficiency results in failure of postpartum lactation. The anterior pituitary also is a rich source of MSH, synthesized from the same precursor molecule that produces ACTH; therefore, one of the manifestations of hypopituitarism is pallor from loss of stimulatory effects of MSH on melanocytes.

## POSTERIOR PITUITARY SYNDROMES

The posterior pituitary, or neurohypophysis, is composed of modified glial cells (termed *pituicytes*) and axonal processes extending from nerve cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus. The hypothalamic neurons produce two peptides: antidiuretic hormone (ADH) and oxytocin. They are stored in axon terminals in the neurohypophysis and released into the circulation in response to appropriate stimuli. Oxytocin stimulates the contraction of smooth muscle in the pregnant uterus and of muscle surrounding the lactiferous ducts of the mammary glands. Impairment of oxytocin synthesis and release has not been associated with significant clinical abnormalities. The clinically important posterior pituitary syndromes involve ADH production. They include *diabetes insipidus* and *secretion of inappropriately high levels of ADH.*

ADH is a nonapeptide hormone synthesized predominantly in the supraoptic nucleus. In response to several different stimuli, including increased plasma oncotic pressure, left atrial distention, exercise, and certain emotional states, ADH is released from axon terminals in the neurohypophysis into the general circulation. The hormone acts on the collecting tubules of the kidney to promote the resorption of free water. ADH deficiency causes *diabetes insipidus,* a condition characterized by excessive urination (polyuria) caused by an inability of the kidney to properly resorb water from the urine. Diabetes insipidus can result from several causes, including head trauma, neoplasms, and inflammatory disorders of the hypothalamus and pituitary, and from surgical procedures involving the hypothalamus or pituitary. The condition sometimes arises spontaneously (*idiopathic*) in the absence of an underlying disorder. Diabetes insipidus from ADH deficiency is designated as *central,* to differentiate it from *nephrogenic* diabetes insipidus as a result of renal tubular unresponsiveness to circulating ADH. The clinical manifestations of both diseases are similar and include the excretion of large volumes of dilute urine with an inappropriately low specific gravity. Serum sodium and osmolality are increased as a result of excessive renal loss of free water, resulting in thirst and polydipsia. Patients who can drink water generally can compensate for urinary losses; patients who are obtunded, bedridden, or otherwise limited in their ability to obtain water may develop life-threatening dehydration.

In the *syndrome of inappropriate ADH (SIADH)* secretion, ADH excess is caused by several extracranial and intracranial disorders. This condition leads to resorption of excessive amounts of free water, with resultant hyponatremia. The most common causes of SIADH include the secretion of ectopic ADH by malignant neoplasms (particularly small cell carcinomas of the lung), non-neoplastic diseases of the lung, and local injury to the hypothalamus or neurohypophysis. The clinical manifestations of SIADH are dominated by hyponatremia, cerebral edema, and resultant neurologic dysfunction. Although total body water is increased, blood volume remains normal, and peripheral edema does not develop.

# THYROID

The thyroid gland consists of two bulky lateral lobes connected by a relatively thin isthmus, usually located below and anterior to the larynx. The thyroid gland develops embryologically from an evagination of the developing pharyngeal epithelium that descends from the foramen cecum at the base of the tongue to its normal position in the anterior neck. This pattern of descent explains the occasional presence of *ectopic thyroid tissue,* most commonly located at the base of the tongue (*lingual thyroid*) or at other sites abnormally high in the neck.

The thyroid is divided into lobules, each composed of about 20 to 40 evenly dispersed follicles. The follicles range from uniform to variable in size and are lined by cuboidal to low columnar epithelium, which is filled with thyroglobulin, the iodinated precursor protein of active thyroid hormone. In response to trophic factors from the hypothalamus, TSH (also called *thyrotropin*) is released by thyrotrophs in the anterior pituitary into the circulation. The binding of TSH to its receptor on the thyroid follicular epithelium results in activation and conformational change in the receptor, allowing it to associate with a stimulatory G protein (Fig. 19–5). Activation of the G protein eventually results in an increase in intracellular cAMP levels, which stimulates thyroid hormone synthesis and release mediated by cAMP-dependent protein kinases. Thyroid follicular epithelial cells convert thyroglobulin into *thyroxine* ($T_4$) and lesser amounts of *triiodothyronine* ($T_3$). $T_4$ and $T_3$ are released into the systemic circulation, where most of these

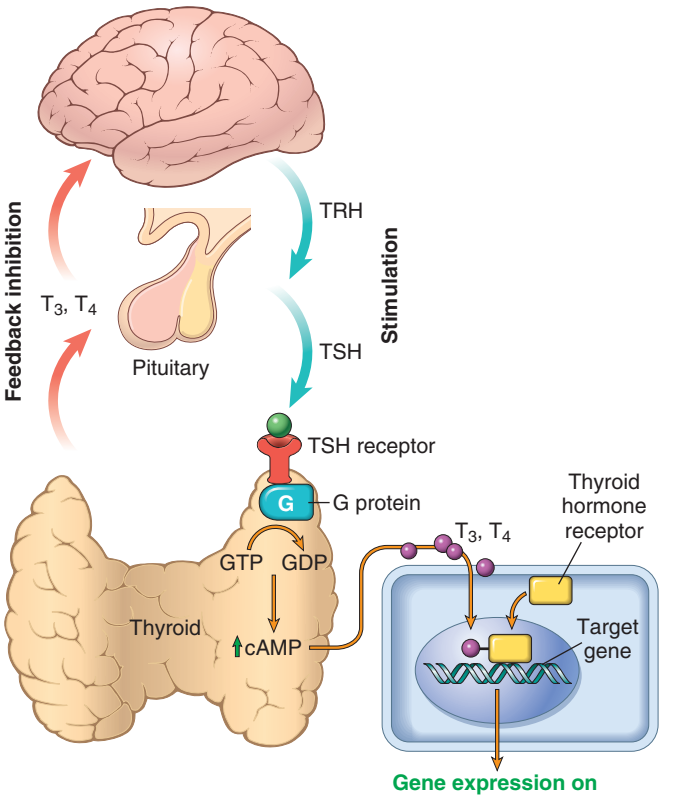

**Figure 19–5** Homeostasis in the hypothalamus-pituitary-thyroid axis and mechanism of action of thyroid hormones. Secretion of thyroid hormones ($T_3$ and $T_4$) is controlled by trophic factors secreted by both the hypothalamus and the anterior pituitary. Decreased levels of $T_3$ and $T_4$ stimulate the release of thyrotropin-releasing hormone (TRH) from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary, causing $T_3$ and $T_4$ levels to rise. Elevated $T_3$ and $T_4$ levels, in turn, suppress the secretion of both TRH and TSH. This relationship is termed a negative-feedback loop. TSH binds to the TSH receptor on the thyroid follicular epithelium, which causes activation of G proteins, release of cyclic AMP (cAMP), and cAMP-mediated synthesis and release of thyroid hormones (i.e., $T_3$ and $T_4$). In the periphery, $T_3$ and $T_4$ interact with the thyroid hormone receptor (TR) and form a complex that translocates to the nucleus and binds to so-called thyroid response elements (TREs) on target genes, thereby initiating transcription.

peptides are reversibly bound to circulating plasma proteins, such as $T_4$-binding globulin, for transport to peripheral tissues. The binding proteins serve to maintain the serum unbound (*free*) $T_3$ and $T_4$ concentrations within narrow limits while ensuring that the hormones are readily available to the tissues. In the periphery the majority of free $T_4$ is deiodinated to $T_3$; the latter binds to thyroid hormone nuclear receptors in target cells with 10-fold greater affinity than that observed for $T_4$ and has proportionately greater activity. *The interaction of thyroid hormone with its nuclear thyroid hormone receptor (TR) results in the formation of a hormone-receptor complex that binds to thyroid hormone response elements (TREs) in target genes, regulating their transcription.* Thyroid hormone has diverse cellular effects, including upregulation of carbohydrate and lipid catabolism and stimulation of protein synthesis in a wide range of cells. The net result of these processes is an increase in the basal metabolic rate.

Clinical recognition of diseases of the thyroid is important, because most are amenable to medical or surgical management. Such diseases include conditions associated with excessive release of thyroid hormones (hyperthyroidism), those associated with thyroid hormone deficiency (hypothyroidism), and mass lesions of the thyroid. Considered next are the clinical consequences of disturbed thyroid function, followed by an overview of the disorders that generate these problems.

## HYPERTHYROIDISM

Thyrotoxicosis is a hypermetabolic state due to elevated circulating levels of free $T_3$ and $T_4$. Because it is caused most commonly by hyperfunction of the thyroid gland, thyrotoxicosis often is referred to as hyperthyroidism. In certain conditions, however, the oversupply either is related to excessive release of pre-formed thyroid hormone (e.g., in thyroiditis) or comes from an extrathyroidal source, rather than a hyperfunctioning gland (Table 19–2). *Thus, strictly speaking, hyperthyroidism is only one (albeit the most common) category of thyrotoxicosis.* Despite this clear distinction, the following discussion adheres to the common practice of using the terms *thyrotoxicosis* and *hyperthyroidism* interchangeably.

The clinical manifestations of thyrotoxicosis are truly protean and include changes referable to the *hypermetabolic state* induced by excessive amounts of thyroid hormone as well as those related to *overactivity of the sympathetic nervous system*:

- *Constitutional symptoms*: The skin of thyrotoxic persons tends to be soft, warm, and flushed; *heat intolerance* and excessive sweating are common. Increased sympathetic activity and hypermetabolism result in *weight loss despite increased appetite.*
- *Gastrointestinal*: Stimulation of the gut results in hypermotility, malabsorption, and diarrhea.
- *Cardiac*: Palpitations and tachycardia are common; elderly patients may develop congestive heart failure

**Table 19–2** Causes of Thyrotoxicosis

| |
|---|
| **Associated with Hyperthyroidism** |
| Primary |
| Diffuse toxic hyperplasia (Graves disease) |
| Hyperfunctioning ("toxic") multinodular goiter |
| Hyperfunctioning ("toxic") adenoma |
| Iodine-induced hyperthyroidism |
| Secondary |
| TSH-secreting pituitary adenoma (rare)* |
| **Not Associated with Hyperthyroidism** |
| Granulomatous (de Quervain) thyroiditis (*painful*) |
| Subacute lymphocytic thyroiditis (*painless*) |
| Struma ovarii (ovarian teratoma with thyroid) |
| Factitious thyrotoxicosis (exogenous thyroxine intake) |

TSH, thyroid-stimulating hormone.
*Associated with increased TSH; all other causes of thyrotoxicosis associated with decreased TSH.

**Figure 19–6** Patient with hyperthyroidism. A wide-eyed, staring gaze, caused by overactivity of the sympathetic nervous system, is one of the classic features of this disorder. In Graves disease, one of the most important causes of hyperthyroidism, accumulation of loose connective tissue behind the orbits also adds to the protuberant appearance of the eyes.

as a consequence of aggravation of preexisting heart disease.

- *Neuromuscular*: Patients frequently experience nervousness, tremor, and irritability. Nearly 50% develop proximal muscle weakness (*thyroid myopathy*).
- *Ocular manifestations*: a wide, staring gaze and lid lag are present because of sympathetic overstimulation of the levator palpebrae superioris (Fig. 19–6). However, true *thyroid ophthalmopathy* associated with proptosis is a feature seen only in Graves disease (discussed later).
- *Thyroid storm* is used to designate the abrupt onset of severe hyperthyroidism. This condition occurs most commonly in patients with underlying Graves disease, probably resulting from an acute elevation in catecholamine levels, as might be encountered during stress. Thyroid storm constitutes a medical emergency: A significant number of untreated patients die of cardiac arrhythmias.
- *Apathetic hyperthyroidism* refers to thyrotoxicosis occurring in elderly persons, in whom the typical features of thyroid hormone excess seen in younger patients are blunted. In these patients the diagnosis is often made during laboratory workup for unexplained weight loss or worsening cardiovascular disease.

The diagnosis of hyperthyroidism is based on clinical features and laboratory data. *The measurement of serum TSH is the most useful single screening test for hyperthyroidism,* because TSH levels are decreased even at the earliest stages, when the disease may still be subclinical. In rare cases of pituitary- or hypothalamus-associated (secondary) hyperthyroidism, TSH levels are either normal or raised. A low TSH value usually is associated with increased levels of free $T_4$. In the occasional patient, hyperthyroidism results predominantly from increased circulating levels of $T_3$ ($T_3$ toxicosis). In such cases, free $T_4$ levels may be decreased, and direct measurement of serum $T_3$ may be useful. Once the diagnosis of thyrotoxicosis has been confirmed by a combination of TSH and free thyroid hormone assays, measurement of radioactive iodine uptake by the thyroid gland often is valuable in determining the etiology. For example, such scans may show diffusely increased (whole-gland) uptake in Graves disease, increased uptake in a solitary nodule in toxic adenoma, or decreased uptake in thyroiditis.

## HYPOTHYROIDISM

Hypothyroidism is caused by any structural or functional derangement that interferes with the production of adequate levels of thyroid hormone. As in the case of hyperthyroidism, this disorder is sometimes divided into primary and secondary categories, depending on whether the hypothyroidism arises from an intrinsic abnormality in the thyroid or from hypothalamic or pituitary disease (Table 19–3). Worldwide, the most common cause of hypothyroidism is dietary deficiency of iodine (see further on), while in most developed nations, autoimmune causes predominate. Genetic defects that perturb thyroid development itself (*thyroid dysgenesis*) or the synthesis of thyroid hormone (*dyshormonogenetic goiter*) are relatively rare.

The clinical manifestations of hypothyroidism include cretinism and myxedema.

- *Cretinism* refers to hypothyroidism developing in infancy or early childhood. This disorder formerly was fairly common in areas of the world where dietary iodine deficiency is endemic, including mountainous areas such as the Himalayas and the Andes (*endemic cretinism*). It is now much less frequent because of the widespread supplementation of foods with iodine. By contrast, enzyme defects that interfere with thyroid hormone synthesis are a cause of *sporadic cretinism.* Clinical features of cretinism include impaired development of the skeletal system and central nervous system, with severe mental retardation, short stature, coarse facial features, a protruding tongue, and umbilical hernia. The severity of the

**Table 19–3** Causes of Hypothyroidism

| **Secondary (Central)** |
| Pituitary failure |
| Hypothalamic failure (rare) |

*FOXE1*, forkhead box E1 gene; *PAX8*, paired box 8 gene.
*Associated with enlargement of thyroid ("goitrous hypothyroidism"). Hashimoto thyroiditis and postablative hypothyroidism account for a majority of cases of hypothyroidism in developed countries.

mental impairment in cretinism seems to be directly influenced by the timing of onset of the deficient state in utero. Normally, maternal hormones that are critical to fetal brain development, including $T_3$ and $T_4$, cross the placenta. If maternal thyroid deficiency is present before the development of the fetal thyroid gland, mental retardation is severe. By contrast, reduction in maternal thyroid hormones later in pregnancy, after the fetal thyroid has developed, allows normal brain development.

- Hypothyroidism developing in older children and adults results in a condition known as *myxedema.* Myxedema, or Gull disease, was first linked with thyroid dysfunction in 1873 by Sir William Gull in a paper addressing the development of a *cretinoid state* in adults. Manifestations of myxedema include generalized apathy and mental sluggishness that in the early stages of disease may mimic depression. Patients with myxedema are listless, cold intolerant, and often obese. Mucopolysaccharide-rich edematous fluid accumulates in skin, subcutaneous tissue, and a number of visceral sites, with resultant broadening and coarsening of facial features, enlargement of the tongue, and deepening of the voice. Bowel motility is decreased, resulting in constipation. Pericardial effusions are common; in later stages, the heart is enlarged, and heart failure may supervene.

Laboratory evaluation has a vital role in the diagnosis of suspected hypothyroidism. As in the case of hyperthyroidism, *measurement of serum TSH is the most sensitive screening test for this disorder.* The serum TSH is increased in primary hypothyroidism because of a loss of feedback inhibition of thyrotropin-releasing hormone (TRH) and TSH production by the hypothalamus and pituitary, respectively. The TSH concentration is not increased in persons with hypothyroidism caused by primary hypothalamic or pituitary disease. Serum $T_4$ is decreased in patients with hypothyroidism of any origin.

## THYROIDITIS

Thyroiditis, or inflammation of the thyroid gland, encompasses a diverse group of disorders characterized by some form of thyroid inflammation. These diseases include conditions that result in acute illness with severe thyroid pain (e.g., infectious thyroiditis, granulomatous [de Quervain] thyroiditis) and disorders in which relatively little inflammation occurs and the illness is manifested primarily by thyroid dysfunction (subacute lymphocytic ["painless"] thyroiditis and fibrous [Reidel] thyroiditis). This section focuses on the more common and clinically significant types of thyroiditis: (1) Hashimoto thyroiditis (or chronic lymphocytic thyroiditis); (2) granulomatous (de Quervain) thyroiditis; and (3) subacute lymphocytic thyroiditis.

### Chronic Lymphocytic (Hashimoto) Thyroiditis

*Hashimoto thyroiditis is the most common cause of hypothyroidism in areas of the world where iodine levels are sufficient.* It is characterized by gradual thyroid failure secondary to autoimmune destruction of the thyroid gland. It is most prevalent between the ages of 45 and 65 years and is more common in women than in men, with female predominance in a ratio of 10:1 to 20:1. Although it is primarily a disease of older women, it can occur in children and is a major cause of nonendemic goiter in children.

#### PATHOGENESIS

Hashimoto thyroiditis is caused by a breakdown in **self-tolerance** (Chapter 4) to thyroid autoantigens. Thus, circulating autoantibodies against thyroid antigens are present in the vast majority of patients, who demonstrate progressive depletion of thyroid epithelial cells (thyrocytes) and their replacement by mononuclear cell infiltration and fibrosis. The inciting events leading to breakdown in self-tolerance have not been fully elucidated, but multiple immunologic mechanisms that may contribute to thyrocyte damage have been identified (Fig. 19–7), including

- **CD8+ cytotoxic T cell–mediated cell death:** CD8+ cytotoxic T cells may cause thyrocyte destruction.
- **Cytokine-mediated cell death:** Excessive T cell activation leads to the production of inflammatory cytokines such as interferon-γ in the thyroid gland, with resultant recruitment and activation of macrophages and damage to follicles.
- Binding of **antithyroid antibodies** (antithyroglobulin, and antithyroid peroxidase antibodies), followed by antibody-dependent cell–mediated cytotoxicity (Chapter 4).

A significant genetic component to the disease pathogenesis is supported by the concordance of disease in as many as 40% of monozygotic twins, as well as the presence of circulating antithyroid antibodies in approximately 50% of asymptomatic siblings of affected patients. Increased susceptibility to Hashimoto thyroiditis is associated with polymorphisms in multiple immune regulation–associated genes, the most significant of which is the linkage to **cytotoxic T lymphocyte–associated antigen-4** gene (*CTLA4*), which codes for a negative regulator of T cell function (Chapter 4).

#### MORPHOLOGY

The thyroid usually is diffusely and symmetrically enlarged, although more localized enlargement may be seen in some cases. The cut surface is pale and gray-tan in appearance, and the tissue is firm and somewhat friable. Microscopic examination reveals widespread infiltration of the parenchyma by a **mononuclear inflammatory infiltrate** containing small lymphocytes, plasma cells, and well-developed **germinal centers** (Fig. 19–8). The thyroid follicles are atrophic and are lined in many areas by epithelial cells distinguished by the presence of abundant eosinophilic, granular cytoplasm, termed **Hürthle,** or **oxyphil, cells.** This is a metaplastic response of the normally low cuboidal follicular epithelium to ongoing injury; on ultrastructural examination, the Hürthle cells are characterized by numerous prominent

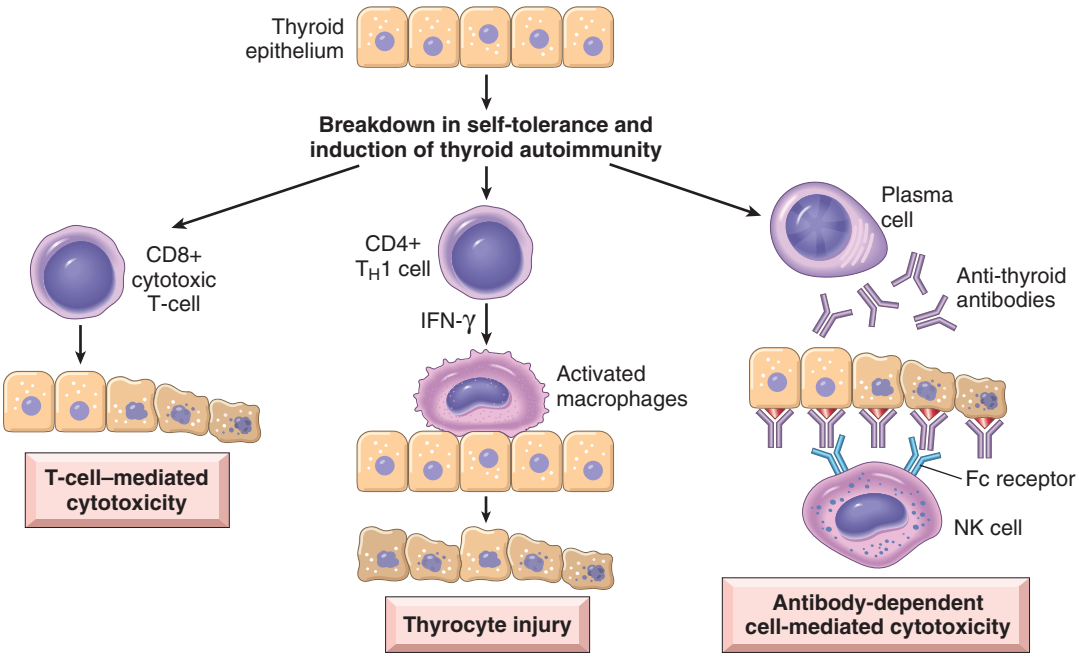

**Figure 19–7** Pathogenesis of Hashimoto thyroiditis. Breakdown of immune tolerance to thyroid autoantigens results in progressive autoimmune destruction of thyrocytes by infiltrating cytotoxic T cells, locally released cytokines, or antibody-dependent cytotoxicity.

mitochondria. Interstitial connective tissue is increased and may be abundant. Less commonly, the thyroid is small and atrophic as a result of more extensive fibrosis **(fibrosing variant).** Unlike in Reidel thyroiditis, the fibrosis does not extend beyond the capsule of the gland.

### Clinical Features

Hashimoto thyroiditis comes to clinical attention as *painless enlargement of the thyroid, usually associated with some degree of hypothyroidism,* in a middle-aged woman. The enlargement of the gland usually is symmetric and diffuse, but in some cases it may be sufficiently localized to raise suspicion for neoplasm. In the usual clinical course, hypothyroidism develops gradually. In some cases, however, it *may be preceded by transient thyrotoxicosis* caused by disruption of thyroid follicles, with secondary release of thyroid hormones (*hashitoxicosis*). During this phase, free $T_4$ and $T_3$ concentrations are elevated, TSH is diminished, and radioactive iodine uptake is decreased. As hypothyroidism supervenes, $T_4$ and $T_3$ levels progressively fall, accompanied by a compensatory increase in TSH. Patients with Hashimoto thyroiditis often have *other autoimmune diseases* and are at *increased risk for the development of B cell non-Hodgkin lymphomas* (Chapter 11), which typically arise within the thyroid gland. The relationship between Hashimoto disease and thyroid epithelial cancers remains controversial, with some morphologic and molecular studies suggesting a predisposition to papillary carcinomas.

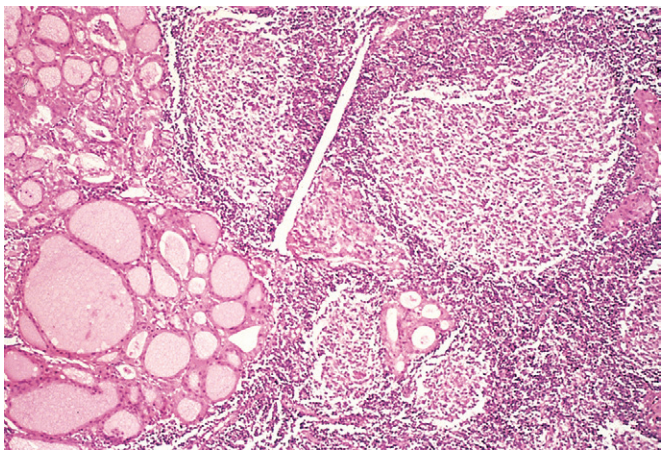

**Figure 19–8** Hashimoto thyroiditis. The thyroid parenchyma contains a dense lymphocytic infiltrate with germinal centers. Residual thyroid follicles lined by deeply eosinophilic Hürthle cells also are seen.

## Subacute Granulomatous (de Quervain) Thyroiditis

Subacute granulomatous thyroiditis, also known as de Quervain thyroiditis, is much less common than Hashimoto disease. De Quervain thyroiditis is most common between the ages of 30 and 50 and, like other forms of thyroiditis, occurs more frequently in women than in men. Subacute thyroiditis is believed to be caused by a viral infection or an inflammatory process triggered by viral infections. A majority of patients have a history of an upper respiratory infection just before the onset of thyroiditis. By contrast with autoimmune thyroid disease, the immune response is not self-perpetuating, so the process is limited.

### MORPHOLOGY

The gland is firm, with an intact capsule, and may be unilaterally or bilaterally enlarged. Histologic examination reveals disruption of thyroid follicles, with extravasation of colloid leading to a polymorphonuclear infiltrate, which is replaced over time by lymphocytes, plasma cells, and macrophages. The extravasated colloid provokes an exuberant granulomatous reaction with giant cells, some containing fragments of colloid. Healing occurs by resolution of inflammation and fibrosis.

Clinical Features

The onset of this form of thyroiditis often is acute, characterized by *pain* in the neck (particularly with swallowing), fever, malaise, and variable enlargement of the thyroid. Transient hyperthyroidism may occur, as in other cases of thyroiditis, as a result of disruption of thyroid follicles and release of excessive thyroid hormone. The leukocyte count and erythrocyte sedimentation rates are increased. With progression of disease and gland destruction, a transient hypothyroid phase may ensue. The condition typically is self-limited, with most patients returning to a euthyroid state within 6 to 8 weeks.

## Subacute Lymphocytic Thyroiditis

Subacute lymphocytic thyroiditis also is known as *silent* or *painless* thyroiditis; in a subset of patients the onset of disease follows pregnancy (*postpartum thyroiditis*). This disease is most likely to be autoimmune in etiology, because circulating antithyroid antibodies are found in a majority of patients. It mostly affects middle-aged women, who present with a *painless* neck mass or features of thyroid hormone excess. The initial phase of thyrotoxicosis (which is likely to be secondary to thyroid tissue damage) is followed by return to a euthyroid state within a few months. In a minority of affected persons the condition eventually progresses to hypothyroidism. Except for possible mild symmetric enlargement, the thyroid appears normal on gross inspection. The histologic features consist of lymphocytic infiltration and hyperplastic germinal centers within the thyroid parenchyma.

## Other Forms of Thyroiditis

*Riedel thyroiditis,* a rare disorder of unknown etiology, is characterized by extensive fibrosis involving the thyroid and contiguous neck structures. Clinical evaluation demonstrates a hard and fixed thyroid mass, simulating a thyroid neoplasm. It may be associated with idiopathic fibrosis in other sites in the body, such as the retroperitoneum. The presence of circulating antithyroid antibodies in most patients suggests an autoimmune etiology.

### SUMMARY

#### Thyroiditis

- Chronic lymphocytic (Hashimoto) thyroiditis is the most common cause of hypothyroidism in regions where dietary iodine levels are sufficient.
- Hashimoto thyroiditis is an autoimmune disease characterized by progressive destruction of thyroid parenchyma, Hürthle cell change, and mononuclear (lymphoplasmacytic) infiltrates, with or without extensive fibrosis.
- Multiple autoimmune mechanisms account for Hashimoto disease, including cytotoxicity mediated by CD8+ T cells, cytokines (IFN-γ), and antithyroid antibodies.
- Subacute granulomatous (de Quervain) thyroiditis is a self-limited disease, probably secondary to a viral infection, and is characterized by pain and the presence of a granulomatous inflammation in the thyroid.
- Subacute lymphocytic thyroiditis is a self-limited disease that often occurs after a pregnancy (postpartum thyroiditis), typically is painless, and is characterized by lymphocytic inflammation in the thyroid.

# GRAVES DISEASE

In 1835 Robert Graves reported on his observations of a disease characterized by "violent and long continued palpitations in females" associated with enlargement of the thyroid gland. *Graves disease is the most common cause of endogenous hyperthyroidism.* It is characterized by a triad of manifestations:

- *Thyrotoxicosis,* caused by a diffusely enlarged, hyperfunctional thyroid, is present in all cases.
- An infiltrative *ophthalmopathy* with resultant exophthalmos is noted in as many as 40% of patients.
- A localized, infiltrative *dermopathy* (sometimes designated *pretibial myxedema*) is seen in a minority of cases.

Graves disease has a peak incidence between the ages of 20 and 40, with *women being affected up to seven times more commonly than men.* This very common disorder is estimated to affect 1.5% to 2.0% of women in the United States. Genetic factors are important in the causation of Graves disease; the incidence is increased in relatives of affected patients, and the concordance rate in monozygotic twins is as high as 60%. As with other autoimmune disorders, a genetic susceptibility to Graves disease is associated with the presence of certain human leukocyte antigen (HLA) haplotypes, specifically HLA-DR3, and polymorphisms in genes encoding the inhibitory T cell receptor CTLA-4 and the tyrosine phosphatase PTPN22.

### PATHOGENESIS

**Graves disease is characterized by a breakdown in self-tolerance to thyroid autoantigens, of which the most important is the TSH receptor.** The result is the production of multiple autoantibodies, including:

- **Thyroid-stimulating immunoglobulin:** An IgG antibody that binds to the TSH receptor and mimics the action of TSH, stimulating adenyl cyclase, with resultant increased release of thyroid hormones. Almost all persons with Graves disease have detectable amounts of this autoantibody, which is relatively specific for Graves disease.
- **Thyroid growth-stimulating immunoglobulins:** Also directed against the TSH receptor, these antibodies

have been implicated in the proliferation of thyroid follicular epithelium.

- **TSH-binding inhibitor immunoglobulins:** These anti-TSH receptor antibodies prevent TSH from binding to its receptor on thyroid epithelial cells and in so doing may actually **inhibit** thyroid cell function. The coexistence of stimulating *and* inhibiting immunoglobulins in the serum of the same patient is not unusual—a finding that may explain why some patients with Graves disease spontaneously develop episodes of hypothyroidism.

A T cell–mediated autoimmune phenomenon also is involved in the development of the **infiltrative ophthalmopathy** characteristic of Graves disease. In Graves ophthalmopathy, the volume of the retroorbital connective tissues and extraocular muscles is increased as a result of several causes, including (1) marked infiltration of the retroorbital space by mononuclear cells, predominantly T cells; (2) inflammatory edema and swelling of extraocular muscles; (3) accumulation of extracellular matrix components, specifically hydrophilic glycosaminoglycans such as hyaluronic acid and chondroitin sulfate; and (4) increased numbers of adipocytes (fatty infiltration). These changes displace the eyeball forward, potentially interfering with the function of the extraocular muscles.

*Autoimmune disorders of the thyroid thus span a continuum on which Graves disease, characterized by hyperfunction of the thyroid, lies at one extreme and Hashimoto disease, manifesting as hypothyroidism, occupies the other end.* Sometimes hyperthyroidism may supervene on preexisting Hashimoto thyroiditis (*hashitoxicosis*), while at other times persons with Graves disease may spontaneously develop thyroid hypofunction; occasionally, Hashimoto thyroiditis and Graves disease may coexist within an affected kindred. Not surprisingly, there is also an element of histologic overlap between the autoimmune thyroid disorders (most characteristically, prominent intrathyroidal lymphoid cell infiltrates with germinal center formation). In both disorders, the frequency of other autoimmune diseases, such as systemic lupus erythematosus, pernicious anemia, type 1 diabetes, and Addison disease, is increased.

## MORPHOLOGY

In the typical case of Graves disease, the thyroid gland is enlarged (usually symmetrically) due to **diffuse hypertrophy and hyperplasia** of thyroid follicular epithelial cells. The gland is usually smooth and soft, and its capsule is intact. On microscopic examination, the follicular epithelial cells in untreated cases are tall, columnar, and more crowded than usual. This crowding often results in the formation of small papillae, which project into the follicular lumen (Fig. 19–9). Such papillae lack fibrovascular cores, in contrast with those of papillary carcinoma. The colloid within the follicular lumen is pale, with scalloped margins. Lymphoid infiltrates, consisting predominantly of T cells, with fewer B cells and mature plasma cells, are present throughout the interstitium; germinal centers are common.

Changes in extrathyroidal tissues include generalized lymphoid hyperplasia. In persons with ophthalmopathy, the tissues of the orbit are edematous because of the presence of hydrophilic glycosaminoglycans. In addition, there is infiltration by lymphocytes, mostly T cells. Orbital muscles initially are edematous but may undergo fibrosis late in the course of the disease. The dermopathy, if present, is characterized by thickening of the dermis, as a result of deposition of glycosaminoglycans and lymphocyte infiltration.

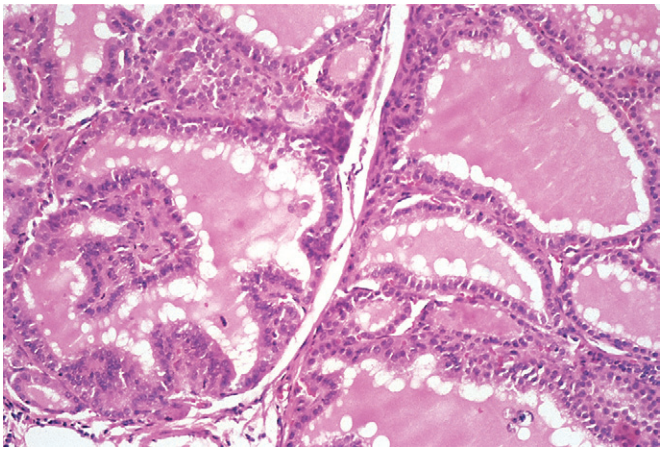

**Figure 19–9** Graves disease. The thyroid is diffusely hyperplastic. The follicles are lined by tall columnar epithelial cells that project into the lumina. These cells actively resorb the colloid in the centers of the follicles, resulting in the "scalloped" appearance of the edges of the colloid.

### Clinical Features

The clinical manifestations of Graves disease include those common to all forms of thyrotoxicosis (discussed earlier), as well as those associated uniquely with Graves disease: *diffuse hyperplasia of the thyroid, ophthalmopathy,* and *dermopathy*. The degree of thyrotoxicosis varies from case to case, and the related changes may sometimes be less conspicuous than other manifestations of the disease. Increased flow of blood through the hyperactive gland often produces an audible bruit. Sympathetic overactivity produces a characteristic wide, staring gaze and lid lag. The ophthalmopathy of Graves disease results in abnormal protrusion of the eyeball (exophthalmos). The extraocular muscles often are weak. The exophthalmos may persist or progress despite successful treatment of the thyrotoxicosis, sometimes resulting in corneal injury. The infiltrative dermopathy, or pretibial myxedema, most commonly involves the skin overlying the shins, where it manifests as scaly thickening and induration of the skin. The skin lesions may be slightly pigmented papules or nodules and often have an orange peel texture. Laboratory findings in Graves disease include elevated serum free $T_4$ and $T_3$ and depressed serum TSH. Because of ongoing stimulation of the thyroid follicles by TSIs, radioactive iodine uptake is increased, and radioiodine scans show a *diffuse uptake* of iodine.

## SUMMARY

### Graves Disease

- Graves disease, the most common cause of endogenous hyperthyroidism, is characterized by the triad of thyrotoxicosis, ophthalmopathy, and dermopathy.

- Graves disease is an autoimmune disorder caused by autoantibodies to the TSH receptor that mimic TSH action and activate TSH receptors on thyroid epithelial cells.
- The thyroid in Graves disease is characterized by diffuse hypertrophy and hyperplasia of follicles and lymphoid infiltrates; glycosaminoglycan deposition and lymphoid infiltrates are responsible for the ophthalmopathy and dermopathy.
- Laboratory features include elevations in serum free $T_3$ and $T_4$ and decreased serum TSH.

## DIFFUSE AND MULTINODULAR GOITER

Enlargement of the thyroid, or *goiter,* is the most common manifestation of thyroid disease. *Diffuse and multinodular goiters reflect impaired synthesis of thyroid hormone,* most often caused by dietary iodine deficiency. Impairment of thyroid hormone synthesis leads to a compensatory rise in the serum TSH, which in turn causes hypertrophy and hyperplasia of thyroid follicular cells and, ultimately, gross enlargement of the thyroid gland. The compensatory increase in functional mass of the gland is enough to overcome the hormone deficiency, ensuring a *euthyroid* metabolic state in the vast majority of affected persons. If the underlying disorder is sufficiently severe (e.g., a congenital biosynthetic defect), the compensatory responses may be inadequate to overcome the impairment in hormone synthesis, resulting in *goitrous hypothyroidism.* The degree of thyroid enlargement is proportional to the level and duration of thyroid hormone deficiency.

Goiters can be endemic or sporadic.

- *Endemic goiter* occurs in geographic areas where the soil, water, and food supply contain little iodine. The designation *endemic* is used when goiters are present in more than 10% of the population in a given region. Such conditions are particularly common in mountainous areas of the world, including the Himalayas and the Andes. With increasing availability of dietary iodine supplementation, the frequency and severity of endemic goiter have declined significantly.
- *Sporadic goiter* occurs less commonly than endemic goiter. The condition is more common in females than in males, with a peak incidence in puberty or young adulthood, when there is an increased physiologic demand for $T_4$. Sporadic goiter may be caused by several conditions, including the ingestion of substances that interfere with thyroid hormone synthesis at some level, such as excessive calcium and vegetables belonging to the Brassicaceae (also called Cruciferae) family (e.g., cabbage, cauliflower, Brussels sprouts, turnips). In other instances, goiter may result from hereditary enzymatic defects that interfere with thyroid hormone synthesis *(dyshormonogenetic goiter).* In most cases, however, the cause of sporadic goiter is not apparent.

### MORPHOLOGY

In most cases, TSH-induced hypertrophy and hyperplasia of thyroid follicular cells result initially in diffuse, symmetric enlargement of the gland **(diffuse goiter).** The follicles are lined by crowded columnar cells, which may pile up and form projections similar to those seen in Graves disease. If dietary iodine subsequently increases, or if the demands for thyroid hormone decrease, the stimulated follicular epithelium involutes to form an enlarged, colloid-rich gland **(colloid goiter).** The cut surface of the thyroid in such cases usually is brown, somewhat glassy-appearing, and translucent. On microscopic examination, the follicular epithelium may be hyperplastic in the early stages of disease or flattened and cuboidal during periods of involution. Colloid is abundant during the latter periods. With time, recurrent episodes of hyperplasia and involution combine to produce a more irregular enlargement of the thyroid, termed **multinodular goiter.** Virtually all long-standing diffuse goiters convert into multinodular goiters. Multinodular goiters typically are hormonally silent, although a minority (approximately 10% over 10 years) can manifest with thyrotoxicosis secondary to the development of **autonomous** nodules that produce thyroid hormone independent of TSH stimulation. This condition, known as toxic multinodular goiter or **Plummer syndrome,** is not accompanied by the infiltrative ophthalmopathy and dermopathy of Graves disease–associated thyrotoxicosis.

Multinodular goiters are multilobulate, asymmetrically enlarged glands, which may attain massive size. On cut surface, irregular nodules containing variable amounts of brown, gelatinous colloid are evident (Fig. 19–10, *A*). Older lesions often show areas of fibrosis, hemorrhage, calcification, and cystic change. The microscopic appearance includes colloid-rich follicles lined by flattened, inactive epithelium and areas of follicular epithelial hypertrophy and hyperplasia, accompanied by the regressive changes just noted (Fig. 19–10, *B*).

### Clinical Features

The dominant clinical features of goiter are those caused by the *mass effects* of the enlarged gland. In addition to the obvious cosmetic problem of a large neck mass, goiters also may cause airway obstruction, dysphagia, and compression of large vessels in the neck and upper thorax (so-called *superior vena cava syndrome*). As stated, a hyperfunctioning (*toxic*) nodule may develop within a long-standing goiter, resulting in *hyperthyroidism.* The incidence of malignancy in long-standing multinodular goiters is low (less than 5%) but not zero, and concern for malignancy arises with goiters that demonstrate sudden changes in size or associated symptoms (e.g., hoarseness).

## NEOPLASMS OF THE THYROID

The thyroid gland gives rise to a variety of neoplasms, ranging from circumscribed, benign adenomas to highly aggressive, anaplastic carcinomas. From a clinical standpoint, the possibility of a tumor is of major concern in patients who present with *thyroid nodules.* Fortunately, the overwhelming majority of solitary nodules of the thyroid

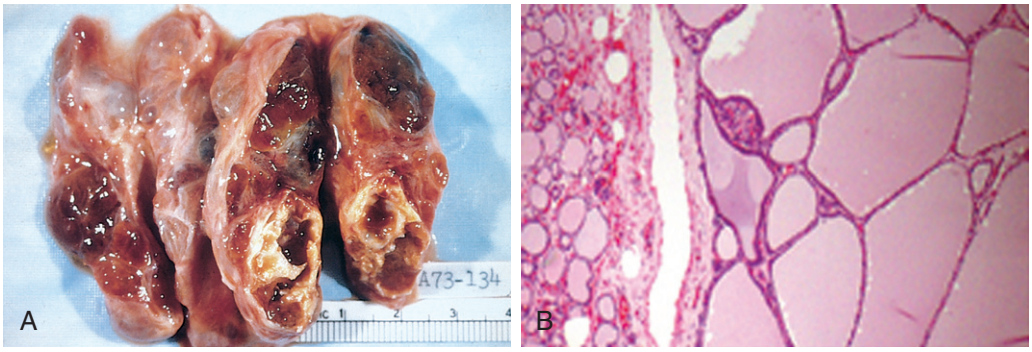

**Figure 19–10** Multinodular goiter. **A,** Gross morphologic appearance. The coarsely nodular gland contains areas of fibrosis and cystic change. **B,** Photomicrograph of specimen from a hyperplastic nodule, with compressed residual thyroid parenchyma on the periphery. The hyperplastic follicles contain abundant pink "colloid" within their lumina. Note the absence of a prominent capsule, a feature distinguishing such lesions from neoplasms of the thyroid.

*(B, Courtesy of Dr. William Westra, Department of Pathology, Johns Hopkins University, Baltimore, Maryland.)*

prove to be either follicular adenomas or localized, non-neoplastic conditions (e.g., a dominant nodule in multinodular goiter, simple cysts, or foci of thyroiditis). Carcinomas of the thyroid, by contrast, are uncommon, accounting for much less than 1% of solitary thyroid nodules. Several clinical criteria provide a clue to the nature of a given thyroid nodule:

- *Solitary nodules,* in general, are more likely to be neoplastic than are multiple nodules.
- *Nodules in younger patients* are more likely to be neoplastic than are those in older patients.
- *Nodules in males* are more likely to be neoplastic than are those in females.
- A history of *radiation* treatment to the head and neck region is associated with an increased incidence of thyroid malignancy.
- Nodules that take up radioactive iodine in imaging studies (*hot nodules*) are more likely to be benign than malignant, reflecting well-differentiated cells.

Such statistics and general trends, however, are of little significance in the evaluation of a given patient, in whom the timely recognition of a malignancy, however uncommon, can be lifesaving. Ultimately, it is the morphologic evaluation of a given thyroid nodule by fine needle aspiration, combined with histologic study of surgically resected thyroid parenchyma, that provides the most definitive information about its nature. This section presents an overview of the major thyroid neoplasms, including adenomas and carcinomas of various types.

## Adenomas

Adenomas of the thyroid are benign neoplasms derived from follicular epithelium. As in the case of all thyroid neoplasms, follicular adenomas usually are solitary. On clinical and morphologic grounds, they may be difficult to distinguish from a dominant nodule in multinodular goiter, for example, or from the less common follicular carcinomas. Although the vast majority of adenomas are nonfunctional, a small proportion produce thyroid hormones (*toxic adenomas*), causing clinically apparent thyrotoxicosis. In general, follicular adenomas are *not* forerunners to carcinomas; nevertheless, shared genetic alterations support the possibility that at least a subset of follicular carcinomas arise in preexisting adenomas (see further on).

### PATHOGENESIS

The TSH receptor signaling pathway plays an important role in the pathogenesis of toxic adenomas. Activating (gain-of-function) somatic mutations in one of two components of this signaling system—most often the gene encoding the TSH receptor itself (TSHR) and, less commonly, the α-subunit of $G_s$ (GNAS)—allow follicular cells to secrete thyroid hormone independent of TSH stimulation (thyroid autonomy). The result of this overabundance is symptomatic hyperthyroidism, with a "hot" thyroid nodule seen on imaging studies. Overall, somatic mutations in the TSH receptor signaling pathway seem to be present in slightly over half of toxic adenomas. Not surprisingly, such mutations also are observed in a subset of autonomous nodules that give rise to toxic multinodular goiters, as described earlier. A minority of nonfunctioning follicular adenomas (less than 20%) exhibit mutations of RAS or phosphatidylinositol-3-kinase (PIK3CA), or bear a *PAX8/PPARG* fusion gene, all of which are genetic alterations shared with follicular carcinomas. These are discussed in further detail under "Carcinomas" (see further on).

### MORPHOLOGY

The typical thyroid adenoma is a **solitary,** spherical lesion that compresses the adjacent non-neoplastic thyroid. The neoplastic cells are demarcated from the adjacent parenchyma by a **well-defined, intact capsule** (Fig. 19–11, *A*). **These features are important in making the distinction from multinodular goiters,** which contain multiple nodules on their cut surface (even though the patient may present clinically with a solitary dominant nodule), do not demonstrate compression of the adjacent thyroid parenchyma, and lack a well-formed capsule. On microscopic examination, the constituent cells are arranged in uniform follicles that contain colloid (Fig. 19–11, *B*). Papillary growth

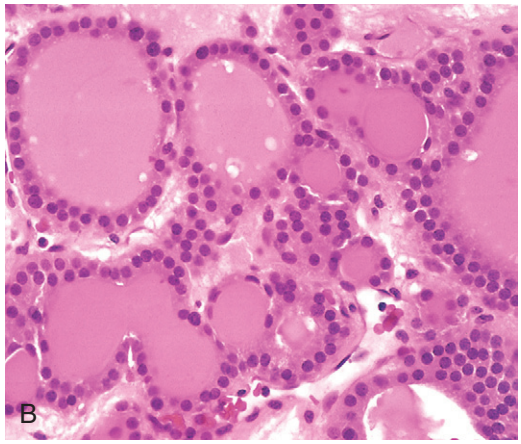

**Figure 19–11** Follicular adenoma of the thyroid. **A,** A solitary, well-circumscribed nodule is visible in this gross specimen. **B,** The photomicrograph shows well-differentiated follicles resembling those of normal thyroid parenchyma.

patterns, if present, should raise suspicion for an encapsulated papillary carcinoma (discussed later). Occasionally, the neoplastic cells acquire brightly eosinophilic granular cytoplasm (oxyphil or Hürthle cell change) (Fig. 19–12); the clinical presentation and behavior of a **Hürthle cell adenoma** are no different from those of a conventional adenoma. Similar to endocrine tumors at other anatomic sites, even benign follicular adenomas may, on occasion, exhibit focal nuclear pleomorphism, atypia, and prominent nucleoli **(endocrine atypia);** by themselves, these features do not constitute evidence of malignancy. The hallmark of all follicular adenomas is the presence of an intact well-formed capsule encircling the tumor. **Careful evaluation of the integrity of the capsule is therefore critical in distinguishing follicular adenomas from follicular carcinomas,** which demonstrate capsular and/or vascular invasion (see later).

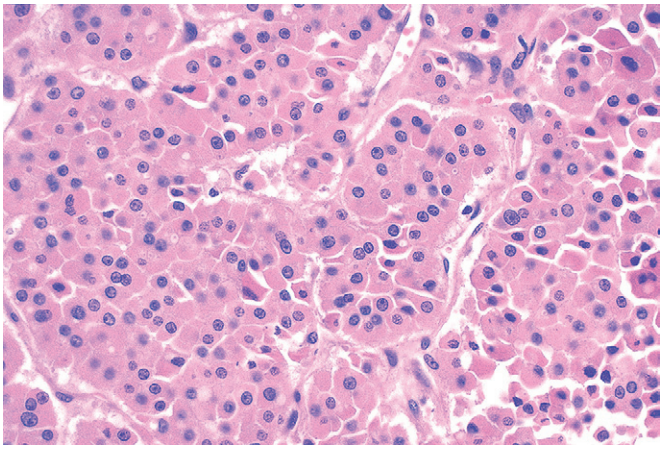

**Figure 19–12** Hürthle cell adenoma. On this high-power view, the tumor is composed of cells with abundant eosinophilic cytoplasm and small regular nuclei.

### Clinical Features

Most adenomas of the thyroid manifest as painless nodules, often discovered during a routine physical examination. Larger masses may produce local symptoms such as difficulty in swallowing. As previously stated, persons with toxic adenomas can present with features of thyrotoxicosis. After injection of radioactive iodine, most adenomas take up iodine less avidly than normal thyroid parenchyma. On radionuclide scanning, therefore, adenomas appear as *cold* nodules relative to the adjacent normal thyroid gland. Toxic adenomas, however, will appear as *warm* or *hot* nodules in the scan. As many as 10% of *cold* nodules eventually prove to be malignant. By contrast, malignancy is rare in *hot* nodules. Essential techniques used in the preoperative evaluation of suspected adenomas are ultrasonography and fine needle aspiration biopsy. Because of the need for evaluating capsular integrity, *the definitive diagnosis of thyroid adenoma can be made only after careful histologic examination of the resected specimen.* Suspected adenomas of the thyroid are therefore removed surgically to exclude malignancy. Thyroid adenomas carry an excellent prognosis and do not recur or metastasize.

## Carcinomas

Carcinomas of the thyroid are relatively uncommon in the United States, accounting for about 1.5% of all cancers. A female predominance has been noted among patients who develop thyroid carcinoma in the early and middle adult years. By contrast, cases manifesting in childhood and late adult life are distributed equally between males and females. Most thyroid carcinomas (except medullary carcinomas) are derived from the thyroid follicular epithelium, and of these, the vast majority are well-differentiated lesions. The major subtypes of thyroid carcinoma and their relative frequencies are

- Papillary carcinoma (accounting for more than 85% of cases)
- Follicular carcinoma (5% to 15% of cases)
- Anaplastic (undifferentiated) carcinoma (less than 5% of cases)
- Medullary carcinoma (5% of cases)

Because of the unique clinical and biologic features associated with each variant of thyroid carcinoma, these subtypes are described separately. Presented next is an overview of the molecular pathogenesis of all thyroid cancers.

## PATHOGENESIS

Both genetic and environmental factors are implicated in the pathogenesis of thyroid cancers.

**Genetic Factors.** Distinct molecular events are involved in the pathogenesis of the four major variants of thyroid cancer. As stated, medullary carcinomas do not arise from the follicular epithelium. Genetic alterations in the three follicular cell–derived malignancies are clustered along two oncogenic pathways—the mitogen-activated protein (MAP) kinase pathway and the phosphatidylinositol-3-kinase (PI-3K)/AKT pathway (Fig. 19–13). In normal cells, these pathways are transiently activated by binding of soluble growth factor ligands to the extracellular domain of receptor tyrosine kinases, which results in autophosphorylation of the cytoplasmic domain of the receptor, permitting intracellular signal transduction. In thyroid carcinomas, as with many solid cancers (Chapter 5), gain-of-function mutations along components of these pathways lead to constitutive activation even in the absence of ligand, thus promoting carcinogenesis.

- **Papillary thyroid carcinomas: Activation of the MAP kinase pathway is a feature of most papillary carcinomas** and can occur by one of two major mechanisms. The first mechanism involves rearrangements of *RET* or *NTRK1* (neurotrophic tyrosine kinase receptor 1), both of which encode transmembrane receptor tyrosine kinases, and the second mechanism involves activating point mutations in *BRAF*, whose product is an intermediate signaling component in the MAP kinase pathway (Fig. 19–13). The *RET* gene is not normally expressed in thyroid follicular cells. In papillary cancers, chromosomal rearrangements place the tyrosine kinase domain of *RET* under the transcriptional control of genes that are constitutively expressed in the thyroid epithelium. The novel fusion proteins that are so formed are known as RET/PTC (papillary thyroid carcinoma) and are present in approximately 20% to 40% of papillary thyroid cancers. The frequency of *RET/PTC* rearrangements is significantly higher in papillary cancers arising in the backdrop of radiation exposure. Similarly, rearrangements of *NTRK1* are present in 5% to 10% of papillary thyroid cancers, and the resultant fusion proteins are constitutively expressed in thyroid cells, leading to activation of MAP kinase pathways. One third to one half of papillary thyroid carcinomas harbor a gain-of-function mutation in the *BRAF* gene, which most commonly is a valine-to-glutamate change on codon 600 ($BRAF^{V600E}$). Since chromosomal rearrangements of the *RET* or *NTRK1* genes and mutations of *BRAF* have redundant effects on the thyroid epithelium (both mechanisms result in activation of the MAP kinase signaling pathway), papillary thyroid carcinomas demonstrate either one or the other molecular abnormality, but not both. *RET/PTC* rearrangements and *BRAF* point mutations are not observed in follicular adenomas or carcinomas.
- **Follicular thyroid carcinomas:** Approximately one third to one half of follicular thyroid carcinomas harbor **mutations in the PI-3K/AKT signaling pathway,** resulting in constitutive activation of this oncogenic pathway. This subset of tumors includes those with gain-of-function point mutations of *RAS* and *PIK3CA,* those with amplification of *PIK3CA,* and those with loss-of-function mutations of *PTEN,* a tumor suppressor gene and negative regulator of this pathway. The progressive increase in the prevalence of *RAS* and *PIK3CA* mutations from benign follicular adenomas to follicular carcinomas to anaplastic carcinomas (see next) suggests a shared histogenesis and molecular evolution among these follicular cell–derived tumors. A unique (2;3)(q13;p25) translocation has been described in one third to one half of follicular carcinomas. This translocation creates a fusion gene composed of portions of *PAX8*, a paired homeobox gene that is important in thyroid development, and the peroxisome proliferator–activated receptor gene (*PPARG*), whose gene product is a nuclear hormone receptor implicated in terminal differentiation of cells. Less than 10% of follicular adenomas harbor ***PAX8/PPARG* fusion genes,** and thus far these have not been documented in other thyroid neoplasms.
- **Anaplastic carcinomas:** These highly aggressive and lethal tumors can arise de novo or, more commonly, by **dedifferentiation** of a well-differentiated papillary or follicular carcinoma. Molecular alterations present in anaplastic carcinomas include those also seen in well-differentiated carcinomas (e.g., *RAS* or *PIK3CA* mutations), albeit at a significantly higher rate, suggesting that the presence of these mutations might predispose existing thyroid neoplasms to transform. Other genetic *hits,* such as inactivation of *TP53*, are essentially restricted to anaplastic carcinomas and may also relate to their aggressive behavior.
- **Medullary thyroid carcinomas:** In contrast with the subtypes described earlier, these neoplasms arise from the

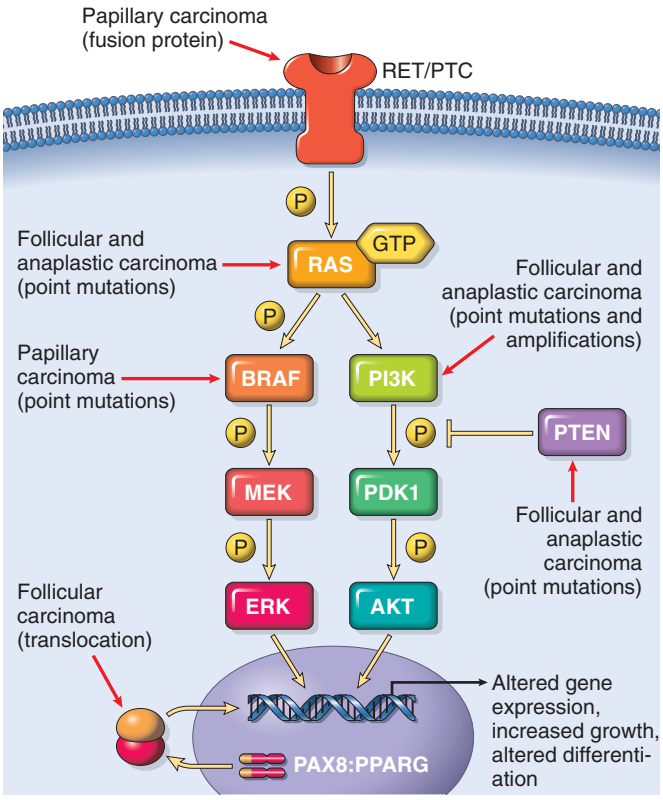

**Figure 19–13** Genetic alterations in follicular cell–derived malignancies of the thyroid gland.

parafollicular C cells, rather than the follicular epithelium. Familial medullary thyroid carcinomas occur in multiple endocrine neoplasia type 2 (MEN-2) (see later) and are associated with germline ***RET* proto-oncogene mutations** that lead to constitutive activation of the receptor. *RET* mutations are also seen in approximately one half of nonfamilial (sporadic) medullary thyroid cancers. Chromosomal rearrangements involving *RET,* such as the *RET/PTC* translocations reported in papillary cancers, are not seen in medullary carcinomas.

**Environmental Factors.** The major risk factor predisposing to thyroid cancer is exposure to **ionizing radiation,** particularly during the first 2 decades of life. In keeping with this finding, there was a marked increase in the incidence of papillary carcinomas among children exposed to ionizing radiation after the Chernobyl nuclear disaster in 1986. **Deficiency of dietary iodine** (and by extension, an association with goiter) is linked with a higher frequency of follicular carcinomas.

### *Papillary Carcinoma*

As mentioned earlier, papillary carcinomas represent the most common form of thyroid cancer. These tumors may occur at any age, and they account for the vast majority of thyroid carcinomas associated with previous exposure to ionizing radiation.

#### MORPHOLOGY

Papillary carcinomas may manifest as solitary or multifocal lesions within the thyroid. In some cases, they may be well circumscribed and even encapsulated; in other instances, they infiltrate the adjacent parenchyma with ill-defined margins. The lesions may contain areas of fibrosis and calcification and often are cystic. On cut surface, they may appear granular and sometimes contain grossly discernible papillary foci (Fig. 19–14, *A*). The definitive diagnosis of papillary carcinoma can be made only after microscopic examination. In current practice, **the diagnosis of papillary carcinoma is based on nuclear features** even in the absence of a papillary architecture. The nuclei of papillary carcinoma cells contain very finely dispersed chromatin, which imparts an **optically clear** appearance, giving rise to the designation **ground glass** or "Orphan Annie eye" nuclei (Fig. 19–14, *C* and *D*). In addition, invaginations of the cytoplasm may give the appearance of intranuclear inclusions (hence the designation **pseudoinclusions**) in cross-sections. A **papillary architecture** is common (Fig. 19–14, *B*); unlike hyperplastic papillary lesions seen in Graves disease, the neoplastic papillae have dense fibrovascular cores. Concentrically calcified structures termed **psammoma bodies** often are present within the papillae. Foci of lymphatic permeation by tumor cells are often present, but invasion of blood vessels is relatively uncommon, particularly in smaller lesions. Metastases to adjacent cervical lymph nodes are estimated to occur in about half of

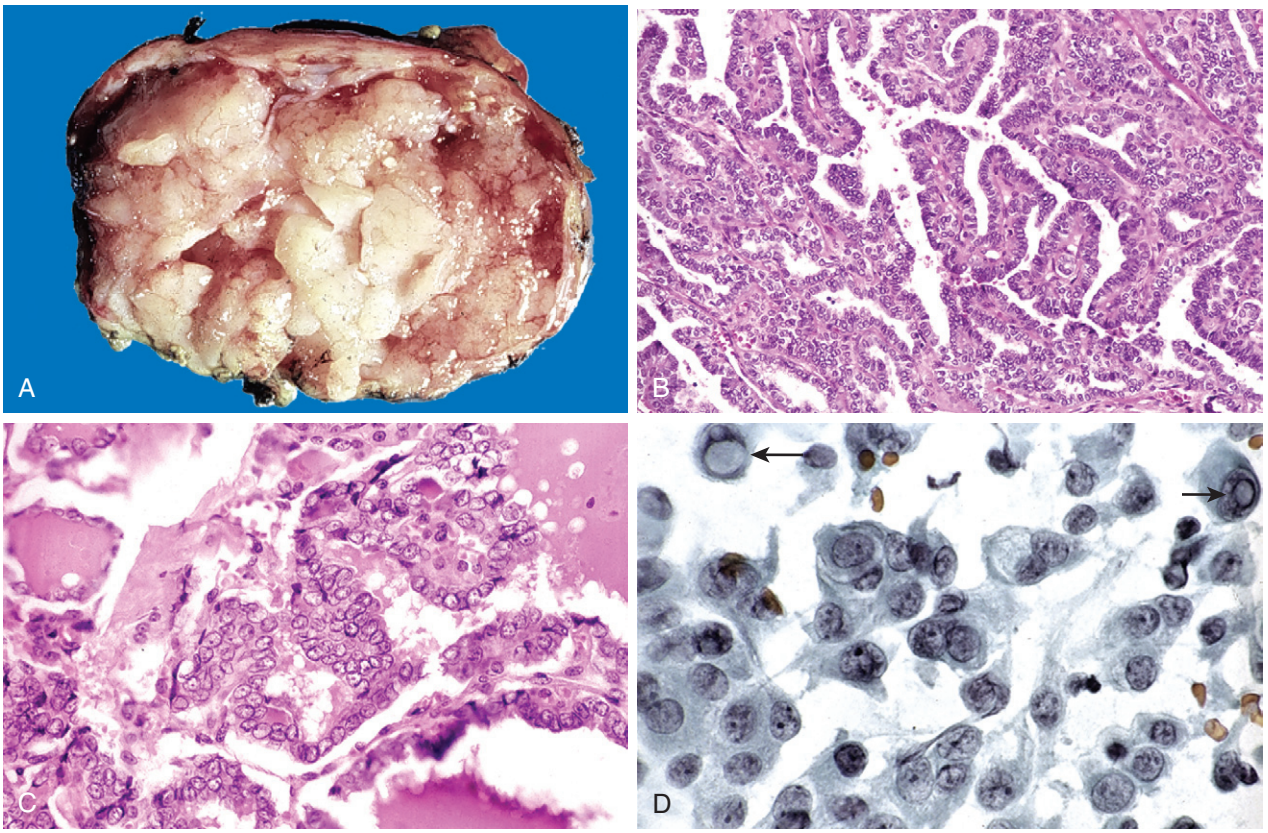

**Figure 19–14** Papillary carcinoma of the thyroid. **A–C,** A papillary carcinoma with grossly discernible papillary structures. In this particular example, well-formed papillae (**B**) are lined by cells with characteristic empty-appearing nuclei, sometimes termed "Orphan Annie eye" nuclei (**C**). **D,** Cells obtained by fine-needle aspiration of a papillary carcinoma. Characteristic intranuclear inclusions are visible in some of the aspirated cells (*arrows*).

cases. There are over a dozen variants of papillary thyroid carcinoma, but the most common is one composed predominantly or exclusively of follicles (**follicular variant** of papillary thyroid carcinoma). The follicular variant more frequently is encapsulated and is associated with a lower incidence of lymph node metastases and extrathyroidal extension than that typical for conventional papillary carcinomas.

Clinical Features

Papillary carcinomas are nonfunctional tumors, so they manifest most often as a painless mass in the neck, either within the thyroid or as metastasis in a cervical lymph node. A preoperative diagnosis usually can be established by fine-needle aspiration on the basis of the characteristic nuclear features described earlier. Papillary carcinomas are indolent lesions, with 10-year survival rates in excess of 95%. Of interest, the presence of isolated cervical nodal metastases does not seem to have a significant influence on the generally good prognosis of these lesions. In a minority of patients, hematogenous metastases are present at the time of diagnosis, most commonly to the lung. The long-term survival of patients with papillary thyroid cancer is dependent on several factors, including age (in general, the prognosis is less favorable among patients older than 40 years), the presence of extrathyroidal extension, and presence of distant metastases (stage).

### *Follicular Carcinoma*

Follicular carcinomas account for 5% to 15% of primary thyroid cancers. They are more common in women (occurring in a ratio of 3:1) and manifest at an older age than that typical for papillary carcinomas, with a peak incidence between the ages of 40 and 60 years. Follicular carcinoma is more frequent in areas with dietary iodine deficiency (accounting for 25% to 40% of thyroid cancers), while its incidence has either decreased or remained stable in iodine-sufficient areas of the world.

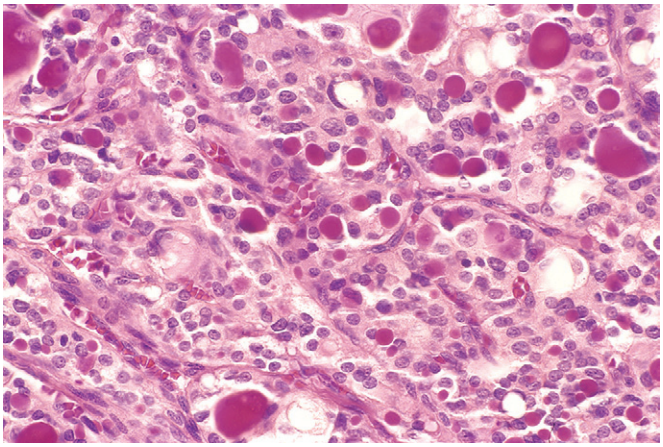

**Figure 19–15** Follicular carcinoma of the thyroid. A few of the glandular lumina contain recognizable colloid.

#### MORPHOLOGY

On microscopic examination, most follicular carcinomas are composed of fairly uniform cells forming small follicles, reminiscent of normal thyroid (Fig. 19–15); in other cases, follicular differentiation may be less apparent. As with follicular adenomas, Hürthle cell variants of follicular carcinomas may be seen. Follicular carcinomas may be **widely invasive,** infiltrating the thyroid parenchyma and extrathyroidal soft tissues, or **minimally invasive.** The latter type are sharply demarcated lesions that may be impossible to distinguish from follicular adenomas on gross examination. **This distinction requires extensive histologic sampling of the tumor capsule–thyroid interface, to exclude capsular and/or vascular invasion** (Fig. 19–16). As mentioned earlier, follicular lesions in which the nuclear features are typical of papillary carcinomas should be regarded as follicular variants of papillary cancers.

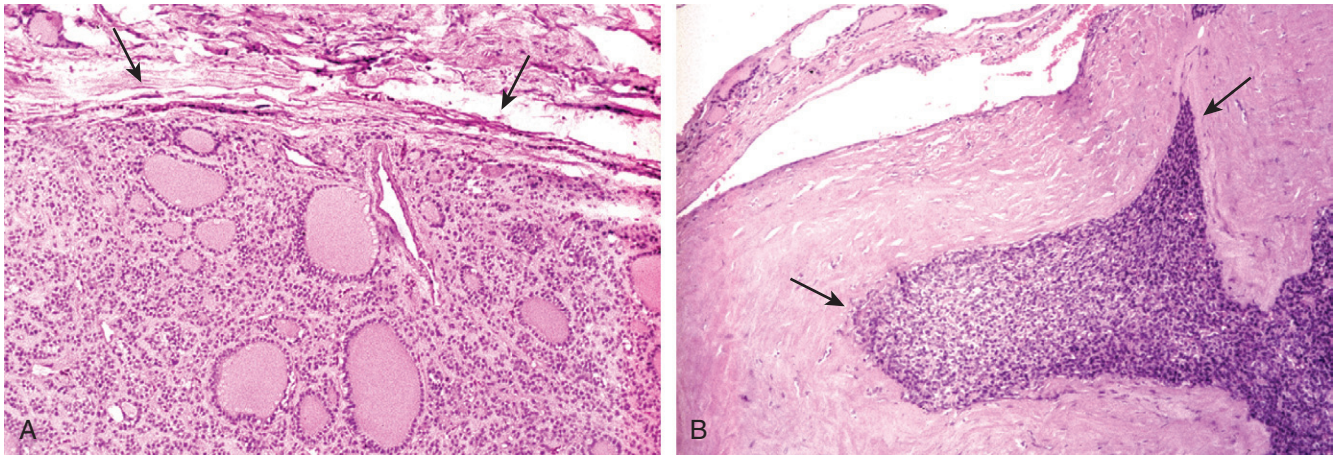

**Figure 19–16** Capsular invasion in follicular carcinoma. Evaluating the integrity of the capsule is critical in distinguishing follicular adenomas from follicular carcinomas. **A,** In adenomas, a fibrous capsule, usually thin but occasionally more prominent, surrounds the neoplastic follicles and no capsular invasion is seen (*arrows*); compressed normal thyroid parenchyma usually is present external to the capsule (*top*). **B,** By contrast, follicular carcinomas demonstrate capsular invasion (*arrows*) that may be minimal, as in this case, or widespread, with extension into local structures of the neck.

Clinical Features

Follicular carcinomas manifest most frequently as solitary *cold thyroid nodules*. In rare cases, they may be hyperfunctional. These neoplasms tend to metastasize through the bloodstream (*hematogenous dissemination*) to the lungs, bone, and liver. In contrast with papillary carcinomas, regional nodal metastases are uncommon. As many as half of patients with widely invasive carcinomas succumb to their disease within 10 years, while less than 10% of patients with minimally invasive follicular carcinomas die within the same time span. Follicular carcinomas are treated with surgical excision. Well-differentiated metastases may take up radioactive iodine, which can be used to identify and also ablate such lesions. Because better-differentiated lesions may be stimulated by TSH, patients usually are placed on a thyroid hormone regimen after surgery to suppress endogenous TSH.

### *Anaplastic Carcinoma*

Anaplastic carcinomas are undifferentiated tumors of the thyroid follicular epithelium, accounting for less than 5% of thyroid tumors. They are aggressive, with a mortality rate approaching 100%. Patients with anaplastic carcinoma are older than those with other types of thyroid cancer, with a mean age of 65 years. Approximately a quarter of patients with anaplastic thyroid carcinomas have a past history of a well-differentiated thyroid carcinoma, and another quarter harbor a concurrent well-differentiated tumor in the resected specimen.

#### MORPHOLOGY

Anaplastic carcinomas manifest as bulky masses that typically grow rapidly beyond the thyroid capsule into adjacent neck structures. On microscopic examination, these neoplasms are composed of highly anaplastic cells, which may take on any of several histologic patterns, including those populated by

- Large, pleomorphic giant cells
- Spindle cells with a sarcomatous appearance
- Mixed spindle and giant cell lesions

Foci of papillary or follicular differentiation may be present in some tumors, suggesting origin from a better-differentiated carcinoma.

Clinical Features

Anaplastic carcinomas grow with wild abandon despite therapy. Metastases to distant sites are common, but in most cases death occurs in less than 1 year as a result of aggressive local growth and compromise of vital structures in the neck.

### *Medullary Carcinoma*

Medullary carcinomas of the thyroid are neuroendocrine neoplasms derived from the parafollicular cells, or C cells, of the thyroid. Like normal C cells, medullary carcinomas secrete calcitonin, the measurement of which plays an important role in the diagnosis and postoperative follow-up evaluation of patients. In some cases, the tumor cells elaborate other polypeptide hormones such as somatostatin, serotonin, and vasoactive intestinal peptide (VIP). Medullary carcinomas arise *sporadically* in about 70% of cases. The remaining 30% are *familial* cases occurring in the setting of MEN syndrome 2A or 2B, or familial medullary thyroid carcinoma without an associated MEN syndrome, as discussed later. Of note, both familial and sporadic medullary forms demonstrate activating *RET* mutations. Sporadic medullary carcinomas, as well as familial cases without an associated MEN syndrome, occur in adults, with a peak incidence in the fifth and sixth decades. Cases associated with MEN-2A or MEN-2B, by contrast, have been reported in younger patients, including children.

#### MORPHOLOGY

Medullary carcinomas may arise as a solitary nodule or may manifest as multiple lesions involving both lobes of the thyroid. **Multicentricity** is particularly common in familial cases. Larger lesions often contain areas of necrosis and hemorrhage and may extend through the capsule of the thyroid. On microscopic examination, medullary carcinomas are composed of polygonal to spindle-shaped cells, which may form nests, trabeculae, and even follicles. **Amyloid deposits,** derived from altered calcitonin molecules, are present in the adjacent stroma in many cases (Fig. 19–17) and are a distinctive feature. Calcitonin is readily demonstrable both within the cytoplasm of the tumor cells and in the stromal amyloid by immunohistochemical methods. Electron microscopy reveals variable numbers of intracytoplasmic membrane-bound, electron-dense granules (Fig. 19–18). One of the peculiar features of familial medullary carcinomas is the presence of **multicentric C cell hyperplasia** in the surrounding thyroid parenchyma, a feature usually absent in sporadic lesions. Foci of C cell hyperplasia are believed to represent the precursor lesions from which medullary carcinomas arise.

Clinical Features

In the sporadic cases, medullary carcinoma manifests most often as a mass in the neck, sometimes associated with compression effects such as dysphagia or hoarseness. In

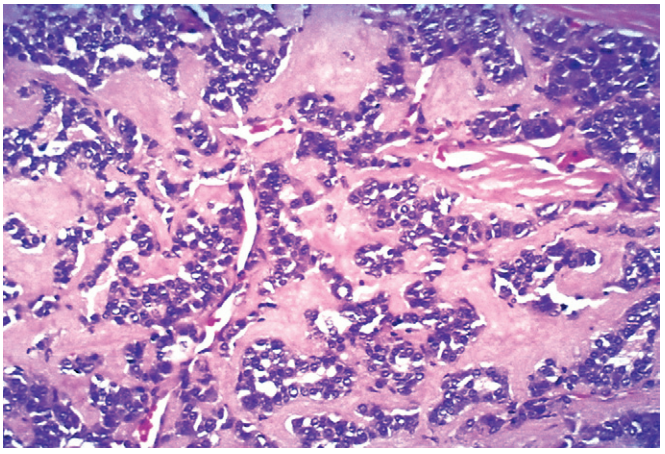

**Figure 19–17** Medullary carcinoma of the thyroid. These tumors typically contain amyloid, visible here as homogeneous extracellular material, derived from calcitonin molecules secreted by the neoplastic cells.

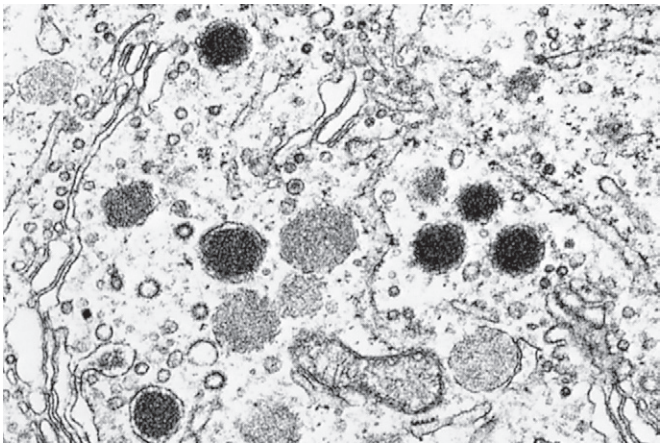

**Figure 19–18** Electron micrograph of medullary thyroid carcinoma. These cells contain membrane-bound secretory granules, which are the sites of storage of calcitonin and other peptides. (Original magnification ×30,000.)

some instances, the initial manifestations are caused by the secretion of a peptide hormone (e.g., diarrhea caused by the secretion of VIP). Screening of the patient's relatives for elevated calcitonin levels or *RET* mutations permits early detection of tumors in familial cases. As discussed at the end of this chapter, all members of MEN-2 kindreds carrying *RET* mutations are offered prophylactic thyroidectomies to preempt the development of medullary carcinomas; often, the only histologic finding in the resected thyroid of these asymptomatic carriers is the presence of C cell hyperplasia or small (less than 1 cm) *micromedullary* carcinomas. Recent studies have shown that specific *RET* mutations correlate with an aggressive behavior in medullary carcinomas.

## SUMMARY

### Thyroid Neoplasms

- Most thyroid neoplasms manifest as *solitary thyroid nodules*, but only 1% of all thyroid nodules are neoplastic.
- *Follicular adenomas* are the most common benign neoplasms, while papillary carcinoma is the most common malignancy.
- Multiple genetic pathways are involved in *thyroid carcinogenesis*. Some of the genetic abnormalities that are fairly unique to thyroid cancers include *PAX8/PPARG* fusion (in follicular carcinoma), chromosomal rearrangements involving the *RET* oncogene (in papillary cancers), and mutations of *RET* (in medullary carcinomas).
- *Follicular adenomas and carcinomas* both are composed of well-differentiated follicular epithelial cells; the latter are distinguished by evidence of capsular and/or vascular invasion.
- *Papillary carcinomas* are recognized based on nuclear features (ground glass nuclei, pseudoinclusions) even in the absence of papillae. These neoplasms typically metastasize by way of lymphatics, but the prognosis is excellent.
- *Anaplastic carcinomas* are thought to arise by dedifferentiation of more differentiated neoplasms. They are highly aggressive, uniformly lethal cancers.
- *Medullary cancers* are nonepithelial neoplasms arising from the parafollicular C cells and can occur in either sporadic (70%) or familial (30%) settings. Multicentricity and C cell hyperplasia are features of familial cases. Amyloid deposits are a characteristic histologic finding.

# PARATHYROID GLANDS

The parathyroid glands are derived from the developing pharyngeal pouches that also give rise to the thymus. They normally lie in close proximity to the upper and lower poles of each thyroid lobe but may be found anywhere along the pathway of descent of the pharyngeal pouches, including the carotid sheath and the thymus and elsewhere in the anterior mediastinum. Most of the gland is composed of *chief cells.* On hematoxylin-eosin (H&E) staining, the chief cells range from light to dark pink, depending on their glycogen content. They contain secretory granules of *parathyroid hormone* (PTH). *Oxyphil cells* are found throughout the normal parathyroid either singly or in small clusters. They are slightly larger than the chief cells, have acidophilic cytoplasm, and are tightly packed with mitochondria. *The activity of the parathyroid glands is controlled by the level of free (ionized) calcium in the bloodstream, rather than by trophic hormones secreted by the hypothalamus and pituitary.* Normally, decreased levels of free calcium stimulate the synthesis and secretion of PTH, with the following effects:

- Increase in renal tubular reabsorption of calcium
- Increase in urinary phosphate excretion, thereby lowering serum phosphate levels (since phosphate binds to ionized calcium)
- Increase in the conversion of vitamin D to its active dihydroxy form in the kidneys, which in turn augments gastrointestinal calcium absorption
- Enhancement of osteoclastic activity (i.e., bone resorption, thus releasing ionized calcium), mediated indirectly by promoting the differentiation of osteoclast progenitor cells into mature osteoclasts

The net result of these activities is an increase in the level of free calcium, which inhibits further PTH secretion. Abnormalities of the parathyroids include both hyperfunction and hypofunction. *Tumors of the parathyroid glands, unlike thyroid tumors, usually come to attention because of excessive secretion of PTH, rather than mass effects.*

## HYPERPARATHYROIDISM

Hyperparathyroidism occurs in two major forms, *primary* and *secondary,* and, less commonly, as *tertiary* hyperparathyroidism. The first condition represents an autonomous, spontaneous overproduction of PTH, while the latter two conditions typically occur as secondary phenomena in patients with chronic renal insufficiency.

## Primary Hyperparathyroidism

Primary hyperparathyroidism is a common endocrine disorder, and an important cause of *hypercalcemia.* There has been a dramatic increase in the detection of cases in the latter half of the last century, mainly as a result of the routine inclusion of serum calcium assays in testing for a variety of clinical conditions that bring a patient to the hospital. The frequency of occurrence of the various parathyroid lesions underlying the hyperfunction is as follows:

- Adenoma—85% to 95%
- Primary hyperplasia (diffuse or nodular)—5% to 10%
- Parathyroid carcinoma—1%

In more than 95% of cases, primary hyperparathyroidism is caused by a sporadic parathyroid adenoma or sporadic hyperplasia. The genetic defects identified in *familial primary hyperparathyroidism* include multiple endocrine neoplasia syndromes, specifically MEN-1 and MEN-2A (see further on). *Familial hypocalciuric hypercalcemia* is a rare cause of hyperparathyroidism, caused by inactivating mutations in the calcium-sensing receptor gene on parathyroid cells, leading to constitutive PTH secretion.

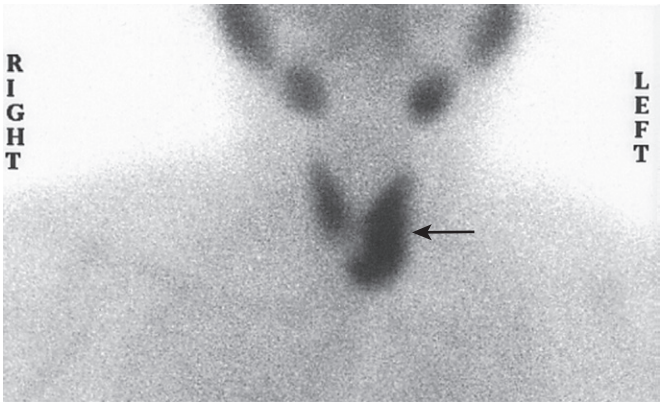

**Figure 19–19** Technetium-99 radionuclide scan demonstrates an area of increased uptake corresponding to the left inferior parathyroid gland (*arrow*). This proved to be a parathyroid adenoma. Preoperative scintigraphy is useful in localizing and distinguishing adenomas from parathyroid hyperplasia, in which more than one gland will demonstrate increased uptake.

### PATHOGENESIS

Although the details of genetic alterations in sporadic parathyroid tumors are beyond the scope of this discussion, abnormalities in two specific genes are commonly associated with these tumors:

- **Cyclin D1 gene inversions:** Cyclin D1 is a positive regulator of the cell cycle. A **chromosomal inversion** on chromosome 11 results in relocation of the *cyclin D1* gene (normally on 11q), so that it is now positioned adjacent to the 5′-flanking region of the *PTH* gene (on 11p), leading to abnormal expression of cyclin D1 protein and increased proliferation. Between 10% and 20% of adenomas have this clonal genetic defect. In addition, cyclin D1 is overexpressed in approximately 40% of parathyroid adenomas, suggesting that mechanisms other than *cyclin D1* gene inversion can lead to its overexpression.
- **MEN1 mutations:** Approximately 20% to 30% of parathyroid tumors not associated with the MEN-1 syndrome have mutations in both copies of the *MEN1* gene (see later). The spectrum of *MEN1* mutations in the sporadic tumors is virtually identical to that in familial parathyroid adenomas.

### MORPHOLOGY

The morphologic changes seen in primary hyperparathyroidism include those in the parathyroid glands as well as those in other organs affected by elevated levels of calcium. In 75% to 80% of cases, one of the parathyroids harbors a solitary **adenoma,** which, like the normal parathyroids, may lie in close proximity to the thyroid gland or in an ectopic site (e.g., the mediastinum). The typical parathyroid adenoma is a well-circumscribed, soft, tan nodule, invested by a delicate capsule. **By definition, parathyroid adenomas are almost invariably confined to single glands** (Fig. 19–19), and the remaining glands are normal in size or somewhat shrunken, as a result of feedback inhibition by elevated serum calcium. Most parathyroid adenomas weigh between 0.5 and 5 g. On microscopic examination, parathyroid adenomas are composed predominantly of chief cells (Fig. 19–20). In most cases, at least a few nests of larger oxyphil cells also are present. A rim of compressed, non-neoplastic parathyroid tissue, generally separated by a fibrous capsule, often is visible at the edge of the adenoma. This finding constitutes a helpful internal control, since the chief cells of the adenoma are larger and show greater nuclear size variability than that typical for the normal chief cells. Cells with bizarre and pleomorphic nuclei are often seen within adenomas (so-called **endocrine atypia**) and must not be taken as a sign of malignancy. Mitotic figures are rare. In contrast with the normal parathyroid parenchyma, adipose tissue is inconspicuous within adenomas.

**Parathyroid hyperplasia is typically a multiglandular process.** In some cases, however, enlargement may be grossly apparent in only one or two glands, complicating the distinction between hyperplasia and adenoma. The combined weight of all glands rarely exceeds 1.0 g and often is less. Microscopically, the most common pattern seen is that of chief cell hyperplasia, which may involve the glands in a diffuse or multinodular pattern. Less commonly, the constituent cells contain abundant clear cytoplasm as a consequence of accumulation of glycogen—a condition designated "water-clear cell hyperplasia." As in the case of adenomas, stromal fat is inconspicuous within foci of hyperplasia.

**Parathyroid carcinomas** may be circumscribed lesions that are difficult to distinguish from adenomas, or they may be clearly invasive neoplasms. These tumors enlarge one parathyroid gland and consist of gray-white, irregular masses that sometimes exceed 10 g in weight. The cells usually are uniform and resemble normal parathyroid cells. They are arrayed in nodular or trabecular patterns with a dense, fibrous capsule enclosing the mass. There is general agreement that a **diagnosis of carcinoma based on cytologic detail is unreliable, and invasion of surrounding tissues and metastasis are the only definitive**

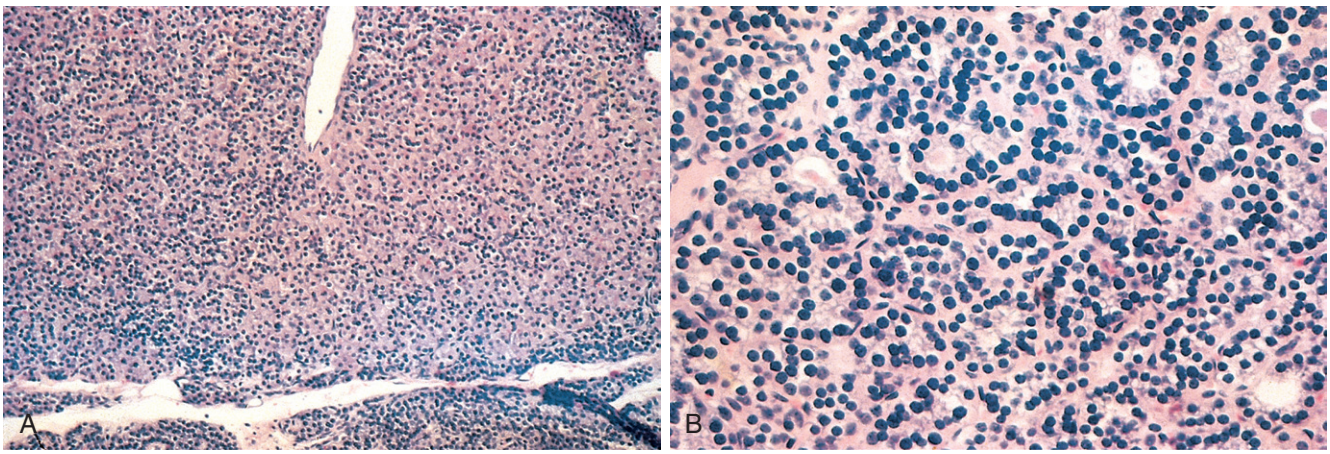

**Figure 19–20** Chief cell parathyroid adenoma. **A,** On this low-power view, a solitary adenoma is clearly delineated from the residual gland below. **B,** High-power detail shows slight variation in nuclear size and tendency to follicular formation but no anaplasia.

**criteria.** Local recurrence occurs in one third of cases, and more distant dissemination occurs in another third.

**Morphologic changes in other organs** deserving special mention are found in the skeleton and kidneys. **Skeletal changes** include increased osteoclastic activity, which results in erosion of bone matrix and mobilization of calcium salts, particularly in the metaphyses of long tubular bones. Bone resorption is accompanied by increased osteoblastic activity and the formation of new bone trabeculae. In more severe cases the cortex is grossly thinned and the marrow contains increased amounts of fibrous tissue accompanied by foci of hemorrhage and cysts **(osteitis fibrosa cystica)** (Chapter 20). Aggregates of osteoclasts, reactive giant cells, and hemorrhagic debris occasionally form masses that may be mistaken for neoplasms (**brown tumors** of hyperparathyroidism). PTH-induced hypercalcemia favors the formation of urinary tract stones (nephrolithiasis) as well as calcification of the renal interstitium and tubules (nephrocalcinosis). Metastatic calcification secondary to hypercalcemia also may be seen in other sites, including the stomach, lungs, myocardium, and blood vessels.

**Table 19–4** Causes of Hypercalcemia

| Raised PTH | Decreased PTH |
|---|---|
| Hyperparathyroidism | Hypercalcemia of malignancy |
| Primary (adenoma > hyperplasia)* | Osteolytic metastases |
| Secondary† | PTH-rP–mediated |
| Tertiary† | Vitamin D toxicity |
| Familial hypocalciuric hypercalcemia | Immobilization |
| | Drugs (thiazide diuretics) |
| | Granulomatous diseases (sarcoidosis) |

PTH, parathyroid hormone; PTH-rP, PTH-related protein.
*Primary hyperparathyroidism is the most common cause of hypercalcemia overall. Malignancy is the most common cause of *symptomatic* hypercalcemia. Primary hyperparathyroidism and malignancy together account for nearly 90% of cases of hypercalcemia.
†Secondary and tertiary hyperparathyroidism are most commonly associated with progressive renal failure.

## Clinical Features

Primary hyperparathyroidism usually is a disease of adults and is much more common in women than in men (gender ratio of nearly 4:1). *The most common manifestation of primary hyperparathyroidism is an increase in serum ionized calcium.* In fact, primary hyperparathyroidism is the most common cause of *clinically silent hypercalcemia.* Of note, other conditions also may produce hypercalcemia (Table 19–4). The most common cause of clinically apparent hypercalcemia in adults is paraneoplastic syndromes associated with *malignancy* and bone metastases (Chapter 5). The prognosis for patients with malignancy-associated hypercalcemia is poor, because it often occurs in those with advanced cancers. In persons with hypercalcemia caused by parathyroid hyperfunction, serum PTH is inappropriately elevated, whereas serum PTH is low to undetectable in those with hypercalcemia caused by nonparathyroid diseases, including malignancy. Other laboratory alterations referable to PTH excess include hypophosphatemia and increased urinary excretion of both calcium and phosphate.

Primary hyperparathyroidism traditionally has been associated with a constellation of symptoms that included "painful bones, renal stones, abdominal groans, and psychic moans." Pain, secondary to fractures of bones weakened by osteoporosis or osteitis fibrosa cystica and resulting from renal stones, with obstructive uropathy, was at one time a prominent manifestation of primary hyperparathyroidism. Because serum calcium is now routinely assessed in the workup of most patients who need blood tests for unrelated conditions, clinically silent hyperparathyroidism is detected early. Hence, many of the classic clinical manifestations, particularly those referable to bone and renal disease, are seen much less frequently. Additional signs and symptoms that may be encountered in some cases include

- *Gastrointestinal disturbances,* including constipation, nausea, peptic ulcers, pancreatitis, and gallstones
- *Central nervous system alterations,* including depression, lethargy, and seizures
- *Neuromuscular abnormalities,* including weakness and hypotonia
- *Polyuria* and secondary polydipsia

Although some of these alterations, for example, polyuria and muscle weakness, are clearly related to hypercalcemia,

the pathogenesis of many of the other manifestations of the disorder remains poorly understood.

### Secondary Hyperparathyroidism

Secondary hyperparathyroidism is caused by any condition associated with a chronic depression in the serum calcium level, because low serum calcium leads to compensatory overactivity of the parathyroids. *Renal failure is by far the most common cause of secondary hyperparathyroidism.* The mechanisms by which chronic renal failure induces secondary hyperparathyroidism are complex and not fully understood. Chronic renal insufficiency is associated with decreased phosphate excretion, which in turn results in hyperphosphatemia. The elevated serum phosphate levels directly depress serum calcium levels and thereby stimulate parathyroid gland activity. In addition, loss of renal substances reduces the availability of $\alpha_1$-hydroxylase enzyme necessary for the synthesis of the active form of vitamin D, which in turn reduces intestinal absorption of calcium (Chapter 7).

#### MORPHOLOGY

**The parathyroid glands in secondary hyperparathyroidism are hyperplastic.** As in the case of primary hyperplasia, the degree of glandular enlargement is not necessarily symmetric. On microscopic examination, the hyperplastic glands contain an increased number of chief cells, or cells with more abundant, clear cytoplasm **(water-clear cells),** in a diffuse or multinodular distribution. Fat cells are decreased in number. **Bone changes** similar to those seen in primary hyperparathyroidism also may be present. **Metastatic calcification** may be seen in many tissues.

#### Clinical Features

The clinical manifestations of secondary hyperparathyroidism usually are dominated by those related to chronic renal failure. Bone abnormalities (*renal osteodystrophy*) and other changes associated with PTH excess are, in general, less severe than those seen in primary hyperparathyroidism. Serum calcium remains near normal because the compensatory increase in PTH levels sustains serum calcium. The metastatic calcification of blood vessels (secondary to hyperphosphatemia) occasionally may result in significant ischemic damage to skin and other organs—a process sometimes referred to as *calciphylaxis.* In a minority of patients, parathyroid activity may become autonomous and excessive, with resultant hypercalcemia—a process sometimes termed *tertiary hyperparathyroidism.* Parathyroidectomy may be necessary to control the hyperparathyroidism in such patients.

#### SUMMARY

##### Hyperparathyroidism

- Primary hyperparathyroidism is the most common cause of asymptomatic hypercalcemia.
- In a majority of cases, primary hyperparathyroidism is caused by a sporadic parathyroid adenoma and, less commonly, by parathyroid hyperplasia.
- Parathyroid adenomas are solitary, while hyperplasia typically is a multiglandular process.
- Skeletal manifestations of hyperparathyroidism include bone resorption, *osteitis fibrosa cystica,* and *brown tumors.* Renal changes include nephrolithiasis (stones) and nephrocalcinosis.
- The clinical manifestations of hyperparathyroidism can be summarized as "painful bones, renal stones, abdominal groans, and psychic moans."
- Secondary hyperparathyroidism most often is caused by renal failure, and the parathyroid glands are hyperplastic.
- Malignancies are the most important cause of symptomatic hypercalcemia, which results from osteolytic metastases or release of PTH-related protein from nonparathyroid tumors.

## HYPOPARATHYROIDISM

Hypoparathyroidism is far less common than hyperparathyroidism. The major causes of hypoparathyroidism include the following:

- *Surgically induced hypoparathyroidism*: The most common cause is inadvertent removal of parathyroids during thyroidectomy or other surgical neck dissections.
- *Congenital absence*: This occurs in conjunction with thymic aplasia (Di George syndrome) and cardiac defects, secondary to deletions on chromosome 22q11.2 (Chapter 6)
- *Autoimmune hypoparathyroidism*: This is a hereditary polyglandular deficiency syndrome arising from autoantibodies to multiple endocrine organs (parathyroid, thyroid, adrenals, and pancreas). Chronic fungal infections involving the skin and mucous membranes (mucocutaneous candidiasis) are sometimes encountered in affected persons. This condition is caused by mutations in the *autoimmune regulator* gene (*AIRE*) and is discussed more extensively later on, in the context of autoimmune adrenalitis. As one consequence of the failure of self-tolerance, some of these patients make autoantibodies against their own IL-17, accounting for the increased susceptibility to *Candida* infections (in which the $T_H17$ response plays an important protective role).

The major clinical manifestations of hypoparathyroidism are secondary to hypocalcemia and include *increased neuromuscular irritability* (*tingling, muscle spasms, facial grimacing,* and *sustained carpopedal spasm or tetany*), cardiac arrhythmias, and, on occasion, *increased intracranial pressures* and *seizures.* Morphologic changes generally are inconspicuous but may include cataracts, calcification of the cerebral basal ganglia, and dental abnormalities.

# ENDOCRINE PANCREAS

The endocrine pancreas consists of about 1 million microscopic clusters of cells, the islets of Langerhans, which contain four major cell types—beta, alpha, delta, and PP (pancreatic polypeptide) cells. The cells can be differentiated morphologically by their staining properties, by the ultrastructural characteristics of their granules, and by their hormone content. *The beta cell produces insulin,* which is the most potent anabolic hormone known, with multiple synthetic and growth-promoting effects; *the alpha cell secretes glucagon,* inducing hyperglycemia by its glycogenolytic activity in the liver; *delta cells contain somatostatin,* which suppresses both insulin and glucagon release; and *PP cells contain a unique pancreatic polypeptide,* VIP, that exerts several gastrointestinal effects, such as stimulation of secretion of gastric and intestinal enzymes and inhibition of intestinal motility. The most important disease of the endocrine pancreas is diabetes mellitus, caused by deficient production or action of insulin.

# DIABETES MELLITUS

Diabetes mellitus is not a single disease entity but rather a *group of metabolic disorders sharing the common underlying feature of hyperglycemia.* Hyperglycemia in diabetes results from defects in insulin secretion, insulin action, or, most commonly, both. The chronic hyperglycemia and attendant metabolic deregulation of diabetes mellitus may be associated with secondary damage in multiple organ systems, especially the kidneys, eyes, nerves, and blood vessels. According to the American Diabetes Association, diabetes affects over 20 million children and adults, or 7% of the population, in the United States, nearly a third of whom are currently unaware that they have hyperglycemia. Approximately 1.5 million new cases of diabetes are diagnosed each year in the United States, and diabetes is the leading cause of end-stage renal disease, adult-onset blindness, and nontraumatic lower extremity amputations. A staggering 54 million adults in this country have *prediabetes*, which is defined as elevated blood sugar that does not reach the criterion accepted for an outright diagnosis of diabetes (discussed next); persons with prediabetes have an elevated risk for development of frank diabetes.

## Diagnosis

Blood glucose levels normally are maintained in a very narrow range, usually 70 to 120 mg/dL. The diagnosis of diabetes is established by elevation of blood glucose by any one of three criteria:

1. A random blood glucose concentration of 200 mg/dL or higher, with classical signs and symptoms (discussed next)
2. A fasting glucose concentration of 126 mg/dL or higher on more than one occasion
3. An abnormal oral glucose tolerance test (OGTT), in which the glucose concentration is 200 mg/dL or higher 2 hours after a standard carbohydrate load (75 g of glucose).

Derangements in carbohydrate metabolism proceed along a continuum. Persons with serum fasting glucose values less than 110 mg/dL, or less than 140 mg/dL for an OGTT, are considered to be euglycemic. However, those with serum fasting glucose greater than 110 but less than 126 mg/dL, or OGTT values of greater than 140 but less than 200 mg/dL, are considered to have *impaired glucose tolerance,* also known as *prediabetes.* Persons with impaired glucose tolerance have a significant risk for progression to overt diabetes over time, with as many as 5% to 10% advancing to full-fledged diabetes mellitus per year. In addition, those with impaired glucose tolerance are at *risk for cardiovascular disease,* as a consequence of abnormal carbohydrate metabolism and the coexistence of other risk factors (Chapter 9).

## Classification

Although all forms of diabetes mellitus share hyperglycemia as a common feature, the underlying causes of hyperglycemia vary widely. *The vast majority of cases of diabetes fall into one of two broad classes*:

- *Type 1 diabetes (T1D)* is characterized by an absolute deficiency of insulin secretion caused by pancreatic beta cell destruction, usually resulting from an autoimmune attack. Type 1 diabetes accounts for approximately 10% of all cases.
- *Type 2 diabetes (T2D)* is caused by a combination of peripheral resistance to insulin action and an inadequate compensatory response of insulin secretion by the pancreatic beta cells (*relative insulin deficiency*). Approximately 80% to 90% of patients have type 2 diabetes.

A variety of monogenic and secondary causes make up the remaining cases of diabetes (Table 19–5). An important point is that although the major types of diabetes arise by different pathogenic mechanisms, *the long-term complications in kidneys, eyes, nerves, and blood vessels are the same and are the principal causes of morbidity and death.*

## Normal Insulin Physiology and Glucose Homeostasis

Before discussing the pathogenesis of the two major types of diabetes, we briefly review normal insulin physiology and glucose metabolism. *Normal glucose homeostasis is tightly regulated by three interrelated processes*: (1) glucose production in the liver, (2) glucose uptake and utilization by peripheral tissues, chiefly skeletal muscle, and (3) actions of insulin and counterregulatory hormones (e.g., glucagon).

*The principal metabolic function of insulin is to increase the rate of glucose transport into certain cells in the body* (Fig. 19–21). These are the *striated* muscle cells (including myocardial cells) and, to a lesser extent, *adipocytes,* representing collectively about two thirds of total body weight. Glucose uptake in other peripheral tissues, most notably the brain, is insulin-independent. In muscle cells, glucose is then

Modified from the American Diabetes Association: Position statement from the American Diabetes Association on the diagnosis and classification of diabetes mellitus. Diabetes Care 31(Suppl 1):S55–S60, 2008.

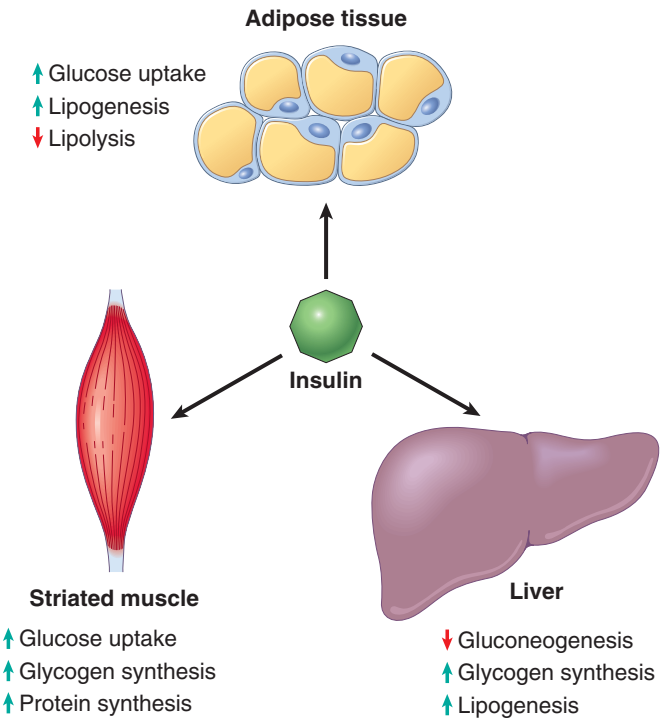

**Figure 19–21** Metabolic actions of insulin in striated muscle, adipose tissue, and liver.

either stored as glycogen or oxidized to generate adenosine triphosphate (ATP). In adipose tissue, glucose is stored primarily as lipid. Besides promoting lipid synthesis (lipogenesis), insulin also inhibits lipid degradation (lipolysis) in adipocytes. Similarly, insulin promotes amino acid uptake and protein synthesis while inhibiting protein degradation. *Thus, the metabolic effects of insulin can be summarized as anabolic, with increased synthesis and reduced degradation of glycogen, lipid, and protein.* In addition to these metabolic effects, insulin has several *mitogenic* functions, including initiation of DNA synthesis in certain cells and stimulation of their growth and differentiation.

*Insulin reduces the production of glucose from the liver.* Insulin and glucagon have opposing regulatory effects on glucose homeostasis. During *fasting* states, low insulin and high glucagon levels facilitate hepatic gluconeogenesis and glycogenolysis (glycogen breakdown) while decreasing glycogen synthesis, thereby preventing hypoglycemia. Thus, *fasting* plasma glucose levels are determined primarily by hepatic glucose output. After a meal, insulin levels rise and glucagon levels fall in response to the large glucose load. *The most important stimulus that triggers insulin release is glucose itself, which initiates insulin synthesis in the pancreatic beta cells.* In peripheral tissues (skeletal muscle and adipose tissue), secreted insulin binds to the *insulin receptor,* triggering a number of intracellular responses that promote glucose uptake and postprandial glucose utilization, thereby maintaining glucose homeostasis. Abnormalities at various points along this complex signaling cascade, from synthesis and release of insulin by beta cells to insulin receptor interactions in peripheral tissues, can result in the diabetic phenotype.

## PATHOGENESIS

### Type 1 Diabetes Mellitus

**Type 1 diabetes is an autoimmune disease in which islet destruction is caused primarily by immune effector cells reacting against endogenous beta cell antigens.** Type 1 diabetes most commonly develops in childhood, becomes manifest at puberty, and progresses with age. Most patients with type 1 diabetes depend on exogenous insulin for survival; without insulin they develop serious metabolic complications such as ketoacidosis and coma.

Although the clinical onset of type 1 diabetes is abrupt, this disease in fact results from a chronic autoimmune attack on beta cells that usually starts many years before the disease becomes evident (Fig. 19–22). The classic manifestations of the disease (hyperglycemia and ketosis) occur late in its course, after more than 90% of the beta cells have been destroyed. **The fundamental immune abnormality in type 1 diabetes is a failure of self-tolerance in T cells.** This failure of tolerance may be a result of some combination of defective clonal deletion of self-reactive T cells in the thymus, as well as defects in the functions of regulatory T cells or resistance of effector T cells to suppression by regulatory cells. Thus, autoreactive T cells not only survive but are poised to respond to self-antigens. Not surprisingly, **autoantibodies** against a variety of beta cell antigens, including insulin and the beta cell enzyme glutamic acid decarboxylase, are detected in the blood of 70% to 80% of patients. In the rare cases in which the pancreatic lesions have been examined early in the disease process, the islets show necrosis of beta cells and lymphocytic infiltration (so-called insulitis).

As with most autoimmune diseases, the pathogenesis of type 1 diabetes involves the interplay of genetic susceptibility and environmental factors. Genome-wide association studies (Chapter 6) have identified over 20 susceptibility loci for type 1 diabetes. Of these, **the principal susceptibility locus for type 1 diabetes resides in the chromosomal region that encodes the class II MHC molecules on *6p21 (HLA-D)*.** Between 90% and 95% of white patients with type 1 diabetes have *HLA-DR3*, or *DR4*, or both, in contrast with about 40% of normal subjects, and 40% to 50% of patients are *DR3/DR4* heterozygotes, in contrast with 5% of normal subjects. Of note, despite the high relative risk in persons with particular class II alleles, most people who inherit these alleles do not develop diabetes. Several *non-HLA genes* also confer susceptibility to type 1 diabetes, including polymorphisms within the gene encoding insulin itself, as well as *CTLA4* and *PTPN22*. CTLA-4 is an inhibitory receptor of T cells and PTPN-22 is a protein tyrosine phosphatase; both are thought to inhibit T cell responses, so polymorphisms that interfere with their functional activity are expected to set the stage for excessive T cell activation. Polymorphisms in the insulin gene may reduce expression of this protein in the thymus, thus reducing the elimination of T cells reactive with this self protein (Chapter 4). Additional evidence suggests that **environmental factors,** especially infections, may be involved in type 1 diabetes. It has been proposed that certain viruses (mumps, rubella, and coxsackie B viruses, in particular) may be an initiating trigger, perhaps because some viral antigens are antigenically similar to beta cell antigens **(molecular mimicry),** leading to bystander damage to the islets, but this idea is not conclusively established.

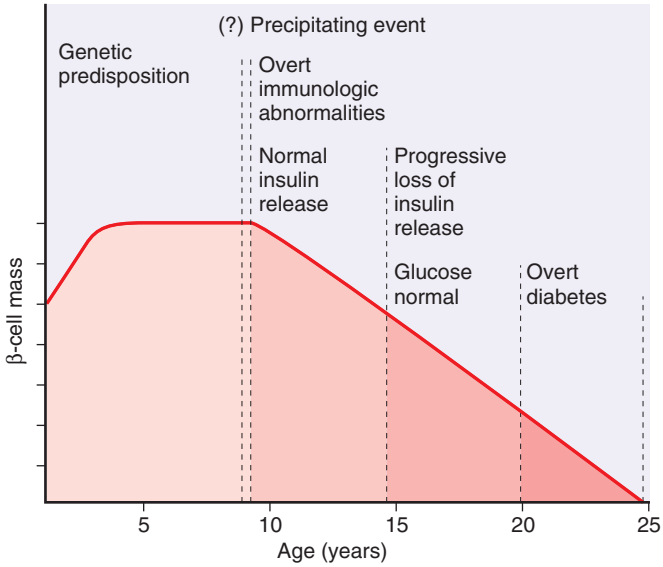

**Figure 19–22** Stages in the development of type 1 diabetes mellitus. The stages are listed *from left to right*, and hypothetical beta cell mass is plotted against age.

*(From Eisenbarth GE: Type 1 diabetes—a chronic autoimmune disease. N Engl J Med 314:1360, 1986.)*

### Type 2 Diabetes Mellitus

Type 2 diabetes is a prototypical complex multifactorial disease. Environmental factors, such as a sedentary life style and dietary habits, unequivocally play a role, as described in the subsequent discussion of the association with obesity. Genetic factors are also involved in the pathogenesis, as evidenced by the disease concordance rate of 35% to 60% in monozygotic twins compared with nearly half that in dizygotic twins. Such concordance is even greater than in type 1 diabetes, suggesting perhaps an even larger genetic component in type 2 diabetes. **Additional evidence for a genetic basis has emerged from recent large-scale genome-wide association studies, which have identified more than a dozen susceptibility loci called "diabetogenic" genes.** Unlike type 1 diabetes, however, the disease is not linked to genes involved in immune tolerance and regulation (e.g., *HLA, CTLA4*), and evidence of an autoimmune basis is lacking. The two metabolic defects that characterize type 2 diabetes are (1) a decreased ability of peripheral tissues to respond to insulin (insulin resistance) and (2) beta cell dysfunction that is manifested as inadequate insulin secretion in the face of insulin resistance and hyperglycemia (Fig. 19–23). Insulin resistance predates the development of hyperglycemia and usually is accompanied by compensatory beta cell hyperfunction and hyperinsulinemia in the early stages of the evolution of diabetes.

## Insulin Resistance

*Insulin resistance* is defined as the failure of target tissues to respond normally to insulin. It leads to decreased uptake of glucose in muscle, reduced glycolysis and fatty acid oxidation in the liver, and an inability to suppress hepatic gluconeogenesis. A variety of functional defects have been

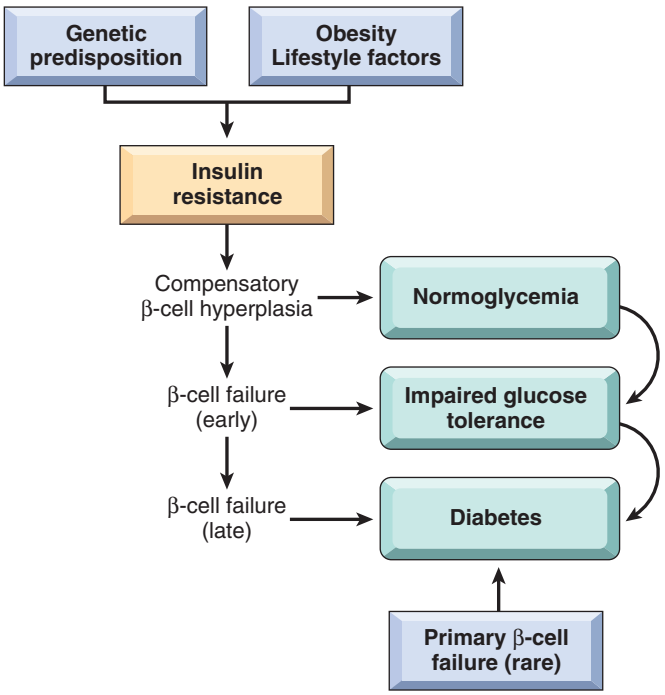

**Figure 19–23** Pathogenesis of type 2 diabetes mellitus. Genetic predisposition and environmental influences converge to cause insulin resistance. Compensatory beta cell hyperplasia can maintain normoglycemia, but eventually beta cell secretory dysfunction sets in, leading to impaired glucose tolerance and, ultimately, frank diabetes. Rare instances of primary beta cell failure can lead directly to type 2 diabetes without an intervening state of insulin resistance.

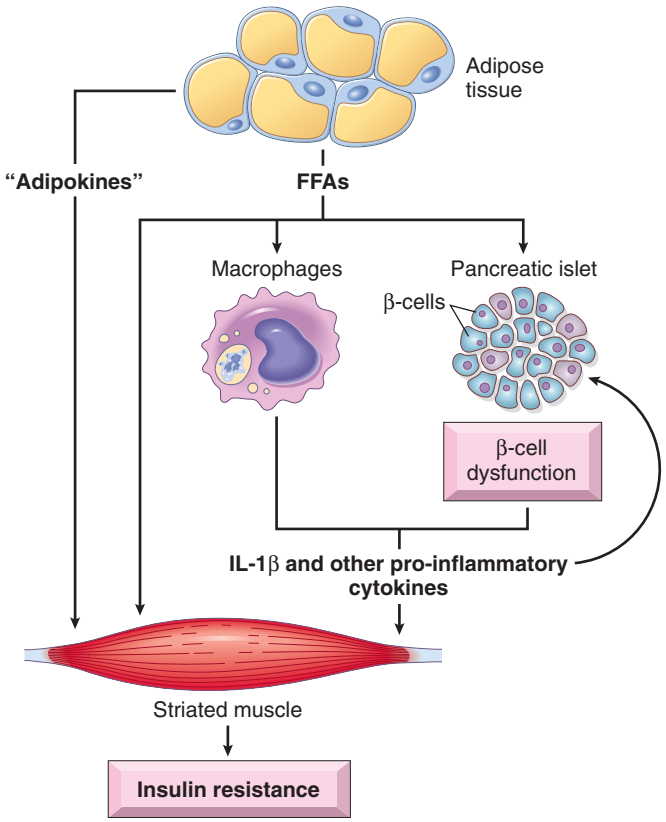

**Figure 19–24** Mechanisms of beta cell dysfunction and insulin resistance in type 2 diabetes. Free fatty acids directly cause beta cell dysfunction and induce insulin resistance in target tissues (such as striated muscle, *shown here*), and also induce the secretion of pro-inflammatory cytokines that cause more beta cell dysfunction and insulin resistance.

reported in the insulin signaling pathway in states of insulin resistance (for example, reduced phosphorylation-dependent activation of the insulin receptor and its downstream components), which attenuate signal transduction. *Few factors play as important a role in the development of insulin resistance as obesity.*

### *Obesity and Insulin Resistance*

The association of obesity with type 2 diabetes has been recognized for decades, with visceral obesity being common in a majority of affected patients. Insulin resistance is present even with simple obesity unaccompanied by hyperglycemia, indicating a fundamental abnormality of insulin signaling in states of fatty excess. In fact, the term *metabolic syndrome* has been applied to a constellation of findings dominated by visceral obesity, which is accompanied by insulin resistance, glucose intolerance, and cardiovascular risk factors such as hypertension and abnormal lipid profiles (Chapter 7). In the absence of weight loss and lifestyle modifications, persons with metabolic syndrome are at significant risk for the development of frank type 2 diabetes, underscoring the importance of obesity to the pathogenesis of this disease. The risk of diabetes increases as the body mass index (a measure of body fat content) increases, suggesting a dose-response relationship between body fat and insulin resistance. Although many details of the so-called *adipo-insulin axis* remain to be elucidated, recognition of some of the putative pathways leading to insulin resistance has increased substantially (Fig. 19–24):

- *Role of excess free fatty acids* (FFAs): Cross-sectional studies have demonstrated an inverse correlation between fasting plasma FFAs and insulin sensitivity. The level of intracellular triglycerides often is markedly increased in muscle and liver tissues in obese persons, presumably because excess circulating FFAs are deposited in these organs. Intracellular triglycerides and products of fatty acid metabolism are potent inhibitors of insulin signaling and result in an acquired insulin resistance state. These *lipotoxic* effects of FFAs are mediated through a decrease in activity of key insulin-signaling proteins.
- *Role of inflammation*: Over the past several years, inflammation has emerged as a major player in the pathogenesis of type 2 diabetes. It is now known that a permissive inflammatory milieu (mediated *not* by an autoimmune process as in type 1 diabetes but rather by pro-inflammatory cytokines that are secreted in response to excess nutrients such as FFAs) results in both peripheral insulin resistance and beta cell dysfunction (see later). Excess FFAs within macrophages and beta cells can engage the *inflammasome*, a multiprotein cytoplasmic complex that leads to secretion of the cytokine interleukin IL-1β (Chapter 2). IL-1β, in turn, mediates the

secretion of additional pro-inflammatory cytokines from macrophages, islets, and other cells that are released into the circulation and act on the major sites of insulin action to promote insulin resistance. Thus, excess FFAs can impede insulin signaling directly within peripheral tissues, as well as indirectly through the release of pro-inflammatory cytokines. Not surprisingly, there are now several ongoing trials of cytokine antagonists (particularly of IL-1β) in patients with type 2 diabetes.

- *Role of adipokines*: Adipose tissue is not merely a passive storage depot for fat; it can operate as a functional endocrine organ, releasing so-called *adipokines* in response to extracellular stimuli or changes in metabolic status. Thus, adipocytes also release IL-1β and other pro-inflammatory cytokines into the circulation in response to excess FFAs, which promote peripheral insulin resistance. By contrast, *adiponectin* is an adipokine with insulin sensitizing activity, which probably acts by dampening the inflammatory response.
- *Peroxisome proliferator-activated receptor-γ* (PPARγ): PPARγ is a nuclear receptor and transcription factor expressed in adipose tissue and plays a seminal role in adipocyte differentiation. A class of antidiabetic medications known as thiazolidinediones acts as agonist ligands for PPARγ and improves insulin sensitivity. Activation of PPARγ promotes secretion of antihyperglycemic adipokines such as adiponectin, and shifts the deposition of FFAs toward adipose tissue and away from liver and skeletal muscle.

## Beta Cell Dysfunction

Beta cell dysfunction in type 2 diabetes reflects the inability of these cells to adapt themselves to the long-term demands of peripheral insulin resistance and increased insulin secretion. In states of insulin resistance, insulin secretion initially is higher for each level of glucose than in controls. This hyperinsulinemic state is a compensation for peripheral resistance and often can maintain normal plasma glucose for years. Eventually, however, beta cell compensation becomes inadequate, and there is progression to hyperglycemia, which is accompanied by an absolute loss in beta cell mass. The molecular mechanisms underlying beta cell dysfunction in type 2 diabetes are multifactorial and in many instances overlap with those implicated in insulin resistance. Thus, excess nutrients such as FFAs and glucose can promote the secretion of pro-inflammatory cytokines from beta cells, which leads to recruitment of mononuclear cells (macrophages and T cells) into the islets, resulting in more local cytokine production. The consequences of this abnormal inflammatory microenvironment are beta cell dysfunction and, ultimately, beta cell death. Amyloid replacement of islets is a characteristic finding in persons with *long-standing* type 2 diabetes and is present in more than 90% of diabetic islets examined (see later). The islet amyloid polypeptide (IAPP), also known as amylin, is secreted by the beta cells in conjunction with insulin, and its abnormal aggregation results in amyloid. IAPP also engages the inflammasome and promotes IL-1β secretion, thus sustaining the inflammatory onslaught on surviving beta cells even late in the disease.

## Monogenic Forms of Diabetes

Type 1 and type 2 diabetes are genetically complex, and despite the associations with multiple susceptibility loci, no single-gene defect (mutation) can account for predisposition to these entities. By contrast, monogenic forms of diabetes (Table 19–5) are uncommon examples of the *diabetic phenotype occurring as a result of loss-of-function mutations within a single gene.* Monogenic causes of diabetes include either a primary defect in beta cell function or a defect in insulin receptor signaling. The largest subgroup of patients in this category traditionally was designated as having *maturity-onset diabetes of the young (MODY)* because of its superficial resemblance to type 2 diabetes and its occurrence in younger patients; MODY can be the result of inactivating mutations in one of six genes. Other uncommon causes include *maternally inherited diabetes and bilateral deafness,* secondary to mitochondrial DNA mutations, and mutations within the *insulin* gene itself, which most commonly manifests with diabetes in the neonatal period. Finally, rare instances of *insulin receptor* mutations that affect receptor synthesis, insulin binding, or downstream signal transduction can cause severe insulin resistance, accompanied by hyperinsulinemia and diabetes.

## Complications of Diabetes

Diabetes can be a devastating disease because the abnormal glucose metabolism and other metabolic derangements have serious pathologic effects on virtually all the systems of the body. The most significant complications of diabetes are vascular abnormalities, renal damage, and lesions affecting the peripheral nerves and eyes (Fig. 19–25). The pathologic findings in these tissues and their clinical consequences are described below. There is extreme variability among patients in the time of onset of these complications, their severity, and the particular organ or organs involved. In persons with tight control of their diabetes, the onset may be delayed.

*The pathogenesis of the long-term complications of diabetes is multifactorial, although persistent hyperglycemia (glucotoxicity) seems to be a key mediator.* At least three distinct metabolic pathways seem to be involved in the pathogenesis of long-term complications; it is likely that all of them play a role in a tissue-specific manner.

1. *Formation of advanced glycation end products* (AGEs). AGEs are formed as a result of nonenzymatic reactions between intracellular glucose-derived precursors (glyoxal, methylglyoxal, and 3-deoxyglucosone) with the amino groups of both intracellular and extracellular proteins. The natural rate of AGE formation is greatly accelerated in the presence of hyperglycemia. AGEs bind to a specific receptor (RAGE), which is expressed on inflammatory cells (macrophages and T cells) and in endothelium and vascular smooth muscle. The detrimental effects of the AGE-RAGE signaling axis within the vascular compartment include
   - Release of pro-inflammatory *cytokines and growth factors* from intimal macrophages
   - Generation of *reactive oxygen species* in endothelial cells

- Increased *procoagulant activity* on endothelial cells and macrophages
- Enhanced *proliferation of vascular smooth muscle cells and synthesis of extracellular matrix*

  In addition to receptor-mediated effects, *AGEs can directly cross-link extracellular matrix proteins,* which decreases protein removal while enhancing protein deposition. AGEs cross-linked proteins can *trap* other plasma or interstitial proteins; for example, low-density lipoprotein (LDL) gets trapped within AGE-modified large vessel walls, accelerating atherosclerosis (Chapter 9), while albumin can get trapped within capillaries, accounting in part for the basement membrane thickening that is characteristic of diabetic microangiopathy (see later).

2. *Activation of protein kinase C.* Activation of intracellular protein kinase C (PKC) by calcium ions and the second messenger diacylglycerol (DAG) is an important signal transduction pathway in many cellular systems. Intracellular hyperglycemia can stimulate the de novo synthesis of DAG from glycolytic intermediates and hence cause activation of PKC. The downstream effects of PKC activation are numerous and include production of *pro-angiogenic molecules* such as vascular endothelial growth factor (VEGF), implicated in the neovascularization seen in diabetic retinopathy, and profibrogenic molecules such as transforming growth factor-β, leading to increased deposition of extracellular matrix and basement membrane material.
3. *Disturbances in polyol pathways.* In some tissues that do not require insulin for glucose transport (e.g., nerves, lens, kidneys, blood vessels), hyperglycemia leads to an increase in intracellular glucose that is then metabolized by the enzyme *aldose reductase* to sorbitol, a polyol, and eventually to fructose, in a reaction that uses NADPH (the reduced form of nicotinamide dinucleotide phosphate) as a cofactor. NADPH is also required by the enzyme glutathione reductase in a reaction that regenerates reduced glutathione (GSH). As described in Chapter 1, GSH is one of the important antioxidant mechanisms in the cell, and any reduction in GSH increases cellular susceptibility to *oxidative stress.* In neurons, persistent hyperglycemia appears to be the major underlying cause of diabetic neuropathy (*glucose neurotoxicity*).

## MORPHOLOGY

### Diabetes and Its Late Complications

Pathologic findings in the diabetic pancreas are variable and not necessarily dramatic. The important morphologic changes are related to the many late systemic complications of diabetes. In most patients, morphologic changes are likely to be found in arteries **(macrovascular disease),** basement membranes of small vessels **(microangiopathy),** kidneys **(diabetic nephropathy),** retina **(retinopathy),** nerves **(neuropathy),** and other tissues. These changes are seen in both type 1 and type 2 diabetes (Fig. 19–25).

**Pancreas.** Lesions in the pancreas are inconstant and rarely of diagnostic value. One or more of the following alterations may be present:

- **Reduction in the number and size of islets.** This change most often is seen in type 1 diabetes, particularly with rapidly advancing disease. Most of the islets are small, inconspicuous, and not easily detected.
- **Leukocytic infiltration of the islets,** which are principally composed of mononuclear cells (lymphocytes and macrophages) (Fig. 19–26, *A*). Of note, both type 1 and type 2 diabetes may demonstrate islet inflammation early in the disease, although it is typically more severe in T1D. In both types inflammation is often absent by the time the disease is clinically evident.
- **Amyloid replacement of islets in long-standing type 2 diabetes,** appearing as deposition of pink, amorphous material beginning in and around capillaries and between cells. At advanced stages the islets may be virtually obliterated (Fig. 19–26, *B*); fibrosis also may be observed. While inflammation is observed early in the natural history of type 2 diabetes, amyloid deposition occurs in long-standing cases.
- **An increase in the number and size of islets, especially characteristic of nondiabetic newborns of diabetic mothers.** Presumably, fetal islets undergo hyperplasia in response to the maternal hyperglycemia.

**Diabetic Macrovascular Disease.** Diabetes exacts a heavy toll on the vascular system. The hallmark of diabetic macrovascular disease is accelerated atherosclerosis affecting the aorta and large and medium-sized arteries. Except for its greater severity and earlier age at onset, atherosclerosis in diabetics is indistinguishable from that in nondiabetics (Chapter 9). Myocardial infarction, caused by atherosclerosis of the coronary arteries, is the most common cause of death in diabetics. Significantly, it is almost as common in diabetic women as in diabetic men. By contrast, myocardial infarction is uncommon in nondiabetic women of reproductive age. Gangrene of the lower extremities, as a result of advanced vascular disease, is about 100 times more common in persons with diabetes than in the general population. The larger renal arteries also are subject to severe atherosclerosis, but the most damaging effect of diabetes on the kidneys is exerted at the level of the glomeruli and the microcirculation, as discussed later on.

**Hyaline arteriolosclerosis,** the vascular lesion associated with hypertension (Chapters 9 and 13), is both more prevalent and more severe in diabetics than in nondiabetics, but it is not specific for diabetes and may be seen in elderly persons who do not suffer from either diabetes or hypertension. It takes the form of an amorphous, hyaline thickening of the wall of the arterioles, which causes narrowing of the lumen (Fig. 19–27). Not surprisingly, in diabetic patients, its severity is related not only to the duration of the disease but also to the presence or absence of hypertension.

**Diabetic Microangiopathy.** One of the most consistent morphologic features of diabetes is **diffuse thickening of basement membranes.** The thickening is most evident in the capillaries of the skin, skeletal muscle, retina, renal glomeruli, and renal medulla. However, it also may be seen in such nonvascular structures as renal tubules, the Bowman

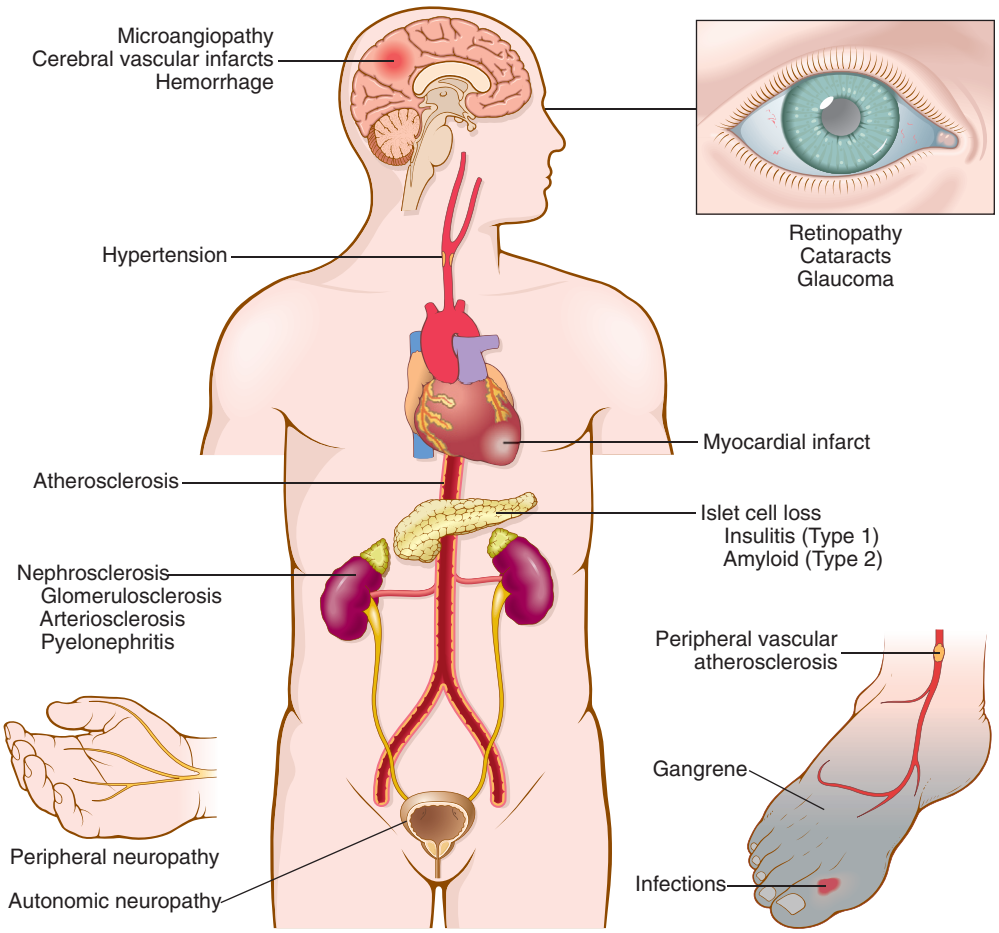

**Figure 19–25** Long-term complications of diabetes.

capsule, peripheral nerves, and placenta. By both light and electron microscopy, the basal lamina separating parenchymal or endothelial cells from the surrounding tissue is markedly thickened by concentric layers of hyaline material composed predominantly of type IV collagen (Fig. 19–28).

Of note, **despite the increase in the thickness of basement membranes, diabetic capillaries are more leaky than normal to plasma proteins. The microangiopathy underlies the development of diabetic nephropathy, retinopathy, and some forms of**

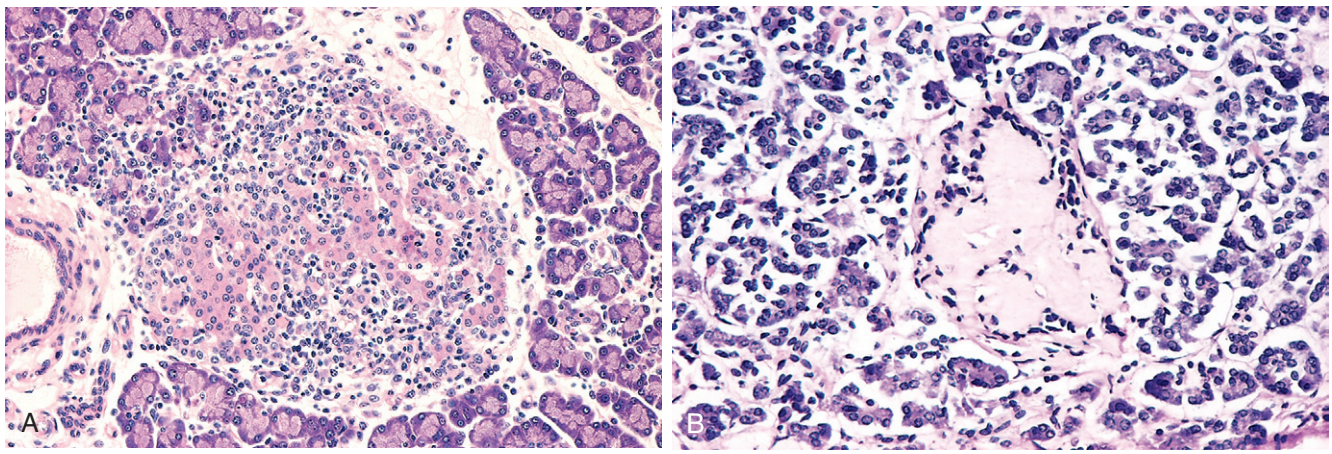

**Figure 19–26 A,** Autoimmune insulitis in a rat (BB) model of autoimmune diabetes. This disorder also is seen in type 1 human diabetes. **B,** Amyloidosis of a pancreatic islet in type 2 diabetes. Amyloidosis typically is observed late in the natural history of this form of diabetes, with islet inflammation noted at earlier observations.

**neuropathy.** An indistinguishable microangiopathy can be found in aged nondiabetic patients, but rarely to the extent seen in persons with long-standing diabetes.

**Diabetic Nephropathy.** The kidneys are prime targets of diabetes (see also Chapter 13). Renal failure is second only to myocardial infarction as a cause of death from this disease. Three lesions are encountered: (1) glomerular lesions; (2) renal vascular lesions, principally arteriolosclerosis; and (3) pyelonephritis, including necrotizing papillitis.

The most important glomerular lesions are capillary basement membrane thickening, diffuse mesangial sclerosis, and nodular glomerulosclerosis. The glomerular capillary basement membranes are thickened along their entire length. This change can be detected by electron microscopy within a few years of the onset of diabetes, sometimes without any associated change in renal function (Fig. 19–29).

**Diffuse mesangial sclerosis** consists of a diffuse increase in mesangial matrix along with mesangial cell proliferation and is always associated with basement membrane thickening. It is found in most individuals with disease of more than 10 years' duration. When glomerulosclerosis becomes marked, patients manifest the nephrotic syndrome, characterized by proteinuria, hypoalbuminemia, and edema (Chapter 13).

**Nodular glomerulosclerosis** describes a glomerular lesion made distinctive by ball-like deposits of a laminated matrix situated in the periphery of the glomerulus (Fig. 19–30). These nodules are PAS-positive and usually contain trapped mesangial cells. This distinctive change has been called the **Kimmelstiel-Wilson lesion,** after the two pathologists who first described it. Nodular glomerulosclerosis is encountered in approximately 15% to 30% of persons with long-term diabetes and is a major contributor to

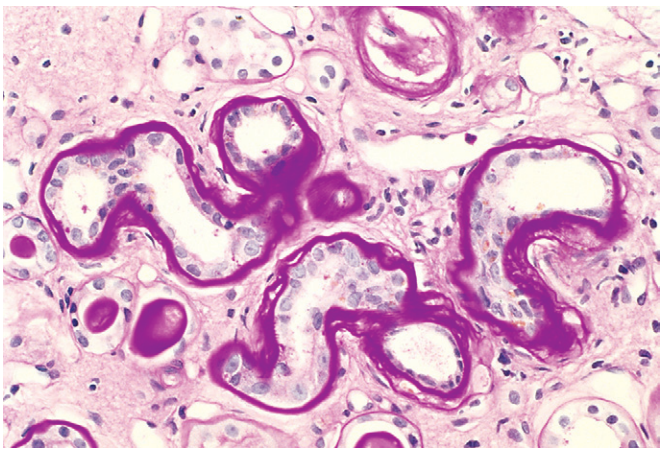

**Figure 19–28** Renal cortex showing thickening of tubular basement membranes in a specimen from a diabetic patient. Periodic acid–Schiff stain.

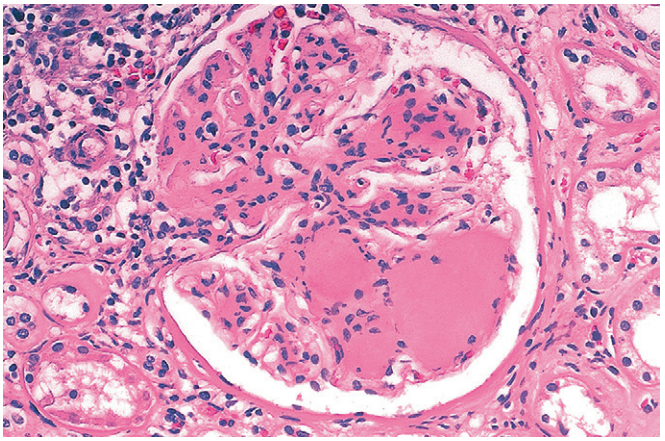

**Figure 19–30** Nodular glomerulosclerosis in a renal specimen from a patient with long-standing diabetes.

morbidity and mortality. Diffuse mesangial sclerosis also may be seen in association with old age and hypertension; by contrast, the nodular form of glomerulosclerosis, once certain unusual forms of nephropathies have been excluded (Chapter 13), is essentially pathognomonic of diabetes. Both the diffuse and the nodular forms of glomerulosclerosis induce sufficient ischemia to cause scarring of the kidneys, manifested by a finely granular-appearing cortical surface (Fig. 19–31).

**Renal atherosclerosis and arteriolosclerosis constitute part of the macrovascular disease seen in diabetics.** The kidney is one of the most frequently and severely affected organs; however, the changes in the arteries and arterioles are similar to those found throughout the body. **Hyaline arteriolosclerosis affects not only the afferent but also the efferent arterioles.** Such efferent arteriolosclerosis is rarely if ever encountered in persons who do not have diabetes.

**Pyelonephritis is an acute or chronic inflammation of the kidneys that usually begins in the interstitial tissue and then spreads to involve the tubules.** Both the acute and chronic forms of this disease occur in nondiabetics as well as in diabetics but are more common in persons with diabetes than in the general population; once affected, diabetics tend to have more severe involvement. One special pattern of acute pyelonephritis, **necrotizing papillitis** (or papillary necrosis), is much more prevalent in diabetics than in nondiabetics.

**Ocular Complications of Diabetes.** Visual impairment, sometimes even total blindness, is one of the more feared consequences of long-standing diabetes. **The ocular involvement may take the form of retinopathy, cataract formation, or glaucoma.** Retinopathy, the most common pattern, consists of a constellation of changes that together are considered by many ophthalmologists to be virtually diagnostic of the disease. **The lesion in the retina takes two forms: nonproliferative (background) retinopathy and proliferative retinopathy.**

**Nonproliferative retinopathy** includes intraretinal or preretinal hemorrhages, retinal exudates, microaneurysms, venous dilations, edema, and, most importantly, thickening of the retinal capillaries (microangiopathy). The retinal exudates can be either "soft" (microinfarcts) or "hard" (deposits of plasma proteins and lipids) (Fig. 19–32). The microaneurysms are discrete saccular dilations of retinal choroidal capillaries that appear through the ophthalmoscope as small red dots. Dilations tend to occur at focal points of weakening, resulting from loss of pericytes. Retinal edema presumably results from excessive capillary permeability. Underlying all of these changes is the microangiopathy, which is thought to lead to loss of capillary pericytes and hence to focal weakening of capillary structure.

**The so-called proliferative retinopathy is a process of neovascularization and fibrosis.** This lesion leads to serious consequences, including blindness, especially if it involves the macula. Vitreous hemorrhages can result from rupture of newly formed capillaries; the subsequent organization of the hemorrhage can pull the retina off its substratum (retinal detachment).

**Diabetic Neuropathy.** The central and peripheral nervous systems are not spared by diabetes. The most frequent pattern of involvement is that of a peripheral, symmetric neuropathy of the lower extremities affecting both motor and sensory function, particularly the latter. Other forms include autonomic neuropathy, which produces disturbances in bowel and bladder function and sometimes sexual

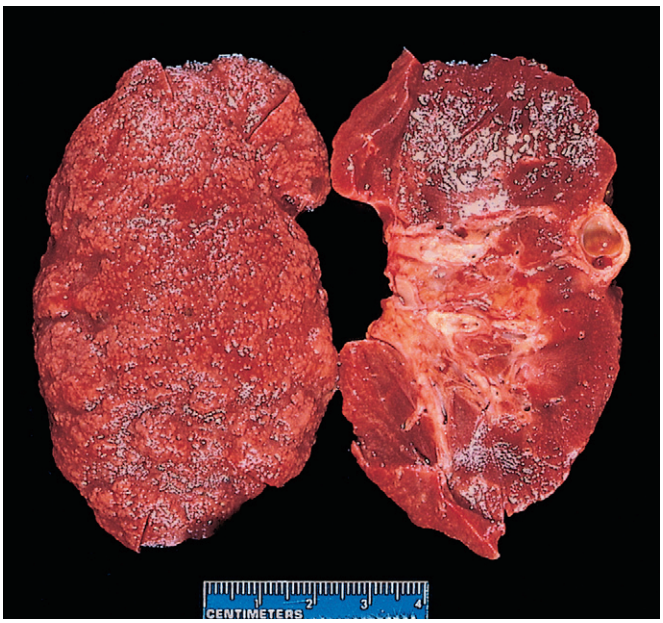

**Figure 19–31** Nephrosclerosis in a patient with long-standing diabetes. The kidney has been bisected to demonstrate both diffuse granular transformation of the surface (*left*) and marked thinning of the cortical tissue (*right*). Additional features include some irregular depressions, the result of pyelonephritis, and an incidental cortical cyst (*far right*).

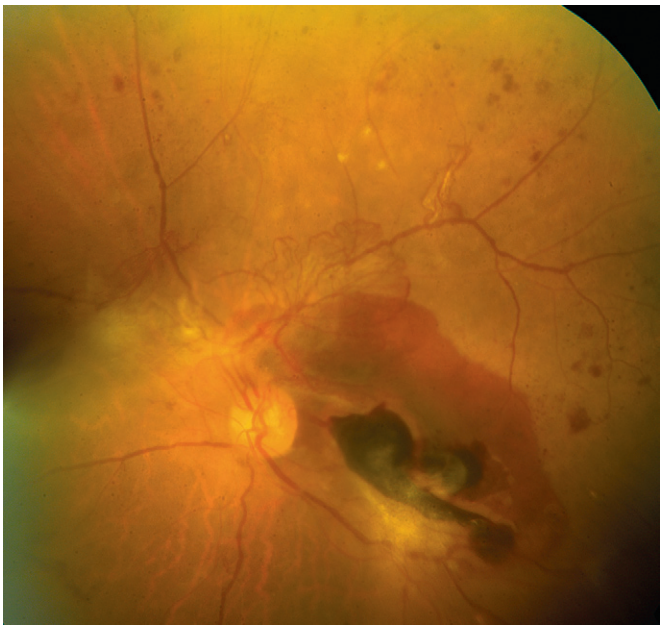

**Figure 19–32** Characteristic morphologic changes of diabetic retinopathy. Features include advanced proliferative retinopathy with retinal hemorrhages, exudates, neovascularization, and tractional retinal detachment (*lower right corner*).
*(Courtesy of Dr. Rajendra Apte, Washington University School of Medicine, St. Louis, Missouri.)*

impotence, and diabetic mononeuropathy, which may manifest as sudden footdrop or wristdrop or isolated cranial nerve palsies. The neurologic changes may be the result of microangiopathy and increased permeability of the capillaries that supply the nerves, as well as direct axonal damage.

### Clinical Features

It is difficult to discuss with brevity the diverse clinical presentations of diabetes mellitus. Only a few characteristic patterns are presented here. In the initial 1 or 2 years after manifestation of overt *type 1 diabetes* (referred to as the "honeymoon period"), exogenous insulin requirements may be minimal to none because of residual ongoing endogenous insulin secretion, but thereafter the beta cell reserve is exhausted and insulin requirements increase dramatically. Although beta cell destruction is a gradual process, the transition from impaired glucose tolerance to overt diabetes may be abrupt, heralded by an event associated with increased insulin requirements such as infection. The onset is marked by polyuria, polydipsia, polyphagia, and in severe cases, ketoacidosis, all resulting from metabolic derangements (Fig. 19–33).

Since insulin is a major anabolic hormone in the body, *deficiency of insulin results in a catabolic state that affects not only glucose metabolism but also fat and protein metabolism.* The assimilation of glucose into muscle and adipose tissue is sharply diminished or abolished. Not only does storage of glycogen in liver and muscle cease, but also reserves are depleted by glycogenolysis. The resultant hyperglycemia exceeds the renal threshold for reabsorption, and glycosuria ensues. The glycosuria induces an osmotic diuresis and, consequently, *polyuria,* causing a profound loss of water and electrolytes. The obligatory renal water loss combined with the hyperosmolarity resulting from the increased levels of glucose in the blood tends to deplete intracellular water, triggering the osmoreceptors of the thirst centers of the brain. This sequence of events generates intense thirst (*polydipsia*). With a deficiency of insulin, the scales swing from insulin-promoted anabolism to catabolism of proteins and fats. Proteolysis follows, and the gluconeogenic amino acids are removed by the liver and used as building blocks for glucose. The catabolism of proteins and fats tends to induce a negative energy balance, which in turn leads to increasing appetite (*polyphagia*), thus completing the classic triad of diabetes: *polyuria, polydipsia,* and *polyphagia.* Despite the increased appetite, catabolic effects prevail, resulting in weight loss and muscle weakness. The combination of polyphagia and weight loss is paradoxical and should always point to the diagnostic possibility of diabetes.

In patients with type 1 diabetes, deviations from normal dietary intake, unusual physical activity, infection, or any other forms of stress may rapidly influence the treacherously fragile metabolic balance, predisposing the affected person to *diabetic ketoacidosis.* The plasma glucose usually is in the range of 500 to 700 mg/dL as a result of absolute insulin deficiency and unopposed effects of counterregulatory hormones (epinephrine, glucagon). The marked hyperglycemia causes an osmotic diuresis and dehydration characteristic of the ketoacidotic state. The second major effect is activation of the ketogenic machinery. Insulin deficiency leads to activation of lipoprotein lipase, with resultant excessive breakdown of adipose stores, giving rise to increased FFAs, which are oxidized by the liver to produce *ketones.* Ketogenesis is an adaptive phenomenon in times of starvation, generating ketones as a source of energy for consumption by vital organs (e.g., brain). The rate at which ketones are formed may exceed the rate at which they can be used by peripheral tissues, leading to *ketonemia* and *ketonuria.* If the urinary excretion of ketones is compromised by dehydration, the accumulating ketones decrease blood pH, resulting in metabolic ketoacidosis.

*Type 2 diabetes mellitus* also may manifest with polyuria and polydipsia, but unlike in type 1 diabetes, patients often are older than 40 years and frequently are obese. Unfortunately, with the increase in obesity and sedentary life style in Western society, type 2 diabetes is now seen in children and adolescents with increasing frequency. In some cases, medical attention is sought because of unexplained weakness or weight loss. *Most frequently, however, the diagnosis is made after routine blood or urine testing in asymptomatic persons.*

In the decompensated state, patients with type 2 diabetes may develop *hyperosmolar nonketotic coma.* This syndrome is engendered by severe dehydration resulting from sustained osmotic diuresis and urinary fluid loss due to chronic hyperglycemia. Typically, the affected person is an elderly diabetic who is disabled by a stroke or an infection and is unable to maintain adequate water intake. The absence of ketoacidosis and its symptoms (nausea, vomiting, respiratory difficulties) delays recognition of the seriousness of the situation until the onset of severe dehydration and coma. Table 19–6 summarizes some of the pertinent clinical, genetic, and histopathologic features that distinguish between type 1 and type 2 diabetes.

As previously discussed, it is the long-term effects of diabetes, more than the acute metabolic complications, which are responsible for the overwhelming preponderance of morbidity and mortality attributable to this disease. In most instances, these complications appear approximately 15 to 20 years after the onset of hyperglycemia.

- In both forms of long-standing diabetes, cardiovascular events such as myocardial infarction, renal vascular insufficiency, and stroke (cerebrovascular accident) are the most common contributors to mortality. The impact of cardiovascular disease can be gauged by its involvement in as many as 80% of deaths among persons with type 2 diabetes; in fact, diabetics have a 3 to 7.5 times greater incidence of death from cardiovascular causes than nondiabetic populations. The hallmark of cardiovascular disease is accelerated atherosclerosis of the large and medium-sized arteries (i.e., macrovascular disease). The importance of obesity in the pathogenesis of insulin resistance has already been discussed, but it also is an independent risk factor for development of atherosclerosis.
- Diabetic nephropathy is a leading cause of end-stage renal disease in the United States. The earliest manifestation of diabetic nephropathy is the appearance of small amounts of albumin in the urine (greater than 30 but less than 300 mg/day—i.e., microalbuminuria). Without specific interventions, approximately 80% of patients with type 1 diabetes and 20% to 40% of those with type

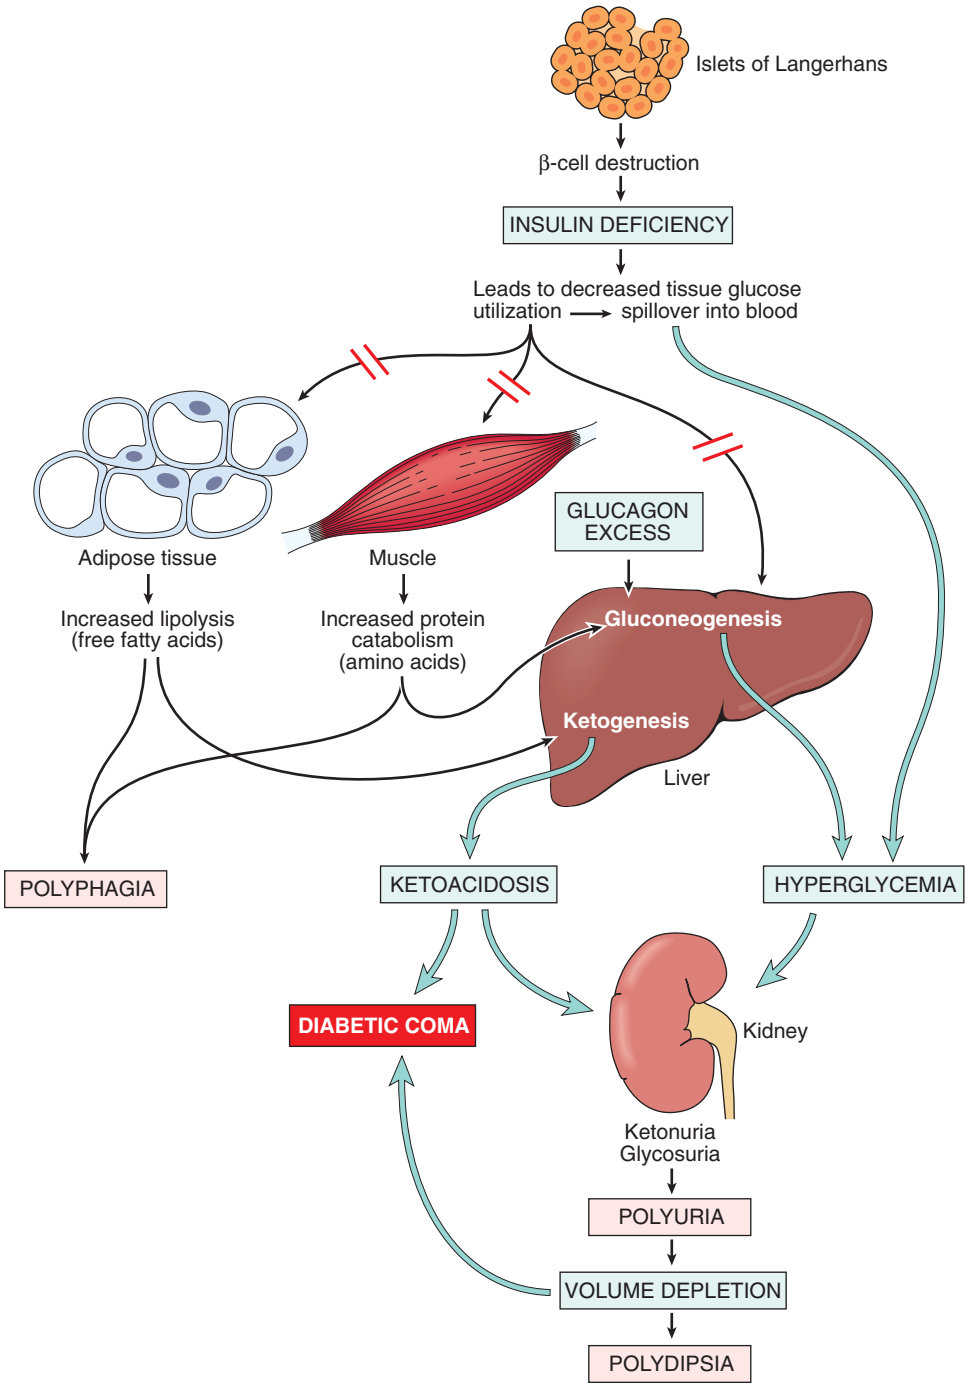

**Figure 19–33** Sequence of metabolic derangements leading to diabetic coma in type 1 diabetes mellitus. An absolute insulin deficiency leads to a catabolic state, eventuating in ketoacidosis and severe volume depletion. These derangements bring about sufficient central nervous system compromise to cause coma and, eventually, death if left untreated.

2 diabetes will develop overt nephropathy with macroalbuminuria (excretion of more than 300 mg/day) over the succeeding 10 to 15 years, usually accompanied by the appearance of hypertension. The progression from overt nephropathy to end-stage renal disease can be highly variable and is evidenced by a progressive drop in glomerular filtration rate. By 20 years after diagnosis, more than 75% of persons with type 1 diabetes and about 20% of those with type 2 diabetes with overt nephropathy will develop end-stage renal disease, necessitating dialysis or renal transplantation.

- Visual impairment, sometimes even total blindness, is one of the more feared consequences of long-standing diabetes. This disease currently is the fourth leading cause of acquired blindness in the United States. Approximately 60% to 80% of patients develop some form of diabetic retinopathy approximately 15 to 20 years after diagnosis. In addition to retinopathy, diabetic patients

**Table 19–6** Type 1 Versus Type 2 Diabetes Mellitus

| Type 1 Diabetes Mellitus | Type 2 Diabetes Mellitus |
|---|---|
| **Clinical** | |
| Onset usually in childhood and adolescence | Onset usually in adulthood; increasing incidence in childhood and adolescence |
| Normal weight or weight loss preceding diagnosis | Vast majority of patients are obese (80%) |
| Progressive decrease in insulin levels | Increased blood insulin (early); normal or moderate decrease in insulin (late) |
| Circulating islet autoantibodies | No islet autoantibodies |
| Diabetic ketoacidosis in absence of insulin therapy | Nonketotic hyperosmolar coma |
| **Genetics** | |
| Major linkage to MHC class I and II genes; also linked to polymorphisms in *CTLA4* and *PTPN22* | No HLA linkage; linkage to candidate diabetogenic and obesity-related genes |
| **Pathogenesis** | |
| Dysfunction in regulatory T cells (Tregs) leading to breakdown in self-tolerance to islet autoantigens | Insulin resistance in peripheral tissues, failure of compensation by beta cells<br>Multiple obesity-associated factors (circulating nonesterified fatty acids, inflammatory mediators, adipocytokines) linked to pathogenesis of insulin resistance |
| **Pathology** | |
| Autoimmune "insulitis" | *Early*: inflammation; *late*: amyloid deposition in islets |
| Beta cell depletion, islet atrophy | Mild beta cell depletion |

HLA, human leukocyte antigen; MHC, major histocompatibility complex.

also have an increased propensity for glaucoma and cataract formation, both of which contribute to visual impairment in diabetes.

- Diabetic neuropathy can elicit a variety of clinical syndromes, afflicting the central nervous system, peripheral sensorimotor nerves, and autonomic nervous system. The most frequent pattern of involvement is a distal symmetric polyneuropathy of the lower extremities that affects both motor and sensory function, particularly the latter (Chapter 21). Over time, the upper extremities may be involved as well, thus approximating a "glove and stocking" pattern of polyneuropathy. Other forms include autonomic neuropathy, which produces disturbances in bowel and bladder function and sometimes sexual impotence, and diabetic mononeuropathy, which may manifest as sudden footdrop, wristdrop, or isolated cranial nerve palsies.
- Diabetic patients are plagued by an enhanced susceptibility to infections of the skin, as well as to tuberculosis, pneumonia, and pyelonephritis. Such infections cause about 5% of diabetes-related deaths. In a person with diabetic neuropathy, a trivial infection in a toe may be the first event in a long succession of complications (gangrene, bacteremia, pneumonia) that may ultimately lead to death.

Several large-scale prospective studies have convincingly demonstrated that the long-term complications, and the associated morbidity and mortality, from diabetes are attenuated by strict glycemic control. For patients with type 1 diabetes, insulin replacement therapy is the mainstay of treatment, while non-pharmacologic approaches such as dietary restrictions and exercise (which improves insulin sensitivity) are often the "first line of defense" for type 2 diabetes. Most patients with type 2 diabetes will eventually require therapeutic intervention to reduce hyperglycemia, which can be achieved by administration of a number of agents that lower glucose levels through several distinct mechanisms of action. Glycemic control is assessed clinically by measuring the percentage of glycosylated hemoglobin, also known as HbA1C, which is formed by non-enzymatic addition of glucose moieties to hemoglobin in red cells. Unlike blood glucose levels, HbA1C is a measure of glycemic control over long periods of time (2 to 3 months) and is relatively unaffected by day-to-day variations. An HbA1C below 7% is taken as evidence of tight glycemic control, but patients with HbA1C levels in this range also have an increased risk of potentially life-threatening episodes of therapy-related hypoglycemia, and "optimal" control of glucose levels in diabetic patients remains an unsettled area of clinical investigation.

## SUMMARY

### Diabetes Mellitus: Pathogenesis and Long-Term Complications

- Type 1 diabetes is an autoimmune disease characterized by progressive destruction of islet beta cells, leading to absolute insulin deficiency. Both autoreactive T cells and autoantibodies are involved.
- Type 2 diabetes is caused by insulin resistance and beta cell dysfunction, resulting in relative insulin deficiency. Autoimmunity is not involved.
- Obesity has an important relationship with insulin resistance (and hence type 2 diabetes), probably mediated by cytokines released from adipose tissues (adipocytokines). Other players in the *adipo-insulin axis* include FFAs (which may cause *lipotoxicity*) and the PPARγ receptor, which modulates adipocytokine levels.
- Monogenic forms of diabetes are uncommon and are caused by single-gene defects that result in primary beta cell dysfunction (e.g., *glucokinase* mutation) or lead to

abnormalities of insulin–insulin receptor signaling (e.g., insulin receptor gene mutations).

- The long-term complications of diabetes are similar in both types and affect mainly blood vessels, and the kidneys, nerves and eyes. The development of these complications is attributed to three underlying mechanisms: formation of AGEs, activation of PKC, and disturbances in polyol pathways leading to oxidative stress.

## PANCREATIC NEUROENDOCRINE TUMORS

*Pancreatic neuroendocrine tumors (PanNETs),* also known as *islet cell tumors,* are rare in comparison with tumors of the exocrine pancreas, accounting for only 2% of all pancreatic neoplasms. PanNETs are most common in adults and may be single or multifocal; when they are malignant, the liver is the most common site of organ metastases. These tumors have a propensity to elaborate pancreatic hormones, but some are nonfunctional. The latter typically are larger lesions at diagnosis, since they come to clinical attention later in their natural history than functional PanNETs, which often present with symptoms related to excessive hormone production. All PanNETs, with the exception of insulinomas (see later), are regarded as having malignant potential, and in fact, 65% to 80% of PanNETs manifest with overtly malignant features of biologic aggressiveness, such as invasion into local tissues or distant metastases. The *proliferative rate of PanNETs* (measured using either mitotic counts or nuclear labeling with the proliferation marker Ki-67) is one of the best correlates of outcome. Genomic sequencing of sporadic PanNETs has identified recurrent somatic alterations in three major genes or pathways:

- *MEN1*, which causes familial MEN syndrome, type 1 (see later), is also mutated in many sporadic neuroendocrine tumors
- Loss-of-function mutations in tumor suppressor genes such as *PTEN* and *TSC2,* which are negative regulators of the oncogenic mammalian TOR (mTOR) signaling pathway
- Inactivating mutations in two genes, *ATRX* and *DAXX,* which have multiple cellular functions. Of note, nearly half of PanNETs have a somatic mutation in either *ATRX* or *DAXX,* but not both, suggesting that the encoded proteins function in a critical but redundant pathway.

### Insulinomas

Beta cell tumors (insulinomas) are the most common type of PanNET and may be responsible for the elaboration of sufficient insulin to induce clinically significant hypoglycemia. The characteristic clinical picture is dominated by attacks of hypoglycemia, which occur when plasma blood glucose levels fall below 50 mg/dL. The attacks consist principally of such central nervous system manifestations as confusion, stupor, and loss of consciousness. They are precipitated by fasting or exercise and are promptly relieved by feeding or parenteral administration of glucose. Most insulinomas are cured by surgical resection.

#### MORPHOLOGY

Insulinomas exhibit favorable biologic behavior, possibly because the vast majority are identified while they are small (less than 2 cm in diameter) and localized to the pancreas. Most are solitary lesions, although multifocal tumors or tumors ectopic to the pancreas may be encountered. Malignancy in insulinomas, constituting less than 10% of cases, is diagnosed on the basis of local invasion or metastases. On histologic examination, these benign tumors look remarkably like giant islets, with preservation of the regular cords of monotonous cells and their orientation to the vasculature. Not even malignant lesions present much evidence of anaplasia, and they may be deceptively encapsulated. **Deposition of amyloid** in the extracellular tissue is a characteristic feature of many insulinomas (Fig. 19–34, *A*). Under the electron microscope, neoplastic beta cells, like their normal counterparts, display distinctive round granules (Fig. 19–34, *B*).

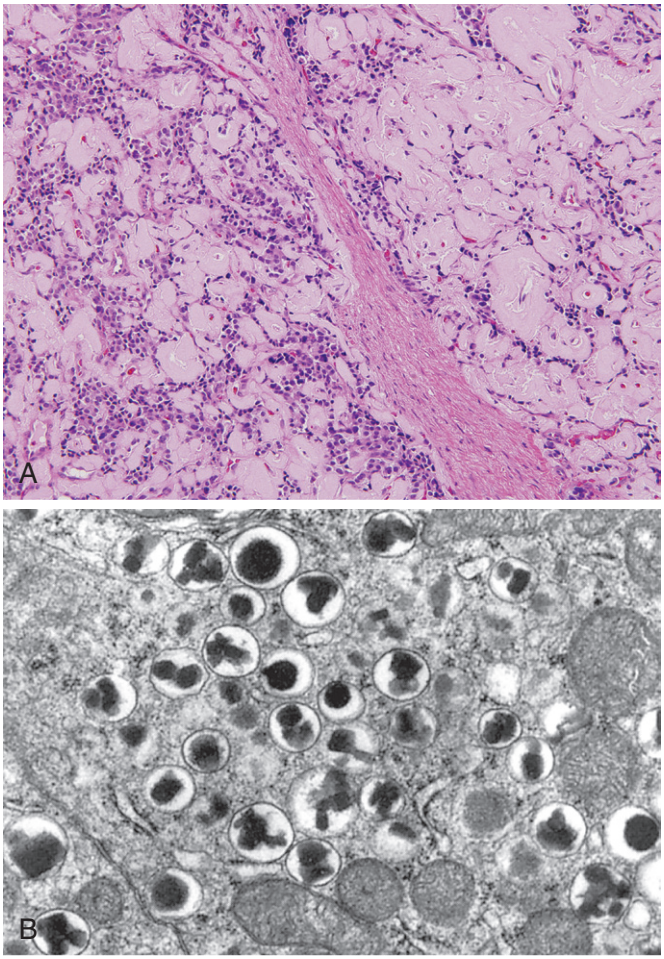

**Figure 19–34** Pancreatic neuroendocrine tumor (PanNET), also called islet cell tumor. **A,** The neoplastic cells are monotonous in appearance and demonstrate minimal pleomorphism or mitotic activity. There is abundant amyloid deposition, characteristic of an insulinoma. On clinical evaluation, the patient had episodic hypoglycemia. **B,** Electron micrograph of a normal beta cell shows the characteristic membrane-bound granules, each containing a dense, often rectangular core and distinct halo. Insulinomas contain comparable granules.

### Gastrinomas

Marked hypersecretion of gastrin usually has its origin in gastrin-producing tumors (*gastrinomas*), which are just as likely to arise in the duodenum and peripancreatic soft tissues as in the pancreas (the so-called gastrinoma triangle). Zollinger and Ellison first called attention to the *association of pancreatic islet cell lesions with hypersecretion of gastric acid and severe peptic ulceration,* which are present in 90% to 95% of patients with gastrinomas—the clinical hallmark of Zollinger-Ellison syndrome. In this condition, hypergastrinemia from a pancreatic or duodenal tumor stimulates extreme gastric acid secretion, which in turn causes *peptic ulceration.* The duodenal and gastric ulcers often are *multiple*; although they are identical to those found in the general population, they often are *unresponsive* to usual therapy. In addition, ulcers may occur in *unusual locations* such as the jejunum; when intractable jejunal ulcers are found, Zollinger-Ellison syndrome should be considered. More than half of the affected patients have diarrhea; in 30%, it is the presenting manifestation.

#### MORPHOLOGY

Gastrinomas may arise in the pancreas, the peripancreatic region, or the wall of the duodenum. **Over half of gastrin-producing tumors are locally invasive or have already metastasized at the time of diagnosis.** In approximately 25% of patients, gastrinomas arise in conjunction with other endocrine tumors, thus conforming to the MEN-1 syndrome (see further on); MEN-1–associated gastrinomas frequently are multifocal, while sporadic gastrinomas usually are single. As with insulin-secreting tumors of the pancreas, gastrin-producing tumors are histologically bland and rarely exhibit marked anaplasia.

## ADRENAL CORTEX

The *adrenal glands* are paired endocrine organs consisting of two regions, the cortex and medulla, which differ in their development, structure, and function. The *cortex* consists of three layers of distinct cell types. Beneath the capsule of the adrenal is the narrow layer of zona glomerulosa. An equally narrow zona reticularis abuts the medulla. Intervening is the broad zona fasciculata, which makes up about 75% of the total cortex. The adrenal cortex synthesizes three different types of steroids:

- *Glucocorticoids* (principally cortisol), which are synthesized primarily in the zona fasciculata, with a small contribution from the zona reticularis
- *Mineralocorticoids,* the most important being aldosterone, which are generated in the zona glomerulosa
- *Sex steroids* (estrogens and androgens), which are produced largely in the zona reticularis

The *adrenal medulla* is composed of chromaffin cells, which synthesize and secrete *catecholamines,* mainly epinephrine. This section deals first with disorders of the adrenal cortex and then of the medulla. Diseases of the adrenal cortex can be conveniently divided into those associated with cortical hyperfunction and those characterized by cortical hypofunction.

## ADRENOCORTICAL HYPERFUNCTION (HYPERADRENALISM)

There are three distinctive hyperadrenal clinical syndromes, each caused by abnormal production of one or more of the hormones produced by the three layers of the cortex: (1) *Cushing syndrome,* characterized by an excess of cortisol; (2) *hyperaldosteronism*; and (3) *adrenogenital* or *virilizing syndromes,* caused by an excess of androgens. The clinical features of some of these syndromes overlap somewhat because of the overlapping functions of some of the adrenal steroids.

### Hypercortisolism and Cushing Syndrome

Hypercortisolism, typically manifested as *Cushing syndrome,* is caused by any condition that produces an elevation in glucocorticoid levels. In clinical practice, the vast majority of cases of Cushing syndrome are the result of administration of exogenous glucocorticoids (iatrogenic). The remaining cases are endogenous, and the three most common etiologic disorders are (Fig. 19–35):

- Primary hypothalamic-pituitary diseases associated with hypersecretion of ACTH
- The secretion of ectopic ACTH by non-pituitary neoplasms
- Primary adrenocortical neoplasms (adenoma or carcinoma) and rarely, primary cortical hyperplasia

Primary hypothalamic-pituitary disease associated with hypersecretion of ACTH, also known as *Cushing disease,* accounts for approximately 70% of cases of spontaneous, endogenous Cushing syndrome. The prevalence of this disorder is about four times higher among women than among men, and it occurs most frequently during young adulthood (the 20s and 30s). In the vast majority of cases, the *pituitary gland contains an ACTH-producing microadenoma* that does not produce mass effects in the brain; some corticotroph tumors qualify as macroadenomas (larger than 10 mm across). In the remaining patients, the anterior pituitary contains areas of *corticotroph cell hyperplasia* without a discrete adenoma. Corticotroph cell hyperplasia may be primary or, much less commonly, secondary to excessive ACTH release by a hypothalamic corticotropin-releasing hormone (CRH)–producing tumor. The adrenal glands in patients with Cushing disease are characterized by a variable degree of bilateral nodular cortical hyperplasia (discussed later), secondary to the elevated levels of ACTH ("ACTH-dependent" Cushing syndrome). The cortical hyperplasia is in turn responsible for the hypercortisolism.

*Secretion of ectopic ACTH* by nonpituitary tumors accounts for about 10% of cases of Cushing syndrome. In

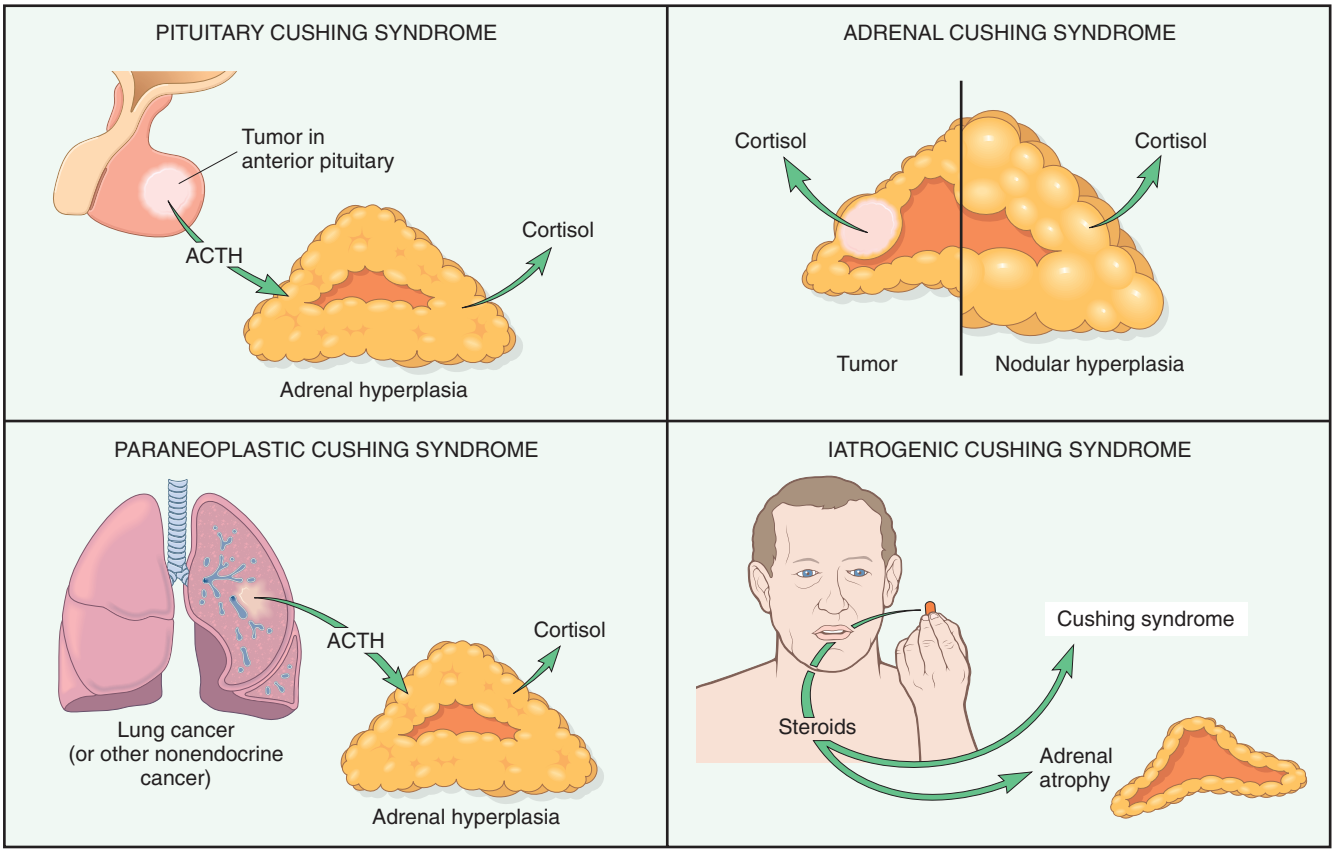

**Figure 19–35** Schematic representation of the various forms of Cushing syndrome: The three endogenous forms, as well as the more common exogenous (iatrogenic) form. ACTH, adrenocorticotropic hormone.

many instances the responsible tumor is a *small cell carcinoma of the lung*, although other neoplasms, including carcinoids, medullary carcinomas of the thyroid, and PanNETs, have been associated with the syndrome. In addition to tumors that elaborate ectopic ACTH, an occasional neuroendocrine neoplasm produces ectopic CRH, which in turn causes ACTH secretion and hypercortisolism. As in the pituitary variant, the adrenal glands undergo bilateral cortical hyperplasia secondary to elevated ACTH, but the rapid downhill course of patients with these cancers often cuts short the adrenal enlargement.

*Primary adrenal neoplasms,* such as adrenal adenoma and carcinoma, and rarely, *primary cortical hyperplasia,* are responsible for about 15% to 20% of cases of endogenous Cushing syndrome. This form of Cushing syndrome is also designated *ACTH-independent Cushing syndrome,* or adrenal Cushing syndrome, because the adrenals function autonomously. The biochemical hallmark of adrenal Cushing syndrome is elevated levels of cortisol with low serum levels of ACTH. In most cases, adrenal Cushing syndrome is caused by a unilateral adrenocortical neoplasm, which may be either benign (adenoma) or malignant (carcinoma). The overwhelming majority of hyperplastic adrenals are ACTH-dependent, and primary cortical hyperplasia of the adrenal cortices is a rare cause of Cushing syndrome. There are two variants of this entity; the first presents as macronodules of varying sizes (3 cm or greater in diameter) and the second as micronodules (1 to 3 mm).

## MORPHOLOGY

The main lesions of Cushing syndrome are found in the pituitary and adrenal glands. The **pituitary** in Cushing syndrome shows changes that vary with different causes. The most common alteration, resulting from high levels of endogenous or exogenous glucocorticoids, is termed **Crooke hyaline change.** In this condition, the normal granular, basophilic cytoplasm of the ACTH-producing cells in the anterior pituitary is replaced by homogeneous, lightly basophilic material. This alteration is the result of the accumulation of intermediate keratin filaments in the cytoplasm.

Morphologic changes in the adrenal glands also depend on the cause of the hypercortisolism and include: (1) cortical atrophy, (2) diffuse hyperplasia, (3) macronodular or micronodular hyperplasia, or (4) an adenoma or a carcinoma.

In patients in whom the syndrome results from exogenous glucocorticoids, suppression of endogenous ACTH results in bilateral **cortical atrophy,** due to a lack of stimulation of the zona fasciculata and zona reticularis by ACTH. The zona glomerulosa is of normal thickness in such cases, because this portion of the cortex functions independently of ACTH. In cases of endogenous hypercortisolism, by contrast, the adrenals either are hyperplastic or contain a cortical neoplasm. **Diffuse hyperplasia** is found in patients with ACTH-dependent Cushing syndrome (Fig. 19–36). Both glands are enlarged, either subtly or markedly, each weighing up to

**Figure 19–36** Diffuse hyperplasia of the adrenal (*bottom*) contrasted with normal adrenal gland (*top*). In cross-section, the adrenal cortex is yellow and thickened, and a subtle nodularity is evident. The abnormal gland was from a patient with ACTH-dependent Cushing syndrome, in whom both adrenals were diffusely hyperplastic. ACTH, adrenocorticotropic hormone.

30 g. The adrenal cortex is diffusely thickened and variably nodular, although the latter is not as pronounced as in cases of ACTH-independent nodular hyperplasia. The yellow color of diffusely hyperplastic glands derives from presence of **lipid-rich** cells, which appear vacuolated under the microscope. In primary cortical hyperplasia, the cortex is replaced almost entirely by **macro- or micronodules,** with the latter composed of 1- to 3-mm darkly pigmented nodules. The pigment is believed to be lipofuscin, a wear-and-tear pigment (Chapter 1).

**Functional adenomas or carcinomas** of the adrenal cortex as the source of cortisol are not morphologically distinct from nonfunctioning adrenal neoplasms (described later). Both the benign and the malignant lesions are more common in women in their 30s to 50s. Adrenocortical **adenomas** are yellow tumors surrounded by thin or well-developed capsules, and most weigh less than 30 g (Fig. 19–37, *A*). On microscopic examination, they are composed of cells similar to those encountered in the normal zona fasciculata (Fig. 19–37, *B*). The **carcinomas** associated with Cushing syndrome, by contrast, tend to be larger than the adenomas. These tumors are nonencapsulated masses frequently exceeding 200 to 300 g in weight, having all of the anaplastic characteristics of cancer, as detailed later on. With functioning tumors, both benign and malignant, the adjacent adrenal cortex and that of the contralateral adrenal gland are atrophic, as a result of suppression of endogenous ACTH by high cortisol levels.

### Clinical Features

The signs and symptoms of Cushing syndrome represent an exaggeration of the known actions of glucocorticoids. Cushing syndrome usually develops gradually and, like many other endocrine abnormalities, may be quite subtle in its early stages. A major exception to this insidious onset is with Cushing syndrome associated with small cell carcinomas of the lung, when the rapid course of the underlying disease precludes development of many of the characteristic features. Early manifestations of Cushing syndrome include *hypertension* and *weight gain.* With time, the more characteristic centripetal distribution of adipose tissue becomes apparent, with resultant truncal obesity, "moon facies," and accumulation of fat in the posterior neck and

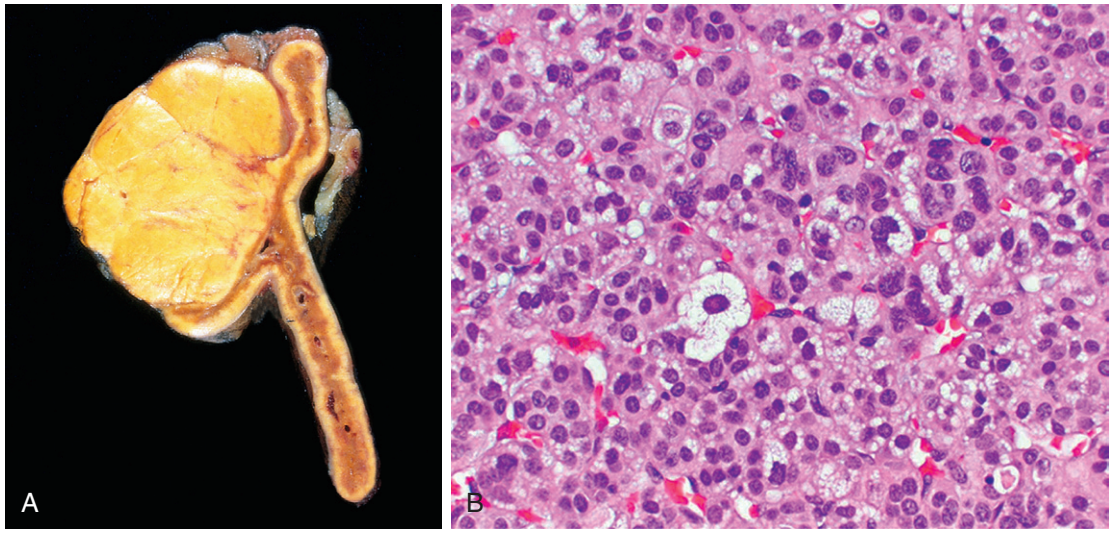

**Figure 19–37** Adrenocortical adenoma. **A,** The adenoma is distinguished from nodular hyperplasia by its solitary, circumscribed nature. The functional status of an adrenocortical adenoma cannot be predicted from its gross or microscopic appearance. **B,** Histologic features of an adrenal cortical adenoma. The neoplastic cells are vacuolated because of the presence of intracytoplasmic lipid. There is mild nuclear pleomorphism. Mitotic activity and necrosis are not seen.

**Figure 19–38** A patient with Cushing syndrome. Characteristic features include central obesity, "moon facies," and abdominal striae.

back ("buffalo hump") (Fig. 19–38). Hypercortisolism causes selective atrophy of fast-twitch (type II) myofibers, with resultant decreased muscle mass and proximal limb weakness. Glucocorticoids induce gluconeogenesis and inhibit the uptake of glucose by cells, with resultant *hyperglycemia, glucosuria,* and *polydipsia,* mimicking diabetes mellitus. The catabolic effects on proteins cause loss of collagen and resorption of bone. Thus, the skin is thin, fragile, and easily bruised; *cutaneous striae* are particularly common in the abdominal area. Bone resorption results in the development of *osteoporosis,* with consequent increased susceptibility to fractures. Because glucocorticoids suppress the immune response, patients with Cushing syndrome also are at increased risk for a variety of infections. Additional manifestations include *hirsutism* and *menstrual abnormalities,* as well as a number of *mental disturbances,* including mood swings, depression, and frank psychosis. Extraadrenal Cushing syndrome caused by pituitary or ectopic ACTH secretion usually is associated with increased skin pigmentation secondary to melanocyte-stimulating activity in the ACTH precursor molecule.

## SUMMARY

### Hypercortisolism (Cushing Syndrome)

- The most common cause of hypercortisolism is exogenous administration of steroids.
- Endogenous hypercortisolism most often is secondary to an ACTH-producing pituitary microadenoma (*Cushing disease*), followed by primary adrenal neoplasms (*ACTH-independent* hypercortisolism) and paraneoplastic ACTH production by tumors (e.g., small cell lung cancer).
- The morphologic features in the adrenal include bilateral cortical atrophy (in exogenous steroid-induced disease), bilateral diffuse or nodular hyperplasia (most common finding in endogenous Cushing syndrome), or an adrenocortical neoplasm.

## Hyperaldosteronism

*Hyperaldosteronism* is the generic term for a group of closely related conditions characterized by chronic excess aldosterone secretion. Hyperaldosteronism may be primary, or it may be secondary to an extraadrenal cause. In *secondary hyperaldosteronism,* aldosterone release occurs in response to activation of the renin-angiotensin system. This condition is characterized by *increased levels of plasma renin* and is encountered in association with

- Decreased renal perfusion (arteriolar nephrosclerosis, renal artery stenosis)
- Arterial hypovolemia and edema (congestive heart failure, cirrhosis, nephrotic syndrome)
- Pregnancy (caused by estrogen-induced increases in plasma renin substrate)

*Primary hyperaldosteronism,* by contrast, indicates a primary, autonomous overproduction of aldosterone, with resultant suppression of the renin-angiotensin system and *decreased plasma renin activity.* The potential causes of primary hyperaldosteronism are:

- *Bilateral idiopathic hyperaldosteronism,* characterized by bilateral nodular hyperplasia of the adrenal glands. This mechanism is the most common underlying cause of primary hyperaldosteronism, accounting for about 60% of cases. The pathogenesis is unclear.
- *Adrenocortical neoplasm,* either an aldosterone-producing adenoma (the most common cause) or, rarely, an adrenocortical carcinoma. In approximately 35% of cases, primary hyperaldosteronism is caused by a solitary aldosterone-secreting adenoma, a condition referred to as *Conn syndrome.*
- Rarely, familial hyperaldosteronism may result from a genetic defect that leads to overactivity of the *aldosterone synthase* gene, *CYP11B2.*

## MORPHOLOGY

**Aldosterone-producing adenomas** are almost always solitary, small (less than 2 cm in diameter), well-circumscribed lesions. They are bright yellow on cut section and, surprisingly, are composed of lipid-laden cortical cells more closely resembling fasciculata cells than glomerulosa cells (the normal source of aldosterone). In general, the cells tend to be uniform in size and shape; occasionally there is some nuclear and cellular pleomorphism. A characteristic feature of aldosterone-producing adenomas is the presence of eosinophilic, laminated cytoplasmic inclusions, known as **spironolactone bodies.** These typically are found after treatment with the antihypertensive agent spironolactone, which is the

drug of choice in primary hyperaldosteronism. In contrast with cortical adenomas associated with Cushing syndrome, those associated with hyperaldosteronism do not usually suppress ACTH secretion. Therefore, the adjacent adrenal cortex and that of the contralateral gland are not atrophic. **Bilateral idiopathic hyperplasia** is marked by diffuse or focal hyperplasia of cells resembling those of the normal zona glomerulosa.

Clinical Features

*The clinical hallmark of hyperaldosteronism is hypertension*. With an estimated prevalence rate of 5% to 10% among unselected hypertensive patients, primary hyperaldosteronism may be the most common cause of secondary hypertension (i.e., hypertension secondary to an identifiable cause). The long-term effects of hyperaldosteronism-induced hypertension are cardiovascular compromise (e.g., left ventricular hypertrophy and reduced diastolic volumes) and an increase in the prevalence of adverse events such as stroke and myocardial infarction. *Hypokalemia* results from renal potassium wasting and, when present, can cause a variety of neuromuscular manifestations, including weakness, paresthesias, visual disturbances, and occasionally frank tetany. In primary hyperaldosteronism, the therapy varies according to cause. Adenomas are amenable to surgical excision. By contrast, surgical intervention is not very beneficial in patients with primary hyperaldosteronism due to bilateral hyperplasia, which often occurs in children and young adults. These patients are best managed medically with an *aldosterone antagonist* such as spironolactone. The treatment of secondary hyperaldosteronism rests on correcting the underlying cause of the renin-angiotensin system hyperstimulation.

## Adrenogenital Syndromes

Excess of androgens may be caused by a number of diseases, including primary gonadal disorders and several primary adrenal disorders. The adrenal cortex secretes two compounds—dehydroepiandrosterone and androstenedione—which require conversion to testosterone in peripheral tissues for their androgenic effects. Unlike gonadal androgens, adrenal androgen formation is regulated by ACTH; thus, excessive secretion can present as an isolated syndrome or in combination with features of Cushing disease. The adrenal causes of androgen excess include *adrenocortical neoplasms* and an uncommon group of disorders collectively designated *congenital adrenal hyperplasia* (CAH). Adrenocortical neoplasms associated with symptoms of androgen excess (*virilization*) are more likely to be carcinomas than adenomas. They are morphologically identical to other functional or nonfunctional cortical neoplasms.

CAH represents a group of autosomal recessive disorders, each characterized by a hereditary defect in an enzyme involved in adrenal steroid biosynthesis, particularly cortisol. In these conditions, decreased cortisol production results in a compensatory increase in ACTH secretion due to absence of feedback inhibition. The resultant adrenal hyperplasia causes increased production of cortisol precursor steroids, which are then channeled into synthesis of androgens with virilizing activity. Certain enzyme defects also may impair aldosterone secretion, adding salt loss to the virilizing syndrome. *The most common enzymatic defect in CAH is 21-hydroxylase deficiency,* which accounts for more than 90% of cases. 21-Hydroxylase deficiency may range in degree from a total lack to a mild loss, depending on the nature of the underlying mutation involving the *CYP21A2* gene, which encodes this enzyme.

### MORPHOLOGY

In all cases of CAH, the adrenals are **hyperplastic bilaterally,** sometimes expanding to 10 to 15 times their normal weights. The adrenal cortex is thickened and nodular, and on cut section, the widened cortex appears brown as a result of depletion of all lipid. The proliferating cells mostly are compact, eosinophilic, lipid-depleted cells, intermixed with lipid-laden clear cells. In addition to cortical abnormalities, **adrenomedullary dysplasia** also has recently been reported in patients with the salt-losing 21-hydroxylase deficiency. This is characterized by incomplete migration of the chromaffin cells to the center of the gland, with pronounced intermingling of nests of chromaffin and cortical cells in the periphery. Hyperplasia of corticotroph (ACTH-producing) cells is present in the anterior pituitary in most patients.

Clinical Features

The clinical manifestations of CAH are determined by the specific enzyme deficiency and include abnormalities related to androgen metabolism, sodium homeostasis, and (in severe cases) glucocorticoid deficiency. Depending on the nature and severity of the enzymatic defect, the onset of clinical symptoms may occur in the perinatal period, later childhood, or (less commonly) adulthood.

In 21-hydroxylase deficiency, *excessive androgenic activity* causes signs of masculinization in females, ranging from clitoral hypertrophy and pseudohermaphroditism in infants to oligomenorrhea, hirsutism, and acne in postpubertal girls. In males, androgen excess is associated with enlargement of the external genitalia and other evidence of precocious puberty in prepubertal patients and with oligospermia in older patients. In some forms of CAH (e.g., 11β-hydroxylase deficiency), the accumulated intermediary steroids have mineralocorticoid activity, with resultant *sodium retention* and *hypertension*. In other cases, however, including about one third of persons with 21-hydroxylase deficiency, the enzymatic defect is severe enough to produce mineralocorticoid deficiency, with resultant *salt (sodium) wasting*. Cortisol deficiency places persons with CAH at risk for *acute adrenal insufficiency* (discussed later).

CAH should be suspected in any neonate with ambiguous genitalia; severe enzyme deficiency in infancy can be a life-threatening condition, with vomiting, dehydration, and salt wasting. In the milder variants, women may present with delayed menarche, oligomenorrhea, or hirsutism. In all such cases, an androgen-producing ovarian neoplasm must be excluded. Treatment of CAH is with exogenous glucocorticoids, which, in addition to providing adequate levels of glucocorticoids, also suppress ACTH levels, thereby decreasing the excessive synthesis of the

steroid hormones responsible for many of the clinical abnormalities.

## SUMMARY

### Adrenogenital Syndromes

- The adrenal cortex can secrete excess androgens in either of two settings: adrenocortical neoplasms (usually *virilizing* carcinomas) or congenital adrenal hyperplasia (CAH).
- CAH consists of a group of autosomal recessive disorders characterized by defects in steroid biosynthesis, usually cortisol; the most common subtype is caused by deficiency of the enzyme 21-hydroxylase.
- Reduction in cortisol production causes a compensatory increase in ACTH secretion, which in turn stimulates androgen production. Androgens have virilizing effects, including masculinization in females (ambiguous genitalia, oligomenorrhea, hirsutism), precocious puberty in males, and in some instances, salt (sodium) wasting and hypotension.
- Bilateral hyperplasia of the adrenal cortex is characteristic.

# ADRENAL INSUFFICIENCY

Adrenocortical insufficiency, or hypofunction, may be caused by either primary adrenal disease (primary hypoadrenalism) or decreased stimulation of the adrenals resulting from a deficiency of ACTH (secondary hypoadrenalism). The patterns of adrenocortical insufficiency can be divided into three general categories: (1) primary *acute* adrenocortical insufficiency (adrenal crisis); (2) primary *chronic* adrenocortical insufficiency (*Addison disease*); and (3) secondary adrenocortical insufficiency.

## Acute Adrenocortical Insufficiency

Acute adrenocortical insufficiency occurs most commonly in the clinical settings listed in Table 19–7. Persons with chronic adrenocortical insufficiency may develop an acute crisis after any stress that taxes their limited physiologic reserves. In patients maintained on exogenous corticosteroids, rapid withdrawal of steroids or failure to increase steroid doses in response to an acute stress may precipitate a similar adrenal crisis, because of the inability of the atrophic adrenals to produce glucocorticoid hormones. *Massive adrenal hemorrhage* may destroy enough of the adrenal cortex to cause acute adrenocortical insufficiency. This condition may occur in patients maintained on anticoagulant therapy, in postoperative patients who develop disseminated intravascular coagulation, during pregnancy, and in patients suffering from overwhelming sepsis; in this last setting it is known as the Waterhouse-Friderichsen syndrome (Fig. 19–39). This catastrophic syndrome is classically associated with *Neisseria meningitidis* septicemia but can also be caused by other organisms, including *Pseudomonas* spp., pneumococci, and *Haemophilus influenzae*. The pathogenesis of the Waterhouse-Friderichsen syndrome remains unclear but probably involves endotoxin-induced vascular injury with associated disseminated intravascular coagulation (Chapter 3).

APS1, APS2, autoimmune polyendocrine syndrome types 1 and 2.

## Chronic Adrenocortical Insufficiency: Addison Disease

Addison disease, or chronic adrenocortical insufficiency, is an uncommon disorder resulting from progressive destruction of the adrenal cortex. More than 90% of all cases are attributable to one of four disorders: *autoimmune adrenalitis, tuberculosis,* the *acquired immune deficiency syndrome* (AIDS), or *metastatic cancer* (Table 19–7).

- *Autoimmune adrenalitis* accounts for 60% to 70% of cases and is by far the most common cause of primary adrenal insufficiency in developed countries. As the name implies, there is autoimmune destruction of steroid-producing cells, and autoantibodies to several key

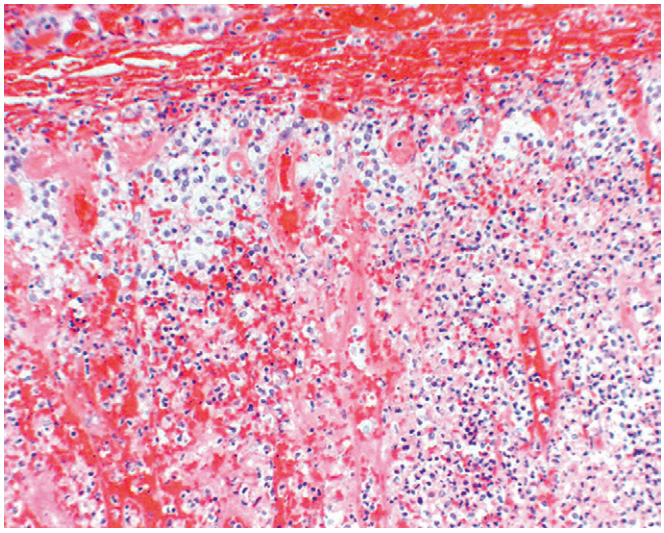

**Figure 19–39** Waterhouse-Friderichsen syndrome. Bilateral adrenal hemorrhage in an infant with overwhelming sepsis, resulting in acute adrenal insufficiency. At autopsy, the adrenals were grossly hemorrhagic and shrunken; in this photomicrograph, little residual cortical architecture is discernible.

steroidogenic enzymes have been detected in affected patients. Autoimmune adrenalitis occurs in one of two *a*utoimmune *p*olyendocrine *s*yndromes: APS1, which is caused by mutations in the *autoimmune regulator (AIRE)* gene on chromosome 21 and is characterized by chronic mucocutaneous candidiasis and abnormalities of skin, dental enamel, and nails (ectodermal dystrophy) occurring in association with a combination of organ-specific autoimmune disorders (autoimmune adrenalitis, autoimmune hypoparathyroidism, idiopathic hypogonadism, pernicious anemia) that result in destruction of target organs. The AIRE protein is involved in the expression of tissue antigens in the thymus and the elimination of T cells specific for these antigens (Chapter 4). The second setting is that of APS2, which manifests in early adulthood and manifests as a combination of adrenal insufficiency and autoimmune thyroiditis or type 1 diabetes. Unlike in APS1, in APS2 mucocutaneous candidiasis, ectodermal dysplasia, and autoimmune hypoparathyroidism do not occur.

- *Infections,* particularly tuberculosis and those produced by fungi, also may cause primary chronic adrenocortical insufficiency. Tuberculous adrenalitis, which once accounted for as many as 90% of cases of Addison disease, has become less common with the advent of antituberculosis therapy. With the resurgence of tuberculosis in many urban centers, however, this cause of adrenal deficiency must be borne in mind. When present, tuberculous adrenalitis usually is associated with active infection in other sites, particularly the lungs and genitourinary tract. Among fungi, disseminated infections caused by *Histoplasma capsulatum* and *Coccidioides immitis* also may result in chronic adrenocortical insufficiency. Patients with AIDS are at risk for the development of adrenal insufficiency from several infectious (cytomegalovirus, *Mycobacterium avium-intracellulare*) and noninfectious (Kaposi sarcoma) complications of their disease.
- *Metastatic neoplasms* involving the adrenals are another potential cause of adrenal insufficiency. The adrenals are a fairly common site for metastases in patients with disseminated carcinomas. Although adrenal function is preserved in most such instances, the metastatic growths sometimes destroy sufficient adrenal cortex to produce a degree of adrenal insufficiency. Carcinomas of the lung and breast are the source of a majority of metastases in the adrenals, although many other neoplasms, including gastrointestinal carcinomas, malignant melanomas, and hematopoietic neoplasms, also may metastasize to the organ.

## Secondary Adrenocortical Insufficiency

Any disorder of the hypothalamus and pituitary, such as metastatic cancer, infection, infarction, or irradiation, that reduces the output of ACTH leads to a syndrome of hypoadrenalism having many similarities to Addison disease. *With secondary disease, the hyperpigmentation of primary Addison disease is lacking because melanotropic hormone levels are low* (discussed later). ACTH deficiency may occur alone, but in some instances, it is only one part of panhypopituitarism, associated with multiple tropic hormone deficiencies. In patients with primary disease, serum ACTH levels may be normal, but the destruction of the adrenal cortex does not permit a response to exogenously administered ACTH in the form of increased plasma levels of cortisol. By contrast, secondary adrenocortical insufficiency is characterized by low serum ACTH and a prompt rise in plasma cortisol levels in response to ACTH administration.

### MORPHOLOGY

The appearance of the adrenal glands varies with the cause of the adrenocortical insufficiency. In **secondary hypoadrenalism** the adrenals are reduced to small, flattened structures that usually retain their yellow color because of a small amount of residual lipid. A uniform, thin rim of atrophic yellow cortex surrounds a central, intact medulla. Histologic evaluation reveals atrophy of cortical cells with loss of cytoplasmic lipid, particularly in the zona fasciculata and zona reticularis. **Primary autoimmune adrenalitis** is characterized by irregularly shrunken glands, which may be exceedingly difficult to identify within the suprarenal adipose tissue. On histologic examination, the cortex contains only scattered residual cortical cells in a collapsed network of connective tissue. A variable lymphoid infiltrate is present in the cortex and may extend into the subjacent medulla (Fig. 19–40). The medulla is otherwise preserved. In **tuberculosis or fungal diseases,** the adrenal architecture may be effaced by a granulomatous inflammatory reaction identical to that encountered in other sites of infection. When hypoadrenalism is caused by **metastatic carcinoma,** the adrenals are enlarged, and their normal architecture is obscured by the infiltrating neoplasm.

### Clinical Features

In general, clinical manifestations of adrenocortical insufficiency do not appear until at least 90% of the adrenal cortex has been compromised. The initial manifestations often include progressive weakness and easy fatigability, which may be dismissed as nonspecific complaints. *Gastrointestinal disturbances* are common and include anorexia, nausea, vomiting, weight loss, and diarrhea. In patients with primary adrenal disease, increased levels of ACTH precursor hormone stimulate melanocytes, with resultant *hyperpigmentation* of the skin and mucosal surfaces. The

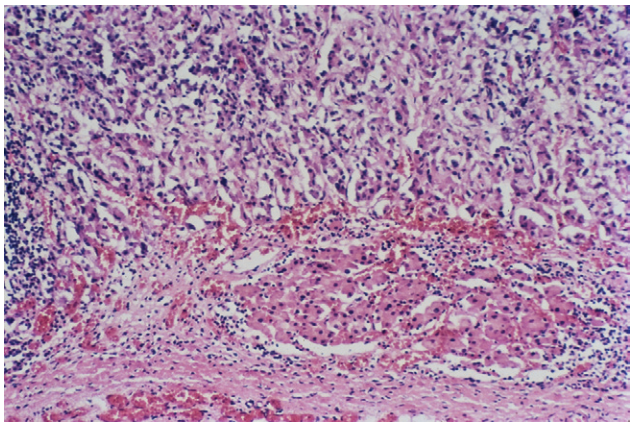

**Figure 19–40** Autoimmune adrenalitis. In addition to loss of all but a subcapsular rim of cortical cells, there is an extensive mononuclear cell infiltrate.

face, axillae, nipples, areolae, and perineum are particularly common sites of hyperpigmentation. By contrast, hyperpigmentation is not seen in patients with secondary adrenocortical insufficiency. Decreased mineralocorticoid (aldosterone) activity in patients with primary adrenal insufficiency results in potassium retention and sodium loss, with consequent *hyperkalemia, hyponatremia, volume depletion,* and *hypotension*, whereas secondary hypoadrenalism is characterized by deficient cortisol and androgen output but normal or near-normal aldosterone synthesis. Hypoglycemia occasionally may occur as a result of glucocorticoid deficiency and impaired gluconeogenesis. Stresses such as infections, trauma, or surgical procedures in affected patients may precipitate an acute adrenal crisis, manifested by intractable vomiting, abdominal pain, hypotension, coma, and vascular collapse. Death follows rapidly unless corticosteroids are replaced immediately.

### SUMMARY

#### Adrenocortical Insufficiency (Hypoadrenalism)

- Primary adrenocortical insufficiency can be acute (Waterhouse-Friderichsen syndrome) or chronic (Addison disease).
- Chronic adrenal insufficiency in the Western world most often is secondary to autoimmune adrenalitis, which occurs in the context of one of two autoimmune polyendocrine syndromes: APS1 (caused by mutations in the *AIRE* gene) or APS2.
- Tuberculosis and infections due to opportunistic pathogens associated with the human immunodeficiency virus and tumors metastatic to the adrenals are the other important causes of chronic hypoadrenalism.
- Patients typically present with fatigue, weakness, and gastrointestinal disturbances. Primary adrenocortical insufficiency also is characterized by high ACTH levels with associated skin pigmentation.

## ADRENOCORTICAL NEOPLASMS

It should be evident from the discussion of adrenocortical hyperfunction that functional adrenal neoplasms may be responsible for any of the various forms of hyperadrenalism. While functional adenomas are most commonly associated with hyperaldosteronism and with Cushing syndrome, a virilizing neoplasm is more likely to be a carcinoma. Not all adrenocortical neoplasms, however, elaborate steroid hormones. Determination of whether a cortical neoplasm is functional or not is based on clinical evaluation and measurement of the hormone or its metabolites in the laboratory.

### MORPHOLOGY

**Adrenocortical adenomas** were described earlier in the discussions of Cushing syndrome and hyperaldosteronism. Most cortical adenomas do not cause hyperfunction and usually are encountered as incidental findings at the time of autopsy or during abdominal imaging for an unrelated cause. In fact, the half-facetious appellation of **"adrenal incidentaloma"** has crept into the medical lexicon to describe these incidentally discovered tumors. On cut surface, adenomas usually are yellow to yellow-brown, owing to the presence of lipid within the neoplastic cells (Fig. 19–37). As a general rule they are small, averaging 1 to 2 cm in diameter. On microscopic examination, adenomas are composed of cells similar to those populating the normal adrenal cortex. The nuclei tend to be small, although some degree of pleomorphism may be encountered even in benign lesions **(endocrine atypia).** The cytoplasm of the neoplastic cells ranges from eosinophilic to vacuolated, depending on their lipid content; mitotic activity generally is inconspicuous.

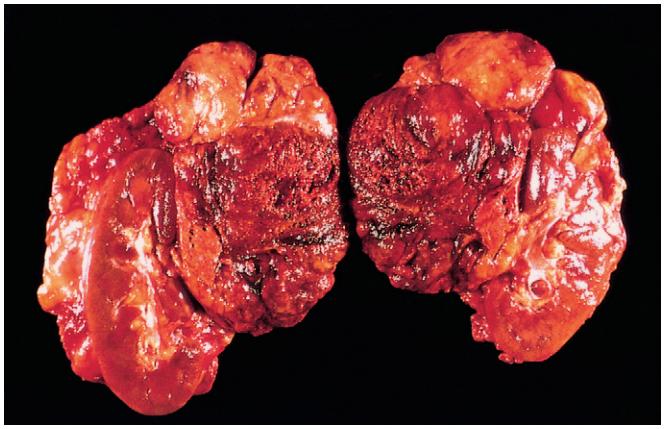

**Figure 19–41** Adrenal carcinoma. The tumor dwarfs the kidney and compresses the upper pole. It is largely hemorrhagic and necrotic.

**Adrenocortical carcinomas** are rare neoplasms that may occur at any age, including in childhood. Two rare inherited causes of adrenal cortical carcinomas are Li-Fraumeni syndrome (Chapter 5) and Beckwith-Wiedemann syndrome (Chapter 6). In most cases, adrenocortical carcinomas are large, invasive lesions that efface the native adrenal gland. On cut surface, adrenocortical carcinomas typically are variegated, poorly demarcated lesions containing areas of necrosis, hemorrhage, and cystic change (Fig. 19–41). Microscopic examination typically shows these tumors to be composed of well-differentiated cells resembling those seen in cortical adenomas or bizarre, pleomorphic cells, which may be difficult to distinguish from those of an undifferentiated carcinoma metastatic to the adrenal (Fig. 19–42). Adrenal

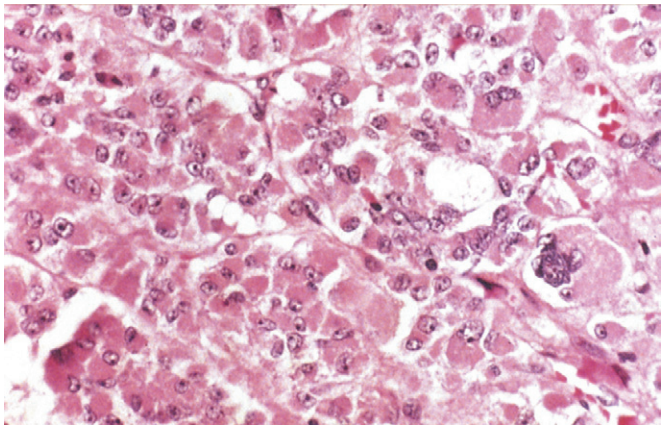

**Figure 19–42** Adrenal carcinoma with marked anaplasia.

cancers have a strong tendency to invade the adrenal vein, vena cava, and lymphatics. Metastases to regional and periaortic nodes are common, as is distant hematogenous spread to the lungs and other viscera. Bone metastases are unusual. The median patient survival is about 2 years. Of note, carcinomas metastatic to the adrenal cortex are significantly more frequent than a primary adrenocortical carcinoma.

# ADRENAL MEDULLA

The adrenal medulla is embryologically, functionally, and structurally distinct from the adrenal cortex. It is populated by cells derived from the neural crest (*chromaffin cells*) and their supporting (sustentacular) cells. The chromaffin cells, so named because of their brown-black color after exposure to potassium dichromate, synthesize and secrete catecholamines in response to signals from preganglionic nerve fibers in the sympathetic nervous system. Similar collections of cells are distributed throughout the body in the extraadrenal paraganglion system. The most important diseases of the adrenal medulla are neoplasms, which include both neuronal neoplasms (including neuroblastomas and more mature ganglion cell tumors) and neoplasms composed of chromaffin cells (pheochromocytomas).

## TUMORS OF THE ADRENAL MEDULLA

### Pheochromocytoma

Pheochromocytomas are neoplasms composed of chromaffin cells, which, like their non-neoplastic counterparts, synthesize and release catecholamines and, in some cases, other peptide hormones. These tumors are of special importance because although uncommon, they (like aldosterone-secreting adenomas) give rise to a surgically correctable form of hypertension.

Pheochromocytomas usually subscribe to a convenient "rule of 10s":

- *10% of pheochromocytomas are extraadrenal,* occurring in sites such as the organ of Zuckerkandl and the carotid body, where they usually are called *paragangliomas,* rather than pheochromocytomas.
- *10% of adrenal pheochromocytomas are bilateral*; this proportion may rise to 50% in cases that are associated with familial syndromes.
- *10% of adrenal pheochromocytomas are malignant,* although the associated hypertension represents a serious and potentially lethal complication of even *benign* tumors. Frank malignancy is somewhat more common in tumors arising in extraadrenal sites.
- One "traditional" 10% rule that has since been modified pertains to familial cases. It is now recognized that *as many as 25% of persons with pheochromocytomas and paragangliomas harbor a germ line mutation* in one of at least six known genes, including *RET*, which causes type 2 MEN syndromes (described later); *NF1*, which causes type 1 neurofibromatosis (Chapter 21); *VHL*, which causes von Hippel-Lindau disease (Chapters 13 and 22); and three genes encoding subunits within the succinate dehydrogenase complex (*SDHB, SDHC,* and *SDHD*), which is involved in mitochondrial oxidative phosphorylation.

#### MORPHOLOGY

Pheochromocytomas range in size from small, circumscribed lesions confined to the adrenal to large, hemorrhagic masses weighing several kilograms. On cut surface, smaller pheochromocytomas are yellow-tan, well-defined lesions that compress the adjacent adrenal (Fig. 19–43). Larger lesions tend to be hemorrhagic, necrotic, and cystic and typically efface the adrenal gland. Incubation of the fresh tissue with potassium dichromate solutions turns the tumor dark brown, as noted previously.

On microscopic examination, pheochromocytomas are composed of polygonal to spindle-shaped chromaffin cells and their supporting cells, compartmentalized into small nests, or **Zellballen,** by a rich vascular network (Fig. 19–44). The cytoplasm of the neoplastic cells often has a finely granular appearance, highlighted by a variety of silver stains, because of the presence of granules containing catecholamines. Electron microscopy reveals variable numbers of membrane-bound, electron-dense granules, representing catecholamines and sometimes other peptides. The nuclei of the neoplastic cells are often quite pleomorphic. Both

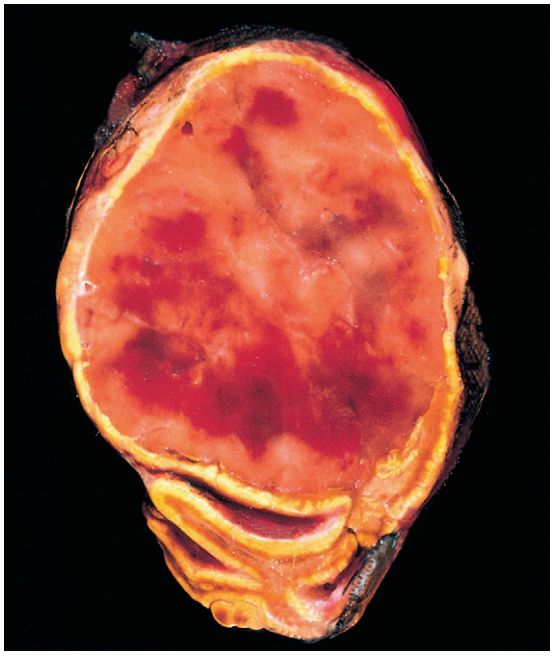

**Figure 19–43** Pheochromocytoma. The tumor is enclosed within an attenuated cortex and demonstrates areas of hemorrhage. The comma-shaped residual adrenal is seen *below*.

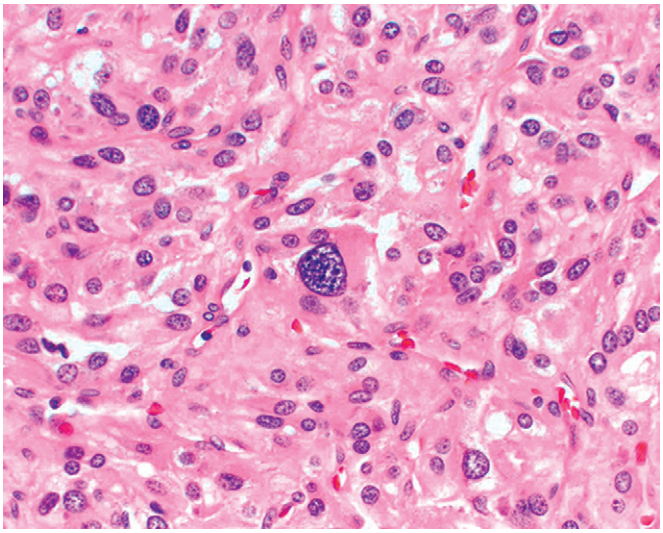

**Figure 19–44** Photomicrograph of pheochromocytoma, demonstrating characteristic nests of cells (*Zellballen*) with abundant cytoplasm. Granules containing catecholamine are not visible in this preparation. It is not uncommon to find bizarre cells even in pheochromocytomas that are biologically benign, and this criterion by itself should not be used to diagnose malignancy.

capsular and vascular invasion may be encountered in benign lesions, and the mere presence of mitotic figures does not imply malignancy. **Therefore, the definitive diagnosis of malignancy in pheochromocytomas is based exclusively on the presence of metastases.** These may involve regional lymph nodes as well as more distant sites, including liver, lung, and bone.

### Clinical Features

The predominant clinical manifestation of pheochromocytoma is *hypertension.* The characteristic presentation with a hypertensive episode is one of abrupt, precipitous elevation in blood pressure, associated with tachycardia, palpitations, headache, sweating, tremor, and a sense of apprehension. Such episodes also may be associated with pain in the abdomen or chest, nausea, and vomiting. In clinical practice, *isolated, paroxysmal episodes of hypertension occur in fewer than half of patients* with pheochromocytoma. In about two thirds of patients the hypertension occurs in the form of a chronic, sustained elevation in blood pressure, although an element of labile hypertension often is present as well. Whether sustained or episodic, the hypertension is associated with an increased risk of myocardial ischemia, heart failure, renal injury, and stroke (cerebrovascular accident). Sudden cardiac death may occur, probably secondary to catecholamine-induced myocardial irritability and ventricular arrhythmias. In some cases, pheochromocytomas secrete other hormones such as ACTH and somatostatin and may therefore be associated with clinical features related to the effects of these and other peptide hormones. The laboratory diagnosis of pheochromocytoma is based on demonstration of increased urinary excretion of free catecholamines and their metabolites, such as vanillylmandelic acid and metanephrines. Isolated benign pheochromocytomas are treated with surgical excision. With multifocal lesions, long-term medical treatment for hypertension may be required.

## Neuroblastoma and Other Neuronal Neoplasms

Neuroblastoma is the most common extracranial solid tumor of childhood. These neoplasms occur most commonly during the first 5 years of life and may arise during infancy. Neuroblastomas may occur anywhere in the sympathetic nervous system and occasionally within the brain, but they are most common in the abdomen; a majority of these tumors arise in either the adrenal medulla or the retroperitoneal sympathetic ganglia. Most neuroblastomas are sporadic, although familial cases also have been described. These tumors are discussed in Chapter 6, along with other pediatric neoplasms.

# MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

The MEN syndromes are a group of inherited diseases resulting in proliferative lesions (hyperplasias, adenomas, and carcinomas) of multiple endocrine organs. Like other inherited cancer disorders (Chapter 5), endocrine tumors arising in the context of MEN syndromes have certain distinctive features that are not shared with their sporadic counterparts:

- These tumors occur at a *younger age* than that typical for sporadic cancers.
- They arise in *multiple endocrine organs,* either *synchronously* or *metachronously.*
- Even in one organ, the tumors often are *multifocal.*
- The tumors usually are preceded by an *asymptomatic stage of endocrine hyperplasia* involving the cell of origin of the tumor (for example, patients with MEN-2 almost universally demonstrate C cell hyperplasia in the thyroid parenchyma adjacent to medullary thyroid carcinomas).
- These tumors are usually *more aggressive* and *recur* in a higher proportion of cases than similar endocrine tumors that occur sporadically.

Unraveling the genetic basis of the MEN syndromes with clinical application of this knowledge in therapeutic decision making has been one of the success stories of translational research. The salient features of the MEN syndromes are discussed next.

## Multiple Endocrine Neoplasia Type 1

MEN type 1 is inherited in an autosomal dominant pattern. The gene (*MEN1*) is located at 11q13 and is a tumor suppressor gene; thus, inactivation of both alleles of the gene is believed to be the basis for tumorigenesis. Organs most commonly involved are the parathyroid, the pancreas, and the pituitary—the "3 Ps."

- *Parathyroid*: *Primary hyperparathyroidism* is the most common manifestation of MEN-1 (80% to 95% of patients) and is the initial manifestation of the disorder in most patients, appearing in almost all patients by age 40 to 50. Parathyroid abnormalities include both hyperplasia and adenomas.
- *Pancreas*: Endocrine tumors of the pancreas are the leading cause of death in MEN-1. These tumors usually are aggressive and manifest with metastatic disease. It is not uncommon to find multiple "microadenomas" scattered throughout the pancreas in conjunction with one or two dominant lesions. Pancreatic endocrine tumors often are functional (i.e., secrete hormones). Zollinger-Ellison syndrome, associated with gastrinomas, and hypoglycemia, related to insulinomas, are common endocrine manifestations. Of note, the gastrinomas arising in MEN-1 syndrome are far more likely to be located within the duodenum than in the pancreas.
- *Pituitary*: The most frequent pituitary tumor in patients with MEN-1 is a prolactin-secreting macroadenoma. In some cases, acromegaly develops in association with somatotropin-secreting tumors.

## Multiple Endocrine Neoplasia Type 2

MEN type 2 actually comprises two distinct groups of disorders that are unified by the occurrence of activating (i.e., gain-of-function) mutations of the *RET* proto-oncogene at chromosomal locus 10q11.2. A strong *genotype-phenotype correlation* has been recognized for the MEN-2 syndromes, and differences in mutation patterns account for the variable features in the two subtypes. MEN-2 is inherited in an autosomal dominant pattern.

### *Multiple Endocrine Neoplasia Type 2A*

Organs commonly involved in MEN type 2A include

- *Thyroid*: Medullary carcinoma of the thyroid develops in virtually all untreated cases, and the tumors usually occur in the first 2 decades of life. The tumors commonly are multifocal, and foci of C cell hyperplasia can be found in the adjacent thyroid. *Familial medullary thyroid cancer* is a variant of MEN-2A characterized by medullary thyroid cancers, but not the other characteristic manifestations listed here. In comparison with MEN-2, familial medullary carcinoma typically occurs at an older age and follows a more indolent course.
- *Adrenal medulla*: Adrenal pheochromocytomas develop in 50% of the patients; fortunately, no more than 10% of these tumors are malignant.
- *Parathyroid*: Approximately 10% to 20% of patients develop parathyroid gland hyperplasia with manifestations of primary hyperparathyroidism.

### *Multiple Endocrine Neoplasia Type 2B*

Patients with MEN-2B harbor a distinct germline *RET* mutation involving a single–amino acid change. Organs commonly involved include the thyroid and the adrenal medulla. The spectrum of thyroid and adrenal medullary disease is similar to that in MEN-2A, with the following differences:

- *Primary hyperparathyroidism does not develop* in patients with MEN-2B.
- *Extraendocrine manifestations* are characteristic in patients with MEN-2B. These include ganglioneuromas of mucosal sites (gastrointestinal tract, lips, tongue) and a *marfanoid habitus,* in which overly long bones of the axial skeleton give an appearance resembling that in Marfan syndrome (Chapter 6).

Before the advent of genetic testing, relatives of patients with the MEN-2 syndrome were screened with annual biochemical tests, which often lacked sensitivity. Now, routine genetic testing identifies *RET* mutation carriers earlier and more reliably in MEN-2 kindreds; *all persons carrying germline RET mutations are advised to have prophylactic thyroidectomy to prevent the inevitable development of medullary carcinomas.*

The musculoskeletal system and the integrated neural connections enable locomotion by the human body. Aside from providing the fulcrums and levers against which muscles contract to allow movement, the skeleton is critical for mineral (particularly calcium) homeostasis and also protects viscera and supplies an environment conducive to both hematopoietic and mesenchymal stem cell development. The term diseases of the bones and joints embraces a large number of conditions ranging from localized, benign tumors of bone and soft tissue such as the osteochondroma and lipoma, respectively, to generalized disorders such as osteoporosis and osteogenesis imperfecta. In this chapter we will first consider some of the more common conditions affecting the bones and joints, then discuss tumors arising in the various soft tissues of the body. Diseases of the muscles and peripheral nerves are discussed in Chapter 21.

## BONES

The skeletal system is composed of 206 bones that vary in size and shape and are interconnected by a variety of joints that allow for a wide range of movement and promote structural stability. Bones are composed of a unique type of mineralized connective tissue that undergoes mineralization with a distinctive admixture of organic matrix (35%) and inorganic elements (65%). The inorganic mineral component consists mainly of calcium hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. This mineral gives bone strength and hardness and serves as the storehouse for 99% of the body's calcium, 85% of the body's phosphorus, and 65% of the body's sodium and magnesium. The organic component

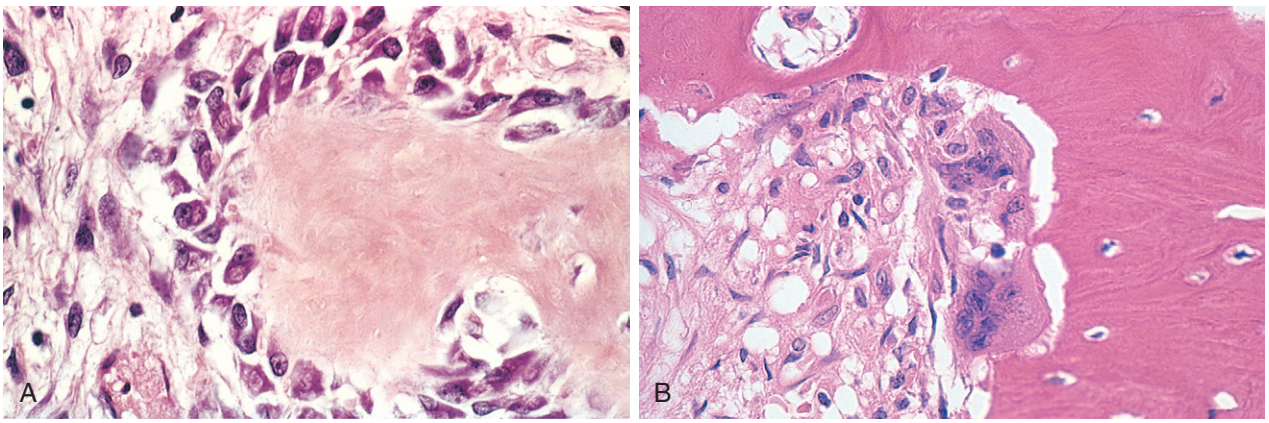

**Figure 20–1** Cells of bone. **A,** Active osteoblasts synthesizing bone matrix proteins. The surrounding spindle cells are osteoprogenitor cells. **B,** Two osteoclasts resorbing bone. The smaller blue nuclei surrounded by a halo of clearing in the dense pink lamellar bone are osteocytes in their individual lacunae.

includes the cells of bone and the proteinaceous osteoid. The bone-forming cells include osteoblasts and osteocytes, while cells of the bone-digesting lineage include osteoclast precursor cells and mature functional osteoclasts (Fig. 20–1).

To the uninitiated, bone appears to be an inert, stable tissue, but in fact it is very dynamic and subject to constant breakdown and renewal, a process referred to as *remodeling*. The net effects of remodeling may be bone maintenance, bone loss, or bone deposition, with the balance being determined by the relative activities of osteoblasts, which deposit bone, and osteoclasts, which resorb bone (Fig. 20–1, *A* and *B*). As might be imagined, osteoblast and osteoclast activity is highly regulated and tightly integrated under normal circumstances, both by local crosstalk between these two cell types and by circulating factors that impact their activity, such as vitamin D and parathyroid hormone.

Among the local factors that regulate bone remodeling, the most important are RANK (receptor activator for nuclear factor-κB), RANK ligand (RANKL), and osteoprotegerin (OPG) (Fig 20–2). RANK, a member of the tumor necrosis factor (TNF) receptor family, is expressed on the cell membranes of preosteoclasts and mature osteoclasts. Its ligand, RANKL, is expressed by osteoblasts and marrow stromal cells. RANK stimulation by RANKL leads to activation of the transcription factor NF-κB, which drives the expression of genes that stimulate osteoclast formation, fusion, differentiation, function, and survival. RANKL production is upregulated by factors that stimulate osteoclastic activity. The actions of RANKL can be blocked by another member of the TNF receptor family, OPG, which is a "decoy" receptor produced by a number of tissues including bone, hematopoietic marrow, and immune cells. OPG competitively binds to RANKL, preventing RANK from interacting with RANKL. OPG production is regulated by signals similar to those that stimulate RANKL. Therefore, these molecules enable osteoblasts and stromal cells to control osteoclast development and activity and provide a mechanism for a wide variety of biologic mediators (hormones, cytokines, growth factors) to influence the homeostasis of bone tissue and bone mass.

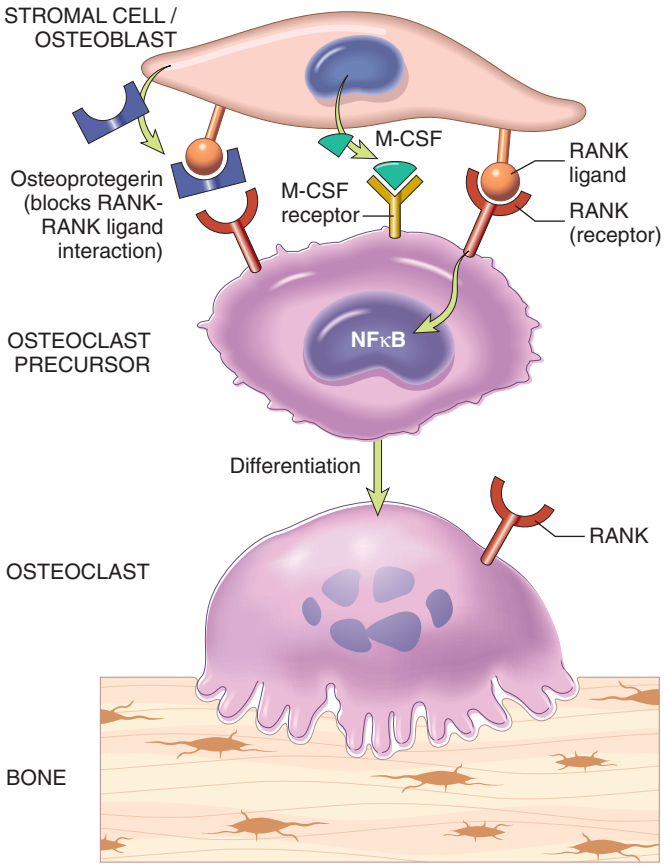

**Figure 20–2** Paracrine mechanisms regulating osteoclast formation and function. Osteoclasts are derived from the same stem cells that produce macrophages. RANK (*r*eceptor *a*ctivator for *n*uclear factor-κB) receptors on osteoclast precursors bind RANK ligand (RANKL) expressed by osteoblasts and marrow stromal cells. Along with macrophage colony-stimulating factor (M-CSF), the RANK-RANKL interaction drives the differentiation of functional osteoclasts. Stromal cells also secrete osteoprotegerin (OPG), which acts as a decoy receptor for RANKL, preventing it from binding the RANK receptor on osteoclast precursors. Consequently, OPG prevents bone resorption by inhibiting osteoclast differentiation.

Primary and secondary diseases of bone are varied and numerous and are classified in this chapter according to their perceived biologic defect or pathologic process.

# CONGENITAL DISORDERS OF BONE AND CARTILAGE

Congenital disorders of the skeleton are various and, depending on the resulting defect, become manifest at different ages. The most severe produce developmental abnormalities that are evident from the earliest stages of skeletogenesis.

- Developmental anomalies resulting from localized problems in the migration of mesenchymal cells and the formation of condensations are called *dysostoses* and may affect individual or a group of bones and can result from mutations in specific homeobox genes. The more common lesions include *aplasia* (e.g., congenital absence of a digit or rib), the formation of extra bones (e.g., supernumerary digits or ribs), and abnormal fusion of bones (e.g., premature closure of the cranial sutures or congenital fusion of the ribs). Such malformations may occur as isolated, sporadic lesions or as components of a more complex syndrome.
- Mutations that interfere with bone or cartilage formation, growth, and/or maintenance of normal matrix components have more diffuse effects; such disorders are called *dysplasias*—more specifically, *osteodysplasias* and *chondrodysplasias*. *Dysplasia* in this context refers to abnormal growth and does not imply precancerous lesions, as it does in other tissues (Chapter 5). They number well over 350, and only select examples are discussed here.
- Other genetic metabolic disorders not usually thought of as primary skeletal diseases (e.g., mucopolysaccharidoses such as Hurler syndrome) also affect the bone matrix; such conditions are discussed briefly with other genetic disorders in Chapter 6.

## Osteogenesis Imperfecta

*Osteogenesis imperfecta (OI), also known as "brittle bone disease," is actually a group of genetic disorders caused by defective synthesis of type I collagen.* Because type I collagen is a major component of extracellular matrix in other parts of the body, there are also numerous extraskeletal manifestations (affecting skin, joints, teeth, and eyes, for example). The mutations underlying OI characteristically involve the coding sequences for $\alpha_1$ or $\alpha_2$ chains of type I collagen. Because collagen synthesis and extracellular export require formation of a complete and intact triple helix, any primary defect in a collagen chain tends to disrupt the entire structure and results in its premature degradation (an example of a *dominant negative mutation*) (Chapter 6). As a consequence, most defects manifest as autosomal dominant disorders and may be associated with severe malformations. There is, however, a broad spectrum of severity, and mutations that result in qualitatively normal collagen but at only reduced levels generally have milder manifestations.

*The fundamental abnormality in all forms of OI is too little bone,* resulting in extreme skeletal fragility. Four major subtypes are recognized. The type II variant is uniformly fatal in utero or immediately postpartum as a consequence of multiple fractures that occur before birth. By contrast, patients with type I OI have a normal lifespan, with only a modestly increased proclivity for fractures during childhood (decreasing in frequency after puberty). The classic finding of *blue sclerae* in type I OI is attributable to decreased scleral collagen content; this deficit causes a relative transparency that allows the underlying choroid to be seen. *Hearing loss* can be related to conduction defects in the middle and inner ear bones, and *small misshapen teeth* are a result of dentin deficiency.

## Achondroplasia and Thanatophoric Dwarfism

*Achondroplasia is the most common form of dwarfism.* It is caused by activating point mutations in fibroblast growth factor receptor 3 (FGFR3), a receptor with tyrosine kinase activity that transmits intracellular signals. Signals transmitted by FGFR3 *inhibit* the proliferation and function of growth plate chondrocytes; consequently, the growth of normal epiphyseal plates is suppressed, and the length of long bones is severely stunted. The disorder can be inherited in autosomal dominant fashion, but many cases arise from new spontaneous mutations.

Achondroplasia affects all bones that develop by enchondral ossification. The most conspicuous changes include short stature, disproportionate shortening of the proximal extremities, bowing of the legs, and frontal bossing with midface hypoplasia. The cartilage of the growth plates is disorganized and hypoplastic.

*Thanatophoric dwarfism* is a lethal variant of dwarfism, affecting 1 in every 20,000 live births (*thanatophoric* means "death-loving"). This disease is caused by missense or point mutations most commonly located in the extracellular domains of FGFR3. Affected heterozygotes exhibit extreme shortening of the limbs, frontal bossing of the skull, and an extremely small thorax, which is the cause of fatal respiratory failure in the perinatal period.

## Osteopetrosis

*Osteopetrosis is a group of rare genetic disorders characterized by defective osteoclast-mediated bone resorption. Osteopetrosis* (literally, "bone-that-is-like-stone disorder") is an appropriate name, since the bones are dense, solid, and stone-like. Paradoxically, because turnover is decreased, the persisting bone tissue becomes weak over time and predisposed to fractures like a piece of chalk. Several variants are known, the two most common being an autosomal dominant adult form with mild clinical manifestations, and autosomal recessive infantile, with a severe/lethal phenotype.

The defects that cause osteopetrosis are categorized into those that disturb osteoclast function and those that interfere with osteoclast formation and differentiation. The

precise nature of the osteoclast dysfunction is unknown in many cases. Nevertheless, in some cases the abnormalities have been identified. These include carbonic anhydrase II deficiency, proton pump deficiency and chloride channel defect, all of which interfere with the ability of osteoclasts to resorb bone. A mouse model of osteopetrosis is caused by mutations in the monocyte-colony stimulating factor (M-CSF), which is required for osteoclast differentiation. No comparable defect has been identified in humans.

Besides fractures, patients with osteopetrosis frequently have cranial nerve palsies (due to compression of nerves within shrunken cranial foramina), recurrent infections because of reduced marrow size and activity, and hepatosplenomegaly caused by extramedullary hematopoiesis resulting from reduced marrow space. Morphologically, the primary spongiosa, which normally is removed during growth, persists, filling the medullary cavity, and bone is deposited in increased amounts woven into the architecture. Because osteoclasts are derived from marrow monocyte precursors, hematopoietic stem cell transplantation holds the promise of repopulating recipients with progenitor cells capable of differentiating into fully functional osteoclasts. Indeed, many of the skeletal abnormalities appear to be reversible once normal precursor cells are provided.

### SUMMARY

#### Congenital Disorders of Bone and Cartilage

- Abnormalities in a single or group of bones are called *dysostoses* and can result in the absence of bones, supernumerary bones, or inappropriately fused bones; some of these result from mutations in homeobox genes affecting localized migration and condensation of primitive mesenchymal cells.
- Abnormalities in bone or cartilage organogenesis are called *dysplasias*; these can be caused by mutations that affect signal transduction pathways or components of the extracellular matrix:
  - Achondroplasia and thanatophoric dwarfism occur as a consequence of constitutive FGFR3 activation, resulting in defective cartilage synthesis at growth plates.
  - Osteogenesis imperfecta (brittle bone disease) is a group of disorders caused by mutations in the genes for type I collagen that interfere with its normal production, with resultant bone fragility and susceptibility to fractures.
  - Osteopetrosis is caused by mutations that interfere with osteoclast function and is associated with dense but architecturally unsound bone owing to defective bone resorption.

## ACQUIRED DISEASES OF BONE

Many nutritional, endocrine, and systemic disorders affect the development of the skeletal system. Nutritional deficiencies causing bone disease include deficiencies of vitamin C (involved in collagen cross-linking; deficiency causes *scurvy*) and vitamin D (involved in calcium uptake; deficiency causes *rickets* and *osteomalacia*). Both of these are discussed in greater detail with other nutritional diseases in Chapter 7. Primary and secondary forms of hyperparathyroidism (discussed in Chapter 19) also cause significant skeletal changes, which are briefly reviewed in this section. Many of these disorders are characterized by inadequate osteoid, also called *osteopenia;* the most important clinically significant osteopenia is *osteoporosis*.

### Osteoporosis

*Osteoporosis is an acquired condition characterized by reduced bone mass,* leading to bone fragility and susceptibility to fractures. The bone loss may be confined to certain bones or regions, as in *disuse osteoporosis of a limb,* or be generalized, involving the entire skeleton. Generalized osteoporosis may be primary or occur secondary to a large variety of insults, including metabolic diseases, vitamin deficiencies, and drug exposures (Table 20–1).

Primary forms of osteoporosis are most common and may be associated with aging (senile osteoporosis) or the postmenopausal state in women. The drop in estrogen following menopause tends to exacerbate the loss of bone that occurs with aging, placing older women at high risk of osteoporosis relative to men. The risk of osteoporosis with aging is related to the peak bone mass earlier in life, which is influenced by genetic, nutritional, and environmental factors. Bone mass peaks during young adulthood; the greater the peak bone mass, the greater the delay in onset of osteoporosis. In both men and women, beginning in the third or fourth decade of life, bone resorption begins to outpace bone formation. The bone loss, averaging 0.5% per year, is a seemingly inevitable consequence of aging and is most prominent in areas containing abundant trabecular bone—namely the spine and femoral neck. The amount of bone loss with each cycle of remodeling is accelerated after menopause; hence, the vulnerability of women to osteoporosis and its complications. Regardless of the underlying cause, the progressive loss of bone mass is clinically significant because of the resultant increase in the risk of fractures. Roughly 1.5 million Americans each year experience an osteoporosis-related fracture, with those of greatest clinical significance involving the vertebrae and the hips. All told, the annual health care costs associated with osteoporosis-related fractures in the United States exceeds $18 billion.

### MORPHOLOGY

The hallmark of osteoporosis is a loss of bone. The cortices are thinned, with dilated haversian canals, and the trabeculae are reduced in thickness and lose their interconnections. Osteoclastic activity is present but is not dramatically increased, and the mineral content of the bone tissue is normal. Once enough bone is lost, susceptibility to fractures increases (Fig. 20–3). In postmenopausal osteoporosis, trabecular bone loss often is severe, resulting in compression

**Table 20–1** Categories of Generalized Osteoporosis

| |

| Anemia |

fractures and collapse of vertebral bodies. In senile osteoporosis, cortical bone loss is prominent, predisposing to fractures in other weight-bearing bones, such as the femoral neck.

## PATHOGENESIS

Osteoporosis occurs when the dynamic balance between bone formation by osteoblasts and bone resorption by osteoclasts (Fig. 20–2) tilts in favor of resorption. Several factors may tip the scales (Fig. 20–4):

- **Age-related changes.** With increasing age, the replicative and matrix production activities of osteoblasts progressively diminish. The various growth factors deposited in the extracellular matrix also diminish with time. Unfortunately, while new bone synthesis wanes with advancing age, osteoclasts retain their youthful vigor.

**Figure 20–3** Osteoporotic vertebral body (*right*) shortened by compression fractures, compared with a normal vertebral body. The osteoporotic vertebra exhibits a characteristic loss of horizontal trabeculae and thickened vertical trabeculae.

- **Hormonal influences.** The decline in estrogen levels associated with menopause correlates with an acceleration of cortical bone and trabecular (cancellous) bone loss. Over 30 to 40 years, this can result in the loss of up to 35% of cortical bone and 50% of trabecular bone! It is therefore not surprising that roughly half of postmenopausal women will suffer an osteoporotic fracture (compared with 2% to 3% of men of comparable age). It appears that the postmenopausal drop in estrogen leads to increased cytokine production (especially IL-1, IL-6, and TNF), presumably from cells in the bone. These stimulate RANK–RANK ligand activity and suppress OPG production (Fig. 20–2). There is some compensatory osteoblastic activity, but it is inadequate to keep pace with osteoclastic bone resorption. While estrogen replacement can ameliorate some of the bone loss, such therapy is increasingly associated with cardiovascular risks (Chapter 10).

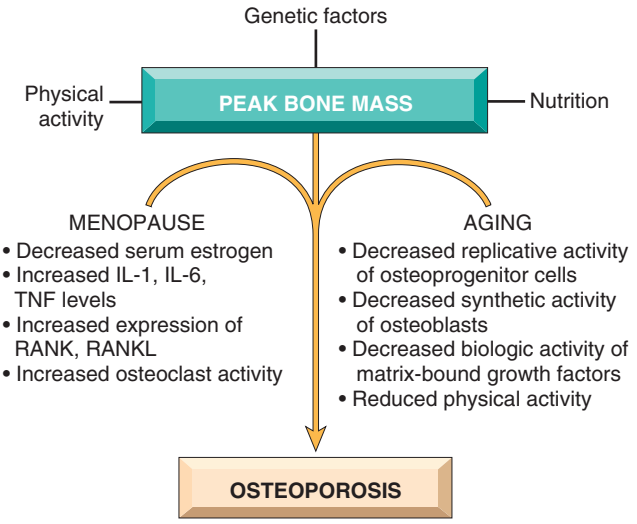

**Figure 20–4** Pathophysiology of postmenopausal and senile osteoporosis (see text).

- **Physical activity.** Because mechanical forces stimulate bone remodeling, reduced physical activity increases bone loss. This effect is obvious in an immobilized limb and also occurs throughout the skeleton in astronauts working in a gravity-free environment. Decreased physical activity in older persons also contributes to senile osteoporosis. Because the magnitude of skeletal loading influences bone density more than does the number of load cycles, the type of physical activity is important. Thus, resistance exercises such as weight training increase bone mass more effectively than endurance activities such as jogging.
- **Genetic factors.** Vitamin D receptor polymorphisms appear to influence the peak bone mass early in life. Additional genetic variables can influence either calcium uptake or PTH synthesis and responses.
- **Calcium nutritional state.** A majority of adolescent girls (but not boys) have insufficient dietary calcium. Unfortunately, this calcium deficiency occurs during a period of rapid bone growth. As a result, girls typically do not achieve the peak bone mass that could be otherwise expected and are accordingly more likely to develop clinically significant osteoporosis at an earlier age than their male counterparts.
- **Secondary causes of osteoporosis.** These include prolonged glucocorticoid therapy, which increases bone resorption and reduces bone synthesis. Cigarette smoking and excess alcohol also can result in reduced bone mass.

### Clinical Course

The clinical outcome with osteoporosis depends on which bones are involved. Thoracic and lumbar vertebral fractures are extremely common, leading to loss of height and various deformities, including kyphoscoliosis, which can compromise respiratory function. Pulmonary embolism and pneumonia are common complications of fractures of the femoral neck, pelvis, or spine and result in as many as 50,000 deaths annually.

Osteoporosis is difficult to diagnose because it is asymptomatic until skeletal fragility is announced with a fracture. Moreover, it cannot be reliably detected in plain radiographs until 30% to 40% of bone mass has already disappeared; serum levels of calcium, phosphorus, and alkaline phosphatase are notoriously insensitive. Current state-of-the-art methods for bone loss estimation consist of specialized radiographic techniques to assess bone mineral density, such as dual-energy absorptiometry and quantitative computed tomography.

Osteoporosis prevention and treatment begin with adequate dietary calcium intake, vitamin D supplementation, and a regular exercise regimen—starting before the age of 30—to maximize the peak bone mass. Calcium and vitamin D supplements later in life can also modestly reduce bone loss. Pharmacologic treatments include use of antiresorptive and osteoanabolic agents. The antiresorptive agents, such as bisphosphonates, calcitonin, estrogen, and denosumab, decrease bone resorption by osteoclasts. The main anabolic agent is parathyroid hormone or an analogue, given in amounts that stimulate osteoblastic activity.

## Paget Disease (Osteitis Deformans)

This unique skeletal disease is characterized by repetitive episodes of frenzied, regional osteoclastic activity and bone resorption (*osteolytic stage*), followed by exuberant bone formation (*mixed osteoclastic-osteoblastic stage*), and finally by an apparent exhaustion of cellular activity (*osteosclerotic stage*). The net effect of this process is a *gain in bone mass*; however, the newly formed bone is disordered and weak, so bones may become enlarged and misshapen.

Paget disease usually presents in mid- to late adulthood. Marked variation in prevalence has been reported in different populations: The disorder is rare in Scandinavia, China, Japan, and Africa and relatively common in much of Europe, Australia, New Zealand, and the United States, affecting up to 2.5% of the adult populations. Of interest, it appears that the incidence of Paget disease is decreasing.

### MORPHOLOGY

Paget disease may manifest as a solitary lesion (monostotic) or may occur at multiple sites (polyostotic) usually asynchronously. In the initial **lytic phase,** osteoclasts (and their associated Howship lacunae) are numerous, abnormally large, and have increased numbers of nuclei. Osteoclasts persist in the **mixed phase,** but the bone surfaces become lined by prominent osteoblasts. The marrow is replaced by loose connective tissue containing osteoprogenitor cells, as well as numerous blood vessels needed to meet the increased metabolic demands of the tissue. The newly formed bone may be woven or lamellar, but eventually all of it is remodeled into abnormal lamellar bone with a pathognomonic **mosaic pattern** (likened to a jigsaw puzzle) due to prominent haphazardly arranged cement lines (Fig. 20–5). As the osteoblastic activity ceases, the periosseous fibrovascular tissue recedes and is replaced by normal marrow. Although thickened, the resulting cortex is softer than normal and prone to deformation and fracture under stress.

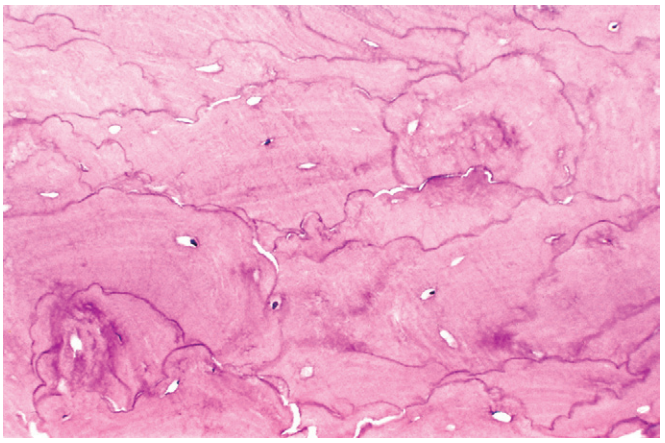

**Figure 20–5** Paget disease, showing a mosaic pattern of lamellar bone.

### PATHOGENESIS

When he first described the disease, Sir James Paget attributed the skeletal changes to an inflammatory process, and assigned the moniker **osteitis deformans.** After many years and multiple alternative theories, Paget's original idea may prove to be correct. It has long been postulated that a **paramyxovirus** infection (a slow virus) underlies Paget disease. Paramyxovirus antigens and particles resembling paramyxovirus can be demonstrated in osteoclasts. The causal connection is that paramyxoviruses can induce IL-1 and IL-6 secretion from infected cells, and these cytokines—as well as macrophage colony-stimulating factor (M-CSF)—are produced in large amounts in pagetic bone. As noted earlier, these potently activate osteoclasts. Nevertheless, as intriguing as these observations are, no infectious virus has been isolated from affected tissue. About 10% of affected patients have germline mutations in the gene *SQSTM1*, which encodes a protein that appears to increase osteoclastogenesis; these mutations are associated with earlier onset disease, a greater number of affected bones, and an increased incidence of fractures.

#### Clinical Course

The clinical findings depend on the extent and site of the disease. Paget disease is *monostotic* (tibia, ilium, femur, skull, vertebrae, and humerus) in about 15% of cases and *polyostotic* in the remainder; the axial skeleton or the proximal femur is involved in as many as 80% of cases. Involvement of the ribs, fibulae, and small bones of the hands and feet is unusual. Although Paget disease can produce a plethora of skeletal, neuromuscular, and cardiovascular complications, most cases are clinically mild, and the bone changes are discovered only incidentally in radiographs. Elevations in serum alkaline phosphatase and increased urinary excretion of hydroxyproline reflect exuberant bone turnover.

In some patients, the early hypervascular bone lesions cause warmth of the overlying skin and subcutaneous tissue. With extensive polyostotic disease, hypervascularity can result in high-output congestive heart failure. In the proliferative phase of the disease involving the skull, common symptoms attributable to nerve impingement include headache and visual and auditory disturbances. Vertebral lesions cause back pain and may be associated with disabling fractures and nerve root compression. Affected long bones in the legs often are deformed, as a consequence of the inability of pagetoid bone to remodel appropriately in response to the stress of weight bearing. Brittle long bones in particular are subject to *chalkstick fractures.*

The development of sarcoma is a dreaded but fortunately rare complication of Paget disease, occurring in only an estimated 1% of patients. The sarcomas usually are osteogenic, although other histologic variants can occur. The distribution of osteosarcoma generally parallels that of the Paget disease lesions, with the exception of vertebral bodies, which rarely harbor malignancy. The prognosis for patients who develop secondary sarcomas is exceedingly poor, but otherwise Paget disease usually follows a relatively benign course. Most patients have mild symptoms that are readily controlled with bisphosphonates, drugs that interfere with bone resorption.

## Rickets and Osteomalacia

Both rickets and osteomalacia are manifestations of vitamin D deficiency or its abnormal metabolism (and are detailed in Chapter 7). The fundamental defect is an impairment of mineralization and a resultant accumulation of unmineralized matrix. This contrasts with osteoporosis, in which the mineral content of the bone is normal and the total bone mass is decreased. *Rickets* refers to the disorder in children, in which it interferes with the deposition of bone in the growth plates. *Osteomalacia* is the adult counterpart, in which bone formed during remodeling is undermineralized, resulting in predisposition to fractures.

## Hyperparathyroidism

As discussed in Chapter 19, parathyroid hormone (PTH) plays a central role in calcium homeostasis through the following effects:

- Osteoclast activation, increasing bone resorption and calcium mobilization. PTH mediates the effect indirectly by increased RANKL expression on osteoblasts.
- Increased resorption of calcium by the renal tubules
- Increased urinary excretion of phosphates
- Increased synthesis of active vitamin D, $1,25(OH)_2$-D, by the kidneys, which in turn enhances calcium absorption from the gut and mobilizes bone calcium by inducing RANKL on osteoblasts

The net result of the actions of PTH is an elevation in serum calcium, which, under normal circumstances, inhibits further PTH production. However, excessive or inappropriate levels of PTH can result from autonomous parathyroid secretion (*primary hyperparathyroidism*) or can occur in the setting of underlying renal disease (*secondary hyperparathyroidism*) (see also Chapter 19).

In either setting, *hyperparathyroidism leads to significant skeletal changes related to unabated osteoclast activity.* The entire skeleton is affected, although some sites can be more severely affected than others. PTH is directly responsible for the bone changes seen in primary hyperparathyroidism, but additional influences contribute to the development of bone disease in secondary hyperparathyroidism. In chronic renal insufficiency there is inadequate $1,25\text{-}(OH)_2$-D synthesis, which ultimately affects gastrointestinal calcium absorption. The hyperphosphatemia of renal failure also suppresses renal $\alpha_1$-hydroxylase, further impairing vitamin D synthesis; additional influences include metabolic acidosis and aluminum deposition in bone. As bone mass decreases, affected patients are increasingly susceptible to fractures, bone deformation, and joint problems. Fortunately, a reduction in PTH levels to normal can completely reverse the bone changes.

## MORPHOLOGY

The hallmark of PTH excess is **increased osteoclastic activity, with bone resorption.** Cortical and trabecular bone are diminished and replaced by loose connective tissue. Bone resorption is especially pronounced in the subperiosteal regions and produces characteristic radiographic changes, best seen along the radial aspect of the middle phalanges of the second and third fingers. Microscopically, there are **increased numbers of osteoclasts boring into the centers of bony trabeculae (dissecting osteitis) and expanding haversian canals (cortical cutting cones)** (Fig. 20–6, *A*). The marrow space contains increased amounts of loose fibrovascular tissue. Hemosiderin deposits are present, reflecting episodes of hemorrhage resulting from microfractures of the weakened bone. In some instances, collections of osteoclasts, reactive giant cells, and hemorrhagic debris form a distinct mass termed a **brown tumor of hyperparathyroidism** (Fig. 20–6, *B*). Cystic change is common in such lesions (hence the name **osteitis fibrosa cystica**), which can be confused with primary bone neoplasms.

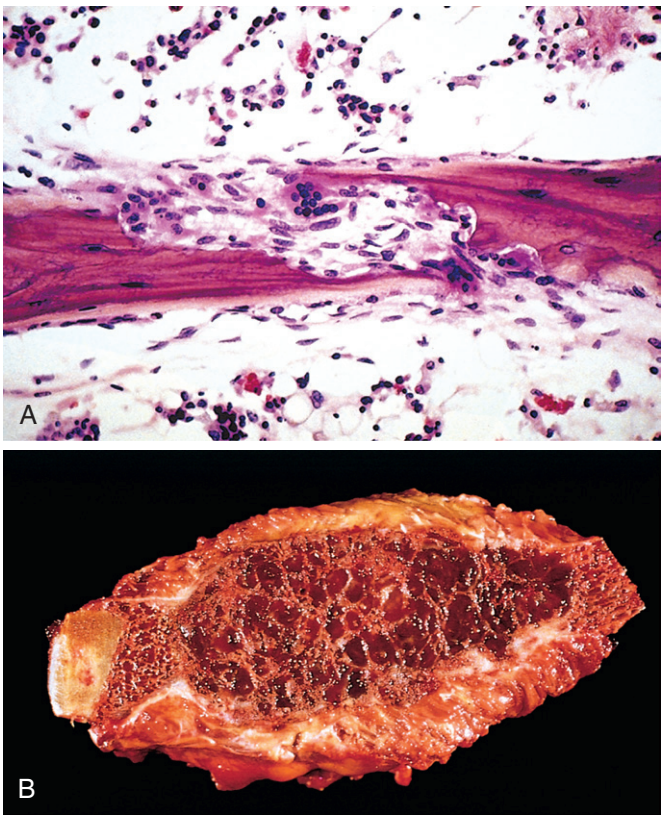

**Figure 20–6** Bone manifestations of hyperparathyroidism. **A,** Osteoclasts gnawing into and disrupting lamellar bone. **B,** Resected rib, with expansile cystic mass (so-called brown tumor).

## SUMMARY

### Acquired Diseases of Bone Development and Mass

- Nutritional deficiencies can affect bone integrity by altering the quality of the organic matrix (e.g., vitamin C is involved in collagen cross-linking) or by influencing bone mineralization (e.g., vitamin D is involved in calcium uptake).
- Osteoporosis results from decreased bone mass and is clinically significant because it predisposes bone to fracture. Although osteoporosis is multifactorial, the two most common forms are *senile osteoporosis* due to aging-related losses of osteoblast function, and *postmenopausal osteoporosis* due to increased osteoclastic activity caused by the relative absence of estrogen.
- Paget disease may result from a paramyxovirus infection in genetically susceptible persons and is caused by aberrant and excessive osteoclast activity, followed by exuberant—but structurally unsound—osteoblast deposition of bone.
- Primary or secondary (due to renal failure) overproduction of PTH (*hyperparathyroidism*) results in increased osteoclast activity and bone resorption, leading to fractures and deformities.

## FRACTURES

Fractures rank among the most common pathologic conditions of bone. They are classified as follows:

- *Complete* or *incomplete*
- *Closed,* in which the overlying tissue is intact, or *compound,* in which the fracture extends into the overlying skin
- *Comminuted,* in which the bone is splintered
- *Displaced,* in which the fractured bone is not aligned

If the break occurs at the site of previous disease (e.g., a bone cyst, a malignant tumor, or a brown tumor associated with elevated PTH), it is termed a *pathologic fracture.* A *stress fracture* develops slowly over time as a collection of microfractures associated with increased physical activity, especially with new repetitive mechanical loads on bone (as sustained in military bootcamp activities).

In all cases, the repair of a fracture is a highly regulated process that involves overlapping stages:

- The trauma of the bone fracture ruptures associated blood vessels; the resulting blood clot creates a fibrin mesh scaffold to recruit inflammatory cells, fibroblasts, and endothelium. Degranulated platelets and marauding inflammatory cells subsequently release a host of cytokines (e.g., platelet-derived growth factor, fibroblast growth factor) that activate bone progenitor cells, and within a week, the involved tissue is primed for new matrix synthesis. This *soft tissue callus* can hold the ends of the fractured bone in apposition but is noncalcified and cannot support weight bearing.
- Bone progenitors in the periosteum and medullary cavity deposit new foci of woven bone, and activated

mesenchymal cells at the fracture site differentiate into cartilage-synthesizing chondroblasts. In uncomplicated fractures, this early repair process peaks within 2 to 3 weeks. The newly formed cartilage acts as a nidus for *endochondral ossification,* recapitulating the process of bone formation in epiphyseal growth plates. This connects the cortices and trabeculae in the juxtaposed bones. With ossification, the fractured ends are bridged by a *bony callus.*

- Although excess fibrous tissue, cartilage, and bone are produced in the early callus, subsequent weight bearing leads to remodeling of the callus from nonstressed sites; at the same time there is fortification of regions that support greater loads. This process restores the original size, shape, and integrity of the bone.

The healing of a fracture can be disrupted by many factors:

- Displaced and comminuted fractures frequently result in some deformity; devitalized fragments of splintered bone require resorption, which delays healing, enlarges the callus, and requires inordinately long periods of remodeling and may never completely normalize.
- Inadequate immobilization permits constant movement at the fracture site, so that the normal constituents of callus do not form. In such instances, the healing site is composed mainly of fibrous tissue and cartilage, perpetuating the instability and resulting in delayed union and nonunion. Too much motion along the fracture gap (as in nonunion) causes the central portion of the callus to undergo cystic degeneration; the luminal surface can actually become lined by synovial-type cells, creating a false joint, or *pseudoarthrosis.* In the setting of a nonunion or pseudoarthrosis, normal healing can be achieved only if the interposed soft tissues are removed and the fracture site is stabilized.
- *Infection* (a risk in comminuted and open fractures) is a serious obstacle to fracture healing. The infection must be eradicated before successful bone reunion and remodeling can occur.
- Bone repair obviously will be impaired in the setting of inadequate levels of calcium or phosphorus, vitamin deficiencies, systemic infection, diabetes, or vascular insufficiency.

With uncomplicated fractures in children and young adults, practically perfect reconstitution is the norm. When fractures occur in older age groups or in abnormal bones (e.g., osteoporotic bone), repair frequently is less than optimal without orthopedic intervention.

## OSTEONECROSIS (AVASCULAR NECROSIS)

Ischemic necrosis with resultant bone infarction occurs relatively frequently. Mechanisms contributing to bone ischemia include

- Vascular compression or disruption (e.g., after a fracture)
- Steroid administration
- Thromboembolic disease (e.g., nitrogen bubbles in caisson disease—see Chapter 3)
- Primary vessel disease (e.g., vasculitis)
- Sickle cell crisis (Chapter 11)

Most cases of bone necrosis are due to fracture or occur after corticosteroid use, but in many instances the etiology is unknown.

### MORPHOLOGY

The pathologic features of bone necrosis are the same regardless of cause. Dead bone with empty lacunae is interspersed with areas of fat necrosis and insoluble calcium soaps. The cortex usually is not affected, because of collateral blood supply; in subchondral infarcts, the overlying articular cartilage also remains viable because the synovial fluid can provide nutritive support. With time, osteoclasts can resorb some of the necrotic bony trabeculae; any dead bone fragments that remain act as scaffolding for new bone formation, a process called **creeping substitution.**

### Clinical Course

Symptoms depend on the size and location of injury. *Subchondral infarcts* initially present with pain during physical activity that becomes more persistent with time. *Medullary infarcts* usually are silent unless large in size (as may occur with Gaucher disease, caisson disease, or sickle cell disease). Medullary infarcts usually are stable, but subchondral infarcts often collapse and may lead to severe osteoarthritis. Roughly 50,000 joint replacements are performed each year in the United States to treat the consequences of osteonecrosis.

## OSTEOMYELITIS

*Osteomyelitis* is defined as inflammation of bone and marrow, but in common use it is virtually synonymous with infection. Osteomyelitis can be secondary to systemic infection but more frequently occurs as a primary isolated focus of disease; it can be an acute process or a chronic, debilitating illness. Although any microorganism can cause osteomyelitis, the most common etiologic agents are pyogenic bacteria and *Mycobacterium tuberculosis.*

### Pyogenic Osteomyelitis

Most cases of acute osteomyelitis are caused by bacteria. The offending organisms reach the bone by one of three routes: (1) hematogenous dissemination (most common); (2) extension from an infection in adjacent joint or soft tissue; or (3) traumatic implantation after compound fractures or orthopedic procedures. Overall, *Staphylococcus aureus* is the most frequent causative organism; its propensity to infect bone may be related to the expression of surface proteins that allow adhesion to bone matrix. *Escherichia coli* and group B streptococci are important causes of acute osteomyelitis in neonates, and *Salmonella* is an especially common pathogen in persons with sickle cell

disease. Mixed bacterial infections, including anaerobes, typically are responsible for osteomyelitis secondary to bone trauma. In as many as 50% of cases, no organisms can be isolated.

### MORPHOLOGY

The morphologic changes in osteomyelitis depend on the chronicity and location of the infection. Causal bacteria proliferate, inducing an acute inflammatory reaction, with consequent cell death. Entrapped bone rapidly becomes necrotic; this non-viable bone is called a **sequestrum.** Bacteria and inflammation can percolate throughout the haversian systems to reach the periosteum. In children, the periosteum is loosely attached to the cortex; therefore, sizable **subperiosteal** abscesses can form and extend for long distances along the bone surface. Lifting of the periosteum further impairs the blood supply to the affected region, and both suppurative and ischemic injury can cause segmental bone necrosis. Rupture of the periosteum can lead to abscess formation in the surrounding soft tissue that may lead to a **draining sinus.** Sometimes the sequestrum crumbles, releasing fragments that pass through the sinus tract.

In infants (and uncommonly in adults), epiphyseal infection can spread into the adjoining joint to produce suppurative arthritis, sometimes with extensive destruction of the articular cartilage and permanent disability. An analogous process can involve vertebrae, with an infection destroying intervertebral discs and spreading into adjacent vertebrae.

After the first week of infection, chronic inflammatory cells become more numerous. Leukocyte cytokine release stimulates osteoclastic bone resorption, fibrous tissue ingrowth, and bone formation in the periphery. Reactive woven or lamellar bone can be deposited; when it forms a shell of living tissue around a sequestrum, it is called an **involucrum** (Fig. 20–7). Viable organisms can persist in the sequestrum for years after the original infection.

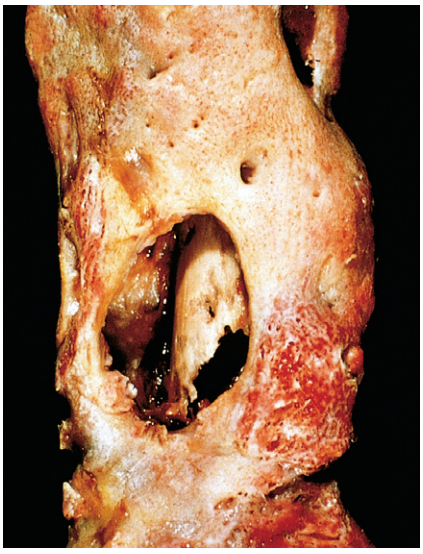

**Figure 20–7** Resected femur from a patient with chronic osteomyelitis. Necrotic bone (the sequestrum) visible in the center of a draining sinus tract is surrounded by a rim of new bone (the involucrum).

Clinical Features

Osteomyelitis classically manifests as an acute systemic illness, with malaise, fever, leukocytosis, and throbbing pain over the affected region. Symptoms also can be subtle, with only unexplained fever, particularly in infants, or only localized pain in the adult. The diagnosis is suggested by characteristic radiologic findings: a destructive lytic focus surrounded by edema and a sclerotic rim. In many untreated cases, blood cultures are positive, but biopsy and bone cultures are usually required to identify the pathogen. A combination of antibiotics and surgical drainage usually is curative, but up to a quarter of cases do not resolve and persist as chronic infections. Chronicity may develop with delay in diagnosis, extensive bone necrosis, abbreviated antibiotic therapy, inadequate surgical debridement, and/or weakened host defenses. Besides occasional acute flare-ups, chronic osteomyelitis also may be complicated by pathologic fracture, secondary amyloidosis, endocarditis, sepsis, development of squamous cell carcinoma if the infection creates a sinus tract, and rarely osteosarcoma.

### Tuberculous Osteomyelitis

Mycobacterial infection of bone has long been a problem in developing countries; with the resurgence of tuberculosis (due to immigration patterns and increasing numbers of immunocompromised persons) it is becoming an important disease in other countries as well.

Bone infection complicates an estimated 1% to 3% of cases of pulmonary tuberculosis. The organisms usually reach the bone through the bloodstream, although direct spread from a contiguous focus of infection (e.g., from mediastinal nodes to the vertebrae) also can occur. With hematogenous spread, *long bones and vertebrae are favored sites.* The lesions often are solitary but can be multifocal, particularly in patients with an underlying immunodeficiency. Because the tubercle bacillus is microaerophilic, the synovium, with its higher oxygen pressures, is a common site of initial infection. The infection then spreads to the adjacent epiphysis, where it elicits typical granulomatous inflammation with caseous necrosis and extensive bone destruction. *Tuberculosis of the vertebral bodies is a clinically serious form of osteomyelitis.* Infection at this site causes vertebral deformity, collapse, and posterior displacement (Pott disease), leading to neurologic deficits. Spinal deformities due to Pott disease afflicted several men of letters (including Alexander Pope and William Henley) and likely served as the inspiration for Victor Hugo's *Hunchback of Notre Dame.* Extension of the infection to the adjacent soft tissues with the development of psoas muscle abscesses is fairly common.

## BONE TUMORS

Primary bone tumors are considerably less common than bone metastases from other primary sites; metastatic disease is discussed at the end of this section.

*Primary bone tumors exhibit great morphologic diversity and clinical behaviors – from benign to aggressively malignant.* Most are classified according to the normal cell counterpart and line of differentiation; Table 20–2 lists the salient features

**Table 20–2** Tumors of Bone

| Tumor Type | Common Locations | Age (yr) | Morphology |
|---|---|---|---|
| **Bone-Forming** | | | |
| Benign | | | |
| Osteoma | Facial bones, skull | 40–50 | Exophytic growths attached to bone surface; histologically similar to normal bone |
| Osteoid osteoma | Metaphysis of femur and tibia | 10–20 | Cortical tumors, characterized by pain; histologic pattern consisting of interlacing trabeculae of woven bone |
| Osteoblastoma | Vertebral column | 10–20 | Arise in vertebral transverse and spinous processes; histologically similar to osteoid osteoma |
| Malignant | | | |
| Primary osteosarcoma | Metaphysis of distal femur, proximal tibia, and humerus | 10–20 | Grow outward, lifting periosteum, and inward to the medullary cavity; microscopy shows malignant cells forming osteoid; cartilage also may be present |
| Secondary osteosarcoma | Femur, humerus, pelvis | >40 | Complications of polyostotic Paget disease; histologically similar to primary osteosarcoma |
| **Cartilaginous** | | | |
| Benign | | | |
| Osteochondroma | Metaphysis of long tubular bones | 10–30 | Bony excrescences with a cartilaginous cap; may be solitary or multiple and hereditary |
| Enchondroma | Small bones of hands and feet | 30–50 | Well-circumscribed single tumors resembling normal cartilage; arise within medullary cavity of bone; uncommonly multiple and hereditary |
| Malignant | | | |
| Chondrosarcoma | Bones of shoulder, pelvis, proximal femur, and ribs | 40–60 | Arise within medullary cavity and erode cortex; microscopy shows well-differentiated cartilage-like or anaplastic features |
| **Miscellaneous** | | | |
| Giant cell tumor (usually benign) | Epiphysis of long bone | 20–40 | Lytic lesions that erode cortex; microscopy shows osteoclast-like giant cells and round to spindle-shaped mononuclear cells; most are benign |
| Ewing sarcoma | Diaphysis and metaphysis | 10–20 | Arise in medullary cavity; microscopy shows sheets of small round cells that contain glycogen; aggressive neoplasm |

of the most common primary bone neoplasms, excluding multiple myeloma and other hematopoietic tumors. Overall, matrix-producing and fibrous tumors are the most common, and among the benign tumors, osteochondroma and fibrous cortical defect occur most frequently. Osteosarcoma is the most common primary bone cancer, followed by chondrosarcoma and Ewing sarcoma. Benign tumors greatly outnumber their malignant counterparts, particularly before the age of 40 years; bone tumors in elderly persons are much more likely to be malignant.

Most bone tumors develop during the first several decades of life and have a propensity to originate in the long bones of the extremities. Nevertheless, specific tumor types target certain age groups and anatomic sites; these associations are often helpful in arriving at the correct diagnosis. For instance, most osteosarcomas occur during adolescence, with half arising around the knee, either in the distal femur or proximal tibia. By contrast, chondrosarcomas tend to develop during mid- to late adulthood and involve the trunk, limb girdles, and proximal long bones.

Most bone tumors arise without any previous known cause. Nevertheless, genetic syndromes (e.g., Li-Fraumeni and retinoblastoma syndromes) (Chapter 5) are associated with osteosarcomas, as are (rarely) bone infarcts, chronic osteomyelitis, Paget disease, irradiation, and use of metal orthopedic devices.

In terms of clinical presentation, benign lesions frequently are asymptomatic and are detected as incidental findings. Others produce pain or a slowly growing mass. Occasionally, a pathologic fracture is the first manifestation. Radiologic imaging is critical in the evaluation of bone tumors; however, biopsy and histologic study and, in some cases, molecular tests are necessary for diagnosis.

## Bone-Forming Tumors

The tumor cells in the following neoplasms all produce bone that usually is woven and variably mineralized.

### *Osteoma*

*Osteomas* are benign lesions most commonly encountered in the head and neck, including the paranasal sinuses, but which can occur elsewhere as well. They typically present in middle age as solitary, slowly growing, hard, exophytic

masses on a bone surface. Multiple lesions are a feature of Gardner syndrome, a hereditary condition discussed later. On histologic examination, osteomas recapitulate cortical-type bone and are composed of a mixture of woven and lamellar bone. Although they may cause local mechanical problems (e.g., obstruction of a sinus cavity) and cosmetic deformities, they are not locally aggressive and do not undergo malignant transformation.

### *Osteoid Osteoma and Osteoblastoma*

*Osteoid osteomas* and *osteoblastomas* are benign neoplasms with very similar histologic features. Both lesions typically appear during the teenage years and 20s, with a male predilection (2:1 for osteoid osteomas). They are distinguished from each other primarily by their size and clinical presentation. *Osteoid osteomas* arise most often beneath the periosteum or within the cortex in the proximal femur and tibia or posterior spinal elements and are by definition less than 2 cm in diameter, whereas osteoblastomas are larger. Localized pain, most severe at night, is an almost universal complaint with osteoid osteomas, and usually is relieved by aspirin. *Osteoblastomas* arise most often in the vertebral column; they also cause pain, although it often is more difficult to localize and is not responsive to aspirin. Local excision is the treatment of choice; incompletely resected lesions can recur. Malignant transformation is rare *unless* the lesion is treated with irradiation.

#### MORPHOLOGY

On gross inspection, both lesions are round-to-oval masses of hemorrhagic, gritty-appearing tan tissue. A rim of sclerotic bone is present at the edge of both types of tumors; however, it is much more conspicuous in osteoid osteomas. On microscopic examination, both neoplasms are composed of interlacing trabeculae of woven bone surrounded by osteoblasts (Fig. 20–8). The intervening stroma is loose, vascular connective tissue containing variable numbers of giant cells.

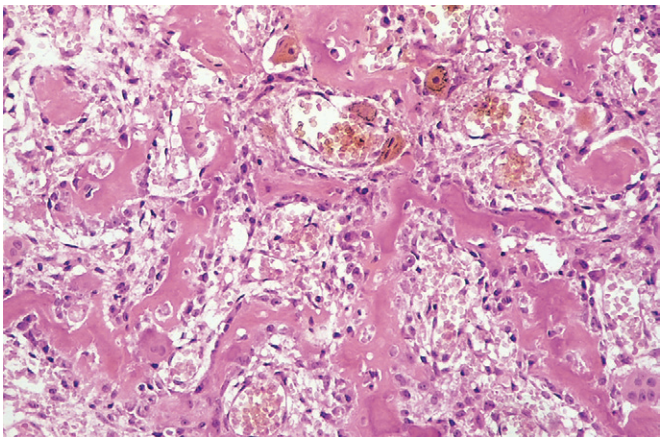

**Figure 20–8** Osteoid osteoma showing randomly oriented trabeculae of woven bone rimmed by prominent osteoblasts. The intertrabecular spaces are filled by vascular loose connective tissue.

### *Osteosarcoma*

*Osteosarcoma is a bone-producing malignant mesenchymal tumor.* After myeloma and lymphoma, osteosarcoma is the most common primary malignant tumor of bone, accounting for approximately 20% of primary bone cancers; a little over 2000 cases are diagnosed annually in the United States. Osteosarcomas occur in all age groups, but about 75% of patients are younger than 20 years of age, with a second peak occurring in elderly persons, usually in association with other conditions, including Paget disease, bone infarcts, and previous irradiation. Men are more commonly affected than women (1.6:1). Although any bone can be involved, most tumors arise in the metaphyseal region of the long bones of the extremities, with almost 60% occurring about the knee, 15% around the hip, 10% at the shoulder, and 8% in the jaw. Several subtypes of osteosarcoma are distinguished on the basis of the site of involvement within the bone (e.g., medullary versus cortical), degree of differentiation, number of involved sites, presence of underlying disease, and histologic features; the most common type of osteosarcoma is primary, solitary, intramedullary, and poorly differentiated, producing a predominantly bony matrix.

#### MORPHOLOGY

On gross evaluation, osteosarcomas are gritty-appearing, gray-white tumors, often exhibiting hemorrhage and cystic degeneration. Tumors frequently destroy the surrounding cortices, producing soft tissue masses (Fig. 20–9, *A*). They spread extensively in the medullary canal, infiltrating and replacing the marrow but only infrequently penetrating the epiphyseal plate or entering the joint space. Tumor cells vary in size and shape and frequently have large hyperchromatic

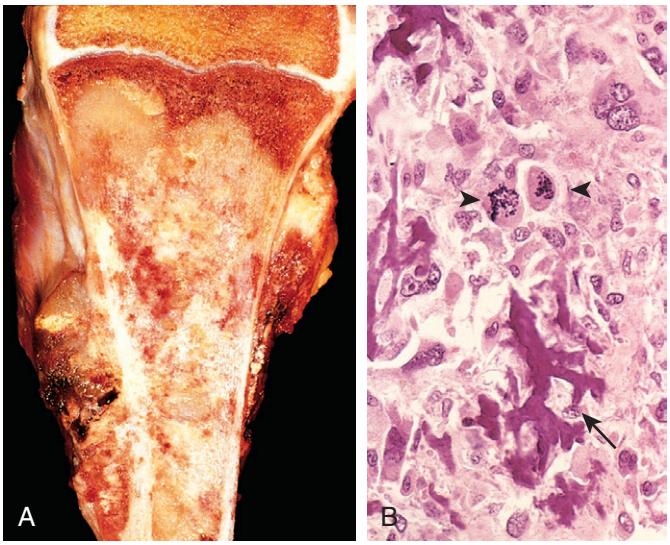

**Figure 20–9** Osteosarcoma. **A,** Mass involving the upper end of the tibia. The tan-white tumor fills most of the medullary cavity of the metaphysis and proximal diaphysis. It has infiltrated through the cortex, lifted the periosteum, and formed soft tissue masses on both sides of the bone. **B,** Histologic appearance, with coarse, lacelike pattern of neoplastic bone (*arrow*) produced by anaplastic tumor cells. Note the wildly aberrant mitotic figures (*arrowheads*).

nuclei; bizarre tumor giant cells are common, as are mitotic figures. **The production of mineralized or unmineralized bone (osteoid) by malignant cells is essential for diagnosis of osteosarcoma** (Fig. 20–9, *B*). The neoplastic bone typically is coarse and lacelike but also can be deposited in broad sheets. Cartilage and fibroblastic differentiation can also be present in varying amounts. When malignant cartilage is abundant, the tumor is called a **chondroblastic osteosarcoma.** Vascular invasion is common, as is spontaneous tumor necrosis.

## PATHOGENESIS

Several mutations are closely associated with the development of osteosarcoma. In particular, *RB* gene mutations occur in 60% to 70% of sporadic tumors, and persons with hereditary retinoblastomas (due to germline mutations in the *RB* gene) have a thousand-fold greater risk for development of osteosarcoma. Like many other cancers, spontaneous osteosarcomas also frequently exhibit mutations in *TP53* and in genes that regulate the cell cycle, including cyclins, cyclin-dependent kinases, and kinase inhibitors. Many osteosarcomas develop at sites of greatest bone growth, perhaps because rapidly dividing cells provide a fertile soil for mutations.

### Clinical Features

Osteosarcomas typically manifest as painful enlarging masses, although a pathologic fracture can be the first sign. Radiographic imaging usually shows a large, destructive, mixed lytic and blastic mass with indistinct infiltrating margins. The tumor frequently breaks through the cortex and lifts the periosteum, resulting in reactive periosteal bone formation. A triangular shadow on the x-ray film between the cortex and raised periosteum (*Codman triangle*) is characteristic of osteosarcomas. Osteosarcomas typically spread hematogenously; at the time of diagnosis, approximately 10% to 20% of patients have demonstrable pulmonary metastases, and a larger number have microscopic metastases.

Despite aggressive behavior, standard treatment with chemotherapy and limb salvage therapy currently yields long-term survivals of 60% to 70%.

Secondary osteosarcomas occur in older adults most commonly in the setting of Paget disease or previous radiation exposure. Like primary osteosarcomas, secondary osteosarcomas are highly aggressive tumors, but they do not respond well to therapy and are usually fatal.

## Cartilage-Forming Tumors

Cartilage-forming tumors produce hyaline or myxoid cartilage; fibrocartilage and elastic cartilage are rare components. Like the bone-forming tumors, cartilaginous tumors constitute a spectrum from benign, self-limited growths to highly aggressive malignancies; again, benign cartilage tumors are much more common than malignant ones. Only the more common types are discussed here.

### *Osteochondroma*

Osteochondromas are relatively common benign, cartilage-capped tumors attached by a bony stalk to the underlying skeleton. Solitary osteochondromas typically are first diagnosed in late adolescence and early adulthood (male-to-female ratio of 3:1); multiple osteochondromas become apparent during childhood, occurring as *multiple hereditary osteochondromas,* an autosomal dominant disorder. Inactivation of both copies of the *EXT1* or *EXT2* genes through mutation and loss of heterozygosity in chondrocytes of the growth plate is implicated in both sporadic and hereditary osteochondromas. These tumor suppressor genes encode glycosyltransferases essential for polymerization of heparin sulfate, an important component of cartilage. This finding and other molecular genetic studies support the concept that osteochondromas are true neoplasms and not developmental malformations.

Osteochondromas develop only in bones of endochondral origin arising at the metaphysis near the growth plate of long tubular bones, especially about the knee; they tend to stop growing once the normal growth of the skeleton is completed (Fig. 20–10). Occasionally they develop from bones of the pelvis, scapula, and ribs and in these sites frequently are sessile. Rarely, osteochondromas arise in the short tubular bones of hands and feet.

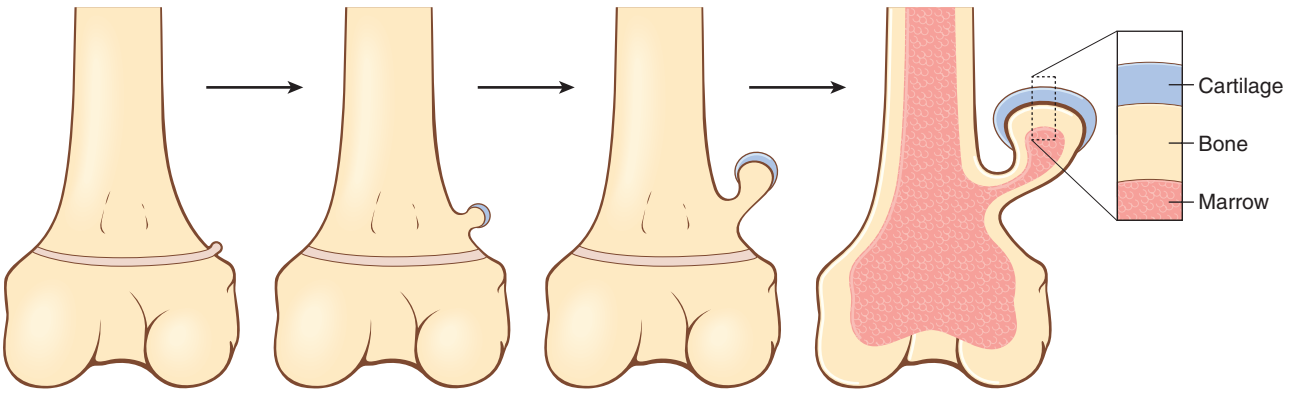

**Figure 20–10** The development of an osteochondroma, beginning with an outgrowth from the epiphyseal cartilage.

### MORPHOLOGY

Osteochondromas range from 1 to 20 cm in size and have a cartilaginous cap that is usually less than 2 cm in thickness. The hyaline cartilage resembles a disorganized growth plate undergoing endochondral ossification. Newly formed bone forms the inner portion of the head and stalk, with the stalk cortex and central region merging with the cortex and medullary cavity, respectively, of the host bone.

Clinical Features

Osteochondromas are slow-growing masses that can be painful if they impinge on a nerve or if the stalk is fractured. In many cases, they are incidental findings. In multiple hereditary osteochondromas, deformity of the underlying bone suggests an associated disturbance in epiphyseal growth. Solitary osteochondromas rarely progress to chondrosarcoma or other sarcomas, but malignant transformation occurs more frequently in those with multiple hereditary osteochondromas.

### *Chondroma*

Chondromas are benign neoplasms of hyaline cartilage. When they arise within the medulla, they are termed *enchondromas*; when on the bone surface, they are called *juxtacortical chondromas.* Enchondromas usually are diagnosed in persons between the ages of 20 and 50 years; they typically are solitary and located in the metaphyseal region of tubular bones, the favored sites being the short tubular bones of the hands and feet. *Ollier disease* is characterized by *multiple chondromas* preferentially involving one side of the body, and *Maffucci syndrome* is characterized by *multiple chondromas associated with soft tissue spindle cell hemangiomas.*

### PATHOGENESIS

Enchondromas occurring in Ollier disease and Maffucci syndrome frequently contain point mutations in either isocitrate dehydrogenase 1 (IDH1) or IDH2 that create a new enzyme activity. The same IDH mutations occur as somatic mutations in acute myeloid leukemias and gliomas, but in Ollier and Maffucci disease the mutations are also found at low frequency in normal tissues, suggesting the mutations occurred early during embryonic development, an example of genetic mosaicism.

### MORPHOLOGY

Enchondromas are gray-blue, translucent nodules usually smaller than 5 cm in greatest dimension. On microscopic examination, they are well circumscribed and composed of hyaline cartilage containing cytologically benign chondrocytes. At the periphery, there is endochondral ossification, while the center frequently calcifies and dies. In the hereditary multiple chondromatoses, the islands of cartilage exhibit greater cellularity and atypia, making them more difficult to distinguish from chondrosarcoma.

Clinical Features

Most enchondromas are detected as incidental findings; occasionally they are painful or cause pathologic fractures. On x-ray imaging, the unmineralized nodules of cartilage produce well-circumscribed oval lucencies surrounded by thin rims of radiodense bone (*O-ring sign*). Calcified matrix manifests as irregular opacities. The growth potential of chondromas is limited, and most remain stable, although they can recur if incompletely excised. Solitary chondromas rarely undergo malignant transformation, but those associated with enchondromatoses are at increased risk for such change. Maffucci syndrome is associated with an increased risk for development of other types of malignancies, including ovarian carcinomas and brain gliomas.

### *Chondrosarcoma*

Chondrosarcoma is a malignant connective tissue tumor (sarcoma) whose cells manufacture and secrete neoplastic cartilage matrix. It is subclassified according to site (e.g., *intramedullary* versus *juxtacortical*) and histologic variants (discussed next). Chondrosarcomas occur roughly half as frequently as osteosarcomas; most patients are age 40 or older, with men affected twice as frequently as women.

### MORPHOLOGY

**Conventional chondrosarcoma, the most common variant,** arises within the medullary cavity of the bone to form an expansile glistening mass that often erodes the cortex (Fig. 20–11, *A*). It is composed of malignant hyaline and myxoid cartilage. **Myxoid chondrosarcomas** are viscous and gelatinous in consistency, and the matrix oozes from the cut surface. The adjacent cortex is thickened or eroded, and the tumor grows with broad pushing fronts into marrow spaces and the surrounding soft tissue. Tumor grade is determined by cellularity, degree of cytologic atypia, and mitotic activity (Fig. 20–11, *B*). Low-grade tumors may be difficult to distinguish from enchondroma. Higher-grade lesions contain pleomorphic chondrocytes with frequent mitotic figures.

Approximately 10% of patients with conventional low-grade chondrosarcomas have a second high-grade poorly differentiated component **(dedifferentiated chondrosarcomas)** that includes foci of fibro- or osteosarcomas. Other histologic variants include **clear cell** and **mesenchymal chondrosarcomas.**

Clinical Features

Chondrosarcomas commonly arise in the pelvis, shoulder, and ribs; in contrast with enchondromas, chondrosarcomas rarely involve the distal extremities. They typically manifest as painful, progressively enlarging masses. A slowly growing low-grade tumor causes reactive thickening of the cortex, whereas a more aggressive high-grade neoplasm destroys the cortex and forms a soft tissue mass; consequently, the more radiolucent the tumor the greater the likelihood that it is high grade. There is also a direct correlation between grade and biologic behavior of the tumor. Fortunately, most conventional chondrosarcomas are indolent and low-grade, with a 5-year survival rate of 80% to 90% (versus 43% for grade 3 tumors); grade 1 tumors rarely

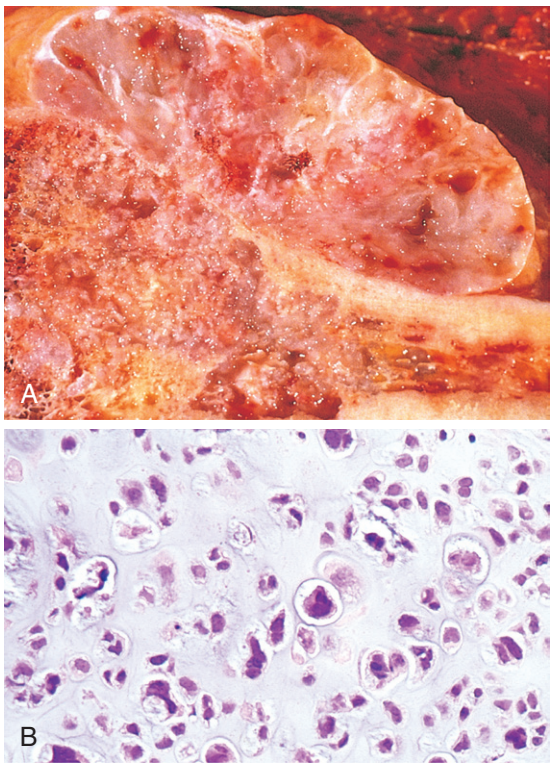

**Figure 20–11** Chondrosarcoma. **A,** Islands of hyaline and myxoid cartilage expand the medullary cavity and grow through the cortex to form a sessile paracortical mass. **B,** Anaplastic chondrocytes within a chondroid matrix.

metastasize, whereas 70% of the grade 3 tumors disseminate. Size is another prognostic feature, with tumors larger than 10 cm being significantly more aggressive than smaller tumors. Chondrosarcomas metastasize hematogenously, preferentially to the lungs and skeleton. Conventional chondrosarcomas are treated with wide surgical excision; chemotherapy is added for the mesenchymal and dedifferentiated variants because of their aggressive clinical course.

## Fibrous and Fibroosseous Tumors

Fibrous tumors of the skeleton are extremely common and exhibit a wide diversity of morphologic variants.

### *Fibrous Cortical Defect and Nonossifying Fibroma*

*Fibrous cortical defects* are probably developmental abnormalities rather than true neoplasms. The vast majority are smaller than 0.5 cm in diameter and arise eccentrically in the metaphysis of the distal femur or proximal tibia; almost 50% are bilateral or multiple. Larger lesions (5 to 6 cm) develop into *nonossifying fibromas.*

#### MORPHOLOGY

Fibrous cortical defects and nonossifying fibromas both manifest as sharply demarcated radiolucencies surrounded by a thin zone of sclerosis. On gross inspection, they are gray to yellow-brown; microscopic examination shows cellular lesions composed of cytologically benign fibroblasts and activated macrophages, including multinucleate forms. The fibroblasts classically exhibit a storiform (pinwheel) pattern (Fig. 20–12). Hemorrhage and hemosiderin deposits are a common finding.

#### Clinical Features

Fibrous cortical defects are asymptomatic and typically are detected only as incidental radiographic lesions. The usual clinical course is characterized by spontaneous differentiation into normal cortical bone within a few years, so as a rule, biopsy is not required. The few that enlarge into nonossifying fibromas can manifest with pathologic fracture; in such cases, biopsy is necessary to rule out other tumors.

### *Fibrous Dysplasia*

Fibrous dysplasia is a benign tumor in which all components of normal bone are present, but they fail to differentiate into mature structures. Fibrous dysplasia manifests with one of three clinical patterns: (1) involvement of a single bone (monostotic); (2) involvement of multiple bones (polyostotic); and (3) polyostotic disease, associated with café au lait skin pigmentations and endocrine abnormalities, especially precocious puberty (*McCune-Albright syndrome*). Mutations of the *GNAS* gene, resulting in a constitutively active $G_s$ protein (Chapter 2), are responsible for all forms of fibrous dysplasia. The mutation occurs during embryogenesis (somatic mutations) resulting in mosaicism in the fetus and adult. The extent of manifestation (mono-ostotic, polyostotic, or McCune-Albright syndrome) depends on (1) the stage of embryogenesis when the mutation is acquired and (2) the fate of the cell harboring the initial mutation.

*Monostotic fibrous dysplasia* accounts for 70% of cases. The tumor usually arises during the second and third decades of life; there is no gender predilection. In descending order of frequency, ribs, femur, tibia, jawbones, calvariae, and humerus are most commonly affected. Lesions often are asymptomatic and frequently are discovered incidentally. However, fibrous dysplasia can cause marked enlargement

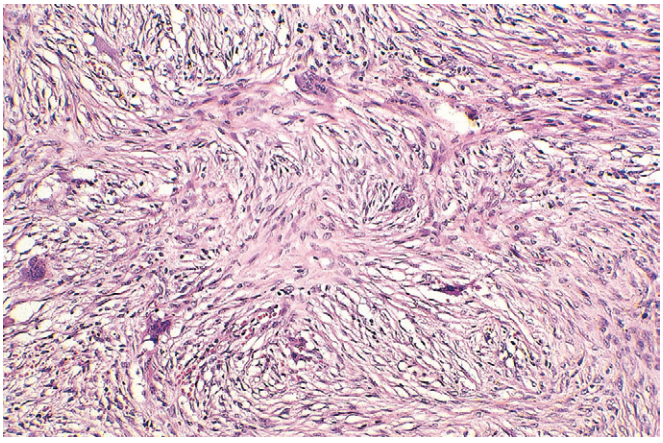

**Figure 20–12** Fibrous cortical defect or nonossifying fibroma. Characteristic storiform pattern of spindle cells interspersed with scattered osteoclast-type giant cells.

and distortion of bone, so that if the face or skull is involved, disfigurement can occur, or it can cause pain and pathologic fracture.

*Polyostotic fibrous dysplasia without endocrine dysfunction* accounts for a majority of the remaining cases. It manifests at a slightly earlier age than that for the monostotic type. In descending order of frequency, femur, skull, tibia, and humerus are most commonly involved. Craniofacial involvement is present in 50% of patients with moderate skeletal involvement and in 100% of patients with extensive skeletal disease. Polyostotic disease tends to involve the shoulder and pelvic girdles, resulting in severe deformities and spontaneous fractures.

*McCune-Albright syndrome* accounts for 3% of all cases. The associated endocrinopathies include sexual precocity (girls more often than boys), hyperthyroidism, growth hormone–secreting pituitary adenomas, and primary adrenal hyperplasia. The severity of manifestations depends on the number and cell types that harbor the G protein mutation. The bone lesions may be unilateral, and the skin pigmentation usually is limited to the same side of the body. The cutaneous macules classically are large, dark to light brown (*café au lait*), and irregular in configuration.

### MORPHOLOGY

On gross inspection, fibrous dysplasia is characterized by well-circumscribed, intramedullary lesions of varying sizes; large masses expand and distort the bone. Lesional tissue is tan-white and gritty-appearing; on microscopic examination, it exhibits curved trabeculae of woven bone (mimicking Chinese characters), without osteoblastic rimming, surrounded by a moderately cellular fibroblastic proliferation (Fig. 20–13).

#### Clinical Course

The natural history depends on the extent of skeletal involvement; patients with monostotic disease usually have minimal symptoms. On x-ray imaging, lesions exhibit a characteristic ground glass appearance with well-defined margins. Symptomatic lesions are readily cured by conservative surgery. Polyostotic involvement frequently is associated with progressive disease and more severe skeletal complications (e.g., fractures, long bone deformities, craniofacial distortion). Rarely, polyostotic disease can transform into osteosarcoma, *especially after radiotherapy*.

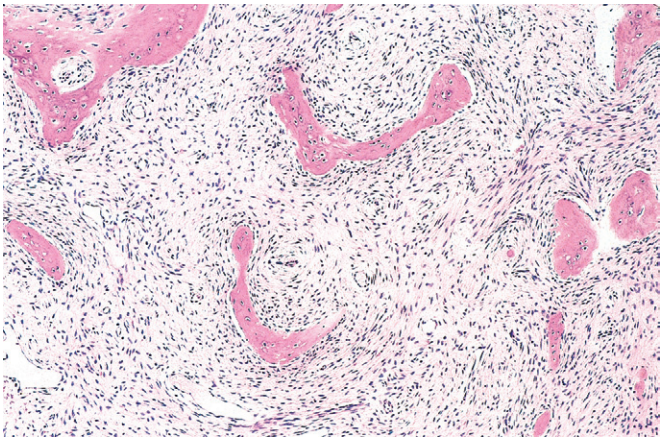

**Figure 20–13** Fibrous dysplasia. Curved trabeculae of woven bone arising in a fibrous tissue. Note the absence of osteoblasts rimming the bones.

## Miscellaneous Bone Tumors

### *Ewing Sarcoma and Primitive Neuroectodermal Tumor*

Ewing sarcoma and primitive neuroectodermal tumors (PNETs) are primary malignant small round cell tumors of bone and soft tissue. They share certain molecular features (described below) and are best viewed as variants of the same tumor, differing only in degree of neuroectodermal differentiation and clinical features. PNETs demonstrate clear neural differentiation, whereas Ewing sarcomas are undifferentiated.

Ewing sarcoma accounts for 6% to 10% of primary malignant bone tumors. After osteosarcoma, it is the second most common pediatric bone sarcoma. Most patients are 10 to 15 years of age, and 80% are younger than 20 years. Boys are affected slightly more frequently than girls, and there is a striking racial predilection for whites; blacks and Asians are rarely afflicted. The common chromosomal abnormality is a translocation that causes fusion of the *EWS* gene on 22q12 with a member of the *ETS* family of transcription factors. The most common fusion partners are the *FL1* gene on 11q24 and the *ERG* gene on 21q22. The resulting chimeric protein functions as a transcription factor, but precisely how it contributes to oncogenesis remains uncertain; effects on differentiation, proliferation, and survival have all been proposed. At a practical level, these translocations are of diagnostic importance, as approximately 95% of tumors have t(11;22)(q24;q12) or t(21;22)(q22;q12).

### MORPHOLOGY

Ewing sarcoma/PNET arises in the medullary cavity and invades the cortex and periosteum to produce a soft tan-white tumor mass, frequently with hemorrhage and necrosis. It is composed of sheets of uniform small, round cells that are slightly larger than lymphocytes; typically, there are few mitotic figures and little intervening stroma (Fig. 20–14). The cells have scant glycogen-rich cytoplasm. The presence of **Homer-Wright rosettes** (tumor cells circled about a central fibrillary space) indicates neural differentiation.

#### Clinical Features

Ewing sarcoma/PNET typically manifests as a painful enlarging mass in the diaphyses of long tubular bones (especially the femur) and the pelvic flat bones. Some patients have systemic signs and symptoms suggestive of infection. Imaging studies show a destructive lytic tumor with infiltrative margins and extension into surrounding soft tissues. There is a characteristic periosteal reaction with deposition of bone in an onion-skin pattern.

Treatment includes chemotherapy and surgical excision with or without irradiation. The 5-year survival rate is currently 75% for patients presenting with localized tumors.

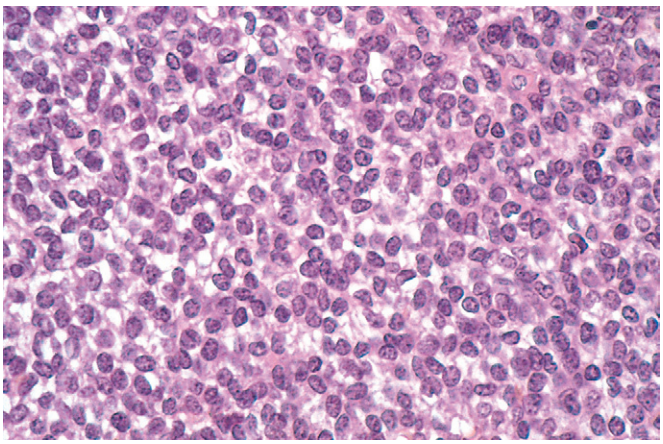

**Figure 20–14** Ewing sarcoma. Sheets of small round cells with scant, clear cytoplasm.

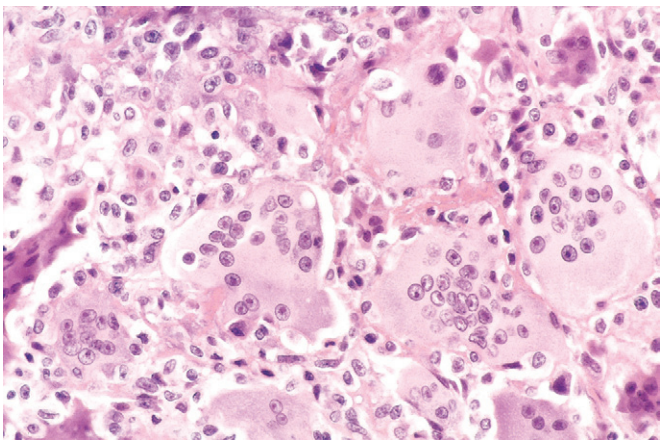

**Figure 20–15** Benign giant cell tumor showing abundant multinucleate giant cells and a background of mononuclear cells.

### *Giant Cell Tumor of Bone*

Giant cell tumors (GCTs) contain prominent by multinucleate osteoclast-type giant cells—hence the synonym *osteoclastoma.* GCT is a relatively common benign but locally aggressive bone tumor, usually arising in persons in their 20s to 40s. Despite the name, molecular analyses have shown that it is the mononuclear cells in the tumor that are neoplastic. These cells may be related to osteoblast precursor cells, as they express RANK ligand, which may stimulate the development of surrounding non-neoplastic osteoclast-like cells.

#### MORPHOLOGY

GCTs are large and red-brown, and often show cystic degeneration. They are composed of uniform oval mononuclear cells and scattered osteoclast-type giant cells containing 100 or more nuclei (Fig. 20–15). Mitotic figures are typically frequent. Necrosis, hemorrhage, and reactive bone formation also are commonly present.

#### Clinical Course

Although almost any bone may be involved, a majority of GCTs arise in the epiphysis and involve the metaphysis of long bones around the knee (distal femur and proximal tibia), frequently causing pain. Occasionally, GCTs manifest with pathologic fractures. Most are solitary tumors. Radiographically, GCTs are large, purely lytic, and eccentric; the overlying cortex frequently is destroyed, producing a bulging soft tissue mass with a thin shell of reactive bone. Although GCTs are considered benign, roughly half recur after simple curettage, and as many as 2% spread to the lungs as localized lesions that are cured by local excision.

### *Metastatic Disease*

*Metastatic tumors are the most common malignant tumors involving bone.* Pathways of spread include (1) direct extension, (2) lymphatic or hematogenous dissemination, and (3) intraspinal seeding. Any cancer can spread to bone, but certain tumors exhibit a distinct skeletal predilection. In adults more than 75% of skeletal metastases originate from cancers of the prostate, breast, kidney, and lung. In children, neuroblastoma, Wilms tumor, osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma are the common sources of bony metastases.

Most metastases involve the axial skeleton (vertebral column, pelvis, ribs, skull, sternum), proximal femur, and humerus, in descending order. The red marrow in these areas, with its rich capillary network, slow blood flow, and nutrient environment rich in growth factors, facilitates tumor cell implantation and growth.

The radiologic appearance of metastases can be purely lytic, purely blastic, or both. In lytic lesions (e.g., with kidney and lung tumors and melanoma), the metastatic cells secrete substances such as prostaglandins, interleukins, and PTH-related protein (PTHrP) that stimulate osteoclastic bone resorption; the tumor cells themselves do not directly resorb bone. Similarly, metastatic tumors that elicit an osteoblastic response (e.g., prostate adenocarcinoma) do so by stimulating osteoblastic bone formation. Most metastases induce a mixed lytic and blastic reaction.

#### SUMMARY

##### Bone Tumors

- Most bone tumors are categorized according to their normal tissue counterpart; chondroid and bony matrices are roughly equally represented. Benign lesions far outnumber malignant tumors. Metastatic tumors are the most common form of skeletal malignancy.
- Major tumor types can be subdivided as follows:
  - Benign neoplasms
    - Fibrous cortical defect/nonossifying fibroma—spindle cells arranged in storiform pattern
    - Fibrous dysplasia—curvilinear trabeculae of woven bone surrounded by benign fibroblasts
    - Osteoid osteoma—islands of woven bone, typically involving the proximal femur or tibia
    - Osteochondroma—cartilage-capped outgrowths at epiphyseal growth plates

- Enchondroma—nodules of hyaline cartilage
- Giant cell tumor—composed of a mixture of neoplastic mononuclear cells and reactive osteoclast-like giant cells, typically occupying long bone epiphyses
- Malignant neoplasms
  - Osteosarcoma—malignant mesenchymal tumor forming bone; 20% of primary bone tumors
  - Chondrosarcoma—malignant mesenchymal tumor forming cartilage
  - Ewing sarcoma—aggressive small round cell tumor of adolescents with EWS gene rearrangements.

# JOINTS

The joints are subject to a wide variety of disorders, including degeneration, infections, immune-mediated injury, metabolic derangements, and neoplasms. Discussed in this section are the most common forms of arthritis—namely, osteoarthritis or degenerative joint disease, select autoimmune arthritides, gout, and infectious arthritis—along with the two most common benign joint tumors.

## ARTHRITIS

### Osteoarthritis

*Osteoarthritis,* or *degenerative joint disease,* is the most common joint disorder. It is a frequent, if not inevitable, part of aging and is an important cause of physical disability in persons older than 65 years of age. *The fundamental feature of osteoarthritis is degeneration of the articular cartilage;* structural changes in the underlying bone are likely secondary. Although the term *osteoarthritis* implies an inflammatory disease, osteoarthritis is primarily a degenerative disorder of articular cartilage in which the chondrocytes respond to biomechanical and biologic stresses in a way that results in breakdown of the matrix.

In most cases, osteoarthritis appears insidiously with age and without apparent initiating cause (*primary osteoarthritis*). In such cases the disease usually is *oligoarticular* (i.e., affecting only a few joints), with the joints of the hands, knees, hips, and spine most commonly affected. In the unusual circumstance (less than 5% of cases) when osteoarthritis strikes in youth, there is typically some predisposing condition, such as previous trauma, developmental deformity, or underlying systemic disease such as ochronosis, hemochromatosis, or marked obesity. In these settings the disease is called *secondary osteoarthritis* and often involves one or several predisposed joints. Gender has some influence; knees and hands are more commonly affected in women, whereas hips are more commonly affected in men. It is estimated that the economic toll of osteoarthritis in the United States is more than $33 billion annually.

#### MORPHOLOGY

The early changes in osteoarthritis include alterations in the composition and structure of the matrix. The chondrocytes have limited capacity to proliferate, and some divide to form small clones of cells that secrete newly synthesized matrix. Subsequently, vertical and horizontal **fibrillation and cracking of the matrix** occur as the superficial layers of the cartilage are degraded (Fig. 20–16, *A*). Gross examination at this stage reveals a soft granular-appearing articular cartilage surface, a condition known as **chondromalacia.** Eventually, full-thickness portions of the cartilage are lost, and the subchondral bone plate is exposed and is smoothened and burnished by friction, giving it the appearance of polished ivory **(bone eburnation)** (Fig. 20–16, *B*). The underlying cancellous bone becomes rebuttressed by osteoblastic activity. Small fractures can dislodge pieces of cartilage and subchondral bone into the joint, forming loose bodies

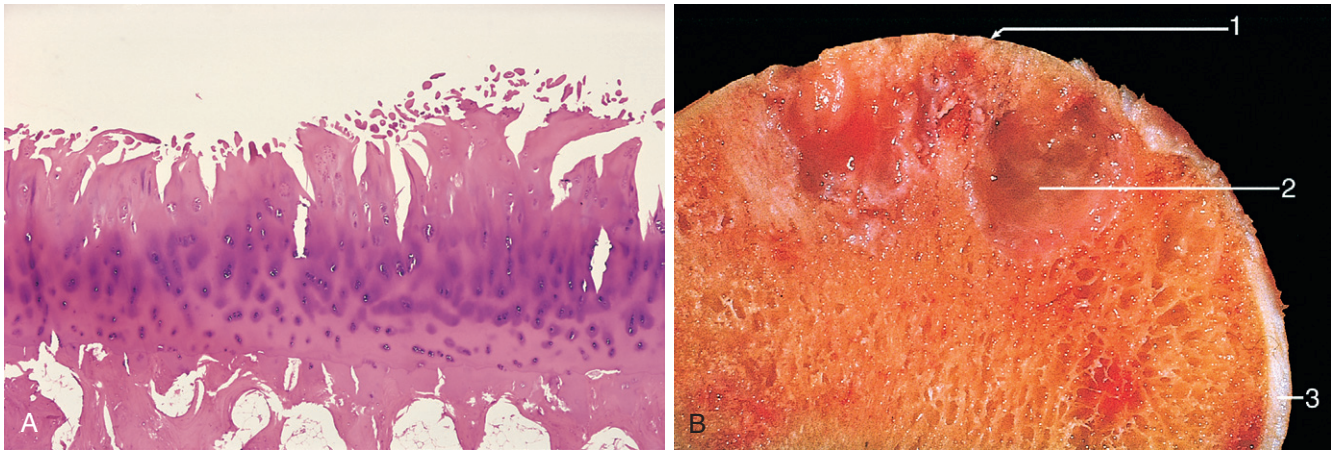

**Figure 20–16** Osteoarthritis. **A,** Histologic demonstration of the characteristic fibrillation of the articular cartilage. **B,** Severe osteoarthritis, with eburnated articular surface exposing subchondral bone (*1*), subchondral cyst (*2*), and residual articular cartilage (*3*).

**(joint mice).** The fracture gaps allow synovial fluid to be forced into the subchondral regions to form fibrous walled cysts. Mushroom-shaped **osteophytes** (bony outgrowths) develop at the margins of the articular surface. In severe disease, a fibrous synovial **pannus** covers the peripheral portions of the articular surface.

## PATHOGENESIS

**Articular cartilage bears the brunt of the degenerative changes in osteoarthritis.** Normal articular cartilage performs two functions: (1) Along with the synovial fluid, it provides virtually friction-free movement within the joint; and (2) in weight-bearing joints, it spreads the load across the joint surface in a manner that allows the underlying bones to absorb shock and weight. These functions require the cartilage to be elastic (i.e., to regain normal architecture after compression) and to have high tensile strength. These attributes are provided by proteoglycans and type II collagen, respectively, both produced by chondrocytes. As with adult bone, articular cartilage constantly undergoes matrix degradation and replacement. Normal chondrocyte function is critical to maintain cartilage synthesis and degradation; any imbalance can lead to osteoarthritis.

Chondrocyte function is affected by a variety of influences. Although osteoarthritis is not exclusively a wear-and-tear phenomenon, mechanical stresses and aging nevertheless figure prominently. **Genetic factors,** including polymorphisms and mutations in genes encoding components of the matrix and signaling molecules, contribute to osteoarthritis susceptibility. The risk of osteoarthritis also is increased with increasing bone density, as well as sustained high estrogen levels.

Regardless of the inciting stimulus, there is an imbalance in the expression, activity, and signaling of cytokines and growth factors that results in degradation and loss of matrix.

Early osteoarthritis is marked by degenerating cartilage containing more water and less proteoglycan (the proteoglycan component conveys turgor and elasticity). The type II collagen network also is diminished, presumably as a result of decreased local synthesis and increased breakdown; chondrocyte apoptosis is increased. Overall, cartilage tensile strength and resilience are compromised. In response to these degenerative changes, chondrocytes proliferate and attempt to "repair" the damage by synthesizing new collagen and proteoglycans. Although these reparative changes initially are able to keep pace, matrix changes and chondrocyte loss eventually predominate.

### Clinical Course

Osteoarthritis is an insidious disease, predominantly affecting patients beginning in their 50s and 60s. Characteristic symptoms and signs include deep, aching pain exacerbated by use, morning stiffness, crepitus (grating or popping sensation in the joint), and limitation in range of movement. Osteophyte impingement on spinal foramina can cause nerve root compression with radicular pain, muscle spasms, muscle atrophy, and neurologic deficits. Hips, knees, lower lumbar and cervical vertebrae, proximal and distal interphalangeal joints of the fingers, first carpometacarpal joints, and first tarsometatarsal joints of the feet are commonly involved. *Heberden nodes* in the fingers, representing prominent osteophytes at the distal interphalangeal joints, are characteristic in women. Aside from complete inactivity, there is no predicted way to prevent or halt the progression of primary osteoarthritis; it can stabilize for years but generally is slowly progressive. With time, significant joint deformity can occur, but unlike in rheumatoid arthritis (discussed next), fusion does not take place. Treatment usually is based on symptoms, with joint replacement in severe cases. A comparison of the important morphologic features of these two disorders is presented in Figure 20–17.

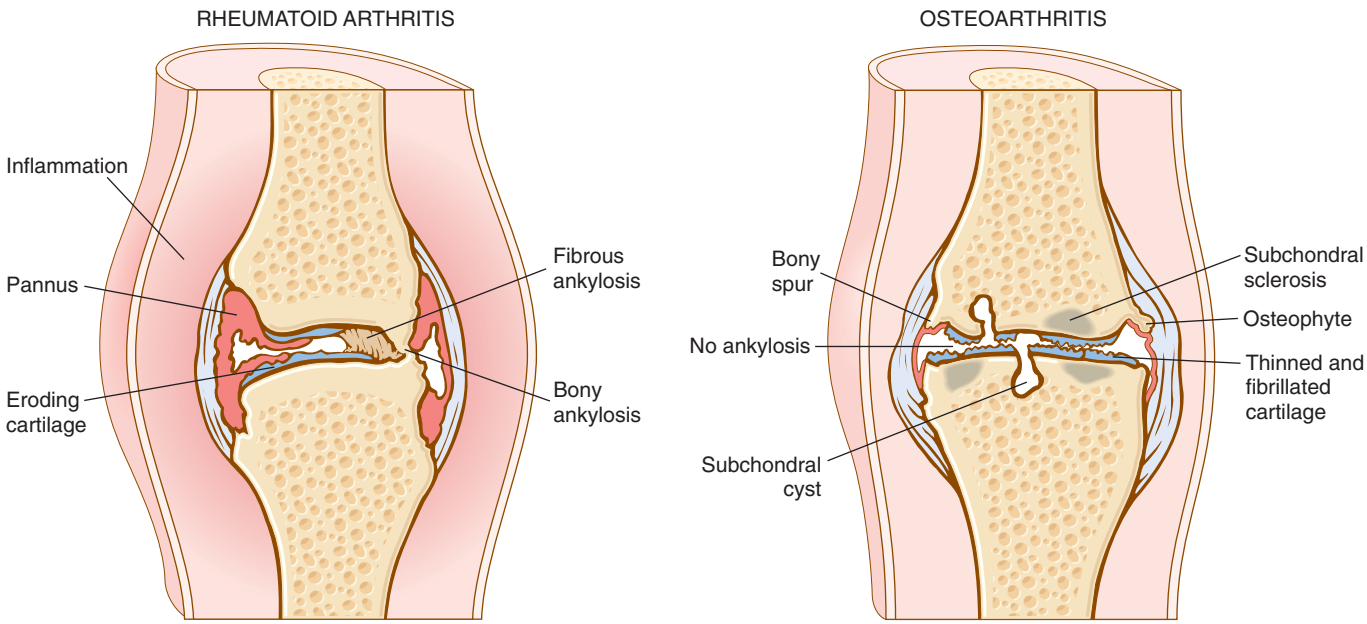

**Figure 20–17** Comparison of the morphologic features of rheumatoid arthritis (RA) and osteoarthritis.

## Rheumatoid Arthritis

*Rheumatoid arthritis (RA)* is a systemic, chronic inflammatory autoimmune disease affecting many tissues but principally attacking the joints. It causes a nonsuppurative proliferative synovitis that frequently progresses to destroy articular cartilage and underlying bone with resulting disabling arthritis. When extraarticular involvement develops—for example, of the skin, heart, blood vessels, muscles, and lungs—RA may resemble lupus or scleroderma.

RA is a relatively common condition, with a prevalence of approximately 1%; it is three to five times more common in women than in men. The peak incidence is in the second to fourth decades of life, but no age is immune.

### PATHOGENESIS

RA is an autoimmune disease involving complex, and still poorly understood, interactions of genetic risk factors, environment, and the immune system. The pathologic changes are caused mainly by **cytokine-mediated inflammation, with CD4+ T cells being the principal source of the cytokines** (Fig. 20–18). Many patients also produce **antibodies against cyclic citrullinated peptides (CCPs),** which may contribute to the joint lesions. CCPs are derived from proteins in which arginine residues are converted to citrulline residues posttranslationally. In RA, antibodies to citrullinated fibrinogen, type II collagen, α-enolase, and vimentin are the most important and may form immune complexes that deposit in the joints. These antibodies are a diagnostic marker for the disease and may be involved in tissue injury.

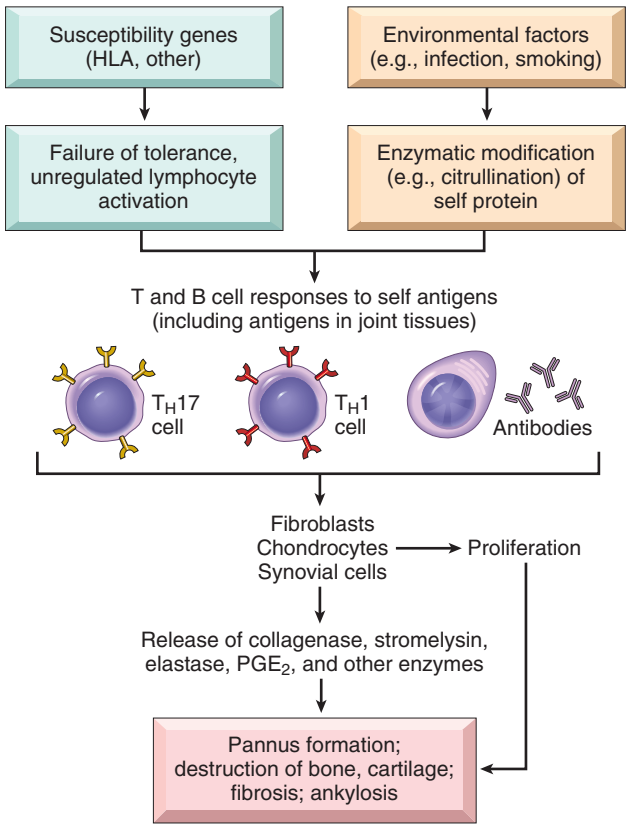

**Figure 20–18** Major processes involved in pathogenesis of rheumatoid arthritis.

Like other autoimmune diseases, RA is a disorder in which genetic and environmental factors contribute to the breakdown of tolerance to self-antigens.

- **Genetic factors:** It is estimated that 50% of the risk of developing RA is related to genetic factors. Susceptibility to rheumatoid arthritis is linked to the HLA-DRB1 locus. Recent linkage and genome-wide association studies have revealed a large number of non-HLA genes in which polymorphisms are associated with RA. There is a strong association with a polymorphism in the *PTPN22* gene, which encodes a tyrosine phosphatase that is postulated to inhibit T cell activation.
- **Environmental factors:** Many candidate infectious agents whose antigens may activate T or B cells have been considered, but none has been conclusively implicated. As mentioned above, in at least 70% of patients the blood contains anti-CCP antibody, which may be produced during inflammation. Inflammatory and environmental insults such as smoking and infections may induce the citrullination of some self proteins, creating new epitopes that trigger autoimmune reactions.

It is proposed that the disease is initiated in a genetically predisposed person by activation of CD4+ helper T cells responding to some arthritogenic agent, possibly microbial, or to a self-antigen such as CCP (Fig. 20–18). CD4+ $T_H1$ and $T_H17$ cells, activated B lymphocytes, plasma cells, and macrophages, as well as other inflammatory cells, are found in the inflamed synovium, and in severe cases, well-formed lymphoid follicles with germinal centers may be present. Numerous cytokines, including IL-1, IL-8, TNF, IL-6, IL-17, and interferon-γ, have been detected in the synovial fluid. Cytokines produced by the activated T cells recruit leukocytes such as macrophages, whose products cause tissue injury, and also activate resident synovial cells to produce proteolytic enzymes, such as collagenase, that mediate destruction of the cartilage, ligaments, and tendons of the joints. Increased osteoclast activity in the joints contributes to the bone destruction in rheumatoid arthritis; this may be caused by the production of the TNF family cytokine RANK ligand by activated T cells. Despite the plethora of cytokines produced in the joint in RA, TNF appears to play a pivotal role. This is demonstrated by the remarkable effectiveness of TNF antagonists in patients with the disease, even those who are resistant to other therapies.

It is suspected from a variety of experimental and clinical observations that antibodies also play a role in the disease. The contribution of anti-CCP was previously mentioned. About 80% of patients have serum immunoglobulin M (IgM) (and, less frequently, IgA) autoantibodies that bind to the Fc portions of their own (self) IgG. These autoantibodies are called **rheumatoid factor.** They may form immune complexes with self-IgG that deposit in joints and other tissues, leading to inflammation and tissue damage. However, the role of rheumatoid factor in the pathogenesis of the joint or extraarticular lesions has not been established. Of interest, there seem to be two variants of RA, one characterized by presence of anti-CCP and rheumatoid factor and another in which these autoantibodies are lacking.

## MORPHOLOGY

A broad spectrum of morphologic alterations are seen in RA; the most severe occur in the joints. RA typically manifests as **symmetric arthritis, principally affecting the small joints** of the hands and feet, ankles, knees, wrists, elbows, and shoulders. Most often, the proximal interphalangeal and metacarpophalangeal joints are affected, but distal interphalangeal joints are spared. Axial involvement, when it occurs, is limited to the upper cervical spine; similarly, hip joint involvement is extremely uncommon. On histologic examination, the affected joints show **chronic papillary synovitis,** characterized by (1) synovial cell hyperplasia and proliferation; (2) dense perivascular inflammatory cell infiltrates (frequently forming lymphoid follicles) in the synovium composed of CD4+ T cells, plasma cells, and macrophages; (3) increased vascularity due to angiogenesis; (4) neutrophils and aggregates of organizing fibrin on the synovial surface and in the joint space; and (5) increased osteoclast activity in the underlying bone, leading to synovial penetration and periarticular bone erosion. The classic appearance is that of a **pannus,** formed by proliferating synovial lining cells admixed with inflammatory cells, granulation tissue, and fibrous connective tissue; the overgrowth of this tissue is so exuberant that the usually thin, smooth synovial membrane is transformed into lush, edematous, frondlike (villous) projections (Fig. 20–19, *A–C*). With full-blown inflammatory joint involvement, periarticular soft tissue edema usually develops, classically manifested first by fusiform swelling of the proximal interphalangeal joints. With progression of the disease, the articular cartilage subjacent to the pannus is eroded and, in time, virtually destroyed. The subarticular bone also may be attacked and eroded. Eventually the pannus fills the joint space, and subsequent **fibrosis and ossification** may cause permanent **ankylosis.** The radiographic hallmarks are joint effusions and juxtaarticular osteopenia with erosions and narrowing of the joint space and loss of articular cartilage. Destruction of tendons, ligaments, and joint capsules produces the characteristic deformities, including radial deviation of the wrist, ulnar deviation of the fingers, and flexion-hyperextension abnormalities of the fingers (swan-neck deformity, boutonnière deformity).

**Rheumatoid subcutaneous nodules** develop in about one fourth of patients, occurring along the extensor surface of the forearm or other areas subjected to mechanical pressure; rarely, they can form in the lungs, spleen, heart, aorta, and other viscera. Rheumatoid nodules are firm, nontender, oval or rounded masses as large as 2 cm in diameter. They are characterized microscopically by a central focus of fibrinoid necrosis surrounded by a palisade of macrophages, which in turn is rimmed by granulation tissue and lymphocytes (Fig. 20–20).

Patients with severe erosive disease, rheumatoid nodules, and high titers of **rheumatoid factor** are at risk of developing vasculitic syndromes; acute necrotizing vasculitis may involve small or large arteries. Serosal involvement may manifest as fibrinous pleuritis or pericarditis or both. Lung parenchyma may be damaged by progressive interstitial fibrosis. Ocular changes such as uveitis and keratoconjunctivitis (similar to those seen in Sjögren syndrome; see Chapter 4) may be prominent in some cases.

### Clinical Features

Although RA is basically a symmetric polyarticular arthritis, there also may be constitutional symptoms such as weakness, malaise, and low-grade fever. Many of the systemic manifestations result from the same mediators that cause joint inflammation (e.g., IL-1, TNF). The arthritis first appears insidiously, with aching and stiffness of the joints, particularly in the morning. As the disease advances, the joints become enlarged, motion is limited, and in time complete ankylosis may appear. Vasculitic involvement of the extremities may give rise to Raynaud phenomenon and

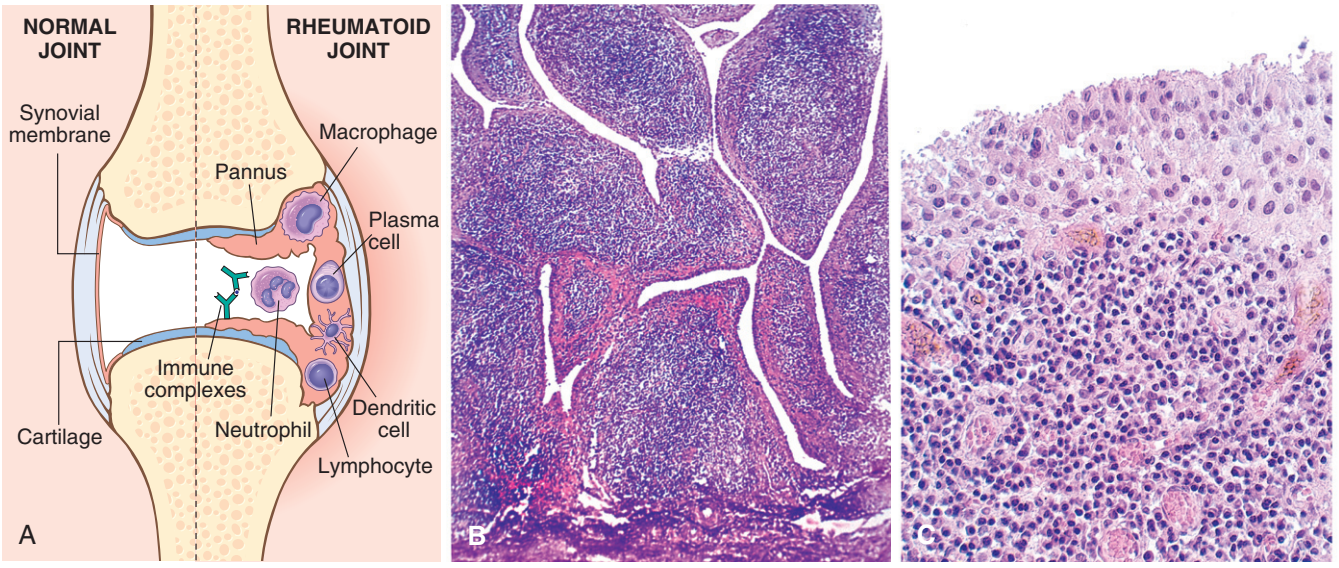

**Figure 20–19** Rheumatoid arthritis. **A,** A joint lesion. **B,** Synovium demonstrating papillary hyperplasia caused by dense inflammatory infiltrate. **C,** Hypertrophied synoviocytes with numerous underlying lymphocytes and plasma cells.

chronic leg ulcers. Such multisystem involvement must be distinguished from lupus, scleroderma, polymyositis, dermatomyositis, and Lyme disease, as well as other forms of arthritis. Helpful in making the correct diagnosis are (1) characteristic radiographic findings; (2) sterile, turbid synovial fluid with decreased viscosity, poor mucin clot formation, and inclusion-bearing neutrophils; and (3) anti-CCP and rheumatoid factor (80% of patients).

The clinical course of RA is highly variable. In a minority of patients, the disease may stabilize or even regress; in most patients, however, it pursues a chronic, remitting-relapsing course. Historically, the natural history of the disease has been one of progressive joint destruction leading to disability after 10 to 15 years. The outcome has been dramatically improved by recent advances in therapy, including aggressive treatment of early RA and the introduction of highly effective biologic agents that antagonize TNF. RA is an important cause of reactive amyloidosis (Chapter 4), which develops in 5% to 10% of these patients, particularly those with long-standing severe disease.

## Juvenile Rheumatoid Arthritis

*Juvenile rheumatoid arthritis* (JRA) is not a single disease but a group of multifactorial disorders with environmental and genetic components. These disorders are of unknown etiology and are classified according to their presentation into oligoarthritis, polyarthritis, and systemic (Still's disease) variants. Large joints often are affected, and symptoms and signs such as joint swelling, warmth, pain, and loss of function begin before the age of 16 years and persist for more than 6 weeks. Extraarticular inflammatory manifestations such as uveitis also may be present. Common risk factors include genetic susceptibility (such as particular HLA and PTPN22 gene variants) and perhaps infection. As in adult RA, the pathogenesis is likely to involve activation of $T_H1$ and $T_H17$ cells, which in turn activate B cells, macrophages, and fibroblasts to produce antibodies and a variety of cytokines including TNF, IL-1, and IL-6, which eventually result in damage to articular structures.

## Seronegative Spondyloarthropathies

Clinical, morphologic, and genetic features distinguish these disorders from rheumatoid arthritis and other arthritides. The spondyloarthropathies are characterized by the following:

- Pathologic changes that begin in the ligamentous attachments to bone rather than in the synovium
- Involvement of the sacroiliac joints, with or without arthritis in other peripheral joints
- Absence of rheumatoid factor (hence the designation *seronegative*)
- Association with HLA-B27

This group of disorders includes several clinical entities, of which ankylosing spondylitis is the prototype. Others include Reiter syndrome, psoriatic arthritis, spondylitis associated with inflammatory bowel diseases, and reactive arthropathies after infections (e.g., with *Yersinia, Shigella, Salmonella, Helicobacter,* or *Campylobacter*). Sacroiliitis is a common manifestation in all of these disorders; they are distinguished from one another by the particular peripheral joints involved, as well as on the basis of associated extraskeletal manifestations (for example, urethritis, conjunctivitis, and uveitis are characteristic of Reiter syndrome). Although triggering infections and immune mechanisms are thought to underlie most of the seronegative spondyloarthropathies, their pathogenesis remains obscure.

## Gout

Gout affects about 1% of the population, and shows a predeliction for males. It is caused by excessive amounts of *uric acid, an end product of purine metabolism, within tissues and body fluids.* Monosodium urate crystals precipitate from supersaturated body fluids and induce an acute inflammatory reaction. Gout is marked by recurrent episodes of acute arthritis, sometimes accompanied by the formation of large crystalline aggregates called *tophi,* and eventual permanent joint deformity. Although an elevated level of uric acid is an essential component of gout, not all such persons develop gout, and genetic and environmental factors also contribute to its pathogenesis. Gout traditionally is divided into primary and secondary forms, accounting for about 90% and 10% of cases, respectively (Table 20–3). *Primary gout* designates cases in which the basic cause is unknown or (less commonly) in which the disorder is due to an inborn metabolic defect that causes hyperuricemia. In *secondary gout,* the cause of the hyperuricemia is known, but gout is not necessarily the main or even dominant clinical disorder.

### MORPHOLOGY

The major morphologic manifestations of gout are acute arthritis, chronic tophaceous arthritis, tophi in various sites, and gouty nephropathy.

**Acute arthritis** is characterized by a dense neutrophilic infiltrate permeating the synovium and synovial fluid. Long, slender, needle-shaped **monosodium urate crystals**

**Table 20–3** Classification of Gout

| Clinical Category | Metabolic Defect |
|---|---|
| **Primary Gout (90% of cases)** | |
| Enzyme defects—unknown (85% to 90% of cases) | Overproduction of uric acid<br>Normal excretion (majority)<br>Increased excretion (minority)<br>Underexcretion of uric acid with normal production |
| Known enzyme defects—e.g., partial HGPRT deficiency (rare) | Overproduction of uric acid |
| **Secondary Gout (10% of cases)** | |
| Associated with increased nucleic acid turnover—e.g., leukemias | Overproduction of uric acid with increased urinary excretion |
| Chronic renal disease | Reduced excretion of uric acid with normal production |
| Inborn errors of metabolism | Overproduction of uric acid with increased urinary excretion, e.g., complete HGPRT deficiency (Lesch-Nyhan syndrome) |

HGPRT, hypoxanthine guanine phosphoribosyl transferase.

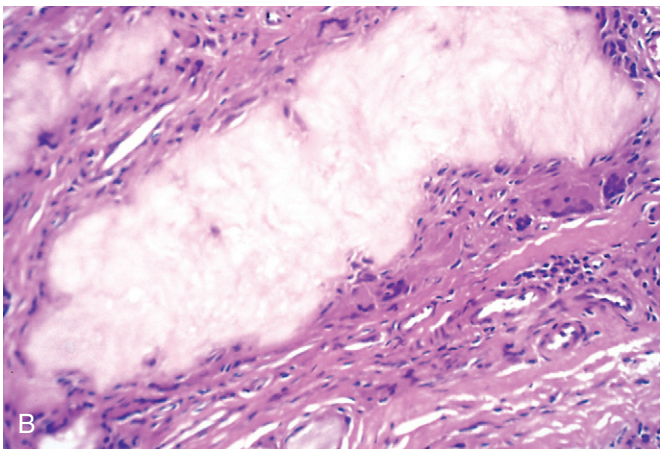

**Figure 20–21** Gout. **A,** Amputated great toe with white tophi involving the joint and soft tissues. **B,** Photomicrograph of a gouty tophus. An aggregate of dissolved urate crystals is surrounded by reactive fibroblasts, mononuclear inflammatory cells, and giant cells.

frequently are found in the cytoplasm of the neutrophils as well as in small clusters in the synovium. The synovium is edematous and congested and contains scattered mononuclear inflammatory cells. When the episode of crystallization abates and the crystals resolubilize, the attack remits.

**Chronic tophaceous arthritis** evolves from repetitive precipitation of urate crystals during acute attacks. The urates can heavily encrust the articular surfaces and form visible deposits in the synovium (Fig. 20–21, *A*). The synovium becomes hyperplastic, fibrotic, and thickened by inflammatory cells, forming a pannus that destroys the underlying cartilage, leading to juxtaarticular bone erosions. In severe cases, fibrous or bony ankylosis ensues, resulting in loss of joint function.

**Tophi are pathognomonic for gout.** They are formed by large aggregations of urate crystals surrounded by an intense inflammatory reaction of lymphocytes, macrophages, and foreign-body giant cells, attempting to engulf the masses of crystals (Fig. 20–21, *B*). Tophi can appear in the articular cartilage of joints and in the periarticular ligaments, tendons, and soft tissues, including the ear lobes, nasal cartilages, and skin of the fingertips. Superficial tophi can lead to large ulcerations of the overlying skin.

**Gouty nephropathy** refers to renal complications associated with urate deposition, variously forming medullary tophi, intratubular precipitations, or free uric acid crystals and renal calculi. Secondary complications such as pyelonephritis can occur, especially when there is urinary obstruction.

## PATHOGENESIS

Elevated uric acid levels can result from overproduction or reduced excretion of uric acid, or both (Table 20–3). Most cases of gout are characterized by a primary overproduction of uric acid. Less commonly, uric acid is produced at normal rates, and hyperuricemia occurs because of decreased renal excretion of urate. For an understanding of these influences, a brief review of normal uric acid synthesis and excretion is warranted.

- **Uric acid synthesis.** Uric acid is the end product of purine catabolism; consequently increased urate synthesis typically reflects some abnormality in purine nucleotide production. The synthesis of purine nucleotides involves two different but interlinked pathways: the de novo and salvage pathways.
- The **de novo pathway** is involved in the synthesis of purine nucleotides from nonpurine precursors.
- The **salvage pathway** is involved in the synthesis of purine nucleotides from free purine bases, derived from dietary intake and by catabolizing nucleic acids and purine nucleotides.
- **Uric acid excretion.** Circulating uric acid is freely filtered by the glomerulus and virtually completely resorbed in the proximal tubules of the kidney. A small fraction of the resorbed uric acid is subsequently secreted by the distal nephron and excreted in the urine.

Although the cause of excessive uric acid biosynthesis in **primary gout** is unknown in most cases, rare patients have identifiable enzymatic defects. For example, complete lack of

HGPRT, an enzyme essential in the salvage pathway, gives rise to the **Lesch-Nyhan syndrome.** In **secondary gout,** hyperuricemia can be caused by increased urate production (e.g., rapid cell lysis during chemotherapy for lymphoma or leukemia) or decreased excretion (chronic renal insufficiency), or both. Reduced renal excretion may also be caused by drugs such as thiazide diuretics, presumably because of effects on uric acid tubular transport.

Whatever the cause, increased levels of uric acid in the blood and other body fluids (e.g., synovium) lead to the precipitation of monosodium urate crystals. This, in turn, triggers a chain of events that culminate in joint injury (Fig. 20–22). Urate crystals are thought to directly activate the complement system, leading to production of chemotactic and pro-inflammatory mediators. The crystals are phagocytosed by macrophages and recognized by the intracellular sensor called the inflammasome (Chapter 2), which is activated and stimulates the production of the cytokine IL-1. IL-1 is a mediator of inflammation, and causes local accumulation of neutrophils and macrophages in the joints and synovial membranes. These cells become activated, leading to the release of a host of additional mediators including chemokines, other cytokines, toxic free radicals, and leukotrienes—particularly leukotriene $B_4$. The activated neutrophils also liberate destructive lysosomal enzymes. The cytokines can also directly activate synovial cells and cartilage cells to release proteases (e.g., collagenase) that exacerbate tissue injury. The resulting acute arthritis typically remits in days to weeks, even if untreated. Repeated bouts, however, can lead to the permanent damage seen in chronic tophaceous arthritis.

### Clinical Features

Gout is more common in men than in women; it does not usually cause symptoms before the age of 30. Risk factors for the disease include obesity, excess alcohol intake, consumption of purine-r ich foods, diabetes, the metabolic syndrome, and renal failure. Polymorphisms in genes involved in the transport and homeostasis of urate such as *URAT1* and *GLUT9* also are associated with hyperuricemia and gout.

Four stages are classically recognized: (1) asymptomatic hyperuricemia, (2) acute gouty arthritis, (3) "intercritical" gout, and (4) chronic tophaceous gout. *Asymptomatic hyperuricemia* appears around puberty in males and after menopause in women. After a long interval of years, *acute arthritis* appears in the form of sudden onset, excruciating joint pain associated with localized erythema, and warmth; constitutional symptoms are uncommon, except possibly mild fever. The vast majority of first attacks are monoarticular; 50% occur in the first metatarsophalangeal joint

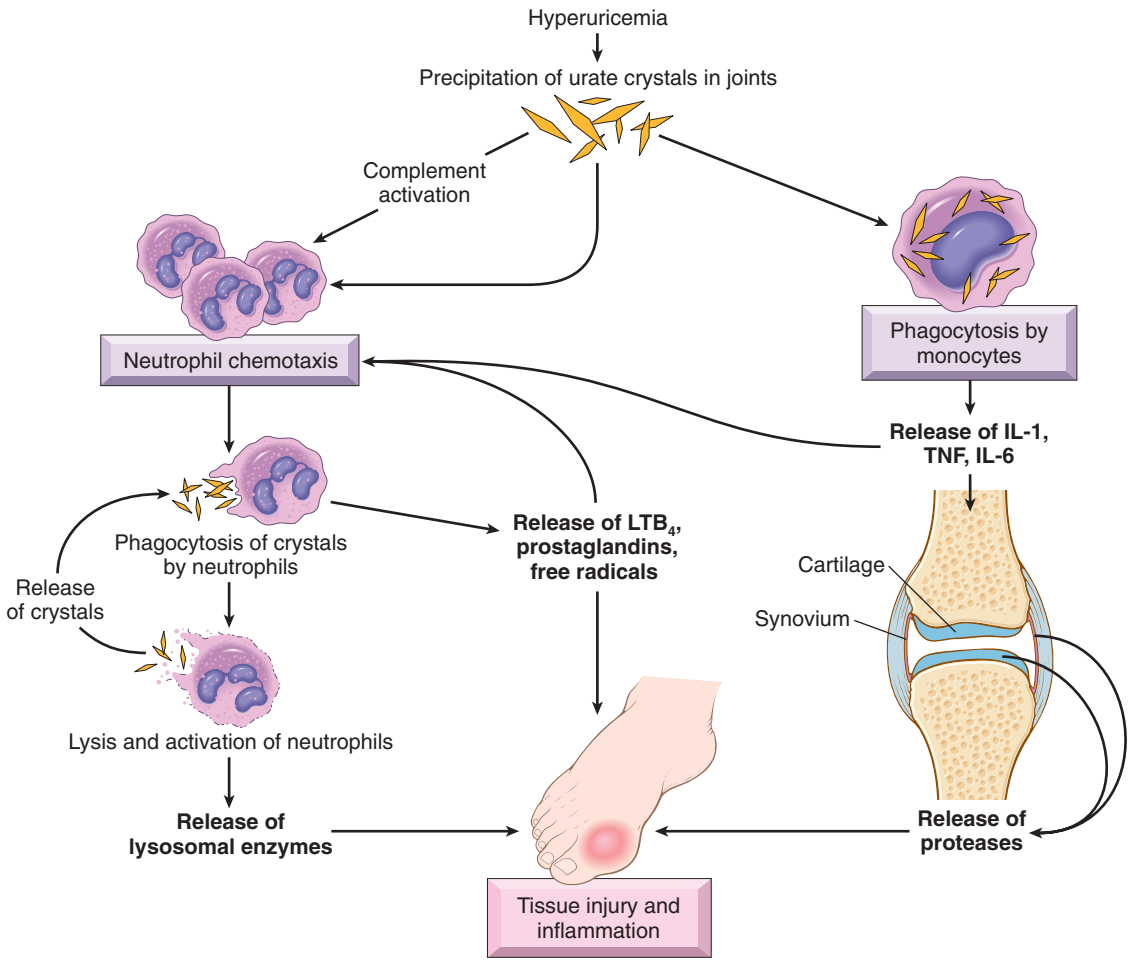

**Figure 20–22** Pathogenesis of acute gouty arthritis. IL, interleukin; $LTB_4$, leukotriene $B_4$; TNF, tumor necrosis factor.

(great toe), and 90% in the instep, ankle, heel, or wrist. Untreated, acute gouty arthritis may last for hours to weeks, but it gradually completely resolves, and the patient enters an *asymptomatic intercritical period.* Although some fortunate persons never have another attack, most experience a second episode within months to a few years. In the absence of appropriate therapy, the attacks recur at shorter intervals and frequently become polyarticular. Eventually, after a decade or so, symptoms fail to resolve completely after each attack, and the disease progresses to *chronic tophaceous gout.* At this stage, radiographs show characteristic juxtaarticular bone erosion caused by the crystal deposits and loss of the joint space. Progression leads to severe crippling disease.

Renal manifestations of gout can appear as renal colic associated with the passage of gravel and stones, and can evolve into chronic gouty nephropathy. About 20% of persons with chronic gout die of renal failure.

Numerous drugs are available to abort or prevent acute attacks of arthritis and mobilize tophaceous deposits. Their use is important, because many aspects of gout are related to the duration and severity of hyperuricemia. Generally, gout does not materially shorten the life span, but it can certainly impair quality of life.

## Pseudogout

*Pseudogout* also is known as *chondrocalcinosis* or, more formally, calcium pyrophosphate crystal deposition disease. The crystal deposits first appear in structures composed of cartilage such as menisci, intervertebral discs, and articular surfaces. When the deposits enlarge enough, they may rupture, inducing an inflammatory reaction. Pseudogout typically first occurs in persons 50 years of age or older, becoming more common with increasing age, and eventually reaching a prevalence of 30% to 60% in those age 85 or older. There is no gender or race predilection.

Although pathways leading to crystal formation are not understood, they are likely to involve the overproduction or decreased breakdown of pyrophosphate, resulting in its accumulation and eventual crystallization with calcium in the matrix surrounding chondrocytes. Mutations in a transmembrane pyrophosphate transporter are associated with a rare familial form of the disease, in which crystals develop relatively early in life and there is severe osteoarthritis.

Much of the subsequent joint pathology in pseudogout involves the recruitment and activation of inflammatory cells and is similar to that in gout (see earlier). Duration of clinical signs can be from several days to weeks, and joint involvement may be monoarticular or polyarticular; the knees, followed by the wrists, elbows, shoulders, and ankles, are most commonly affected. Ultimately, approximately 50% of patients experience significant joint damage. Therapy is supportive; no known treatment prevents or retards crystal formation.

## Infectious Arthritis

Microorganisms of any type can lodge in joints during hematogenous dissemination. Articular structures can also become infected by direct inoculation or by contiguous spread from osteomyelitis or a soft tissue abscess. Infectious arthritis is serious because it can cause rapid joint destruction and permanent deformities.

### *Suppurative Arthritis*

Bacteria can seed joints during episodes of bacteremia; joint infection with such microorganisms almost uniformly results in a suppurative arthritis. Although virtually any bacteria can be causal, *Haemophilus influenzae* predominates in children younger than 2 years of age, *S. aureus* is the main causative agent in older children and adults, and the gonococcus is prevalent in older adolescents and young adults. Patients with sickle cell disease are prone to *Salmonella* infection at any age. Both genders are affected equally, except for gonococcal arthritis, which occurs mainly in sexually active women. In this group, those with deficiency of certain complement proteins (C5, C6, and C7) are particularly susceptible to disseminated gonococcal infections and hence arthritis.

The classic presentation is one of sudden onset of pain, redness, and swelling of the affected joint(s), with restricted range of motion. Fever, leukocytosis, and elevated erythrocyte sedimentation rate are common. In gonococcal infections, the course tends to be more subacute. In 90% of cases of nongonococcal suppurative arthritis, the infection involves only a single joint—usually the knee—followed in order by hip, shoulder, elbow, wrist, and sternoclavicular joints. Joint aspiration typically yields a purulent fluid in which the causal agent can be identified.

### *Lyme Arthritis*

Lyme disease is caused by infection with the spirochete *Borrelia burgdorferi,* transmitted by deer ticks of the *Ixodes ricinus* complex; it is named for the Connecticut town where the disease was first recognized in the 1970s. With more than 20,000 cases reported annually, it is the leading arthropod-borne disease in the United States. As with another major spirochetal disease, syphilis, Lyme disease involves multiple organ systems and in its classic form progresses through three successive stages. In *stage 1, Borrelia* spirochetes multiply at the site of the tick bite and cause an expanding area of redness, often with an indurated or pale center. This skin lesion, called *erythema chronicum migrans,* may be accompanied by fever and lymphadenopathy but usually disappears in a few weeks' time. In *stage 2,* the *early disseminated stage,* spirochetes spread hematogenously and cause secondary annular skin lesions, lymphadenopathy, migratory joint and muscle pain, cardiac arrhythmias, and meningitis, often with cranial nerve involvement. Diagnostically useful antibodies (usually both IgM and IgG) against *Borrelia* antigens appear in the serum at this stage of the disease. Some spirochetes, however, escape host antibody and T cell responses by sequestering themselves in the central nervous system or within endothelial cells. In *stage 3,* the *late disseminated stage,* which occurs 2 or 3 years after the initial bite, Lyme *Borrelia* organisms cause a chronic arthritis, sometimes with severe damage to large joints, and an encephalitis that ranges in severity from mild to debilitating.

*Lyme arthritis* develops in roughly 60% to 80% of untreated patients and is the dominant feature of late

disease. The arthritis may be caused by immune responses against *Borrelia* antigens that cross-react with proteins in the joints, but the exact mechanisms are not yet understood. The disease tends to be migratory, with remissions and relapses. It involves mainly large joints, especially the knees, shoulders, elbows, and ankles, in descending order of frequency. Histologic examination reveals a chronic papillary synovitis with synoviocyte hyperplasia, fibrin deposition, mononuclear cell infiltrates, and onion-skin thickening of arterial walls; in severe cases, the morphology closely resembles that of rheumatoid arthritis. In only 25% of cases do silver stains reveal a sprinkling of organisms, and formal diagnosis of Lyme arthritis may depend on the clinical picture, including history, and/or appropriate serologic studies. Chronic arthritis with pannus formation and permanent deformities develops in roughly 1 in 10 patients.

### SUMMARY

#### Arthritis

- *Osteoarthritis (degenerative joint disease)* is by far the most common joint disease; it is primarily a degenerative disorder of articular cartilage in which matrix breakdown exceeds synthesis. Inflammation is secondary. The vast majority of cases occur without apparent precipitating cause except increasing age. Local production of proinflammatory cytokines and other mediators (IL-1, TNF, nitric oxide) may contribute to the progression of the joint degeneration.
- *Rheumatoid arthritis (RA)* is a chronic autoimmune inflammatory disease that affects mainly the joints, especially small joints, but can affect multiple tissues. RA is caused by an autoimmune response against self-antigen(s) such as citrullinated proteins, which leads to T cell reactions in the joint with production of cytokines that activate phagocytes that damage tissues and stimulate proliferation of synovial cells (synovitis). The cytokine TNF plays a central role, and antagonists against TNF are of great clinical benefit. Antibodies may also contribute to the disease.
- *Gout and pseudogout.* Increased circulating levels of uric acid (*gout*) or calcium pyrophosphate (*pseudogout*) can lead to crystal deposition in the joint space. Resulting inflammatory cell recruitment and activation lead to cartilage degradation, fibrosis, and arthritis.
- Either direct infection of a joint space (*suppurative arthritis*) or cross-reactive immune responses to systemic infections (e.g., in some cases of *Lyme arthritis*) can lead to joint inflammation and injury.

## JOINT TUMORS AND TUMOR-LIKE LESIONS

Primary neoplasms of joints are uncommon and usually benign; in general, they reflect the cells and tissue types (synovial membrane, vessels, fibrous tissue, and cartilage) native to the joints. Benign tumors are much more frequent than their malignant counterparts. The rare malignant neoplasms of these structures are discussed below with the soft tissue tumors. In comparison, reactive *tumor-like lesions such as ganglions and synovial cysts* are much more common than neoplasms; these typically result from trauma or degenerative processes. Here we discuss the more common or clinically significant tumor-like lesions and neoplasms of joints and associated soft tissues.

### Ganglion and Synovial Cysts

A *ganglion* is a small cyst (less than 1.5 cm in diameter) located near a joint capsule or tendon sheath; the wrist is an especially common site. Lesions manifest as firm to fluctuant pea-sized nodules that are translucent to light. Microscopically, they consist of fluid-filled spaces that lack a true cell lining, apparently because they stem from cystic degeneration of connective tissue. Coalescence of adjacent cysts can produce multilocular lesions. The cyst contents resemble synovial fluid, although often there is no communication with the joint space. Ganglions typically are completely asymptomatic. Classically, these can be treated by "Bible therapy": Whacking the affected area with a large tome usually is sufficient to rupture the cyst, but reaccumulation may recur. Despite their name, they have no relationship to ganglia of the nervous system.

Herniation of synovium through a joint capsule or massive enlargement of a bursa can produce a *synovial cyst.* A good example is the *Baker cyst* that occurs in the popliteal fossa.

### Tenosynovial Giant Cell Tumor

*Tenosynovial giant cell tumor* (TGCT) is a catchall term for several closely related benign neoplasms of synovium. Although these lesions previously were considered reactive proliferations (hence the earlier designation *synovitis*), they are consistently associated with an acquired (1;2) translocation that fuses the promoter of the collagen 6A3 gene to the coding sequence of the growth factor M-CSF. Classic examples are diffuse tenosynovial giant cell tumor, previously known as *pigmented villonodular synovitis* (PVNS), involving joint synovium, and localized tenosynovial giant cell tumor, also known as *giant cell tumor of tendon sheath*. Both types typically arise in people in their 20s to 40s, without gender predilection.

### MORPHOLOGY

Grossly, TGCTs are red-brown to orange-yellow. In the diffuse variant the joint synovium becomes a contorted mass of red-brown folds, finger-like projections, and nodules (Fig. 20–23, *A*). By contrast, the localized type is well circumscribed and contained. Tumor cells in both lesions resemble synoviocytes, and numerous hemosiderin-laden macrophages, osteoclast-like giant cells and hyalinized stromal collagen also are present (Fig. 20–23, *B*). The tumor cells spread along the surface and infiltrate the subsynovial compartment. In localized TGCT, the cells grow in a solid nodular aggregate. Other typical findings include hemosiderin deposits, foamy macrophages, multinucleate giant cells, and zones of scarring.

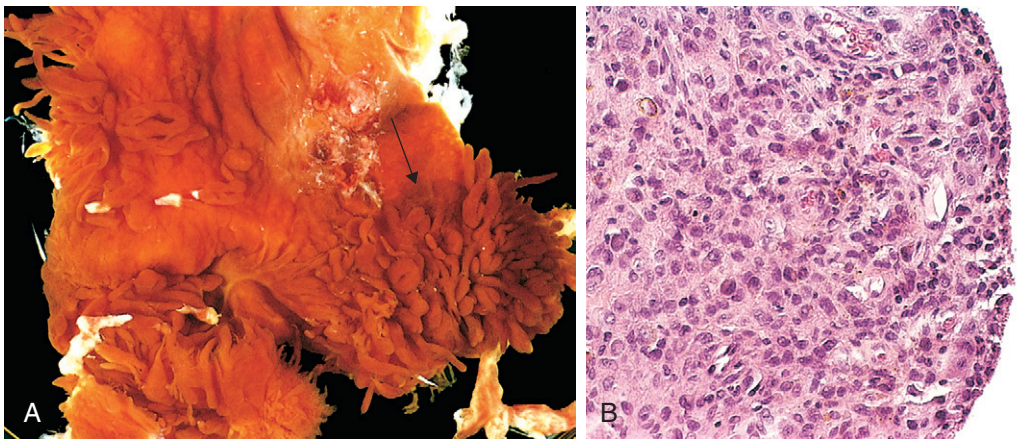

**Figure 20–23** Tenosynovial giant cell tumor, diffuse type. **A,** Excised synovium with fronds and nodules typical of the diffuse variant (*arrow*). **B,** Sheets of proliferating cells in tenosynovial giant cell tumor bulging the synovial lining.

### Clinical Features

Diffuse TGCT usually mimics a monoarticular arthritis; it affects the knee in 80% of cases, followed by the hip and ankle. Patients typically complain of pain, locking, and recurrent swelling. Tumor progression limits the range of movement of the joint. Aggressive lesions erode into adjacent bones and soft tissues, causing confusion with other tumors. In contrast, localized TGCT presents as a solitary, slowly growing, painless mass frequently involving wrist and finger tendon sheaths; it is the most common soft tissue tumor of the hand. Cortical erosion of adjacent bone occurs in approximately 15% of cases. Both lesions are amenable to surgical resection, but also prone to local recurrence. Recognition of the association of TGCT and M-CSF gene rearrangement and overexpression has inspired trials of antagonists of M-CSF or its cognate receptor (M-CSFR, a tyrosine kinase); some excellent responses have been reported.

## SOFT TISSUE

By convention, the term *soft tissue* describes any nonepithelial tissue other than bone, cartilage, central nervous system, hematopoietic, and lymphoid tissues. The focus of this section is on soft tissue tumors, which are classified according to the tissue type they recapitulate, including fat, fibrous tissue, and neurovascular tissue (Table 20–4). In some soft tissue neoplasms, however, no corresponding normal counterpart is known. Although soft tissue tumors are classified based on recognizable lines of differentiation, current evidence indicates that these tumors arise from pluripotent mesenchymal stem cells and are not the result of malignant transformation of mature mesenchymal cells. With the exception of skeletal muscle neoplasms (see further on), benign soft tissue tumors outnumber their malignant counterparts by at least a hundred-fold. In the United States, approximately 12,000 soft tissue sarcomas are diagnosed annually, representing less than 1% of all invasive malignancies. However, they cause 2% of all cancer deaths, reflecting their lethal nature.

Most soft tissue tumors arise without antecedent causes; rarely, radiation exposure, burn injury, or toxin exposure is implicated. Kaposi sarcoma (Chapter 9) is associated with the human herpesvirus 8, but viruses probably are not important in the pathogenesis of most sarcomas in humans. A small minority of soft tissue tumors are associated with genetic syndromes, most notably neurofibromatosis type 1 (neurofibroma, malignant schwannoma), Gardner syndrome (fibromatosis), Li-Fraumeni syndrome (soft tissue sarcoma), and Osler-Weber-Rendu syndrome (telangiectasia). Specific chromosomal abnormalities and genetic derangements in these syndromes provide important clues to the genesis of the neoplasms. Like their mesenchymal brethren, the hematopoietic neoplasms, many soft tissue tumors are associated with highly characteristic chromosomal rearrangements, most commonly translocations that provide insight into pathogenesis and are diagnostically useful. Indeed, some tumors, such as synovial sarcoma, are virtually defined by their associated translocations.

Soft tissue tumors can arise in any location, but approximately 40% of sarcomas occur in the lower extremities, especially the thigh. While the overall incidence of sarcomas increases with age, 15% arise in children. Certain sarcomas tend to appear in certain age groups—for example, rhabdomyosarcoma in childhood, synovial sarcoma in young adulthood, and liposarcoma and pleomorphic fibroblastic or undifferentiated sarcomas in later adult life. Soft tissue sarcomas usually are treated with wide surgical excision (frequently limb-sparing), with irradiation and systemic therapy reserved for large high-grade tumors.

Several features of soft tissue sarcomas influence prognosis:

- *Diagnostic classification.* This is based not only on histology, but also on immunohistochemistry, electron microscopy, cytogenetics, and molecular genetics, which are indispensable in assigning the correct diagnosis in some cases.

- *Grading.* Grading, usually on a scale of I to III, is based on the degree of differentiation, the average number of mitoses per high-power field, cellularity, pleomorphism, and an estimate of the extent of necrosis (presumably a reflection of rate of growth). Mitotic counts and necrosis are the most important predictors.
- *Staging.* With tumors larger than 20 cm, metastases develop in 80% of cases; by contrast, for tumors 5 cm or smaller, metastases occur in only 30% of cases.
- *Location.* In general, tumors arising in superficial locations (e.g., skin) have a better prognosis than deep-seated lesions; overall, the 10-year survival rate for sarcomas is approximately 40%.

Presented next is an overview of the individual tumors and tumor-like lesions; only the more common forms are covered here. Others are covered elsewhere in the book.

# TUMORS OF ADIPOSE TISSUE

## Lipoma

*Lipomas* are benign tumors of fat and are the most common soft tissue tumors in adults. Most lipomas are solitary lesions; multiple lipomas usually suggest the presence of rare hereditary syndromes. Lipomas can be subclassified on the basis of their histologic features and/or characteristic chromosomal rearrangements. Most lipomas are mobile, slowly enlarging, painless masses (although angiolipomas can manifest with local pain); complete excision usually is curative.

*Conventional lipomas* (the most common subtype) are soft, yellow, well-encapsulated masses of mature adipocytes; they can vary considerably in size. On histologic examination, they consist of mature white fat cells with no pleomorphism.

## Liposarcoma

*Liposarcomas* are malignant neoplasms with adipocyte differentiation. They occur most commonly in the fifth and sixth decades of life. Most liposarcomas arise in the deep soft tissues or in the retroperitoneum. The prognosis of liposarcomas is greatly influenced by the histologic subtype; well-differentiated tumors grow slowly and are associated with a more favorable outlook than the aggressive myxoid/round cell and pleomorphic variants, which tend to recur after excision and metastasize to lungs. Amplification of a region of 12q is common in well-differentiated liposarcomas; this region contains the *MDM2* gene, whose product binds and degrades the p53 protein. A t(12;16) chromosomal translocation is associated with myxoid/round cell liposarcomas; this rearrangement creates a fusion gene encoding an abnormal transcription factor that may interfere with adipocyte differentiation.

### MORPHOLOGY

Liposarcomas usually manifest as relatively well-circumscribed lesions. Several different histologic subtypes are recognized, including the low-grade variant, **well-differentiated liposarcoma,** and the **myxoid/round cell liposarcoma,** characterized by abundant, mucoid extracellular matrix. Some well-differentiated lesions can be difficult to distinguish from lipomas, whereas very poorly differentiated tumors can resemble various other high-grade malignancies. In most cases, cells indicative of fatty differentiation known as **lipoblasts are present;** they have cytoplasmic lipid vacuoles that scallop the nucleus (Fig. 20–24), and appearance recapitulating that of fetal fat cells.

# FIBROUS TUMORS AND TUMOR-LIKE LESIONS

Fibrous tissue proliferations are a heterogeneous group of lesions. At one end of the spectrum, *nodular fasciitis* is not a true tumor but rather a reactive, self-limited proliferation.

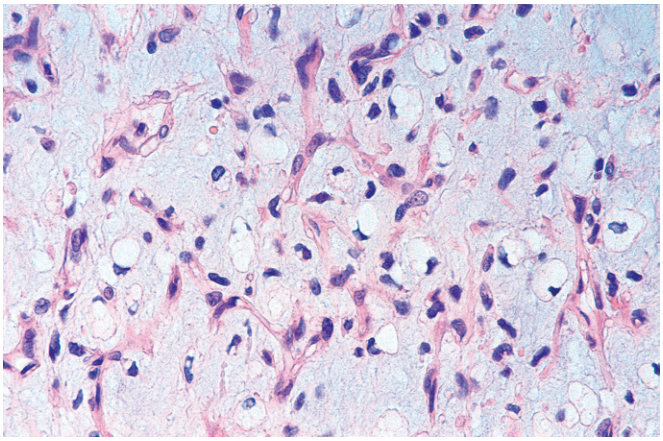

**Figure 20–24** Myxoid liposarcoma. Adult-appearing fat cells and more primitive cells, with lipid vacuoles (*lipoblasts*), are scattered in abundant myxoid matrix and a rich, arborizing capillary network.

At the other end, *fibrosarcomas* are highly malignant neoplasms that tend to recur locally and can metastasize. *Fibromatoses* fall somewhere in the middle; these are benign lesions that infiltrate locally and often can defy attempts at surgical excision. Distinguishing among the various lesions requires considerable skill and diagnostic experience.

## Reactive Proliferations

### *Nodular Fasciitis*

Nodular fasciitis is a self-limited fibroblastic proliferation (Fig. 20–25) that typically occurs in adults on the volar aspect of the forearm, the chest, or the back. Patients characteristically present with a several-week history of a solitary, rapidly growing, and occasionally painful mass. Preceding trauma is noted in 10% to 15% of cases. Nodular fasciitis rarely recurs after excision.

### *Myositis Ossificans*

Myositis ossificans is distinguished from other fibroblastic proliferations by the presence of *metaplastic bone.* It usually develops in the proximal muscles of the extremities in athletic adolescents and young adults after trauma. The affected area initially is swollen and painful, and subsequently evolves into a painless, hard, well-demarcated mass. It is critical to distinguish this lesion from extraskeletal osteosarcoma. Simple excision usually is curative.

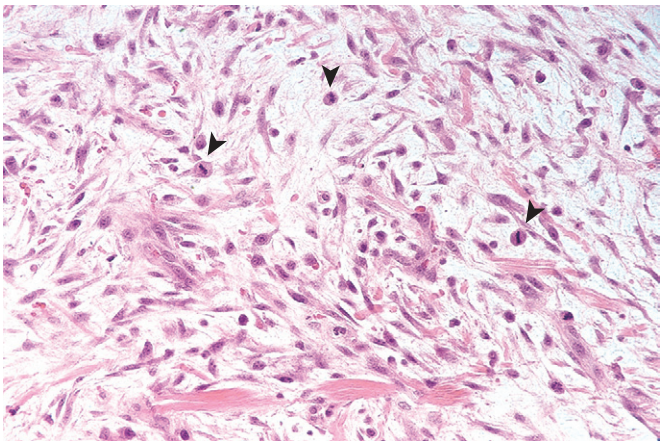

**Figure 20–25** Nodular fasciitis. A highly cellular lesion composed of plump, randomly oriented spindle cells surrounded by myxoid stroma. Note the prominent mitotic activity (*arrowheads*).

## Fibromatoses

The fibromatoses are a group of fibroblastic proliferations distinguished by their tendency to grow in an infiltrative fashion and, in many cases, to recur after surgical removal. Although some lesions are *locally aggressive, they do not metastasize.* The fibromatoses are divided into two major clinicopathologic groups: superficial and deep.

- The *superficial fibromatoses* arise in the superficial fascia and include such entities as palmar fibromatosis (*Dupuytren contracture*) and penile fibromatosis (*Peyronie disease*). Superficial lesions are genetically distinct from their deep-seated cousins and are generally more innocuous (they can be associated with trisomy 3 and 8); they also come to clinical attention earlier, because they cause deformity of the involved structure.
- The *deep fibromatoses* include the so-called *desmoid tumors* that arise in the abdominal wall and muscles of the trunk and extremities, and within the abdomen (mesentery and pelvic walls). They can be isolated lesions, or multiple, as a component of *Gardner syndrome,* an autosomal dominant disorder including colonic adenomatous polyps and osteomas. Mutations in the *APC* or β-catenin genes are present in a majority of these tumors. Deep fibromatoses tend to grow in a locally aggressive manner and often recur after excision.

### MORPHOLOGY

Fibromatoses are gray-white, firm to rubbery, poorly demarcated, infiltrative masses 1 to 15 cm in greatest dimension. On histologic examination, they are composed of plump spindle cells arranged in broad sweeping fascicles that penetrate the adjacent tissue; mitoses are few in number. Immunohistochemical and ultrastructural studies show that the tumor cells are fibroblasts and **myofibroblasts.** Some lesions may be quite cellular, particularly early in their evolution, whereas others contain abundant dense collagen.

In addition to being disfiguring or disabling, fibromatoses occasionally are painful. Although curable by adequate excision, they often recur when incompletely removed due to their infiltrative nature. For those tumors that cannot be resected, therapeutic options include watchful waiting, radiation therapy, and chemotherapy.

## Fibrosarcoma

Fibrosarcomas are malignant neoplasms composed of fibroblasts. Most occur in adults, typically in the deep tissues of the thigh, knee, and retroperitoneal area. They tend to grow slowly, and have usually been present for several years at the time of diagnosis. As with other

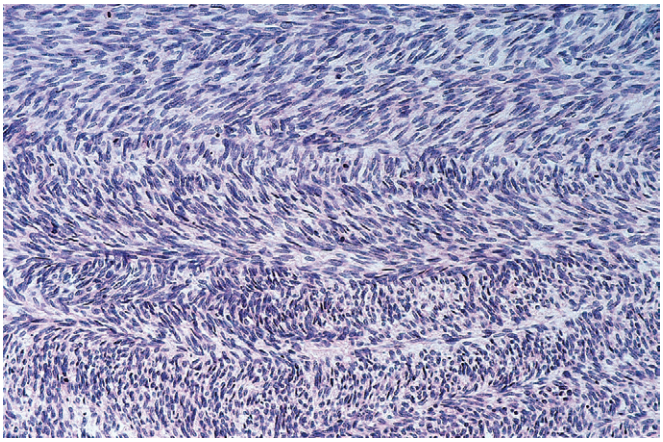

**Figure 20–26** Fibrosarcoma. Malignant spindle cells here are arranged in a *herringbone pattern*.

sarcomas, fibrosarcomas often recur locally after excision (in more than 50% of cases) and can metastasize hematogenously (in greater than 25% of cases), usually to the lungs.

### MORPHOLOGY

Fibrosarcomas are soft unencapsulated, infiltrative masses that frequently contain areas of hemorrhage and necrosis. Better-differentiated lesions can appear deceptively circumscribed. Histologic examination discloses all degrees of differentiation, from tumors that closely resemble fibromatoses, to densely packed lesions with spindle cells growing in a herringbone fashion (Fig. 20–26), while others have a myxoid stroma (myxofibrosarcoma), and some are highly cellular neoplasms exhibiting architectural disarray, pleomorphism, frequent mitoses, and necrosis.

## FIBROHISTIOCYTIC TUMORS

Fibrohistiocytic tumors are composed of a mixture of fibroblasts and phagocytic, lipid-laden cells resembling activated tissue macrophages (also called *histiocytes* by morphologists). The neoplastic cells in many cases are fibroblasts and myofibroblasts. Consequently, the term *fibrohistiocytic* is descriptive and does not connote a specific line of differentiation. These tumors span a broad range of histologic patterns and biologic behavior, from self-limited benign lesions to aggressive high-grade sarcomas.

### Benign Fibrous Histiocytoma (Dermatofibroma)

Dermatofibromas are relatively common benign lesions in adults manifesting as circumscribed, small (less than 1 cm) mobile nodules in the dermis or subcutaneous tissue. On histologic evaluation, these typically consist of bland, interlacing spindle cells admixed with foamy, lipid-rich histiocyte-like cells. The borders of the lesions tend to be infiltrative, but extensive local invasion does not occur. They are cured by simple excision. The pathogenesis of these lesions is uncertain.

### Pleomorphic Fibroblastic Sarcoma/Pleomorphic Undifferentiated Sarcoma

Tumors of this type originally fell under the diagnostic rubric "malignant fibrous histiocytoma," but with use of objective immunohistochemical markers it became evident that this was a wastebasket diagnostic category that included a number of poorly differentiated sarcomas, such as leiomyosarcomas and liposarcomas. The common histologic features that define this group of poorly differentiated sarcomas are cytologic pleomorphism, the presence of bizarre multinucleate cells, and storiform architecture. Currently, tumors with this histologic appearance that exhibit fibroblastic differentiation are designated undifferentiated pleomorphic spindle cell sarcoma or pleomorphic fibroblastic sarcoma (Fig. 20–27). They usually are large (5 cm to 20 cm), gray-white unencapsulated masses that often appear deceptively circumscribed. They usually arise in the musculature of the proximal extremities or in the retroperitoneum. Most of these tumors are extremely aggressive, recur unless widely excised, and have a metastatic rate of 30% to 50%.

## SKELETAL MUSCLE TUMORS

Tumors of skeletal muscle differentiation are almost all malignant. Rhabdomyoma, a benign type of skeletal muscle tumor, is rare and is most often found in the heart (Chapter 10).

### Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood and adolescence, usually appearing before age 20. Of interest, it occurs most commonly in the head and neck or genitourinary tract, usually at sites where there is little, if any, normal skeletal muscle.

This tumor occurs in three different histologic types, as described below. *Chromosomal translocations* are found in most cases of the alveolar variant; the more common t(2;13) translocation fuses the *PAX3* gene on chromosome 2 with the *FKHR* gene on chromosome 13. *PAX3* functions

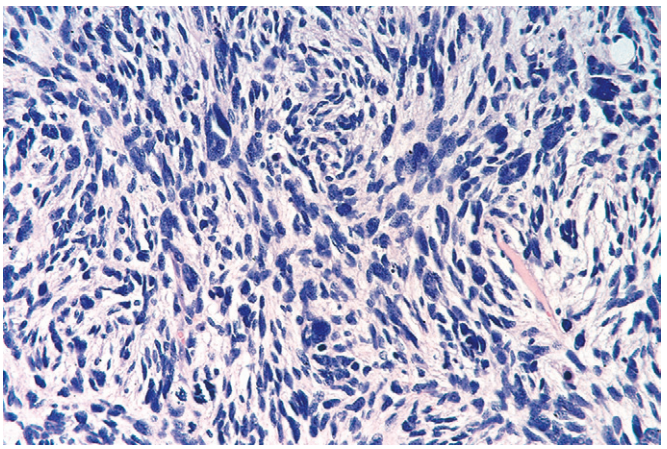

**Figure 20–27** Pleomorphic fibroblastic sarcoma. There are fascicles of plump spindle cells in a *swirling (storiform) pattern*.

upstream of genes that control skeletal muscle differentiation, and tumor development probably involves dysregulation of muscle differentiation by the chimeric PAX3-FKHR protein.

### MORPHOLOGY

Rhabdomyosarcoma is histologically subclassified into the **embryonal, alveolar,** and **pleomorphic** variants. The gross appearance of these tumors is variable. Some, particularly the embryonal variant when arising near the mucosal surfaces of the bladder or vagina, can manifest as soft, gelatinous, grapelike masses, designated **sarcoma botryoides.** In other cases they are poorly defined, infiltrating tan-white masses. The **rhabdomyoblast** is the diagnostic cell in all types; it has granular eosinophilic cytoplasm rich in thick and thin filaments. The rhabdomyoblasts may be round or elongated; the latter are known as **tadpole or strap cells** (Fig. 20–28) and may contain cross-striations visible by light microscopy. The diagnosis of rhabdomyosarcoma is based on the demonstration of skeletal muscle differentiation, either in the form of sarcomeres under the electron microscope or by immunohistochemical demonstration of skeletal muscle–specific transcription factors such as myogenin and MYOD-1, and the muscle-associated intermediate filament desmin.

Rhabdomyosarcomas are aggressive neoplasms treated with a combination of surgery, chemotherapy, and radiation. Location, histologic appearance, and tumor genetics all impact the likelihood of cure, with progressively worsening rates for embryonal, pleomorphic, and alveolar variants, in that order. The malignancy is curable in almost two thirds of children; the prognosis is much less favorable in adults with the pleomorphic type.

## SMOOTH MUSCLE TUMORS

### Leiomyoma

Benign smooth muscle tumors, or *leiomyomas,* are common, well-circumscribed neoplasms that can arise from smooth muscle cells anywhere in the body but are encountered most commonly in the uterus (Chapter 18) and the skin.

### Leiomyosarcoma

Leiomyosarcomas account for 10% to 20% of soft tissue sarcomas. They occur in adults, more commonly females. Skin and deep soft tissues of the extremities and retroperitoneum (inferior vena cava) are common sites. These neoplasms manifest as firm, painless masses; retroperitoneal tumors can be large and bulky and cause abdominal symptoms. Histologic examination shows spindle cells with cigar-shaped nuclei arranged in interwoven fascicles. Treatment depends on the size, location, and grade of the tumor. Superficial or cutaneous leiomyosarcomas usually are small and carry a good prognosis, whereas retroperitoneal tumors are large and difficult to excise and cause death by both local extension and metastatic spread.

## SYNOVIAL SARCOMA

Synovial sarcoma was originally believed to recapitulate synovium; however, the phenotype of the neoplastic cells bears no resemblance to a synoviocyte, and despite the name, less than 10% of tumors are intra-articular. Synovial sarcomas account for approximately 10% of all soft tissue sarcomas, typically occurring in persons in their 20s to 40s. They usually develop in deep soft tissues around the large joints of the extremities, with 60% to 70% occurring around the knee; many have been present for several years at the time of presentation. Most synovial sarcomas show a characteristic (X;18) translocation that produces a fusion gene encoding a chimeric transcription factor.

### MORPHOLOGY

On histologic examination, synovial sarcomas may be biphasic or monophasic. Classic **biphasic** synovial sarcoma exhibits differentiation of tumor cells into both epithelial-type cells and spindle cells. The epithelial cells are cuboidal to columnar and form glands or grow in solid cords or aggregates. The spindle cells are arranged in densely cellular fascicles that surround the epithelial cells (Fig. 20–29). Many synovial

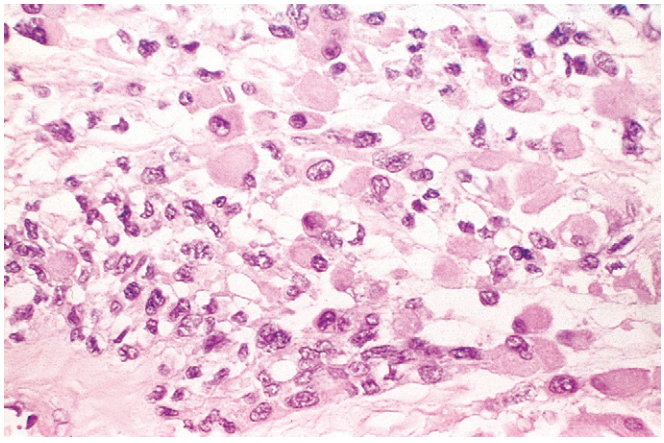

**Figure 20–28** Rhabdomyosarcoma. The rhabdomyoblasts are large and round and have abundant eosinophilic cytoplasm; no cross-striations are evident here.

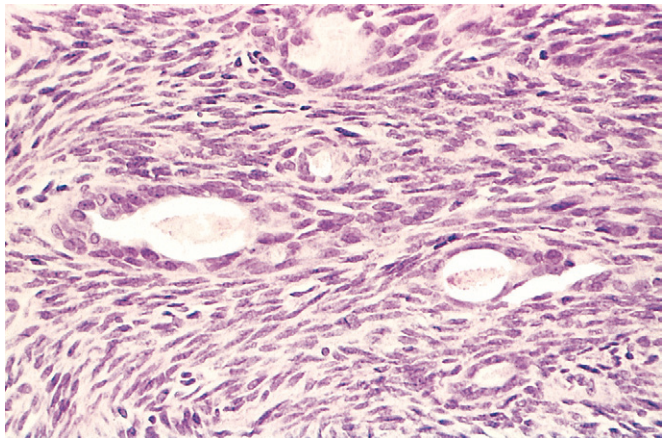

**Figure 20–29** Synovial sarcoma exhibiting a classic biphasic spindle cell and glandlike histologic appearance.

sarcomas are **monophasic**—that is, composed of spindle cells only. Lesions composed solely of spindle cells are easily mistaken for fibrosarcomas or malignant peripheral nerve sheath tumors. Immunohistochemistry is helpful, because the tumor cells are positive for keratin and epithelial membrane antigen, differentiating them from most other sarcomas.

Synovial sarcomas are treated aggressively with limb-sparing surgery and chemotherapy. Common metastatic sites are lung, bone, and regional lymph nodes. Reported 5-year survival rates range from 25% to 62%, and only 10% to 30% of the patients live longer than 10 years.

Malignant Peripheral Nerve Sheath Tumors 808
Neurofibromatosis Type 1 808
Traumatic Neuroma 808

The major components of the neuromuscular system, the peripheral nerves and skeletal muscles, act as both effectors and sensors for the central nervous system, and in doing so allow thought and sensation to give rise to physical actions and cognitive responses. The principal component of the motor system is the *motor unit,* which is composed of one lower motor neuron and its associated peripheral axon, neuromuscular junctions, and innervated skeletal muscle fibers. Both the anatomic distribution of lesions and specific signs and symptoms are helpful in classifying neuromuscular diseases and in distinguishing them from diseases of the central nervous system. Accordingly, the discussion of neuromuscular disorders is organized along anatomic lines, highlighting the clinical features that are most useful in their diagnosis.

## DISORDERS OF PERIPHERAL NERVES

The two major functional elements of peripheral nerves are axonal processes and their myelin sheaths, which are made by Schwann cells. Axonal diameter and myelin thickness are correlated with each other and with conduction velocity; they can be used to distinguish among different types of axons, which mediate distinct sensory modalities and motor function. Light touch, for example, is transmitted by thickly myelinated large-diameter axons with fast conduction velocities, while temperature sensation is transmitted by slow, unmyelinated thin axons. In the case of myelinated axons, one Schwann cell makes and maintains exactly one myelin segment, or internode, along a single axon (Fig. 21–1, *A*). Adjacent internodes are separated by nodes of Ranvier. Peripheral nerves contain a mixture of different types of axons. These and the intervening endoneurial connective tissue are arranged into fascicles that are ensheathed by a layer of perineurial cells. The perineurial cells are similar to meningeal cells and help to maintain the blood-nerve barrier in the individual fascicles.

### Patterns of Peripheral Nerve Injury

Most peripheral neuropathies can be subclassified as either axonal or demyelinating, even though some diseases exhibit mixed features. *Axonal neuropathies* are caused by insults that directly injure the axon. The entire distal portion of an affected axon degenerates. Axonal degeneration is associated with secondary myelin loss (Fig. 21–1, *B*), a process sometimes referred to as *Wallerian* degeneration. Regeneration takes place through axonal regrowth and subsequent remyelination of the distal axon (Fig. 21–1, *C*). The morphologic hallmark of axonal neuropathies is a decrease in the density of axons, which in electrophysiologic studies correlates with a decrease in the strength of amplitude of nerve impulses.

*Demyelinating neuropathies* are characterized by damage to Schwann cells or myelin with relative axonal sparing, resulting in abnormally slow nerve conduction velocities. Demyelination typically occurs in individual myelin internodes randomly; this process is termed *segmental demyelination* (Fig. 21–1, *B*). Morphologically, demyelinating neuropathies show a relatively normal density of axons and features of segmental demyelination and repair. This is recognized by the presence of axons with abnormally thin myelin sheaths and short internodes (Fig. 21–1, *C*). These latter changes are best demonstrated on teased fiber preparations, which allow the examination of several adjacent myelin internodes along a segment of an individual axon (described later).

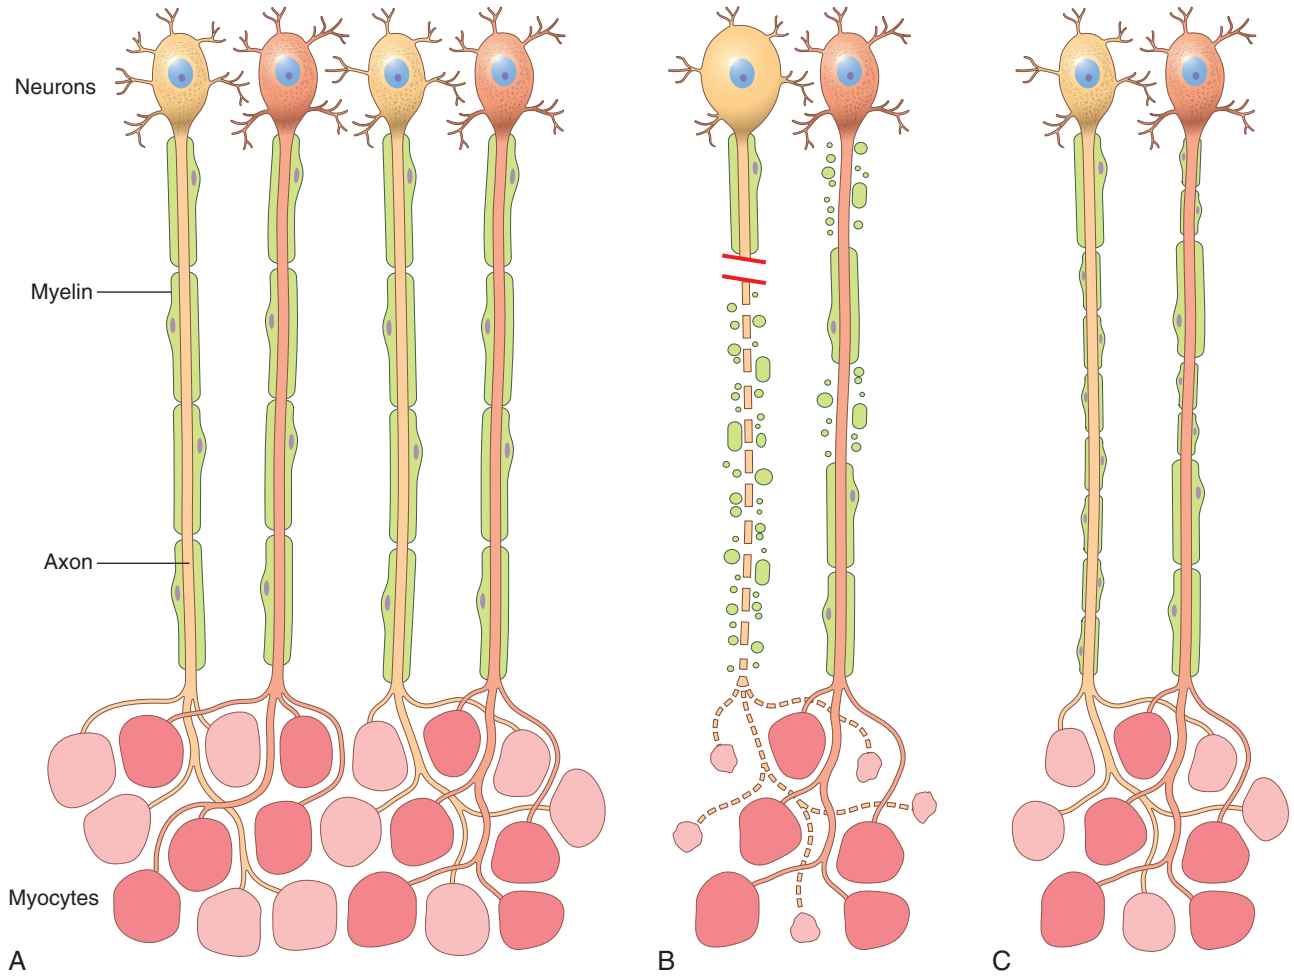

**Figure 21–1** Patterns of peripheral nerve damage. **A,** In normal motor units, type I and type II myofibers are arranged in a "checkerboard" distribution, and the internodes along the motor axons are uniform in thickness and length. **B,** Acute axonal injury (*left axon*) results in degeneration of the distal axon and its associated myelin sheath, with atrophy of denervated myofibers. By contrast, acute demyelinating disease (*right axon*) produces random segmental degeneration of individual myelin internodes, while sparing the axon. **C,** Regeneration of axons after injury (*left axon*) allows connections with myofibers to re-form. The regenerated axon is myelinated by proliferating Schwann cells, but the new internodes are shorter and the myelin sheaths are thinner than the original ones. Remission of demyelinating disease (*right axon*) allows remyelination to take place, but the new internodes also are shorter and have thinner myelin sheaths than flanking normal undamaged internodes.

Peripheral neuropathies fall into several anatomic patterns and may cause selective sensory or motor axon damage, or a mixture of both.

- *Polyneuropathies* usually affect peripheral nerves in a symmetric, length-dependent fashion. Axonal loss is typically diffuse and more pronounced in the distal segments of the longest nerves. Patients commonly present with loss of sensation and paresthesias that start in the toes and spread upward to the knees and then involve the hands in a "stocking-and-glove" distribution.
- *Polyneuritis multiplex,* in which the damage randomly affects portions of individual nerves, resulting (for example) in a right radial nerve palsy and wrist drop together with loss of sensation in the left foot
- A simple *mononeuropathy* involving only a single nerve most commonly is the result of traumatic injury or entrapment (e.g., carpal tunnel syndrome).

## Disorders Associated with Peripheral Nerve Injury

Many different diseases may be associated with peripheral neuropathy (Table 21–1). We discuss next in some detail selected entities that are prototypical for a specific type of polyneuropathy (e.g., Guillain-Barré syndrome) or are common (e.g., diabetic neuropathy).

### *Guillain-Barré Syndrome*

Guillain-Barré syndrome is one of the most common life-threatening diseases of the peripheral nervous system. It is a rapidly progressive acute demyelinating disorder affecting motor axons that results in ascending weakness that may lead to death from failure of respiratory muscles over a period of only several days. It appears to be triggered by an infection or a vaccine that breaks down self-tolerance,

**Table 21–1** Peripheral Neuropathies

| Etiologic Category | Causative Disorders/Agents |
|---|---|
| Nutritional and metabolic | Diabetes mellitus<br>Uremia<br>Vitamin deficiencies—thiamine, vitamin $B_6$, vitamin $B_{12}$ |
| Toxic | Drugs, including vinblastine, vincristine, paclitaxel, colchicine, and isoniazid<br>Other toxins—alcohol, lead, aluminum, arsenic, mercury, acrylamide |
| Vasculopathic | Vasculitis<br>Amyloidosis |
| Inflammatory | Autoimmune diseases: systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, Sjögren syndrome<br>Guillain-Barré syndrome<br>Chronic inflammatory demyelinating polyneuropathy (CIDP) |
| Infections | Herpes zoster—most often ganglionitis<br>Leprosy<br>HIV infection<br>Lyme disease—often facial nerve palsy |
| Inherited | Charcot-Marie-Tooth neuropathy, type 1: autosomal dominant (many cases with tandem duplications in *PMP22*)<br>Charcot-Marie-Tooth neuropathy, type 3: autosomal dominant or recessive (some with point mutations in *PMP22*)<br>Charcot-Marie-Tooth neuropathy, X-linked (connexin 32 gene mutations)<br>Hereditary neuropathy with liability to pressure palsy: autosomal dominant deletions of *PMP22* |
| Others | Paraneoplastic, some leukodystrophies |

thereby leading to an autoimmune response. Associated infectious agents include *Campylobacter jejuni*, Epstein-Barr virus, cytomegalovirus, and human immunodeficiency virus. The injury is most extensive in the nerve roots and proximal nerve segments and is associated with mononuclear cell infiltrates rich in macrophages. Both humoral and cellular immune responses are believed to play a role in the disease process. Treatments include plasmapheresis (to remove offending antibodies), intravenous immunoglobulin infusions (which suppress immune responses through unclear mechanisms) and supportive care, such as ventilatory support. Patients who survive the initial acute phase of the disease usually recover over time.

### *Chronic Inflammatory Demyelinating Polyneuropathy*

*Chronic inflammatory demyelinating polyneuropathy* (CIDP) typically manifests as a symmetric demyelinating disease. Both motor and sensory abnormalities are common, such as difficulty in walking, weakness, numbness, and pain or tingling sensations. Like Guillain-Barré syndrome, CIDP is immune-mediated and occurs at increased frequency in patients with other immune disorders, such as systemic lupus erythematosus and HIV infection. In contrast with Guillain-Barré syndrome, however, CIDP follows a chronic, relapsing-remitting or progressive course. The peripheral nerves show segments of demyelination and remyelination (Fig. 21-2, *A*). In long-standing cases, chronically regenerating Schwann cells may concentrically wrap around axons in multiple layers in an onion-skin pattern. Treatment includes plasmapheresis and administration of immunosuppressive agents. Some patients recover completely, but more often recurrent bouts of symptomatic disease lead to permanent loss of nerve function.

### *Diabetic Peripheral Neuropathy*

*Diabetes is the most common cause of peripheral neuropathy* (Chapter 19). Neuropathies usually arise in diabetics with long-standing disease. They include autonomic neuropathy, lumbosacral radiculopathies, and distal symmetric sensorimotor polyneuropathy; these may occur singly or together. *Autonomic neuropathy* is characterized by changes in bowel, bladder, cardiac, or sexual function. *Lumbosacral radiculopathy* usually manifests with asymmetric pain that can progress to lower extremity weakness and muscle atrophy. *Distal symmetric sensorimotor polyneuropathy* is the most common form of diabetic neuropathy. Sensory axons are more severely affected than motor axons, so the clinical presentation usually is dominated by paresthesias and numbness. This form of diabetic polyneuropathy results from the length-dependent degeneration of peripheral nerves and does not neatly fit into the axonal or demyelinating category but instead often exhibits features of both. The pathogenesis of diabetic neuropathy is complex; accumulation of advanced glycosylation end products, hyperglycemia, increased levels of reactive oxygen species, microvascular changes, changes in axonal metabolism, abnormal protein C levels, and neurotrophic factors all have been implicated. Strict glycemic control is the best form of therapy.

### *Toxic, Vasculitic, and Inherited Forms of Peripheral Neuropathy*

- *Drugs* and *environmental toxins* that interfere with axonal transport or cytoskeletal function often produce peripheral neuropathies. The longest axons are most susceptible, so the resulting clinical presentation is often most pronounced in the distal extremities.
- Peripheral nerves are often damaged in many different forms of *systemic vasculitis* (Fig. 21–2, *B*) (Chapter 9), including polyarteritis nodosa, Churg-Strauss syndrome, and Wegener granulomatosis. Overall, peripheral nerve damage is seen in about a third of all patients with vasculitis at the time of presentation. The most common clinical picture is that of *mononeuritis multiplex* with a painful asymmetric mixed sensory and motor peripheral neuropathy. Patchy involvement also is apparent at the microscopic level, as single nerves may show considerable interfascicular variation in the degree of axonal damage (Fig. 21–2, *C*).
- *Inherited diseases of peripheral nerves* are a heterogeneous but relatively common group of disorders, with a prevalence of 1 to 4 in 10,000. They can be demyelinating or axonal. Most such disorders manifest in adulthood and follow a slowly progressive course that may mimic that of acquired polyneuropathies. The most common cause is mutations in the *PMP22* gene, which encodes a protein that is a component of the myelin sheath.

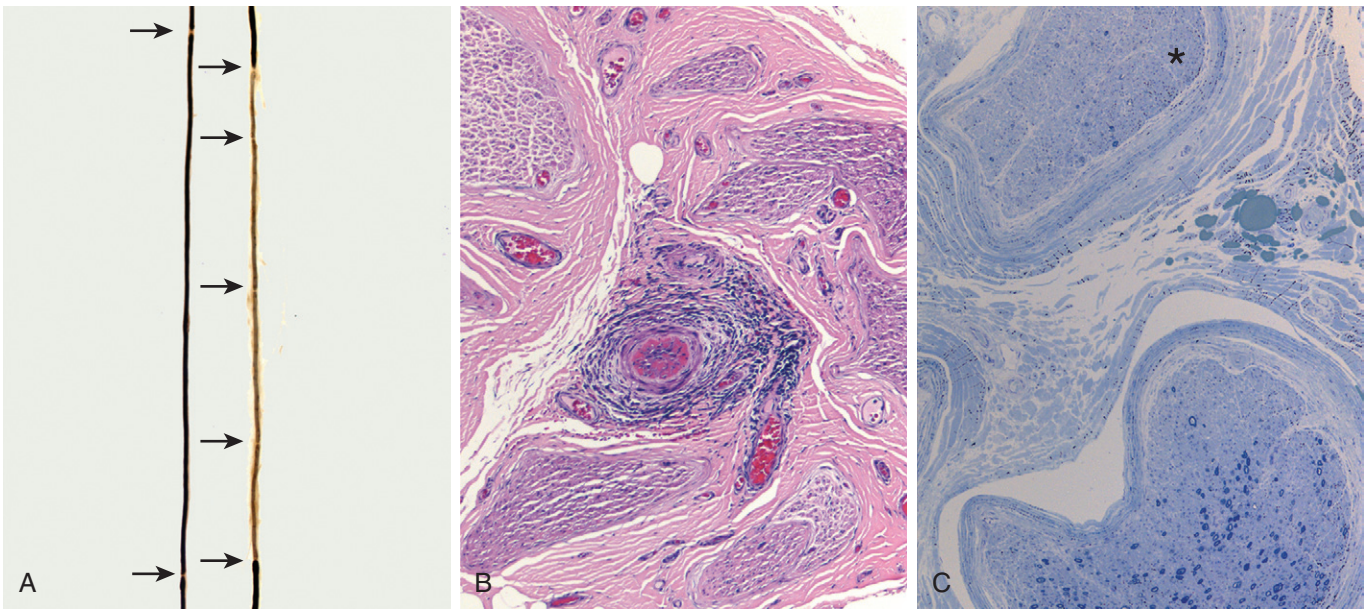

**Figure 21–2** Pathologic changes in peripheral neuropathies. **A,** Regeneration after segmental demyelination. Teased fiber preparations allow for examination of individual axons of peripheral nerves. A normal axon (*left*) has a myelin sheath of uniform thickness that is interrupted at the nodes of Ranvier (*arrows*). By contrast, the right axon contains a poorly myelinated segment with unevenly distributed nodes of Ranvier. The area of remyelination is segmental and therefore flanked by internodes with normal myelination. **B** and **C,** Vasculitic neuropathy. In **B,** the perineurial connective tissue contains a vasculocentric inflammatory infiltrate that has obliterated a small vessel. In **C,** a special stain that colors myelinated axons dark blue reveals that the nerve fascicle in the upper portion of this field (*asterisk*) has lost almost all of its large myelinated axons, in contrast with the other fascicle shown. Such interfascicular variation in axonal density often is seen in neuropathies resulting from vascular injury.

## SUMMARY

### Peripheral Neuropathies

- Peripheral neuropathies may result in weakness and/or sensory deficits and may be symmetric or consist of random involvement of individual nerves.
- Axonal and demyelinating peripheral neuropathies can be distinguished on the basis of clinical and pathologic features. Some disorders are associated with a mixed pattern of injury.
- Diabetes is the most common cause of peripheral neuropathy.
- Guillain-Barré syndrome and chronic idiopathic demyelinating polyneuropathy are immune-mediated demyelinating diseases that follow acute and chronic courses, respectively.
- Metabolic diseases, drugs, toxins, connective tissue diseases, vasculitides, and infections all can result in peripheral neuropathy.
- A number of mutations cause peripheral neuropathy. Many of these are late-onset diseases that may mimic acquired ones.

# DISORDERS OF NEUROMUSCULAR JUNCTION

The neuromuscular junction is a specialized interface between synaptic nerve endings and muscle fibers. Nerve impulses depolarize the presynaptic membrane, stimulating calcium influx and the release of acetylcholine into the synaptic cleft. Acetylcholine diffuses across the synaptic cleft to bind its receptor on the postsynaptic membrane, leading to depolarization of the myofiber and contraction through electromechanical coupling. Often disorders of the neuromuscular junction produce functional abnormalities in the absence of any significant alterations in morphology beyond ultrastructural changes. Considered in this section are some of the more common or pathogenically interesting disorders that disrupt the transmission of signals across the neuromuscular junction.

## Myasthenia Gravis

*Myasthenia gravis is caused by autoantibodies that block the function of postsynaptic acetylcholine receptors at motor end plates, which results in the degradation and depletion of the receptors.* The disease has an incidence of roughly 3 in 100,000 persons, can manifest at any age, and (like many autoimmune disorders) is more common in females. The disease can be transferred to animals with serum from affected patients, demonstrating the causal role of circulating anti-acetylcholine receptor antibodies. Some 60% of cases are associated with a peculiar reactive hyperplasia of intrathymic B cells (often referred to as thymic hyperplasia), and another 20% are associated with thymoma, a tumor of thymic epithelial cells (Chapter 11). These thymic lesions may perturb tolerance to self antigens, thereby setting the stage for the generation of autoreactive T and B cells.

Clinically, myasthenia gravis frequently manifests with *ptosis* (drooping eyelids) or *diplopia* (double vision) due to weakness in the extraocular muscles. This pattern of

weakness is distinctly different from that in most primary myopathic processes, in which there is relative sparing of facial and extraocular muscles. The severity of the weakness often fluctuates dramatically, sometimes over periods of only a few minutes. Characteristically, repetitive use or electrophysiologic stimulation of muscles makes the weakness more severe, whereas administration of cholinesterase inhibitors improves strength markedly; both of these features are diagnostically useful. Effective treatments include cholinesterase inhibitory drugs, immunosuppression, plasmapheresis, and (in patients with thymic lesions) thymectomy. These interventions have improved the 5-year survival rate to greater than 95%.

### Lambert-Eaton Syndrome

*Lambert-Eaton syndrome is caused by autoantibodies that inhibit the function of presynaptic calcium channels, which reduces the release of acetylcholine into the synaptic cleft.* In contrast with those suffering from myasthenia gravis, patients with Lambert-Eaton syndrome experience improvement in weakness with repetitive stimulation. This serves to build up sufficient intracellular calcium to facilitate acetylcholine release.

Like myasthenia gravis, however, the disorder can be transferred to animals through the serum of affected patients. It often arises as a paraneoplastic disorder, particularly in patients with small cell lung carcinoma. Cholinesterase inhibitors are not effective, and therapy is therefore directed toward reducing the titer of causative antibodies, through either plasmapheresis or immunosuppression. Owing to the strong link to lung cancer, the overall prognosis for patients with Lambert-Eaton syndrome is substantially worse than for those affected by myasthenia gravis.

### Miscellaneous Neuromuscular Junction Disorders

Several other neuromuscular junction disorders merit brief mention.

- *Congenital myasthenic syndromes* comprise a heterogeneous group of genetic diseases that result from mutations that disrupt the function of various neuromuscular junction proteins. Depending on the affected protein, the defects can occur at the level of acetylcholine release (presynaptic), the transport of acetylcholine across the synaptic cleft (synaptic), or the responsiveness of skeletal muscle (postsynaptic), and may produce symptoms suggestive of Lambert-Eaton syndrome or myasthenia gravis. Some forms respond to treatment with acetylcholinesterase inhibitors.
- *Infections* may be associated with defects in neural transmission and muscle contraction. *Clostridium tetani* and *Clostridium botulinum* (Chapter 8) both release extremely potent neurotoxins that interfere with neuromuscular transmission. Tetanus toxin (known as tetanospasmin) blocks the action of inhibitory neurons, leading to increased release of acetylcholine and sustained muscle contraction and spasm (tetanus). Botulinum toxin, by contrast, inhibits acetylcholine release, producing a flaccid paralysis. The purified toxin (Botox) is remarkably stable after injection, an attribute that has led to its widespread use as an antidote for wrinkles and a variety of other conditions associated with unwanted muscular activity (e.g., blepharospasm and strabismus).

#### SUMMARY

##### Neuromuscular Junction Disorders

- Disorders of neuromuscular junctions manifest with weakness that often affects facial and extraocular muscles and may show marked fluctuation in severity.
- Both myasthenia gravis and Lambert-Eaton syndrome, the most common forms, are immune-mediated, being caused by antibodies to postsynaptic acetylcholine receptors and presynaptic calcium channels, respectively.
- Myasthenia gravis often is associated with thymic hyperplasia or thymoma. Lambert-Eaton syndrome in a majority of cases is a paraneoplastic disorder; the strongest association is with small cell lung cancer.
- Genetic defects in neuromuscular junction proteins and bacterial toxins also can cause symptomatic disturbances in neuromuscular transmission.

## DISORDERS OF SKELETAL MUSCLE

### Patterns of Skeletal Muscle Injury

Skeletal muscle consists of different fiber types broadly classified as slow twitch "aerobic" type I and fast twitch "anaerobic" type II fibers. They are normally distributed in checkerboard pattern (Fig. 21–1, *A*). Function of both types of fibers depends on the unique protein complexes that make up the sarcomeres and the dystrophin-glycoprotein complex (Fig. 21–3), as well as enzymes that meet the special metabolic requirements of muscle.

*Primary muscle diseases or myopathies* have to be distinguished from *secondary neuropathic changes* caused by disorders that disrupt muscle innervation. Both are associated with altered muscle function and morphology, but each has distinctive features (Fig. 21–4). Myopathic conditions are often associated with segmental necrosis and regeneration of individual muscle fibers (Fig. 21–4, *B*). As discussed later on, specific types of myopathies have additional morphologic features, such as inflammatory infiltrates or intracellular inclusions. Disruption of muscle by endomysial fibrosis and fatty replacement is a feature of disease chronicity associated with myopathic or neuropathic conditions.

*Muscle fiber atrophy* is shared by both neuropathic and myopathic processes. However, certain disorders are associated with particular patterns of atrophy, as follows:

- *Neuropathic changes* are characterized by fiber type grouping and grouped atrophy. Changes in muscle innervation result in larger groups of fibers that share the same fiber type with the resultant replacement of the normal checkerboard distribution by groups of fibers that are type I or II (Fig. 21–4, *D*). The presence of fewer but larger motor units and the segregation of innervated fibers results in groups of atrophic fibers (Fig. 21–4, *C*). Remarkably, the fiber type of myofibers is not an

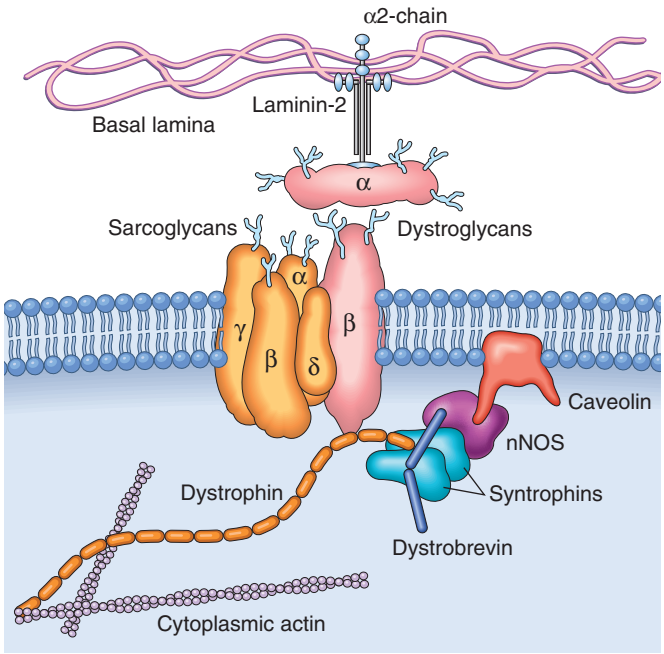

**Figure 21–3** The dystrophin-glycoprotein complex (DGC). This complex of glycoproteins serves to couple the cell membrane (the sarcolemma) to the extracellular matrix proteins such as laminin-2 and the intracellular cytoskeleton. One key set of connections is made by dystrophin, a scaffolding protein that tethers the myofibrillar cytoskeleton to the transmembrane dystroglycans and sarcoglycans, and also binds complexes containing dystrobrevin, syntrophin, neuronal nitric oxide synthetase (nNOS), and caveolin, which participate in intracellular signaling pathways. Mutations in dystrophin are associated with X-linked Duchenne and Becker muscular dystrophies; mutations in caveolin and the sarcoglycan proteins, with autosomal limb-girdle muscular dystrophies; and mutations in $\alpha_2$-laminin (merosin), with a form of congenital muscular dystrophy.

inherent feature, but is dictated by the innervating motor neuron. Thus, if injury and regeneration of peripheral nerves alters muscle innervation, it will change the distribution of type I and type II myofibers. Degeneration and regeneration of individual fibers and inflammatory infiltrates usually are absent in skeletal muscle disorders caused by abnormal innervation.

- *Prolonged disuse of muscles* due to any cause (e.g., prolonged bed rest in the sick, casting of a broken bone) can cause focal or generalized muscle atrophy, which tends to affect type II fibers more than type I fibers.
- *Glucocorticoid exposure,* whether exogenous or endogenous (e.g., in Cushing syndrome), also can cause muscle atrophy. Proximal muscles and type II myofibers are affected preferentially by these agents.

## Inherited Disorders of Skeletal Muscle

Genetic disorders affecting skeletal muscle include *muscular dystrophies, congenital muscular dystrophies, and congenital myopathies. Muscular dystrophies* are inherited diseases that result in progressive muscle injury in patients who usually appear normal at birth. *Congenital muscular dystrophies* are progressive, early-onset diseases. Some are also associated with central nervous system manifestations. *Congenital myopathies* are a heterogeneous group of inherited diseases that often have a perinatal or early childhood presentation and result in relatively static deficits.

The following discussion of the muscular dystrophies follows a long-standing classification that is based on inheritance patterns and clinical features. Of note, however, the classification of the muscular dystrophies is evolving based on new insights into the molecular pathogenesis of these disorders and genotype-phenotype relationships. For example, mutations in several different genes present as autosomal recessive limb-girdle muscular dystrophy, whereas different mutations in a single gene (such as dystrophin) can lead to two very different clinical phenotypes, the Duchenne and Becker types of muscular dystrophy.

### *Dystrophinopathies: Duchenne and Becker Muscular Dystrophy*

Dystrophinopathies are the most common form of muscular dystrophy. Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are the two most important disease manifestations linked to mutations in the dystrophin gene. Duchenne muscular dystrophy has an incidence of about 1 per 3500 live male births and follows an inexorable fatal course. DMD becomes clinically evident by the age of 5 years; most patients are wheelchair-bound by the time they are teenagers and dead of their disease by early adulthood. The Becker type of muscular dystrophy is less common and much less severe.

#### MORPHOLOGY

The histologic alterations in skeletal muscles affected by DMD and BMD are similar, except that the changes are milder in BMD (Fig. 21–5). The hallmarks of these as well as other muscular dystrophies are ongoing myofiber necrosis and regeneration. Progressive replacement of muscle tissue by fibrosis and fat is the result of degeneration outpacing repair. As a result of ongoing repair muscles typically show marked variation in myofiber size and abnormal internally placed nuclei. Both DMD and BMD also affect cardiac muscles, which show variable degrees of myofiber hypertrophy and interstitial fibrosis.

#### PATHOGENESIS

Both DMD and BMD are caused by loss-of-function mutations in the **dystrophin** gene located on the short arm of the X chromosome (Xp21). Dystrophin is a very large protein (427 kD in molecular weight) found in skeletal and cardiac muscle, brain, and peripheral nerves; it is part of the dystrophin-glycoprotein complex (Fig. 21–3). This complex stabilizes the muscle cell during contraction and may be involved in cell signaling through interaction with other proteins. Dystrophin-glycoprotein complex defects are thought to make muscle cells vulnerable to transient membrane tears during contraction that lead to calcium influx, and may also disrupt intracellular signaling. The result is myofiber degeneration that with time outpaces the capacity for repair. The dystrophin-glycoprotein complex also is important for cardiac muscle function; this explains why cardiomyopathy eventually develops in many patients.

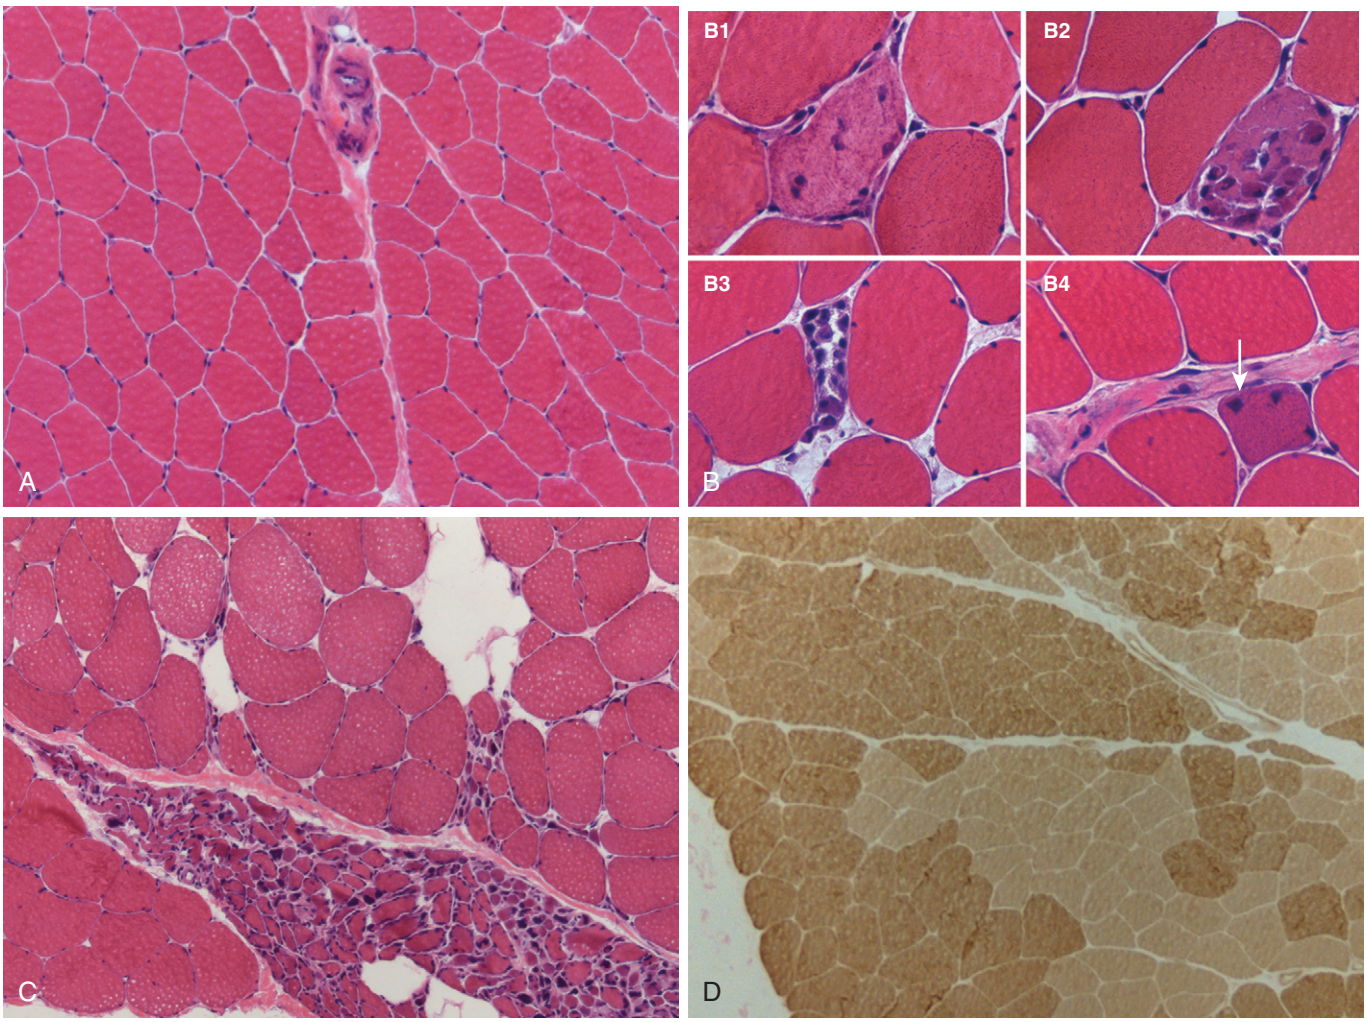

**Figure 21–4** Patterns of skeletal muscle injury. **A,** Normal skeletal muscle has relatively uniform polygonal myofibers with peripherally placed nuclei that are tightly packed together into fascicles separated by scant connective tissue. A perimysial interfascicular septum containing a blood vessel is present (*top center*). **B,** Myopathic conditions often are associated with segmental necrosis and regeneration of individual myofibers. Necrotic cells (*B1-B3*) are infiltrated by variable numbers of inflammatory cells. Regenerative myofibers (*B4*, *arrow*) are characterized by cytoplasmic basophilia and enlarged nucleoli (not visible at this power). **C** and **D,** Clusters of both atrophic myofibers **(C)** (grouped atrophy) and fiber-type grouping **(D),** patchy areas in which myofibers share the same fiber type, are features of neurogenic remodeling. The ATPase reaction shown in **D** is one method of distinguishing between fiber types, as type I fibers stain more lightly than type II fibers. Note loss of the "checkerboard" pattern (Fig 21–1, *A*).

The dystrophin gene spans roughly 2.4 megabases (about 1% of the X chromosome), making it one of the largest human genes. Its enormous size may explain in part its vulnerability to sporadic mutations that disrupt dystrophin production. The most common mutations are deletions, followed by frameshift and point mutations. Muscle biopsy specimens from patients with DMD show a complete absence of dystrophin, whereas patients with BMD have mutations that permit some dystrophin (albeit often a defective form) to be made; thus, **the severity of the disease correlates with the degree of the dystrophin deficiency.**

### Clinical Features

Often the first symptoms of DMD are clumsiness and an inability to keep up with peers due to muscle weakness. The weakness typically begins in the pelvic girdle and next involves the shoulder girdle. Enlargement of the calf muscles, termed *pseudohypertrophy,* is an important early physical finding. The increased muscle bulk initially stems from myofiber hypertrophy, but as myofibers progressively degenerate, an increasing part of the muscle is replaced by adipose tissue and endomysial fibrosis. Cardiac muscle damage and fibrosis can lead to heart failure and arrhythmias, which may prove fatal. Although no structural abnormalities in the central nervous system have been described, cognitive impairment is also sometimes seen and may be severe enough to manifest as mental retardation. Owing to ongoing muscle degeneration, high serum creatine kinase levels are present at birth and persist through the first decade of life but fall as muscle mass is lost during disease progression. Death results from respiratory insufficiency, pneumonia, and cardiac decompensation.

BMD becomes symptomatic later in childhood or adolescence and progresses at a slower and more variable rate. Many patients live well into adulthood and have a nearly normal life span. Cardiac involvement can be the dominant

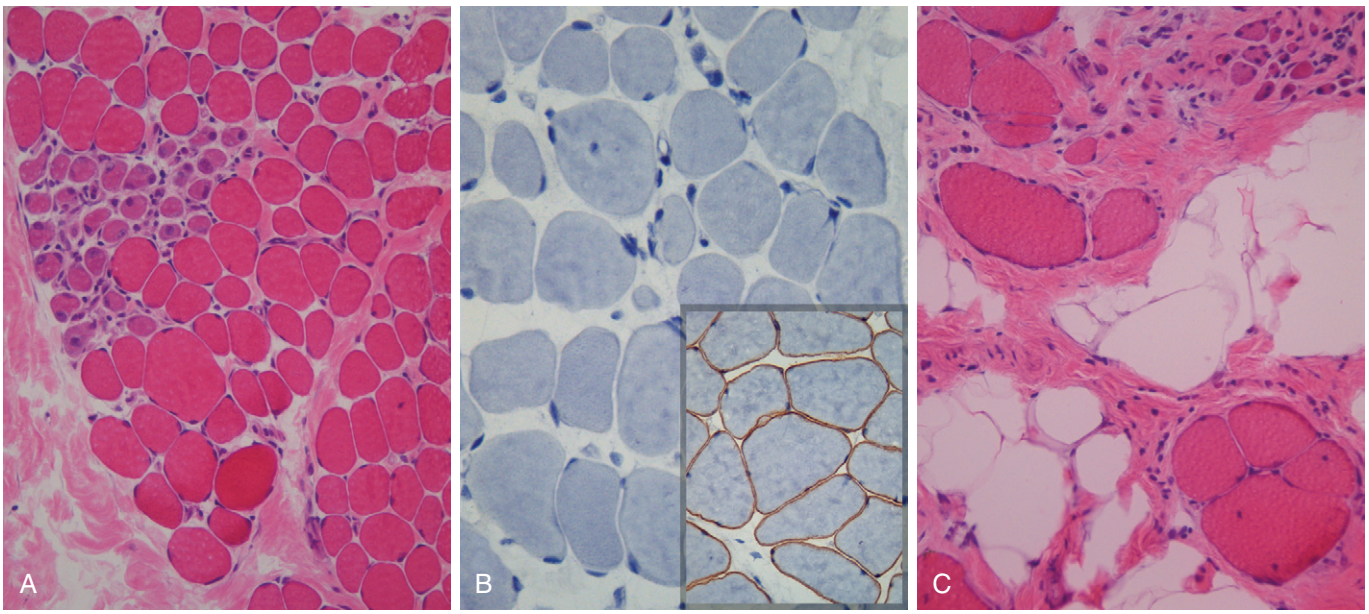

**Figure 21–5** Duchenne muscular dystrophy. Histologic images of muscle biopsy specimens from two brothers. **A** and **B,** Specimens from a 3-year-old boy. **C,** Specimen from his brother, 9 years of age. As seen in **A,** at a younger age fascicular muscle architecture is maintained, but myofibers show variation in size. Additionally, there is a cluster of basophilic regenerating myofibers *(left side)* and slight endomysial fibrosis, seen as focal pink-staining connective tissue between myofibers. In **B,** immunohistochemical staining shows a complete absence of membrane-associated dystrophin, seen as a brown stain in normal muscle (*inset*). In **C,** the biopsy from the older brother illustrates disease progression, which is marked by extensive variation in myofiber size, fatty replacement, and endomysial fibrosis.

clinical feature and may result in death in the absence of significant skeletal muscle weakness.

### *Other X-Linked and Autosomal Muscular Dystrophies*

Other forms of muscular dystrophy share some features with DMD and BMD but have distinct clinical, genetic, and pathologic features.

- *Myotonic dystrophy.* Myotonia, the sustained involuntary contraction of a group of muscles, is the cardinal neuromuscular symptom in myotonic dystrophy. Patients often complain of stiffness and difficulty releasing their grip, for instance, after a handshake. Myotonic dystrophy is inherited as an autosomal dominant trait. More than 95% of patients with myotonic dystrophy have mutations in the gene that encodes the dystrophia myotonica protein kinase (DMPK). In normal subjects, this gene contains fewer than 30 repeats of the sequence CTG, whereas in severely affected persons, several thousand repeats may be present. Myotonic dystrophy thus falls into the group of disorders associated with trinucleotide repeat expansions (Chapter 6). As is the case with other disorders with similar mutations, myotonic dystrophy exhibits the phenomenon of *anticipation,* characterized by worsening of the disease manifestations with each passing generation due to further trinucleotide repeat expansion. The CTG repeat expansion is located in the 3′ untranslated region of the DMPK mRNA, and the manner in which it produces disease is unclear. The disease often manifests in late childhood with gait abnormalities due to weakness of foot dorsiflexors, with subsequent progression to weakness of the intrinsic muscles of the hands and wrist extensors, atrophy of the facial muscles, and ptosis. Other tissues may also be affected, presenting as cardiac arrhythmias, cataracts, early frontal balding, endocrinopathies, and testicular atrophy.
- *Limb-girdle muscular dystrophies.* These autosomal muscular dystrophies preferentially affect the proximal musculature of the trunk and limbs. The genetic basis for these is heterogeneous. The growing list includes at least 6 dominant subtypes and 12 autosomal recessive subtypes. Some of the responsible mutations affect components of the dystrophin-glycoprotein complex other than dystrophin. Others affect proteins involved in vesicle transport and repair of cell membrane after injury (caveolin-3 and dysferlin), cytoskeletal proteins, or posttranslational modification of dystroglycan, a component of the dystrophin-glycoprotein complex.
- *Emery-Dreifuss muscular dystrophy* (EMD) is a rare but fascinating disorder caused by mutations affecting structural proteins found in the nucleus. An X-linked form results from mutations in the gene encoding the protein emerin, while an autosomal dominant form is caused by mutations in the gene encoding lamin A/C. It is hypothesized that defects in these proteins compromise the structural integrity of the nucleus in cells that are subjected to repetitive mechanical stress (e.g., cardiac and skeletal muscle). These proteins also may regulate chromatin structure. The clinical picture is characterized by progressive muscle weakness and wasting, contractures of the elbows and ankles, and cardiac disease. The cardiac involvement is severe, being associated with cardiomyopathy and arrhythmias that lead to sudden death in up to 40% of patients.
- *Fascioscapulohumeral dystrophy* is an autosomal dominant form of muscular dystrophy that is usually associated with deletions in chromosomal region 4q35. The pathophysiologic relationship between this chromosomal

defect and the disease phenotype is not known. Most patients become symptomatic by the age of 20 years, usually owing to weakness in the facial muscles and the shoulder. Patients also exhibit weakness in the lower trunk and the dorsiflexors of the foot. Most affected persons have a normal life expectancy.

### *Channelopathies, Metabolic Myopathies, and Mitochondrial Myopathies*

Other important inherited disorders of skeletal muscle are the result of defects in ion channels (channelopathies), metabolism, and mitochondrial function.

- *Ion channel myopathies* are a group of familial disorders characterized by myotonia, relapsing episodes of hypotonic paralysis associated with abnormal serum potassium levels, or both. As implied by their name, these diseases stem from inherited defects in genes encoding ion channels. *Hyperkalemic periodic paralysis* results from mutations in the gene encoding the skeletal muscle sodium channel protein SCN4A, which regulates sodium entry during contraction. *Malignant hyperthermia* is a rare syndrome characterized by a dramatic hypermetabolic state (tachycardia, tachypnea, muscle spasms, and finally hyperpyrexia). It is triggered when patients carrying mutations in the ryanodine receptor, a calcium release channel protein, are given halogenated anesthetic agents or succinylcholine during surgery. Some of these patients also show features of a congenital myopathy referred to as central core disease, so called because the center of the myofiber contains a collection of disorganized myofibrils.
- *Myopathies due to inborn errors of metabolism* include disorders of glycogen synthesis and degradation (Chapter 6), and abnormalities in lipid handling. The latter include disorders of the carnitine transport system or deficiencies of the mitochondrial dehydrogenase enzyme system, both of which can lead to significant accumulation of lipid in myocytes (lipid myopathies). These storage disorders can manifest as systemic disease or result in a muscle-specific phenotype. Some are associated with ongoing muscle damage and weakness. Others manifest with recurring episodes of massive exercise- or fasting-induced muscle damage, sometimes associated with acute renal failure and myoglobulinuria (rhabdomyolysis).
- *Mitochondrial myopathies* can stem from mutations in either the mitochondrial or nuclear genomes, the latter because some mitochondrial enzymes are encoded in nuclear DNA. The forms caused by mitochondrial mutations show maternal inheritance (Chapter 6). Mitochondrial myopathies usually manifest in early adulthood with proximal muscle weakness and sometimes with severe involvement of the ocular musculature (*external ophthalmoplegia*). There can also be neurologic signs and symptoms, lactic acidosis, and cardiomyopathy. Some mitochondrial diseases are associated with normal muscle morphology, whereas others show aggregates of abnormal mitochondria; the latter impart a blotchy red appearance in special stains—hence the term *ragged red fibers.* On ultrastructural examination, these correspond to abnormal aggregates of mitochondria with abnormal shape and size, some containing paracrystalline *parking lot inclusions*.

## Acquired Disorders of Skeletal Muscle

A diverse group of acquired disorders can manifest with muscle weakness, muscle cramping, or muscle pain. These include inflammatory myopathies, toxic muscle injuries, postinfectious rhabdomyolysis, and muscle infarction in the setting of diabetes. In most instances these are disorders of adults with acute or subacute onsets.

### *Inflammatory Myopathies*

Polymyositis, dermatomyositis, and inclusion body myositis are the most important primary inflammatory myopathies. Other immune disorders (e.g., SLE, sarcoidosis) also can involve skeletal muscle.

- *Polymyositis* is an autoimmune disorder associated with increased expression of MHC class I molecules on myofibers and predominantly endomysial inflammatory infiltrates containing CD8+ cytotoxic T cells. The autoimmune attack leads to myofiber necrosis and subsequent regeneration (Fig. 21–6, *A*). Patients with polymyositis are often successfully treated with corticosteroids or other immunosuppressive agents.
- *Dermatomyositis* is the most common inflammatory myopathy in children, in whom it appears as an isolated entity. In adults, it can manifest as a paraneoplastic disorder. In both contexts, it is believed to have an autoimmune basis. On microscopic examination, it is associated with perivascular mononuclear cell infiltrates, "dropout" of capillaries, the presence of so-called tubuloreticular inclusions in endothelial cells, and myofiber damage in a paraseptal or perifascicular pattern (Fig. 21–6, *B*). Type 1 interferon-induced gene products are strongly upregulated in affected muscles. Some patients have autoantibodies that are relatively specific for dermatomyositis; these include antibodies against Mi-2 (a nuclear helicase) and p155 and p140, proteins with uncertain functions.
- *Inclusion body myositis* is the most common inflammatory myopathy in patients older than 60 years of age. It is lumped in with other forms of myositis, but it has yet to be determined whether inflammation is cause or effect in this disorder. The morphologic hallmark of inclusion body myositis is the presence of rimmed vacuoles (Fig. 21–6, *C*) that contain aggregates of the same proteins that accumulate in the brains of patients with neurodegenerative diseases—hyperphosphorylated tau, amyloid derived from β-amyloid precursor protein and TDP-43 (Chapter 20)—leading some to speculate that this is a degenerative disorder of aging. Other features typical of chronic inflammatory myopathies, including myopathic changes, mononuclear cell infiltrates, endomysial fibrosis, and fatty replacement, also are evident. The disease follows a chronic, progressive course and generally does not respond well to immunosuppressive agents, another feature suggesting that inflammation is a secondary event.

### *Toxic Myopathies*

A number of insults can cause toxic muscle injury, including intrinsic factors (e.g., thyroxine) and extrinsic factors (e.g., acute alcohol intoxication, various drugs).

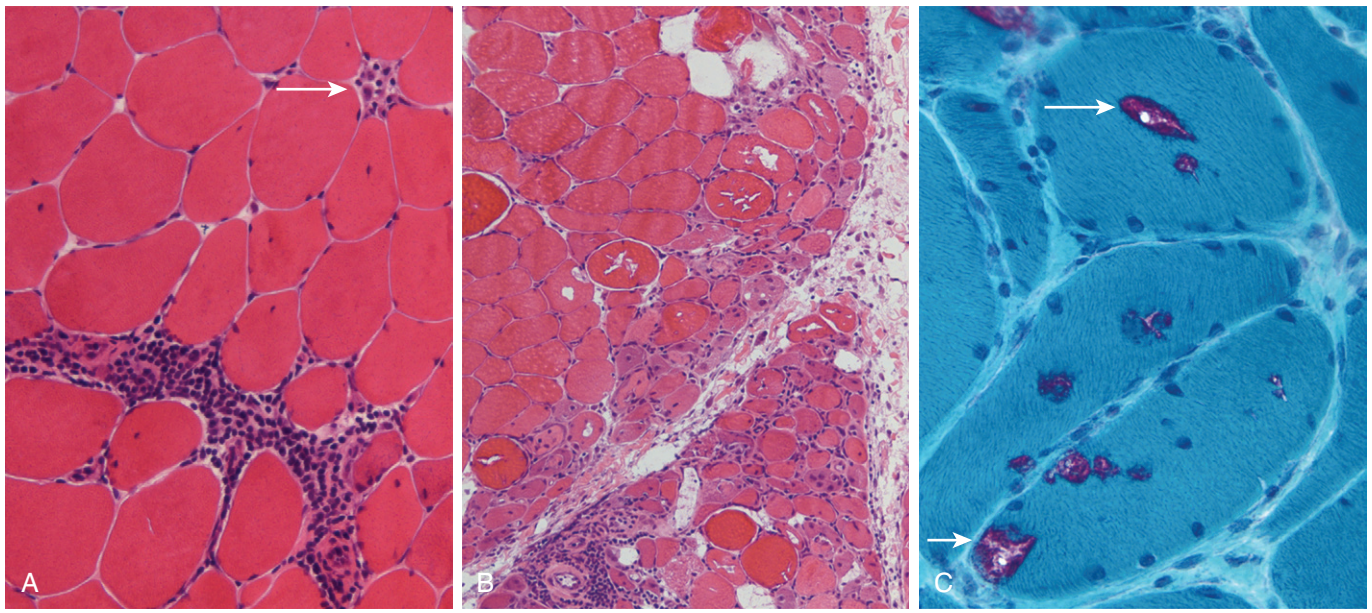

**Figure 21–6** Inflammatory myopathies. **A,** Polymyositis is characterized by endomysial inflammatory infiltrates and myofiber necrosis (*arrow*). **B,** Dermatomyositis often shows prominent perifascicular and paraseptal atrophy. **C,** Inclusion body myositis, showing myofibers containing rimmed vacuoles (*arrows*). Modified Gomori trichrome stain.

- *Thyrotoxic myopathy* may take the form of either acute or chronic proximal muscle weakness, and can be the first indication of thyrotoxicosis. Histologic findings include myofiber necrosis and regeneration.
- *Ethanol myopathy* occurs after an episode of binge drinking. The degree of rhabdomyolysis may be severe, sometimes leading to acute renal failure secondary to myoglobinuria. Patients usually complain of acute muscle pain, which may be generalized or confined to a single muscle group. Microscopically, there is myocyte swelling, necrosis, and regeneration.
- *Drug myopathy* can be produced by a variety of agents. Currently the most commonly implicated drugs are those belonging to the statin family. The affected muscles show evidence of myopathic injury, usually without an inflammatory component.

## SUMMARY

### Disorders of Skeletal Muscle

- Skeletal muscle function can be impaired secondarily because of problems with muscle innervation or by a primary myopathy that can be inherited or acquired.
- The genetic forms of myopathy fall into several fairly distinct clinical phenotypes, including muscular dystrophy, congenital myopathy, and congenital muscular dystrophy.
- Dystrophinopathies are X-linked disorders caused by mutations in the dystrophin gene and disruption of the dystrophin-glycoprotein complex. Depending on the type of mutation the disease may be severe, such as Duchenne muscular dystrophy, or mild (e.g., Becker dystrophy).
- Acquired myopathies have diverse causes, including inflammation and toxic exposures.

## PERIPHERAL NERVE SHEATH TUMORS

A number of different tumors arise from peripheral nerves. Such tumors may manifest as soft tissue masses or with pain or loss of function related to impingement on nerves or other surrounding structures. In most peripheral nerve tumors, the neoplastic cells show evidence of Schwann cell differentiation. These tumors usually occur in adults and include both benign and malignant variants. An important feature is their frequent association with the familial tumor syndromes neurofibromatosis type 1 (NF1) and neurofibromatosis type 2 (NF2). Tumors with skeletal muscle differentiation also occur; these are discussed in Chapter 20, along with other tumors of soft tissues.

### Schwannomas and Neurofibromatosis Type 2

Schwannomas are benign encapsulated tumors that may occur in soft tissues, internal organs, or spinal nerve roots. The most commonly affected cranial nerve is the vestibular portion of the eighth nerve. Tumors arising in a nerve root or the vestibular nerve may be associated with symptoms related to nerve root compression, which includes hearing loss in the case of vestibular schwannomas.

Most schwannomas are sporadic, but about 10% are associated with familial neurofibromatosis type 2. NF2 patients are at risk of developing multiple schwannomas, meningiomas, and ependymomas (the latter are described in Chapter 22). The presence of bilateral vestibular schwannomas is a hallmark of NF2. Affected patients carry a dominant loss of function mutation of the merlin gene on chromosome 22. Merlin is a cytoskeletal protein that functions as a tumor suppressor by facilitating E-cadherin–mediated contact inhibition (Chapter 5). Of note, merlin expression is also disrupted in sporadic schwannomas. Despite the name of the syndrome, neurofibromas are not a feature of NF2. Schwannomatosis is a familial condition

associated with multiple schwannomas in which vestibular schwannomas are absent. Some cases have recently been linked to loss-of-function mutations in a tumor suppressor gene on chromosome 22 that encodes a protein that regulates chromatin structure.

### MORPHOLOGY

On gross inspection, most schwannomas appear as circumscribed masses abutting an adjacent nerve. On microscopic examination, these tumors often show an admixture of dense and loose areas referred to as Antoni A and B, respectively (Fig. 21–7, *A* and *B*). They are comprised of a uniform proliferation of neoplastic Schwann cells. In the dense Antoni A areas, bland spindle cells with buckled nuclei are arranged into intersecting fascicles. These cells often align to produce nuclear palisading, resulting in alternating bands of nuclear and anuclear areas called Verocay bodies. Axons are largely excluded from the tumor. Thick-walled hyalinized vessels often are present. Hemorrhage or cystic change are also seen sometimes.

## Neurofibromas

Neurofibromas are benign peripheral nerve sheath tumors. Three important subtypes are recognized:

- *Localized cutaneous neurofibromas* arise as superficial nodular or polypoid tumors. These occur either as solitary sporadic lesions or as often multiple lesions in the context of neurofibromatosis type 1 (NF1).
- *Plexiform neurofibromas* grow diffusely within the confines of a nerve or nerve plexus. Surgical enucleation of such lesions is therefore difficult and is often associated with lasting neurologic deficits. Plexiform neurofibromas are virtually pathognomonic for NF1 (discussed later on). Unlike other benign nerve sheath tumors, these tumors are associated with a small but real risk of malignant transformation.
- *Diffuse neurofibromas* are infiltrative proliferations that can take the form of large, disfiguring subcutaneous masses. These also are often associated with NF1.

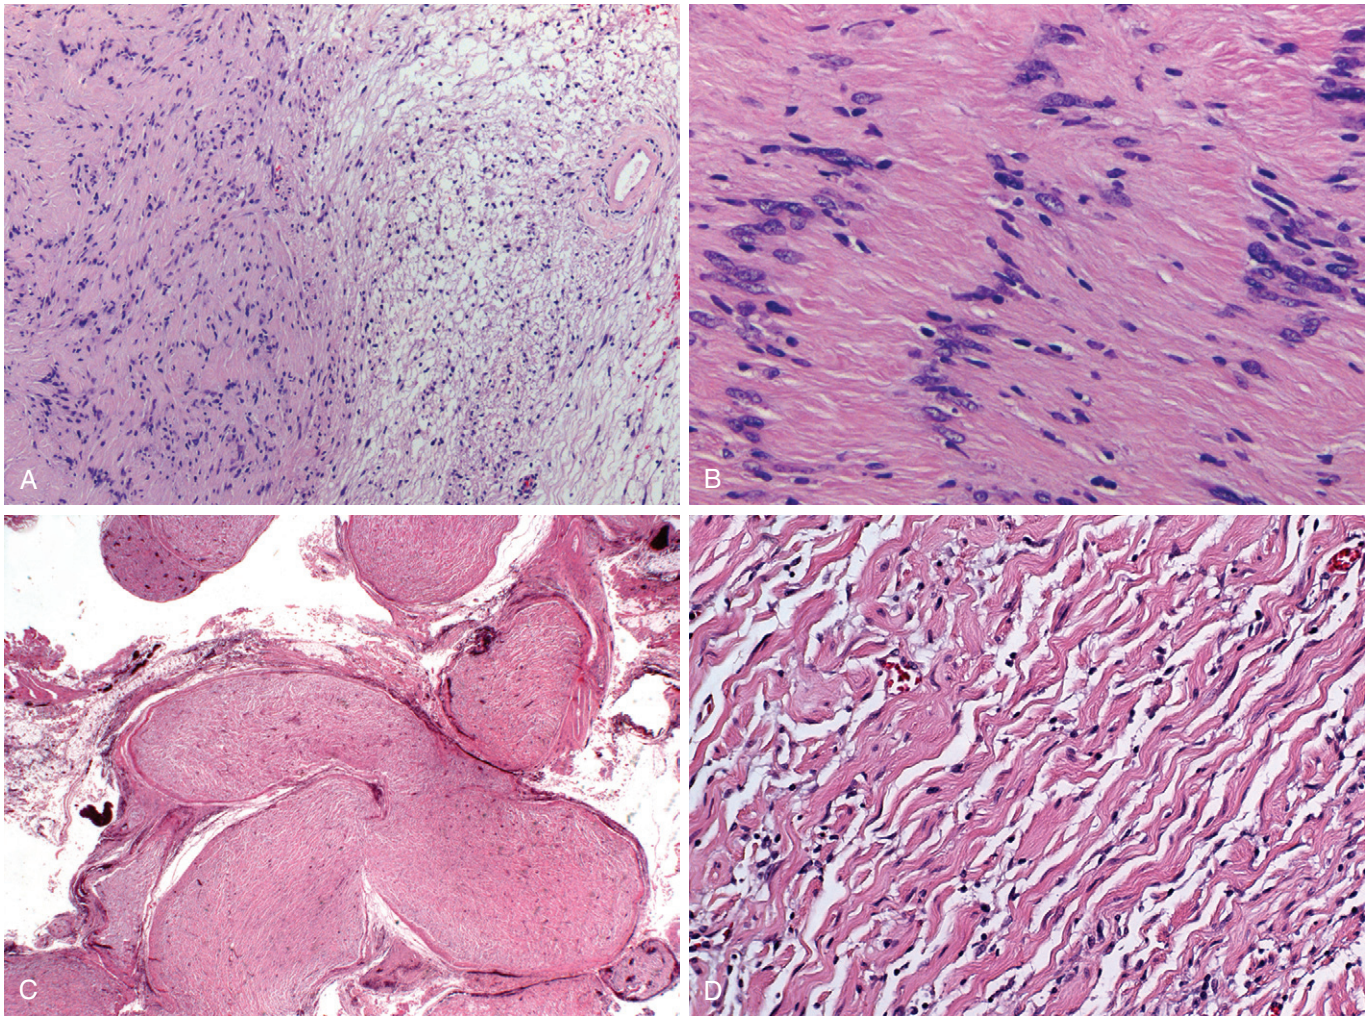

**Figure 21–7** Schwannoma and plexiform neurofibroma. **A** and **B,** Schwannoma. As seen in **A,** schwannomas often contain dense pink Antoni A areas (*left*) and loose, pale Antoni B areas (*right*), as well as hyalinized blood vessels (*right*). **B,** Antoni A area with the nuclei of tumor cells aligned in palisading rows. **C** and **D,** Plexiform neurofibroma. Multiple nerve fascicles are expanded by infiltrating tumor cells **(C),** which at higher power **(D)** are seen to consist of bland spindle cells admixed with wavy collagen bundles likened to carrot shavings.

### MORPHOLOGY

Unlike schwannomas, neurofibromas are not encapsulated. They may appear circumscribed, as in **localized cutaneous neurofibromas,** or exhibit a diffuse infiltrative growth pattern. Also in contrast with schwannomas, the neoplastic Schwann cells in neurofibroma are admixed with other cell types, including mast cells, fibroblast-like cells and perineurial-like cells. As a result, the cellular growth pattern of neurofibromas is more haphazard than that of schwannomas. The background stroma often contains loose wavy collagen bundles but also can be myxoid or contain dense collagen (Fig. 21–7, *D*). **Plexiform neurofibromas** involve multiple fascicles of individual affected nerves (Fig. 21–7, *C*). Residual axons are found embedded within the diffuse neoplastic Schwann cell proliferation, which expand the fascicles while leaving the perineurium intact. **Diffuse neurofibromas** show an extensive infiltrative pattern of growth within the dermis and subcutis of the skin.

## Malignant Peripheral Nerve Sheath Tumors

Malignant peripheral nerve sheath tumors are neoplasms seen in adults that typically show evidence of Schwann cell derivation and sometimes a clear origin from a peripheral nerve. They may arise from transformation of a neurofibroma, usually of the plexiform type. About one half of such tumors arise in patients with NF1, and 3% to 10% of all patients with NF1 develop a malignant peripheral nerve sheath tumor during their lifetime.

### MORPHOLOGY

Malignant peripheral nerve sheath tumors manifest as large, poorly defined soft tissue masses. On histologic examination, these tumors are highly cellular and exhibit features of overt malignancy, including anaplasia, necrosis, infiltrative growth pattern, pleomorphism, and high proliferative activity. The low-power view often shows alternating areas of high and low cellularity that result in an appearance described as "marble-like." Also frequently seen are perivascular areas of increased cellular density.

## Neurofibromatosis Type 1

NF1 is an autosomal dominant disorder caused by mutations in the tumor suppressor neurofibromin, encoded on the long arm of chromosome 17 (17q). Neurofibromin is a negative regulator of the potent oncoprotein Ras (Chapter 5). Disruption of neurofibromin function and Ras hyperactivity appear to be a cardinal feature of NF1-associated tumors. As would be anticipated for a tumor suppressor gene, the sole normal neurofibromin allele is mutated or silenced in tumors arising in the setting of NF1, which include neurofibromas of all three main types, malignant peripheral nerve sheath tumors, optic gliomas, and other glial tumors. In addition, patients with NF1 exhibit learning disabilities, seizures, skeletal abnormalities, vascular abnormalities with arterial stenoses, pigmented nodules of the iris (*Lisch nodules*), and pigmented skin lesions (axillary freckling and café au lait spots) in various degrees.

## Traumatic Neuroma

Traumatic neuroma is a non-neoplastic proliferation associated with previous injury of a peripheral nerve. Injuries that lead to the transection of axons activate a regenerative program (see Fig. 21–1) characterized by sprouting and elongation of processes from the proximal axonal stump. With severe injuries that disrupt the perineurial sheath, these new processes may "miss" their target, the distal end of the transected nerve. The misguided elongating axonal processes can induce a reactive proliferation of Schwann cells, leading to the formation of a painful localized nodule that consists of a haphazard mixture of axons, Schwann cells, and connective tissue.

### SUMMARY

#### Peripheral Nerve Sheath Tumors

- In most peripheral nerve sheath tumors, the neoplastic cells show evidence of Schwann cell differentiation.
- Peripheral nerve sheath tumors are important features of the familial tumor syndromes neurofibromatosis type 1 (NF1) and type 2 (NF2).
- Schwannomas and neurofibromas are benign nerve sheath tumors.
- Schwannomas are circumscribed, usually encapsulated tumors that abut the nerve of origin and are a feature of NF2.
- Neurofibromas may manifest as a sporadic subcutaneous nodule, as a large, poorly defined soft tissue lesion, or as a growth within a nerve. Neurofibromas are associated with NF1.
- About 50% of malignant peripheral nerve sheath tumors occur de novo in otherwise normal persons, while the remainder arise from the malignant transformation of a preexisting NF1-associated neurofibroma.

Degenerative, inflammatory, infectious, and neoplastic disorders of the central nervous system (CNS) are some of the most serious diseases of mankind. The pathology of these diseases has many features that reflect the unique properties of the CNS. In fact, the diagnosis and analysis of CNS disorders requires specialized expertise, a realization that has led to the creation of the field of neuropathology.

## PATTERNS OF INJURY IN THE NERVOUS SYSTEM

The cells of the nervous system respond to various forms of injury with distinct morphologic changes.

### MORPHOLOGY

**Features of Neuronal Injury.** In response to injury, a number of changes occur in neurons and their processes (axons and dendrites). Within 12 hours of an irreversible hypoxic-ischemic insult, acute neuronal injury becomes evident on routine hematoxylin and eosin (H&E) staining (Fig. 22–1, *A*). There is shrinkage of the cell body, pyknosis of the nucleus, disappearance of the nucleolus, and loss of Nissl substance, with intense eosinophilia of the cytoplasm ("red neurons"). Often, the nucleus assumes the angulated shape of the shrunken cell body. Injured axons undergo swelling and show disruption of axonal transport. The swellings **(spheroids)** can be recognized on H&E stains (Fig. 22–1, *B*) and can be highlighted by silver staining or immunohistochemistry. Axonal injury also leads to cell body enlargement and rounding, peripheral displacement of the nucleus, enlargement of the nucleolus, and peripheral dispersion of Nissl substance **(central chromatolysis)** (Fig. 22–1, *C*). In addition, acute injuries typically result in breakdown of the blood-brain barrier and variable degrees of cerebral edema (described later).

Many neurodegenerative diseases are associated with specific intracellular inclusions (e.g., Lewy bodies in Parkinson disease and tangles in Alzheimer disease), also described later. Pathogenic viruses can also form inclusions in neurons, just as they do in other cells of the body. In some neurodegenerative diseases, neuronal processes also become thickened and tortuous; these are termed **dystrophic neurites.** With age, neurons also accumulate complex lipids **(lipofuscin)** in their cytoplasm and lysosomes.

**Astrocytes in Injury and Repair.** Astrocytes are the principal cells responsible for repair and scar formation in the

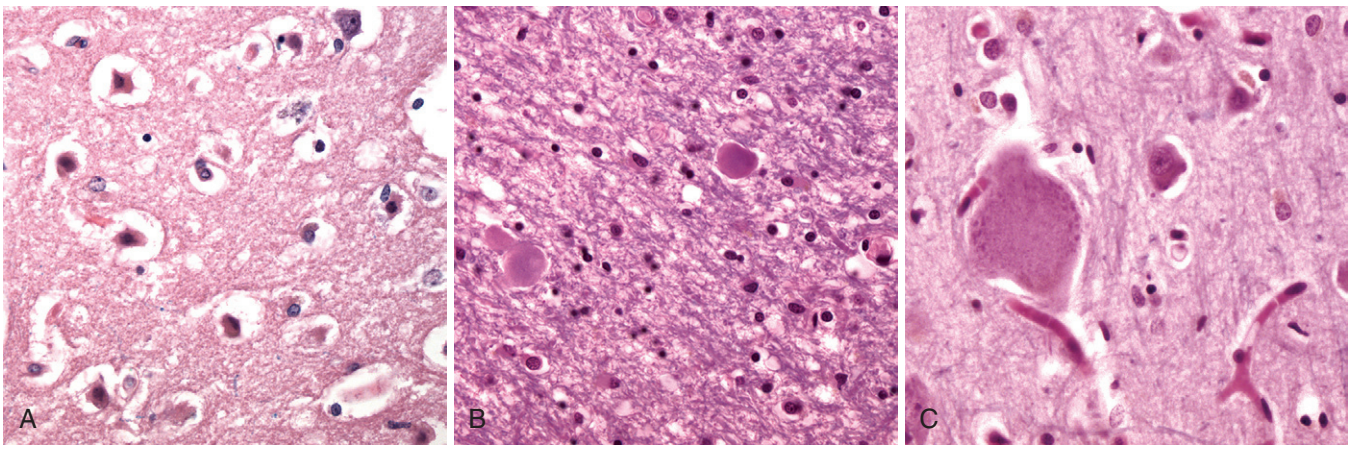

**Figure 22–1** Patterns of neuronal injury. **A,** Acute hypoxic-ischemic injury in cerebral cortex, where the individual cell bodies are shrunken, along with the nuclei. They also are prominently stained by eosin ("red neurons"). **B,** Axonal spheroids are visible as bulbous swellings at points of disruption, or altered axonal transport. **C,** With axonal injury there can be swelling of the cell body and peripheral dispersal of the Nissl substance, termed chromatolysis.

brain, a process termed **gliosis.** In response to injury, astrocytes undergo both hypertrophy and hyperplasia. The nucleus enlarges and becomes vesicular, and the nucleolus becomes prominent. The previously scant cytoplasm expands and takes on a bright pink hue, and the cell extends multiple stout, ramifying processes **(gemistocytic astrocyte).** Unlike elsewhere in the body, fibroblasts participate in healing after brain injury to a limited extent except in specific settings (penetrating brain trauma or around abscesses). In long-standing gliosis, the cytoplasm of reactive astrocytes shrinks in size and the cellular processes become more tightly interwoven **(fibrillary astrocytes). Rosenthal fibers** are thick, elongated, brightly eosinophilic protein aggregates found in astrocytic processes in chronic gliosis and in some low-grade gliomas.

**Changes in Other Cell Types. Oligodendrocytes,** which produce myelin, exhibit a limited spectrum of specific morphologic changes in response to various injuries. In progressive multifocal leukoencephalopathy, viral inclusions can be seen in oligodendrocytes, with a smudgy, homogeneous-appearing enlarged nucleus.

**Microglial cells** are bone-marrow–derived cells that function as the resident phagocytes of the CNS. When activated by tissue injury, infection, or trauma, they proliferate and become more prominent histologically. Microglial cells take on the appearance of activated macrophages in areas of demyelination, organizing infarct, or hemorrhage; in other settings such as neurosyphilis or other infections, they develop elongated nuclei **(rod cells).** Aggregates of elongated microglial cells at sites of tissue injury are termed **microglial nodules.** Similar collections can be found congregating around and phagocytosing injured neurons **(neuronophagia).**

**Ependymal cells** line the ventricular system and the central canal of the spinal cord. Certain pathogens, particularly cytomegalovirus (CMV), can produce extensive ependymal injury, with typical viral inclusions. **Choroid plexus** is in continuity with the ependyma, and its specialized epithelial covering is responsible for the secretion of cerebrospinal fluid (CSF).

## EDEMA, HERNIATION, AND HYDROCEPHALUS

The brain and spinal cord exist within the protective and rigid skull and spinal canal, with nerves and blood vessels passing through specific foramina. The advantage of housing the delicate CNS within such a protective environment is obvious, but this arrangement provides little room for brain parenchymal expansion in disease states. Disorders that may cause dangerous increases in brain volume within the fixed space of the skull include generalized cerebral edema, hydrocephalus, and mass lesions such as tumors.

### Cerebral Edema

Cerebral edema is the accumulation of excess fluid within the brain parenchyma. There are two types, which often occur together particularly after generalized injury.

- *Vasogenic edema* occurs when the integrity of the normal blood-brain barrier is disrupted, allowing fluid to shift from the vascular compartment into the extracellular spaces of the brain. Vasogenic edema can be either localized (e.g., increased vascular permeability due to inflammation or in tumors) or generalized.
- *Cytotoxic edema* is an increase in intracellular fluid secondary to neuronal and glial cell membrane injury, as might follow generalized hypoxic-ischemic insult or after exposure to some toxins.

The edematous brain is softer than normal and often appears to "over fill" the cranial vault. In generalized edema the gyri are flattened, the intervening sulci are narrowed, and the ventricular cavities are compressed (Fig. 22–2).

### Hydrocephalus

After being produced by the choroid plexus within the ventricles, CSF circulates through the ventricular system

**Figure 22–2** Cerebral edema. The surfaces of the gyri are flattened as a result of compression of the expanding brain by the dura mater and inner surface of the skull. Such changes are associated with a dangerous increase in intracranial pressure.

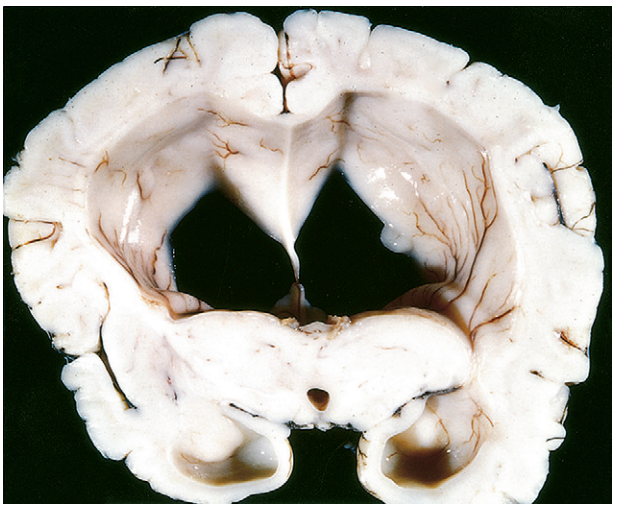

**Figure 22–3** Hydrocephalus. Dilated lateral ventricles seen in a coronal section through the midthalamus.

and flows through the foramina of Luschka and Magendie into the subarachnoid space, where it is absorbed by arachnoid granulations. The balance between rates of generation and resorption regulates CSF volume.

*Hydrocephalus* refers to the accumulation of excessive CSF within the ventricular system. This disorder most often is a consequence of impaired flow or resorption; overproduction of CSF, typically seen with tumors of the choroid plexus, only rarely causes hydrocephalus. If there is a localized obstacle to CSF flow within the ventricular system, then a portion of the ventricles enlarges while the remainder does not. This pattern is referred to as *noncommunicating hydrocephalus* and most commonly is caused by masses obstructing the foramen of Monro or compressing the cerebral aqueduct. In *communicating hydrocephalus,* the entire ventricular system is enlarged; it is usually caused by reduced CSF resorption.

If hydrocephalus develops in infancy before closure of the cranial sutures, the head enlarges. Once the sutures fuse, hydrocephalus causes ventricular expansion and increased intracranial pressure, but no change in head circumference (Fig. 22–3). In contrast with these states, in which increased CSF volume is the primary process, a compensatory increase in CSF volume can also follow the loss of brain parenchyma (*hydrocephalus ex vacuo*), as after infarcts or with degenerative diseases.

## Herniation

When the volume of tissue and fluid inside the skull increases beyond the limit permitted by compression of veins and displacement of CSF, intracranial pressure rises. The cranial vault is subdivided by rigid dural folds (falx and tentorium), and a focal expansion of the brain displaces it in relation to these partitions. If the expansion is sufficiently large, herniation occurs. Herniation often leads to "pinching" and vascular compromise of the compressed tissue, producing infarction, additional swelling, and further herniation. There are three main types of herniation (Fig. 22–4).

- *Subfalcine (cingulate)* herniation occurs when unilateral or asymmetric expansion of a cerebral hemisphere displaces the cingulate gyrus under the edge of falx. This may be associated with compression of the anterior cerebral artery.
- *Transtentorial (uncinate)* herniation occurs when the medial aspect of the temporal lobe is compressed against the free margin of the tentorium. As the temporal lobe is displaced, the third cranial nerve is compromised, resulting in pupillary dilation and impaired ocular

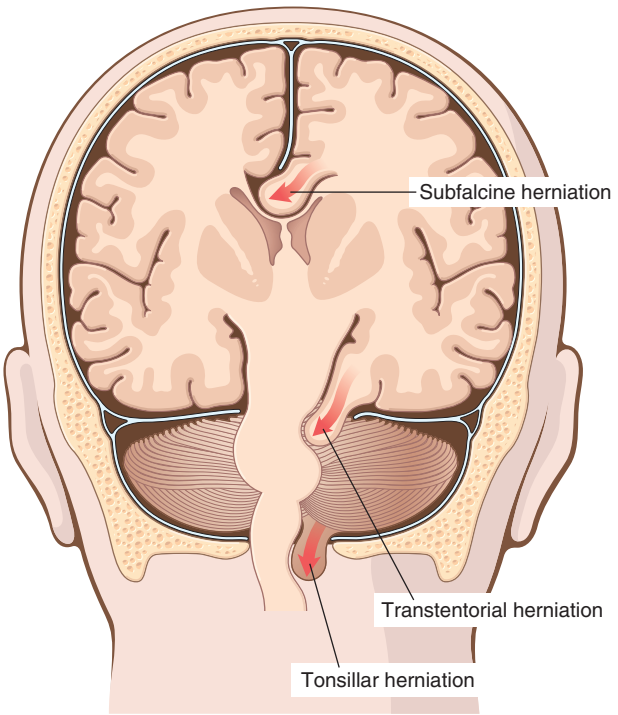

**Figure 22–4** Herniation syndromes. Displacement of brain parenchyma across fixed barriers can be subfalcine, transtentorial, or tonsillar (into the foramen magnum).

movements on the side of the lesion ("blown pupil"). The posterior cerebral artery may also be compressed, resulting in ischemic injury to tissue supplied by that vessel, including the primary visual cortex. If the amount of displaced temporal lobe is large enough, the pressure on the midbrain can compress the contralateral cerebral peduncle against the tentorium, resulting in hemiparesis ipsilateral to the side of the herniation (a so-called false localizing sign). The compression of the peduncle creates a deformation known as Kernohan's notch. Progression of transtentorial herniation is often accompanied by linear or flame-shaped hemorrhages in the midbrain and pons, termed *Duret hemorrhages* (Fig. 22–5). These lesions usually occur in the midline and paramedian regions and are believed to be the result of tearing of penetrating veins and arteries supplying the upper brain stem.

- *Tonsillar* herniation refers to displacement of the cerebellar tonsils through the foramen magnum. This type of herniation is life-threatening, because it causes brain stem compression and compromises vital respiratory and cardiac centers in the medulla.

## SUMMARY

### Edema, Herniation, and Hydrocephalus

- Cerebral edema is the accumulation of excess fluid within the brain parenchyma. Hydrocephalus is defined as an increase in CSF volume within all or part of the ventricular system.
- Increases in brain volume (as a result of increased CSF volume, edema, hemorrhage, or tumor) raise the pressure inside the fixed capacity of the skull.
- Increases in pressure can damage the brain either by decreasing perfusion or by displacing tissue across dural partitions inside the skull or through openings in the skull (herniations).

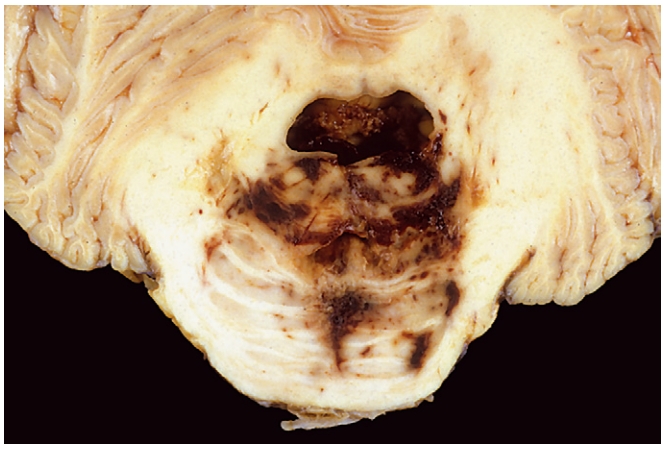

**Figure 22–5** Duret hemorrhage. As mass effect displaces the brain downward, there is disruption of the vessels that enter the pons along the midline, leading to hemorrhage.

# CEREBROVASCULAR DISEASES

Cerebrovascular diseases—the broad category of brain disorders caused by pathologic processes involving blood vessels—constitute a major cause of death in the developed world and are the most prevalent cause of neurologic morbidity. The three main pathogenic mechanisms are (1) thrombotic occlusion, (2) embolic occlusion, and (3) vascular rupture. *Stroke* is the clinical designation applied to all of these conditions when symptoms begin acutely. Thrombosis and embolism have similar consequences for the brain: loss of oxygen and metabolic substrates, resulting in infarction or ischemic injury of regions supplied by the affected vessel. Similar injury occurs globally when there is complete loss of perfusion, severe hypoxemia (e.g., hypovolemic shock), or profound hypoglycemia. Hemorrhage accompanies rupture of vessels and leads to direct tissue damage as well as secondary ischemic injury. Traumatic vascular injury is discussed separately in the context of trauma.

## Hypoxia, Ischemia, and Infarction

The brain is a highly oxygen-dependent tissue that requires a continual supply of glucose and oxygen from the blood. Although it constitutes no more than 2% of body weight, the brain receives 15% of the resting cardiac output and is responsible for 20% of total body oxygen consumption. Cerebral blood flow normally remains stable over a wide range of blood pressure and intracranial pressure because of autoregulation of vascular resistance. The brain may be deprived of oxygen by two general mechanisms:

- *Functional hypoxia,* caused by a low partial pressure of oxygen (e.g., high altitude), impaired oxygen-carrying capacity (e.g., severe anemia, carbon monoxide poisoning), or inhibition of oxygen use by tissue (e.g., cyanide poisoning)
- *Ischemia,* either *transient* or *permanent,* due to tissue hypoperfusion, which can be caused by hypotension, vascular obstruction, or both

### *Global Cerebral Ischemia*

Widespread ischemic-hypoxic injury can occur in the setting of severe systemic hypotension, usually when systolic pressures fall below 50 mm Hg, as in cardiac arrest, shock, and severe hypotension. The clinical outcome varies with the severity and duration of the insult. When the insult is mild, there may be only a transient postischemic confusional state, with eventual complete recovery. Neurons are more susceptible to hypoxic injury than are glial cells, and the most susceptible neurons are the pyramidal cells of the hippocampus and neocortex and Purkinje cells of the cerebellum. In some individuals, even mild or transient global ischemic insults may cause damage to these vulnerable areas. In severe global cerebral ischemia, widespread neuronal death occurs irrespective of regional vulnerability. Patients who survive often remain severely impaired neurologically and in a persistent vegetative state. Other patients meet the clinical criteria for so-called brain death, including evidence of diffuse cortical injury (isoelectric, or "flat," electroencephalogram) and brain

stem damage, including absence of reflexes and respiratory drive. When patients with this form of irreversible injury are maintained on mechanical ventilation, the brain gradually undergoes autolysis, resulting in the so-called "respirator brain."

## MORPHOLOGY

In the setting of global ischemia, the brain is swollen, with wide gyri and narrowed sulci. The cut surface shows poor demarcation between gray and white matter. The histopathologic changes that accompany irreversible ischemic injury (infarction) are grouped into three categories. **Early changes,** occurring 12 to 24 hours after the insult, include acute neuronal cell change (red neurons) (Fig. 22–1, *A*) characterized initially by microvacuolization, followed by cytoplasmic eosinophilia, and later nuclear pyknosis and karyorrhexis. Similar changes occur somewhat later in astrocytes and oligodendroglia. After this, the reaction to tissue damage begins with infiltration by neutrophils (Fig. 22–6, *A*). **Subacute changes,** occurring at 24 hours to 2 weeks, include necrosis of tissue, influx of macrophages, vascular proliferation, and reactive gliosis (Fig. 22–6, *B*). **Repair,** seen after 2 weeks, is characterized by removal of all necrotic tissue, loss of organized CNS structure, and gliosis (Fig. 22–6, *C*). The distribution of neuronal loss and gliosis in the neocortex typically is uneven with preservation of some layers and devastation of others—a pattern termed pseudolaminar necrosis.

**Border zone ("watershed") infarcts** are wedge-shaped areas of infarction that occur in regions of the brain and spinal cord that lie at the most distal portions of arterial territories. They are usually seen after hypotensive episodes. In the cerebral hemispheres, the border zone between the anterior and the middle cerebral artery distributions is at greatest risk. Damage to this region produces a band of necrosis over the cerebral convexity a few centimeters lateral to the interhemispheric fissure.

### *Focal Cerebral Ischemia*

Cerebral arterial occlusion leads first to focal ischemia and then to infarction in the distribution of the compromised vessel. The size, location, and shape of the infarct and the extent of tissue damage that results may be modified by collateral blood flow. Specifically, collateral flow through the circle of Willis or cortical-leptomeningeal anastomoses can limit damage in some regions. By contrast, there is little if any collateral flow to structures such as the thalamus, basal ganglia, and deep white matter, which are supplied by deep penetrating vessels.

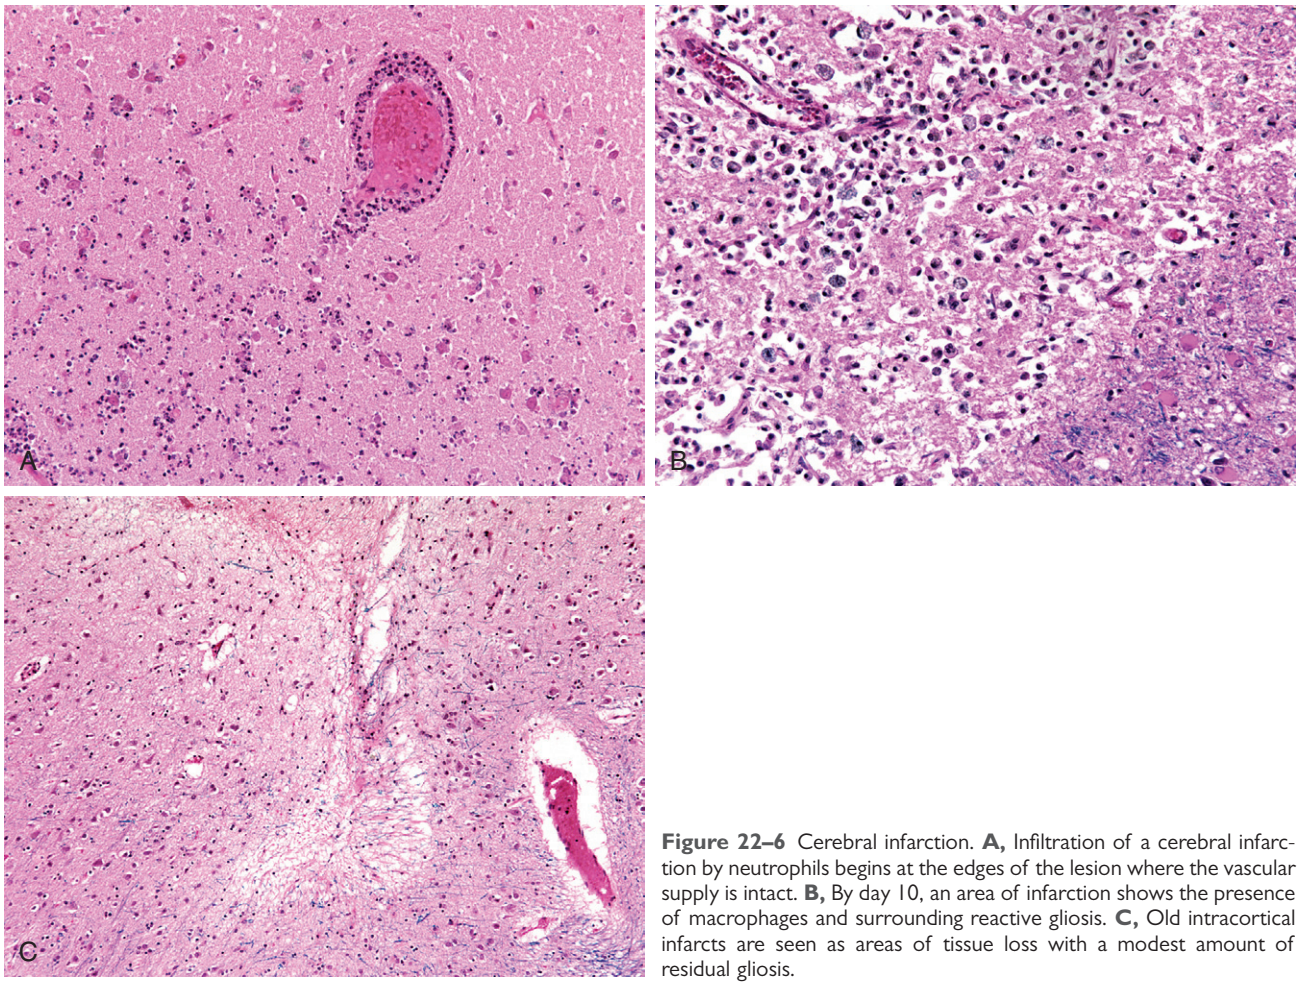

**Figure 22–6** Cerebral infarction. **A,** Infiltration of a cerebral infarction by neutrophils begins at the edges of the lesion where the vascular supply is intact. **B,** By day 10, an area of infarction shows the presence of macrophages and surrounding reactive gliosis. **C,** Old intracortical infarcts are seen as areas of tissue loss with a modest amount of residual gliosis.

*Embolic* infarctions are more common than infarctions due to *thrombosis.* Cardiac mural thrombi are a frequent source of emboli; myocardial dysfunction, valvular disease, and atrial fibrillation are important predisposing factors. Thromboemboli also arise in arteries, most often from atheromatous plaques within the carotid arteries or aortic arch. Other emboli of venous origin cross over to the arterial circulation through cardiac defects and lodge in the brain (paradoxical embolism; see Chapter 3); these include thromboemboli from deep leg veins and fat emboli, usually following bone trauma. The territory of the middle cerebral artery, a direct extension of the internal carotid artery, is most frequently affected by embolic infarction. Emboli tend to lodge where vessels branch or in areas of stenosis, usually caused by *atherosclerosis.*

Thrombotic occlusions causing cerebral infarctions usually are superimposed on atherosclerotic plaques; common sites are the carotid bifurcation, the origin of the middle cerebral artery, and at either end of the basilar artery. These occlusions may be accompanied by anterograde extension, as well as thrombus fragmentation and distal embolization.

Infarcts can be divided into two broad groups based on their macroscopic and corresponding radiologic appearance (Fig. 22–7). *Nonhemorrhagic infarcts* result from acute vascular occlusions and can be treated with thrombolytic therapies, especially if identified shortly after presentation. This approach is contraindicated in *hemorrhagic infarcts,* which result from reperfusion of ischemic tissue, either through collaterals or after dissolution of emboli, and often produce multiple, sometimes confluent petechial hemorrhages (Fig. 22–7, *A* and *B*).

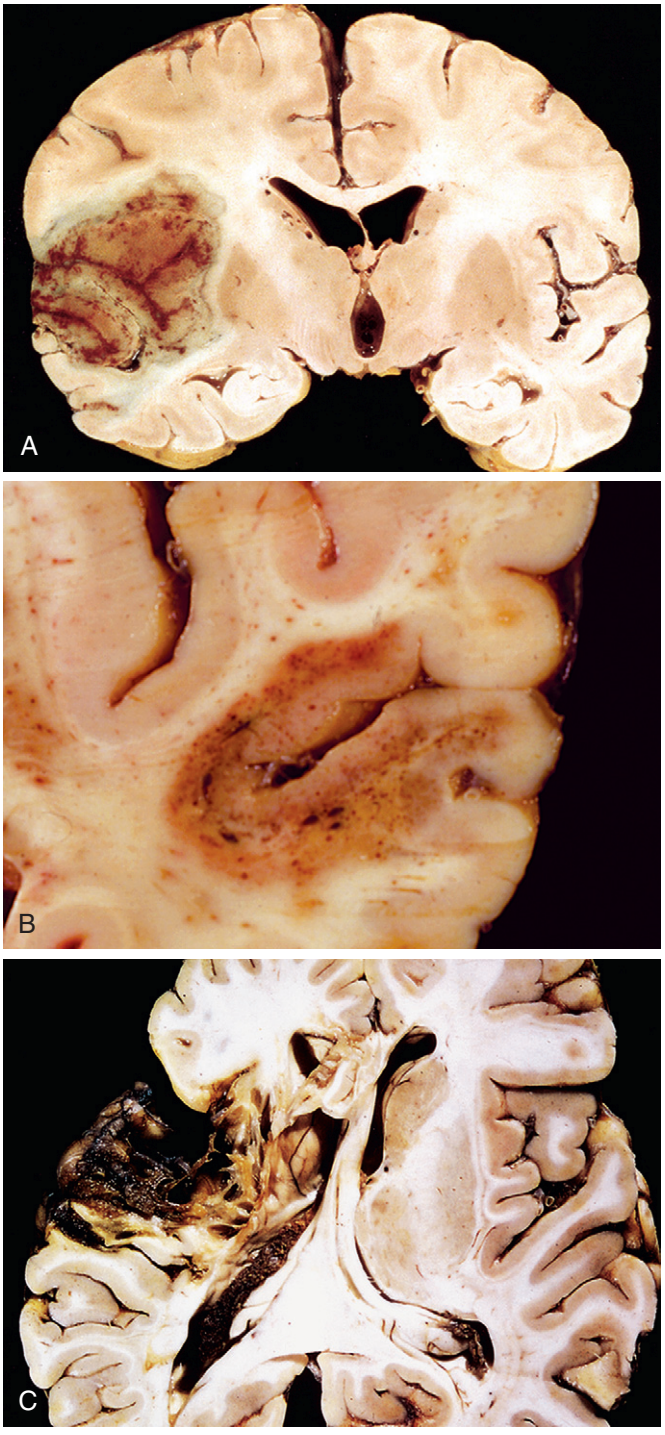

**Figure 22–7** Cerebral infarction. **A,** Section of the brain showing a large, discolored, focally hemorrhagic region in the left middle cerebral artery distribution (hemorrhagic, or red, infarction). **B,** An infarct with punctate hemorrhages, consistent with ischemia-reperfusion injury, is present in the temporal lobe. **C,** Old cystic infarct shows destruction of cortex and surrounding gliosis.

## MORPHOLOGY

The macroscopic appearance of a **nonhemorrhagic infarct** evolves over time. During the first 6 hours the tissue is unchanged in appearance, but by 48 hours, the tissue becomes pale, soft, and swollen. From days 2 to 10, the brain turns gelatinous and friable, and the boundary between normal and abnormal tissue becomes more distinct as edema resolves in the adjacent viable tissue. From day 10 to week 3, the tissue liquefies, eventually leaving a fluid-filled cavity lined by dark gray tissue, which gradually expands as dead tissue is resorbed (Fig. 22–7, *C*).

Microscopically, the tissue reaction follows a characteristic sequence. **After the first 12 hours,** ischemic neuronal change (red neurons) (Fig. 22–1, *A*) and cytotoxic and vasogenic edema predominate. Endothelial and glial cells, mainly astrocytes, swell, and myelinated fibers begin to disintegrate. **Up to 48 hours,** there is some neutrophilic emigration, which is followed by mononuclear phagocytic cells during the ensuing **2 to 3 weeks.** Macrophages containing myelin or red cell breakdown products may persist in the lesion for months to years. As the process of phagocytosis and liquefaction proceeds, astrocytes at the edges of the lesion progressively enlarge, divide, and develop a prominent network of cytoplasmic extensions.

**After several months,** the striking astrocytic nuclear and cytoplasmic enlargement regresses. In the wall of the cavity, astrocyte processes form a dense feltwork of glial fibers admixed with new capillaries and a few perivascular connective tissue fibers. In the cerebral cortex, the cavity is delimited from the meninges and subarachnoid space by a gliotic layer of tissue, derived from the molecular layer of the

cortex. The pia and arachnoid are not affected and do not contribute to the healing process.

The microscopic picture and evolution of **hemorrhagic infarction** parallel those of ischemic infarction, with the addition of blood extravasation and resorption. In persons with coagulopathies, hemorrhagic infarcts may be associated with extensive intracerebral hematomas.

## Intracranial Hemorrhage

Hemorrhages within the brain are associated with (1) hypertension and other diseases leading to vascular wall injury, (2) structural lesions such as arteriovenous and cavernous malformations, and (3) tumors. Subarachnoid hemorrhages most commonly are caused by ruptured aneurysms but also occur with other vascular malformations. Subdural or epidural hemorrhages usually are associated with trauma.

### *Primary Brain Parenchymal Hemorrhage*

Spontaneous (nontraumatic) intraparenchymal hemorrhages are most common in mid- to late adult life, with a peak incidence at about 60 years of age. Most are due to the rupture of a small intraparenchymal vessel. Hypertension is the leading underlying cause, and brain hemorrhage accounts for roughly 15% of deaths among persons with chronic hypertension. Intracerebral hemorrhage can be clinically devastating when it affects large portions of the brain or extends into the ventricular system; alternatively, it can affect small regions and be clinically silent. Hypertensive intraparenchymal hemorrhages typically occur in the basal ganglia, thalamus, pons, and cerebellum (Fig. 22–8), with the location and the size of the bleed determining its clinical manifestations. If the person survives the acute event, gradual resolution of the hematoma ensues, sometimes with considerable clinical improvement.

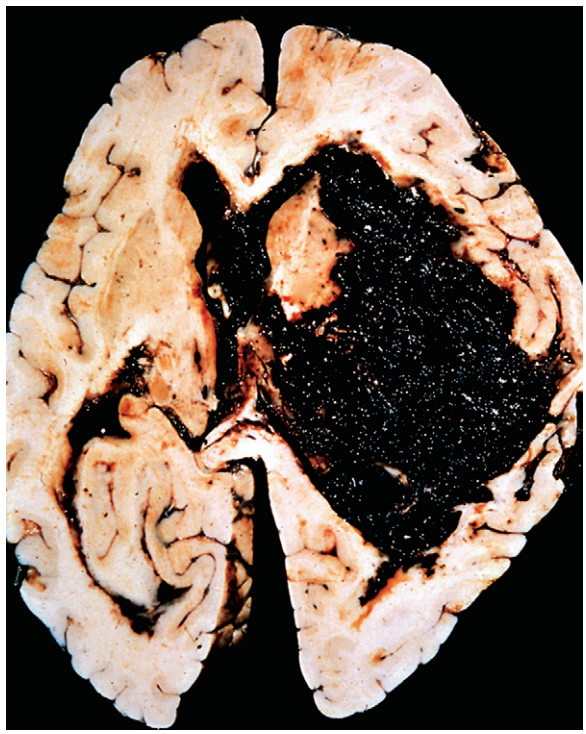

**Figure 22–8** Cerebral hemorrhage. Massive hypertensive hemorrhage rupturing into a lateral ventricle.

#### MORPHOLOGY

Acute hemorrhages are characterized by extravasated blood, which compresses the adjacent parenchyma. With time, hemorrhages are converted to a cavity with a brown, discolored rim. On microscopic examination, early lesions consist of clotted blood surrounded by brain tissue showing anoxic neuronal and glial changes as well as edema. Eventually the edema resolves, pigment- and lipid-laden macrophages appear, and proliferation of reactive astrocytes becomes visible at the periphery of the lesion. The cellular events then follow the same time course observed after cerebral infarction.

### *Cerebral Amyloid Angiopathy*

Cerebral amyloid angiopathy (CAA) is a disease in which amyloidogenic peptides, typically the same ones found in Alzheimer disease (discussed later), deposit in the walls of medium- and small-caliber meningeal and cortical vessels. The amyloid confers a rigid, pipelike appearance and stains with Congo red. Amyloid deposition weakens vessel walls and increases the risk of hemorrhages, which differ in distribution from those associated with hypertension. Specifically, CAA-associated hemorrhages often occur in the lobes of the cerebral cortex (*lobar hemorrhages*).

### *Subarachnoid Hemorrhage and Saccular Aneurysms*

The most frequent cause of clinically significant nontraumatic subarachnoid hemorrhage is rupture of a *saccular (berry) aneurysm.* Hemorrhage into the subarachnoid space also may result from vascular malformation, trauma (usually associated with other signs of the injury), rupture of an intracerebral hemorrhage into the ventricular system, hematologic disturbances, and tumors.

Rupture can occur at any time, but in about one third of cases it is associated with acute increases in intracranial pressure, such as with straining at stool or sexual orgasm. Blood under arterial pressure is forced into the subarachnoid space, and the patient is stricken with sudden, excruciating headache (classically described as "the worst headache I've ever had") and rapidly loses consciousness. Between 25% and 50% of affected persons die from the first bleed, and recurrent bleeds are common in survivors. Not surprisingly, the prognosis worsens with each bleeding episode.

About 90% of saccular aneurysms occur in the anterior circulation near major arterial branch points (Fig. 22–9); multiple aneurysms exist in 20% to 30% of cases. Although they are sometimes referred to as *congenital,* they are not present at birth but develop over time because of underlying defects in the vessel media. There is an increased risk of aneurysms in patients with autosomal dominant polycystic kidney disease (Chapter 13), as well as those with genetic disorders of extracellular matrix proteins. Overall, roughly 1.3% of aneurysms bleed per year, with the

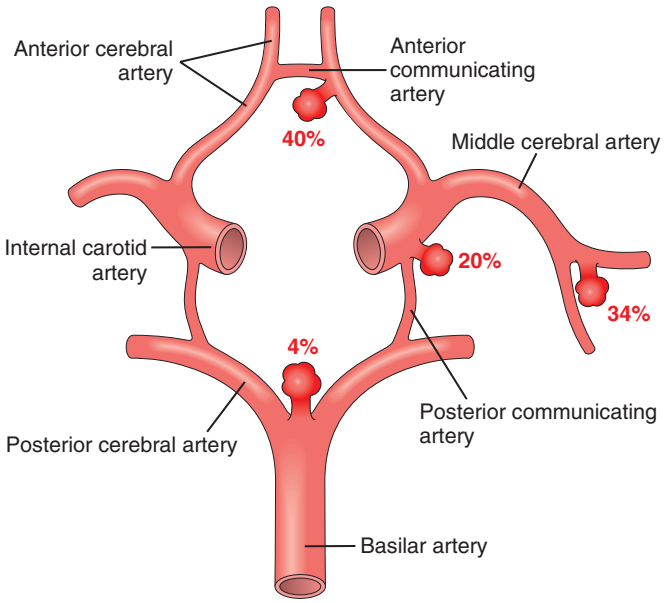

**Figure 22–9** Common sites of saccular aneurysms.

probability of rupture increasing nonlinearly with size. For example, aneurysms larger than 1 cm in diameter have a roughly 50% risk of bleeding per year. In the early period after a subarachnoid hemorrhage, there is an additional risk of ischemic injury from vasospasm of other vessels. Healing and the attendant meningeal fibrosis and scarring sometimes obstruct CSF flow or disrupt CSF resorption, leading to hydrocephalus.

## MORPHOLOGY

An unruptured saccular aneurysm is a thin-walled outpouching of an artery (Fig. 22–10). Beyond the neck of the aneurysm, the muscular wall and intimal elastic lamina are absent, such that the aneurysm sac is lined only by thickened hyalinized intima. The adventitia covering the sac is continuous with that of the parent artery. Rupture usually occurs at the apex of the sac, releasing blood into the subarachnoid space or the substance of the brain, or both.

In addition to saccular aneurysms, atherosclerotic, mycotic, traumatic, and dissecting aneurysms also occur intracranially. The last three types (like saccular aneurysms) most often are found in the anterior circulation, whereas atherosclerotic aneurysms frequently are fusiform and most commonly involve the basilar artery. Nonsaccular aneurysms usually manifest with cerebral infarction due to vascular occlusion instead of subarachnoid hemorrhage.

### *Vascular Malformations*

Vascular malformations of the brain are classified into four principal types based on the nature of the abnormal vessels: *arteriovenous malformations* (AVMs), *cavernous malformations, capillary telangiectasias,* and *venous angiomas.* AVMs, the most common of these, affect males twice as frequently as females and most commonly manifest between the ages of 10 and 30 years with seizures, an intracerebral hemorrhage, or a subarachnoid hemorrhage. Large AVMs occurring in the newborn period can lead to high-output congestive heart failure because of blood shunting from arteries to veins. The risk of bleeding makes AVM the most dangerous type of vascular malformation. Multiple AVMs can be seen in the setting of hereditary hemorrhagic telangiectasia, an autosomal dominant condition often associated with mutations affecting the TGFβ pathway.

## MORPHOLOGY

**AVMs** may involve subarachnoid vessels extending into brain parenchyma or occur exclusively within the brain. On gross inspection, they resemble a tangled network of wormlike

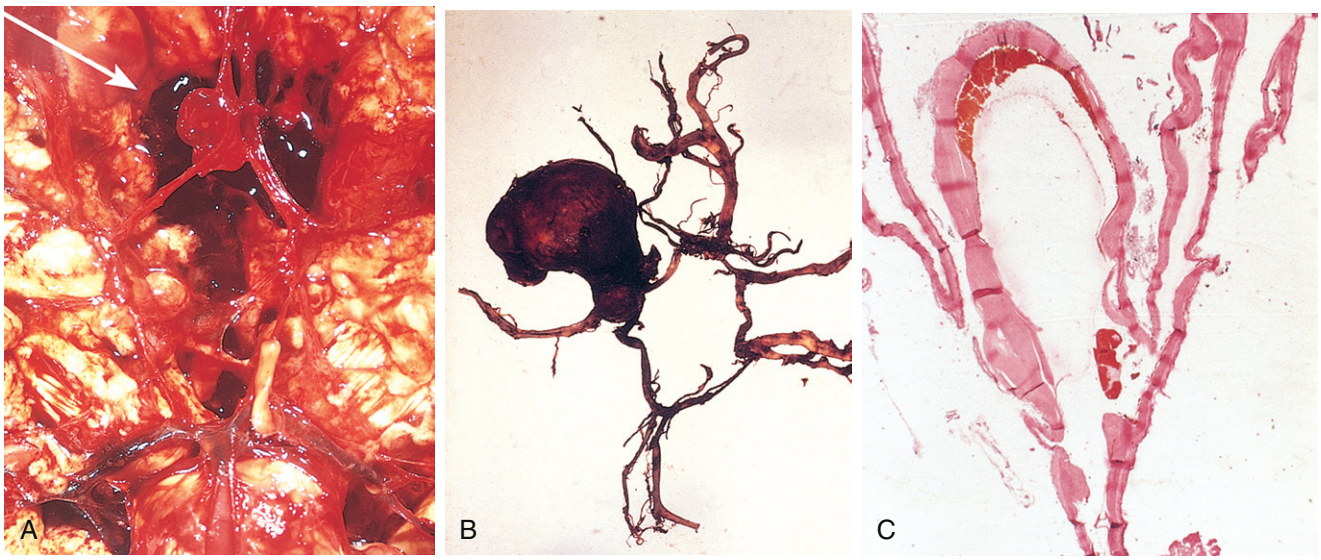

**Figure 22–10** Saccular aneurysms. **A,** View of the base of the brain, dissected to show the circle of Willis with an aneurysm of the anterior cerebral artery *(arrow)*. **B,** Circle of Willis dissected to show large aneurysm. **C,** Section through a saccular aneurysm showing the hyalinized fibrous vessel wall. Hematoxylin-eosin stain.

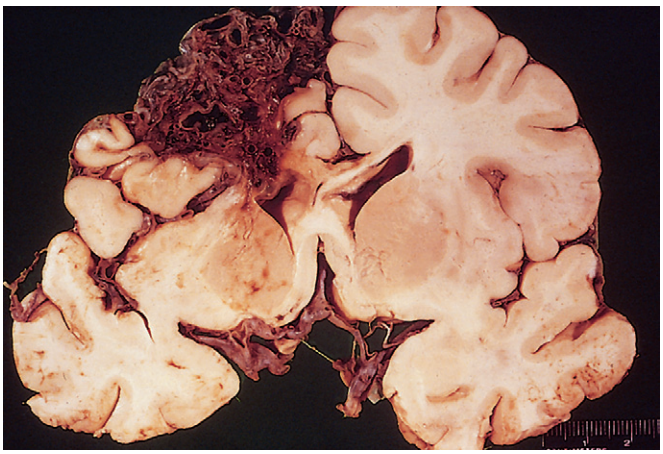

**Figure 22–11** Arteriovenous malformation.

vascular channels (Fig. 22–11). Microscopic examination shows enlarged blood vessels separated by gliotic tissue, often with evidence of previous hemorrhage. Some vessels can be recognized as arteries with duplicated and fragmented internal elastic lamina, while others show marked thickening or partial replacement of the media by hyalinized connective tissue.

**Cavernous malformations** consist of distended, loosely organized vascular channels with thin collagenized walls without intervening nervous tissue. They occur most often in the cerebellum, pons, and subcortical regions, and have a low blood flow without significant arteriovenous shunting. Foci of old hemorrhage, infarction, and calcification frequently surround the abnormal vessels.

**Capillary telangiectasias** are microscopic foci of dilated thin-walled vascular channels separated by relatively normal brain parenchyma that occur most frequently in the pons. **Venous angiomas** (varices) consist of aggregates of ectatic venous channels. These latter two types of vascular malformation are unlikely to bleed or to cause symptoms, and most are incidental findings.

## Other Vascular Diseases

### *Hypertensive Cerebrovascular Disease*

Hypertension causes *hyaline arteriolar sclerosis* of the deep penetrating arteries and arterioles that supply the basal ganglia, the hemispheric white matter, and the brain stem. Affected arteriolar walls are weakened and are more vulnerable to rupture. In some instances, minute aneurysms (*Charcot-Bouchard microaneurysms*) form in vessels less than 300 µm in diameter. In addition to massive intracerebral hemorrhage (discussed earlier), several other pathologic brain processes are related to hypertension.

- *Lacunes* or *lacunar infarcts* are small cavitary infarcts, just a few millimeters in size, found most commonly in the deep gray matter (basal ganglia and thalamus), the internal capsule, the deep white matter, and the pons. They are caused by occlusion of a single penetrating branch of a large cerebral artery. Depending on their location, lacunes can be silent clinically or cause significant neurologic impairment.
- *Rupture of the small-caliber penetrating vessels* may occur, leading to the development of small hemorrhages. In time, these hemorrhages resorb, leaving behind a slitlike cavity (*slit hemorrhage*) surrounded by brownish discoloration.
- *Acute hypertensive encephalopathy* most often is associated with sudden sustained rises in diastolic blood pressure to greater than 130 mm Hg. It is characterized by increased intracranial pressure and global cerebral dysfunction, manifesting as headaches, confusion, vomiting, convulsions, and sometimes coma. Rapid therapeutic intervention to reduce the intracranial pressure is essential. Postmortem examination may show brain edema, with or without transtentorial or tonsillar herniation. Petechiae and fibrinoid necrosis of arterioles in the gray and white matter may be seen microscopically.

### *Vasculitis*

A variety of inflammatory processes involving blood vessels may compromise blood flow and cause cerebral infarction. Infectious arteritis of small and large vessels was previously seen mainly in association with syphilis and tuberculosis, but is now more often caused by opportunistic infections (such as aspergillosis, herpes zoster, or CMV) arising in the setting of immunosuppression. Some systemic forms of vasculitis, such as polyarteritis nodosa, may involve cerebral vessels and cause single or multiple infarcts throughout the brain. *Primary angiitis of the CNS* is a form of vasculitis involving multiple small to medium-sized parenchymal and subarachnoid vessels that is characterized by chronic inflammation, multinucleate giant cells (with or without granuloma formation), and destruction of vessel walls. Affected persons present with a diffuse encephalopathy, often with cognitive dysfunction. Treatment consists of an appropriate regimen of immunosuppressive agents.

## SUMMARY

### Cerebrovascular Diseases

- *Stroke* is the clinical term for acute-onset neurologic deficits resulting from hemorrhagic or obstructive vascular lesions.
- Cerebral infarction follows loss of blood supply and can be widespread or focal, or affect regions with the least robust vascular supply ("watershed" infarcts).
- Focal cerebral infarcts are most commonly embolic; with subsequent dissolution of an embolism and reperfusion, a nonhemorrhagic infarct can become hemorrhagic.
- Primary intraparenchymal hemorrhages typically are due to either hypertension (most commonly in white matter, deep gray matter, or posterior fossa contents) or cerebral amyloid angiopathy.
- Spontaneous subarachnoid hemorrhage usually is caused by a structural vascular abnormality, such as an aneurysm or arteriovenous malformation.

# CENTRAL NERVOUS SYSTEM TRAUMA

Trauma to the brain and spinal cord is a significant cause of death and disability. The severity and site of injury affect the outcome: injury of several cubic centimeters of brain parenchyma may be clinically silent (if in the frontal lobe), severely disabling (spinal cord), or fatal (involving the brain stem).

A blow to the head may be *penetrating* or *blunt;* it may cause an *open* or a *closed* injury. The magnitude and distribution of resulting traumatic brain lesions depend on the shape of the object causing the trauma, the force of impact, and whether the head is in motion at the time of injury. Severe brain damage can occur in the absence of external signs of head injury, and conversely, severe lacerations and even skull fractures do not necessarily indicate damage to the underlying brain. When the brain is damaged, the injuries may involve the parenchyma, the vasculature, or both.

Recent evidence suggests that repetitive episodes of trauma (such as occurs in athletes participating in contact sports) can lead to later development of neurodegenerative processes. In addition to a long-recognized association of trauma with the risk of Alzheimer disease, a distinct form of trauma-associated degeneration has been described, *chronic traumatic encephalopathy,* which is characterized by a unique pattern of intraneuronal tau protein inclusions (described later).

## Traumatic Parenchymal Injuries

When an object impacts the head, brain injury may occur at the site of impact—a *coup injury*—or opposite the site of impact on the other side of the brain—a *contrecoup injury*. Both coup and contrecoup lesions are contusions, with comparable gross and microscopic appearances. A *contusion* is caused by rapid tissue displacement, disruption of vascular channels, and subsequent hemorrhage, tissue injury, and edema. Since they are closest to the skull, the crests of the gyri are the part of the brain that is most susceptible to traumatic injury. Contusions are common in regions of the brain overlying rough and irregular inner skull surfaces, such as the orbitofrontal regions and the temporal lobe tips. Penetration of the brain by a projectile such as a bullet or a skull fragment from a fracture causes a laceration, with tissue tearing, vascular disruption, and hemorrhage.

### MORPHOLOGY

On cross-section, contusions are wedge-shaped, with the widest aspect closest to the point of impact (Fig. 22–12, *A*). Within a few hours of injury, blood extravasates throughout the involved tissue, across the width of the cerebral cortex, and into the white matter and subarachnoid spaces. Although functional effects are seen earlier, morphologic evidence of injury in the neuronal cell body (nuclear pyknosis, cytoplasmic eosinophilia, cellular disintegration) takes about 24 hours to appear. The inflammatory response to the injured tissue follows its usual course, with neutrophils preceding the appearance of macrophages. In contrast with ischemic lesions, in which the superficial layer of cortex may be preserved, trauma affects the superficial layers most severely.

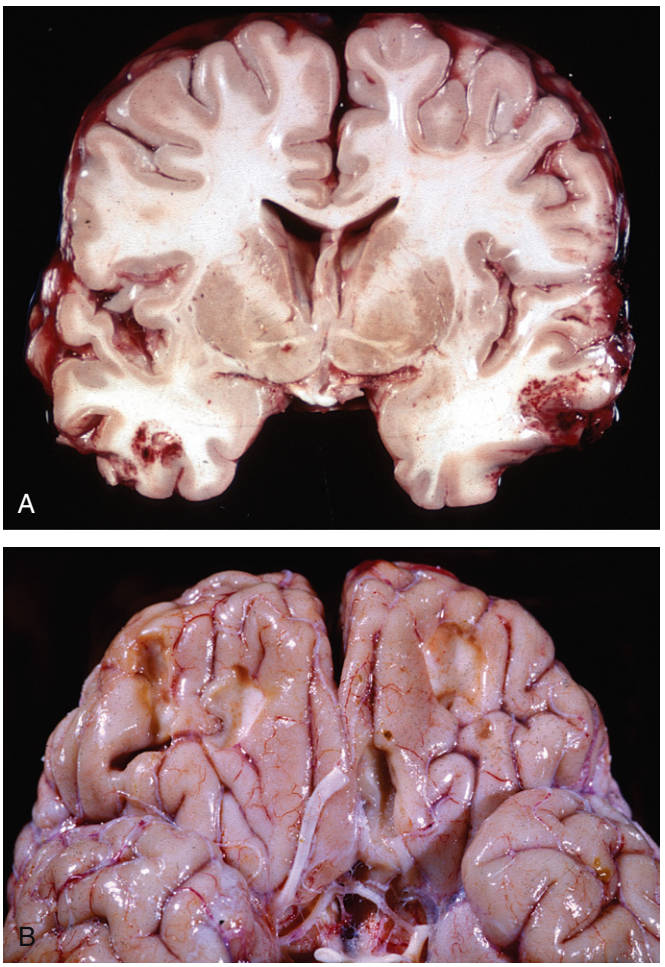

**Figure 22–12** Cerebral trauma. **A,** Acute contusions are present in both temporal lobes, with areas of hemorrhage and tissue disruption. **B,** Remote contusions, seen as discolored *yellow* areas, are present on the inferior frontal surface of this brain.

Old traumatic lesions have a characteristic macroscopic appearance: They are depressed, retracted, yellowish brown patches involving the crests of gyri (Fig. 22–12, *B*). More extensive hemorrhagic regions of brain trauma give rise to larger cavitary lesions, which can resemble remote infarcts. In sites of old contusions, gliosis and residual hemosiderin-laden macrophages predominate.

Although contusions are more easily seen, trauma can also cause more subtle but widespread injury to axons within the brain (called **diffuse axonal injury**), sometimes with devastating consequences. The movement of one region of brain relative to another is thought to disrupt axonal integrity and function. Angular acceleration, even in the absence of impact, may cause axonal injury as well as hemorrhage. As many as 50% of patients who develop coma shortly after trauma are believed to have white matter damage and diffuse axonal injury. Although these injuries may be widespread, the lesions usually are asymmetric and are most commonly found near the angles of the lateral ventricles and in the brain stem. They take the form of axonal swellings that appear within hours of the injury. These are best demonstrated with silver stains or by immunohistochemical stains for axonal proteins.

*Concussion* describes reversible altered consciousness from head injury in the absence of contusion. The characteristic transient neurologic dysfunction includes loss of consciousness, temporary respiratory arrest, and loss of reflexes. Although neurologic recovery is complete, amnesia for the event persists. The pathogenesis of the sudden disruption of nervous activity is unknown.

## Traumatic Vascular Injury

CNS trauma often directly disrupts vessel walls, leading to hemorrhage. Depending on the affected vessel, the hemorrhage may be *epidural, subdural, subarachnoid,* or *intraparenchymal* (Fig. 22–13, *A*), occurring alone or in combination. Subarachnoid and intraparenchymal hemorrhages most often occur at sites of contusions and lacerations.

### *Epidural Hematoma*

Dural vessels—especially the middle meningeal artery—are vulnerable to traumatic injury. In infants, traumatic displacement of the easily deformable skull may tear a vessel, even in the absence of a skull fracture. In children and adults, by contrast, tears involving dural vessels almost always stem from skull fractures. Once a vessel is torn, blood accumulating under arterial pressure can dissect the tightly applied dura away from the inner skull surface (Fig. 22–13, *B*), producing a hematoma that compresses the brain surface. *Clinically, patients can be lucid for several hours between the moment of trauma and the development of neurologic signs.* An epidural hematoma may expand rapidly and constitutes a neurosurgical emergency necessitating prompt drainage and repair to prevent death.

### *Subdural Hematoma*

Rapid movement of the brain during trauma can tear the bridging veins that extend from the cerebral hemispheres through the subarachnoid and subdural space to the dural sinuses. Their disruption produces bleeding into the subdural space. *In patients with brain atrophy, the bridging veins are stretched out, and the brain has additional space within which to move, accounting for the higher rate of subdural hematomas in elderly persons.* Infants also are susceptible to

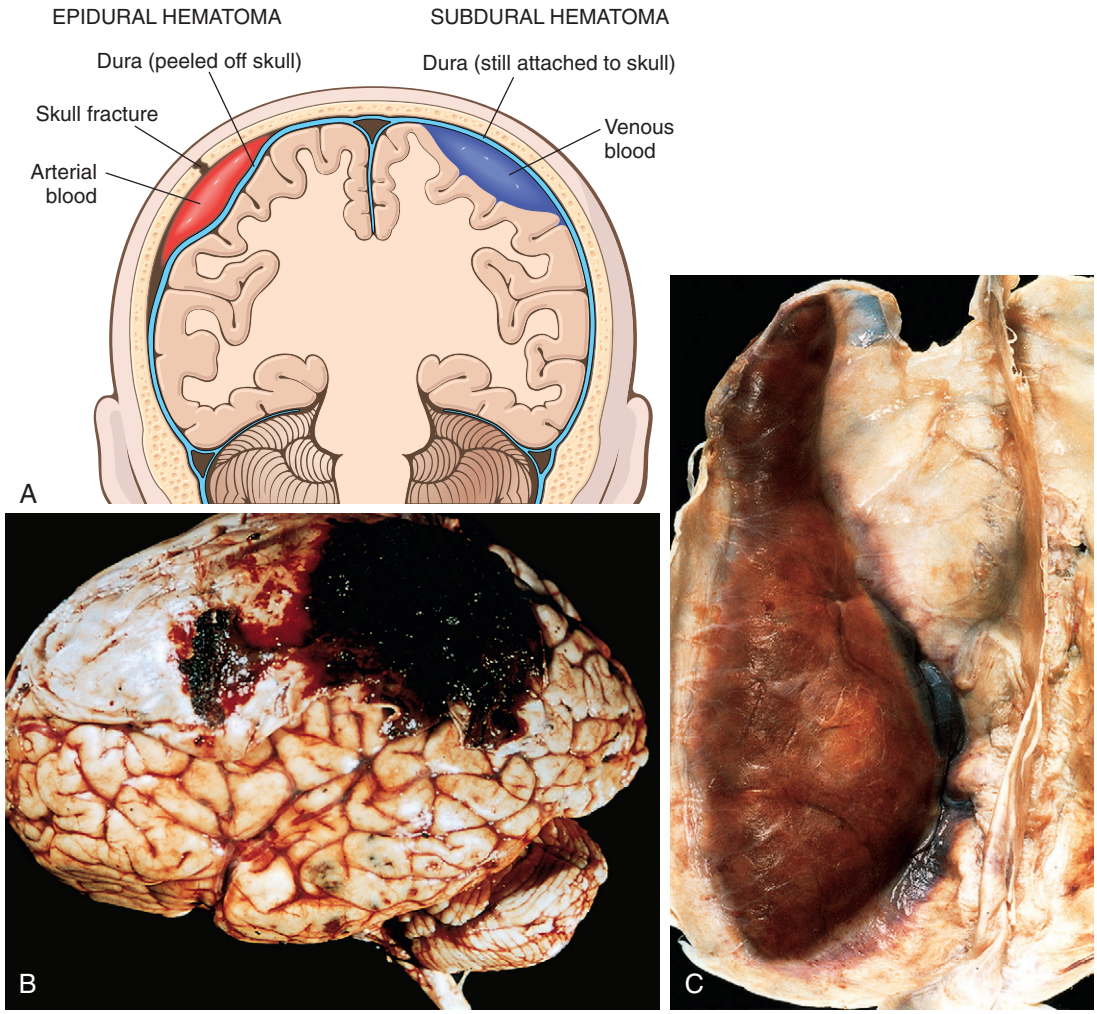

**Figure 22–13** Traumatic intracranial hemorrhages. **A,** Epidural hematoma (*left*) in which rupture of a meningeal artery, usually associated with a skull fracture, has led to accumulation of arterial blood between the dura and the skull. In a subdural hematoma (*right*), damage to bridging veins between the brain and the superior sagittal sinus has led to the accumulation of blood between the dura and the arachnoid. **B,** Epidural hematoma covering a portion of the dura. **C,** Large organizing subdural hematoma attached to the dura.
*(B, Courtesy of the late Dr. Raymond D. Adams, Massachusetts General Hospital, Boston, Massachusetts.)*

subdural hematomas because their bridging veins are thin-walled.

Subdural hematomas typically become manifest within the first 48 hours after injury. They are most common over the lateral aspects of the cerebral hemispheres and may be bilateral. Neurologic signs are attributable to the pressure exerted on the adjacent brain. Symptoms may be localizing but more often are nonlocalizing, taking the form of headache, confusion, and slowly progressive neurologic deterioration.

### MORPHOLOGY

An acute subdural hematoma appears as a collection of freshly clotted blood apposed to the contour of the brain surface, without extension into the depths of sulci (Fig. 22–13, *C*). The underlying brain is flattened, and the subarachnoid space is often clear. Typically, venous bleeding is self-limited; breakdown and organization of the hematoma take place over time. Subdural hematomas organize by lysis of the clot (about 1 week), growth of granulation tissue from the dural surface into the hematoma (2 weeks), and fibrosis (1 to 3 months). Organized hematomas are attached to the dura, but not to the underlying arachnoid. Fibrosing lesions may eventually retract, leaving only a thin layer of connective tissue ("subdural membranes"). Subdural hematomas commonly rebleed (resulting in **chronic subdural hematomas**), presumably from the thin-walled vessels of the granulation tissue, leading to microscopic findings consistent with hemorrhages of varying age. Symptomatic subdural hematomas are treated by surgical removal of the blood and associated reactive tissue.

### SUMMARY

#### Central Nervous System Trauma

- Physical injury to the brain can occur when the inside of the skull comes into forceful contact with the brain.
- In blunt trauma, if the head is mobile there may be brain injury both at the original point of contact (coup injury) and on the opposite side of the brain (contrecoup injury) owing to impacts with the skull.
- Rapid displacement of the head and brain can tear axons (diffuse axonal injury), often causing immediate severe, irreversible neurologic deficits.
- Traumatic tearing of blood vessels leads to epidural hematoma, subdural hematoma, or subarachnoid hemorrhage.

## CONGENITAL MALFORMATIONS AND PERINATAL BRAIN INJURY

The incidence of CNS malformations, giving rise to mental retardation, cerebral palsy, or neural tube defects, is estimated at 1% to 2%. Malformations of the brain are more common in the setting of multiple birth defects. Prenatal or perinatal insults may either interfere with normal CNS development or cause tissue damage. Since different parts of the brain develop at different times during gestation, the timing of an injury will be reflected in the pattern of malformation; earlier events typically lead to more severe phenotypes. Mutations affecting genes that regulate the differentiation, maturation, or intercellular communication of neurons or glial cells can cause CNS malformation or dysfunction. Additionally, various chemicals and infectious agents have teratogenic effects.

Not all developmental disorders are characterized by specific, recognizable gross or microscopic findings, yet such disorders may nevertheless be associated with profound neuronal dysfunction. Genetic underpinnings for various forms of *autism* have emerged recently; many of the implicated genes contribute to the development or maintenance of synaptic connections. Similarly, *Rett syndrome* is an X-linked dominant disorder associated with mutations in the gene encoding methyl-CpG–binding protein-2 (MeCP2), a regulator of epigenetic modifications of chromatin. Development in affected girls initially is normal, but neurologic deficits affecting cognition and movement appear by the age of 1 to 2 years, highlighting the importance of epigenetic processes in neuronal development and synaptic plasticity.

### Malformations

#### *Neural Tube Defects*

On of the earliest steps in brain development is the formation of the neural tube, which gives rise to the ventricular system, brain and spinal cord. Partial failure or reversal of neural tube closure may lead to one of several malformations, each characterized by abnormalities involving some combination of neural tissue, meninges, and overlying bone or soft tissues. Collectively, *neural tube defects* constitute the most frequent type of CNS malformation. The overall recurrence risk in subsequent pregnancies is 4% to 5%, suggesting a genetic component. Folate deficiency during the initial weeks of gestation also increases risk through uncertain mechanisms; of clinical importance, prenatal vitamins containing folate can reduce the risk of neural tube defects by up to 70%. The combination of imaging studies and maternal screening for elevated α-fetoprotein has increased the early detection of neural tube defects.

The most common defects involve the posterior end of the neural tube, from which the spinal cord forms. These can range from asymptomatic bony defects (*spina bifida occulta*) to severe malformation consisting of a flat, disorganized segment of spinal cord associated with an overlying meningeal outpouching. *Myelomeningocele* is an extension of CNS tissue through a defect in the vertebral column that occurs most commonly in the lumbosacral region (Fig. 22–14). Patients have motor and sensory deficits in the lower extremities and problems with bowel and bladder control. The clinical problems derive from the abnormal spinal cord segment and often are compounded by infections extending from the thin or ulcerated overlying skin.

At the other end of the developing CNS, *anencephaly* is a malformation of the anterior end of the neural tube that leads to the absence of the brain and the top of skull. An

**Figure 22–14** Myelomeningocele. Both meninges and spinal cord parenchyma are included in the cystlike structure visible just above the buttocks.

*encephalocele* is a diverticulum of malformed CNS tissue extending through a defect in the cranium. It most often involves the occipital region or the posterior fossa. When it occurs anteriorly, brain tissue can extend into the sinuses.

### *Forebrain Malformations*

In certain malformations, the volume of the brain is abnormally large (*megalencephaly*) or small (*microencephaly*). Microencephaly, by far the more common of the two, usually is associated with a small head as well (microcephaly). It has a wide range of associations, including chromosome abnormalities, fetal alcohol syndrome, and human immunodeficiency virus type 1 (HIV-1) infection acquired in utero. The unifying feature is decreased generation of neurons destined for the cerebral cortex. During the early stages of brain development, as progenitor cells proliferate in the subependymal zone, the balance between cells leaving the progenitor population to begin migration to the cortex and those remaining in the proliferating pool affects the overall number of neurons and glial cells generated. If too many cells leave the progenitor pool prematurely, there is inadequate generation of mature neurons, leading to a small brain.

Disruption of neuronal migration and differentiation during development can lead to abnormalities of gyration and the six-layered neocortical architecture, often taking the form of neurons ending up in the wrong anatomic location. Various mutations in genes that control migration result in these malformations, which include the following:

- *Lissencephaly* (*agyria*) or, with more patchy involvement, *pachygyria,* is characterized by absent gyration leading to a smooth-surfaced brain. The cortex is abnormally thickened and usually has only four layers. Many forms of lissencephaly are associated with defects in genes that control neuronal migration.
- *Polymicrogyria* is characterized by an increased number of irregularly formed gyri that result in a bumpy or cobblestone-like surface. These changes can be focal or widespread. The normal cortical architecture can be altered in various ways, and adjacent gyri often show fusion of the superficial molecular layer.
- *Holoprosencephaly* is characterized by a disruption of the normal midline patterning. Mild forms may just show absence of the olfactory bulbs and related structures (arrhinencephaly). In severe forms the brain is not divided into hemispheres or lobes, and this anomaly may be associated with facial midline defects such as cyclopia. Holoprosencephaly as well as polymicrogyria can be the result of acquired or genetically determined disruption of normal development. Several single-gene defects including mutations in sonic hedgehog have been linked to holoprosencephaly.
- Other examples are focally disordered cortex (confusingly called *dysplastic cortex*) and neurons stranded beneath the cortex, sometimes as nodules and other times as bands.

### *Posterior Fossa Anomalies*

The most common malformations in this region of the brain result in misplacement or absence of portions of the cerebellum. The *Arnold-Chiari malformation* (Chiari type II malformation) combines a small posterior fossa with a misshapen midline cerebellum and downward extension of the vermis through the foramen magnum; hydrocephalus and a lumbar myelomeningocele typically are also present. The far milder *Chiari type I malformation* has low-lying cerebellar tonsils that extend through the foramen magnum. Excess tissue in the foramen magnum results in partial obstruction of CSF flow and compression of the medulla, with symptoms of headache or cranial nerve deficits often manifesting only in adult life. Surgical intervention can alleviate the symptoms.

Syndromes characterized by "missing" cerebellar tissue include *Dandy-Walker malformation,* characterized by an enlarged posterior fossa, absence of the cerebellar vermis, and a large midline cyst, and *Joubert syndrome,* in which there is absence of the vermis and brain stem abnormalities resulting in eye movement problems and disrupted respiratory patterns. A range of recessive genetic lesions have been found to cause Joubert syndrome, with many involving alterations of the primary cilium.

### *Spinal Cord Abnormalities*

In addition to neural tube defects, structural alterations of the spinal cord can occur that are not associated with abnormalities of the bony spine or overlying skin. These include expansions of the ependyma-lined central canal of the cord (*hydromyelia*) or development of fluid-filled cleft-like cavities in the inner portion of the cord (*syringomyelia, syrinx*). These lesions are surrounded by dense reactive gliosis, often with Rosenthal fibers. A syrinx also may develop after trauma or with intramedullary spinal tumors.

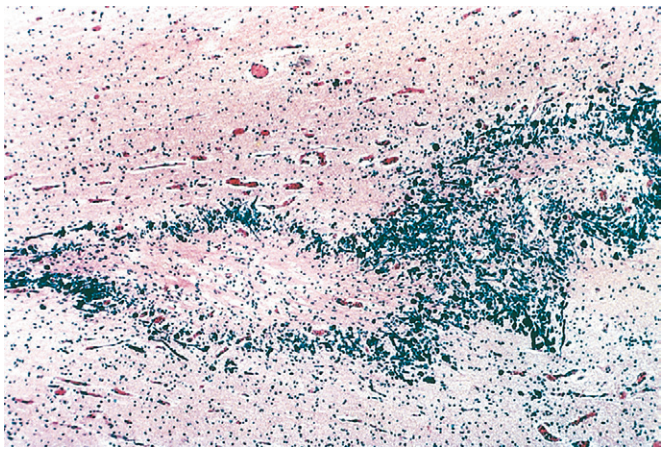

**Figure 22–15** Perinatal brain injury. This specimen from a patient with periventricular leukomalacia contains a central focus of white matter necrosis with a peripheral rim of mineralized axonal processes.

## Perinatal Brain Injury

A variety of exogenous factors can injure the developing brain. Injuries that occur early in gestation may destroy brain tissue without evoking reactive changes, sometimes making them difficult to distinguish from malformations. Brain injury occurring in the perinatal period is an important cause of childhood neurologic disability. *Cerebral palsy* is a term for nonprogressive neurologic motor deficits characterized by spasticity, dystonia, ataxia or athetosis, and paresis attributable to injury occurring during the prenatal and perinatal periods. Signs and symptoms may not be apparent at birth and only declare themselves later, well after the causal event.

*The two major types of injury that occur in the perinatal period are hemorrhages and infarcts.* These differ from the otherwise similar lesions in adults in terms of their locations and the tissue reactions they engender. In premature infants, there is an increased risk of *intraparenchymal hemorrhage* within the germinal matrix, most often adjacent to the anterior horn of the lateral ventricle. Hemorrhages may extend into the ventricular system and from there to the subarachnoid space, sometimes causing hydrocephalus. Infarcts may occur in the supratentorial periventricular white matter (*periventricular leukomalacia*), especially in premature babies. The residua of these infarcts are chalky yellow plaques consisting of discrete regions of white matter necrosis and mineralization (Fig. 22–15). When severe enough to involve the gray and white matter, large cystic lesions can develop throughout the hemispheres, a condition termed *multicystic encephalopathy.*

### SUMMARY

#### Congenital Malformations and Perinatal Brain Injury

- Malformations of the brain can occur because of genetic factors or external insults.
- The developmental timing and position of the injury determine its pattern and characteristics.
- Various malformations stem from failure of neural tube closure, improper formation of neural structures, and altered neuronal migration.
- Perinatal brain injury mostly takes one of two forms: (1) hemorrhage, often in the region of the germinal matrix with the risk of extension into the ventricular system; and (2) ischemic infarcts, leading to periventricular leukomalacia.

# INFECTIONS OF THE NERVOUS SYSTEM

The brain and its coverings, as with all other parts of the body, can be sites of infections. Some infectious agents have a relative or absolute predilection for the nervous system (e.g., rabies), while others can affect many other organs as well as the brain (e.g., *Staphylococcus aureus*). Damage to nervous tissue may be the consequence of direct injury of neurons or glial cells by the infectious agent or microbial toxins, or may be a consequence of the host innate or adaptive immune response.

Infectious agents may reach the nervous system through several routes of entry:

- *Hematogenous spread* by way of the arterial blood supply is the most common means of entry. There can also be retrograde venous spread, through the anastomoses between veins of the face and the venous sinuses of the skull.
- *Direct implantation* of microorganisms is almost invariably due to traumatic introduction of foreign material. In rare cases it can be iatrogenic, as when microbes are introduced with a lumbar puncture needle.
- *Local extension* can occur with infections of the skull or spine. Sources include air sinuses, most often the mastoid or frontal; infected teeth; cranial or spinal osteomyelitis; and congenital malformations, such as meningomyelocele.
- *Peripheral nerves* also may serve as paths of entry for a few pathogens—in particular, viruses such as the rabies and herpes zoster viruses.

## Epidural and Subdural Infections

The epidural and subdural spaces can be involved by bacterial or fungal infections, usually as a consequence of direct local spread. *Epidural abscesses* arise from an adjacent focus of infection, such as sinusitis or osteomyelitis. When abscesses occur in the spinal epidural space, they may cause spinal cord compression and constitute a neurosurgical emergency. Infections of the skull or air sinuses may also spread to the subdural space, producing *subdural empyema.* The underlying arachnoid and subarachnoid spaces usually are unaffected, but a large subdural empyema may produce a mass effect. In addition, thrombophlebitis may develop in the bridging veins that cross the subdural space, resulting in venous occlusion and infarction of the brain. Most patients are febrile, with headache and neck stiffness, and if untreated may develop focal

neurologic signs referable to the site of the infection, lethargy, and coma. With treatment, including surgical drainage, resolution of the empyema occurs from the dural side; if resolution is complete, a thickened dura may be the only residual finding. With prompt treatment, complete recovery is usual.

## Meningitis

*Meningitis* is an inflammatory process involving the leptomeninges within the subarachnoid space; if the infection spreads into the underlying brain it is termed *meningoencephalitis*. Meningitis usually is caused by an infection, but *chemical meningitis* also may occur in response to a nonbacterial irritant introduced into the subarachnoid space. Infectious meningitis can be broadly divided into *acute pyogenic* (usually bacterial), *aseptic* (usually viral), and *chronic* (usually tuberculous, spirochetal, or cryptococcal) subtypes. Examination of the CSF is often useful in distinguishing between various causes of meningitis.

### *Acute Pyogenic Meningitis (Bacterial Meningitis)*

Many bacteria can cause acute pyogenic meningitis, but the most likely organisms vary with patient age. In neonates, common organisms are *Escherichia coli* and the group B streptococci; in adolescents and in young adults, *Neisseria meningitidis* is the most common pathogen; and in older individuals, *Streptococcus pneumoniae* and *Listeria monocytogenes* are more common. In all age groups, patients typically show systemic signs of infection along with meningeal irritation and neurologic impairment, including headache, photophobia, irritability, clouding of consciousness, and neck stiffness. *Lumbar puncture reveals an increased pressure; examination of the CSF shows abundant neutrophils, elevated protein, and reduced glucose.* Bacteria may be seen on a smear or can be cultured, sometimes a few hours before the neutrophils appear. Untreated pyogenic meningitis is often fatal, but with prompt diagnosis and administration of appropriate antibiotics, many patients can be saved.

#### MORPHOLOGY

In acute meningitis, an exudate is evident within the leptomeninges over the surface of the brain (Fig. 22–16, *A*). The meningeal vessels are engorged and prominent. From the areas of greatest accumulation, tracts of pus can be followed along blood vessels on the brain surface. When the meningitis is fulminant, the inflammatory cells infiltrate the walls of the leptomeningeal veins and may spread into the substance of the brain (focal cerebritis), or the inflammation may extend to the ventricles, producing ventriculitis. On microscopic examination, neutrophils fill the entire subarachnoid space in severely affected areas or may be found predominantly around the leptomeningeal blood vessels in less severe cases. In untreated meningitis, Gram stain reveals varying numbers of the causative organism. Bacterial meningitis may be associated with abscesses in the brain (Fig. 22–16, *B*), discussed later. Phlebitis also may lead to venous occlusion and hemorrhagic infarction of the underlying brain. If it is treated early, there may be little or no morphologic residuum.

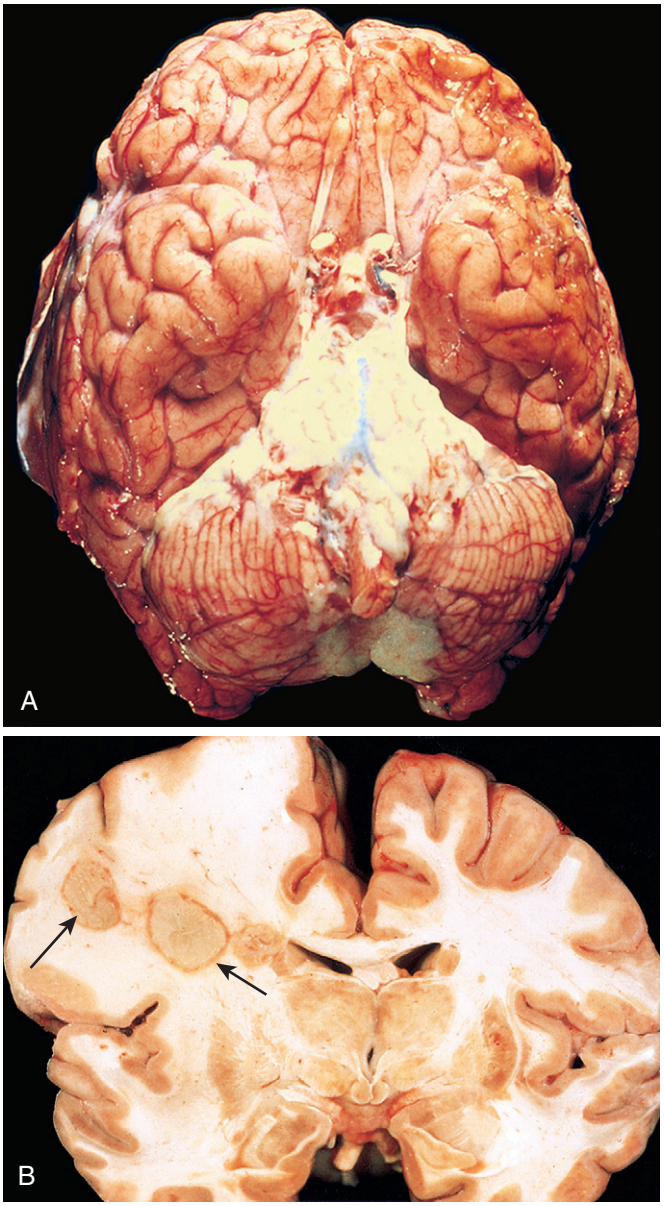

**Figure 22–16** Bacterial infections. **A,** Pyogenic meningitis. A thick layer of suppurative exudate covers the brain stem and cerebellum and thickens the leptomeninges. **B,** Cerebral abscesses in the frontal lobe white matter (*arrows*).

*(A, From Golden JA, Louis DN: Images in clinical medicine: acute bacterial meningitis. N Engl J Med 333:364, 1994. Copyright © 1994 Massachusetts Medical Society. All rights reserved.)*

### *Aseptic Meningitis (Viral Meningitis)*

*Aseptic meningitis* is a clinical term for an illness comprising meningeal irritation, fever, and alterations in consciousness of relatively acute onset. The clinical course is less fulminant than in pyogenic meningitis. In contrast to pyogenic meningitis, examination of the CSF often shows lymphocytosis, moderate protein elevation, and a normal glucose level. The disease typically is self-limiting. It is believed to be of viral origin in most cases, but it is often difficult to identify the responsible virus. There are no distinctive macroscopic characteristics except for brain swelling, seen in only some instances. On microscopic examination, there is either no recognizable abnormality or a mild to moderate leptomeningeal lymphocytic infiltrate.

### *Chronic Meningitis*

Several pathogens, including mycobacteria and some spirochetes, are associated with chronic meningitis; infections with these organisms also may involve the brain parenchyma.

#### Tuberculous Meningitis

Tuberculous meningitis usually manifests with generalized signs and symptoms of headache, malaise, mental confusion, and vomiting. There is only a moderate increase in CSF cellularity, with mononuclear cells or a mixture of polymorphonuclear and mononuclear cells; the protein level is elevated, often strikingly so, and the glucose content typically is moderately reduced or normal. Infection with *Mycobacterium tuberculosis* also may result in a well-circumscribed intraparenchymal mass (*tuberculoma*), which may be associated with meningitis. Chronic tuberculous meningitis is a cause of arachnoid fibrosis, which may produce hydrocephalus.

#### MORPHOLOGY

The subarachnoid space contains a gelatinous or fibrinous exudate, most often at the base of the brain, obliterating the cisterns and encasing cranial nerves. There may be discrete white granules scattered over the leptomeninges. Arteries running through the subarachnoid space may show **obliterative endarteritis** with inflammatory infiltrates and marked intimal thickening. On microscopic examination there are mixtures of lymphocytes, plasma cells, and macrophages. Florid cases show well-formed granulomas, often with caseous necrosis and giant cells, similar to the lesions of tuberculosis elsewhere.

#### Spirochetal Infections

Neurosyphilis, a tertiary stage of syphilis, occurs in about 10% of persons with untreated *Treponema pallidum* infection. Patients with HIV infection are at increased risk for neurosyphilis, which often is more aggressive and severe in this setting. The infection can produce chronic meningitis (*meningovascular neurosyphilis*), usually involving the base of the brain, often with an obliterative endarteritis rich in plasma cells and lymphocytes. There can also be parenchymal involvement by spirochetes (*paretic neurosyphilis*), leading to neuronal loss and marked proliferation of rod-shaped microglial cells. Clinically, this form of the disease causes an insidious progressive loss of mental and physical functions, mood alterations (including delusions of grandeur), and eventually severe dementia. *Tabes dorsalis* is another form of neurosyphilis, resulting from damage to the sensory nerves in the dorsal roots that produces impaired joint position sense and ataxia (locomotor ataxia); loss of pain sensation, leading to skin and joint damage (Charcot joints); other sensory disturbances, particularly characteristic "lightning pains"; and the absence of deep tendon reflexes.

Neuroborreliosis represents involvement of the nervous system by the spirochete *Borrelia burgdorferi,* the pathogen of Lyme disease. Neurologic signs and symptoms are highly variable and include aseptic meningitis, facial nerve palsies, mild encephalopathy, and polyneuropathies.

## Parenchymal Infections

The entire gamut of infectious pathogens (viruses to parasites) can potentially infect the brain, often in characteristic patterns. In general, viral infections are diffuse, bacterial infections (when not associated with meningitis) are localized, while other organisms produce mixed patterns. In immunosuppressed hosts, more widespread involvement with any agent is typical.

### *Brain Abscesses*

Brain abscesses are nearly always caused by bacterial infections. These can arise by direct implantation of organisms, local extension from adjacent foci (mastoiditis, paranasal sinusitis), or hematogenous spread (usually from a primary site in the heart, lungs, or distal bones, or after tooth extraction). Predisposing conditions include acute bacterial endocarditis, from which septic emboli are released that may produce multiple abscesses; cyanotic congenital heart disease, associated with a right-to-left shunt and loss of pulmonary filtration of organisms; and chronic pulmonary infections, as in bronchiectasis, which provide a source of microbes that spread hematogenously.

Abscesses are destructive lesions, and patients almost invariably present with progressive focal deficits as well as general signs related to increased intracranial pressure. The CSF white cell count and protein levels are usually high, while the glucose content tends to be normal. A systemic or local source of infection may be apparent or may have ceased to be symptomatic. The increased intracranial pressure and progressive herniation can be fatal, and abscess rupture can lead to ventriculitis, meningitis, and venous sinus thrombosis. Surgery and antibiotics reduce the otherwise high mortality rate, with earlier intervention leading to better outcomes.

#### MORPHOLOGY

Abscesses are discrete lesions with central liquefactive necrosis and a surrounding fibrous capsule (Fig. 22–16, *B*). On microscopic examination, the necrotic center is surrounded by edema and granulation tissue, often with exuberant vascularization. Outside the fibrous capsule is a zone of reactive gliosis.

### *Viral Encephalitis*

Viral encephalitis is a parenchymal infection of the brain that is almost invariably associated with meningeal inflammation (and therefore is better termed *meningoencephalitis*). While different viruses may show varying patterns of injury, the most characteristic histologic features are perivascular and parenchymal mononuclear cell infiltrates, microglial nodules, and neuronophagia (Fig. 22–17, *A* and *B*). Certain viruses also form characteristic inclusion bodies.

The nervous system is particularly susceptible to certain viruses such as rabies virus and poliovirus. Some viruses infect specific CNS cell types, while others preferentially involve particular brain regions (such as the medial temporal lobes, or the limbic system) that lie along the viral route of entry. Intrauterine viral infection may cause *congenital malformations,* as occurs with rubella. In addition to

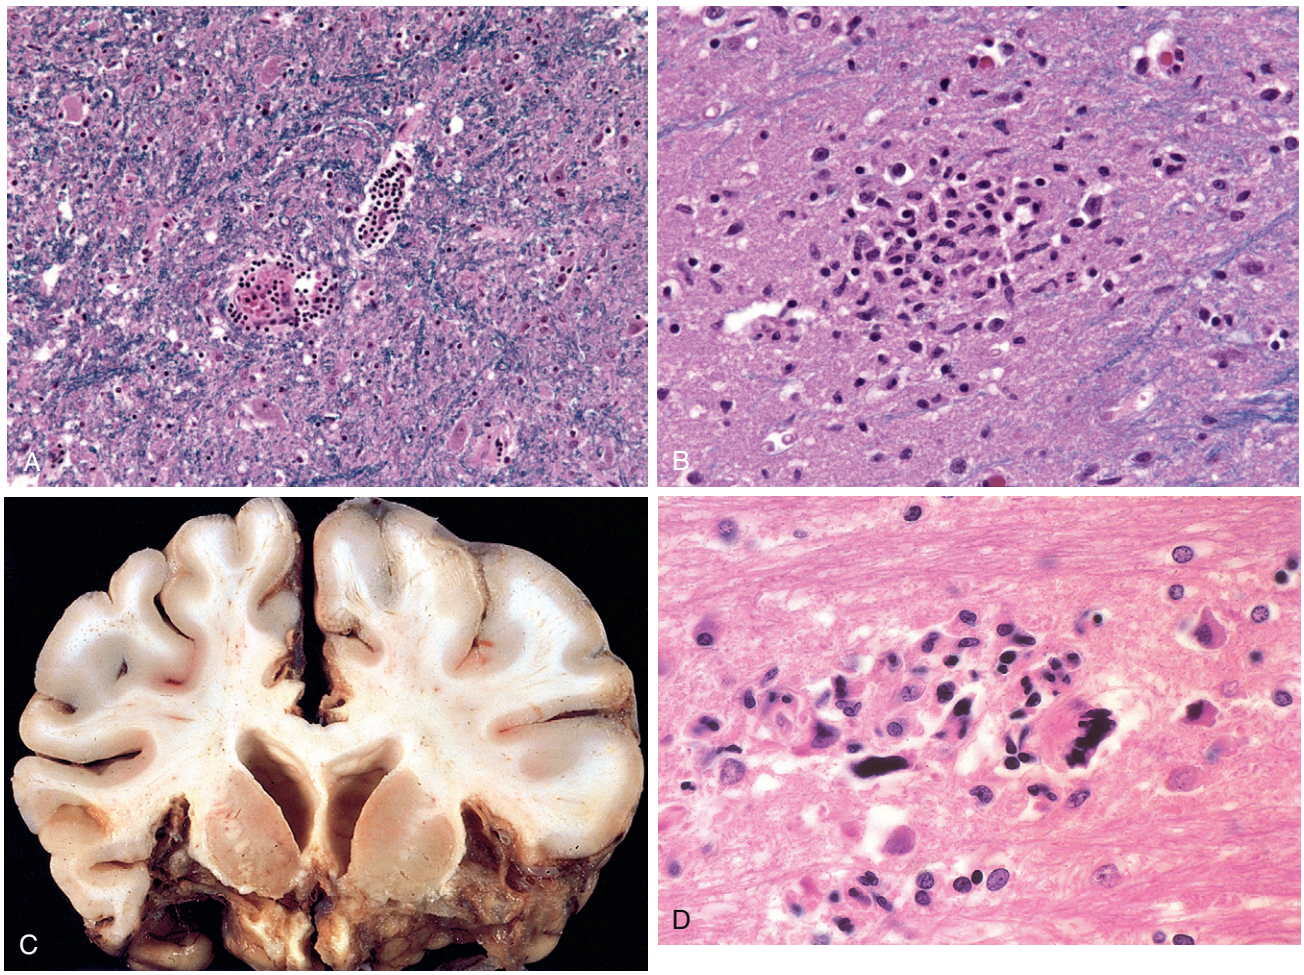

**Figure 22–17** Viral infections. **A** and **B,** Characteristic findings in many forms of viral meningitis include perivascular cuffing of lymphocytes **(A)** and microglial nodules **(B). C,** Herpes encephalitis showing extensive destruction of inferior frontal and anterior temporal lobes. **D,** Human immunodeficiency virus (HIV) encephalitis. Note the accumulation of microglia forming a microglial nodule and multinucleate giant cell.
*(C, Courtesy of Dr. T.W. Smith, University of Massachusetts Medical School, Worcester, Massachusetts.)*

direct infection of the nervous system, the CNS also can be injured by immune mechanisms after systemic viral infections.

### Arboviruses

Arboviruses (arthropod-borne viruses) are an important cause of epidemic encephalitis, especially in tropical regions of the world, and are capable of causing serious morbidity and high mortality. Among the more commonly encountered types are Eastern and Western equine encephalitis and West Nile virus infection. Patients develop generalized neurologic symptoms, such as seizures, confusion, delirium, and stupor or coma, as well as focal signs, such as reflex asymmetry and ocular palsies. The CSF usually is colorless but with a slightly elevated pressure and an early neutrophilic pleocytosis that rapidly converts to a lymphocytosis; the protein level is elevated, but the glucose is normal.

#### MORPHOLOGY

Arbovirus encephalitides produce a similar histopathologic picture. Characteristically, there is a perivascular lymphocytic meningoencephalitis (sometimes with neutrophils) (Fig. 22–17, *A*). Multifocal gray and white matter necrosis is seen, often associated with neuronophagia, the phagocytosis of neuronal debris, as well as localized collections of microglia termed microglial nodules (Fig. 22–17, *B*). In severe cases there may be a necrotizing vasculitis with associated focal hemorrhages.

### Herpesviruses

HSV-1 encephalitis may occur in any age group but is most common in children and young adults. It typically manifests with alterations in mood, memory, and behavior, reflecting involvement of the frontal and temporal lobes. Recurrent HSV-1 encephalitis is sometimes associated with inherited mutations that interfere with Toll-like receptor signaling (specifically that of TLR-3), which has an important role in antiviral defense.

#### MORPHOLOGY

Herpes encephalitis starts in, and most severely involves, the inferior and medial regions of the temporal lobes and the

orbital gyri of the frontal lobes (Fig. 22–17, *C*). The infection is necrotizing and often hemorrhagic in the most severely affected regions. Perivascular inflammatory infiltrates usually are present, and large eosinophilic intranuclear viral inclusions (Cowdry type A bodies) can be found in both neurons and glial cells.

HSV-2 also affects the nervous system, usually in the form of meningitis in adults. Disseminated severe encephalitis occurs in many neonates born by vaginal delivery to women with active primary HSV genital infections.

Varicella-zoster virus (VZV) causes chickenpox during primary infection, usually without any evidence of neurologic involvement. The virus establishes latent infection in neurons of dorsal root ganglia. Reactivation in adults manifests as a painful, vesicular skin eruption in the distribution of one or a few dermatomes (*shingles*). This usually is a self-limited process, but there may be a persistent pain syndrome in the affected region (*postherpetic neuralgia*). VZV also may cause a granulomatous arteritis that can lead to tissue infarcts. In immunosuppressed patients, acute herpes zoster encephalitis can occur. Inclusion bodies can be found in glial cells and neurons.

### Cytomegalovirus

CMV infects the nervous system in fetuses and immunosuppressed persons. All cells within the CNS (neurons, glial cells, ependyma, and endothelium) are susceptible to infection. Intrauterine infection causes periventricular necrosis, followed later by microcephaly with periventricular calcification. When adults are infected, CMV produces a subacute encephalitis, again often most severe in the periventricular region. Lesions can be hemorrhagic and contain typical viral inclusion–bearing cells.

### Poliovirus

Poliovirus is an enterovirus that most often causes a subclinical or mild gastroenteritis; in a small fraction of cases, it secondarily invades the nervous system and damages motor neurons in the spinal cord and brain stem (paralytic poliomyelitis). With loss of motor neurons, it produces a flaccid paralysis with muscle wasting and hyporeflexia in the corresponding region of the body. In the acute disease, death can occur from paralysis of respiratory muscles. Long after the infection has resolved, typically 25 to 35 years after the initial illness, a *postpolio syndrome* of progressive weakness associated with decreased muscle bulk and pain can appear. The cause of this syndrome is unclear. One hypothesis is that motor neurons that survive the initial insult sprout new nerve terminals to compensate for the death of their neighbors, and that over time the additional demands placed on these neurons leads to injury that diminishes function or causes cell death.

### Rabies Virus

Rabies is a severe encephalitic infection transmitted to humans from rabid animals, usually by a bite. Various mammals are natural reservoirs. Exposure to some bat species, even without evidence of a bite, is also a risk factor. Virus enters the CNS by ascending along the peripheral nerves from the wound site, so the incubation period depends on the distance between the wound and the brain, usually taking a few months. The disease manifests initially with nonspecific symptoms of malaise, headache, and fever. As the infection advances, the patient shows extraordinary CNS excitability; the slightest touch is painful, with violent motor responses progressing to convulsions. Contracture of the pharyngeal musculature may create an aversion to swallowing even water (hydrophobia). Periods of mania and stupor progress to coma and eventually death, typically from respiratory failure.

### Human Immunodeficiency Virus

In the first 15 years or so after recognition of AIDS, neuropathologic changes were demonstrated at postmortem examination in as many as 80% to 90% of cases, owing to direct effects of virus on the nervous system, opportunistic infections, and primary CNS lymphoma. Introduction of highly active antiretroviral therapy (HAART) has decreased the frequency of these secondary effects of HIV infection. However, cognitive dysfunction ranging from mild to full-blown dementia that is lumped under the umbrella term *HIV-associated neurocognitive disorder* (HAND) continues to be a source of morbidity. The cognitive symptoms are believed to stem from HIV infection of microglial cells in the brain. This leads to activation of innate immune responses, both in infected microglial cells and unaffected bystanders. The ensuing neuronal injury likely stems from a combination of cytokine-induced inflammation and toxic effects of HIV-derived proteins.

Aseptic meningitis occurs within 1 to 2 weeks of onset of primary infection by HIV in about 10% of patients; antibodies to HIV can be demonstrated, and the virus can be isolated from the CSF. The few neuropathologic studies of the early and acute phases of symptomatic or asymptomatic HIV invasion of the nervous system have shown mild lymphocytic meningitis, perivascular inflammation, and some myelin loss in the hemispheres. After the acute phase, an HIV encephalitis (HIVE) commonly can be found if affected persons come to autopsy.

#### MORPHOLOGY

HIV encephalitis is best characterized microscopically as a chronic inflammatory reaction with widely distributed infiltrates of **microglial nodules,** sometimes with associated foci of tissue necrosis and reactive gliosis (Fig. 22–17, *D*). The microglial nodules also are found in the vicinity of small blood vessels, which show abnormally prominent endothelial cells and perivascular foamy or pigment-laden macrophages. These changes occur especially in the subcortical white matter, diencephalon, and brain stem. An important component of the microglial nodule is the macrophage-derived **multinucleate giant cell.** In some cases, there is also a disorder of white matter characterized by multifocal or diffuse areas of myelin pallor with associated axonal swellings and gliosis. HIV is present in CD4+ mononuclear and multinucleate macrophages and microglia.

### Polyomavirus and Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is caused by JC virus, a polyomavirus, which preferentially

infects oligodendrocytes, resulting in demyelination as these cells are injured and then die. Most people show serologic evidence of exposure to JC virus during childhood, and it is believed that PML results from virus reactivation, as the disease is restricted to immunosuppressed persons. Patients develop focal and relentlessly progressive neurologic symptoms and signs, and imaging studies show extensive, often multifocal, ring-enhancing lesions in the hemispheric or cerebellar white matter.

### MORPHOLOGY

The lesions are patchy, irregular, ill-defined areas of white matter destruction that enlarge as the disease progresses (Fig. 22–18). Each lesion is an area of demyelination, in the center of which are scattered lipid-laden macrophages and a reduced number of axons. At the edges of the lesion are greatly enlarged oligodendrocyte nuclei whose chromatin is replaced by glassy-appearing amphophilic viral inclusions. The virus also infects astrocytes, leading to bizarre giant forms with irregular, hyperchromatic, sometimes multiple nuclei that can be mistaken for tumor.

### *Fungal Encephalitis*

Fungal infections usually produce parenchymal granulomas or abscesses, often associated with meningitis. The most common fungal infections have distinctive patterns:

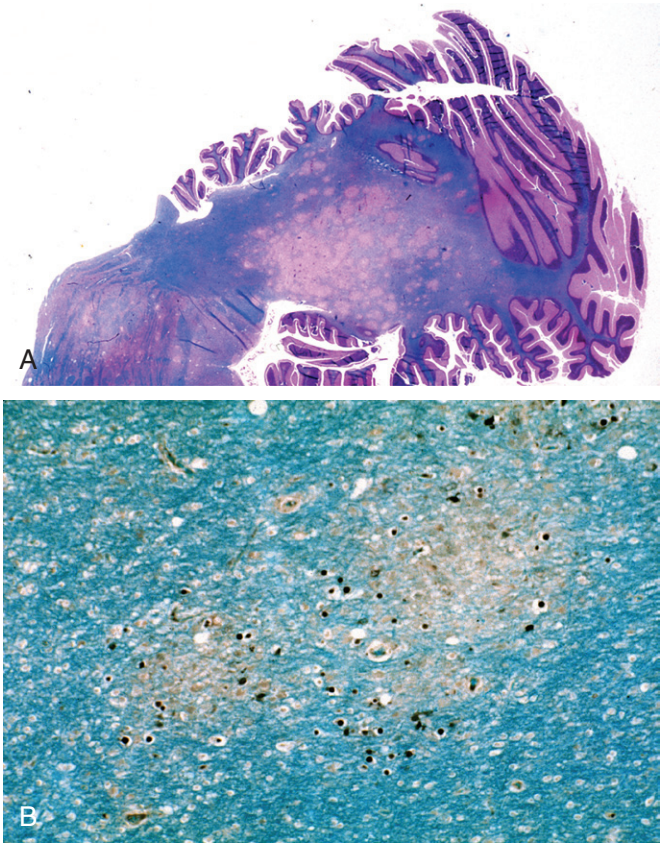

**Figure 22–18** Progressive multifocal leukoencephalopathy. **A,** Section stained for myelin showing irregular, poorly defined areas of demyelination, which become confluent in places. **B,** Enlarged oligodendrocyte nuclei stained for viral antigens surround an area of early myelin loss.

- *Candida albicans* usually produces multiple microabscesses, with or without granuloma formation.
- *Mucormycosis* is the term used to describe rhinocerebral infections caused by several fungi belonging to the order Mucorales. It typically presents as an infection of the nasal cavity or sinuses of a diabetic patient with ketoacidosis. It may spread to the brain through vascular invasion or by direct extension through the cribriform plate. The proclivity of Mucor to invade the brain directly sets it apart from other fungi, which tend to reach the brain by hematogenous dissemination from distant sites.
- *Aspergillus fumigatus* tends to cause a distinctive pattern of widespread septic hemorrhagic infarctions because of its marked predilection for blood vessel wall invasion and subsequent thrombosis.
- *Cryptococcus neoformans* can cause both meningitis and meningoencephalitis, often in the setting of immunosuppression. It can be fulminant and fatal in as little as 2 weeks or may exhibit indolent behavior, evolving over months or years. The CSF may have few cells but elevated protein, and the mucoid encapsulated yeasts can be visualized on India ink preparations. Extension into the brain follows vessels in the Virchow-Robin spaces. As organisms proliferate, these spaces expand, giving rise to a "soap bubble"–like appearance (Fig. 22–19). The diagnosis is usually established by a positive test for cryptococcal antigens in the CSF or the blood.

In endemic areas, *Histoplasma capsulatum, Coccidioides immitis,* and *Blastomyces dermatitidis* also can infect the CNS, especially in the setting of immunosuppression.

### *Other Meningoencephalitides*

While a wide range of other organisms can infect the nervous system and its covering, only three specific entities are considered here.

***Cerebral Toxoplasmosis.*** Cerebral infection with the protozoan *Toxoplasma gondii* can occur in immunosuppressed adults or in newborns who acquire the organism transplacentally from a mother with an active infection. In adults, the clinical symptoms are subacute, evolving during a 1- or 2-week period, and may be both focal and diffuse. Due to inflammation and breakdown of the blood-brain barrier at sites of infection, computed tomography and magnetic resonance imaging studies often show edema around lesions (so-called ring enhancing lesions). In newborns who are infected in utero, the infection classically produces the triad of chorioretinitis, hydrocephalus, and intracranial calcifications. Understandably, the CNS abnormalities are most severe when the infection occurs early in gestation during critical stages of brain development. Necrosis of periventricular lesions gives rise to secondary calcifications as well as inflammation and gliosis, which can lead to obstruction of the aqueduct of Sylvius and hydrocephalus.

### MORPHOLOGY

When the infection is acquired in immunosuppressed adults, the brain shows abscesses, frequently multiple, most often involving the cerebral cortex (near the gray-white junction) and deep gray nuclei. Acute lesions consist of central foci of

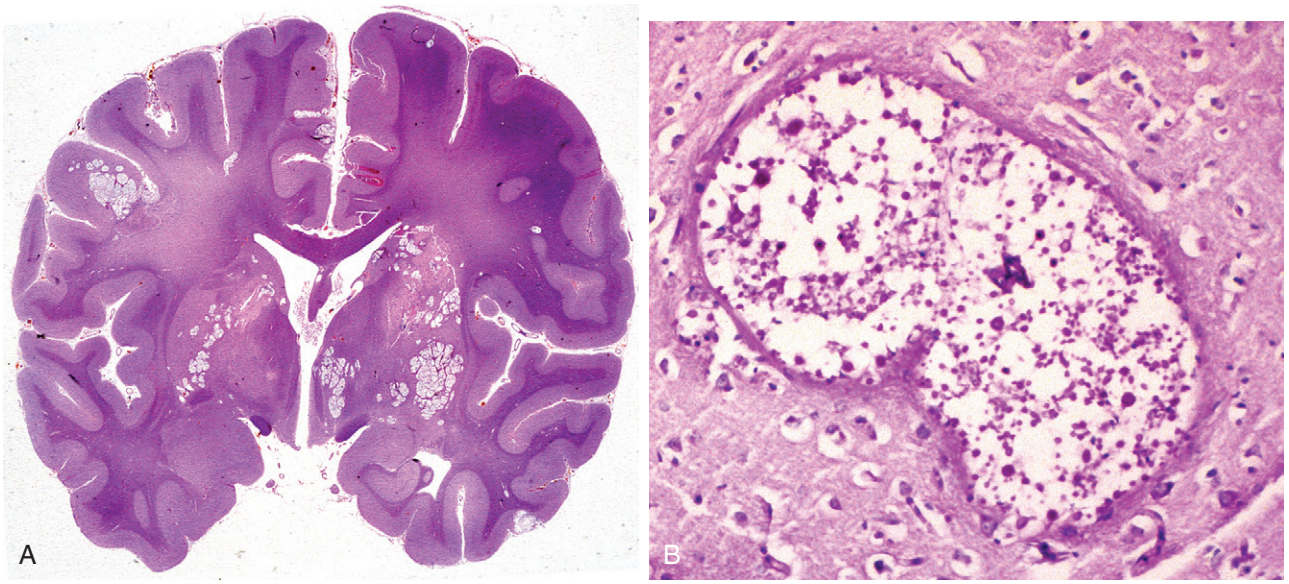

**Figure 22–19** Cryptococcal infection. **A,** Whole-brain section showing the numerous areas of tissue destruction associated with the spread of organisms in the perivascular spaces. **B,** At higher magnification, it is possible to see the cryptococci in the lesions.

necrosis with variable petechiae surrounded by acute and chronic inflammation, macrophage infiltration, and vascular proliferation. Both free tachyzoites and encysted bradyzoites may be found at the periphery of the necrotic foci (Fig. 22–20).

***Cysticercosis.*** Cysticercosis is the consequence of an end-stage infection by the tapeworm *Tenia solium.* If ingested larval organisms leave the lumen of the gastrointestinal tract, where they would otherwise develop into mature tapeworms, they encyst. Cysts can be found throughout the body but are common within the brain and subarachnoid space. Cysticercosis typically manifests as a mass lesion and can cause seizures. Symptoms can intensify when the encysted organism dies, as happens after therapy.

The organism is found within a cyst with a smooth lining. The body wall and hooklets from mouth parts are most commonly recognized. If the encysted organism has died, there can be an intense inflammatory infiltrate in the surrounding brain, often including eosinophils, which may be associated with marked gliosis.

***Amebiasis.*** *Amebic meningoencephalitis* manifests with different clinical syndromes, depending on the responsible pathogen. *Naegleria* spp., associated with swimming in nonflowing warm fresh water, cause a rapidly fatal

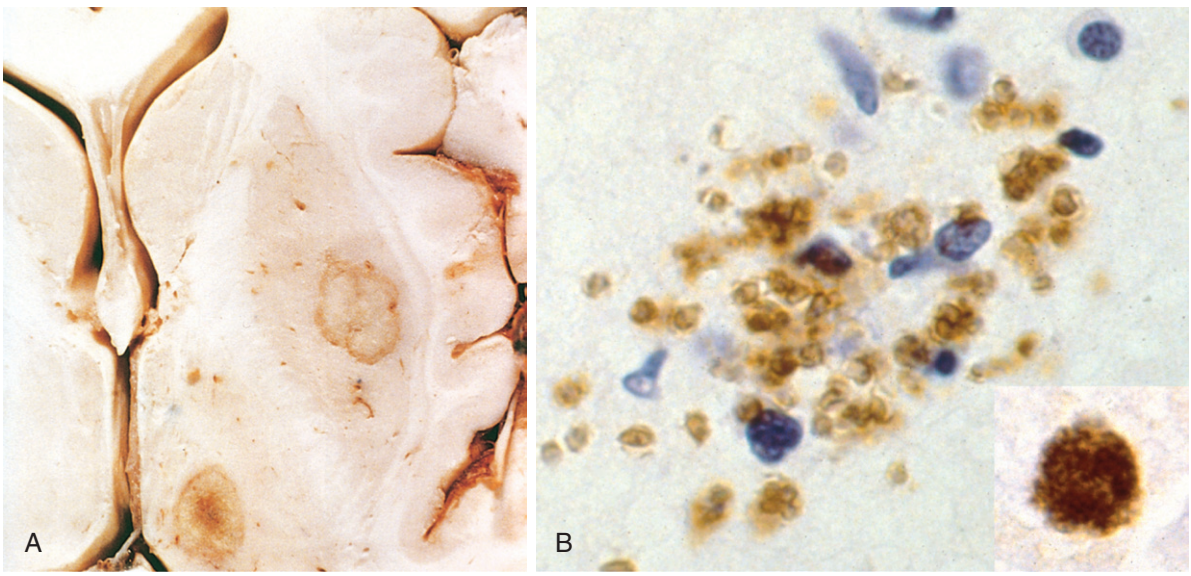

**Figure 22–20** *Toxoplasma* infection. **A,** Abscesses are present in the putamen and thalamus. **B,** Free tachyzoites are demonstrated by immunohistochemical staining. *Inset*, Bradyzoites are present as a pseudocyst, again highlighted by immunohistochemical staining.

necrotizing encephalitis. By contrast, *Acanthamoeba* causes a chronic granulomatous meningoencephalitis.

## Prion Diseases

Prion diseases are a group of rare but fascinating disorders that include sporadic, familial, iatrogenic, and variant forms of Creutzfeldt-Jakob disease (CJD), as well as animal diseases such as scrapie in sheep and bovine spongiform encephalopathy in cattle ("mad cow disease"). Unlike in other infectious diseases, the agent in prion diseases is an abnormal form of a cellular protein. This protein, termed prion protein (PrP), may undergo a conformational change from its normal shape ($PrP^c$) to an abnormal conformation called $PrP^{sc}$ (*sc* for scrapie). PrP normally is rich in α-helices, but $PrP^{sc}$ has a high content of β-sheets, a characteristic that makes it resistant to proteolysis (hence an alternative term for the pathogenic form, $PrP^{res}$—i.e., protease-resistant). More important, when $PrP^{sc}$ physically interacts with PrP molecules it induces them to also adopt the $PrP^{sc}$ conformation (Fig. 22–21), a property that accounts for the "infectious nature" of $PrP^{sc}$. Over time, this self-amplifying process leads to the accumulation of a high burden of pathogenic $PrP^{sc}$ molecules in the brain. $PrP^c$ also may change its conformation spontaneously (but at an extremely low rate), accounting for sporadic cases of prion disease (sCJD). Certain mutations in the gene encoding $PrP^c$ (*PRNP*) accelerate the rate of spontaneous conformational change; these variants are associated with early-onset familial forms of prion disease (fCJD). Accumulation of $PrP^{sc}$ in neural tissue seems to be the cause of cell injury, but the mechanisms underlying the cytopathic changes and eventual neuronal death are still unknown.

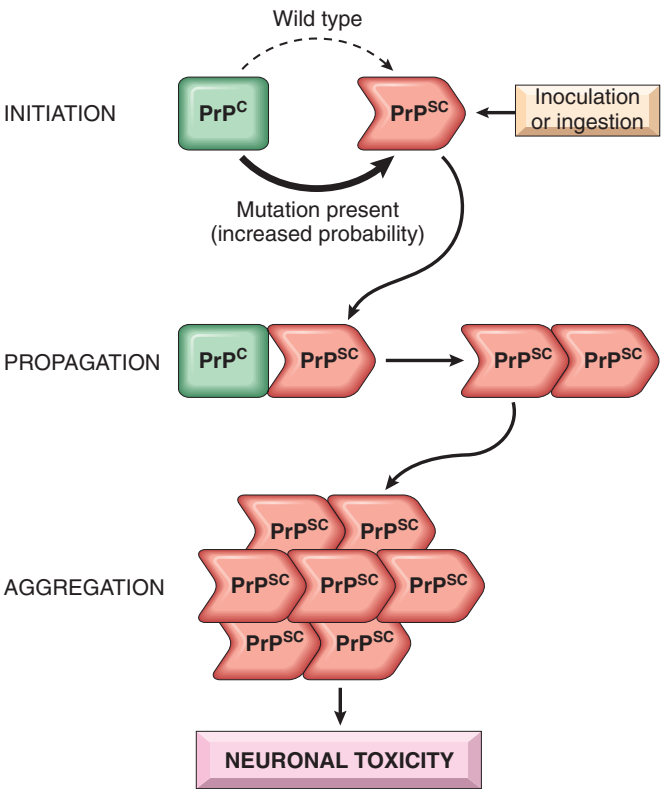

**Figure 22–21** Pathogenesis of prion disease. α-Helical $PrP^c$ may spontaneously shift to the β-sheet $PrP^{sc}$ conformation, an event that occurs at a much higher rate in familial disease associated with germ line PrP mutations. $PrP^{sc}$ may also be from exogenous sources, such as contaminated food, medical instrumentation, or medicines. Once present, $PrP^{sc}$ converts additional molecules of $PrP^c$ into $PrP^{sc}$ through physical interaction, eventually leading to the formation of pathogenic $PrP^{sc}$ aggregates.

### *Creutzfeldt-Jakob Disease*

CJD is a rapidly progressive dementing illness, with a typical duration from first onset of subtle changes in memory and behavior to death in only 7 months. It is sporadic in approximately 85% of cases and has a worldwide annual incidence of about 1 per million. While commonly affecting persons older than 70 years of age, familial forms caused by mutations in *PRNP* may present in younger people. In keeping with the infectious nature of $PrP^{sc}$, there are well-established cases of iatrogenic transmission by contaminated deep implantation electrodes and human growth hormone preparations.

#### MORPHOLOGY

The progression to death in CJD usually is so rapid that there is little, if any, macroscopic evidence of brain atrophy. On microscopic examination, the pathognomonic finding is a **spongiform transformation of the cerebral cortex and deep gray matter structures** (caudate, putamen); this multifocal process results in the uneven formation of small, apparently empty, microscopic vacuoles of varying sizes within the neuropil and sometimes in the perikaryon of neurons (Fig. 22–22, *A*). In advanced cases, there is severe neuronal loss, reactive gliosis, and sometimes expansion of the vacuolated areas into cystlike spaces ("status spongiosus"). No inflammatory infiltrate is present. Immunohistochemical staining demonstrates the presence of proteinase K–resistant $PrP^{sc}$ in tissue, while western blotting of tissue extracts after partial protease digestion allows detection of diagnostic $PrP^{sc}$.

### *Variant Creutzfeldt-Jakob Disease*

Starting in 1995, cases of a CJD-like illness appeared in the United Kingdom. The neuropathologic findings and molecular features of these new cases were similar to those of CJD, suggesting a close relationship between the two illnesses, yet this new disorder differed from typical CJD in several important respects: The disease affected young adults, behavioral disorders figured prominently in early disease stages, and the neurologic syndrome progressed more slowly than in other forms of CJD. Multiple lines of evidence indicate that this new disease, termed *variant Creutzfeldt-Jakob disease* (vCJD) is a consequence of exposure to the prion disease of cattle, called bovine spongiform encephalopathy. There has now also been documentation of transmission by blood transfusion. This variant form has a similar pathologic appearance to that in other types of CJD, with spongiform change and absence of inflammation. In vCJD, however, there are abundant cortical amyloid plaques, surrounded by the spongiform change (Fig. 22–22, *B*).

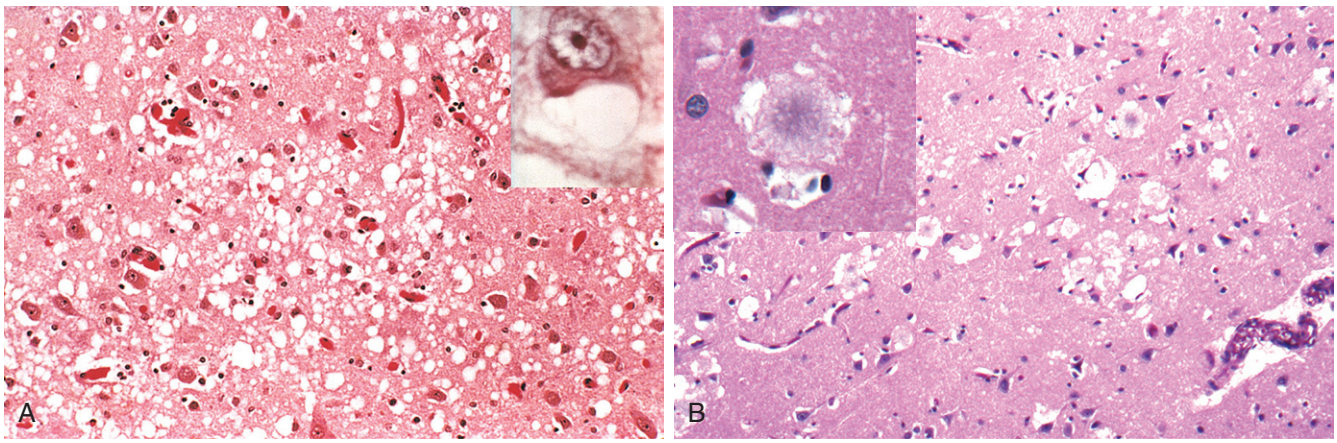

**Figure 22–22** Prion disease. **A,** Histologic features of Creutzfeldt-Jakob disease (CJD) include spongiform change in the cerebral cortex. *Inset*, High magnification of neuron with vacuoles. **B,** Variant CJD (vCJD) is characterized by amyloid plaques (see *inset*) that sit in the regions of greatest spongiform change.

## SUMMARY

### Infections of the Nervous System

- Pathogens from viruses through parasites can infect the brain; in addition, prion disease is a protein-induced transmissible disease unique to the nervous system.
- Different pathogens use distinct routes to reach the brain, and cause different patterns of disease.
- Bacterial infections may cause meningitis, cerebral abscesses, or a chronic meningoencephalitis.
- Viral infections can cause meningitis or meningoencephalitis.
- HIV can directly cause meningoencephalitis, or indirectly affect the brain by increasing the risk of opportunistic infections (toxoplasmosis, CMV) or CNS lymphoma.
- Prion diseases are transmitted by an altered form of a normal cellular protein. They can be sporadic, transmitted, or inherited.

# PRIMARY DISEASES OF MYELIN

Within the CNS, axons are tightly ensheathed by myelin, an electrical insulator that allows rapid propagation of neural impulses. Myelin consists of multiple layers of highly specialized, closely apposed plasma membranes that are assembled by oligodendrocytes. Although myelinated axons are present in all areas of the brain, they are the dominant component in the white matter; therefore, most diseases of myelin are primarily white matter disorders. The myelin in peripheral nerves is similar to the myelin in the CNS but has several important differences: (1) peripheral myelin is made by Schwann cells, not oligodendrocytes; (2) each Schwann cell in a peripheral nerve provides myelin for only one internode, while in the CNS, many internodes are created by processes coming from a single oligodendrocyte; and (3) the specialized proteins and lipids are also different. Therefore, most diseases of CNS myelin do not involve the peripheral nerves to any significant extent, and vice versa.

In general, diseases involving myelin are separated into two broad groups.

- *Demyelinating diseases* of the CNS are acquired conditions characterized by preferential damage to previously normal myelin. The most common diseases in this group result from immune-mediated injury, such as multiple sclerosis (MS) and related disorders. Other processes that can cause this type of disease include viral infection of oligodendrocytes, as in progressive multifocal leukoencephalopathy (see earlier), and injury caused by drugs and other toxic agents.
- By contrast, in *dysmyelinating diseases,* myelin is not formed properly or has abnormal turnover kinetics. As would be expected, dysmyelinating diseases are associated with mutations that disrupt the function of proteins that are required for the formation of normal myelin sheaths. The other general term for these diseases is *leukodystrophy.*

## Multiple Sclerosis

MS is an autoimmune demyelinating disorder characterized by *distinct episodes of neurologic deficits, separated in time, attributable to white matter lesions that are separated in space.* It is the most common of the demyelinating disorders, having a prevalence of approximately 1 per 1000 persons in most of the United States and Europe. The disease may become clinically apparent at any age, although onset in childhood or after age 50 is relatively rare. Women are affected twice as often as men. In most patients with MS, the illness shows relapsing and remitting episodes of neurologic impairment. The frequency of relapses tends to decrease during the course of the illness, but a steady neurologic deterioration is characteristic in a subset of patients.

## PATHOGENESIS

It is believed that MS, like other autoimmune diseases, is caused by a combination of environmental and genetic factors that result in a loss of tolerance to self proteins (in this case, myelin antigens). The nature of the initiating agent, often suggested to be an infectious agent, remains uncertain. Many lines of evidence indicate a significant contribution of genetic factors to the risk of developing MS. The disease risk is 15-fold higher when the disease is present in a first-degree relative, and the concordance rate for monozygotic twins is approximately 25%, with a much lower rate for dizygotic twins. A significant fraction of the genetic risk for MS is attributable to HLA-DR variants, the DR2 allele being the one that most significantly increases the risk for developing MS. Many other genetic polymorphisms have been linked to the disease by genome-wide association studies. Two that have received considerable recent interest are polymorphisms in the genes encoding receptors for the cytokines IL-2 and IL-7, which are known to control the activation and regulation of T cell–mediated immune responses.

In view of the prominence of chronic inflammatory cells within and around MS plaques as well as the genetic evidence, immune-mediated myelin destruction is thought to have a central role in MS. Evidence from human studies as well as from experimental allergic encephalomyelitis—an animal model of MS in which demyelination and inflammation occur after immunization with myelin, myelin proteins, or certain peptides from myelin proteins—has suggested that a range of immune cells contribute to lesion development in MS. A central role for CD4+ T cells has been suggested, with an increase in $T_H17$ and $T_H1$ CD4+ cells thought to be a critical component of the injury to myelin. There is also evidence for important contributions from CD8+ T cells and B cells. While MS is characterized by the presence of demyelination out of proportion to axonal loss, some injury to axons does occur. Toxic effects of lymphocytes, macrophages, and their secreted molecules have been implicated in initiating the process of axonal injury, sometimes even leading to neuronal death.

## MORPHOLOGY

MS is primarily a white matter disease with affected areas showing multiple, well-circumscribed, slightly depressed, glassy-appearing, gray-tan, irregularly shaped lesions termed **plaques** (Fig. 22–23, *A*). These commonly arise near the ventricles. They also are frequent in the optic nerves and chiasm, brain stem, ascending and descending fiber tracts, cerebellum, and spinal cord. The lesions have sharply defined borders at the microscopic level (Fig. 22–23, *B*). In an **active plaque** there is evidence of ongoing myelin breakdown with abundant macrophages containing myelin debris. Lymphocytes and macrophages are present, mostly as perivascular cuffs. Small active lesions often are centered on small veins. Axons are relatively preserved but may be reduced in number.

Active plaques fall into four classes, only one of which typically is seen in a particular affected patient. The recognized microscopic patterns are **type I,** which has macrophage infiltrates with sharp margins; **type II,** which is similar to type I but also shows complement deposition (suggesting an antibody-mediated component); **type III,** with less well-defined borders and oligodendrocyte apoptosis; and **type IV,** with nonapoptotic oligodendrocyte loss. When plaques become quiescent **(inactive plaques),** the inflammation mostly disappears, leaving behind little to no myelin. Instead, astrocytic proliferation and gliosis are prominent.

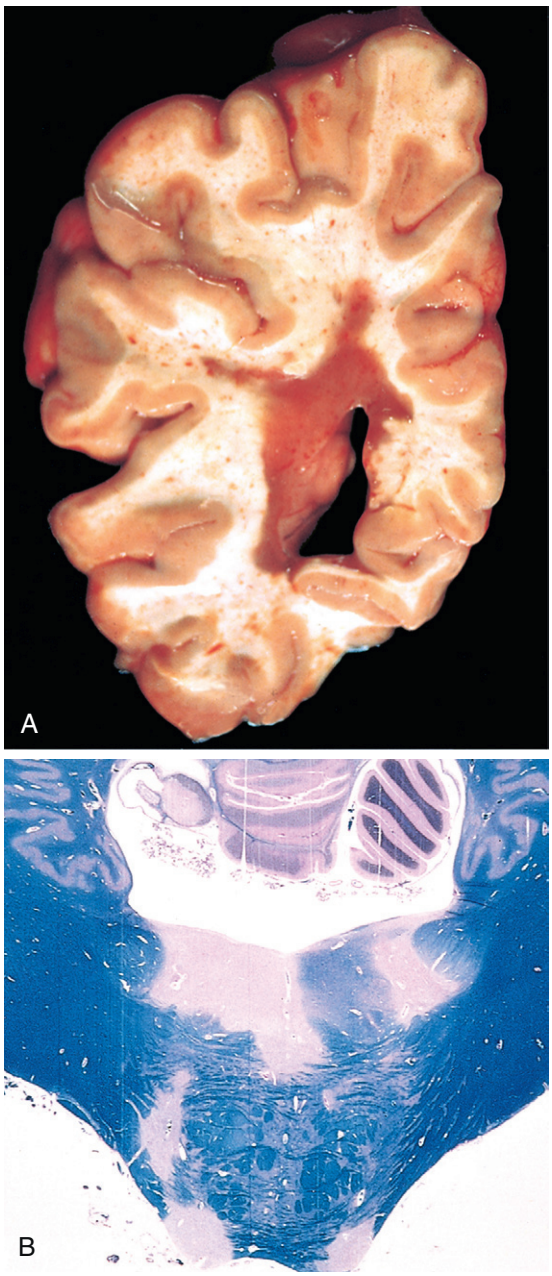

**Figure 22–23** Multiple sclerosis (MS). **A,** Section of fresh brain showing a plaque around occipital horn of the lateral ventricle. **B,** Unstained regions of demyelination (MS plaques) around the fourth ventricle. Luxol fast blue–periodic acid–Schiff stain for myelin.

### Clinical Features

The course of MS is variable, but commonly there are multiple *relapses* followed by episodes of *remission*; typically, recovery during remissions is not complete. As a consequence, over time there is usually a gradual, often stepwise, accumulation of neurologic deficits. Imaging studies

have demonstrated that there are often more lesions in the brains of patients with MS than might be expected from the clinical examination, and that lesions can come and go much more often than was previously suspected. Changes in cognitive function can be present, but are often much milder than the other deficits. In any individual patient, it is hard to predict when the next relapse will occur; most current treatments, which are intended to control the immune response, aim at decreasing the rate and severity of relapses rather than recovering lost function.

The CSF in patients with MS shows a mildly elevated protein level with an increased proportion of immunoglobulin; in one third of cases, there is moderate pleocytosis. When the immunoglobulin is examined further, *oligoclonal bands* usually are identified. These antibodies are directed against a variety of antigenic targets and can be used as markers of disease activity. Although B cells are clearly involved in the pathogenesis of MS, the contribution of these characteristic antibodies to the disease process is unknown.

## Other Acquired Demyelinating Diseases

Immune-mediated demyelination can occur after a number of systemic infectious illnesses, including relatively mild viral diseases. These are not thought to be related to direct spread of the infectious agents to the nervous system. Rather, it is believed that immune cells responding to pathogen-associated antigens are cross reactive against myelin antigens, resulting in myelin damage.

There are two general patterns of postinfectious autoimmune reactions to myelin; unlike in MS, they are associated with acute-onset monophasic illnesses. In *acute disseminated encephalomyelitis,* symptoms typically develop a week or two after an antecedent infection and are nonlocalizing (headache, lethargy, and coma), in contrast with the focal findings of MS. Symptoms progress rapidly, and the illness is fatal in as many as 20% of cases; in the remaining patients, there is complete recovery. *Acute necrotizing hemorrhagic encephalomyelitis* is a more devastating related disorder, which typically affects young adults and children.

*Neuromyelitis optica* (NMO) is an inflammatory demyelinating disease centered on the optic nerves and spinal cord. Previously thought to be a form of MS with stereotypic anatomic regions of susceptibility, this is now recognized to be an antibody-mediated autoimmune disorder. Antibodies to the water channel aquaporin-4 are both diagnostic and pathogenic.

*Central pontine myelinolysis* is a nonimmune process characterized by loss of myelin involving the center of the pons, most often after rapid correction of hyponatremia. The mechanism of oligodendroglial cell injury is uncertain, but it may be related to edema induced by sudden changes in osmotic pressure. It occurs in a variety of clinical settings including alcoholism and severe electrolyte or osmolar imbalance. Although the most characteristic lesion occurs in the pons, similar lesions can be found elsewhere in the brain. Because of the involvement of fibers in the pons carrying signals to motor neurons in the spinal cord, patients often present with rapidly evolving quadriplegia.

As discussed earlier, *progressive multifocal leukoencephalopathy* (PML) is a demyelinating disease that occurs after reactivation of JC virus in immunosuppressed patients.

## Leukodystrophies

*Leukodystrophies* exemplify inherited dysmyelinating diseases in which the clinical symptoms derive from abnormal myelin synthesis or turnover. Some of these disorders involve lysosomal enzymes, while others involve peroxisomal enzymes; a few are associated with mutations in myelin proteins. Most are of autosomal recessive inheritance, although X-linked diseases also occur (Table 22–1).

### MORPHOLOGY

Much of the pathologic change of leukodystrophy is found in the white matter, which is diffusely abnormal in color (gray and translucent) and volume (decreased). Early in their course, some diseases may show patchy involvement, while others have a predilection for occipital lobe involvement. In the end, though, nearly all of the white matter usually is affected. With the loss of white matter, the brain becomes atrophic, the ventricles enlarge, and secondary changes can be found in the gray matter. Myelin loss leads to infiltration of macrophages, which often become stuffed with lipid. Some of these diseases also show specific inclusions created by the accumulation of particular lipids.

### Clinical Features

Each of the various leukodystrophies has a characteristic clinical presentation, and most can be diagnosed by genetic or biochemical methods. Despite differences in underlying mechanisms, the leukodystrophies share many features because of the common myelin target. Affected children are normal at birth but begin to miss developmental milestones during infancy and childhood. Diffuse involvement of white matter leads to deterioration in motor skills, spasticity, hypotonia, or ataxia. In general, the earlier the age at onset, the more severe the deficiency and clinical course.

**Table 22–1** Selected Leukodystrophies

| Metabolic Disorder | Inheritance Mode | Abnormality |
|---|---|---|
| Metachromatic leukodystrophy | AR | Arylsulfatase A deficiency |
| Krabbe disease | AR | Galactocerebroside β-galactosidase deficiency |
| Adrenoleukodystrophy | AR, X | Peroxisomal defects; elevated very-long-chain fatty acids |
| Canavan disease | AR | Aspartoacylase deficiency |
| Pelizaeus-Merzbacher disease | X | Mutations in proteolipid protein |
| Vanishing white matter disease | AR | Translation initiation factor; link to myelin unclear |
| Alexander disease | AR | Mutations in glial fibrillary acidic protein |

AR, autosomal recessive; X, X-linked.

## SUMMARY

### Primary Diseases of Myelin

- Because of the critical role of myelin in nerve conduction, diseases of myelin can lead to widespread and severe neurologic deficits.
- Diseases of myelin can be grouped into *demyelinating diseases* (in which normal myelin is broken down for inappropriate reasons—often by inflammatory processes), and *dysmyelinating diseases* (metabolic disorders that include the leukodystrophies in which myelin structure or its turnover is abnormal).
- Multiple sclerosis, an autoimmune demyelinating disease, is the most common disorder of myelin, affecting young adults. It often pursues a relapsing-remitting course, with eventual progressive accumulation of neurologic deficits.
- Other, less common forms of immune-mediated demyelination often follow infections and are more acute illnesses.

# ACQUIRED METABOLIC AND TOXIC DISTURBANCES

Toxic and acquired metabolic diseases are relatively common causes of neurologic illnesses. Because of its high metabolic demands, the brain is particularly vulnerable to nutritional diseases and alterations in metabolic state. Surprisingly, even though metabolic alterations might be expected to affect the entire brain uniformly, there can be very distinct clinical presentations because of unique features or requirements of different anatomic regions. A few of the more common types of injury, particularly those with distinct patterns of damage, are discussed here.

## Nutritional Diseases

***Thiamine Deficiency.*** In addition to the systemic effects of thiamine deficiency (*beriberi*), there also may be abrupt onset of confusion, abnormalities in eye movement, and ataxia—a syndrome termed *Wernicke encephalopathy.* Treatment with thiamine can reverse these deficits. If the acute stages go untreated, they are followed by largely irreversible profound memory disturbances (Korsakoff syndrome). Because the two syndromes are closely linked, the term *Wernicke-Korsakoff syndrome* is often applied.

The syndrome is particularly common in the setting of chronic alcoholism but also may be encountered in patients with thiamine deficiency resulting from gastric disorders, including carcinoma and chronic gastritis, or from persistent vomiting.

## MORPHOLOGY

Wernicke encephalopathy is characterized by foci of hemorrhage and necrosis, particularly in the mammillary bodies but also adjacent to the ventricles, especially the third and fourth ventricles. Despite the presence of necrosis, there is relative preservation of many of the neurons in these structures. Early lesions show dilated capillaries with prominent endothelial cells and progress to hemorrhage. As the lesions resolve, a cystic space appears along with hemosiderin-laden macrophages. Lesions in the medial dorsal nucleus of the thalamus seem to best correlate with the memory disturbance in Korsakoff syndrome.

***Vitamin $B_{12}$ Deficiency.*** In addition to pernicious anemia, deficiency of vitamin $B_{12}$ may lead to neurologic deficits associated with changes in the spinal cord, collectively termed *subacute combined degeneration of the spinal cord*. As the name implies, both ascending and descending tracts of the spinal cord are affected. Symptoms develop over weeks. Early clinical signs often include slight ataxia and lower extremity numbness and tingling, which can progress to spastic weakness of the lower extremities; sometimes even complete paraplegia ensues. Prompt vitamin replacement therapy produces clinical improvement; however, if paraplegia has developed, recovery is poor.

## Metabolic Disorders

Several systemic derangements may produce CNS dysfunction; only those associated with glucose levels and liver dysfunction are considered here.

***Hypoglycemia.*** Since the brain requires glucose as a substrate for energy production, the cellular effects of diminished glucose generally resemble those of global hypoxia. Hippocampal neurons are particularly susceptible to hypoglycemic injury, while cerebellar Purkinje cells are relatively spared. As with anoxia, if the level and duration of hypoglycemia are sufficiently severe, there may be widespread injury to many areas of the brain.

***Hyperglycemia.*** Hyperglycemia is most common in the setting of inadequately controlled diabetes mellitus and can be associated with either ketoacidosis or hyperosmolar coma. Patients develop confusion, stupor, and eventually coma associated with intracellular dehydration caused by the hyperosmolar state. The hyperglycemia must be corrected gradually, because rapid correction can produce severe cerebral edema.

***Hepatic Encephalopathy.*** Decreased hepatic function may be associated with depressed levels of consciousness and sometimes coma. In the early stages, patients exhibit a characteristic "flapping" tremor (asterixis) when extending the arms with palms facing the observer. Elevated levels of ammonia, which the liver normally clears through the urea cycle, in combination with inflammation and hyponatremia, cause the changes in brain function. Because it is only one contributing factor, ammonia levels in symptomatic patients vary widely. Within the CNS, ammonia metabolism occurs only in astrocytes through the action of glutamine synthetase, and in the setting of hyperammonemia, astrocytes in the cortex and basal ganglia develop swollen, pale nuclei (called *Alzheimer type II cells*).

## Toxic Disorders

The list of toxins with effects on the brain is extremely long. Among the major categories of neurotoxic substances are

*metals,* including lead (often causing a diffuse encephalopathy), as well as arsenic and mercury; *industrial chemicals,* including organophosphates (in pesticides) and methanol (causing blindness from retinal damage); and *environmental pollutants* such as carbon monoxide (combining hypoxia with selective injury to the globus pallidus).

*Ethanol* has a variety of effects on the brain. While acute intoxication is reversible, excessive intake can result in profound metabolic disturbances, including brain swelling and death. Chronic alcohol exposure leads to cerebellar dysfunction in about 1% cases, with truncal ataxia, unsteady gait, and nystagmus, associated with atrophy in the anterior vermis of the cerebellum.

*Ionizing radiation,* commonly used to treat intracranial tumors, can cause rapidly evolving signs and symptoms including headaches, nausea, vomiting, and papilledema, even months to years after irradiation. Affected brain regions show large areas of coagulative necrosis, adjacent edema, and blood vessels with thickened walls containing intramural fibrin-like material.

## NEURODEGENERATIVE DISEASES

Degenerative diseases of the CNS are disorders characterized by the cellular degeneration of subsets of neurons that typically are related by function, rather than by physical location in the brain. Many of these disorders are associated with the accumulation of abnormal proteins, which serve as histologic hallmarks of specific disorders (Table 22–2). An important but unanswered question is why these abnormal proteins tend to accumulate in and preferentially affect particular kinds of neurons, since the involved proteins typically are widely expressed throughout the nervous system.

Subtle differences among subtypes of neurons are presumed to explain why particular neurons are affected in specific disorders. Understandably, the clinical manifestations of degenerative diseases are dictated by the pattern of neuronal dysfunction: those that affect the cerebral cortical neurons result in loss of memory, language, insight, and planning, all components of dementia; those that affect the neurons of the basal ganglia result in movement disorders; those that affect the cerebellum result in ataxia; and those that affect motor neurons result in weakness. Although many degenerative diseases have primary targets, other brain regions are often affected later in the course of the illness; thus, while Huntington disease often has movement disorders as an early symptom, later cortical involvement typically results in the development of cognitive changes as well. *Dementia* is defined as the development of memory impairment and other cognitive deficits severe enough to decrease the affected person's capacity to function at the previous level despite a normal level of consciousness. It arises during the course of many neurodegenerative diseases; it also can accompany numerous other diseases that injure the cerebral cortex (Table 22–3). Dementia is an increasing public health concern as the population ages.

**Table 22–2** Protein Inclusions in Degenerative Diseases

| Disease | Protein | Location |

### Alzheimer Disease

Alzheimer disease (AD) is the most common cause of dementia in the elderly population. The disease usually manifests with the insidious onset of impaired higher intellectual function and altered mood and behavior. Later, this progresses to disorientation, memory loss, and aphasia, findings indicative of severe cortical dysfunction, and over another 5 to 10 years, the patient becomes profoundly disabled, mute, and immobile. Death usually occurs from intercurrent pneumonia or other infections. Age is an

important risk factor for AD; the incidence is about 3% in persons 65 to 74 years old, 19% in those 75 to 84 years old, and 47% in those older than 84 years. Most cases of AD are sporadic, but at least 5% to 10% are familial. Sporadic cases rarely present before 50 years of age, but early onset is seen with some heritable forms.

## PATHOGENESIS

Study of the familial forms of AD supports a model in which a peptide called beta amyloid, or Aβ, accumulates in the brain over time, initiating a chain of events that result in AD. Aβ is created when the transmembrane protein amyloid precursor protein (APP) is sequentially cleaved by the enzymes β-amyloid converting enzyme (BACE) and γ-secretase (Fig. 22–24). APP also can be cleaved by α-secretase and γ-secretase, which liberates a different peptide that is nonpathogenic. Mutations in APP or in components of γ-secretase (presenilin-1 or presenilin-2) lead to familial AD by increasing the rate at which Aβ is generated. The *APP* gene is located on chromosome 21, and the risk of AD also is higher in those with an extra copy of the *APP* gene, such as patients with trisomy 21 (Down syndrome) and persons with small interstitial duplications of *APP*, presumably because this too leads to greater Aβ generation. The other major genetic risk factor is a variant of apolipoprotein E called ε4 (ApoE4). Each ApoE4 allele that is present increases the risk of AD by approximately 4 fold and also appears to lower the age of onset. How ApoE4 influences Aβ accumulation is unknown; it may increase Aβ aggregation or deposition, or decrease Aβ clearance.

While large deposits of Aβ are a feature of end-stage AD, small aggregates of Aβ may also be pathogenic, as they alter neurotransmission and are toxic to neurons and synaptic endings. Large deposits, in the form of plaques, also lead to neuronal death, elicit a local inflammatory response that can result in further cell injury, and may cause altered region-to-region communication through mechanical effects on axons and dendrites.

The presence of Aβ also leads to hyperphosphorylation of the neuronal microtubule binding protein tau. This increased

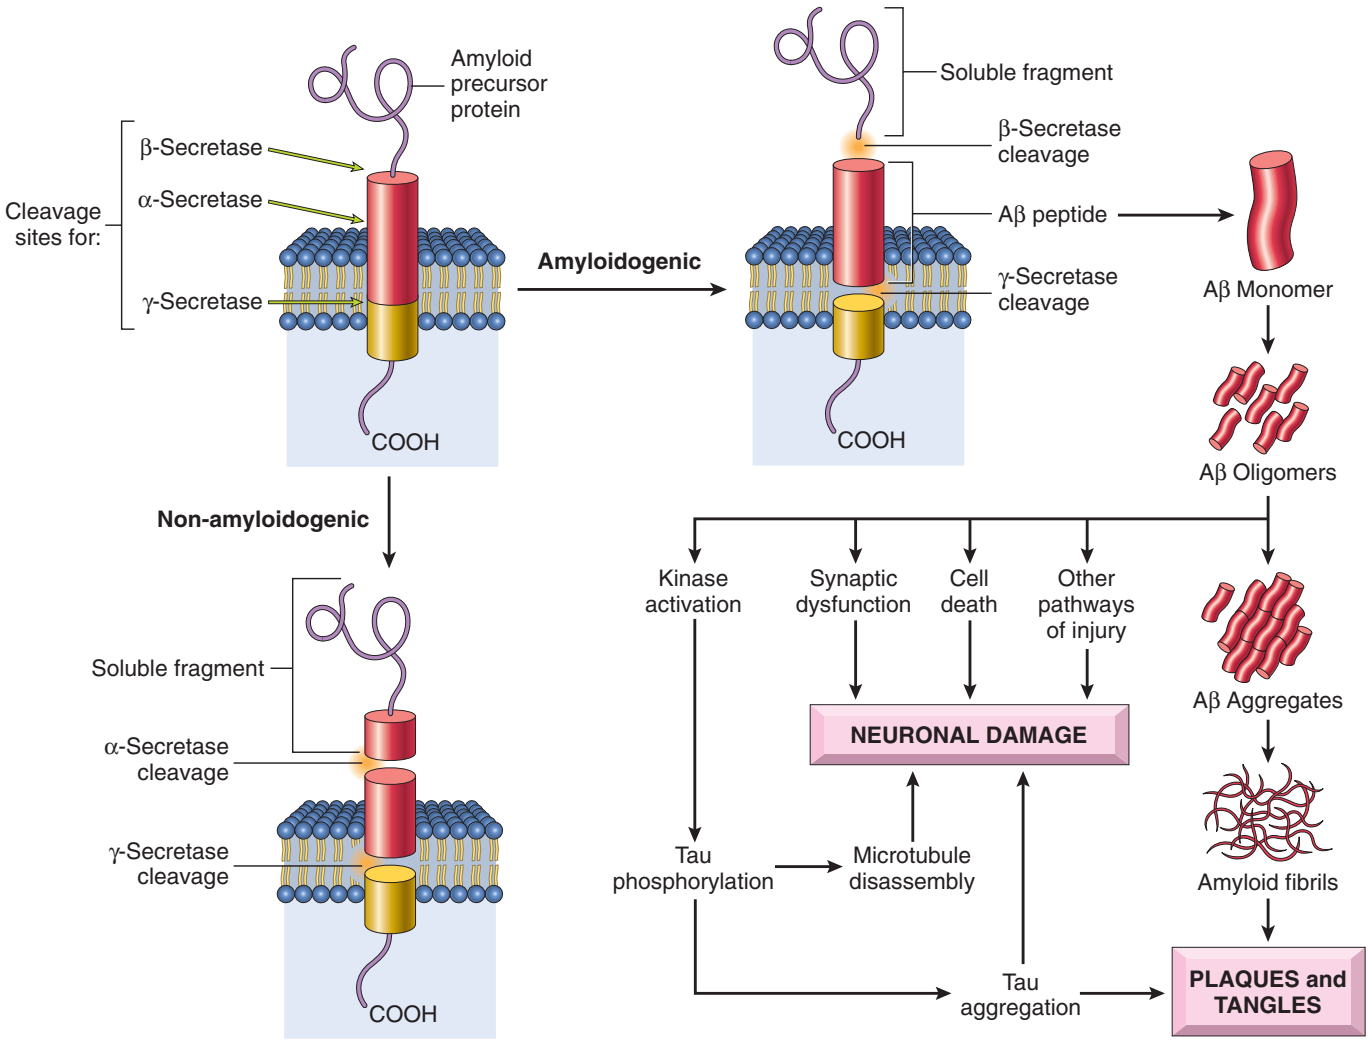

**Figure 22–24** Aβ peptide genesis and consequences in Alzheimer disease. Amyloid precursor protein cleavage by α-secretase and γ-secretase produces a harmless soluble peptide, whereas amyloid precursor protein cleavage by β-amyloid–converting enzyme (BACE) and γ-secretase releases Aβ peptides, which form pathogenic aggregates and contribute to the characteristic plaques and tangles of Alzheimer disease.

level of phosphorylation causes tau to redistribute from axons into dendrites and cell bodies, where it aggregates into tangles, which also contribute to neuronal dysfunction and cell death.

## MORPHOLOGY

Macroscopic examination of the brain shows a variable degree of cortical atrophy, resulting in a widening of the cerebral sulci that is most pronounced in the frontal, temporal, and parietal lobes. With significant atrophy, there is compensatory ventricular enlargement (hydrocephalus ex vacuo). At the microscopic level, AD is diagnosed by the presence of **plaques** (an extracellular lesion); and **neurofibrillary tangles** (an intracellular lesion) (Fig. 22–25). Because these may also be present to a lesser extent in the brains of elderly nondemented persons, the current criteria for a diagnosis of AD are based on a combination of clinical and pathologic features. There is a fairly constant progressive involvement of different parts of the brain: pathologic changes (specifically plaques, tangles, and the associated neuronal loss and glial reaction) are evident first in the entorhinal cortex, then in the hippocampal formation and isocortex, and finally in the neocortex. Silver staining or immunohistochemistry methods are extremely helpful in assessing the true lesional burden.

**Neuritic plaques** are focal, spherical collections of dilated, tortuous, silver-staining neuritic processes (dystrophic neurites), often around a central amyloid core (Fig. 22–25, *A*). Neuritic plaques range in size from 20 to 200 μm in diameter; microglial cells and reactive astrocytes are present at their periphery. Plaques can be found in the hippocampus and amygdala as well as in the neocortex, although there usually is relative sparing of primary motor and sensory cortices until late in the disease course. The amyloid core contains Aβ (Fig. 22–25, *B*). Aβ deposits also can be found that lack the surrounding neuritic reaction, termed **diffuse plaques;** these typically are found in the superficial cerebral cortex, the basal ganglia, and the cerebellar cortex and may represent an early stage of plaque development.

**Neurofibrillary tangles** are bundles of paired helical filaments visible as basophilic fibrillary structures in the cytoplasm of the neurons that displace or encircle the nucleus; tangles can persist after neurons die, becoming a form of extracellular pathology. They are commonly found in cortical neurons, especially in the entorhinal cortex, as well as in the pyramidal cells of the hippocampus, the amygdala, the basal forebrain, and the raphe nuclei. A major component of paired helical filaments is abnormally hyperphosphorylated **tau** (Fig. 22–25, *C*). Tangles are not specific to AD, being found in other degenerative diseases as well.

### Frontotemporal Lobar Degeneration

Another major category of disease that results in dementia is called *frontotemporal lobar degeneration* (FTLD). These disorders share clinical features (progressive deterioration of language and changes in personality) stemming from the degeneration and atrophy of temporal and frontal lobes; the clinical syndromes commonly are referred to as *frontotemporal dementias.* When the frontal lobe bears the greatest burden of disease, behavioral changes often dominate, whereas when the disease begins in the temporal lobe, language problems often are the presenting complaint. These symptoms precede memory disturbances, which can assist in their separation from AD on clinical grounds.

On gross inspection, there is atrophy of the brain that predominantly affects the frontal and temporal lobes. Different subgroups are characterized by neuronal inclusions involving the affected regions. In some cases the defining inclusions contain tau (FTLD-tau), but the configuration of the tau inclusions differs from the tau-containing tangles of AD. FTLD-tau sometimes is caused by mutations in the gene encoding tau. One well-recognized subtype of FTLD-tau is *Pick disease,* which is associated with smooth, round inclusions known as *Pick bodies.* The other major form of FTLD is characterized by aggregates containing the DNA/RNA-binding protein TDP-43 (FTLD-TDP43). This form of FTLD is associated with predominantly frontal lobe cognitive impairment. It is sometimes caused by mutations in the gene encoding TDP-43, which is also mutated in a subset of cases of amyotrophic lateral sclerosis (described later).

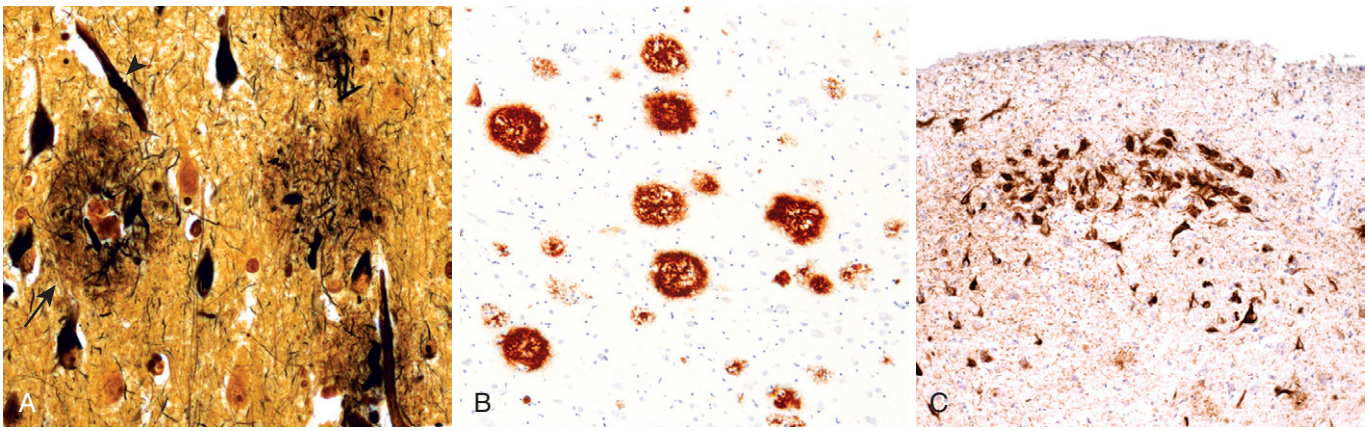

**Figure 22–25** Alzheimer disease. **A,** Plaques (*arrow*) contain a central core of amyloid and a surrounding region of dystrophic neurites (Bielschowsky stain). **B,** Immunohistochemical stain for Aβ. Peptide is present in the core of the plaques as well as in the surrounding region. **C,** Neurons containing tangles stained with an antibody specific for tau.

## Parkinson Disease

*Parkinsonism* is a clinical syndrome characterized by tremor, rigidity, bradykinesia and instability. These types of motor disturbances may be seen in a range of diseases that damage dopaminergic neurons, which project from the substantia nigra to the striatum. Parkinsonism can be induced by drugs such as dopamine antagonists or toxins that selectively injure dopaminergic neurons. Among the neurodegenerative diseases, most cases of parkinsonism are caused by *Parkinson disease* (PD), which is associated with characteristic neuronal inclusions containing α-synuclein. Other diseases in which parkinsonism may be present include *multiple system atrophy* (MSA), in which α-synuclein aggregates are found in oligodendrocytes; *progressive supranuclear palsy* (PSP) and *corticobasal degeneration* (CBD), which are both associated with tau-containing inclusions in neurons and glial cells; and *postencephalitic parkinsonism,* which was associated with the 1918 influenza pandemic.

### PATHOGENESIS

While PD in most cases is sporadic, both autosomal dominant and recessive forms of the disease also exist. Point mutations and duplications of the gene encoding α-synuclein, a protein involved in synaptic transmission, cause autosomal dominant PD. Even in sporadic PD, the diagnostic feature of the disease—the Lewy body—is an inclusion containing α-synuclein. The linkage between α-synuclein and disease pathogenesis is unclear, but other genetic forms of PD provide some clues. Two other causative genetic loci encode the proteins parkin, an E3 ubiquitin ligase, and UCHL-1, an enzyme involved in recycling of ubiquitin from proteins targeted to the proteasome, suggesting that defects in protein degradation may have a pathogenic role. Another tantalizing clue comes from the association of PD with mutations in a protein kinase called LRRK2; histopathologic examination of cases associated with LRRK2 mutations may show either Lewy bodies containing α-synuclein or tangles containing tau. Finally, some forms of familial PD are associated with mutations in the *PARK7* or *PINK1* genes, both of which appear to be important for normal mitochondrial function.

### MORPHOLOGY

A typical gross finding at autopsy is pallor of the substantia nigra (Fig. 22–26, *A* and *B*) and locus ceruleus. Microscopic features include loss of the pigmented, catecholaminergic neurons in these regions associated with gliosis. **Lewy bodies** (Fig. 22–26, *C*) may be found in those neurons that remain. These are single or multiple, intracytoplasmic, eosinophilic, round to elongated inclusions that often have a dense core surrounded by a pale halo. On ultrastructural examination, Lewy bodies consist of fine filaments, densely packed in the core but loose at the rim, composed of α-synuclein and other proteins, including neurofilaments and ubiquitin. The other major histologic finding is **Lewy neurites,** dystrophic neurites that also contain abnormally aggregated α-synuclein.

As implied by the occurrence of a broad array of neurologic deficits in PD, immunohistochemical staining for α-synuclein highlights more subtle Lewy bodies and Lewy neurites in many brain regions outside of the substantia nigra and in nondopaminergic neurons. These lesions appear first in the medulla and then in the pons, before involvement of the substantia nigra. As implied by the dementia, Lewy bodies and Lewy neurites eventually appear in the cerebral cortex and subcortical areas, including the cholinergic cells of the basal nucleus of Meynert and the amygdala.

### Clinical Features

PD commonly manifests as a movement disorder in the absence of a toxic exposure or other known underlying etiology. The disease usually progresses over 10 to 15 years, eventually producing severe motor slowing to the point of near immobility. Death usually is the result of intercurrent infection or trauma from frequent falls caused by postural instability.

Movement symptoms of PD initially respond to L-dihydroxyphenylalanine (L-DOPA), but this treatment does not slow disease progression. Over time, L-DOPA becomes less effective and begins to cause potentially problematic fluctuations in motor function.

While the movement disorder associated with loss of the nigrostriatal dopaminergic pathway is an important feature of PD, it is clear that the disease has more extensive clinical and pathologic manifestations. Lesions can be found lower

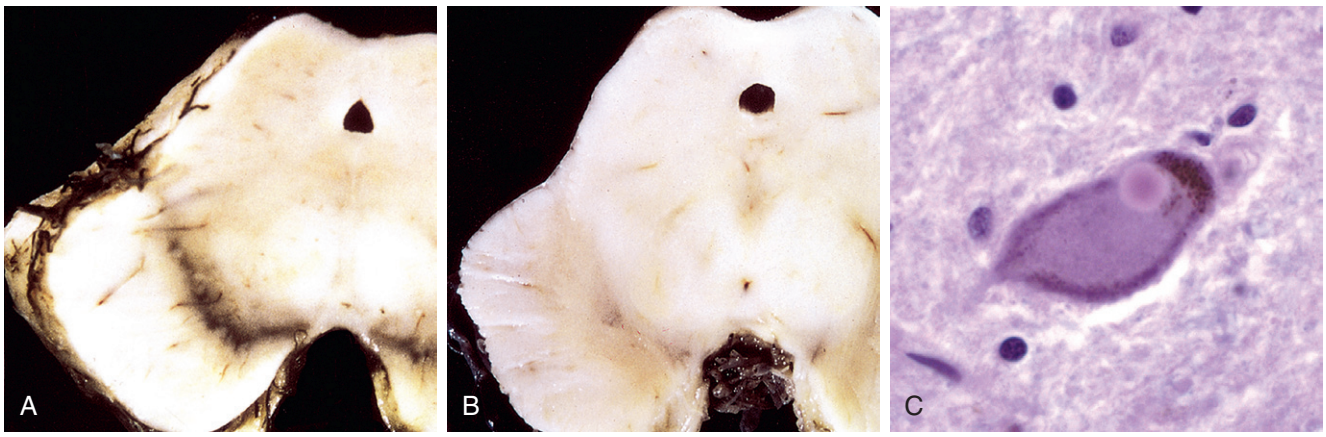

**Figure 22–26** Parkinson disease. **A,** Normal substantia nigra. **B,** Depigmented substantia nigra in idiopathic Parkinson disease. **C,** Lewy body in a neuron from the substantia nigra stains *pink*.

in the brain stem (in the dorsal motor nucleus of the vagus and in the reticular formation) in advance of nigral involvement, in line with clinical studies showing that autonomic dysfunction and behavioral disorders often are present in advance of the motor problems. Dementia, typically with a mildly fluctuating course and hallucinations, emerges in many persons with PD and is attributable to involvement of the cerebral cortex. When dementia arises within 1 year of the onset of motor symptoms, it is referred to *Lewy body dementia* (LBD).

## Huntington Disease

Huntington disease (HD) is an autosomal dominant movement disorder associated with degeneration of the striatum (caudate and putamen). The movement disorder is choreiform (dancelike), with increased and involuntary jerky movements of all parts of the body; writhing movements of the extremities are typical. *The disease is relentlessly progressive, resulting in death after an average course of about 15 years.* Early cognitive symptoms include forgetfulness and thought and affective disorders, and there may be progression to a severe dementia. As a part of these early behavioral changes, HD carries an increased risk of suicide.

### PATHOGENESIS

HD is caused by **CAG trinucleotide repeat expansions** in a gene located on 4p16.3 that encodes the protein huntingtin. Normal alleles contain 11 to 34 copies of the repeat; in disease-causing alleles the number of repeats is increased, sometimes into the hundreds. There is strong genotype-phenotype correlation, with larger numbers of repeats resulting in earlier-onset disease. Once the symptoms appear, however, the course of the illness is not affected by repeat length. Further expansions of the pathologic CAG repeats can occur during spermatogenesis, so paternal transmission may be associated with earlier onset in the next generation, a phenomenon referred to as **anticipation** (Chapter 6).

HD appears to be caused by a toxic gain-of-function mutation somehow related to the expanded polyglutamine tract in huntingtin. The mutant protein is subject to ubiquitination and proteolysis, yielding fragments that can form large intranuclear aggregates. As in other degenerative diseases, smaller aggregates of the abnormal protein fragments are suspected to be the critical toxic agent. These aggregates may sequester transcription factors, disrupt protein degradation pathways, perturb mitochondrial function, or alter brain-derived neurotrophic factor (BDNF) signaling. It is likely that some combination of these aberrations contributes to HD pathogenesis.

### MORPHOLOGY

On gross examination, the brain is small and shows striking atrophy of the caudate nucleus and, sometimes less dramatically, the putamen (Fig. 22–27). Pathologic changes develop over the course of the illness in a medial to lateral direction in the caudate and from dorsal to ventral in the putamen. The globus pallidus may be atrophied secondarily, and the lateral and third ventricles are dilated. Atrophy frequently is also seen in the frontal lobe, less often in the parietal lobe, and occasionally in the entire cortex.

Microscopic examination reveals severe loss of neurons from affected regions of the striatum. The medium-sized, spiny neurons that release the neurotransmitters γ-aminobutyric acid (GABA), enkephalin, dynorphin, and substance P are especially sensitive, disappearing early in the disease. Also seen is fibrillary gliosis, which is more extensive than in the usual reaction to neuronal loss. There is a strong correlation between the degree of degeneration in the striatum and the severity of motor symptoms; there is also an association between cortical neuronal loss and dementia. In remaining striatal neurons and in the cortex, there are intranuclear inclusions that contain aggregates of ubiquitinated huntingtin protein (Fig. 22–27, *inset*).

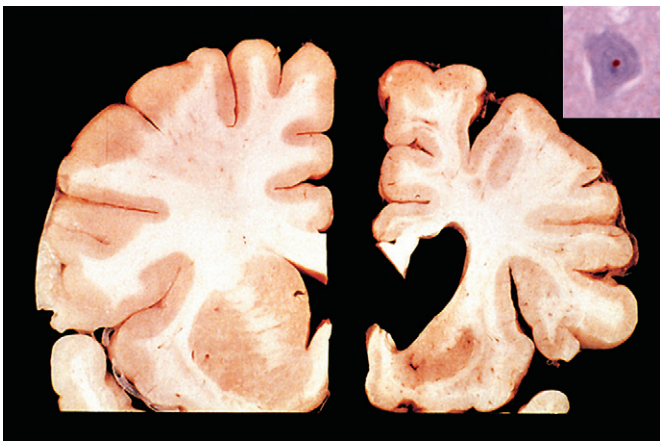

**Figure 22–27** Huntington disease. Normal hemisphere on the *left* compared with the hemisphere with Huntington disease on the *right* showing atrophy of the striatum and ventricular dilation. *Inset,* An intranuclear inclusion in a cortical neuron is strongly immunoreactive for ubiquitin. *(Courtesy of Dr. J.P. Vonsattel, Columbia University, New York, New York.)*

## Spinocerebellar Ataxias

Spinocerebellar ataxias (SCAs) are a clinically heterogeneous group of diseases that are frequently caused by trinucleotide repeat expansion mutations. They are distinguished from one another by differences in causative mutations, patterns of inheritance, age at onset, and signs and symptoms. This group of diseases affects, to a variable extent, the cerebellar cortex, spinal cord, other brain regions, and peripheral nerves. As a result, clinical findings may include a combination of cerebellar and sensory ataxia, spasticity, and sensorimotor peripheral neuropathy. Degeneration of neurons, often without distinctive histopathologic changes, occurs in the affected areas and is associated with mild gliosis. The additional clinical symptoms that accompany the ataxia can help distinguish between well-characterized subtypes. Although more than two dozen distinct genetic types of SCA have been identified, there remain many cases which do not fall into one of the already characterized forms.

As with Huntington disease, several forms of SCA (SCA types 1, 2, 3, 6, 7, and 17 and dentatorubropallidoluysian atrophy) are caused by CAG repeat expansions encoding polyglutamine tracts in various genes. In these forms of SCA, neuronal intranuclear inclusions are present containing the abnormal protein and there is an inverse correlation between the degree of repeat expansion and age of onset. Other SCAs are caused by trinucleotide repeat expansions in untranslated regions or by other types of mutations.

*Friedreich ataxia* is an autosomal recessive disorder that generally manifests in the first decade of life with gait ataxia, followed by hand clumsiness and dysarthria. Most patients develop pes cavus and kyphoscoliosis, and there is a high incidence of cardiac disease and diabetes. The disease usually is caused by a GAA trinucleotide repeat expansion in the gene encoding frataxin, a protein that regulates cellular iron levels, particularly in the mitochondria. The repeat expansion results in decreased protein levels through transcriptional silencing; rare cases in which point mutations produce a nonfunctional frataxin protein also have been described. Decreased frataxin leads to mitochondrial dysfunction as well as increased oxidative damage.

## Amyotrophic Lateral Sclerosis

*Amyotrophic lateral sclerosis* (ALS) results from the death of lower motor neurons in the spinal cord and brain stem, and of upper motor neurons (Betz cells) in the motor cortex. The loss of lower motor neurons results in denervation of muscles, muscular atrophy (the "amyotrophy" of the condition), weakness, and fasciculations, while the loss of upper motor neurons results in paresis, hyperreflexia, and spasticity, along with a Babinski sign. An additional consequence of upper motor neuron loss is degeneration of the corticospinal tracts in the lateral portion of the spinal cord ("lateral sclerosis"). Sensation usually is unaffected, but cognitive impairment does occur, sometimes as a frontotemporal dementia.

The disease affects men slightly more frequently than women and becomes clinically manifest in the fifth decade or later, usually beginning with subtle asymmetric distal extremity weakness. As the disease progresses to involve more of the motor system, muscle strength and bulk diminish and involuntary contractions of individual motor units, termed fasciculations, occur. The disease eventually involves the respiratory muscles, leading to recurrent bouts of pulmonary infection, which is the usual cause of death. The balance between upper and lower motor neuron involvement can vary, although most patients exhibit involvement of both. In some patients, degeneration of the lower brain stem cranial motor nuclei occurs early and progresses rapidly, a pattern of disease referred to as bulbar amyotrophic lateral sclerosis. With this disease pattern, abnormalities of swallowing and speaking dominate.

### PATHOGENESIS

While most cases are sporadic, 5% to 10% are familial, mostly with autosomal dominant inheritance. Familial disease begins earlier in life than sporadic disease, but once symptoms appear, the clinical course is similar in both forms. More than a dozen genes have been implicated, but the most frequent genetic cause (20% of cases) is mutations in the superoxide dismutase gene, *SOD-1*, on chromosome 21. These mutations are thought to generate abnormal misfolded forms of the SOD-1 protein, which may trigger the unfolded protein response and cause apoptotic death of neurons. The next two most common causative genes both encode DNA/RNA binding proteins, TDP-43 and FUS; how these mutations cause disease is unknown. As already mentioned, mutations in TDP-43 also can cause frontotemporal lobar degeneration (FTLD) or a disease with overlapping features of both ALS and FTLD.

### MORPHOLOGY

The most striking gross changes are found in anterior roots of the spinal cord, which are thin and gray (rather than white). In especially severe cases, the precentral gyrus (motor cortex) may be mildly atrophic. Microscopic examination demonstrates a reduction in the number of anterior horn cell neurons throughout the length of the spinal cord associated with reactive gliosis and loss of anterior root myelinated fibers. Similar findings are found with involvement of motor cranial nerve nuclei except those supplying the extraocular muscles, which are spared except in very longstanding survivors. Remaining lower motor neurons often harbor cytoplasmic inclusions that contain TDP-43, except in those cases in which the underlying cause is a mutation in SOD-1.

Death of upper motor neurons—a finding that may be hard to demonstrate microscopically—results in degeneration of the descending corticospinal tracts. This is usually easily seen in the spinal cord. With the loss of innervation from the death of anterior horn cells, skeletal muscles show neurogenic atrophy.

### SUMMARY

#### Neurodegenerative Diseases

- Neurodegenerative diseases cause symptoms that depend on the pattern of brain involvement. Cortical disease usually manifests as cognitive change, alterations in personality, and memory disturbances; basal ganglia disorders usually manifest as movement disorders.
- Many neurodegenerative diseases preferentially affect a primary set of brain regions, but other regions can be involved later in the disease course. This evolving process can change the phenotype of the disease over time—as with the appearance of cognitive impairments in people initially affected by the movement disorder of Parkinson disease.
- Many of the neurodegenerative diseases are associated with various protein aggregates, which serve as pathologic

hallmarks. It is unclear whether these striking inclusions and deposits are critical mediators of cellular degeneration. Familial forms of these diseases are associated with mutations in the genes encoding these proteins or controlling their metabolism.

# TUMORS

The annual incidence of CNS tumors ranges from 10 to 17 per 100,000 persons for intracranial tumors and 1 to 2 per 100,000 persons for intraspinal tumors; about half to three quarters are primary tumors, and the rest are metastatic. Tumors of the CNS make up a larger proportion of childhood cancers, accounting for as many of 20% of all pediatric tumors. Childhood CNS tumors differ from those in adults in both histologic subtype and location. In childhood, tumors are likely to arise in the posterior fossa; in adults, they are mostly supratentorial.

Tumors of the nervous system have unique characteristics that set them apart from neoplastic processes elsewhere in the body.

- These tumors do not have detectable premalignant or in situ stages comparable to those of carcinomas.
- Even low-grade lesions may infiltrate large regions of the brain, leading to serious clinical deficits, nonresectability, and poor prognosis.
- The anatomic site of the neoplasm can influence outcome independent of histologic classification due to local effects (e.g., a benign meningioma may cause cardiorespiratory arrest from compression of the medulla) or nonresectability (e.g., brain stem gliomas).
- Even the most highly malignant gliomas rarely spread outside of the CNS; in addition to local infiltration, the subarachnoid space allows for spread to distant sites along the neuroaxis.

## Gliomas

Gliomas are tumors of the brain parenchyma that are classified histologically on the basis of their resemblance to different types of glial cells. The major types of glial tumors are *astrocytomas, oligodendrogliomas,* and *ependymomas.* The most common types are highly infiltrative or "diffuse gliomas," including astrocytic, oligodendroglial, and mixed forms. In contrast, ependymomas tend to form solid masses.

### *Astrocytoma*

Several different categories of astrocytic tumors are recognized, the most common being diffuse and pilocytic astrocytomas. Different types of astrocytomas have characteristic histologic features, anatomic distributions, and clinical features.

#### Diffuse Astrocytoma

Diffuse astrocytomas account for about 80% of adult gliomas. They are most frequent in the fourth through the sixth decades of life. They usually are found in the cerebral hemispheres. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the anatomic site of involvement. They show a spectrum of histologic differentiation that correlates well with clinical course and outcome. On the basis of histologic features, they are stratified into three groups: well-differentiated astrocytoma (grade II/IV), anaplastic astrocytoma (grade III/IV), and glioblastoma (grade IV/IV), with increasingly grim prognosis as the grade increases.

Well-differentiated astrocytomas can be static for several years, but at some point they progress; the mean survival is more than 5 years. Eventually, patients suffer rapid clinical deterioration that is correlated with the appearance of anaplastic features and more rapid tumor growth. Other patients present with glioblastoma from the start. Once the histologic features of glioblastoma appear, the prognosis is very poor; with treatment (resection, radiotherapy, and chemotherapy), the median survival is only 15 months.

Astrocytomas are associated with a variety of acquired mutations, which cluster in several important pathways. In glioblastoma, loss-of-function mutations in the p53 and Rb tumor suppressor pathways and gain-of-function mutations in the oncogenic PI3K pathways have central roles in tumorigenesis. Surprisingly, mutations that alter the enzymatic activity of two isoforms of the metabolic enzyme isocitrate dehydrogenase (IDH1 and IDH2) are common in lower-grade astrocytomas. As a result, immunostaining for the mutated form of IDH1 has become an important diagnostic tool in evaluating biopsy specimens for the presence of low-grade astrocytoma.

#### MORPHOLOGY

Well-differentiated astrocytomas are poorly defined, gray, infiltrative tumors that expand and distort the invaded brain without forming a discrete mass (Fig. 22–28, *A*). Infiltration beyond the grossly evident margins is always present. The cut surface of the tumor is either firm or soft and gelatinous; cystic degeneration may be seen. In glioblastoma, variation in the gross appearance of the tumor from region to region is characteristic (Fig. 22–28, *B*). Some areas are firm and white, others are soft and yellow (the result of tissue necrosis), and still others show regions of cystic degeneration and hemorrhage.

Well-differentiated astrocytomas are characterized by a mild to moderate increase in the number of glial cell nuclei, somewhat variable nuclear pleomorphism, and an intervening feltwork of fine, glial fibrillary acidic protein (GFAP)-positive astrocytic cell processes that give the background a fibrillary appearance. The transition between neoplastic and normal tissue is indistinct, and tumor cells can be seen infiltrating normal tissue many centimeters from the main lesion. Anaplastic astrocytomas show regions that are more densely cellular and have greater nuclear pleomorphism; mitotic figures are present. Glioblastoma has a histologic appearance similar to that of anaplastic astrocytoma, as well as either necrosis (often with pseudopalisading nuclei) or vascular proliferation (Fig. 22–28, *C*).

#### Pilocytic Astrocytoma

Pilocytic astrocytomas are relatively benign tumors, typically affecting children and young adults. Most commonly

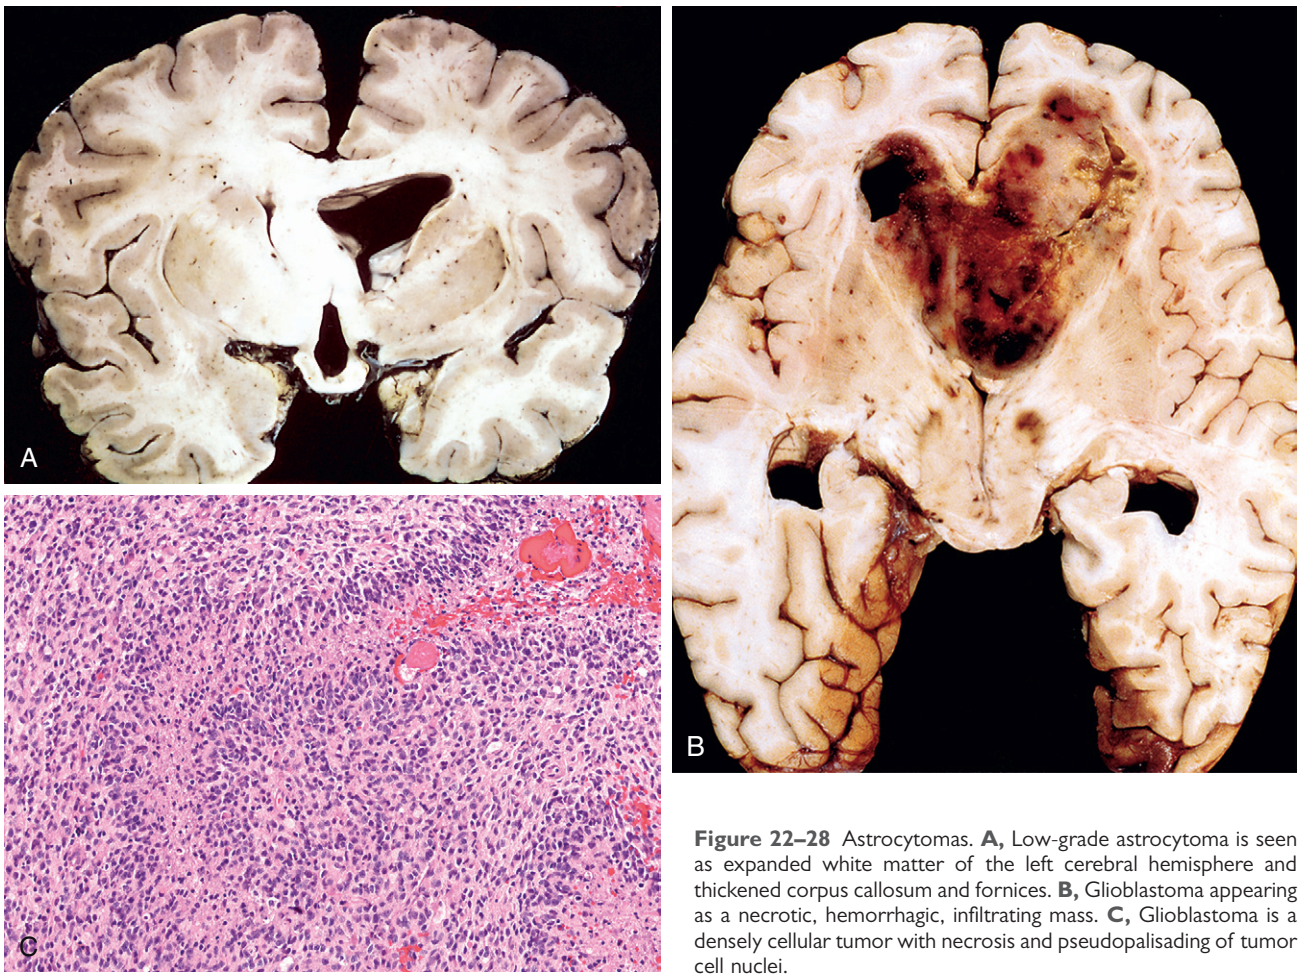

**Figure 22–28** Astrocytomas. **A,** Low-grade astrocytoma is seen as expanded white matter of the left cerebral hemisphere and thickened corpus callosum and fornices. **B,** Glioblastoma appearing as a necrotic, hemorrhagic, infiltrating mass. **C,** Glioblastoma is a densely cellular tumor with necrosis and pseudopalisading of tumor cell nuclei.

located in the cerebellum, they also may involve the third ventricle, the optic pathways, spinal cord, and occasionally the cerebral hemispheres. There is often a cyst associated with the tumor, and symptomatic recurrence from incompletely resected lesions is often associated with cyst enlargement, rather than growth of the solid component. Tumors that involve the hypothalamus are especially problematic because they cannot be resected completely.

A high proportion of pilocytic astrocytomas have activating mutations in the serine-threonine kinase BRAF—either a specific point mutation (V600E) that is also found in many other cancers (Chapter 5), or more commonly a partial tandem duplication event. Mutations in IDH1 and IDH2 (common in low-grade diffuse astrocytomas) are not found in pilocytic tumors. These genetic distinctions support the division of these astrocytomas into two diagnostic categories.

### MORPHOLOGY

A pilocytic astrocytoma often is cystic, with a mural nodule in the wall of the cyst; if solid, it is usually well circumscribed. The tumor is composed of bipolar cells with long, thin "hair-like" processes that are GFAP-positive. Rosenthal fibers, eosinophilic granular bodies, and microcysts are often present; necrosis and mitoses are rare.

### *Oligodendroglioma*

Oligodendrogliomas account for 5% to 15% of gliomas and most commonly are detected in the fourth and fifth decades of life. Patients may have had several years of antecedent neurologic complaints, often including seizures. The lesions are found mostly in the cerebral hemispheres, mainly in the frontal or temporal lobes.

Patients with oligodendrogliomas enjoy a better prognosis than that for patients with astrocytomas of similar grade. Treatment with surgery, chemotherapy, and radiotherapy yields an average survival of 10 to 20 years for well-differentiated (WHO grade II) or 5 to 10 years for anaplastic (WHO grade III) oligodendrogliomas. The most common genetic findings are deletions of chromosomes 1p and 19q, alterations that typically occur together. Tumors with deletions of 1p and 19q are usually highly responsive to chemotherapy and radiotherapy.

### MORPHOLOGY

Well-differentiated oligodendrogliomas (WHO grade II/IV) are infiltrative tumors that form gelatinous, gray masses and may show cysts, focal hemorrhage, and calcification. On microscopic examination, the tumor is composed of sheets of regular cells with spherical nuclei containing finely granular-appearing chromatin (similar to that in normal

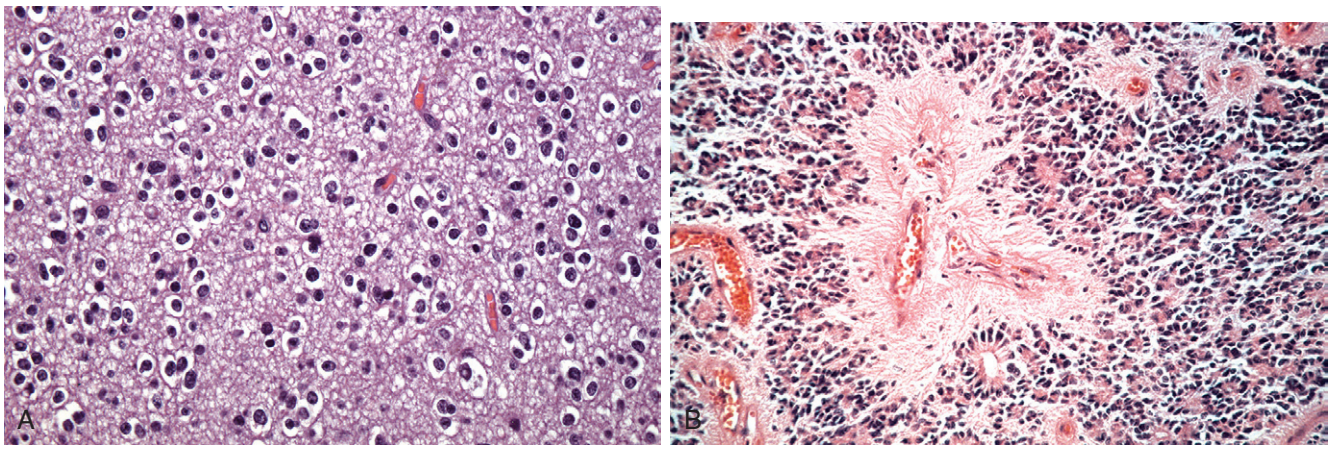

**Figure 22–29** Other gliomas. **A,** In oligodendroglioma tumor cells have round nuclei, often with a cytoplasmic halo. Blood vessels in the background are thin and can form an interlacing pattern. **B,** Microscopic appearance of ependymoma.

oligodendrocytes) surrounded by a clear halo of cytoplasm (Fig. 22–29, *A*). The tumor typically contains a delicate network of anastomosing capillaries. Calcification, present in as many as 90% of these tumors, ranges in extent from microscopic foci to massive depositions. Mitotic activity usually is difficult to detect. Anaplastic oligodendroglioma (WHO grade III/IV) is a more aggressive subtype with higher cell density, nuclear anaplasia and mitotic activity.

### *Ependymoma*

Ependymomas most often arise next to the ependyma-lined ventricular system, including the central canal of the spinal cord. In the first 2 decades of life, they typically occur near the fourth ventricle and constitute 5% to 10% of the primary brain tumors in this age group. In adults, the spinal cord is their most common location; tumors in this site are particularly frequent in the setting of neurofibromatosis type 2 (Chapter 21). The clinical outcome for completely resected supratentorial and spinal ependymomas is better than for those in the posterior fossa.

#### MORPHOLOGY

In the fourth ventricle, ependymomas typically are solid or papillary masses extending from the ventricular floor. The tumors are composed of cells with regular, round to oval nuclei and abundant granular chromatin. Between the nuclei is a variably dense fibrillary background. Tumor cells may form round or elongated structures **(rosettes, canals)** that resemble the embryologic ependymal canal, with long, delicate processes extending into a lumen (Fig. 23–29, *B*); more frequently present are **perivascular pseudorosettes** in which tumor cells are arranged around vessels with an intervening zone containing thin ependymal processes. Anaplastic ependymomas show increased cell density, high mitotic rates, necrosis, and less evident ependymal differentiation.

## Neuronal Tumors

*Central neurocytoma* is a low-grade neoplasm found within and adjacent to the ventricular system (most commonly the lateral or third ventricles), characterized by evenly spaced, round, uniform nuclei and often islands of neuropil.

*Gangliogliomas* are tumors with a mixture of glial elements, usually a low-grade astrocytoma, and mature-appearing neurons. Most of these tumors are slow-growing, but the glial component occasionally becomes frankly anaplastic, and the disease then progresses rapidly. These lesions often manifest with seizures.

*Dysembryoplastic neuroepithelial tumor* is a distinctive, low-grade childhood tumor that grows slowly and carries a relatively good prognosis after resection; it often manifests as a seizure disorder. It typically is located in the superficial temporal lobe and consists of small round neuronal cells arranged in columns and around central cores of processes. These typically form multiple discrete intracortical nodules that have a myxoid background. Also present are well-differentiated "floating" neurons within pools of mucopolysaccharide-rich myxoid fluid.

## Embryonal (Primitive) Neoplasms

Some tumors of neuroectodermal origin have a primitive "small round cell" appearance that is reminiscent of normal progenitor cells encountered in the developing CNS. Differentiation is often limited, but may progress along multiple lineages. The most common is the *medulloblastoma,* accounting for 20% of pediatric brain tumors.

### *Medulloblastoma*

Medulloblastoma occurs predominantly in children and exclusively in the cerebellum. Neuronal and glial markers are nearly always expressed, at least to a limited extent. It is highly malignant, and the prognosis for untreated patients is dismal; however, medulloblastoma is exquisitely radiosensitive. With total excision, chemotherapy, and irradiation, the 5-year survival rate may be as high as 75%. Tumors of similar histologic type and a poor degree of differentiation can be found elsewhere in the nervous system, where they are called *primitive neuroectodermal tumors* (PNETs).

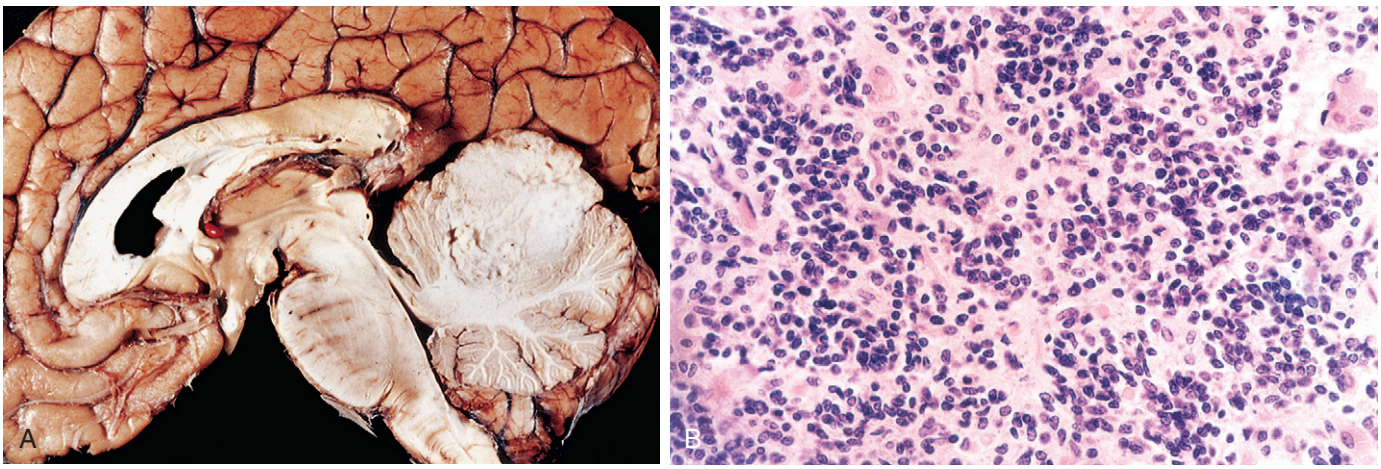

**Figure 22–30** Medulloblastoma. **A,** Sagittal section of brain showing medulloblastoma with destruction of the superior midline cerebellum. **B,** Microscopic appearance of medulloblastoma.

### MORPHOLOGY

In children, medulloblastomas are located in the midline of the cerebellum; lateral tumors occur more often in adults. The tumor often is well circumscribed, gray, and friable and may be seen extending to the surface of the cerebellar folia and involving the leptomeninges (Fig. 22–30, *A*). Medulloblastomas are extremely cellular, with sheets of anaplastic ("small blue") cells (Fig. 22–30, *B*). Individual tumor cells are small, with little cytoplasm and hyperchromatic nuclei; mitoses are abundant. Often, focal neuronal differentiation is seen in the form of the Homer Wright or neuroblastic rosette, which closely resembles the rosettes encountered in neuroblastomas; they are characterized by primitive tumor cells surrounding central neuropil (delicate pink material formed by neuronal processes).

Genetic analysis of medulloblastoma has revealed that morphologically similar tumors commonly exhibit distinct alterations, and that there is a relationship between the underlying mutations and outcome. In general, tumors with *MYC* amplifications are associated with poor outcomes, while those linked with mutations in genes of the WNT signaling pathway have a more favorable course. Many tumors also have mutations that activate the sonic hedgehog (shh) pathway, which has a critical role in tumorigenesis but an uncertain relationship to outcome. These genetic distinctions are beginning to be used to stratify patients into different risk groups and guide therapy. Ideally, it would be best to avoid CNS radiotherapy in young patients, and it is hoped that new therapies targeting mutated gene products will achieve this goal.

## Other Parenchymal Tumors

### *Primary Central Nervous System Lymphoma*

Primary CNS lymphoma, occurring mostly as diffuse large B cell lymphomas, accounts for 2% of extranodal lymphomas and 1% of intracranial tumors. It is the most common CNS neoplasm in immunosuppressed persons, in whom the tumors are nearly always positive for the oncogenic Epstein-Barr virus. In nonimmunosuppressed populations, the age spectrum is relatively wide, with the incidence increasing after 60 years of age. Regardless of the clinical context, primary brain lymphoma is an aggressive disease with relatively poor response to chemotherapy as compared with peripheral lymphomas.

Patients with primary brain lymphoma often are found to have multiple tumor nodules within the brain parenchyma, yet involvement outside of the CNS is an uncommon late complication. Lymphoma originating outside the CNS rarely spreads to the brain parenchyma; when it happens, tumor usually is also within the CSF or involvement of the meninges.

### MORPHOLOGY

Lesions often involve deep gray structures, as well as the white matter and the cortex. Periventricular spread is common. The tumors are relatively well defined as compared with glial neoplasms but are not as discrete as metastases. EBV-associated tumors often show extensive areas of necrosis. The tumors are nearly always aggressive large B-cell lymphomas, although other histologic types can be observed rarely (Chapter 11). Microscopically, malignant cells accumulate around blood vessels and infiltrate the surrounding brain parenchyma.

### *Germ Cell Tumors*

Primary brain *germ cell tumors* occur along the midline, most commonly in the pineal and the suprasellar regions. They account for 0.2% to 1% of brain tumors in people of European descent but as many as 10% of brain tumors in persons of Japanese ethnicity. They are a tumor of the young, with 90% occurring during the first 2 decades of life. Germ cell tumors in the pineal region show a strong male predominance. The most common primary CNS germ cell tumor is germinoma, a tumor that closely resembles testicular seminoma (Chapter 17). Secondary CNS involvement by metastatic gonadal germ cell tumors also occurs.

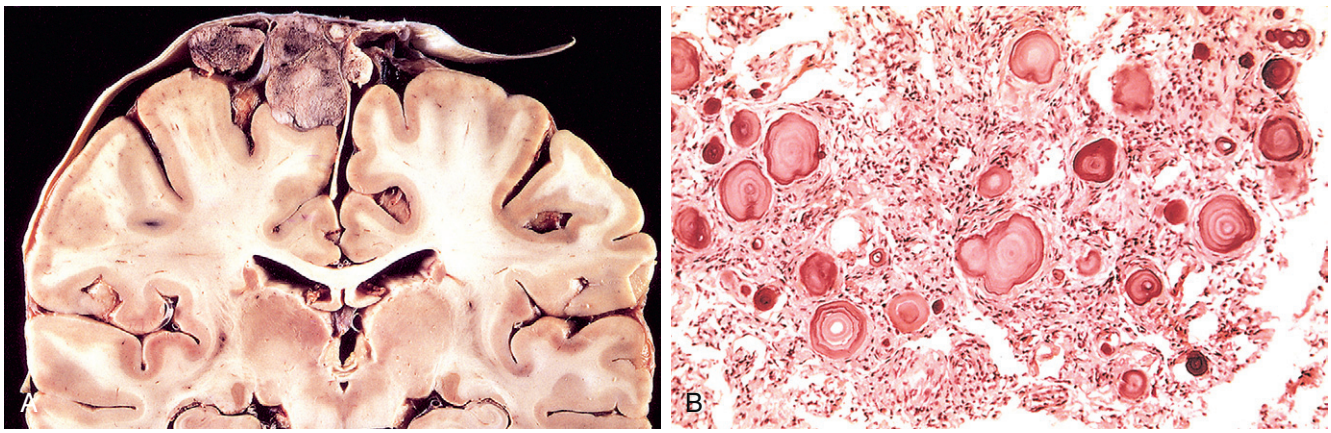

**Figure 22–31** Meningioma. **A,** Parasagittal multilobular meningioma attached to the dura with compression of underlying brain. **B,** Meningioma with a whorled pattern of cell growth and psammoma bodies.

## Meningiomas

*Meningiomas* are predominantly benign tumors that arise from arachnoid meningothelial cells. They usually occur in adults and are often attached to the dura. Meningiomas may be found along any of the external surfaces of the brain as well as within the ventricular system, where they arise from the stromal arachnoid cells of the choroid plexus. They usually come to attention because of vague nonlocalizing symptoms, or with focal findings referable to compression of adjacent brain. Although most meningiomas are easily separable from underlying brain, some tumors infiltrate the brain, a feature that is associated with an increased risk of recurrence. The overall prognosis is determined by the lesion size and location, surgical accessibility, and histologic grade.

When a person has multiple meningiomas, especially in association with eighth-nerve schwannomas or glial tumors, the diagnosis of neurofibromatosis type 2 (NF2) should be considered (Chapter 21). About half of meningiomas not associated with NF2 have acquired loss-of-function mutations in the *NF2* tumor suppressor gene on the long arm of chromosome 22 (22q). These mutations are found in all grades of meningioma, suggesting that they are involved with tumor initiation. Mutations in *NF2* are more common in tumors with certain growth patterns (fibroblastic, transitional, and psammomatous).

### MORPHOLOGY

**Meningiomas** (WHO grade I/IV) grow as well-defined dura-based masses that may compress the brain but do not invade it (Fig. 22–31, *A*). Extension into the overlying bone may be present. Among the varied histologic patterns are **syncytial,** named for whorled clusters of cells without visible cell membranes that sit in tight groups; **fibroblastic,** with elongated cells and abundant collagen deposition between them; **transitional,** which shares features of the syncytial and fibroblastic types; **psammomatous,** with numerous psammoma bodies (Fig. 22–31, *B*); and **secretory,** with gland-like PAS-positive eosinophilic secretions known as pseudopsammoma bodies.

**Atypical meningiomas** (WHO grade II/IV) are recognized by the presence of certain histologic features (prominent nucleoli, increased cellularity, pattern-less growth), and often have a higher mitotic rate. These tumors demonstrate more aggressive local growth and a higher rate of recurrence; they may require therapy in addition to surgery.

**Anaplastic (malignant) meningiomas** (WHO grade III/IV) are highly aggressive tumors that may resemble a high-grade sarcoma or carcinoma, although there usually is some histologic evidence of a meningothelial cell origin.

## Metastatic Tumors

Metastatic lesions, mostly carcinomas, account for approximately one fourth to one half of intracranial tumors. The most common primary sites are lung, breast, skin (melanoma), kidney, and gastrointestinal tract—together these account for about 80% of cases. Metastases form sharply demarcated masses, often at the gray-white junction, and elicit edema (Fig. 22–32). The boundary between tumor and brain parenchyma is sharp at the microscopic level as well, with surrounding reactive gliosis.

In addition to the direct and localized effects produced by metastases, *paraneoplastic syndromes* may involve the peripheral and central nervous systems, sometimes even preceding the clinical recognition of the malignant neoplasm. Many but not all patients with paraneoplastic syndromes have antibodies against tumor antigens. Some of the more common patterns include

- *Subacute cerebellar degeneration* resulting in ataxia, with destruction of Purkinje cells, gliosis, and a mild inflammatory infiltrate
- *Limbic encephalitis* causing a subacute dementia, with perivascular inflammatory cells, microglial nodules, some neuronal loss, and gliosis, all centered in the medial temporal lobe

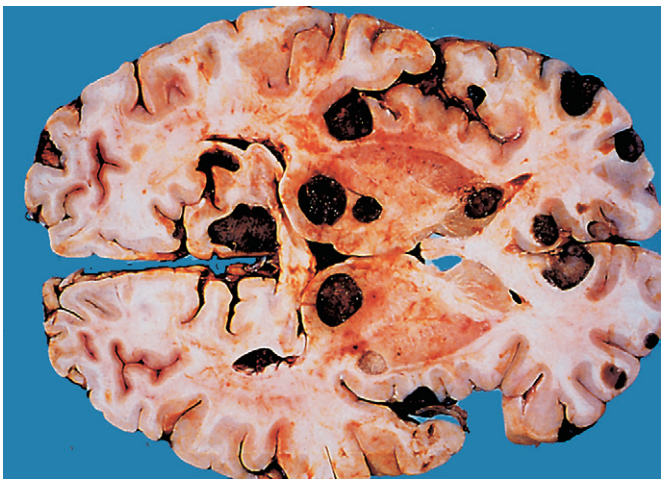

**Figure 22–32** Metastatic melanoma. Metastatic lesions are distinguished grossly from most primary central nervous system tumors by their multicentricity and well-demarcated margins. The dark color of the tumor nodules in this specimen is due to the presence of melanin.

- *Subacute sensory neuropathy* leading to altered pain sensation, with loss of sensory neurons from dorsal root ganglia, in association with inflammation
- *Syndrome of rapid-onset psychosis, catatonia, epilepsy, and coma* associated with ovarian teratoma and antibodies against the *N*-methyl-D-aspartate (NMDA) receptor

## Familial Tumor Syndromes

Several inherited syndromes caused by mutations in various tumor suppressor genes are associated with an increased risk of particular types of cancers. Those with particular involvement of the CNS are discussed here; familial syndromes associated with tumors of the peripheral nervous system are covered in Chapter 21.

### *Tuberous Sclerosis*

Tuberous sclerosis (TSC) is an autosomal dominant syndrome characterized by the development of hamartomas and benign neoplasms involving the brain and other tissues. CNS hamartomas variously consist of cortical tubers and subependymal hamartomas, including a larger tumefactive form known as subependymal giant cell astrocytoma. Because of their proximity to the foramen of Monro, they often present acutely with obstructive hydrocephalus, which requires surgical intervention and/or therapy with an mTOR inhibitor (see below). Seizures are associated with cortical tubers and can be difficult to control with antiepileptic drugs. Extracerebral lesions include renal angiomyolipomas, retinal glial hamartomas, pulmonary lymphangiomyomatosis, and cardiac rhabdomyomas. Cysts may be found at various sites, including the liver, kidneys, and pancreas. Cutaneous lesions include angiofibromas, leathery thickenings in localized patches (shagreen patches), hypopigmented areas (ash leaf patches), and subungual fibromas. TSC results from disruption of either *TSC1,* which encodes hamartin, or *TSC2,* which encodes tuberin. The two TSC proteins form a dimeric complex that negatively regulates mTOR, a kinase that "senses" the cell's nutrient status and regulates cellular metabolism. Loss of either protein leads to increased mTOR activity, which disrupts nutritional signaling and increases cell growth.

#### MORPHOLOGY

Cortical hamartomas are firmer than normal cortex and have been likened in appearance to potatoes—hence the appellation "tubers." They are composed of haphazardly arranged large neurons that lack the normal cortical laminar architecture. These cells may exhibit a mixture of glial and neuronal features, having large vesicular nuclei with nucleoli (like neurons) and abundant eosinophilic cytoplasm (like gemistocytic astrocytes). Similar abnormal cells are present in the subependymal nodules, in which large astrocyte-like cells cluster beneath the ventricular surface.

### *von Hippel–Lindau Disease*

In this autosomal dominant disorder, affected persons develop hemangioblastomas within the cerebellar hemispheres, retina, and, less commonly, the brain stem, spinal cord, and nerve roots. Patients also may have cysts involving the pancreas, liver, and kidneys and have an increased propensity to develop renal cell carcinoma. The disease frequency is 1 in 30,000 to 40,000. Therapy is directed at the symptomatic neoplasms, including surgical resection of cerebellar tumors and laser ablation of retinal tumors. The affected gene, the tumor suppressor *VHL,* encodes a protein that is part of a ubiquitin-ligase complex that targets the transcription factor hypoxia-inducible factor (HIF) for degradation. Tumors arising in patients with von Hippel–Lindau disease generally have lost all VHL protein function. As a result, these tumors express high levels of HIF, which drives the expression of VEGF, various growth factors, and sometimes erythropoietin, leading to a form of paraneoplastic polycythemia.

#### MORPHOLOGY

The cerebellar **capillary hemangioblastoma,** the principal neurologic manifestation of the disease, is a highly vascular neoplasm that occurs as a mural nodule associated with a large, fluid-filled cyst. On microscopic examination, the lesion consists of numerous capillary-sized or somewhat larger thin-walled vessels separated by intervening stromal cells with vacuolated, lightly PAS-positive, lipid-rich cytoplasm.

#### SUMMARY

##### Tumors of the Central Nervous System

- Tumors of the CNS may arise from the cells of the coverings (meningiomas), the brain (gliomas, neuronal tumors, choroid plexus tumors), or other CNS cell populations (primary CNS lymphoma, germ cell tumors), or they may originate elsewhere in the body (metastases).

- Even low-grade or benign tumors can have poor clinical outcomes, depending on where they occur in the brain.
- Distinct types of tumors affect specific brain regions (e.g., cerebellum for medulloblastoma, an intraventricular location for central neurocytoma) and specific age populations (medulloblastoma and pilocytic astrocytomas in pediatric age groups, and glioblastoma and lymphoma in older patients).
- Glial tumors are broadly classified into astrocytomas, oligodendrogliomas, and ependymomas. Increasing tumor malignancy is associated with more cytologic anaplasia, increased cell density, necrosis, and mitotic activity.
- Metastatic spread of brain tumors to other regions of the body is rare, but the brain is not comparably protected against spread of distant tumors. Carcinomas are the dominant type of systemic tumors that metastasize to the nervous system.

## BIBLIOGRAPHY

*In general, many areas of neuropathology and neurologic diseases are well covered in the following standard texts:*

Melanocytic Proliferations 865

Skin diseases are common and diverse, ranging from irritating acne to life-threatening melanoma. Many are intrinsic to the skin, but some are manifestations of diseases involving many tissues, such as systemic lupus erythematosus or genetic syndromes such as neurofibromatosis. In this sense, the skin is a uniquely accessible "window" through which numerous disorders can be viewed and recognized.

Skin is not a mere protective mantle but rather a complex organ that actively participates in regulated cellular and molecular events that govern the body's interactions with the external environment. It is constantly bathed with microbial and nonmicrobial antigens. These are processed by intraepithelial Langerhans cells, which bear their antigenic cargo to regional lymph nodes and initiate immune responses. Squamous cells (keratinocytes) help maintain skin homeostasis by providing a physical barrier to environmental insults and by secreting a plethora of cytokines that influence both the squamous and dermal microenvironments. The dermis contains both CD4+ helper and CD8+ cytotoxic T lymphocytes, some of which home to the skin by virtue of specialized receptors such as cutaneous lymphocyte antigen. The epidermis contains intraepithelial lymphocytes, including γ/δ T cells, which constitute a component of the innate immune system. Local immune responses involving these immune cells and cytokines account for the microscopic patterns and clinical expressions of cutaneous inflammatory and infectious diseases.

This chapter focuses on a small subset of common and pathogenically illustrative skin diseases. In considering these diseases, it is important to appreciate that the practice of dermatopathology relies on close interactions with clinicians, particularly dermatologists. The clinical history and the gross appearance and distribution of lesions reported by clinicians are often as important as the microscopic findings in arriving at a diagnosis.

Diseases of the skin can be confusing for the student, in part because dermatologists and dermatopathologists use a large and unique lexicon to describe skin lesions. Because knowledge of this vocabulary forms the basis of clear understanding and communication, some of the terms and descriptors that are most commonly used are defined below.

### Terms for Macroscopic Lesions

**Excoriation:** Traumatic lesion breaking the epidermis and causing a red linear mark (i.e., a deep scratch); often self-inflicted.

**Lichenification:** Thickened and rough skin characterized by prominent skin markings; usually the result of repeated rubbing (see under "Lichen Simplex Chronicus").

**Macule:** Flat, circumscribed area, 5 mm or less in diameter, distinguished from surrounding skin by coloration. If greater than 5 mm, referred to as a **patch.**

**Papule:** Elevated dome- or flat-topped lesion 5 mm or less in diameter. If greater than 5 mm in diameter, referred to as a **nodule.**

**Plaque:** Elevated flat-topped lesion, usually greater than 5 mm in diameter.

**Pustule:** Discrete, pus-filled raised lesion.

**Scale:** Dry, horny, platelike excrescence; usually the result of imperfect cornification.

**Vesicle:** Fluid-filled raised area 5 mm or less in diameter. If greater than 5 mm in diameter, referred to as a

*The authors thank Drs. Ronald Rapini and Robert Jordan and the Department of Dermatology at the University of Texas Medical School at Houston for many of the clinical photographs in this chapter. The contributions of Dr. George Murphy to this chapter in previous editions are gratefully acknowledged.*

**bulla. Blister** is common term for both vesicles and bullae.

Microscopic Terms

**Acantholysis:** Loss of intercellular adhesion of keratinocytes.

**Acanthosis:** Diffuse epidermal hyperplasia.

**Dyskeratosis:** Abnormal keratinization occurring prematurely within individual cells or groups of cells below the stratum granulosum.

**Hyperkeratosis:** Hyperplasia of the stratum corneum, often associated with a qualitative abnormality of keratin.

**Lentiginous:** Linear melanocyte proliferation along the epidermal basal cell layer; can occur as a reactive change or as part of a melanocytic neoplasm.

**Papillomatosis:** Surface elevation caused by hyperplasia and enlargement of dermal papillae.

**Parakeratosis:** Keratinization characterized by retention of the nuclei in the stratum corneum. On squamous mucosal membranes, such as buccal mucosa, parakeratosis is normal.

**Spongiosis:** Intercellular edema of the epidermis.

# ACUTE INFLAMMATORY DERMATOSES

Thousands of inflammatory dermatoses exist, challenging the diagnostic acumen of even experienced clinicians. In general, acute lesions last from days to weeks and are characterized by inflammation (often marked by mononuclear cells rather than neutrophils and defined as acute due to the limited course of their natural history), edema, and sometimes epidermal, vascular, or subcutaneous injury. Some acute lesions may persist, resulting in transition to a chronic phase, while others are characteristically self-limited.

## Urticaria

Urticaria ("hives") is a common disorder mediated by *localized mast cell degranulation, which leads to dermal microvascular hyperpermeability.* The resulting erythematous, edematous, and pruritic plaques are termed *wheals.*

### PATHOGENESIS

In most cases, urticaria stems from an immediate (type I) hypersensitivity reaction (Chapter 4), in which antigens trigger mast cell degranulation by binding to immunoglobulin E (IgE) antibodies displayed on the mast cell surface. The responsible antigens include pollens, foods, drugs, and insect venom. IgE-independent urticaria may result from exposure to substances that directly incite mast cell degranulation, such as opiates and certain antibiotics. In the vast majority of cases, no clinical cause is discovered despite extensive searching. Hereditary angioedema is caused by an inherited deficiency of C1 esterase inhibitor, which results in uncontrolled activation of complement (Chapter 3). The ensuing urticaria affects the lips, throat, eyelids, genitals, and distal extremities. When the larynx is affected, the condition can be dangerous, since airway patency may be compromised.

### MORPHOLOGY

The histologic features of urticaria often are subtle. There is usually a sparse superficial perivenular infiltrate of mononuclear cells, rare neutrophils, and sometimes eosinophils. Superficial dermal edema creates more widely spaced collagen bundles. Degranulation of mast cells, which normally reside around superficial dermal venules, is difficult to appreciate with routine hematoxylin-eosin (H&E) stains but can be highlighted using a Giemsa stain.

Clinical Features

Urticaria typically affects persons between 20 and 40 years of age, but no age is immune. Individual lesions usually develop and fade within hours, but episodes can persist for days or even months. Persistent lesions sometimes are due to urticarial vasculitis, which is often associated with deposition of complement in dermal venules. Lesions range in size and nature from small, pruritic papules to large, edematous, erythematous plaques. Increased vascular permeability leads to localized dermal edema. Lesions can be confined to a particular part of the body or generalized. In a specific type of urticaria, termed *pressure urticaria,* lesions are found only in areas exposed to pressure (such as the feet or the buttocks). Although not life-threatening, urticaria can compromise quality of life by causing severe pruritus and social embarrassment. Most cases are treated with antihistamines. Systemic steroids are used in more severe refractory cases.

## Acute Eczematous Dermatitis

*Eczema* is a clinical term that embraces a number of conditions with varied underlying etiologies. New lesions take the form of *red papules, often with overlying vesicles, which ooze and become crusted.* With persistence, these lesions develop into raised, *scaling plaques.* The nature and degree of these changes vary among the clinical subtypes, which include the following:

- *Allergic contact dermatitis,* which stems from topical exposure to an allergen
- *Atopic dermatitis,* which has traditionally been attributed to allergen exposure, but is now thought to stem from defects in keratinocyte barrier function, many with a genetic basis
- *Drug-related eczematous dermatitis,* a hypersensitivity reaction to a drug
- *Photoeczematous dermatitis,* in which eczema appears as an abnormal reaction to UV or visible light
- *Primary irritant dermatitis,* which results from exposure to substances that chemically, physically, or mechanically damage the skin

In most cases, the skin lesions resolve completely when the offending stimulus is removed or exposure is limited,

stressing the importance of investigating the underlying cause. Only the most common form, *contact dermatitis,* is considered here.

Contact dermatitis is triggered by exposure to an environmental contact sensitizing agent, such as poison ivy, that chemically reacts with self-proteins. The self-proteins modified by the agent are processed by epidermal Langerhans cells, which migrate to draining lymph nodes and present the antigen to naive T cells. This sensitization event leads to acquisition of immunologic memory; on reexposure to the antigen, the activated memory CD4+ T lymphocytes migrate to the affected skin sites. There they release cytokines that recruit additional inflammatory cells and also mediate epidermal damage, as in any delayed-type hypersensitivity reaction (Chapter 4).

### MORPHOLOGY

In the case of contact dermatitis, the pattern of skin involvement is limited to sites of contact with the triggering agent (Fig. 23–1, *A*), whereas in other forms of eczema, lesions may be widely distributed. **Spongiosis,** or epidermal edema, characterizes all forms of acute eczematous dermatitis—hence the synonym **spongiotic dermatitis.** Edema fluid seeps into the epidermis, where it splays apart keratinocytes (Fig. 23–1, *B*). Intercellular bridges are stretched and become more prominent and are easier to visualize. This change is accompanied by a superficial perivascular lymphocytic infiltrate, edema of dermal papillae, and mast cell degranulation. Eosinophils may be present and are especially prominent in spongiotic eruptions provoked by drugs, but in general the histologic features are similar regardless of cause, emphasizing the need for careful clinical correlation.

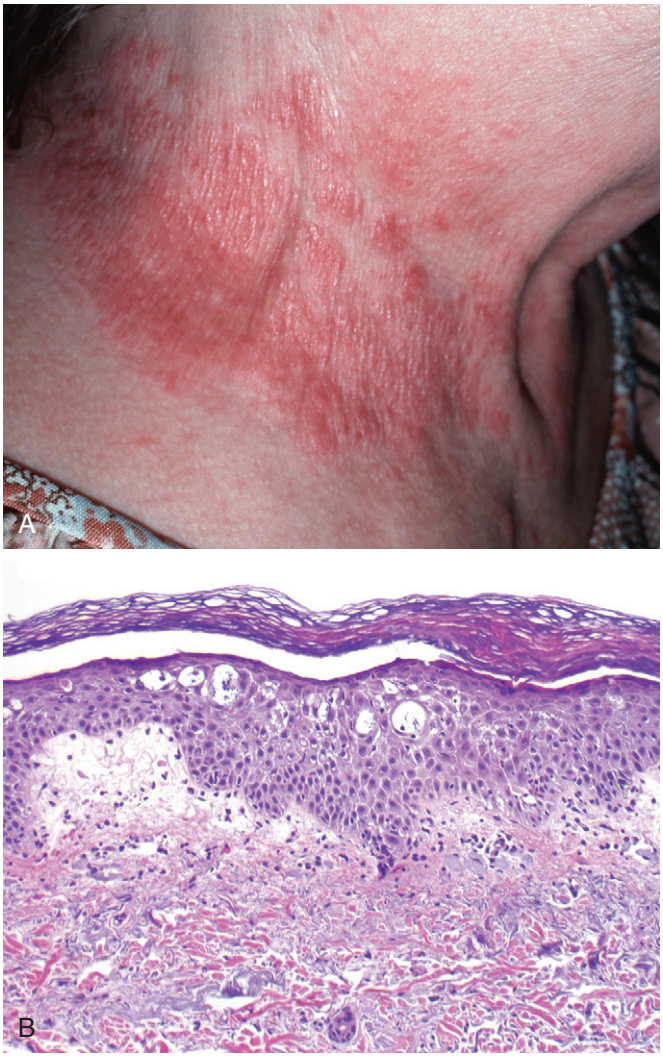

**Figure 23–1** Eczematous dermatitis. **A,** The patterned erythema and scale stems from a nickel-induced contact dermatitis produced by this woman's necklace. **B,** Microscopically, there is fluid accumulation (spongiosis) between epidermal cells that can progress to small vesicles if intercellular connections are stretched until broken.

#### Clinical Features

Lesions of acute eczematous dermatitis are pruritic (itchy), edematous, oozing plaques, often containing vesicles and bullae. With persistent antigen exposure, lesions may become progressively scaly (hyperkeratotic) as the epidermis thickens (acanthosis). Some changes are produced or exacerbated by scratching or rubbing of the lesion (see later under "Lichen Simplex Chronicus"). The clinical causes of eczema are sometimes divided into "inside jobs"—reaction to an internal circulating antigen (such as ingested food or drug)—and "outside jobs"—disease resulting from contact with an external antigen (such as poison ivy).

Susceptibility to atopic dermatitis is often inherited; the disorder is concordant in 80% of identical twins and 20% of fraternal twins. It usually appears in early childhood and in the majority of cases clears in adults. Children with atopic dermatitis often have asthma and allergic rhinitis, termed the atopic triad.

## Erythema Multiforme

Erythema multiforme is an uncommon, usually self-limited disorder that appears to be a *hypersensitivity response to certain infections and drugs.* Antecedent infections include herpes simplex and those caused by mycoplasmas and some fungi. The implicated drugs include sulfonamides, penicillin, salicylates, hydantoins, and antimalarials. Patients present with *a wide diversity of lesions (hence called "multiforme") including macules, papules, vesicles, and bullae, as well as characteristic targetoid lesions consisting of red macules or papules with pale vesicular or eroded centers* (Fig. 23–2). The epithelial damage is believed to result from the action of skin-homing cytotoxic T cells that attack the basal cells of the skin and the mucosae, which may display antigens that cross-react with the inciting drug or microbe.

### MORPHOLOGY

Well-developed lesions have a characteristic "targetoid" appearance (Fig. 23–2, *A*). Early lesions show a superficial perivascular, lymphocytic infiltrate associated with dermal edema and margination of lymphocytes along the dermoepidermal junction in intimate association with degenerating

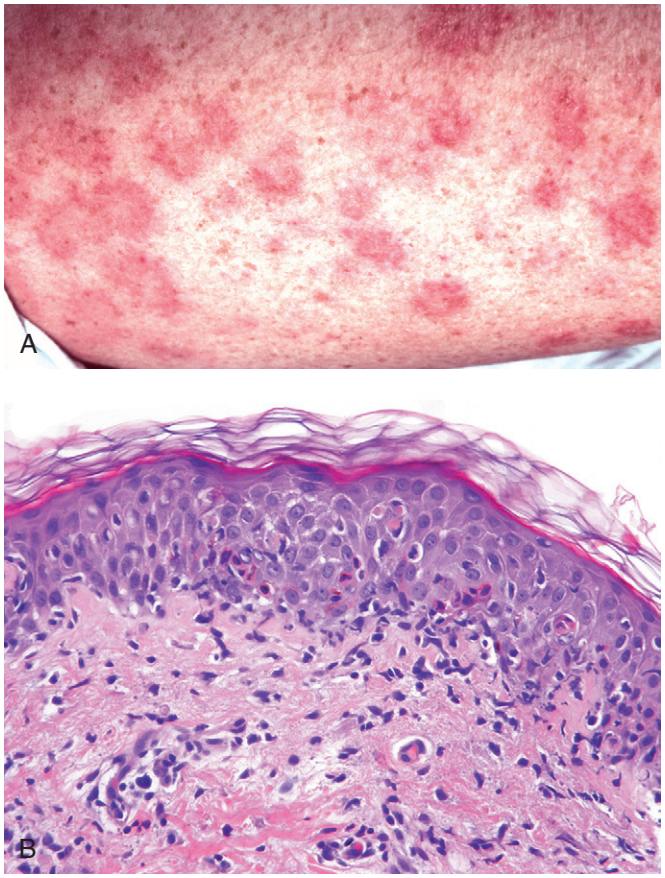

**Figure 23–2** Erythema multiforme. **A,** The target-like lesions consist of a pale central blister or zone of epidermal necrosis surrounded by macular erythema. **B,** Early lesions show a collection of lymphocytes along the dermoepidermal junction (interface dermatitis) associated with scattered keratinocytes with dark shrunken nuclei and eosinophilic cytoplasm that are undergoing apoptosis.

keratinocytes (Fig. 23–2, *B*). With time, discrete, confluent zones of basal epidermal necrosis appear, with concomitant blister formation. In the rarer and more severe form of this disease, **toxic epidermal necrolysis,** the necrosis extends through the full thickness of the epidermis.

### Clinical Features

Erythema multiforme exhibits a broad range of severity. The forms associated with infection (most often herpesvirus) are less severe. Erythema multiforme caused by medications can progress to more serious life-threatening eruptions, such as Stevens-Johnson syndrome or toxic epidermal necrolysis. These forms can be life-threatening because they can cause sloughing of large portions of the epidermis, resulting in fluid loss and infections akin to those seen in burn-injured patients. These severe forms most often occur as idiopathic reactions to drugs.

## CHRONIC INFLAMMATORY DERMATOSES

Chronic inflammatory dermatoses are persistent skin conditions that exhibit their most characteristic features over many months to years, although they may begin with an acute stage. The skin surface in some chronic inflammatory dermatoses is roughened as a result of excessive or abnormal scale formation and shedding (desquamation).

### Psoriasis

Psoriasis is a common chronic inflammatory dermatosis, affecting 1% to 2% of people residing in the United States. Recent epidemiologic studies have shown that psoriasis is associated with an increased risk of heart attack and strokes, a relationship that may be related to a chronic inflammatory state. Psoriasis is also associated in up to 10% of patients with arthritis, which in some cases may be severe.

#### PATHOGENESIS

Psoriasis is a multifactorial immunologic disease; both genetic (e.g., human leukocyte antigen [HLA] types) and environmental factors contribute to risk. It is not known if the inciting antigens are self or environmental. Sensitized populations of T cells home to the dermis, including CD4+ $T_H17$ and $T_H1$ cells and CD8+ T cells, and accumulate in the epidermis. These cells secrete cytokines and growth factors that induce keratinocyte hyperproliferation, resulting in the characteristic lesions. Psoriatic lesions can be induced in susceptible persons by local trauma **(Koebner phenomenon),** which may induce a local inflammatory response that promotes lesion development. GWAS studies have linked an increased risk of psoriasis to polymorphisms in HLA loci and genes affecting antigen presentation, TNF signaling, and skin barrier function.

#### MORPHOLOGY

The typical lesion is a **well-demarcated, pink to salmon–colored plaque covered by loosely adherent silver-white scale** (Fig. 23–3, *A*). There is marked epidermal thickening **(acanthosis),** with regular downward elongation of the rete ridges (Fig. 23–3, *B*). The pattern of this downward growth has been likened to "test tubes in a rack." Increased epidermal cell turnover and lack of maturation results in **loss of the stratum granulosum and extensive parakeratotic scale.** Also seen is thinning of the epidermal cell layer overlying the tips of dermal papillae (suprapapillary plates), and dilated and tortuous blood vessels within the papillae. These vessels bleed readily when the scale is removed, giving rise to multiple punctate bleeding points **(Auspitz sign).** Neutrophils form small aggregates within both the spongiotic superficial epidermis and the parakeratotic stratum corneum. Similar changes can be seen in superficial fungal infections, which need to be excluded with appropriate special stains.

### Clinical Features

Psoriasis most frequently affects the skin of the elbows, knees, scalp, lumbosacral areas, intergluteal cleft, and glans penis. Nail changes on the fingers and toes occur in 30% of cases. In most cases, psoriasis is limited in distribution, but

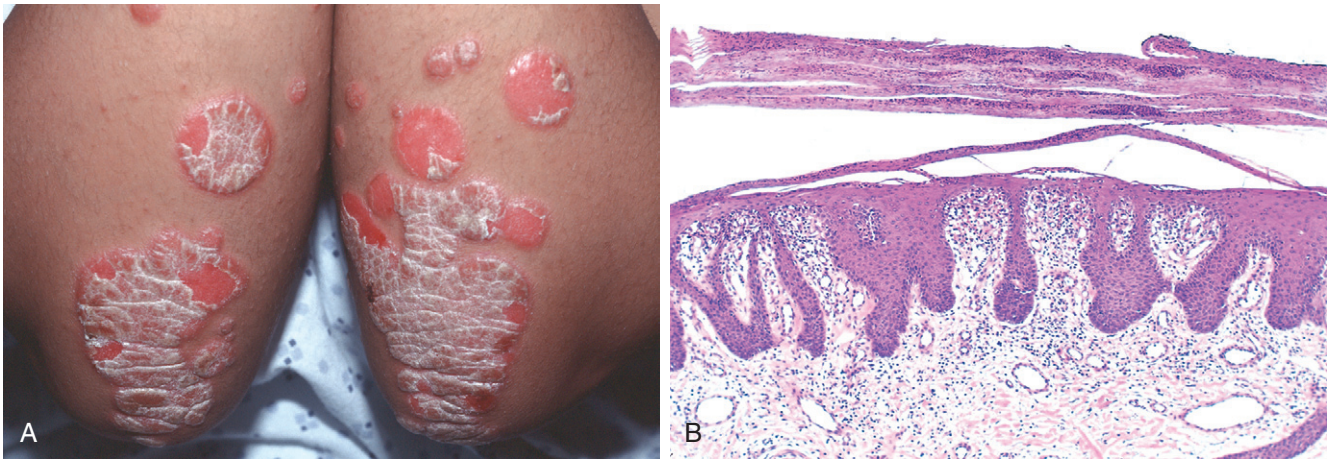

**Figure 23–3** Psoriasis. **A,** Chronic plaques of psoriasis show silvery-white scale on the surface of erythematous plaques. **B,** Microscopic examination reveals marked epidermal hyperplasia, uniform downward extension of rete ridges (psoriasiform hyperplasia), and prominent parakeratotic scale that is focally infiltrated by neutrophils.

it can be widespread and severe. The clinical subtypes are defined by pattern of involvement and severity. Treatment is aimed at preventing the release or actions of inflammatory mediators. Depending upon the disease severity, NSAIDS, immunosuppressive agents such as cyclosporin, and TNF antagonists are used. Newer agents that inhibit $T_H1$ and $T_H17$ immune responses are also being tested.

## Lichen Planus

"Pruritic, purple, polygonal, planar papules, and plaques" are the tongue-twisting *P*s that describe this disorder of skin and squamous mucosa. The lesions may result from a CD8+ T cell–mediated cytotoxic immune response against antigens in the basal cell layer and the dermoepidermal junction that are produced by unknown mechanisms, perhaps as a consequence of a viral infection or drug exposure.

### MORPHOLOGY

Cutaneous lesions of lichen planus consist of **pruritic, violaceous, flat-topped papules,** which may coalesce focally to form plaques (Fig. 23–4, *A*). These papules are often highlighted by white dots or lines called **Wickham striae.** Hyperpigmentation may result from melanin loss into the dermis from damaged keratinocytes. Microscopically, lichen planus is a prototypical **interface dermatitis,** so called because the lesions are concentrated at the interface of the squamous epithelium and papillary dermis. There is a dense, continuous infiltrate of lymphocytes along the dermoepidermal junction (Fig. 23–4, *B*). The lymphocytes are intimately associated with basal keratinocytes, which often atrophy or become necrotic. Perhaps as a response to damage, the basal cells take on the appearance of the more mature cells of the stratum spinosum (squamatization). This pattern of inflammation causes the dermoepidermal interface to assume an angulated, zigzag contour ("sawtoothing"). Anucleate, necrotic basal cells are seen in the inflamed papillary dermis and are referred to as colloid bodies or **Civatte bodies.**

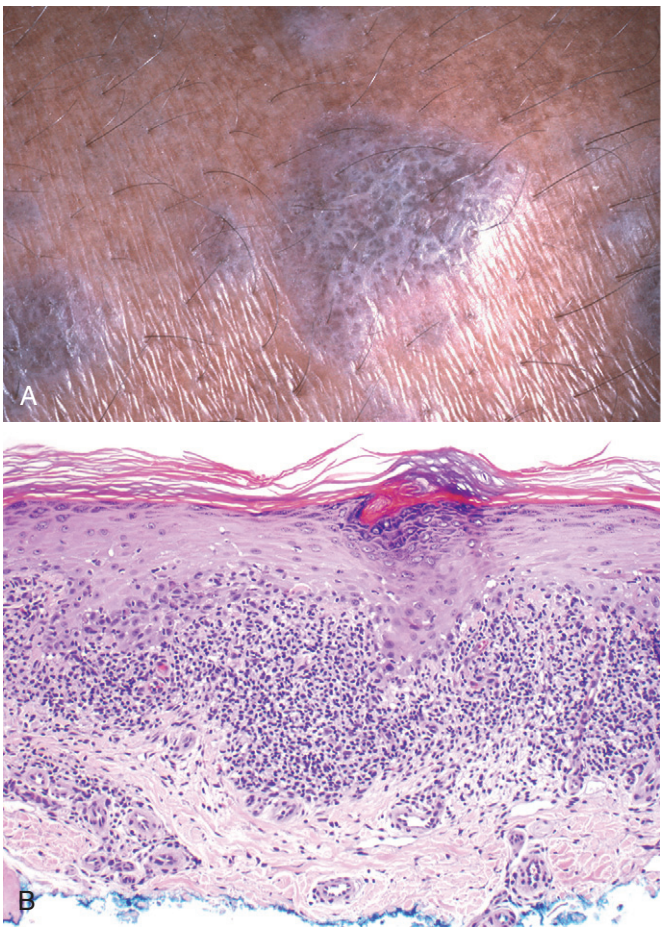

**Figure 23–4** Lichen planus. **A,** This flat-topped pink-purple polygonal papule has white lacelike markings referred to as Wickham striae. **B,** Microscopic features include a bandlike infiltrate of lymphocytes along the dermoepidermal junction, hyperkeratosis, hypergranulosis, and pointed rete ridges ("sawtoothing"), which results from chronic injury of the basal cell layer.

Although these changes bear some similarities to those in erythema multiforme (discussed earlier), lichen planus shows well-developed changes of chronicity, including epidermal hyperplasia, hypergranulosis, and hyperkeratosis.

Clinical Features

Lichen planus is an uncommon disorder that usually presents in middle-aged adults. The cutaneous lesions are multiple and are usually symmetrically distributed, particularly on the extremities, and often occur about the wrists and elbows and on the glans penis. In approximately 70% of cases the oral mucosa is also involved, where the lesions manifest as white papules with a reticulate or netlike appearance. The cutaneous lesions of lichen planus usually resolve spontaneously within 1 to 2 years, but the oral lesions may persist and be of sufficient severity to cause trouble with food intake.

## Lichen Simplex Chronicus

Lichen simplex chronicus manifests as roughening of the skin, which takes on an appearance reminiscent of lichen on a tree. It is a response to local repetitive trauma such as continual rubbing or scratching. Nodular forms exist that are referred to as *prurigo nodularis*. The pathogenesis of lichen simplex chronicus is not understood, but the trauma probably induces epithelial hyperplasia and eventual dermal scarring.

### MORPHOLOGY

Lichen simplex chronicus is characterized by **acanthosis**, **hyperkeratosis,** and **hypergranulosis.** Also seen are elongation of the rete ridges, fibrosis of the papillary dermis, and a dermal chronic inflammatory infiltrate (Fig. 23–5). Of interest, these lesions are similar in appearance to normal volar (palms and soles) skin, in which skin thickening serves as an adaptation to repetitive mechanical stress.

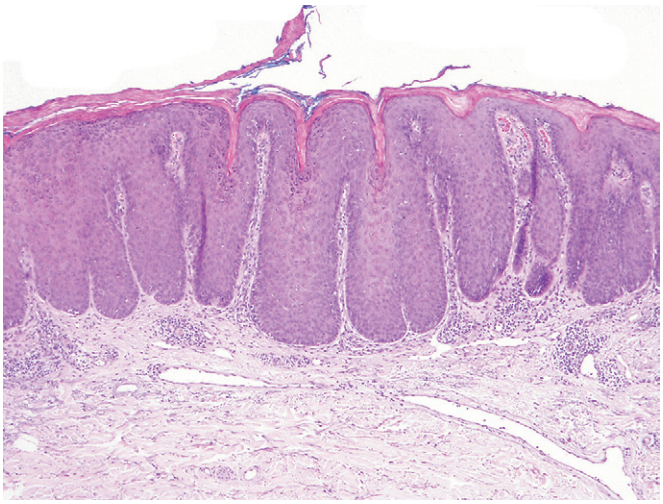

**Figure 23–5** Lichen simplex chronicus. Acanthosis with hyperkeratosis and hypergranulosis are distinctive. Superficial dermal fibrosis and vascular ectasia, both common features, also are present.

Clinical Features

The lesions often are raised, erythematous, and scaly and can be mistaken for keratinocytic neoplasms. Lichen simplex chronicus can be superimposed on and mask another (often pruritic) dermatosis. It is therefore important to rule out an underlying cause while recognizing that the lesion may be entirely trauma-related.

### SUMMARY

#### Inflammatory Dermatoses

- Many specific inflammatory dermatoses exist, which can be mediated by IgE antibodies (urticaria), antigen-specific T cells (eczema, erythema multiforme, and psoriasis), or trauma (lichen simplex chronicus).
- These disorders can be grouped based on patterns of inflammation (e.g., interface dermatitis in lichen planus and erythema multiforme).
- Clinical correlation is essential to diagnose specific skin diseases, since many have overlapping, non-specific histologic features.

# INFECTIOUS DERMATOSES

## Bacterial Infections

Numerous bacterial infections occur in skin. These range from superficial infections known as *impetigo,* to deeper dermal abscesses caused by anaerobes such as *Pseudomonas aeruginosa,* associated with puncture wounds. The pathogenesis is similar to that for microbial infections elsewhere (Chapter 8). Only impetigo is discussed here.

### MORPHOLOGY

Impetigo is characterized by an accumulation of neutrophils beneath the stratum corneum that often produces a subcorneal pustule. Nonspecific reactive epidermal alternation and superficial dermal inflammation accompany these findings. Bacterial cocci in the superficial epidermis can be demonstrated by Gram stain.

Clinical Features

*Impetigo,* one of the most common bacterial infections of the skin, is seen primarily in children. The causative organism is usually *Staphylococcus aureus* or, less commonly, *Streptococcus pyogenes,* and is typically acquired through direct contact with a source. Impetigo often begins as a single small macule, usually on the extremities or the face near the nose or the mouth (Fig. 23–6), which rapidly evolves into a larger lesion with a honey-colored crust of dried serum. Persons colonized by *S. aureus* or *S. pyogenes* (usually nasal or anal) are more likely to be affected. Microbiologic culture with assessment of sensitivity to various antibiotics can be useful clinically. A less common bullous form of childhood impetigo may mimic an autoimmune blistering disorder.

**Figure 23–6** Impetigo. This child's arm is involved by a superficial bacterial infection producing the characteristic erythematous scablike lesions crusted with dried serum.
*(Courtesy of Dr. Angela Wyatt, Bellaire, Texas.)*

## Fungal Infections

Fungal infections are varied and range from superficial infections with *Tinea* or *Candida* spp. to life-threatening infections of immunosuppressed persons with *Aspergillus* spp. Fungal infections can be superficial (stratum corneum, hair, and nails), deep (dermis or subcutis), or systemic, the last type arising through hematogenous spread, often in an immunocompromised patient.

### MORPHOLOGY

The histologic appearance varies depending on the organism, host response, and degree of superinfection. Superficial infections are often associated with a neutrophilic infiltrate in the epidermis. Some show a mild eczematous dermatitis with associated intraepidermal neutrophils, while other infections (e.g., *Candida*) can induce psoriasiform hyperplasia. Deep fungal infections produce greater tissue damage and often elicit a granulomatous response, probably induced by the more vigorous host immune response. *Aspergillus* can be angioinvasive. Periodic acid–Schiff (PAS) and Gomori methenamine silver stains can be helpful in identifying the fungal organisms.

#### Clinical Features

Superficial infections usually produce erythematous macules with superficial scale that can be pruritic, while deeper infections such as those seen with *Aspergillus* spp. in immunocompromised persons are erythematous and often nodular and sometimes show evidence of local hemorrhage. Superficial *Candida* infections often induce lesions that mimic psoriasis, so it is essential to exclude fungal infections when a new diagnosis of psoriasis is being considered.

## Verrucae (Warts)

Verrucae are common lesions of children and adolescents, although they may be encountered in any age group. They are caused by human papillomavirus (HPV). Transmission usually involves direct contact with an infected individual or autoinoculation. Verrucae generally are self-limited, most often regressing spontaneously within 6 months to 2 years.

### PATHOGENESIS

As mentioned earlier, verrucae are caused by HPV. Some members of the HPV family are associated with preneoplastic and invasive cancers of the anogenital region (Chapters 5 and 17). In contrast with HPV-associated carcinomas, most warts are caused by low-risk HPV subtypes that lack transforming potential. Like high-risk viruses, these low-risk viruses express viral E6 and E7 oncoproteins that lead to dysregulated epidermal cell growth and increased survival. Why low-risk viruses cause warts instead of cancer is unclear; subtle functional differences due to structural variation in E6 and E7 proteins that affect interactions with host proteins as well as differences in the abilities of different viral strains to evade the immune response have been proposed.The immune response normally limits the growth of these tumors, and immunodeficiency often is associated with increased numbers and larger sized verrucae.

### MORPHOLOGY

Different kinds of warts are identified on the basis of their gross appearance and location and generally are caused by distinct HPV subtypes. **Verruca vulgaris** (Fig. 23–7, *A*), the most common type of wart, can occur anywhere but is found most frequently on the hands, particularly on the dorsal surfaces and periungual areas, where it appears as a gray-white to tan, flat to convex, 0.1- to 1-cm papule with a rough, pebble-like surface. **Verruca plana,** or **flat wart,** is common on the face or dorsal surfaces of the hands. These warts are flat, smooth, tan macules. **Verruca plantaris** and **verruca palmaris** occur on the soles and palms, respectively. These rough, scaly lesions may reach 1 to 2 cm in diameter and then coalesce to form a surface that can be confused with ordinary calluses. **Condyloma acuminatum (venereal wart)** occurs on the penis, female genitalia, urethra, and perianal areas (Chapters 17 and 18). Histologic features common to verrucae include **epidermal hyperplasia,** which is often undulant in character (so-called verrucous or papillomatous epidermal hyperplasia) (Fig. 23–7, *B, top panel*), and cytoplasmic vacuolization **(koilocytosis),** which preferentially involves the more superficial epidermal layers, producing halos of pallor surrounding infected nuclei. Infected cells also may demonstrate prominent keratohyalin granules and jagged eosinophilic intracytoplasmic protein aggregates as a result of impaired maturation (Fig. 23–7, *B, bottom panel*).

# BLISTERING (BULLOUS) DISORDERS

Although vesicles and bullae (blisters) occur as a secondary phenomenon in several unrelated conditions (e.g., herpesvirus infection, spongiotic dermatitis), there is a group of

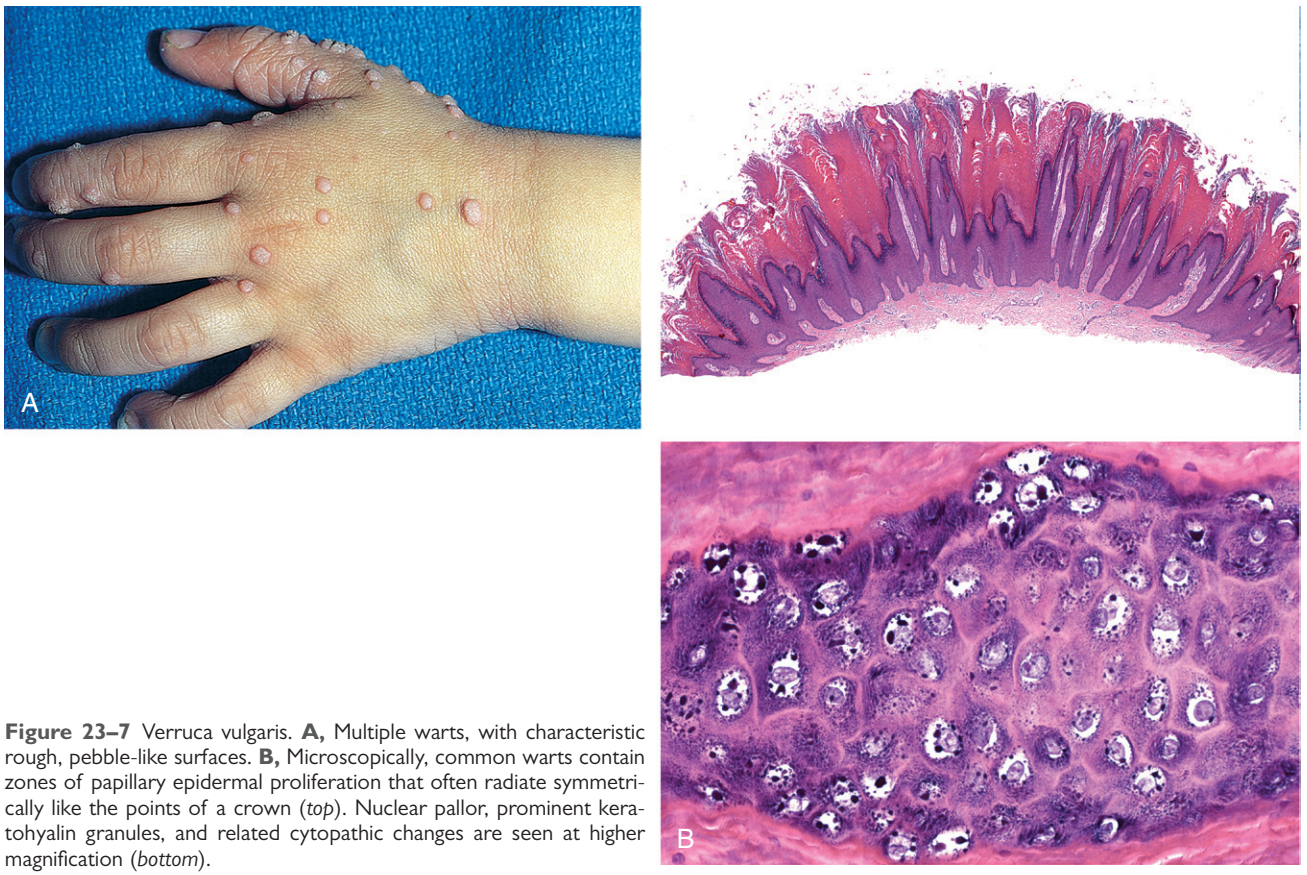

**Figure 23–7** Verruca vulgaris. **A,** Multiple warts, with characteristic rough, pebble-like surfaces. **B,** Microscopically, common warts contain zones of papillary epidermal proliferation that often radiate symmetrically like the points of a crown (*top*). Nuclear pallor, prominent keratohyalin granules, and related cytopathic changes are seen at higher magnification (*bottom*).

disorders in which blisters are the primary and most distinctive feature. Blistering in these diseases tends to occur at specific levels within the skin, a morphologic distinction that is critical for diagnosis (Fig. 23–8).

## Pemphigus (Vulgaris and Foliaceus)

Pemphigus is a rare autoimmune blistering disorder resulting from loss of normal intercellular attachments within the epidermis and the squamous mucosal epithelium. There are three major variants:

- Pemphigus vulgaris (the most common type)
- Pemphigus foliaceus
- Paraneoplastic pemphigus

The last entity is associated with internal malignancy and is not discussed here.

### PATHOGENESIS

Both pemphigus vulgaris and pemphigus foliaceus are autoimmune diseases in which the lesions are caused by antibody-mediated (type II) hypersensitivity reactions (Chapter 4). The

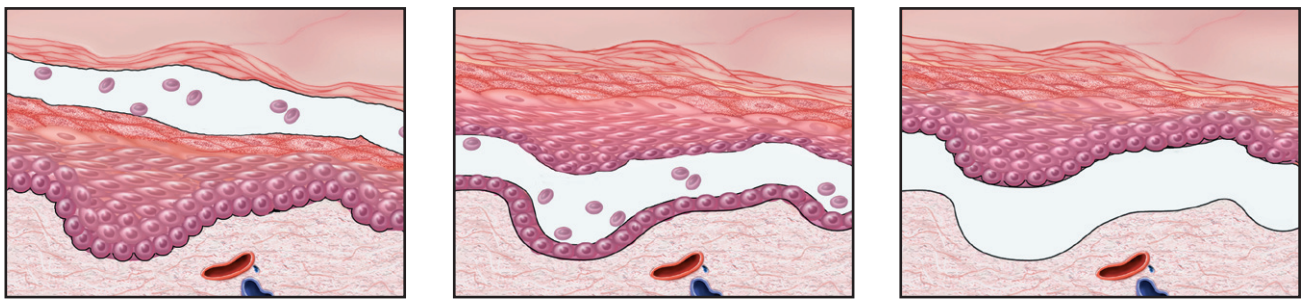

**Figure 23–8** Levels of blister formation. **A,** Subcorneal (as in pemphigus foliaceus). **B,** Suprabasal (as in pemphigus vulgaris). **C,** Subepidermal (as in bullous pemphigoid or dermatitis herpetiformis). The level of epidermal separation forms the basis of the differential diagnosis for blistering disorders.

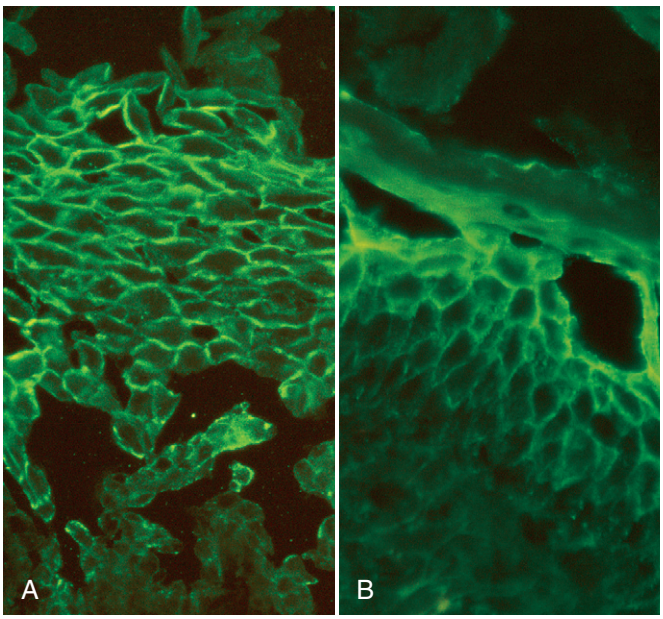

**Figure 23–9** Direct immunofluorescence findings in pemphigus. **A,** Pemphigus vulgaris. There is uniform deposition of immunoglobulin and complement (*green*) along the cell membranes of keratinocytes in a characteristic "fishnet" pattern. **B,** Pemphigus foliaceus. Immunoglobulin deposits are confined to superficial layers of the epidermis.

pathogenic antibodies are IgG autoantibodies that bind to intercellular desmosomal proteins (desmoglein types 1 and 3) of skin and mucous membranes. The antibodies disrupt the intercellular adhesive function of the desmosomes and may activate intercellular proteases as well. The distribution of these proteins within the epidermis determines the location of the lesions. By direct immunofluorescence study, lesional sites show a characteristic fishnet-like pattern of intercellular IgG deposits (Fig. 23–9). As in other autoimmune diseases, pemphigus shows linkage with particular HLA alleles.

## MORPHOLOGY

**Pemphigus vulgaris,** by far the most common type, involves both mucosa and skin, especially on the scalp, face, axillae, groin, trunk, and points of pressure. The lesions are superficial flaccid vesicles and bullae that rupture easily, leaving deep and often extensive erosions covered with a serum crust (Fig. 23–10, *A*). **Pemphigus foliaceus**, a rare, more benign form of pemphigus, results in bullae confined to skin, with only infrequent involvement of mucous membranes. The blisters in this disorder are superficial, such that more limited zones of erythema and crusting of ruptured blisters are seen (Fig. 23–11, *A*).

The common histologic denominator in all forms of pemphigus is **acantholysis,** lysis of the intercellular adhesive junctions between neighboring squamous epithelial cells that results in the rounding up of detached cells. In pemphigus vulgaris, acantholysis selectively involves the layer of cells immediately above the basal cell layer, giving rise to a **suprabasal acantholytic blister** (Fig. 23–10, *B*). In pemphigus foliaceus, acantholysis selectively involves the superficial epidermis at the level of the stratum granulosum (Fig. 23–11, *B*). Variable superficial dermal infiltrates comprised of lymphocytes, macrophages, and eosinophils accompany all forms of pemphigus.

### Clinical Features

Pemphigus vulgaris is a rare disorder that occurs most commonly in the elderly and more often in women than men. Lesions are painful, particularly when ruptured, and secondary infections are common. Most cases are associated with oropharyngeal involvement at some point in their course. Most patients require immunosuppressive therapy, sometimes for the remainder of their lives. Medications can cause pemphigus, and when they do, patients most often present with pemphigus foliaceus rather than pemphigus vulgaris. There is also an unusual endemic form of pemphigus foliaceus in South America (*fogo selvagem*) that is putatively associated with the bite of a black fly.

## Bullous Pemphigoid

Bullous pemphigoid is another distinctive acquired blistering disorder with an autoimmune basis.

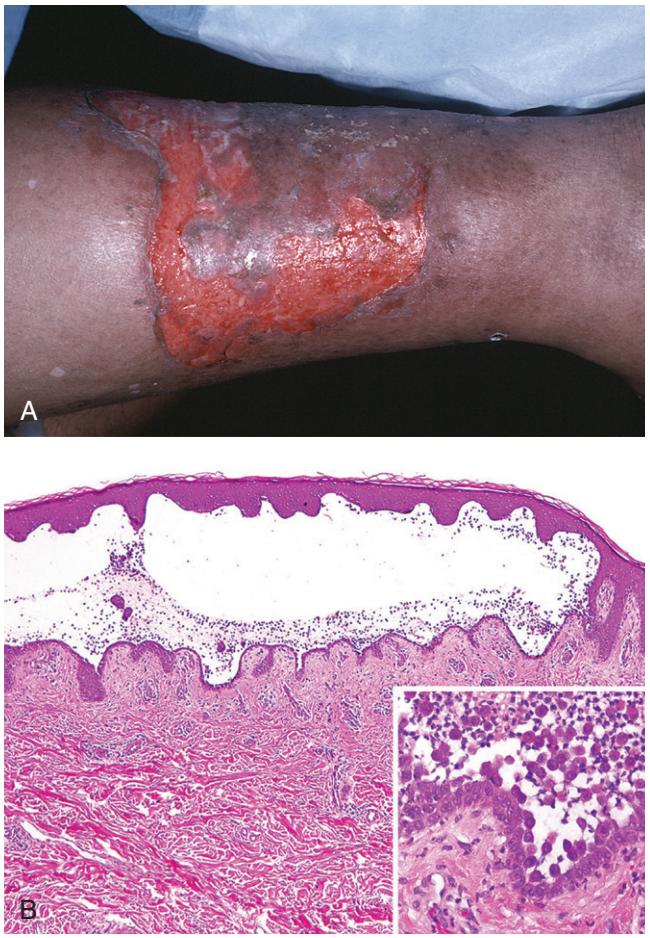

**Figure 23–10** Pemphigus vulgaris. **A,** This erosion on the leg represents a group of confluent, "unroofed" blisters. **B,** Suprabasal acantholysis results in an intraepidermal blister in which rounded, dissociated (acantholytic) keratinocytes are plentiful (*inset*).

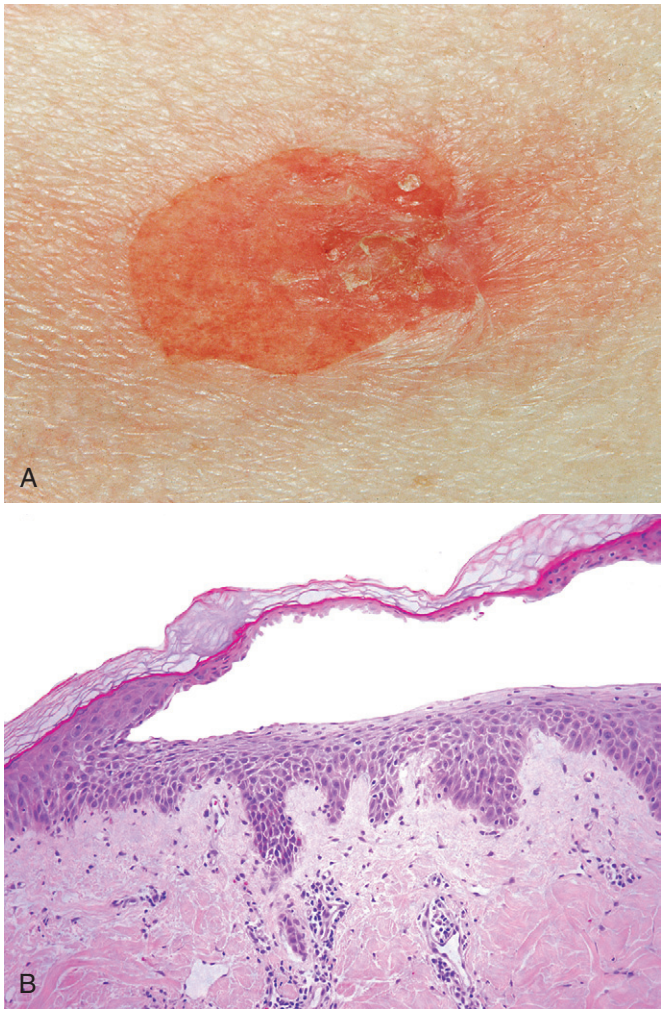

**Figure 23–11** Pemphigus foliaceus. **A,** Gross appearance of a typical blister, which is less severely eroded than those seen in pemphigus vulgaris. **B,** Microscopic appearance of a characteristic subcorneal blister.

## PATHOGENESIS

Blistering in bullous pemphigoid is triggered by the linear deposition of IgG antibodies and complement in the epidermal basement membrane (Fig. 23–12, *A*). Reactivity also occurs in the basement membrane attachment plaques (hemidesmosomes), where most of the bullous pemphigoid antigen (type XVII collagen) is located. This protein normally is involved in dermoepidermal adhesion. IgG autoantibodies to hemidesmosome components fix complement and cause tissue injury by recruiting neutrophils and eosinophils.

## MORPHOLOGY

Grossly, the lesions of bullous pemphigoid appear as tense bullae, filled with clear fluid, on normal or erythematous skin (Fig. 23–12, *B*). Bullous pemphigoid is characterized by **subepidermal nonacantholytic** blisters. Early lesions show a perivascular infiltrate of lymphocytes and variable numbers of eosinophils, occasional neutrophils, superficial dermal edema, and associated basal cell layer vacuolization. The vacuolated basal cell layer eventually gives rise to a fluid-filled

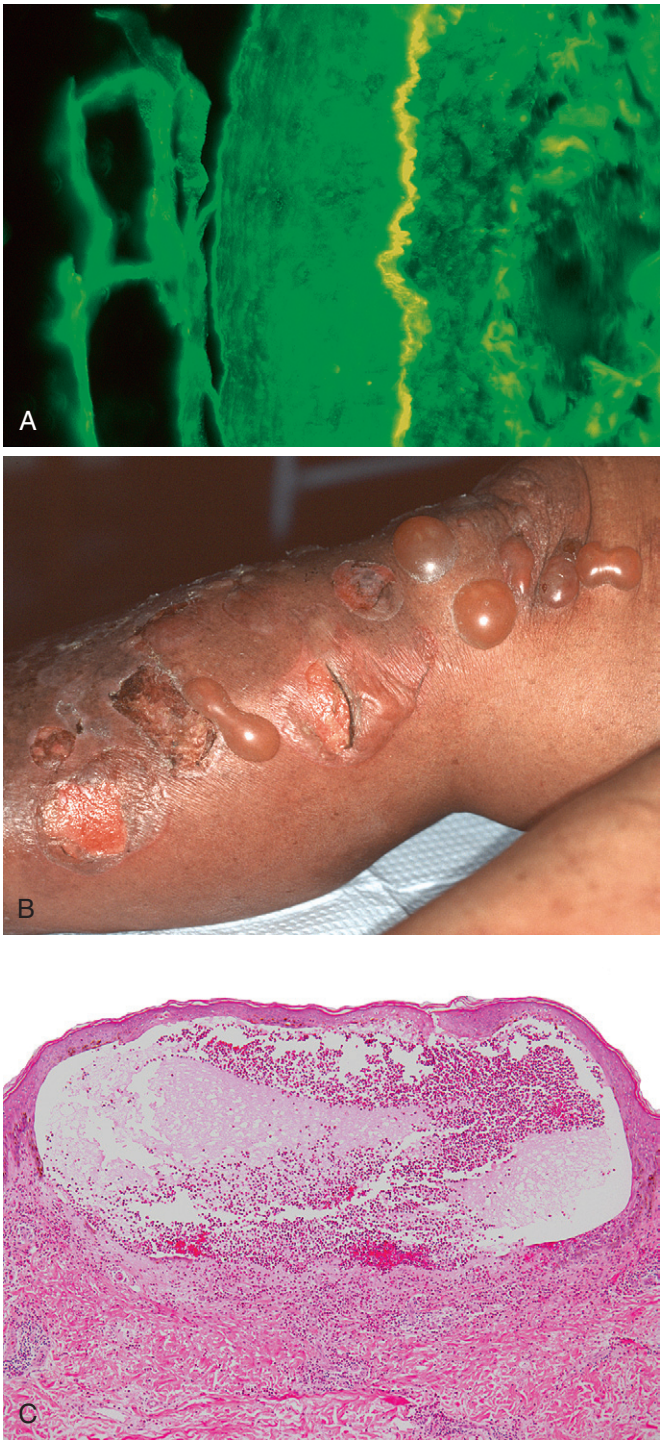

**Figure 23–12** Bullous pemphigoid. **A,** Deposition of IgG antibody detected by direct immunofluorescence as a linear band outlining the subepidermal basement membrane zone (epidermis is on the *left* side of the fluorescent band). **B,** Gross appearance of characteristic tense, fluid-filled blisters. **C,** A subepidermal vesicle with an inflammatory infiltrate rich in eosinophils.
*(C, Courtesy of Dr. Victor G. Prieto, Houston, Texas.)*

blister (Fig. 23–12, *C*). The blister roof consists of full-thickness epidermis with intact intercellular junctions, a key distinction from the blisters seen in pemphigus.

Clinical Features

The bullae do not rupture as readily as in pemphigus and, if uncomplicated by infection, heal without scarring. The disease tends to follow a remitting and relapsing course and responds to topical or systemic immunosuppressive agents. Gestational pemphigoid (also known as *herpes gestationis,* a misnomer) is a clinically distinct subtype that appears suddenly during the second or third trimester of pregnancy. It is also caused by autoantibodies against BPAG. It typically resolves after childbirth, but may recur with future pregnancies.

## Dermatitis Herpetiformis

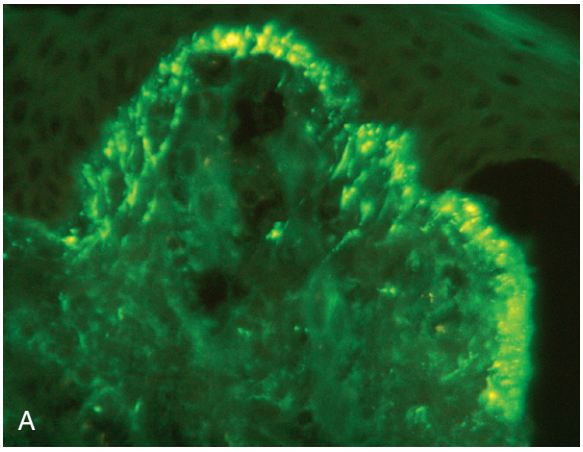
Dermatitis herpetiformis is another type of autoimmune blistering disorder characterized by extremely *pruritic urticaria and grouped vesicles.* The disease affects predominantly males, often in the third and fourth decades of life. In up to 80% of cases, it occurs in association with celiac disease; conversely, only a small minority of patients with celiac disease develop dermatitis herpetiformis. Like celiac disease, dermatitis herpetiformis responds to a gluten-free diet.

### PATHOGENESIS

The strong association of dermatitis herpetiformis with celiac disease provides a clue to its pathogenesis. Genetically predisposed persons develop IgA antibodies to dietary gluten (derived from the wheat protein gliadin) as well as IgA autoantibodies that cross-react with endomysium and tissue transglutaminases, including epidermal transglutaminase expressed by keratinocytes. By direct immunofluorescence, the skin shows discontinuous, **granular deposits of IgA** selectively localized in the tips of dermal papillae (Fig. 23–13, *A*). The resultant injury and inflammation produce a subepidermal blister.

### MORPHOLOGY

The lesions of dermatitis herpetiformis are bilateral, symmetric, and grouped and preferentially involve the extensor surfaces, elbows, knees, upper back, and buttocks (Fig. 23–13, *B*). Initially, neutrophils accumulate selectively at the **tips of dermal papillae,** forming small microabscesses (Fig. 23–13, *C*). The basal cells overlying these microabscesses show vacuolization and focal dermoepidermal separation that ultimately coalesce to form a true **subepidermal blister.**



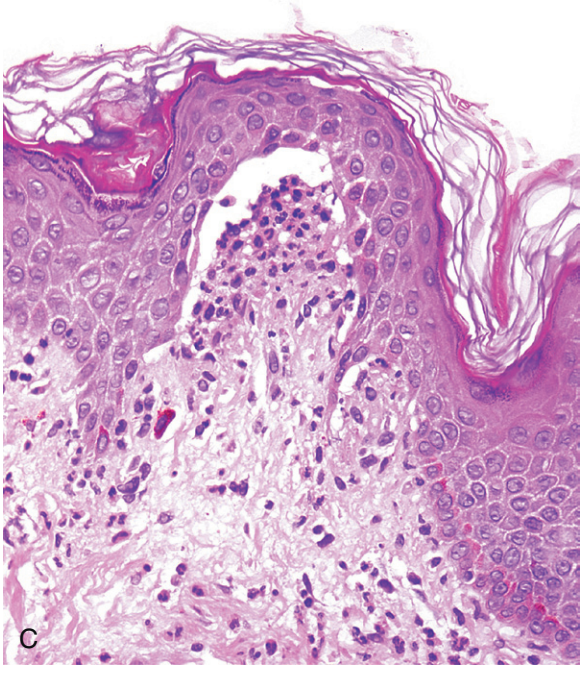


**Figure 23–13** Dermatitis herpetiformis. **A,** Selective deposition of IgA autoantibody at the tips of dermal papillae is characteristic. **B,** Lesions consist of intact and eroded (usually scratched) erythematous blisters, often grouped (seen here on elbows and arms). **C,** The blisters are associated with basal cell layer injury, initially caused by accumulation of neutrophils (microabscesses) at the tips of dermal papillae.
*(A, Courtesy of Dr. Victor G. Prieto, Houston, Texas.)*

## SUMMARY

### Blistering Disorders

- Blistering disorders are classified by the level of epidermal separation.
- These disorders are often caused by autoantibodies specific for epithelial or basement membrane proteins that lead to unmooring of keratinocytes (acantholysis).
- Pemphigus is associated with IgG autoantibodies to various intercellular desmogleins, resulting in bullae that are either subcorneal (pemphigus foliaceus) or suprabasalar (pemphigus vulgaris).
- Bullous pemphigoid is associated with IgG autoantibodies to basement membrane proteins and produces a subepidermal blister.
- Dermatitis herpetiformis is associated with IgA autoantibodies to fibrils that bind the epidermal basement membrane to the dermis, and is also characterized by subepidermal blisters.

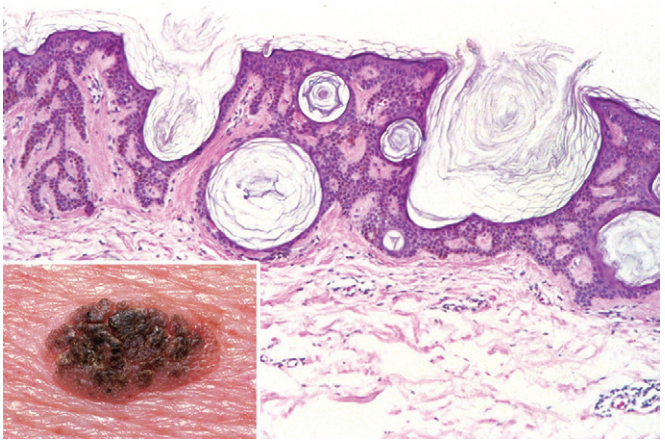

**Figure 23–14** Seborrheic keratosis. This roughened, brown, waxy lesion almost appears to be "stuck on" the skin (*inset*). Microscopic examination shows the lesion to consist of an orderly proliferation of uniform, basaloid keratinocytes that tend to form keratin microcysts (horn cysts).

# BENIGN AND PREMALIGNANT TUMORS

## Benign and Premalignant Epithelial Lesions

Benign epithelial neoplasms are common and probably arise from stem cells residing in the epidermis and hair follicles. These tumors grow to a limited size and generally do not undergo malignant transformation.

### *Seborrheic Keratosis*

These common pigmented epidermal tumors occur most frequently in middle-aged or older persons. They arise spontaneously and are particularly numerous on the trunk, although the extremities, head, and neck also may be sites of involvement.

A significant fraction of these tumors harbor activating mutations in *fibroblast growth factor (FGF) receptor 3*, which possesses a tyrosine kinase activity that stimulates Ras and the PI3K/AKT pathways. Except for cosmetic concerns, they are usually of little clinical importance. However, in rare patients hundreds of lesions may appear suddenly as a *paraneoplastic syndrome* (sign of Lesser-Trelat). Patients with this presentation may harbor internal malignancies, most commonly gastrointestinal tract carcinomas, which produce growth factors that stimulate epidermal proliferation.

#### MORPHOLOGY

Seborrheic keratoses are **round, exophytic, coin-like plaques** varying in diameter from millimeters to centimeters that have a **"stuck-on" appearance** (Fig. 23–14, *inset*). They are tan to dark brown and have a velvety- to granular-appearing surface. Occasionally, their dark color is suggestive of melanoma, leading to surgical removal.

Microscopically, seborrheic keratoses are composed of monotonous sheets of small cells that resemble the basal cells of the normal epidermis (Fig. 23–14). Variable melanin pigmentation is present within these basaloid cells, accounting for the brown coloration seen grossly. Hyperkeratosis occurs at the surface, and the presence of small keratin-filled cysts (horn cysts) and downgrowth of keratin into the main tumor mass (pseudo–horn cysts) are characteristic features.

### *Actinic Keratosis*

Overt malignancy of the epidermis (squamous cell carcinoma) may be preceded by a series of progressive dysplastic changes. Because such lesions usually are the result of chronic exposure to sunlight and are associated with hyperkeratosis, they are called actinic (sun-related) keratoses. Whether all actinic keratoses evolve to carcinoma with time is conjectural; many lesions regress or remain stable. Enough become malignant, however, to warrant local eradication. A high fraction of these lesions are associated with *TP53* mutations caused by UV light–induced DNA damage.

#### MORPHOLOGY

Actinic keratoses usually are less than 1 cm in diameter, tan-brown or red in color, and rough (sandpaper-like) to the touch (Fig. 23–15, *A*). Microscopically, lower portions of the epidermis show **cytologic atypia,** often associated with hyperplasia of basal cells (Fig. 23–15, *B*) or with atrophy and diffuse thinning of the epidermal surface. The dermis contains thickened, blue-gray elastic fibers (solar elastosis), the result of chronic sun damage. The stratum corneum is thickened with retained nuclei (parakeratosis). In some lesions full thickness epidermal atypia is seen; such lesions are considered forms of squamous cell carcinoma in situ (Fig. 23–15, *C*).

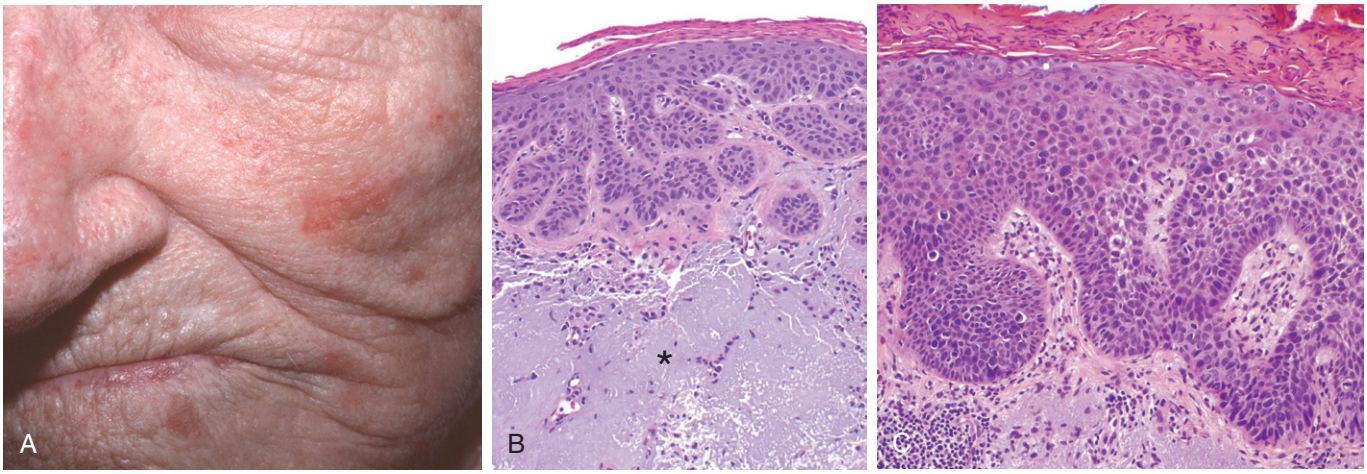

**Figure 23–15** Actinic keratosis. **A,** Most lesions are red and rough (sandpaper-like), owing to excessive scale, as seen in the lesions on the cheek, nose, and chin of this female patient. **B,** Basal cell layer atypia (dysplasia) with epithelial buds, and associated with marked hyperkeratosis, parakeratosis, and dermal solar elastosis (*asterisk*). **C,** More advanced lesions show full-thickness atypia, qualifying as squamous carcinoma in situ.

Clinical Features

Actinic keratoses are very common in fair-skinned people and increase in incidence with age and increasing sun exposure. As would be expected, there is a predilection for sun-exposed areas (face, arms, dorsum of the hands). The lesions can be treated with local cryotherapy (superficial freezing) or topical agents.

## SUMMARY

### Benign and Premalignant Epithelial Lesions

- *Seborrheic keratosis:* Round, flat plaques made up of proliferating monotonous epidermal basal cells, which sometimes contain melanin. Hyperkeratosis and keratin-filled cysts are characteristic.
- *Actinic keratosis:* Present on sun-exposed skin, these lesions show cytologic atypia in lower parts of epidermis and infrequently progress to carcinoma in situ.

## Malignant Epidermal Tumors

### *Squamous Cell Carcinoma*

Squamous cell carcinoma is *a common tumor arising on sun-exposed sites in older people.* These tumors have a higher incidence in men than in women. In addition to sunlight, predisposing factors include industrial carcinogens (tars and oils), chronic ulcers, old burn scars, ingestion of arsenicals, and ionizing radiation. As with squamous cell carcinomas at other sites, those in the skin may be preceded by in situ lesions.

## PATHOGENESIS

The most common exogenous cause of cutaneous squamous cell carcinoma is UV light exposure, which causes DNA damage (Chapter 5). *TP53* mutations caused by UV light–induced DNA damage are common, as are activating mutations in *HRAS* and loss-of-function mutations in Notch receptors, which transmit signals that regulate the orderly differentiation of normal squamous epithelia. In addition to inducing mutations, UV light (UVB in particular) may have a transient immunosuppressive effect on skin by impairing antigen presentation by Langerhans cells. This effect may contribute to tumorigenesis by weakening immunosurveillance. Patients who are immunosuppressed as a result of chemotherapy or organ transplantation, or who have **xeroderma pigmentosum,** are at increased risk. Tumors in immunosuppressed persons, particularly organ transplant recipients, are likely to be associated with HPV infection. *TP53* mutations caused by UV light–induced DNA damage are common, as are activating mutations in *HRAS*. As with squamous cell carcinomas at other sites, those in the skin may be preceded by in situ lesions.

## MORPHOLOGY

Squamous cell carcinomas in situ appear as sharply defined, red, scaling plaques; many arise from prior actinic keratoses. More advanced, invasive lesions are nodular, show variable scale, and may ulcerate (Fig. 23–16, *A*). Microscopically, squamous cell carcinoma in situ is characterized by highly atypical cells at **all levels** of the epidermis, with nuclear crowding and disorganization. Invasive tumors, defined by penetration of the basement membrane (Fig. 23–16, *B*), show variable degrees of differentiation, ranging from tumors with cells arranged in orderly lobules that exhibit extensive keratinization to neoplasms consisting of highly anaplastic cells with foci of necrosis and only abortive, single-cell keratinization (dyskeratosis).

Clinical Features

Invasive squamous cell carcinomas of the skin often are discovered while small and resectable. Less than 5% have metastasized to regional nodes at diagnosis. The likelihood of metastasis is related to the thickness of the lesion and degree of invasion into the subcutis. Tumors arising in the context of actinic keratoses may be locally aggressive but

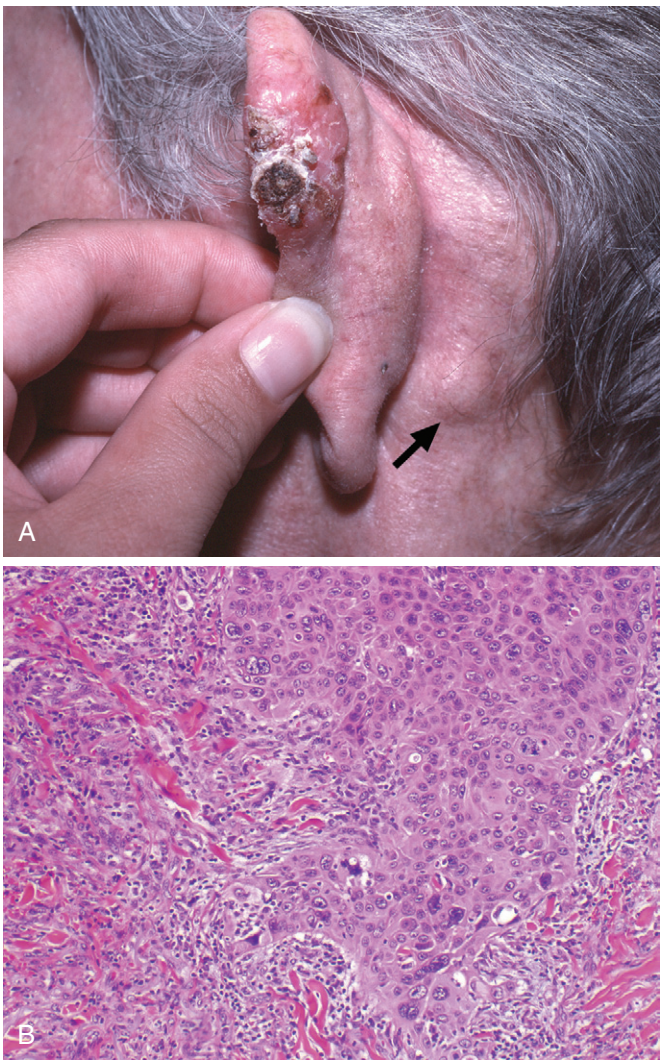

**Figure 23–16** Invasive squamous cell carcinoma. **A,** A nodular, hyperkeratotic lesion occurring on the ear, associated with metastasis to a prominent postauricular lymph node (*arrow*). **B,** The tumor invades the dermis infiltrating collagen as irregular projections of atypical squamous cells, which in this case exhibit acantholysis.

generally metastasize only after long periods of time, while those arising in burn scars, ulcers, and non–sun-exposed skin behave less predictably. Mucosal squamous cell carcinomas (oral, pulmonary, esophageal, etc.) generally are much more aggressive.

### *Basal Cell Carcinoma*

Basal cell carcinoma is a common *slow-growing cancer that rarely metastasizes*. It tends to occur at sites subject to chronic sun exposure and in lightly pigmented individuals.

## PATHOGENESIS

**Basal cell carcinoma is associated with dysregulation of the Hedgehog pathway.** Inherited defects in the *PTCH* gene, a tumor suppressor that regulates Hedgehog pathway signaling, cause familial basal cell carcinomas in Gorlin syndrome. The Hedgehog pathway is an important regulator of embryonic development, and subtle developmental anomalies are also often noted in affected persons. Some component of the hedgehog pathway is mutated in the great majority of sporadic basal cell carcinomas as well. Mutations in *TP53* are also common in both familial and sporadic tumors.

## MORPHOLOGY

Grossly, basal cell carcinomas manifest as **pearly papules, often with prominent, dilated subepidermal blood vessels (telangiectasia)** (Fig. 23–17, *A*). Some tumors contain melanin pigment and thus appear similar to melanocytic nevi or melanomas. Microscopically, the tumor cells resemble the normal epidermal basal cell layer from which they are derived. Because they may arise from either the epidermis or the follicular epithelium, they are not encountered on mucosal surfaces. Two common patterns are seen: **multifocal growths** originating from the epidermis (superficial pattern), or **nodular lesions** growing downward into the dermis as cords and islands of variably basophilic cells with hyperchromatic nuclei, embedded in a fibrotic or mucinous stromal matrix (Fig. 23–17, *B*). Peripheral tumor cell nuclei align in the outermost layer (a pattern termed palisading), which often separates from the stroma, creating a characteristic cleft (Fig. 23–17, *C*).

### Clinical Features

It is estimated that in excess of 1 million basal cell carcinomas are treated in the United States annually. By far the most important risk factor is sun exposure; basal cell carcinoma is more common in warm southern regions of the United States, and its incidence is 40-fold higher in sunny climates near the equator, such as Australia, than it is in Northern European locales. Individual tumors usually are cured by local excision, but approximately 40% of patients will develop another basal cell carcinoma within 5 years. Advanced lesions may ulcerate, and extensive local invasion of bone or facial sinuses may occur if the lesions are neglected for many years.

## SUMMARY

### Malignant Epidermal Tumors

- The incidence of both basal cell and squamous cell carcinoma is strongly correlated with increasing lifetime sun exposure.
- Cutaneous squamous cell carcinoma can progress from actinic keratoses but also arises from chemical exposure, at thermal burn sites, or in association with HPV infection in the setting of immunosuppression.
- Cutaneous squamous cell carcinoma has potential for metastasis but is much less aggressive than squamous cell carcinoma at mucosal sites.
- Basal cell carcinoma, the most common malignancy worldwide, is a locally aggressive tumor associated with mutations in the Hedgehog pathway. Metastasis is very rare.

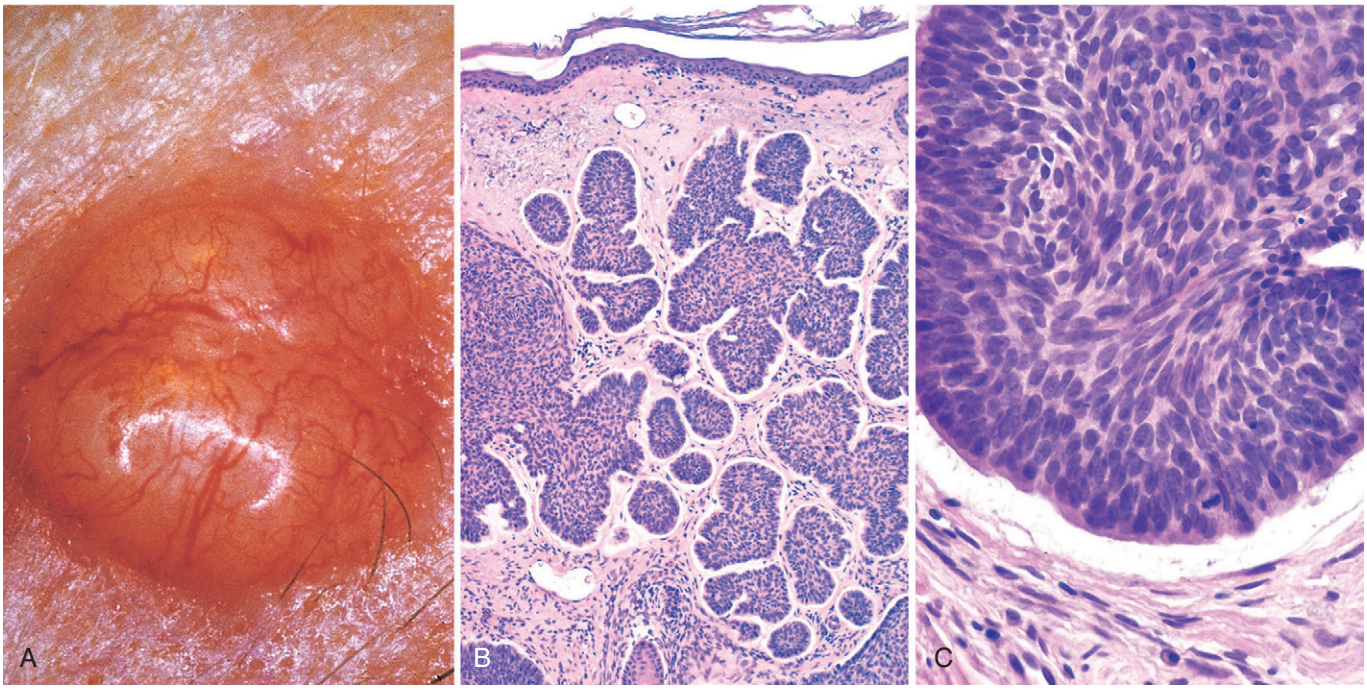

**Figure 23–17** Basal cell carcinoma. **A,** A prototypical pearly, smooth-surfaced papule with associated telangiectatic vessels. **B,** The tumor is composed of nests of basaloid cells infiltrating a fibrotic stroma. **C,** The tumor cells have scant cytoplasm and small hyperchromatic nuclei that palisade on the outside of the nest. The cleft between the tumor cells and the stroma is a highly characteristic artifact of sectioning.

## Melanocytic Proliferations

### *Melanocytic Nevi*

Strictly speaking, the term *nevus* denotes any congenital lesion of the skin. *Melanocytic* nevus, however, refers to any benign congenital or acquired neoplasm of melanocytes.

### PATHOGENESIS

Melanocytic nevi are benign neoplasms derived from melanocytes, highly dendritic, pigment-producing cells that are normally interspersed among basal keratinocytes. Progressive growth and migration of nevus cells from the dermoepidermal junction into the underlying dermis is accompanied by changes that are taken as evidence of cellular **senescence** (Fig. 23–18). Superficial nevus cells are larger and tend to produce melanin pigment and grow in nests; deeper nevus cells are smaller, produce little or no pigment, and grow in cords or single cells. The deepest nevus cells have fusiform contours and grow in fascicles. This sequence of morphologic changes is of diagnostic importance, since they are absent from melanomas. The majority of benign nevi have an activating mutation in *BRAF*, which encodes a serine/threonine kinase downstream from RAS in the extracellular regulated kinase (ERK) pathway, or less commonly in *NRAS* itself. Experimental evidence suggests that unbridled BRAF/RAS signaling initially induces melanocytic proliferation followed by senescence. How these opposing effects are coordinated is unclear, but it is believed that the "brake" on proliferation provided by induced senescence explains why very few nevi transform into malignant melanomas.

### MORPHOLOGY

Common melanocytic nevi are tan-to-brown, uniformly pigmented, small papules (5 mm or less across) with well-defined, rounded borders (Fig. 23–19, *A*). Early lesions are composed of round-to-oval cells that grow in "nests" along the dermoepidermal junction. Nuclei are uniform and round, and contain inconspicuous nucleoli with little or no mitotic activity. Such early-stage lesions are called **junctional nevi.** Eventually, most junctional nevi grow into the underlying dermis as nests or cords of cells **(compound nevi),** and in older lesions the epidermal nests may be lost entirely, creating an **intradermal nevi** (Fig. 23–19, *B*).

#### Clinical Features

There are numerous types of melanocytic nevi, with varied appearances. Although these lesions usually are of only cosmetic concern, they can become irritating or mimic melanoma, requiring their surgical removal. Compound and intradermal nevi often are more elevated than junctional nevi.

### *Dysplastic Nevus*

Dysplastic nevi may be *sporadic or familial*. The latter are important clinically because they are considered potential precursors of melanoma. As with conventional melanocytic nevi, activating *NRAS* or *BRAF* mutations are commonly found in dysplastic nevi and are believed to have a pathogenic role.

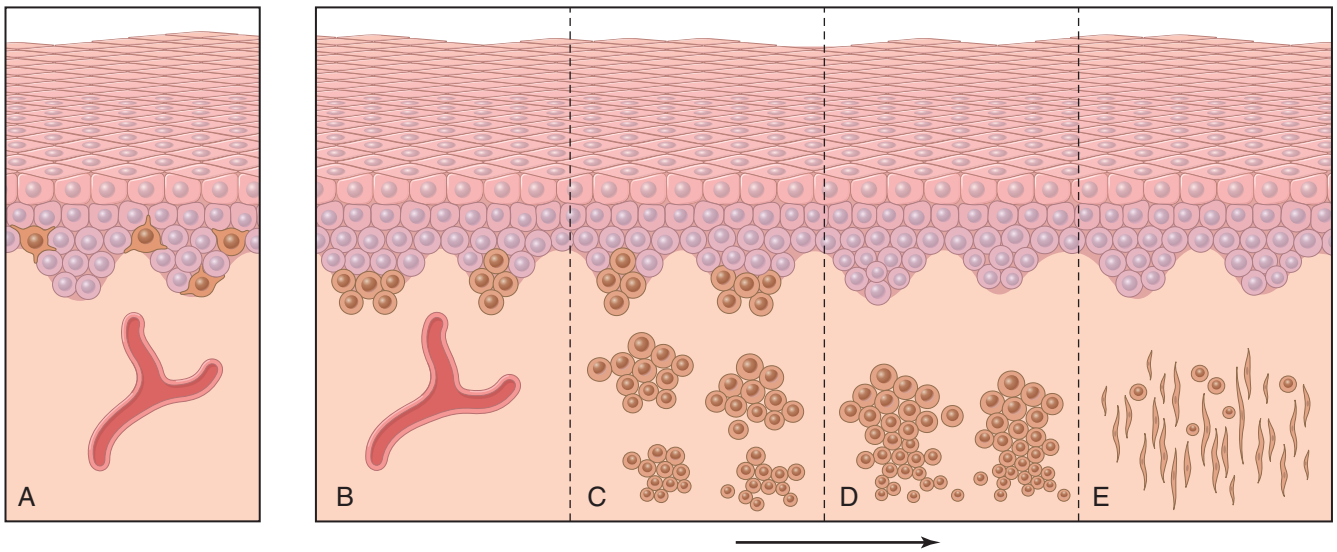

**Figure 23–18** Possible steps in development of melanocytic nevi. **A,** Normal skin shows only scattered melanocytes. **B,** Junctional nevus. **C,** Compound nevus. **D,** Intradermal nevus. **E,** Intradermal nevus with extensive cellular senescence.

## MORPHOLOGY

Dysplastic nevi are larger than most acquired nevi (often more than 5 mm across) and **may number in the hundreds** (Fig. 23–20, *A*). They are flat macules to slightly raised plaques, with a "pebbly" surface. They usually have variable pigmentation (variegation) and irregular borders (Fig. 23–20, *A, inset*).

Microscopically, dysplastic nevi are mostly compound nevi that exhibit both architectural and cytologic evidence of abnormal growth. Nevus cell nests within the epidermis may be enlarged and exhibit abnormal fusion or coalescence with adjacent nests (bridging). As part of this process, single nevus cells begin to replace the normal basal cell layer along the dermoepidermal junction, producing so-called lentiginous hyperplasia (Fig. 23–20, *B*). Cytologic atypia consisting of irregular, often angulated, nuclear contours and hyperchromasia is frequently observed (Fig. 23–20, *B* and *C*). Associated alterations also occur in the superficial dermis. These consist of a sparse lymphocytic infiltrate, release of melanin pigment that is phagocytosed by dermal macrophages (melanin incontinence), and linear fibrosis surrounding epidermal nests of melanocytes. These dermal changes are elements of the host response to these lesions.

### Clinical Features

Unlike ordinary nevi, *dysplastic nevi have a tendency to occur on body surfaces not exposed to the sun* as well as on sun-exposed sites. *Familial dysplastic nevus syndrome is strongly associated with melanoma*, as the lifetime risk for the development of melanoma in affected persons is close to 100%. In sporadic cases, only individuals with 10 or more dysplastic nevi appear to be at an increased risk for melanoma. Transformation of dysplastic nevus to melanoma has been documented, both clinically and histologically. However, such cases are the exception, as most melanomas arise de novo and not from a preexisting nevus. Thus, the likelihood that

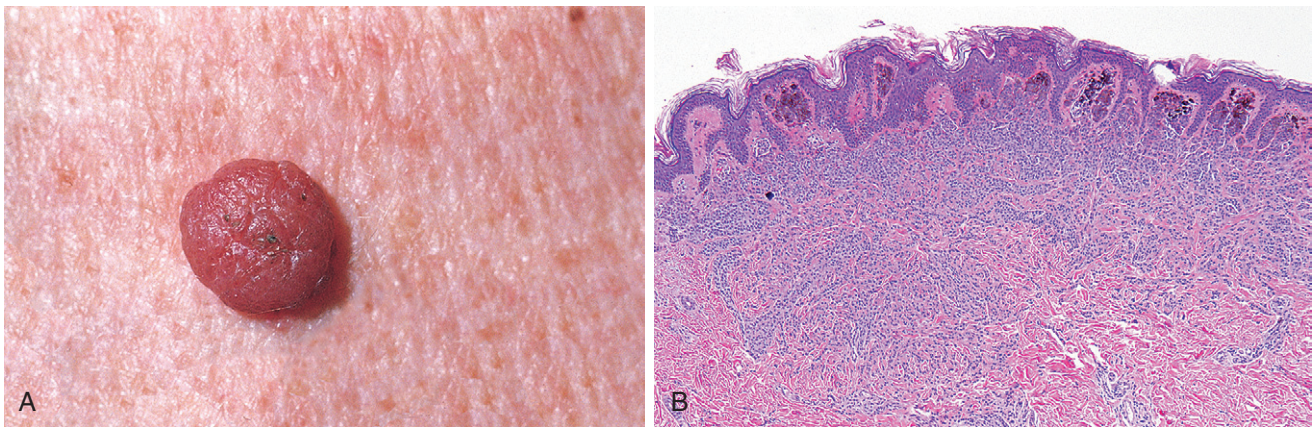

**Figure 23–19** Melanocytic nevus. **A,** Melanocytic nevi are relatively small, symmetric, and uniformly pigmented. **B,** This nevus shows rounded melanocytes that lose their pigmentation and become smaller and more separated as they extend into the dermis—all signs of cellular senescence that speak to the benign nature of the proliferation.

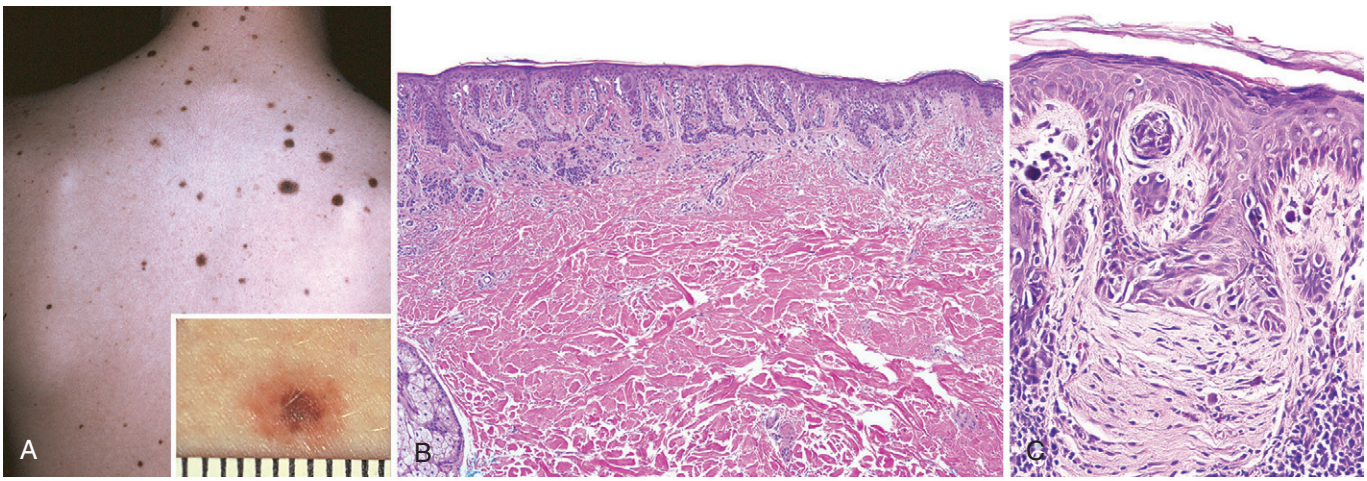

**Figure 23–20** Dysplastic nevus. **A,** Numerous irregular nevi on the back of a patient with the dysplastic nevus syndrome. The lesions usually are greater than 5mm in diameter and have irregular borders and variable pigmentation (*inset*). **B,** Compound dysplastic nevi feature a central dermal component with an asymmetric "shoulder" of exclusively junctional melanocytes (lentiginous hyperplasia). The former corresponds to the more pigmented and raised central zone (see **A,** *inset*), and the latter, to the less pigmented flat peripheral rim. **C,** Other important features are cytologic atypia (irregular, dark-staining nuclei) and characteristic parallel bands of fibrosis—part of the host response to these lesions.

any particular nevus, dysplastic or otherwise, will develop into melanoma is exceedingly low, and these lesions are best viewed as markers of melanoma risk.

### *Melanoma*

Melanoma is less common but much more deadly than basal or squamous cell carcinoma. Today, as a result of increased public awareness of the earliest signs of skin melanomas, most melanomas are cured surgically. Nonetheless, the incidence of these lesions has increased dramatically over the past several decades, at least in part as a result of increasing sun exposure and/or higher detection rates resulting from vigorous surveillance.

## PATHOGENESIS

As with other cutaneous malignancies, sunlight plays an important role in the development of melanoma. The incidence is highest in sun-exposed skin and in geographic locales such as Australia where sun exposure is high and much of the population is fair-skinned. Intense intermittent exposure at an early age is particularly harmful. Recent "deep sequencing" studies have confirmed that tumor genomes contain thousands of acquired mutations, most bearing a signature consistent with UV-induced DNA damage. Sunlight, however, is not the only predisposing factor; hereditary predisposition also plays a role, as already discussed under familial dysplastic nevus syndrome.

As with other cancers, it is believed that melanoma may arise in a stepwise fashion from precursor lesions (Fig. 23–21). **Key phases of tumor development are marked by radial and vertical growth. Radial growth** describes the initial tendency of a melanoma to grow horizontally within the epidermis (*in situ*), often for a prolonged period (Fig. 23–21, *D*). During this stage, melanoma cells do not have the capacity to metastasize, and do not induce angiogenesis. With time, a **vertical growth phase** supervenes, in which the tumor grows downward into the deeper dermal layers as an expansile mass lacking cellular maturation (Fig. 23–21, *E*). This event often is heralded by the development of a nodule in a previously flat lesion (Fig. 23-22, *A*) and correlates with the emergence of a clone of cells with metastatic potential.

Most melanomas occur sporadically, but a few are hereditary (with reported rates ranging from less than 5% to 10%). Molecular genetic analysis of familial and sporadic cases has provided important insights into the pathogenesis of melanoma. As with other tumors, malignant transformation of melanocytes is a multistep process that involves activating mutations in proto-oncogenes and loss-of-function mutations in tumor suppressor genes. Germline mutations in the *CDKN2A* gene (located on 9p21) are found in as many as 40% of the rare individuals who suffer from familial melanoma. This gene encodes the tumor suppressor p16, a cyclin-dependent kinase inhibitor that regulates the $G_1$-S transition of the cell cycle in a retinoblastoma protein–dependent fashion (Chapter 5). The *CDNK2A* gene also is silenced in some sporadic tumors by methylation. Somatic activating mutations in the proto-oncogenes *BRAF* or *NRAS* are observed in a high proportion of melanomas. These mutations, which promote cellular proliferation and survival by activating the extracellular signal–regulated protein kinase (ERK) pathway, generally are mutually exclusive, since *BRAF* functions downstream of *RAS*. Also frequently seen is loss of function of the tumor suppressor *PTEN,* an important negative regulator of PI3K-AKT pathway, which also promotes growth and survival. Some melanomas, particular those arising in acral and mucosal sites, have activating mutations in the c-KIT receptor tyrosine kinase. Agents that selectively inhibit mutant BRAF and c-KIT have produced dramatic responses in patients with metastatic tumors with BRAF and c-KIT mutations, respectively, an encouraging example of molecularly targeted therapy in an otherwise hopeless disease.

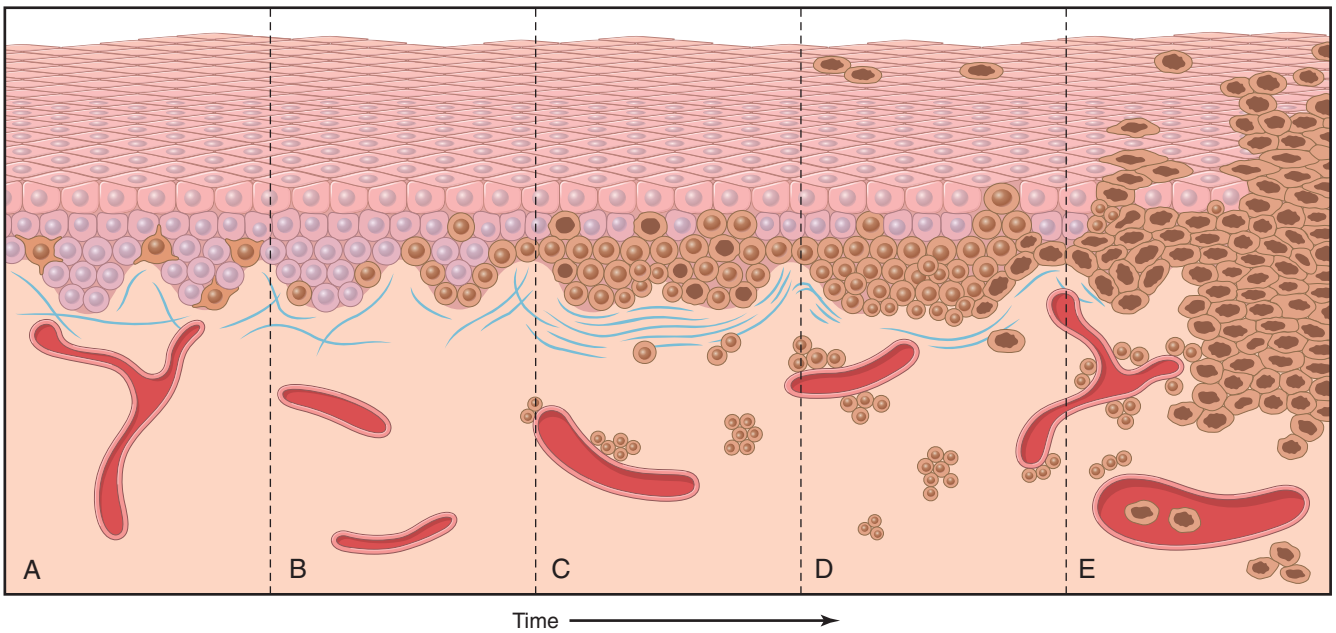

**Figure 23–21** Possible steps in development of melanoma. **A,** Normal skin shows only scattered melanocytes. **B,** Lentiginous melanocytic hyperplasia. **C,** Lentiginous compound nevus with abnormal architecture and cytologic features (dysplastic nevus). **D,** Early or radial growth phase melanoma (*large dark cells* in epidermis) arising in a nevus. **E,** Melanoma in vertical growth phase with metastatic potential. Note that no melanocytic nevus precursor is identified in most cases of melanoma. They are believed to arise de novo, perhaps all using the same pathway.

## MORPHOLOGY

Unlike benign nevi, melanomas exhibit **striking variations in pigmentation,** including shades of black, brown, red, dark blue, and gray (Fig. 23–22, *A*). The **borders are irregular** and often "notched."

Microscopically, malignant cells grow as poorly formed nests or as individual cells at all levels of the epidermis (pagetoid spread) and in expansile dermal nodules; these constitute the radial and vertical growth phases, respectively (Fig. 23–22, *B* and *C*). Of note, superficial spreading melanomas are often associated with a brisk lymphocytic infiltrate (Fig. 23–22, *B*), a feature that may reflect a host response to tumor-specific antigens. **The nature and extent of the vertical growth phase determine the biologic behavior of melanomas.** By recording and using these and other variables in aggregate, accurate prognostication is possible.

Individual melanoma cells usually are considerably larger than nevus cells. They have large nuclei with irregular contours, chromatin that is characteristically clumped at the periphery of the nuclear membrane, and prominent "cherry red" eosinophilic nucleoli (Fig. 23–22, *D*). Immunohistochemical stains can be helpful in identifying metastatic deposits (Fig. 23–22, *D, inset*).

### Clinical Features

Although most of these lesions arise in the skin, they also may involve the *oral* and *anogenital mucosal surfaces,* the *esophagus,* the *meninges,* and the *eye.* The following comments apply to cutaneous melanomas.

Melanoma of the skin usually is asymptomatic, although pruritus may be an early manifestation. *The most important clinical sign is a change in the color or size of a pigmented lesion.* The main clinical warning signs are

1. Rapid enlargement of a preexisting nevus
2. Itching or pain in a lesion
3. Development of a new pigmented lesion during adult life
4. Irregularity of the borders of a pigmented lesion
5. Variegation of color within a pigmented lesion

These principles are expressed in the so-called ABCs of melanoma: *a*symmetry, *b*order, *c*olor, *d*iameter, and *e*volution (change of an existing nevus). It is vitally important to recognize melanomas and intervene as rapidly as possible. The vast majority of superficial lesions are curable surgically, while metastatic melanoma has a very poor prognosis.

The probability of metastasis is predicted by measuring the depth of invasion in millimeters of the vertical growth phase nodule from the top of the granular cell layer of the overlying epidermis (Breslow thickness). Metastasis risk also is increased in tumors with a high mitotic rate and in those that fail to induce a local immune response. When metastases occur, they involve not only regional lymph nodes but also liver, lungs, brain, and virtually any other site that can be seeded hematogenously. Sentinel lymph node biopsy (of the first draining node[s] of a primary melanoma) at the time of surgery provides additional information on biologic aggressiveness.

In some cases, metastases may appear for the first time many years after complete surgical excision of the primary tumor, suggesting a long phase of dormancy, during which time the tumor may be held in check by the host immune response. Recognition of the likely role of the host immune response has led to therapeutic trials of immunomodulators. Some impressive responses in patients with advanced

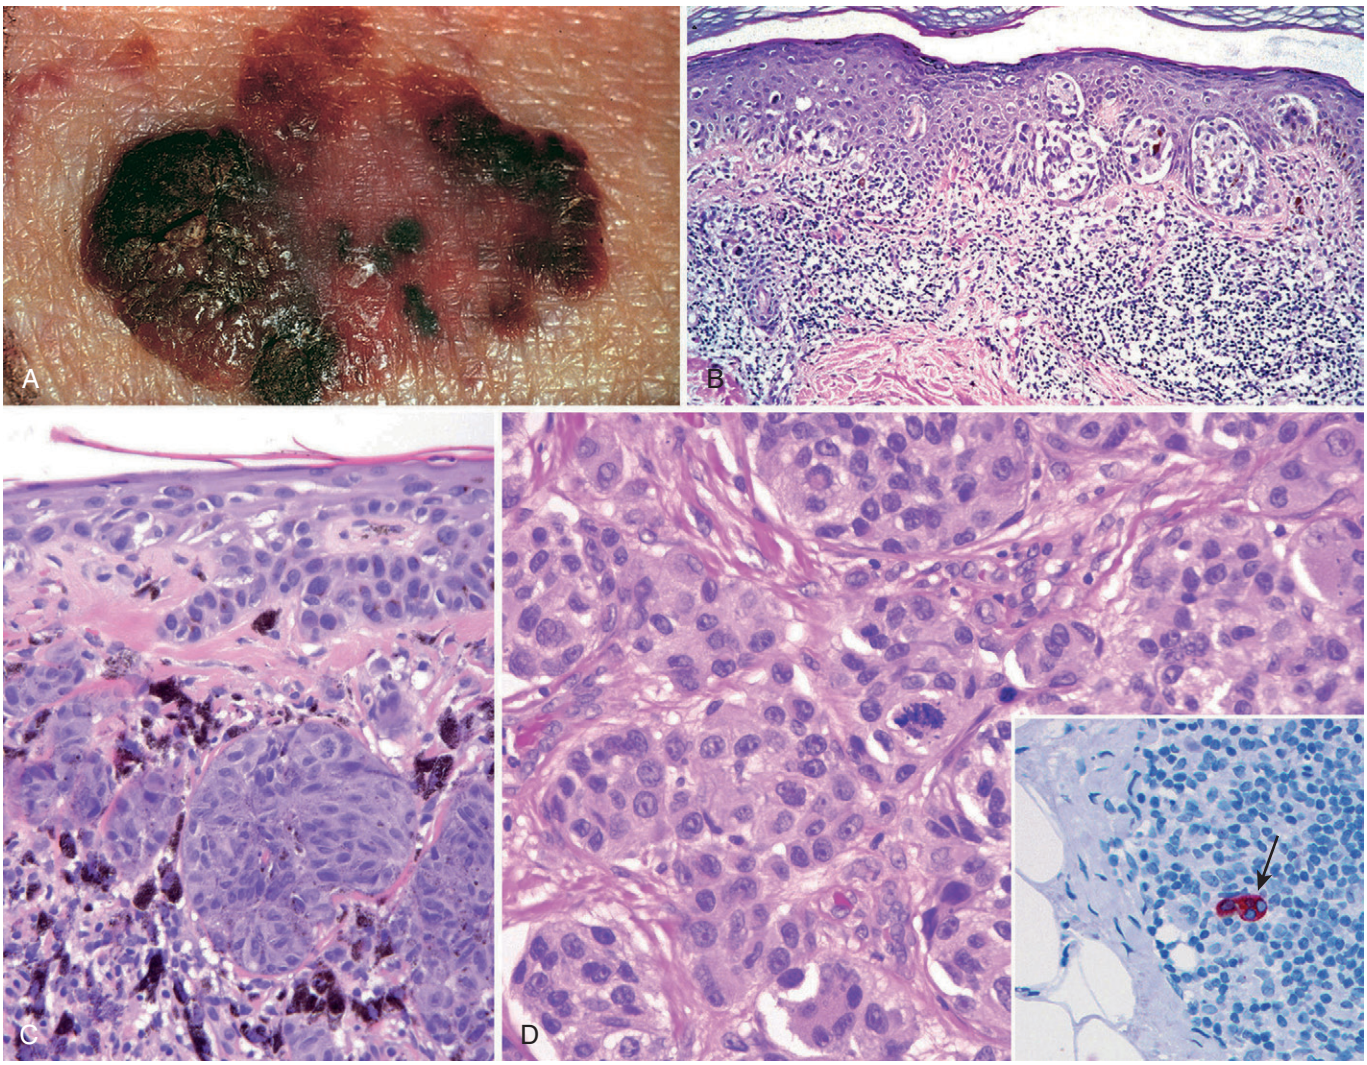

**Figure 23–22** Melanoma. **A,** On clinical evaluation, lesions tend to be larger than nevi, with irregular contours and pigmentation. Macular areas indicate early superficial (radial) growth, while elevated areas often indicate dermal invasion (vertical growth). **B,** Radial growth phase, with spread of nested and single-cell melanoma cells within the epidermis. **C,** Vertical growth phase, with nodular aggregates of infiltrating tumor cells within the dermis (epidermis is on the *right*). **D,** Melanoma cells have hyperchromatic nuclei of irregular size and shape with prominent nucleoli. Mitoses, including atypical forms such as seen in the center of this field, often are encountered. The *inset* shows a sentinel lymph node containing a tiny cluster of metastatic melanoma cells (*arrow*), detected by staining for the melanocytic marker HMB-45.

melanoma have been seen, especially to antibodies that block endogenous inhibitors of immune responses such as CTLA-4 and PD-1, and thus "release the brakes" on host antitumor immunity.

## SUMMARY

### Melanocytic Lesions, Benign and Malignant

- Most *melanocytic nevi* have activating mutations in *BRAF* or less often *NRAS*, but the vast majority never undergo malignant transformation.
- Most sporadic *dysplastic nevi* are best regarded as markers of melanoma risk rather than premalignant lesions. They are characterized by architectural and cytologic atypia.
- *Melanoma* is a highly aggressive malignancy; tumors only a few millimeters in thickness can give rise to deadly metastases.
- In most cases, melanoma progresses from an intraepithelial (in situ) to an invasive (dermal) form. Characteristics of the dermal tumor such as depth of invasion and mitotic activity correlate with survival.

immunohemolytic anemias as 418
Anemia, folate deficiency
clinical features of 423
as megaloblastic anemia 422–423
pathogenesis of 422b
Anemia, immunohemolytic
cold antibody immunohemolytic anemias and 418
as hemolytic anemia 417–418, 417t
summary for 419
warm antibody immunohemolytic anemias and 417–418
Anemia, pernicious 423, 423b. *See also* Vitamin $B_{12}$ deficiency anemia
Anemia, warm antibody immunohemolytic 417–418
Aneuploidy 175
Aneurysm 344–348, 344f
pathogenesis of 344b–345b, 345f
summary for 348b
Aneurysm, berry 330
Aneurysm, saccular 817–818, 818f
morphology of 818b, 818f
Angelman syndrome 243–245, 244f
Angina, unstable 376
Angina pectoris 376
Angiodysplasia 576
Angiogenesis
growth factors involved in 67
scar formation and 66–67, 67f
Angiogenesis, sustained
development of 191–192
summary for 192b
Angiosarcoma 361–362, 361f
morphology of 362b
Anitschkow cells 391b
Annular pancreas 646
Anorexia nervosa 295–296

Antibody-mediated disease
hypersensitivity reactions and 111, 114–115, 114t
mechanisms of 114–115, 115f
summary for 114b
Anti-endothelial cell antibody 350
Antigen-presenting cell (APC)
dendritic cells as 104
immune system and 104
other cells as 104
summary for 105
Anti-inflammatory drugs
prostaglandin production blockage by 46–47
Anti-neutrophil cytoplasmic antibody (ANCA) 349–350
Antiphospholipid antibody syndrome 87–88
Antitumor effector mechanism
cytotoxic T lymphocytes as 206
humoral mechanisms as 206–207
macrophages as 206
natural killer cells as 206
Aortic stenosis, calcific
clinical features of 390
degenerative valve disease and 389–390
morphology of 389f, 390b
Aortic valve sclerosis 390b
Aphthous ulcers (canker sores) 552, 552f
Apoptosis
causes of
in pathologic conditions 18
in physiologic situations 18
cell death and 18–22
evasion of cell death and 189f
summary for 190b
examples of 20–22
mechanisms of
activation and function of caspases as 19
clearance of apoptotic cells and 20
death receptor pathway of 19
introduction to 19–20, 20f
mitochondrial pathway of 19
morphology of 18b, 19f
summary of 22b
TP53 gene and 187b
Apoptotic cell, clearance of 20
Appendicitis, acute
the appendix and 600–601
clinical features of 601
morphology of 601b
pathogenesis of 600b–601b
Appendix
acute appendicitis and 600–601
summary for 601b
tumors of 601
Arachidonic acid (AA) metabolite 46–47, 46t, 47f, 50
Arbovirus 827
morphology of 827b, 827f
Arrhythmia
heart disease and 385–386
myocardial infarction complications and 384
sudden cardiac death and 386
summary for 386b
Arrhythmogenic right ventricular cardiomyopathy (ARVC)
dilated cardiomyopathy as 399–400, 399f
Arsenic 275–276
Arteriolosclerosis, hyaline 333b–334b
diabetes and 744, 746–747, 746f
Arterionephrosclerosis
as blood vessel disease of the kidney 539
clinical course of 539
morphology of 539b, 539f
pathogenesis of 539b
summary for 541
Arteriosclerosis 335
Arteriovenous (AV) fistula 330
Arteritis, Takayasu
clinical features of 351–352
morphology of 351b
vasculitis and 351–352, 351f
Arthritis
gout as 786–789
infectious arthritis as 789–790
juvenile rheumatoid arthritis as 786
osteoarthritis and 782–783
rheumatoid arthritis as 784–786
seronegative spondyloarthropathies as 786
summary for 790b
Arthritis, chronic tophaceous 786b–787b, 787f
Arthritis, infectious
the joints and 789–790
Lyme arthritis as 789–790
suppurative arthritis as 789
Arthritis, Lyme 789–790
Arthritis, suppurative 789
Asbestosis
clinical features of 477–478
morphology of 477b, 477f–478f
pathogenesis of 477b
as pneumoconiosis 477
summary for 478
Aschoff bodies 391b
Ascites
pathogenesis of 609b
and portal hypertension 609
Ascorbic acid. *See* Vitamin C
Aseptic meningitis 825
Aspergillus fumigatus 829
Aspiration pneumonia 488t, 492
Aspirin (acetylsalicylic acid) 284
Aspirin toxicity, chronic (salicylism) 284
Asthma
clinical features of 470
morphology of 469f–470f, 470b
as obstructive lung disease 468–470
pathogenesis of 468b, 469f
summary for 470b
types of 468–470
Asthma, atopic 468
Asthma, drug-induced 470
Asthma, non-atopic 468–470
Astrocytoma 842–843
morphology of 842b, 843f
Astrocytoma, diffuse 842
Asymptomatic hematuria 518
Atelectasis, compression 460
Atelectasis, contraction 460
Atelectasis of lung 460, 460f
Atherosclerosis. *See also* Atherosclerotic plaque
blood vessels and 335–343, 336f
clinical consequences of 342–343, 342f
epidemiology of
additional risk factors for 337–338, 338f
constitutional risk factors for 336
discussion of 335–338, 336t
modifiable major risk factors for 336–337, 337f
morphology of 340b–342b, 340f–341f
pathogenesis of 338b–340b, 339f
summary for 343b–344b

Atherosclerotic plaque
acute plaque change and 342–343, 342f–344f
atherosclerosis morphology and 340b–342b, 341f
Atherosclerotic stenosis 342
ATP, depletion of 12–13, 13f, 16
Atrial septal defect (ASD)
clinical features of 369t, 371
left-to-right shunts and 370–371
morphology of 371b
Atrophy 4–5, 4f
summary for 5b
Atypical adenomatous hyperplasia (AAH) 506b–509b
Autoimmune disease
immune system and 120–135, 121t
immunologic tolerance and 121–122
inflammatory myopathies and 135
mechanisms of autoimmunity and 122–125
mixed connective tissue disease and 135
polyarteritis nodosa/other vasculitides and 135
rheumatoid arthritis 131
Sjögren syndrome and 131–132
systemic lupus erythematosus and 125–131
systemic sclerosis and 132–134
Autoimmune regulator (AIRE) 121
Autoimmunity
genetic factors in 123, 123t–124t
infections and tissue injury and 123–125
mechanisms of 122–125, 123f
self antigens and 110
summary for 124b
Autophagy 22–23, 23f
evasion of cell death and 190
Autosomal dominant cancer syndrome 171–172, 172t
Autosomal dominant inheritance disorder 219–220
Autosomal dominant polycystic kidney disease
clinical course of 543–544
cystic diseases and 542–544
morphology of 543b, 543f
pathogenesis of 542b–543b
summary for 544
Autosomal recessive inheritance disorder 220
Autosomal recessive syndrome
of defective DNA repair 172
Autosplenectomy 412b–413b
Axonal neuropathy 797, 800

B

Bacillary angiomatosis 359, 359f
Bacteria 311–313, 311f–312f, 312t
normal microbiome and 313
Bacterial injury, mechanisms of
adherence to host cells as 320
bacterial toxins as 321, 321f
bacterial virulence as 320
virulence of intracellular bacteria as 320–321
Bacterial meningitis. *See* Pyogenic meningitis, acute
Bacterial pyelonephritis 438b–439b
Balanced translocation 174, 177
Barrett esophagus
clinical features of 562, 564
morphology of 561–562, 561b–562b, 561f
Barrett metaplasia 133–134
Basal cell carcinoma
clinical features of 864
malignant epidermal tumors and 864
morphology of 864b, 865f
pathogenesis of 864b
B cell
HIV infection progression and 149
systemic sclerosis and 127t, 133
B cell non-Hodgkin lymphoma 152
Becker muscular dystrophy (BMD)
clinical features of 803–804
dystrophinopathy and 802–804
morphology of 802b, 804f
pathology of 802b–803b, 802f
Benign prostatic hyperplasia (BPH)
clinical features of 664–665
diseases of the prostate and 664–665
morphology of 664b, 665f
summary for 665b
Beta cell dysfunction 743
Beta cell tumor. *See* Insulinoma
Bile acid 605–606. *See also* Bilirubin
Biliary atresia
clinical course of 642–643
extrahepatic bile ducts and 642–643
Biliary cirrhosis, secondary 642
Bilirubin
jaundice/cholestasis and 605–606, 605f
pathogenesis of 606b, 606t
Bioterrorism 315, 315t
Blastomycosis 499–500
Bleeding disorder
coagulation disorders as 454–455
disseminated intravascular coagulation as 450–452
hematopoietic system and 449–455
summary of 456b
thrombocytopenia as 452–454
Blistering (bullous) disorder
bullous pemphigoid as 859–861
dermatitis herpetiformis as 861
pemphigus as 858–859
the skin and 857–861, 858f
summary for 862b
Blood flow, abnormal 86
Blood flow into liver, impaired
hepatic artery inflow as 632
portal vein obstruction and thrombosis as 632–633
Blood flow through liver, impaired
circulatory disorders and 633
passive congestion and centrilobular necrosis as 633
Blood pressure regulation 330–331, 331f–332f
summary for 331b
Blood vessel
aneurysms/dissections and 344–348
arteriosclerosis and 335
atherosclerosis and 335–343
blood pressure regulation and 330–331
congenital anomalies and 330
disease of the kidney
arterionephrosclerosis as 539
introduction to 538–541
malignant hypertension as 539–540
summary for 541b
thrombotic microangiopathies as 540–541
disorders of hyperactivity of
myocardial vessel vasospasm as 355
Raynaud phenomenon as 355
disorders of hyperreactivity of 355
hypertensive vascular disease and 332–333
structure and function of 327–330, 328f
endothelial cells and 329–330
summary for 330b
vascular smooth muscle cells and 330

tumors and 357–362
vascular intervention pathology and 362–363
vascular wall response to injury and 334–335
vasculitis and 348–355
veins/lymphatics and 356–357
B lymphocyte 101f, 105, 124
activation of 108–109
Body mass index (BMI) 303
Bone disease, acquired
hyperparathyroidism as 771
osteoporosis as 768–770
Paget disease as 770–771
rickets and osteomalacia as 771
summary for 772b
Bone-forming tumor
osteoid osteoma and osteoblastoma as 776
osteoma as 775–776
osteosarcoma as 776–777
Bones
acquired diseases of 768–771
congenital disorders of cartilage and 767–768
fractures of 772–773
introduction to 765–781, 766f
osteomyelitis and 773–774
osteonecrosis and 773
tumors of 774–781
Bowel, vascular disorders of
hemorrhoids as 576
intestines and 574–576
ischemic bowel disease as 574–576
summary for 576b
Brain abscess 826
morphology of 825f, 826b
Brain injury, perinatal 822–824, 824f
summary for 824b
Breast
of the female
fibrocystic changes of 705–706
breast carcinoma and 706
nonproliferative changes and 705
proliferative changes and 705–706
summary for 707b
inflammatory processes and 707
morphology of 707b
introduction to 704–714, 704f
tumors of 707–713
lesions of the male 714
Breast carcinoma, noninvasive 710
Brenner tumor 698
Bronchiectasis
clinical features of 472
morphology of 471b, 471f
as obstructive lung disease 470–472
pathogenesis of 471b
Bronchiolitis, chronic 467b–468b
Bronchiolitis obliterans organizing pneumonia (BOOP). *See* Pneumonia, cryptogenic organizing
Bronchitis, chronic
clinical features of 467
morphology of 467b, 467f
as obstructive lung disease 467
pathogenesis of 467b
summary for 467b–468b
Bruton disease. *See* X-linked agammaglobulinemia (XLA)
Budd-Chiari syndrome. *See* Hepatic vein thrombosis
Buerger disease. *See* Thromboangiitis obliterans
Bulimia 295–296
Bullous emphysema 466
Bullous pemphigoid
blistering disorders and 859–862
clinical features of 861
morphology of 860b–861b, 860f
pathogenesis of 860b
Burkitt lymphoma
clinical features of 437
immunophenotypic features of 437
lymphoid neoplasms 436–437
morphology of 437b, 437f
pathogenesis of 436b–437b
summary for 443

C

Cachexia, cancer and 208–209
Cadmium 276
Calcification, dystrophic 13f, 25–26
Calcification, pathological
apoptosis and 9, 25–26
dystrophic calcification as 25–26
metastatic calcification as 26
morphology of 26b
summary for 26b
Calcium, influx of 13, 14f, 16
Calculous cholecystitis, acute 641, 643
Campylobacter enterocolitis
clinical features of 583
infectious enterocolitis and 582–583
morphology of 582b, 582f
pathogenesis of 582b
Cancer
of the bladder
clinical features of 670–671
morphology of 667f, 669b–670b, 669f–670f, 670t
neoplasms of the bladder and 669–671
pathogenesis of 669b
diet and 306
environmental radiation and 292–293
epidemiology of
acquired preneoplastic lesions and 172
age and 171
geographic/environmental variables for 170–171
heredity and 171–172
incidence of 170, 170f
summary for 173b
etiology of 198–204
hallmarks of 161–162
introduction to 161–162
laboratory diagnosis of
molecular diagnosis of 211
molecular profiling of 211–213
morphologic methods for 210–211
summary of 213b
tumor markers and 211
neoplasia and 169–172
obesity and 305
occupational radiation and 293
Cancer, familial 172–173
Cancer, genetic lesions in
cancer-associated mutations and 173–176
epigenetic modifications and 175–176
karyotypic changes and 173–175
microRNAs and 175
summary for 176b–177b
Candida albicans 829

Candidiasis
clinical features of 502–503
morphology of 502b, 503f
as opportunistic fungal infection 502–503
Canker sores. *See* Aphthous ulcers
Capillary hemangioma 358, 358f
Carbon monoxide (CO) 273
morphology of poisoning by 273b
Carcinogenesis
ionizing radiation and 290
molecular basis of cancer and 173
multistep process of
ability to invade or metastasize and 192–195
cancer progression and 198, 199f
development of sustained angiogenesis and 191–192
evasion of cell death and 189–190
evasion of immune system and 196
genomic instability as enabler and 196–197
insensitivity to growth inhibitory signals and 182–188
limitless replicative potential and 190–191
neoplasia and 177, 177f–178f
reprogramming energy metabolism and 195–196
self-sufficiency in growth signals and 178–182
tumor-promoting inflammation as enabler and 197–198
Carcinogenic agent
chemical carcinogens as 199–200
etiology of cancer and 198–204
radiation carcinogenesis and 200–201
viral and microbial oncogenesis and 201–204
Carcinoid heart disease
morphology of 395b, 396f
pathogenesis of 395b
valvular heart disease and 394f
Carcinoid tumor
of the lung 510–511
morphology of 510b, 511f
of the stomach and 571–573
clinical features of 571–572
morphology of 571b, 572f
Carcinoma
of the adrenal cortex 753b–754b, 754f
of the cervix
cervical neoplasms as 687–688
clinical course of 688
morphology of 688b, 688f
of the female breast
clinical course of 712–713
discussion of 708–713
epidemiology and risk factors of 708–713, 708t
pathogenesis of 709b–710b
summary for 713b–714b
of the gallbladder
clinical features of 643
introduction to 643
morphology of 643b, 643f
of the larynx
and laryngeal tumors 514, 514f
of the lung
clinical course of 510
etiology and pathogenesis of 505b–506b
lung tumors as 505–510, 505t
morphology of 506b–509b, 507f–509f, 509t, 710b–712b
summary for 510b
of the male breast 714
of the prostate
clinical features of 667–668
introduction to 665–668
morphology of 666b–667b, 666f–667f
pathogenesis of 666b
summary for 668b
of the thyroid
anaplastic carcinoma and 734
follicular carcinoma and 733–734
introduction to 730–735
medullary carcinoma and 734–735
papillary carcinoma and 732–733
pathogenesis of 731b–732b, 731f
summary for 735b
of the vulva 683
morphology of 683b
summary of 684
Carcinoma, chromophobe-type renal cell 548b
Carcinoma, embryonal (of testis) 660b–662b, 661f
Carcinoma, endometrial
clinical course of 692
HRT and 282–283
morphology of 692b, 693f
obesity and 305
oral contraceptives and 283
pathogenesis of 692b
proliferative lesions and 692
summary for 692b–693b
Carcinoma, endometrioid 692b, 693f
Carcinoma, follicular
carcinomas and 733–734
morphology of 733b, 733f
pathogenesis of 731
summary for 734–735
Carcinoma, invasive 711–712
Carcinoma, invasive ductal 711–712, 711f
Carcinoma, invasive lobular 711–712
Carcinoma, large cell
lung tumors and 506b–509b
Carcinoma, lymphoepithelioma-like 457b
Carcinoma, medullary 711–712, 712f
of the thyroid
clinical features of 734–735
introduction to 734–735
morphology of 734b, 734f–735f
pathogenesis of 731–732
summary for 735
Carcinoma, tubular 711–712
Cardiac angiosarcoma 405
Cardiac cirrhosis 368
Cardiac transplantation 405, 405f
rejection of 402f, 405
Cardiac tumor 404–405
Cardiac tumor, primary 404–405
Cardiac valve, mechanical 395
Cardiogenic shock 94
Cardiomyopathy
dilated cardiomyopathy as 397–400
heart disease and 396–403, 397f, 397t
hypertrophic cardiomyopathy as 400–401
myocarditis as 401–403
restrictive cardiomyopathy as 401
summary for 403b
Carpal ligaments of wrist 157–158
Carrier state, viral hepatitis and 620
Cartilage-forming tumor
bone tumors and 777–779
chondroma as 778
chondrosarcoma as 778–779
osteochondroma as 777–778
Caspases, activation and function of 19
Caspases, executioner 189

Cat-scratch disease 428
morphology of 428b
Cavernous hemangioma 358f, 359
CD4+ T cell
HIV life cycle and 147, 147t, 149
inflammatory reactions and 106f, 118–119, 120b
T lymphocyte effector function and 107–109
Celiac disease
clinical features of 579
and malabsorptive diarrhea 577–579
morphology of 578b–579b, 579f
pathogenesis of 578b, 578f
summary for 580
Celiac sprue. *See* Celiac disease
Cell cycle, normal 180–182, 181f, 185f
Cell cycle control protein 182
Cell death. *See also* Apoptosis
overview of 6
Cell death, evasion of 189–190, 189f
autophagy and 190
summary for 190b
Cell-derived mediator
arachidonic acid metabolites as 46–47, 46t, 47f
chemical mediators/regulators of inflammation and 46–49
cytokines as 48–49
lysosomal enzymes of leukocytes as 49
neuropeptides as 49
nitric oxide as 49
platelet-activating factor as 47–48
reactive oxygen species as 49
summary of 50b
vasoactive amines as 46–49
Cell injury
causes of 6–7
clinicopathologic correlation examples for
chemical injury as 17–18
ischemia-reperfusion injury as 17
ischemic and hypoxic injury as 17
mechanisms of
accumulation of oxygen-derived free radicals as 14–15
damage to DNA and proteins as 16
defects in membrane permeability as 16
depletion of ATP as 12–13
influx of calcium as 13
introduction to 11–16, 12f
mitochondrial damage and dysfunction as 13
summary for 16b
morphology of
introduction to 6f, 7t, 8–11, 8f
necrosis and 9
patterns of tissue necrosis and 9–11
reversible injury and 8
summary for 11b
morphology of cell and tissue injury and 2f, 8, 11
overview of 6
reversible injury and
morphology of 6f, 8b–9b, 9f
Cell proliferation
control of 59, 59f
Cellular adaptation to stress
atrophy as 4–5
hyperplasia as 4
hypertrophy as 3–4
metaplasia as 5
summary for 5b
Cellular aging 26–28, 27f
cell injury and 7
summary for 28b
Cellular event, leukocyte recruitment/activation as 34–39
Cellular protein, overexpressed 205
Cellular rejection, acute 137f, 138
Cellular response
to stress and noxious stimulus 1–3, 2f
Central nervous system (CNS)
acquired metabolic and toxic disturbances of 835–836
AIDS involvement and 152–153, 152b
cerebrovascular disease of 814–819
congenital malformations/perinatal brain injury and 822–824
edema, herniation, hydrocephalus and 812–814
HIV pathogenesis and 149
infections of 824–831
neurodegenerative diseases and 836–841
patterns of injury in 811
primary disease of myelin and 832–834
SLE morphology and 130
trauma and 820–822
tumors of 842–847
Central neurocytoma 844

Centriacinar emphysema 464, 464f, 465b
Centric pancreatitis, idiopathic duct 650b
Centrilobular hepatic necrosis 284
Centrilobular necrosis
circulatory disorders of liver and 633
morphology of 633b, 633f
Cerebral amyloid angiopathy (CAA) 817
Cerebral ischemia, focal 815–816, 816f, 819
morphology of 812f, 816b–817b
Cerebral toxoplasmosis 829–831
morphology of 829b–830b, 830f
Cerebrovascular disease
central nervous system and 814–819
hypoxia, ischemia, infarction and 814–816
intracranial hemorrhage and 817–818
other vascular diseases of 819
summary of 819b
Cervical intraepithelial neoplasia (CIN) 686, 686t, 687b
Cervical neoplasia
cervical pathology and 685–689, 685f
invasive carcinoma as 687–688
morphology of 687b, 687f–688f
pathogenesis of 685b–686b, 686f
summary of 688b–689b
Cervicitis
cervical pathology and 685
morphology of 685b
sexually transmitted diseases and
summary for 676b
Cervix
cervicitis and 685
neoplasia of 685–689
pathology of 685–689
Chagas myocarditis 402b, 402f
Chamber dilation 384
Chancroid (soft chancre)
morphology of 677b
sexually transmitted disease and 677
summary for 677b
Channelopathy 805
Chemical agent
cell injury and 7
toxicity of 271–272
Chemical carcinogen
direct-acting agents as 199
etiology of cancer and 199–200, 199t

Chemical carcinogen *(Continued)*
indirect-acting agents as 171t, 199–200
mechanisms of action of 200
summary for 200b
Chemical (toxic) injury 17–18
Chemical mediator, inflammation and 44–53, 45f, 45t
Chemokines 48–49
Chemotaxis 36–37, 37f
Chlamydia 311–313
Chloracne 276–277
Cholangiocarcinoma
clinical features of 644
extrahepatic biliary ducts and 643–644
morphology of 644b, 644f
Cholangitis 642
Cholecalciferol 298–299
Cholecystitis
acute acalculous cholecystitis and 641
chronic cholecystitis and 641–642
clinical features of 641–642
inflammation of gallbladder as 641–642
morphology of 641b
Cholecystitis, chronic 641–642
Choledocholithiasis 642
Cholelithiasis (gallstones)
clinical features of 641
gallbladder diseases and 639–641, 643
morphology of 640b, 640f
pathogenesis of 639b–640b
Cholera
clinical features of 582
infectious enterocolitis and 582
pathogenesis of 582b
Cholestasis. *See also* Jaundice
liver disease and 605–606
of sepsis 626–627, 626f
summary for 606b
Cholestasis, drug/toxin-induced 629
Cholestasis, neonatal 626
Cholestatic liver disease
cholestasis of sepsis as 626–627
drug/toxin-induced cholestasis as 628–629
introduction to 626–629
neonatal cholestasis as 626
primary biliary cirrhosis as 627
primary sclerosing cholangitis as 628–629
Cholesterol 23
Cholesterol metabolism, normal 222–223, 222f
Cholesteryl esters 23
Chondrocalcinosis. *See* Pseudogout
Chondroma
as cartilage-forming tumor 778
clinical features of 778
morphology of 778b
pathogenesis of 778b
Chondrosarcoma
as cartilage-forming tumor 778–779
clinical features of 778–779
morphology of 778b, 779f
summary for 782
Choriocarcinoma 660b–662b, 661f
Choristoma 163, 257
Chromosomal disorder 236–237, 249–250
Chronic inflammatory demyelinating polyneuropathy (CIDP) 799, 800f
Chronic lymphocytic leukemia (CLL)
clinical features of 434
immunophenotypic and genetic features of 434
as lymphoid neoplasms 433–434
morphology of 434b, 434f
pathogenesis of 433b–434b
summary for 443
Chronic myelogenous leukemia (CML)
clinical features of 447
morphology of 446b
as myeloproliferative disorder 446
pathogenesis of 446b, 446f
protein-coating gene mutations and 216
Churg-Strauss syndrome 354
Chylothorax 511–512
Circulatory disorder
hepatic outflow obstruction as 634
impaired blood flow into the liver as 632–633
impaired blood flow through the liver as 633
the liver and 632–634, 632f
summary for 634b
Cirrhosis
chronic alcoholism and 281
clinical features of 608
liver disease and 606–607
obesity and 305
pathogenesis of 607b–608b, 608f
summary for 608b
Cirrhosis, posthepatitic 611b–614b
Climate change, health effects of 270f
Clotting factor, activation of 80
Coagulation 51–52, 51f, 52t
Coagulation cascade 83–86, 83f–84f
summary for 86b
Coagulation disorders
bleeding disorder and 454–455
deficiencies of factor VIII-von Willebrand factor complex as 454–455
Coagulation factor
inhibitory effects on 80, 81f
summary for 86b
Coal dust 277
Coal worker's pneumoconiosis (CWP)
clinical features of 475
morphology of 475b
as pneumoconiosis 474t, 475f
summary for 478
Coarctation, adult 373b, 374f
Coarctation, aortic
clinical features of 373–374
morphology of 373b
obstructive lesions and 373–374
Coarctation, infantile 373b
Cobalamin. *See* Vitamin $B_{12}$ deficiency anemia
Cocaine 284–285, 286f
Coccidioidomycosis 499–500
Colitis, indeterminate 591
Colitis, microscopic 580
Colitis, pseudomembranous
clinical features of 585
infectious enterocolitis and 584–585
morphology of 584b, 584f
Colitis, ulcerative
clinical features of 591
inflammatory bowel disease and 590–592
morphology of 590b–591b, 591f
Colitis-associated neoplasia 591–592
Collagen 63
Collagen vascular disease, pulmonary involvement in 474
Collapse of lung. *See* Atelectasis

Colloid carcinoma 711–712, 712f
Colloid goiter 728b
Colonic polyp
adenocarcinoma and 596–599
adenomas as 593–594
familial syndromes and 595–596
hamartomatous polyps as 592–593
hyperplastic polyps as 593
inflammatory polyps as 592
intestines and 592–599
summary for 600b
Comedo ductal carcinoma in situ 710, 710f
Complement protein 142
Complex multigenic disorder 234
Condyloma 683, 683f
Congenital adrenal hyperplasia (CAH). *See* Adrenogenital syndrome
Congenital anomalies
blood vessels and 330
etiology of 247–248, 247t
pathogenesis of 248b–249b
pediatric diseases and 245–248, 245t, 246f
summary for 249b
Congenital disorder (of cartilage and bone)
achondroplasia and thanatophoric dwarfism as 767
introduction to 767–768
osteogenesis imperfecta as 767
osteopetrosis as 767–768
summary for 768b
Congenital heart disease
clinical features of 370
the heart and 368–374, 369t
left-to-right shunts and 370–372
obstructive lesions as 373–374
pathogenesis of 369b, 369t
right-to-left shunts and 372–373
summary for 374b
Congenital syphilis 673–674
Congestion 75
morphology of 75b–76b, 76f
Congestive heart failure (CHF) 365–368, 366f
Congestive hepatomegaly 368
Congestive splenomegaly 368
Conidia 313
Connective tissue
deposition of 66f, 68
growth factors involved in 68
remodeling of 68
Connective tissue disease, mixed 135
Contact inhibition 187–188
Contractile dysfunction 383
Coombs test. *See* Human anti-globulin test
Copy number abnormality
array-based genomic hybridization and 264
fluorescence in situ hybridization and 264
molecular diagnosis of 263–264
Copy number variation (CNV) 216–217
Coronary artery occlusion 377
Cor pulmonale
morphology of 387f, 388b
pulmonary hypertensive heart disease as 388, 388t
Corticotroph cell 720. *See also* Adrenocorticotropic hormone producing adenoma
Crescendo angina. *See* Angina, unstable
Crescentic glomerulonephritis, anti-glomerular basement membrane antibody–mediated 532
morphology of 522f, 532b, 532f
Crescentic glomerulonephritis, Pauci-immune
clinical course of 533
morphology of 533b
as rapidly progressive glomerulonephritis 532–533
Crescentic glomerulonephritis, immune complex–mediated 532
morphology of 532b
Cretinism 723–724
Creutzfeldt-Jakob disease (CJD) 831
morphology of 831b, 832f
Crohn disease
clinical features of 590
morphology of 589b–590b, 589f–590f
summary for 592
Cryoglobulinemia 440
Cryptorchidism 658–659, 659b
Cryptococcosis
clinical features of 504
morphology of 503f, 504b
as opportunistic fungal infection 503–504
Cryptococcus neoformans 829, 830f
Cryptogenic fibrosing alveolitis. *See* Idiopathic pulmonary fibrosis (IPF)
Cushing syndrome
adrenocortical hyperfunction 752–755, 753f
clinical features of 754–755, 755f
morphology of 753b–754b, 754f
summary for 755b
Cyclin. *See also* Cyclin-dependent kinase (CDK)
alterations in cell cycle control proteins and 182
normal cell cycle and 180–182
self-sufficiency in growth signals and 180–182, 181f
Cyclin-dependent kinase (CDK)
alterations in cell cycle control proteins and 182
normal cell cycle and 180–181, 181f
self-sufficiency in growth signals and 178–182, 181f
Cyst
morphology of 705b, 705f
nonproliferative changes and 705
Cyst, dentigerous 557
Cyst, follicle 695
Cyst, luteal 695
Cyst, odontogenic 557–558
summary for 558b
Cyst, periapical 557–558
Cyst, simple 542
Cystic disease
autosomal dominant polycystic kidney disease and 542–544
autosomal recessive polycystic kidney disease and 544
of the kidney 542–544
medullary disease with cysts as 544
simple cysts and 542
summary for 544b
Cysticercosis 830
Cystic fibrosis (CF)
clinical course of 226–227, 226t
gene encoding mutations and 223–227
and malabsorptive diarrhea 577, 580
morphology of 224b–226b, 225f
pathogenesis of 223b–224b, 225f
summary for 227b
Cystic hygroma 255–257
Cytogenetic disorder
chromosomal disorders as 236–237
introduction to 234–241
involving autosomes 237–239
introduction to 237–239, 238f
22q11.2 deletion syndrome as 237–239

Cytogenetic disorder *(Continued)*
summary for 239b
trisomy 21 (Down syndrome) as 237
involving sex chromosomes 239–241
discussion of 239–241
Klinefelter syndrome as 239–240
summary for 241b
Turner syndrome as 240–241
numeric abnormalities as 235
structural abnormalities as 235–236
Cytokines 48–50, 48f
immune system messengers and 106–107
Cytologic (Papanicolaou) smear 210, 210f, 213
Cytomegalovirus (CMV) infection 828
cytomegalovirus mononucleosis as 501
immunosuppressed persons and 501
morphology of 501b, 501f
pneumonia and 500–501
Cytomegalovirus mononucleosis 501
Cytopathic-cytoproliferative reaction 324
morphology of 311f, 324b
Cytotoxic T lymphocyte (CTL)
as antitumor effector mechanisms 206
mediated apoptosis and 22

Death receptor pathway 19, 22
Degenerative joint disease. *See* Osteoarthritis
Degenerative valve disease
calcific aortic stenosis and 389–390
myxomatous mitral valve and 390–391
valvular heart diseases and 389–391, 389f
Delayed-type hypersensitivity (DTH) 117–119, 120f
Deletion, chromosomal 174–175
Demyelinating neuropathy 797, 798f
Dendritic cell (DC), HIV infection and 149
Dermatitis, acute eczematous
acute inflammatory dermatoses and 852–853
clinical features of 853
morphology of 853b, 853f
Dermatitis herpetiformis
blistering disorders and 861–862
morphology of 861b, 861f
pathogenesis of 861b, 861f
Dermatofibroma. *See* Histiocytoma, benign fibrous
Dermatomyositis 805, 806f
Dermatosis, acute inflammatory
acute eczematous dermatitis as 852–853
erythema multiforme as 853–854
summary for 856b
urticaria as 852
Dermatosis, chronic inflammatory
lichen planus as 855–856
lichen simplex chronicus as 856
psoriasis as 854–855
the skin and 854–856
summary for 856b
Dermatosis, infectious
bacterial infections as 856
fungal infections as 857
verrucae as 857
Desquamative interstitial pneumonia (DIP) 481
Diabetes mellitus
beta cell dysfunction and 743
classifications of 739, 740t
clinical features of 748–750, 749f, 750t
complications of 743–750, 745f
morphology of 744b–748b, 745f–746f
summary for 750b–751b
diagnosis of 739
endocrine pancreas and 739–750
genetic heterogeneity and 218–219
insulin resistance and 741–743
monogenic forms of 740t, 743, 750–751
in mothers 248
normal insulin physiology/glucose homeostasis and 739–740
pathogenesis of 741b
summary for 750b–751b
Diabetic embryopathy 248
Diabetic macrovascular disease 744

morphology of 678b
sexually transmitted disease and 678
summary for 678b–679b
Genital system, male
penis and 657–658
prostate and 663–668
scrotum, testis, and epididymis as 658–663
sexually transmitted diseases and 671–678
ureter, bladder, urethra as 663–668
Genome-wide association study (GWAS) 266–267
Genomic hybridization, array-based 264, 265f
Genomic imprinting
diseases caused by alterations of 243–244
summary for 245b
Genomic instability. *See also* Malignancy
Genomic instability, regulated 196–197
GERD (gastroesophageal reflux disease) 560–561, 564
Gestational choriocarcinoma 703
morphology of 703b, 703f
summary for 703
Gestational trophoblastic disease
diseases of pregnancy and 701–703
gestational choriocarcinoma as 703
hydatidiform mole as 701–702
invasive mole as 702–703
placental site trophoblastic tumor as 703
summary for 703b
Giant cell arteritis 350–351
clinical features of 351
morphology of 350b–351b, 350f
pathogenesis of 350b
Giant cell myocarditis 402b
Giant cell tumor of bone (GCT)
bone tumors and 781
clinical course of 781
morphology of 781b, 781f
summary for 782
Gilbert syndrome 606
Glioma
astrocytoma as 842–843
of brain parenchyma 842–844
ependymoma as 844
oligodendroglioma as 843
Global cerebral ischemia 814–815
morphology of 812f, 815b, 815f
Glomangiomas. *See* Glomus tumor (glomangiomas)
Glomerular disease
and the kidney 518–533, 519f–520f, 520t
mechanisms of injury and disease for 519–523
nephritic syndrome and 529–531
nephrotic syndrome and 523–528
rapidly progressive glomerulonephritis and 531–533
tubulointerstitial nephritis and 533–537
Glomerular injury
anti-glomerular basement membrane antibody–mediated glomerulonephritis as 521–522
glomerulonephritis caused by circulating immune complexes as 520
glomerulonephritis caused by in situ immune complexes as 520–521
mechanisms of 519–523, 521f
mediators of immune injury as 522–523, 522f
other mechanisms of glomerular injury as 522–523
summary for 523b
Glomerulonephritis
anti-glomerular basement membrane antibody–mediated 521–522, 521f–522f
caused by circulating immune complexes 522f
as glomerular injury 520, 522f
caused by in situ immune complexes 520–521
Glomerulonephritis, acute postinfectious
clinical course of 529
morphology of 529b, 530f
nephritic syndrome and 529
pathogenesis of 529b
summary for 531
Glomerulosclerosis, nodular 746–747, 746f–747f
Glomus tumor (glomangioma) 359
Glucose homeostasis 739–740. *See also* Insulin physiology, normal

pathogenesis of 840b
Hurler syndrome. *See* Mucopolysaccharidosis (MPS)
Hyaline membrane disease. *See* Respiratory distress syndrome (RDS)
Hyaluronan 64
Hydatid cyst 314
Hydatidiform mole
as gestational trophoblastic disease 701–702, 702t
morphology of 702b, 702f
summary for 703b
Hydrocephalus 812–813, 813f
summary for 814b
Hydronephrosis
clinical course of 546–547
morphology of 546b, 546f
pathogenesis of 546b
and urinary outflow obstruction 545–547
Hydrops, nonimmune 255–257
Hydrops fetalis 254, 255f, 256b, 257
Hydrostatic pressure 77, 77f
Hyperadrenalism. *See* Adrenocortical hyperfunction
Hyperaldosteronism
and adrenocortical hyperfunction 755–756
clinical features of 756
morphology of 755b–756b
Hypercholesterolemia 336–337
Hypercholesterolemia, familial
gene encoding mutations and 222–223
pathogenesis of 222b–223b
summary for 223b
Hypercoagulability 87–88, 87t
Hypercortisolism. *See also* Cushing syndrome
and adrenocortical hyperfunction 752–755, 753f
summary for 755b
Hyperemia 75
morphology of 75b–76b, 76f
Hyperglycemia 835
Hyperhomocysteinemia 337–338
Hyper-IgM syndrome 141, 143
Hyperlipidemia 336–337
Hyperparathyroidism
acquired bone disease as 771
clinical features of 737–738, 737t
morphology of 736b–737b, 736f–737f, 772b, 772f
and parathyroid glands 735–738
pathogenesis of 736b
secondary hyperparathyroidism and 738
summary for 738b
Hyperparathyroidism, secondary
clinical features of 738
introduction to 738
morphology of 738b
summary for 738
Hyperpituitarism
and the pituitary gland 717–720
(*See also* Pituitary adenoma)
summary for 719b
Hyperplasia
as adaptive response 1–2
hypertrophy and 3
stress and 4
summary for 5b
vitamin A and 298

Hyperplasia, endometrial 691–692, 691f
summary for 692b–693b
Hyperplasia, nodular
of the prostate 664–665
Hyperplastic arteriolosclerosis 333b–334b, 334f, 539b–540b
Hyperplastic polyp
colonic polyps and 593, 600
morphology of 593b, 594f
gastric polyps and 569, 572
morphology of 569b
Hypersensitivity, immediate (Type 1)
clinical and pathological manifestations of 113–114
introduction to 111–114
sequence of events in 111–113, 111f, 113f
Hypersensitivity, Type II. *See* Antibody-mediated disease
Hypersensitivity, Type III. *See* Immune complex disease (Type III hypersensitivity)
Hypersensitivity, Type IV. *See* T cell-mediated hypersensitivity (Type IV)
Hypersensitivity myocarditis 401b–402b
Hypersensitivity pneumonitis
clinical features of 481
as granulomatous disease 480–481, 480t
morphology of 481b, 481f
Hypersensitivity reaction
antibody-mediated diseases as 114–115
causes of 109–110
immediate hypersensitivity as 111–114
immune complex diseases as 115–117
summary for 120b
T cell-mediated hypersensitivity as 117–120
types of 110–111, 110t
Hypertension
epidemiology of 332–333
morphology of 333b–334b, 334f
pathogenesis of 333b, 333t
summary of 334b
Hypertension, malignant
as blood vessel disease of the kidney 539–540
clinical course of 540
morphology of 540b, 540f
pathogenesis of 539b–540b
summary for 541
Hypertensive cerebrovascular disease 819
Hypertensive heart disease
cor pulmonale as 388
the heart and 386–388
summary for 388b
systemic hypertensive heart disease as 387
Hypertensive heart disease, Systemic (left-sided)
clinical features of 387
introduction to 387
morphology of 387b, 387f
Hypertensive vascular disease 332–333
epidemiology of hypertension and 332–333
Hyperthermia 289
Hyperthyroidism
and the thyroid 722–723, 722f–723f, 722t
Hypertrophic cardiomyopathy (HCM)
cardiomyopathy as 400–401
clinical features of 400–401
morphology of 400b, 400f
pathogenesis of 400b
Hypertrophy
cellular adaptations to stress and 2f–3f
summary for 5b
Hypoadrenalism. *See* Adrenal insufficiency
Hypoadrenalism, secondary 758b
Hypocalcemia 299–300
Hypogammaglobulinemia 433b–434b, 434
Hypoglycemia 835
Hypogonadism, Klinefelter syndrome and 239–240
Hypoparathyroidism 738
Hypoperfusion thrombosis 97b
Hypophosphatemia 299
Hypopituitarism 720–721
Hypothermia 289
Hypothyroidism
pathogenesis of 725f
and the thyroid 723–724, 723t
Hypoventilation syndrome, obesity and 305
Hypovolemic shock 94
Hypoxia 814–816
Hypoxic injury 17

I

Idiopathic pulmonary fibrosis (IPF)
clinical features of 473
as fibrosing disease 472–473
morphology of 472b–473b, 473f
pathogenesis of 472b, 473f
Idiopathic pulmonary hemosiderosis 485
Idiopathic pulmonary hypertension 134
IgA nephropathy
clinical course of 531
morphology of 530b, 531f
nephritic syndrome and 530–531
pathogenesis of 530b
summary of 531
IgG4-related disease (IgG4-RD) 135
IL-1. *See* Interleukin-1 (IL-1)
Immature teratoma 258
Immune complex-associated vasculitis 350
Immune complex disease (Type III hypersensitivity)
examples of 116t
introduction to 111, 115–117
local immune complex disease as 117
morphology of 117b
summary for 117b
systemic immune complex disease as 116–117
Immune deficiency
diseases of
acquired immunodeficiency syndrome as 143–153
introduction to 139–153
primary immune deficiency as 139–143
secondary immune deficiency as 143
hematopoietic stem cell transplant and 139
with thrombocytopenia and eczema 142
Immune evasion
by microbes 322–323, 322f, 322t, 323b
by tumors 207
Immune response, normal
cell-mediated immunity and 105–108
decline of responses in 109
humoral immunity and 106–107
microbial antigens and 105
overview of 105–109
response to microbes of 105
summary for 109b
Immune surveillance 204, 207
summary for 207b
Immune system
amyloidosis and 153–158
autoimmune diseases of 120–135

cells and tissues of 100–104
antigen-presenting cells and 104
effector cells and 104
lymphocytes and 100–104
lymphoid tissues and 104
summary for 104b–105b
evasion of 196
hypersensitivity reactions of 109–120
immune deficiency diseases of 139–153
innate/adaptive immunity in 99–100
rejection of transplants by 135–139
Immune thrombocytopenic purpura (ITP) 452–453
summary for 456
Immunity, adaptive 99–100
summary for 109
Immunity, innate
genetic deficiencies of 142–143
immune system and 99–100, 100f
summary for 109
Immunocyte dyscrasias with amyloidosis 155
Immunocytochemistry 213
Immunodeficiency
infections and 325
morphology of 311f, 325b, 326f
Immunodeficiency, common variable 141, 143
Immunologic memory 109
Immunologic reactions, cell injury and 7
Immunologic tolerance 121–122, 122f
Immunosuppression 207
Impetigo
bacterial infections and 856
clinical features of 856, 857f
morphology of 856b
Imprinting 217
Imprinting, genomic 218
Inactive hypophosphorylated state 199
Indirect recognition pathway 136
Indoor air pollution 273
Industrial exposure, toxic agents and environmental pollutants and 276–277, 277t
Infarction
cerebrovascular diseases and 814–816
factors influencing development of 93
introduction to 92–93
ischemic cell death as 75
morphology of 92b–93b, 93f
pulmonary diseases of vascular origin and 482–483
summary for 94b
systemic embolization and 90
Infarction, right ventricular 384
Infarction, subendocardial 379
Infection
immunodeficiencies and 325
inflammatory responses to 323–325
of the nervous system 824–831
neuromuscular junction disorders and 801
Infectious agent
categories of 309, 310t
cell injury and 7
identification techniques for 314, 314t
Infectious disease
bioterrorism and 315
emerging types of 314–315
how microorganism cause disease and 319–322
identification techniques for agents of 314
immune evasion by microbes and 322–323
inflammatory responses to 323–325
microbial pathogenesis and 309–314
transmission/dissemination of microbes and 315–318
Infectious enterocolitis
campylobacter enterocolitis as 582–583
cholera as 582
diarrheal disease and 580–586, 581t
Escherichia coli as 583
norovirus as 585
parasitic disease as 585–586
pseudomembranous colitis as 584–585
rotavirus as 585
salmonellosis as 583–584
shigellosis as 583
summary for 586b
typhoid fever as 584
Infectious vasculitis 355
Inferior vena cava syndrome 356
Inflammasome 32–33, 32f
pyrin and 156
Inflammation
antibody-mediated disease mechanisms and 112f, 115
chemical mediators and regulators of 44–53, 45f, 45t
anti-inflammatory mechanisms of 52–53
cell-derived mediators as 46–49
plasma protein-derived mediators as 50–52
immunity and 100
systemic effects of 46t, 48f, 57–58, 426t
summary for 58
Inflammation, acute
anti-inflammatory mechanisms and 52–53
defects in leukocyte function and 40–41, 41t
introduction to 31–42, 31f
leukocyte-induced tissue injury and 39–40, 41t
leukocyte recruitment/activation and 34–39
microbe, necrotic cell, foreign substance recognition and 32–33, 32f
morphologic patterns of 43
morphology of 43b–44b
morphology of 43
outcomes of 41–42, 42f
plasma protein-derived mediators and 50–52
summary for 52b
stimuli for 31
summary for 42b
vascular changes and 33–34
summary for 34b
Inflammation, chronic
acute inflammation and 42
cells and mediators of 53–56
lymphocytes as 55
macrophages as 54–55
other cells as 55–56
granulomatous inflammation and 56
introduction to 30t, 31f, 53–56, 53f
morphology of 56b–57b
overview of 29–30, 53–56
response to infection and 325
morphology of 325b
summary for 57b
Inflammation, fibrinous 43, 43f
Inflammation, mediators of
immediate hypersensitivity and 112, 113t, 114
Inflammation, serous 43, 43f
Inflammation, suppurative 43, 44f
morphology of 323–325, 323b–324b
Inflammation, tumor producing 197–198

Inflammation and tissue repair, overview of 29–30, 30f
summary for 31b
Inflammatory bowel disease (IBD)
colitis-associated neoplasia as 591–592
Crohn disease as 589–590
epidemiology of 587–588
indeterminate colitis as 591
intestinal disease and 587–592, 587f, 587t
pathogenesis of 588b–589b, 588f
summary for 592b
ulcerative colitis as 590–591
Inflammatory carcinoma 711–712
Inflammatory disease, immune-mediated 110
polymorphisms and 234
Inflammatory intestinal disease
inflammatory bowel disease and 587–592
sigmoid diverticulitis as 586–587
Inflammatory mediator 81f, 83f, 95
Inflammatory response
infection and 323–325, 323f
summary for 325b–326b
Influenza infection 491
Influenza virus type A/HINI infection 491
Inherited metabolic disease
$\alpha_1$-antitrypsin deficiency as 631–632
hemochromatosis as 629–630
summary for 632b
Wilson disease as 630–631
Injury
by nontherapeutic toxic agent
drug abuse as 284–287
by physical agent
electrical injury as 289
ionizing radiation as 289–293
mechanical trauma as 287
thermal injury as 288–289
by therapeutic drugs
adverse drug reactions and 282–284
Injury, immune-mediated
hypersensitivity reactions for 109–120
Injury, reversible 8
morphology of 6f, 8b–9b, 9f
Insulinoma
morphology of 751b, 751f
and pancreatic neuroendocrine tumors and 751
Insulin physiology, normal 739–740, 740f. *See also* Glucose homeostasis
Insulin resistance
diabetes mellitus and 741–743
obesity and 742–743, 742f
summary for 750
Interface hepatitis 611b–614b
Interleukin-1 (IL-1) 48, 48f
Interstitial cystitis (ureter) 668
Interstitial lung disease, chronic
fibrosing diseases and 472–478
granulomatous diseases as 478–481
pulmonary eosinophilia as 481
restrictive and infiltrative types of 460f, 472–481, 472t
smoking-related interstitial diseases and 481
Interstitial nephritis, drug-induced
clinical course of 536–537
morphology of 536b, 536f
pathogenesis of 536b
summary for 537
tubulointerstitial nephritis and 536–537
Interstitium. *See* Tubules and interstitium, disease affecting
Intestinal obstruction
abdominal hernia as 574
Hirschsprung disease as 573–574
summary for 574b
Intestinal tuberculosis 497b
Intestine
colonic polyps/neoplastic disease and 592–599
diarrheal disease and 576–586
inflammatory intestinal disease and 586–592
intestinal obstruction and 573–574
vascular disorders of bowel and 574–576
Intimal thickening, vascular injury and 334–335, 335f
Intracellular accumulation 23–24, 24f
Intracranial hemorrhage
cerebral amyloid angiopathy as 817
cerebrovascular disease and 817–818
primary brain parenchymal hemorrhage as 817
subarachnoid hemorrhage and saccular aneurysms as 817–818
vascular malformations as 818
Intraductal papillary mucinous neoplasm (IPMN) 652f
Intraductal papilloma
morphology of 708b
as tumors of the breast 708
Intrinsic pathway 189–190
Invasion-metastasis cascade
extracellular matrix invasion and 192–194
introduction to 192–195, 193f
summary for 195b
vascular dissemination/homing of tumor cells and 194–195
Ion channel myopathy 805
Ionizing radiation
DNA damage/carcinogenesis of 290
effect on organ systems of 292–293
fibrosis and 290–291
injury produced by 289–293
morphology of 291b–292b
summary for 293b
total body irradiation and 293
Iron deficiency anemia
as anemia of diminished erythropoiesis 420–421, 420f
clinical features of 421, 421f
morphology of 421f
pathogenesis of 421b
summary for 424
Irritable bowel syndrome (IBS) 580
Ischemia
cerebrovascular diseases and
focal cerebral ischemia as 815–816
global cerebral ischemia as 814–815
Ischemia-reperfusion injury 17
Ischemic bowel disease
clinical features of 575–576
morphology of 575b, 575f
pathogenesis of 575b
summary for 576
vascular disorders of 574–576
Ischemic coagulative necrosis 92b–93b
Ischemic heart disease (IHD)
angina pectoris and 376
cardiac stem cells and 385
chronic ischemic heart disease 384–385
epidemiology of 375
the heart and 374–385
myocardial infarction and 377–384
pathogenesis of 375b–376b, 376f
summary for 385b

Ischemic heart disease, chronic
cardiomyopathies and 384–385
clinical features of 385
morphology of 384b
Ischemic injury 17
Ischemic necrosis. *See* Infarction
Islet cell tumor. *See* Pancreatic neuroendocrine tumor (PanNET)
Isolated IgA deficiency 141
Isolated-organ tuberculosis 497b

J
Jaundice
bilirubin/bile acids and 605–606
galactosemia and 228
liver disease as 605–606
Joint
arthritis and 782–790
Ehlers-Danlos syndrome and 221
introduction to 782–791
SLE morphology and 130
tumors and tumor-like lesions of 790–791
Juvenile rheumatoid arthritis (JRA) 786
the joints and 785–786

K
Kaposi sarcoma (KS)
clinical features of 360–361
discussion of 360–361
HIV and 152
morphology of 360b, 361f
pathogenesis of 360b
Kaposi sarcoma herpesvirus (KSHV) 152
Karyotype
aneuploidy and 175
balanced translocations and 174
cytogenetic disorders and 234, 235f
deletions and 174–175
gene amplifications and 175
introduction to 173–175
Kawasaki disease
clinical features of 352
morphology of 352b
noninfectious vasculitis and 352
Keratoconjunctivitis sicca 131, 132b
Keratocyst, odontogenic 557–558
Keratomalacia 297–298
Kernicterus 256b, 256f, 257
Kidney
amyloidosis and 156–157
chronic kidney disease and 541–542
clinical manifestations of renal disease and 517–518
cystic diseases and 542–544
diseases affecting tubules and interstitium and 533–538
diseases involving blood vessels and 538–541
glomerular disease and 518–533
SLE and 128–130
systemic sclerosis morphology and 134
tumors and 547–549
urinary outflow obstruction and 545–547
Kidney disease, chronic
clinical course of 542
the kidney and 541–542
morphology of 541b–542b, 542f
Kidney injury, acute 518
Kinin system 51–52. *See also* Coagulation

Laryngeal tuberculosis 497b
Laryngeal tumor
carcinoma of the larynx and 514
nonmalignant lesions and 513–514
and upper respiratory tract lesions 513–514
Lead poisoning 274f–275f
morphology of 274b–275b
*Legionella pneumophila* 490
Leiomyoma
morphology of 693b, 694f
proliferative lesions of endometrium/myometrium and 693–694
summary for 694b
uterine lesions and 693–694, 795
Leiomyosarcoma
morphology of 694b
proliferative lesions of endometrium/myometrium and 694
smooth muscle tumors and 795
summary of 694b
Leptin, obesity and 304
Lesch-Nyhan syndrome 787b–788b
Lesion
of the endometrium
endometrial hyperplasia as 691–692
endometrial polyps as 693
leiomyoma as 693–694
leiomyosarcoma as 694
of the oral cavity
fibrous proliferative lesions and 552–553
leukoplakia and erythroplakia as 553
squamous cell carcinoma as 554
summary for 554
of the penis 657
of the testis 659
Lesion, acquired preneoplastic 173
Leukocyte
activation of
introduction to 37–39, 38f
killing/degradation of phagocytosed microbes and 38–39
neutrophil extracellular traps and 39
phagocytosis and 37–39
secretion of microbicidal substance and 39
summary of 40b
function of
defects in 40–41, 41t
lysosomal enzymes of 49
recruitment of
adhesion and 35–36
chemotaxis and 36–37
introduction to 34–39
margination and rolling as 35–37, 36t
summary for 37b
transmigration and 36
Leukocytoclastic vasculitis 353b, 353f
Leukocytosis 57–58

Leukocytosis, reactive
clinical features of 427
infectious mononucleosis and 426–427
morphology of 427b
pathogenesis of 426b–427b
white cell disorders and 426–427, 426t
Leukodystrophy
clinical features of 834
morphology of 834b
myelin diseases and 834, 834t
Leukoencephalopathy 319
Leukopenia
clinical features of 450b–451b
morphology of 426b
pathogenesis of 425b–426b
white cell disorders and 425–426
Leukoplakia 553–554, 553f
morphology of 554b
Leukotriene 46–47, 47f
Libman-Sacks endocarditis 394f, 395. *See also* Verrucous endocarditis
Lichen planus
chronic inflammatory dermatosis and 855–856
clinical features of 856
morphology of 855b–856b, 855f
Lichen sclerosus 682, 682f
summary of 682
Lichen simplex chronicus
chronic inflammatory dermatosis and 856
clinical features of 856
epithelial disorders and 682, 682f
morphology of 856b, 856f
summary of 682
Li-Fraumeni syndrome 187
Light chain (AL) amyloidosis 438b–439b
Linkage analysis 266–267
Linkage disequilibrium pattern 266–267
Lipofuscin 24, 25f
Lipoma 405, 792
Liposarcoma 792
morphology of 792b, 793f
Lipoxin 46–47
Liquefactive necrosis 10, 10f
Liver
acute and chronic hepatitis and 611–621
alcoholic and nonalcoholic fatty liver disease and 621–625
amyloidosis and 157, 157f
cholestatic liver diseases and 626–629
circulatory disorders of 632–634
clinical syndromes of 604–610, 604t
drug or toxin-induced disease of 610–611
inherited metabolic diseases of 629
introduction to 603
other inflammatory and infectious diseases of 635
SLE morphology and 130
tumors and hepatic nodules of 635–639
Liver disease, alcoholic
clinical features of 624
introduction to 623–624, 623f
pathogenesis of 623b–624b
summary for 624b
Liver disease, drug/toxin-induced 610–611, 611t, 612f
summary for 611b
Lobular carcinoma in situ (LCIS) 710, 711f, 713
Local invasion, neoplasm characteristics and 167–168
Loeffler endomyocarditis 401
Low-density lipoprotein (LDL) receptor gene
autosomal dominant disorders and 219–220
familial hypercholesterolemia and 222, 224f
Lumbar lordosis 300
Lung
acute injury of 460–461
atelectasis of 460
chronic interstitial lung disease and 472–481
discussion of 460f, 512–514
obstructive lung disease and 463–472
obstructive vs restrictive pulmonary diseases of 462–463
pleural lesions and 511–512
pulmonary disease of vascular origin and 482–485
pulmonary infections and 486–504
SLE morphology and 130
systemic sclerosis morphology and 134
tumors of 505–511
upper respiratory tract lesions and 512–514
Lung abscess
clinical features of 492
morphology of 492b
as pulmonary infection 492
Lung injury, acute
acute respiratory distress syndrome 461
discussion of 460–461
Lupus nephritis, diffuse
glomerular disease as 128–130
Lupus nephritis, mesangial proliferative 128–130
Lymphadenitis 497b
as acute nonspecific 428
morphology of 428b
as chronic nonspecific 428
morphology of 428b
Lymphadenitis, reactive
cat-scratch disease and 428
white cell disorders and 427–428
Lymphangiomas 359
Lymphangitis 356–357
Lymphatic obstruction 77
Lymphatic spread, malignant neoplasms and 168
Lymphedema 356–357
Lymph node, sentinel 168
Lymphoblastic lymphoma 430–433
Lymphocyte, self-reactive 21
Lymphocytes
activation defects in 142
chronic inflammatory cells and 55, 55f
immune system and 100–104
B lymphocytes as 103–104
major histocompatibility complex molecules as 102–103
natural killer cells as 104
T lymphocytes as 101–102
summary for 104
Lymphogranuloma venereum (LGV)
morphology of 676b
sexually transmitted disease and 676
summary for 677b
Lymphoid neoplasm
acute lymphoblastic leukemia/lymphoblastic lymphoma as 430–433
adult T cell leukemia/lymphoma 443
Burkitt lymphoma 436–437
chronic lymphocytic leukemia/small lymphocytic lymphoma as 433–434
diffuse large B cell lymphoma as 436
follicular lymphoma as 434–435
Hodgkin lymphoma as 440–442
mantle cell lymphoma as 435

miscellaneous lymphoid neoplasms as 442–443
multiple myeloma and related plasma cell tumors as 437–440
as neoplastic proliferations of white cells 429–448, 430f, 431t–432t
regulated genomic instability and 197
summary for 443b–444b
Lymphoid tissue 104
Lymphoma
as diffuse large B cell
clinical features of 436
immunophenotypic features of 436
as lymphoid neoplasms 436
morphology of 436b, 436f
pathogenesis of 436b
subtypes of 436
summary for 443
as extranodal marginal zone 442
neoplasm nomenclature and 163
of primary central nervous system 845
morphology of 845b
of the stomach 571, 573
Lymphoma, follicular
clinical features of 435
immunophenotypic features of 435
as lymphoid neoplasms 434–435
morphology of 434b–435b, 435f
pathogenesis of 434b
summary for 443
Lymphoma, mantle cell
clinical features of 435
immunophenotypic and genetic features of 435
as lymphoid neoplasms 435
morphology of 435b
summary for 443
Lymphoplasmacytic lymphoma 439–440
Lynch syndrome. *See* Hereditary nonpolyposis colorectal cancer (HNPCC) syndrome
Lyon hypothesis 239
Lymphangiomas 258
Lysosomal enzymes 49–50
Lysosomal storage disease
Gaucher disease as 231–232
gene encoding mutations and 228–232, 229f, 229t
mucopolysaccharidoses as 232
Niemann-Pick disease types A and B as 230–231
Niemann-Pick disease types C as 230–231
summary for 232b
Tay-Sachs disease as 229–230

M

Macroglossia 157–158
Macroorchidism 241
Macrophages
as antitumor effector mechanisms 206
chronic inflammatory cells and 54–55, 54f
HIV infection and 148–149
Major histocompatibility complex molecule (MHC) 102f, 123–125
allograft rejection and 135–136, 136f
Malakoplakia 668
Malaria
clinical features of 419
hemolytic anemia as 418–419
pathogenesis of 418b–419b
Malaria, fatal falciparum 419
Male breast, lesion of
carcinoma as 714
gynecomastia as 714
Malformation, congenital
of the central nervous system 822–824
forebrain malformations as 823
neural tube defects as 822–823
posterior fossa anomalies as 823
spinal cord abnormalities as 823
summary for 824b
Malformation syndrome 247
Malignancy
genomic instability as enabler of
hereditary nonpolyposis colon cancer syndrome and 196–197
introduction to 196–197
lymphoid neoplasms and 197
summary for 197b
xeroderma pigmentosum and 197
tumor-promoting inflammation as enabler of 197–198, 198f
Malignant, nomenclature for 162
Malignant transformation
carcinogenesis and 198
Mallory-Denk bodies 621, 622f
Malnutrition 293–294
chronic alcoholism and 282
Marasmus 294, 295f
Marfan syndrome
aneurysms/dissections and 344b–345b, 345f
gene encoding mutations and 220–221
morphology of 221b
summary for 221b–222b
Margination 35–37, 36t
Marijuana 286–287
Mast cell 55–56
Maternal imprinting 243–244, 244f
Maternal inheritance 243
Maternal PKU 227
Mechanical trauma
hemolytic anemias and 418
injury by physical agent and 287, 287f
morphology of 287b–288b
Medullary disease
clinical course of 544
as cystic disease 544
morphology of 544b
summary for 544
Medulloblastoma 844–845
morphology of 845b, 845f
Megaloblastic anemia
as anemia of diminished erythropoiesis 422–423
folate deficiency anemia as 422–423
morphology of 422b, 422f
pathogenesis of 422b
summary for 425
vitamin $B_{12}$ deficiency anemia as 423
Melanin 24
Melanocytic nevi
clinical features of 865
as melanocytic proliferations of the skin 865, 869
morphology of 865b, 866f
pathogenesis of 865, 865b, 866f
Melanocytic proliferations of the skin
dysplastic nevus as 865–867
melanocytic nevi as 865
melanoma as 867–869
summary for 869b
Melanoma
clinical features of 868–869
as melanocytic proliferations of the skin 867–869

Melanoma *(Continued)*
morphology of 868b, 868f–869f
pathogenesis of 867b, 868f–869f
Membrane attack complex (MAC)
plasma protein-derived mediators and 50–51
Membrane permeability, defects in 16, 16f
Membranoproliferative glomerulonephritis and dense deposit disease (MPGN)
clinical course of 528
morphology of 527b–528b, 528f
nephrotic syndromes and 527–528
pathogenesis of 527b
summary for 529
Membranous lupus nephritis
class V SLE glomerular disease as 128–130
Membranous nephropathy
clinical course of 527
morphology of 522f, 526b, 527f
nephrotic syndrome and 526–527
pathogenesis of 526b
summary for 529
Mendelian disorder
disease caused by mutations in genes encoding
enzyme proteins and 227–233
proteins that regulate cell growth and 233–234
receptor proteins or channels and 222–227
structural proteins and 220–221
single-gene defects and 218–234, 218t–219t
transmission patterns of 219–220
summary for 220b
Meningioma 846
morphology of 846b, 846f
Meningioma, atypical 846b
Meningitis
acute pyogenic meningitis as 825
aseptic meningitis as 825
chronic meningitis as 826
nervous system infections and 825–826
Meningitis, chronic
spirochetal infections as 826
tuberculous meningitis as 826
Mental retardation
fragile X syndrome and 241
phenylketonuria and 227
Mercury 275–276
Mesangial lupus nephritis, minimal
class I SLE glomerular disease as 128–130
Mesothelioma, malignant
morphology of 512b, 512f
as pleural lesion 512
Metabolic disorder
of the nervous system 835
Metabolic myopathy 805
Metal, as environmental pollutant
arsenic as 275–276
cadmium as 276
lead as 274
mercury as 275
summary for 276b
Metaplasia
cellular adaptation to stress and 5, 5f
summary for 5b
Metastasis
molecular genetics of 195
neoplasm characteristics and 168–169, 168f
Metastatic calcification 26
morphology of 26b
Metastatic disease
bone tumors and 781
Metastatic neoplasm
as cardiac tumors 404–405
other cardiac tumors and 405
primary neoplasms and 404–405
Metastatic tumor 846b, 847f
Methylation of promoter region 261–262
MHC molecule. *See* Major histocompatibility complex molecule (MHC)
Microangiopathic hemolytic anemia 418, 418f
Micro-angiopathic hemolytic anemia 450b–451b
Microangiopathy 744
Microbe
summary of 319b
transmission/dissemination of
within the body for 317–318, 317f
release from body of 318
routes of entry for 315–317
Microbe, cell-associated 105–108
Microbe, extracellular 108–109
Microbe, phagocytosed
killing and degradation of 14f, 38–39, 39f
Microbial antigen, capture and display of 101f, 105, 106f
Microbial infection, autoimmunity and 124
Microbial pathogenesis
categories of infectious agents and 309–314, 310t
general principles of 309–314
Microbial substance, secretion of 39
Microorganism
disease caused by 319–322, 322b
host immune response and 321–322
mechanism of bacterial injury and 320–321
mechanism of viral injury and 319–320
MicroRNA (miRNA) 175, 176f, 177
Microscopic infarct 379
Microscopic polyangiitis 352–353
clinical features of 353
morphology of 353b, 353f
Mikulicz syndrome 479b–480b
Miliary pulmonary disease 497b
Minamata disease 275
Minimal-change disease
clinical course of 524–525
morphology of 524b, 525f
nephrotic syndrome and 524–525
summary for 528
Misfolded protein 156b–158b, 158. *See also* Amyloidosis
Misfolded protein, accumulation of 18, 21, 21t
Missense mutation 216
Mitochondrial damage 13, 13f, 16
Mitochondrial gene 243
Mitochondrial myopathy 805
Mitochondrial (intrinsic) pathway of apoptosis 19, 20f–21f, 22
Mixed-cellularity Hodgkin lymphoma 441, 441f
Mixed tumor 163, 163f
Modifier gene 219
Mold, opportunistic
clinical features of 504
as fungal infections 504
morphology of 504b
Mole, invasive 702–703
summary for 703b
Molecular diagnosis
of cancer 211
ectoparasites and 314

of Mendelian and complex disorders
discussion of 263–268
genetic analysis and 267–268
linkage analysis/genome-wide association studies and 266–267
Molecular profiling of tumor
expression profiling as 211–212
summary for 213
whole genome sequencing as 212–213
Mönckeberg medial sclerosis 335
Monocyte
HIV infection and 148–149
Mononeuropathy 798
Mononucleosis, infectious 426–427, 427f
clinical features of 427
Mononuclear inflammation 324
morphology of 324b, 324f
*Moraxella catarrhalis* 489
Morphologic method, of cancer diagnosis
cytologic (Papanicolaou) smears as 210
fine needle aspiration as 210
flow cytometry as 210–211
immunocytochemistry as 210
Mosaicism 235
Mucinous cystic neoplasm 652, 652f
Mucinous tumor of the ovary 697–698
morphology of 698b, 698f
Mucoepidermoid carcinoma 557
morphology of 557b
Mucopolysaccharidosis (MPS) 232
Mucormycosis 829
Mucosa-associated lymphoid tissue (MALT)
gastrointestinal tract and 316
*H. pylori* and 204
Multicentric C cell hyperplasia 734–735
Multifactorial inheritance 248
Multiple endocrine neoplasia syndrome (MEN)
and endocrine system 761–762
and the endocrine system 761–762
multiple endocrine neoplasia type 1 as 761–762
multiple endocrine neoplasia type 2 as 762
Multiple endocrine neoplasia (MEN) type 1 761–762
Multiple endocrine neoplasia (MEN) type 2
multiple endocrine neoplasia syndromes and 762
multiple endocrine neoplasia type 2A and 762
multiple endocrine neoplasia type 2B and 762
Multiple endocrine neoplasia type 2A 762
Multiple endocrine neoplasia type 2B 762
Multiple myeloma
clinical features of 439–440
as lymphoid neoplasms 437–440
lymphoplasmacytic lymphoma as 438
monoclonal gammopathy of undetermined significance as 438
morphology of 438b–439b, 439f
pathogenesis of 438b
solitary plasmacytoma and 437
summary for 443
Multiple sclerosis (MS)
clinical features of 833–834
morphology of 833b, 833f
myelin diseases and 832–835
Mural thrombus 383f, 384
Muscle disease, primary 801
Muscle fiber atrophy 801–802
Muscular dystrophy, limb-girdle 804
Musculoskeletal system 134
Mutated genes, products of 205
Mutation 216
Mutator phenotype 173
Myasthenia gravis 800–801
Myasthenic syndromes, congenital 801
Mycoplasma 313
Mycosis fungoides 443
Myelin
leukodystrophies and 834, 834t
multiple sclerosis as 832–834
other acquired demyelinating diseases and 834
primary diseases of 832–834
summary for 835b
Myelodysplastic syndrome (MDS)
summary for 449
morphology of 445b
as myeloid neoplasms 445–446
pathogenesis of 445b
Myelofibrosis, primary
as chronic myeloproliferative disorder 448
clinical course of 448
morphology of 448b, 448f
pathogenesis of 448b
Myeloid leukemia, trisomy 21 and 237
Myeloid neoplasm
acute myeloid leukemia as 444–445
chronic myeloproliferative disorders and 446–448
myelodysplastic syndromes as 445–446
as neoplastic proliferations of white cells 444–448
summary for 448b–449b
Myeloma nephrosis 438b–439b
Myelophthisic anemia
as anemia of diminished erythropoiesis 424
summary for 425
Myeloproliferative disorders, chronic
chronic myelogenous leukemia as 446
as myeloid neoplasms 446–448
polycythemia vera as 447
primary myelofibrosis as 448
summary for 449
Myocardial infarction (MI)
clinical features of 382–383, 382f
consequences and complications of 383–384, 383f
infarct modification by reperfusion 381–383
ischemic heart disease as 377–384
morphology of 379b–381b, 380f–381f, 380t
pathogenesis of 376f, 377b–379b, 378f–379f
Myocardial rupture 383f, 384
Myocardial vessel vasospasm 355
Myocarditis
cardiomyopathy as 401–403
clinical features of 403
morphology of 402b, 402f
pathogenesis of 401b–402b
Myopathy, inflammatory
dermatomyositis as 805
inclusion body myositis as 805
polymyositis as 805
Myositis, inclusion body 805, 806f
Myositis ossificans 793
Myotonic dystrophy 804
Myxedema 743
Myxoid chondrosarcoma 778b
Myxomas
clinical features of 405
morphology of 404b
primary neoplasms and 404, 404f

Myxomatous mitral valve
clinical features of 390–391
degenerative valve disease as 390–391
morphology of 390b, 390f
pathogenesis of 390b

N

Nasopharyngeal carcinoma 513
Natural killer (NK) cell 105, 125–131
as antitumor effector mechanisms 206
Necrosis
clinicopathologic correlation examples for 16–18
morphology of 6f, 9b
morphology of cell and tissue injury and 9
patterns of 9–11
morphology of 10b–11b, 10f–11f
Necrotizing arteriolitis 333b–334b
Necrotizing enterocolitis (NEC)
discussion of 252, 252f
premature infants and 249
preterm birth complications and 251
Necrotizing glomerulonephritis, focal and segmental 353b–354b
Necrotizing granulomatous vasculitis 353b–354b, 353f
Necrotizing vasculitis 117b
Necrotizing vasculitis, acute 128
Necrotizing vasculitis, noninfectious 135
Neoplasia. *See also* Tumor, benign; Tumor, malignant

morphology of 776b
Osteochondroma
as cartilage-forming tumors 777–778, 777f
clinical features of 778
morphology of 778b
summary for 781
Osteogenesis imperfecta (OI) 767–768
Osteoid osteoma
as bone-forming tumor 776
morphology of 776b, 776f
summary for 781
Osteoma 775–776
Osteomalacia
acquired bone disease and 771
morphology of 300b–301b
vitamin D and 298–300
Osteomyelitis
acquired diseases of bone and 773–774
pyogenic osteomyelitis as 773–774
tuberculous osteomyelitis as 774

Osteopetrosis 767–768
Osteoporosis
  acquired bone disease and 768–770, 769t, 772
  clinical course of 770
  exogenous estrogens and 282–283
  morphology of 768b–769b, 769f
  pathogenesis of 766f, 769b–770b, 769f
  vitamin D and 299–300
Osteosarcoma
  bone tumors as 776–777
  clinical features of 777
  morphology of 776b–777b, 776f
  pathogenesis of 777b
  summary for 782
Ostium primum ASD 371b
Ostium secundum ASD 371b
Outdoor air pollution 272–273
  morphology of 273b
Ovary
  follicle and luteal cysts and 695
  other tumors of 698–700, 699t
  polycystic ovarian disease and 695–696
  tumors of 696–698
Oxidative stress. *See* Free radicals, oxygen-derived
Oxygen deprivation 7
Ozone 272–273, 272t

P

Paget disease (osteitis deformans)
  acquired bone disease as 770–771
  clinical course of 771
  morphology of 770b, 770f
  pathogenesis of 771b
  summary for 772
Paget disease, extramammary 683–684, 684f
  summary of 684
Paget disease of the nipple 710
Panacinar emphysema 464, 464f, 465b
Pancarditis 391b
Pancreas
  congenital anomalies of
    agenesis and 646
    annular pancreas as 646
    congenital cysts as 646
    ectopic pancreas as 646
    pancreas divisum as 646
  overview of 645
  pancreatic neoplasms and 651–654
  pancreatitis and 646–651
Pancreas, congenital cysts of 646
Pancreas, ectopic 646
Pancreas, endocrine
  diabetes mellitus and 739–750
  pancreatic neuroendocrine tumors and 751–752
Pancreas divisum 646
Pancreatic abnormality 223–227
Pancreatic carcinoma
  clinical features of 654
  introduction to 652–654
  morphology of 653b–654b, 654f
  pathogenesis of 653b, 653f
Pancreatic neoplasm
  cystic neoplasms as 651–652
    intraductal papillary mucinous neoplasms as 652
    mucinous cystic neoplasms as 652
    serous cystadenomas as 651
  pancreatic carcinoma and 652–654
  summary for 654b
Pancreatic neuroendocrine tumor (PanNET)
  endocrine pancreas and 751–752
  gastrinomas and 752
  insulinomas and 751
Pancreatic pseudocyst
  acute pancreatitis and 649
  morphology of 649b, 649f
Pancreatitis
  acute pancreatitis and 646–649
  chronic pancreatitis and 649–651
  and the pancreas 646–651
  summary for 651b
Pancreatitis, acute
  clinical features of 648–649
  inflammatory disorders of 646–649, 646t
  morphology of 647b, 647f
  pancreatic pseudocysts as 648–649
  pathogenesis of 647b–648b, 648f
Pancreatitis, chronic
  clinical features of 651
  morphology of 650b, 650f
  the pancreas and 649–651
  pathogenesis of 650b
Pancreatitis, hemorrhagic 647b
Pancreatitis, lymphoplasmacytic sclerosing 650b
Pancytopenia 442–443
Papanicolaou smear. *See* Cytologic (Papanicolaou) smear
Papillary carcinoma of the thyroid
  clinical features of 733
  morphology of 732b–733b, 732f
  summary for 735
  the thyroid and 732–733
Papillary fibroelastoma 405
Papillary muscle dysfunction 383–384
Papilloma 162
Paraneoplastic syndromes 208–209, 209t
Parasitic disease 585–586
Parathyroid carcinoma 736b–737b
Parathyroid gland
  endocrine system and 735–738
  hyperparathyroidism and 735–738
  hypoparathyroidism and 738
Parathyroid hyperplasia 736b–737b
Parenchymal hemorrhage, primary brain 817, 817f, 819
  morphology of 817b
Parenchymal infection
  arboviruses and 827
  brain abscesses and 826
  cytomegalovirus and 828
  fungal encephalitis and 829
  herpesviruses and 827–828
  human immunodeficiency virus and 828
  of nervous system 826–831
  other meningoencephalitides as 829–831
  poliovirus and 828
  polyomavirus and progressive multifocal leukoencephalopathy as 828–829
  rabies virus and 828
  viral encephalitis and 826–829
Parenchymal injury, traumatic 820–821
  morphology of 820b, 820f
Parkinson disease (PD)
  clinical features of 839–840
  morphology of 839b, 839f
  parkinsonism and 839–840
  pathogenesis of 839b

Paroxysmal nocturnal hemoglobinuria (PHN)
hemolytic anemias and 417
pathogenesis of 417b
Parvovirus B19 255–256, 256f
Passive congestion
circulatory disorders of liver and 633
morphology of 633b, 633f
Passive smoke inhalation. *See* Tobacco smoke, environmental
Patent ductus arteriosus
clinical features of 372
left-to-right shunts and 369t, 370f, 371–372
Patent foramen ovale 370–371
Pathology, introduction to 1
Pediatric disease
congenital anomalies and 245–248, 246f
fetal hydrops and 254–257
introduction to 245–268, 245t
molecular diagnosis of Mendelian/complex disorders and 263–268
necrotizing enterocolitis and 252
perinatal infections and 249
prematurity/fetal growth restrictions and 249–250
respiratory distress syndrome and 250–251
sudden infant death syndrome and 252–254
tumors/tumor-like lesions and 257–262
Pemphigus (vulgaris and foliaceus)
blistering disorders and 858–859, 862
clinical features of 859
morphology of 859b, 859f–860f
pathogenesis of 858b–859b, 859f
Penis
inflammatory lesions of 657
malformations of 657
neoplasms of 657–658
Peptic ulceration, acute
clinical features of 565
inflammatory disease of the stomach and 565
morphology of 565b
pathogenesis of 565b
Peptic ulcer disease (PUD)
clinical features of 568–569
epidemiology of 568
inflammatory diseases of the stomach and 568–569
morphology of 568b, 568f
pathogenesis of 565f, 568b
Peptide display system 123–125
Pericardial disease
heart diseases and 403–404
pericardial effusions as 404
pericarditis as 403–404
Pericardial effusion 404
Pericarditis
clinical features of 403–404
morphology of 403b, 403f
pericardial disease as 384, 403–404
Pericarditis, acute bacterial 403b
Pericarditis, chronic 403b
Pericarditis, constrictive 403b
Perinatal infection 249
Peripheral nerve disorder
introduction to 797–799, 798f
nerve injury disorders and 798–799
patterns of injury and 797–798
summary for 800b
Peripheral nerve injury
disorders associated with 799t
chronic inflammatory demyelinating polyneuropathy as 799
diabetic peripheral neuropathy as 799
Guillain-Barre syndrome as 798–799
summary for 800b
toxic, vasculitic, inherited forms of 799–800
patterns of 797–798, 798f
Peripheral nerve sheath
malignant tumors of 808
neurofibromas as 807
neurofibromatosis type 1 as 808
Schwannomas and neurofibromatosis type 2 as 806–807
traumatic neuroma as 808
tumors of 806–808
Peripheral nerve sheath schwannoma 806–808
morphology of 807b, 807f
Peripheral nerve sheath tumor, malignant 808
morphology of 808b
Peripheral neuropathy
summary for 800b
toxic, vasculitic, inherited forms of 799, 800f
Peripheral T cell lymphoma 443
Peutz-Jeghers syndrome 592–593, 594f
Phagocyte oxidase 143
Phagocytosis 37–39, 39f, 112f, 114–115
Phenylketonuria (PKU) 227–228, 227f
summary for 228, 228b
Pheochromocytoma
adrenal medulla tumors and 760–761
clinical features of 761
morphology of 760b–761b, 760f–761f
Phlebothrombosis 356. *See also* Venous thrombosis
Phyllodes tumor 707
Physical agent
cell injury and 7
injury by
electrical injury and 289
ionizing radiation and 289–293
mechanical trauma as 287
thermal injury and 288–289
toxicity of 271–272
Pickwickian syndrome 305
Pigeon breast deformity 300
Pigment 24, 25f
Pilocytic astrocytoma 842–843
morphology of 843b
Pituitary adenoma
adrenocorticotropic hormone producing adenomas as 719–720
growth hormone producing adenomas as 719
morphology of 718b, 718f–719f
other anterior pituitary neoplasms as 720
pathogenesis of 718b
and pituitary gland 717–720, 717t
(*See also* Hyperpituitarism)
prolactinomas as 719
summary of 719, 720b
Pituitary adenoma, nonfunctioning 720
Pituitary carcinoma 720
Pituitary gland
as endocrine system 716–721, 716f–717f
hyperpituitarism/pituitary adenomas and 717–720
hypopituitarism and 720–721
posterior pituitary syndromes and 721
prolactinomas and 719
PKU. *See* Phenylketonuria (PKU)
Placental-fetal transmission 318
Placental inflammation/infection 701

Plasma protein-derived mediator
coagulation and Kinin system as 51–52
complement system as 50–51, 50f
summary for 52b
Plasminogen activator inhibitor (PAI) 80, 85f
Platelet
activation of 80, 82
adhesion and 82
aggregation of 82
discussion of 81–82
endothelial interaction with 81f, 82
normal hemostasis and 80f
normal hemostasis and 79
summary for 82b
Platelet-activating factor (PAF) 47–48
Platelet activation 82, 82b
Platelet adherence 79
Platelet adhesion 80f–81f, 82
Platelet aggregation 81f, 82, 82b
Platelet contraction 82
Pleiotropy 218–219
Pleomorphic undifferentiated sarcoma 794
Pleomorphic adenoma 163, 556–557, 557f
morphology of 556b–557b
Pleomorphic fibroblastic sarcoma 794, 794f
Pleomorphism 165, 165f
Pleural effusion 511
Pleural lesion
of the lungs 511–512
malignant mesothelioma as 512
pleural effusion and pleuritis as 511
pneumothorax, hemothorax, chylothorax as 511–512
Pleuritis 511
Plexiform neurofibroma 807, 808b
Plummer syndrome 728b
Pneumoconiosis
asbestosis as 477
coal worker's pneumoconiosis as 475
as fibrosing disease 474–478, 474t
mineral dust and 277
pathogenesis of 474b–475b
silicosis as 476
summary for 478b
*Pneumocystis* pneumonia
in the immunocompromised host 501–502
morphology of 502b, 502f
Pneumonia
caused by other pathogens
*Haemophilus influenzae* as 489
*Klebsiella pneumoniae* as 489–490
*Legionella pneumophila* as 490
*Moraxella catarrhalis* as 489
*Pseudomonas aeruginosa* as 490
*Staphylococcus aureus* as 489
community-acquired acute
morphology of 488b, 489f
pneumonias caused by other important pathogens and 488–490
as pulmonary infection 486–490
*streptococcus pneumoniae* infections as 487–488
community-acquired atypical
clinical features of 490–491
influenza infections as 491
influenza virus type A/HINI infection as 491
morphology of 490b, 491f
as pulmonary infections 490–491
summary for 491b
in the immunocompromised host
cytomegalovirus infections and 500–501
*pneumocystis* pneumonia and 501–502
as pulmonary infection 500–502
Pneumonia *(P. jiroveci)*
HIV infections and 151, 151t, 313
Pneumonia, chronic
nontuberculous mycobacterial disease as 499
as pulmonary infection 492–499
tuberculosis and 493–498
Pneumonia, cryptogenic organizing 473–474, 474f
Pneumonia, hospital-acquired 491–492
Pneumothorax 511
Podocyte injury 522f, 523, 528
Poliovirus 828
Pollution, environmental
air pollution as 272–273
industrial/agricultural exposures as 276–277
metals as 273–276
Polyarteritis nodosa (PAN)
autoimmune diseases and 135
clinical features of 352
morphology of 352b, 352f
vasculitis and 352
Polycystic kidney disease, autosomal recessive
clinical course of 544
cystic diseases and 544
morphology of 544b
summary for 544
Polycystic ovarian disease 695–696
Polycythemia 425, 425t
Polycythemia vera
as chronic myeloproliferative disorder 447
clinical course of 447–448
morphology of 447b
Polymerase chain reaction (PCR) analysis 264–266, 266f
Polymerase chain reaction (PCR) analysis
molecular diagnosis and 211
Polymorphism
complex multigenic disorders and 234
genetic abnormalities and 216–217
linkage analysis and 245–246

as tumors of the kidney 547–549
Renal cell carcinoma, papillary 548b
Renal disease 517–518
Renal stones
clinical course of 545
morphology of 545b
pathogenesis of 545b, 545t
urinary outflow obstruction and 545
Reperfusion 381–383, 382f
Replicative potential, limitless
cancer cells and 190–191, 191f
summary for 191b
Resorption atelectasis 460
Respiratory bronchiolitis 481
Respiratory distress syndrome (RDS)
of the newborn 250–251, 250f
clinical features of 251
morphology of 251b, 251f
pathogenesis of 250b–251b
summary 251b–252b
premature infants and 249
Respiratory tract
microbe transmission/dissemination through 316–319
Restrictive cardiomyopathy 401
morphology of 401b
Retinoblastoma (RB)
clinical features of 261
discussion of 260–261
morphology of 261b
Retinoblastoma (RB) gene 182–184
pathogenesis of 183f
Retinopathy, diabetic 744, 747, 747f
Retroperitoneal fibrosis (ureter) 668
Rhabdomyomas 404b

Rhabdomyosarcoma 794–795
morphology of 795b, 795f
Rheumatic fever, acute 391b
Rheumatic heart disease 110, 391b
Rheumatic valvular disease
clinical features of 391–392
morphology of 391b, 392f
pathogenesis of 391b
valvular heart disease as 391–392
Rheumatoid arthritis (RA)
autoimmune diseases 131
clinical features of 785–786
of the joints 784–786
morphology of 785b, 785f–786f
pathogenesis of 784b, 784f
summary for 790
Rheumatoid vasculitis 355
Rickets
acquired bone disease and 771
morphology of 300b–301b
vitamin D and 298–300, 300f
Rickettsia 311–313
Riedel thyroiditis 726
RNA virus, oncogenic 201, 201f
summary for 202b
Rolling 35–37, 36t
ROS. *See* Reactive oxygen species (ROS)
Rotavirus 585–586
Roundworms (nematode) 314, 314f

S

Sacrococcygeal teratoma 258, 258f
Saddle embolus 90, 90f
Salivary gland, disease of
neoplasms as 555–557
sialadenitis as 555
summary for 557b
xerostomia as 555
Salmonellosis
infectious enterocolitis and 583–584
pathogenesis of 584b
Sanger sequencing 265, 266f
Sarcoidosis
clinical features of 480
epidemiology of 478–479
etiology and pathogenesis of 479b
as granulomatous disease 478–480
morphology of 479b–480b, 479f
summary for 480b
Sarcoma 162
Sarcoma botryoides 685
Scar formation
angiogenesis and 66–67
connective tissue remodeling and 68
fibroblasts and connective tissue in 68
growth factors involved in 42f, 68
introduction to 65–68
remodeling of connective tissue and 68
steps in 65–66, 66f
summary for 69b
Scarring
chronic inflammation and 309–314
morphology of 325b, 325f
Scleroderma. *See* Systemic sclerosis (SS)
Scleroderma, limited 132
Sclerosing adenosis 706
morphology of 706b, 706f
Scrotum 658–663
Scurvy 301
Seborrheic keratosis
as epithelial lesions of the skin 862–863
morphology of 862b, 862f
Secondary immune deficiency 143
Secondary syphilis 672–673
Secondary tuberculosis
clinical features of 498
morphology of 497b, 497f–498f
as type of tuberculosis 496
Seminoma 163
Sensorimotor polyneuropathy, distal symmetric 799
Septic shock 94, 95f
Sequence 216–217
Sequencing, whole genome 212–213, 212f–213f
Serous carcinoma 692b, 693f
Serous cystadenoma 651, 651f
Serous tumor, ovarian epithelial 697
morphology of 697b, 697f
Severe combined immunodeficiency (SCID) 142–143
Sexually transmitted disease (STD)
chancroid as 677
genital herpes simplex as 678
gonorrhea and 674–675
granuloma inguinale as 677
human papillomavirus infection as 678
lymphogranuloma venereum as 676
male genital system and 671–678, 671t
microbe dissemination and 318
nongonococcal urethritis and cervicitis as 676
trichomoniasis as 677–678
Sézary syndrome 443
Sheehan postpartum pituitary necrosis 452b
Shigellosis
clinical features of 584b
infectious enterocolitis and 583
morphology of 583b
pathogenesis of 583b
Shock
clinical course for 97
introduction to 94–97, 94t
morphology of 97b
pathogenesis of 94–96
stages of 96–97
summary for 97b
Shock lung 97b
Shunt, left-to-right
atrial septal defect/patent foramen ovale and 370–371
congenital heart disease and 370–372, 370f
patent ductus arteriosus and 371–372
ventricular septal defects and 371
Shunt, portosystemic
hepatorenal syndrome and 610
liver disease and 609–610
portopulmonary hypertension/hepatopulmonary syndrome and 610
splenomegaly and 609
Shunt, right-to-left
congenital heart disease and 372–373, 372f
tetralogy of Fallot and 372–373
transposition of the great arteries and 373
Sialadenitis 555, 556f, 557
Sicca syndrome 131
Sickle cell anemia
clinical course of 413
hemolytic anemias and 411–413
incidence of 411–413
morphology of 411f, 412b–413b

Sickle cell anemia *(Continued)*
pathogenesis of 411b–412b, 412f
summary for 419
SIDS. *See* Sudden infant death syndrome (SIDS)
Sigmoid diverticulitis
clinical features of 586–587
inflammatory intestinal disease and 586–587
morphology of 586b, 586f, 591f
pathogenesis of 586b
summary for 587b
Silicosis
clinical features of 476
morphology of 476b, 476f
as pneumoconiosis 476
summary for 478
Single-gene disorder
with atypical patterns of inheritance 241–244
alterations of imprinted region disease as 243–244
mutations in mitochondrial genes disease as 243
triplet repeat mutations as 241
Single-gene disorder, transmission patterns of
autosomal dominant inheritance as 219–220
autosomal recessive inheritance as 220
summary for 220b
X-linked disorders as 220
Single-nucleotide polymorphism (SNP) 222–223
array-based genomic hybridization and 264
linkage analysis and 266
sequence and copy number variations and 216–217
Sinusoidal obstruction syndrome 634, 634f
Sinus venosus ASD 371b
Sjögren syndrome
discussion of 131–132
morphology of 132b, 132f
pathogenesis of 127t, 131b
summary for 132b
Skeletal muscle
acquired disorders of 805–806
inflammatory myopathies as 805
toxic myopathies as 805–806
inherited disorders of 802–805
channelopathies, metabolic and mitochondrial myopathies as 805
dystrophinopathies as 802–804
X-linked and autosomal muscular dystrophies as 804–805
patterns of injury for 801–802, 803f
summary for 806b
Skeletal muscle tumor, rhabdomyosarcoma as 794–795
Skin
benign and premalignant tumors of 862–869
blistering disorders of 857–861
chronic inflammatory dermatoses and 854–856
infectious dermatoses and 856–857
introduction and terminology for 851
microbe transmission/dissemination and 316, 318–319
SLE morphology and 130, 130f
systemic sclerosis morphology and 133, 134f
Skin wound
healing by first intention and 70–71, 70f
healing by second intention and 70f–71f, 71–72
summary for 72b
wound strength and 72
Small airway disease. *See* Chronic bronchiolitis
Small cell carcinoma (SCLC) 506b–509b, 509f
Small-for-gestational-age (SGA) infant 249–250
Small lymphocytic lymphoma (SLL) 433–434
summary for 443
Smog 272–273
Smokeless tobacco 277, 279
Smoking-related interstitial disease 481, 482f
and chronic interstitial lung disease 481
Sodium retention 77–78
Soft tissue
fibrohistiocytic tumors and 794
fibrous tumors and tumor-like lesions of 792
introduction to 791–796, 792t
skeletal muscle tumors and 794–795
smooth muscle tumors and 795
synovial sarcoma and 795
tumors of adipose tissue and 792
Spermatocytic seminoma 660b–662b
Spider telangiectasias 357–358
Spinal cord abnormality 823
Spinocerebellar ataxia (SCA) 840–841
Spirochetal infection
neuroborreliosis as 826
neurosyphilis as 826
Spleen 456–457
amyloidosis and 157
SLE morphology and 130
splenomegaly as 456
Splenomegaly
CML and 447
hairy cell leukemia and 442–443
portosystemic shunt and 609
spleen disorders and 456
Spondyloarthropathy, seronegative 786
Spontaneous maturation 258–259
Spontaneous regression 258–259
Squamous cell carcinoma
clinical features of 863–864
of the esophagus 563–564
clinical features of 563–564
morphology of 563b, 563f
pathogenesis of 563b
lung tumors and 506b–509b
malignant epidermal tumors and 863–864
morphology of 863b, 864f
nomenclature for 162–163, 165f
of the oral cavity 554
morphology of 554b, 555f
pathogenesis of 554b
pathogenesis of 863b
of the vagina 684
Staging, cancer tumor and 208–210
*Staphylococcus aureus* 489
Stasis thrombi. *See* Red thrombi
Steatohepatitis, nonalcoholic 305
Steatosis. *See* Fatty change
Steatosis, drug/toxin-mediated injury with 625
morphology of 626b
Steatosis, hepatocellular 621b–622b, 621f
Stem cell 60, 61b, 61f
cancer of 166–167
Stem cell, adult 60
Stem cell, cardiac 385

T cell lymphoma, adult 443
T cell-mediated hypersensitivity (Type IV)
CD4+ T cell inflammatory reactions and 118–119
delayed-type hypersensitivity and 119
introduction to 111, 117–120, 118t, 119f
summary for 120b
T cell-mediated cytotoxicity and 119–120
T cell mediated rejection 137
T cell receptor (TCR) 101, 101f
Tenosynovial giant cell tumor (TGCT)
clinical features of 791
joint tumors and 790
morphology of 790b, 791f
Teratoma, benign cystic 163, 698–700, 700f
Teratoma, immature malignant 700
Teratoma, specialized 700
Tertiary syphilis 673
Testicular atrophy 658–659
Testicular neoplasm 659–663, 660t
clinical features of 662–663
morphology of 660b–662b, 660f–662f
summary for 663b
Testicular torsion 659
Testis
cryptorchidism/testicular atrophy and 658–659
inflammatory lesions of 659
male genital system and 658–663
neoplasms of 659–663
vascular disturbances and 659
Tetany, hypocalcemic 298
Tetralogy of Fallot
clinical features of 372–373
morphology of 372b
right-to-left shunts and 369t, 372–373, 372f
Thalassemia
clinical course of 416
hemolytic anemias and 413–416
morphology of 415b–416b
pathogenesis of 413b–415b, 414f–415f, 414t
summary for 419
Thanatophoric dwarfism 767
Thermal burn
morphology of 288b–289b
thermal injury and 288
Thermal injury
hyperthermia as 289
hypothermia as 289
thermal burns as 288
Thiamine deficiency 835
Thoracic aortic aneurysm 346
Thrombocytopenia, heparin-induced 453
Thrombin
coagulation cascade and 81f, 83, 85f
platelet aggregation and 82
Thromboangiitis obliterans (Buerger disease) 354–355
clinical features of 354–355
morphology of 354b, 354f
Thrombocytopenia 78, 87, 424
disseminated intravascular coagulation and 452–454, 453t
heparin-induced thrombocytopenia and 453
immune thrombocytopenic purpura and 452–453
thrombotic microangiopathies as 453–454
Thrombocytopenic syndrome, heparin-induced 87

Thromboembolism
embolism and 75, 90
HRT and 283
oral contraceptives and 284
Thromboembolism, systemic
air embolism as 91–92
amniotic fluid embolism as 91
embolism and 91–92

mucinous tumors and 697–698
serous tumors and 697
summary for 700b
surface epithelial tumors and 696–697
of the skin
benign and premalignant epithelial lesions as 862–863
malignant epidermal tumors as 863–864
melanocytic proliferations as 865–869
of the ureter 668
of the vulva 683–684
carcinoma and 683
condylomas and 683
extramammary Paget disease and 683–684
Tumor, benign
focal nodular hyperplasia as 635–636
hepatic adenoma as 636
of infancy and childhood 259–260
of the liver 635–636
Tumor, dysembryoplastic neuroepithelial 844
Tumor, endometrioid 698
Tumor, fibrohistiocytic
benign fibrous histiocytoma as 794
pleomorphic fibroblastic sarcoma/pleomorphic undifferentiated sarcoma 794
and soft tissue 794
Tumor, fibroosseous 779–780
Tumor, fibrous
of the bone
fibrous cortical defect and nonossifying fibroma as 779
fibrous dysplasia as 779–780

Tumor, fibrous *(Continued)*
fibromatoses and 793
fibrosarcoma as 793–794
reactive proliferations and 793
of the soft tissue 792–794
Tumor, germ cell 845
Tumor, Krukenberg 698b
Tumor, malignant
in infancy and childhood 258–262, 258t
neuroblastoma as 258–260
retinoblastoma as 260–261
Wilms tumor as 261–262
Tumor, malignant epidermal
basal cell carcinoma as 864
squamous cell carcinoma as 863–864
summary for 864b
Tumor, neuronal 844
Tumor, odontogenic 558
Tumor, parenchymal
germ cell tumors as 845
primary central nervous system lymphoma as 845
Tumor, smooth muscle
leiomyoma as 795
leiomyosarcoma as 795
Tumor, vascular
benign and tumor-like conditions of 357–359
intermediate-grade of 360–361
introduction to 357–362, 357t
malignant tumors as 361–362
summary for 362b
Tumor antigen
differentiation antigens and 206
glycolipids/glycoproteins and 206
introduction to 204–206, 205f
mutated oncogenes/tumor suppressor genes and 204–205
oncofetal antigens and 206
oncogenic viruses and 206
other mutated genes and 205
overexpressed cellular proteins and 205
Tumor cell, homing of 194–195
Tumor immunity
antigens and 204–206
introduction to 204–207
surveillance and evasion by 207
Tumor marker 211
Tumor necrosis factor (TNF) 48, 48f
Tumor suppressor gene
carcinogenesis and 173, 177, 184
inherited mutations and 171–172
Turner syndrome 240–241, 240f
nonimmune hydrops and 255–256
22q11.2 deletion syndrome 237–239
Type 1 diabetes (T1D)
clinical features of 748, 750t
diabetes mellitus and 739
pathogenesis of 741, 741f
summary for 750
Type 2 diabetes (T2D)
clinical features of 748, 750t
diabetes mellitus and 739
pathogenesis of 741, 742f
summary for 750
Type 1 hypersensitivity. *See* Hypersensitivity, immediate
Type II hypersensitivity. *See* Antibody-mediated disease
Type III hypersensitivity. *See* Immune complex disease
Type I interferon, SLE and 126
Typhoid fever 584
Tyrosine kinases, non-receptor 178–179

U

Ultraviolet (UV) radiation 126
Upper respiratory tract acute infection 512–513
Upper respiratory tract lesion
acute infections and 512–513
laryngeal tumors and 513–514
nasopharyngeal carcinoma and 513
Ureaplasma 313
Ureter 668–671
Ureteropelvic junction (UPJ) obstruction 668
Urinary bladder
neoplasms of 669–671
non-neoplastic conditions of 668–669
Urinary outflow obstruction
hydronephrosis and 545–547
renal stones and 545
Urinary tract infection 518
Urogenital tract 317, 319
Urolithiasis 545
Urticaria
acute inflammatory dermatoses and 852
clinical features of 852
morphology of 852b
pathogenesis of 852b
Uterus, body of
abnormal uterine bleeding and 690–691, 690t
adenomyosis and 689
endometriosis and 689–690
endometritis and 689
proliferative lesions of endometrium/myometrium and 691–694
summary for 691b

V

Vagina
female genital system and 684–685
malignant neoplasms of 684–685
clear cell adenocarcinoma as 685
sarcoma botryoides as 685
squamous cell carcinoma as 684
vaginitis and 684
Vaginitis 684
Variant Creutzfeldt-Jakob disease (vCJD) 831, 832f
Varicose vein
of the extremities 356
clinical features of 356
of other sites 356
Vascular change
acute inflammation and 31, 31f, 33–34
changes in vascular caliber and flow and 31f, 33–34
increased vascular permeability and 33–34, 33f
lymphatic vessel responses and 34
summary of 34b
Vascular dissemination
invasion-metastasis cascade and 194–195
Vascular ectasias 357–358
Vascular injury, traumatic
central nervous system and 821–822, 821f
epidural hematoma as 821
subdural hematoma as 821–822
Vascular intervention, pathology of
endovascular stenting and 362
vascular replacement and 363

Vascular malformation 818
morphology of 818b–819b, 819f
Vascular organization 328–329, 328f
Vascular replacement 363
Vascular smooth muscle cell 330
Vascular tumor, benign
bacillary angiomatosis as 359
glomus tumors as 359
hemangiomas as 358–359
lymphangiomas as 359
vascular ectasias as 357–358
Vascular tumor, intermediate-grade
hemangioendotheliomas as 361
Kaposi sarcoma as 360–361
Vascular tumor, malignant
angiosarcomas as 361–362
hemangiopericytomas as 362
Vascular wall, response to injury by
intimal thickening and 334–335, 335f
Vasculitis 819
discussion of 348–355, 349f
infectious type of 355
noninfectious type of 348–355
summary for 355b
Vasoactive amines 112
Vein, disease of
superior and inferior vena cava syndromes as 356
thrombophlebitis and phlebothrombosis as 356
varicose veins of the extremities as 356
Velocardiofacial syndrome 237–239
Venoocclusive disease. *See* Sinusoidal obstruction syndrome
Venous thrombosis (phlebothrombosis) 87t, 89
paroxysmal nocturnal hemoglobinuria and 417b
Ventricular aneurysm 383f, 384
Ventricular septal defect
clinical features of 371
left-to-right shunts and 369t, 371, 371f
morphology of 371b
Verrucae (warts)
infectious dermatoses and 857
morphology of 857b, 858f
pathogenesis of 857b
Verrucous endocarditis 88b–89b
Verrucous endocarditis, nonbacterial 130
Viral encephalitis 826–829, 827f
Viral hepatitis, acute 619
Viral injury, mechanism of 319–320, 319f
Viral meningitis. *See* Aseptic meningitis
Virchow's triad 86, 86f
Virus
autoimmunity and 124
infectious agents as 309–310, 310t, 311f
Virus, oncogenic 206
Vitamin A
deficiency states of 297–298
discussion of 296–298, 297f–298f
function of 296–298
toxicity of 298
Vitamin $B_{12}$ deficiency 835
Vitamin $B_{12}$ deficiency anemia
clinical features of 423
as megaloblastic anemia 423
pathogenesis of 423b
Vitamin C (ascorbic acid)
deficiency of 301
discussion of 301–302
function of 301–302
toxicity of 301–302
Vitamin D
deficiency states of 299–301, 301f
discussion of 298–301
functions of 299, 299f
metabolism of 298–299, 299f
toxicity of 301
Vitamin deficiency
nutritional disease and 296–302, 302t–303t
Vitamin A and 296–298
Vitamin C and 301–302
Vitamin D and 298–301
Von Gierke disease 232–233, 233t
von Hippel-Lindau disease 847
morphology of 847b
Von Willebrand disease 455
summary for 456
von Willebrand factor (vWF) 80, 81f
Vulva
non-neoplastic epithelial disorders of 682
tumors of 683–684
summary for 684b
vulvitis and 681–682
Vulvitis 681–682

W

WAGR syndrome 261–262
Waldenström macroglobulinemia 439–440
Warts. *See* Verrucae
Waterhouse-Friderichsen syndrome
disseminated intravascular coagulation and 452b
metabolic abnormalities and 96
Water retention 77–78
Wegner granulomatosis (WG) 353–354
clinical features of 354
diffuse alveolar hemorrhage syndromes and 485
morphology of 353b–354b, 353f
Wernicke-Korsakoff syndrome 281, 302t, 835
morphology of 835b
White cell disorder
hematopoietic system and 425–449
neoplastic proliferations of
histiocytic neoplasms and 449
neoplastic proliferations of 428–449
lymphoid neoplasms and 429–443
myeloid neoplasms as 444–448
as white cell disorders 428–449
non-neoplastic disorders of 425–428
leukopenia as 425–426
reactive leukocytosis as 426–427
reactive lymphadenitis as 427–428
White infarcts 92b–93b, 93f, 94
Wilms tumor
discussion of 261–262
morphology of 262b, 262f–263f
summary for 262b–263b
tumors of the kidney and 549
Wilson disease
clinical features of 631
as inherited metabolic disease 630–632
morphology of 631b
pathogenesis of 631b
Wood smoke 273
Wrist, carpal ligaments of 157–158

X
Xenobiotics 271, 271f–272f
summary for 273
Xeroderma pigmentosum 197
Xerophthalmia (dry eye) 297–298
Xerostomia 131, 132b, 555
X-linked agammaglobulinemia (XLA) 140, 143
X-linked disorder 220

Y
Yellow fever 620
Yolk sac tumor 660b–662b, 661f

Z
Zollinger-Ellison syndrome 568b
