# Foreword

*Sataloff's Comprehensive Textbook of Otolaryngology: Head and Neck Surgery* is a component of the most extensive compilation of information in otolaryngology—head and neck surgery to date. The six volumes of the comprehensive textbook are part of a 12-volume, encyclopedic compendium that also includes a six-volume set of detailed, extensively illustrated atlases of otolaryngologic surgical techniques. The vision for the *Comprehensive Textbook* was realized with the invaluable, expert collaboration of eight world-class volume editors. Chapter authors include many of the most prominent otolaryngologists in the world, and coverage of each subspecialty is extensive, detailed and scholarly.

Anil K Lalwani, MD edited the volume on otology/neurotology/skull base surgery. Like all six of the volumes in the *Comprehensive Textbook*, the otology/neurotology/skull base surgery volume is designed not only as part of the multivolume book, but also to stand alone or in combination with the atlas of otological surgery. Dr Lalwani's volume covers anatomy and physiology of hearing and balance, temporal bone radiology, medical and surgical treatment of common and rare disorders of the ear and related structures, occupational hearing loss, aural rehabilitation, cochlear and brainstem implantation, disorders of the facial nerve, and other topics. Each chapter is not only replete with the latest scientific information, but also accessible and practical for clinicians.

The rhinology/allergy and immunology volume by Marvin P Fried and Abtin Tabaee is the most elegant and inclusive book on the topic to date. Drs Fried and Tabaee start with a history of rhinology beginning in ancient times. The chapters on evolution of the nose and sinuses, embryology, sinonasal anatomy and physiology, and rhinological assessment are exceptional. The volume includes discussions of virtually all sinonasal disorders and allergy, including not only traditional medical and surgical therapy but also complementary and integrative medicine. The information is state-of-the-art.

Anthony P Sclafani's volume on facial plastic and reconstructive surgery is unique in its thoroughness and practicality. The volume covers skin anatomy and physiology, principles of wound healing, physiology of grafts and flaps, lasers in facial plastic surgery, aesthetic analysis of the face and other basic topics. There are extensive discussions on essentially all problems and procedures in facial plastic and reconstructive surgery contributed by many of the most respected experts in the field. The volume includes not only cosmetic and reconstructive surgery, but also information on diagnosis and treatment of facial trauma.

The volume on laryngology edited by Dr Michael S Benninger incorporates the most current information on virtually every aspect of laryngology. The authors constitute a who's who of world experts in voice and swallowing. After extensive and practical discussions of science and genetics, the volume reviews diagnosis and treatment (traditional and complementary) of laryngological disorders. Chapters on laser physics and use, voice therapy, laryngeal dystonia, cough, vocal aging and many other topics provide invaluable "pearls" for clinicians. The volume also includes extensive discussion of surgery for airway disorders, office-based laryngeal surgery, laryngeal transplantation and other topics.

For the volume on head and neck surgery, Drs Patrick J Gullane and David P Goldstein have recruited an extraordinary group of contributors who have compiled the latest information on molecular biology of head and neck cancer, principles of radiation, immunobiology, medical oncology, common and rare head and neck malignancies, endocrine neoplasms, lymphoma, deep neck space infections and other maladies. The surgical discussions are thorough and richly illustrated, and they include definitive discussions of free flap surgery, facial transplantation and other subjects.

Dr Christopher J Hartnick's vision for the volume on pediatric otolaryngology was expansive, elegantly scholarly and invaluable clinically. The volume begins with information on embryology, anatomy, genetics, syndromes and other complex topics. Dr Hartnick's contributors include basic discussions of otolaryngologic examination in a pediatric patient, imaging, hearing screening and aural rehabilitation, and diagnosis and treatment of diseases of the ear, nose, larynx, oral cavity, neck and airway. Congenital, syndromic and acquired disorders are covered in detail, as are special, particularly vexing problems such as chronic cough in pediatric patients, breathing and obstructive sleep apnea in children, pediatric voice disorders, and many other subjects. This volume will be invaluable to any otolaryngologist who treats children.

All of us who have been involved with the creation of the six-volume *Sataloff's Comprehensive Textbook of Otolaryngology: Head and Neck Surgery* and its companion six-volume set of surgical atlases hope and believe that our colleagues will find this new offering to be not only the most extensive and convenient compilation of information in our field, but also the most clinically practical and up-to-date resource in otolaryngology. We are indebted to Mr Jitendar P Vij (Group Chairman) and Mr Ankit Vij (Group President) of M/s Jaypee Brothers Medical Publishers (P) Ltd., New Delhi, India, for their commitment to this project, and for their promise to keep this work available not only online but also in print. We are indebted also to the many otolaryngologists who have contributed to this work not only by editing volumes and writing chapters, but also by asking questions that inspired many of us to seek the answers found on these pages. We also thank especially the great academic otolaryngologists who trained us and inspired us to spend our nights, weekends and vacations writing chapters and books. We hope that our colleagues and their patients find this book useful.

Department of Otolaryngology—Head and Neck Surgery
Senior Associate Dean for Clinical Academic Specialties
Drexel University College of Medicine
Philadelphia, Pennsylvania, USA

# Preface

This book represents an enormous amount of hard work and the collective wisdom of a large swath of our Pediatric Otolaryngology community. I challenged the authors to be current, to be clinical, and to provide not only the background required to understand the chapter's topic, but also some sense of best practice and, when possible, evidence-based treatment algorithms. All "written" textbooks are of necessity beginning to become dated the moment they are published, as more recent articles and literature come out. Yet this textbook, I hope, should give the reader some sense of the framework underlying today's as well as tomorrow's knowledge of the underpinnings that are used to understand the clinical problems, particular issues in management that arise, and how they are handled.

I hope you enjoy and learn!

**Christopher J Hartnick** MD

# Acknowledgments

The editor would like to thank Joseph Rusko, Marco Ulloa, Carol Rogers Field, Bridget Meyer, Thomas Gibbons and the rest of the Jaypee Brothers team. Without their perseverance and hard work, this volume would not have been possible. Special thanks are offered to the authors, who have shared their expertise and experience in order to improve the care of the Pediatric Otolaryngology patients.

I would also like to thank Mr Jitendar P Vij (Group Chairman), Mr Ankit Vij (Group President), Ms Chetna Malhotra Vohra (Associate Director), Mr Umar Rashid (Development Editor) and Production team of Jaypee Brothers Medical Publishers (P) Ltd., New Delhi, India.

CHAPTER

# Embryology of the Facial Nerve and Related Structures

1

***Robert Thayer Sataloff***

## INTRODUCTION

Facial nerve embryology is discussed in detail by Sataloff and Sataloff.[1] This chapter is a brief overview of material presented in that book. This chapter is also modified in part from an article on this topic, with permission.[2] In studying the embryology of the facial nerve, it is helpful to keep in mind the final structure toward which development progresses. In the adult, the motor nucleus of the facial nerve (VIIIth cranial nerve) is located deep in the reticular formation of the caudal portion of the pons. The axons leave the motor nucleus and extend dorsally and medially, cranially, and superficially. They bend around the abducens nucleus to form the first genu of the facial nerve. The fibers then course deep through the pons and exit from the central nervous system between the olive and the inferior cerebellar peduncle. At this point, the axons join to form the motor root. The sensory root (nervus intermedius) consists of central processes of neurons located in the geniculate ganglion and axons of parasympathetic neurons from the superior salivatory nucleus. The nervus intermedius enters the central nervous system at the pontocerebellar groove lateral to the motor root and synapses with neurons in the upper part of the solitary tract of the medulla oblongata. The facial nerve and nervus intermedius course with the vestibuloacoustic nerve from the brainstem and enter the internal auditory canal (Fig. 1.1). For approximately 20% of its course, the nervus intermedius is fused with the VIIIth cranial nerve.[3]

At the point where the facial nerve enters the middle ear, it bends a second time at the geniculate ganglion (the second genu) and courses horizontally through the middle ear. It then curves (the pyramidal bend) to course vertically through the mastoid bone and exits at the stylomastoid foramen (Fig. 1.2). The nerve is ordinarily surrounded by a bony sheath called the fallopian canal. Several branches are given off during the intrapetrosal course. The facial nerve spreads extratemporally to innervate the facial musculature (Figs. 1.3A and B).

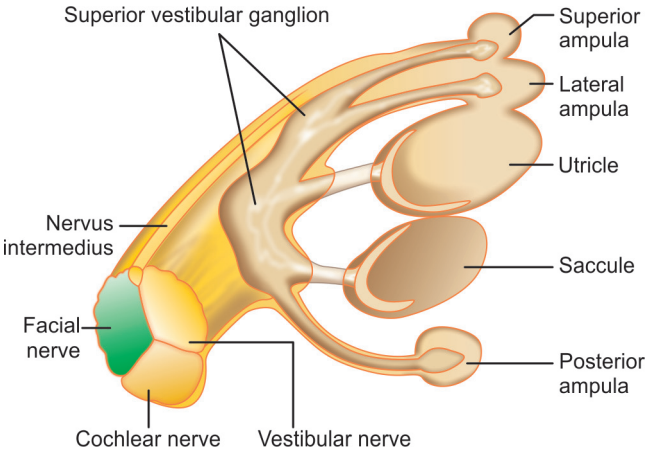

**Fig. 1.1:** The usual relationships of the 7th and 8th cranial nerves as they enter the internal auditory canal and temporal bone.

Medially to laterally, the facial nerve branches include 11 structures of note (Fig. 1.4):

1. Communications in the internal auditory canal with the VIIIth cranial nerve
2. The greater superficial petrosal nerve, which supplies taste fibers to the palatal mucosa, preganglionic parasympathetic axons to the pterygopalatine ganglion,

The figures in this chapter originally appeared as part of Chapters 3 and 4: Embryology and Anomalies of the Facial Nerve by Sataloff RT and Sataloff JB. Philadelphia, Jaypee Medical Inc., 2014.

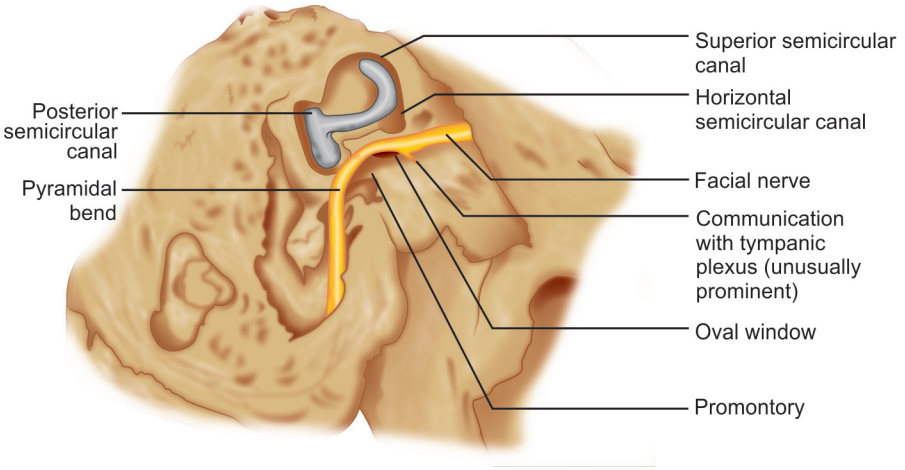

**Fig. 1.2:** The relationship of the facial nerve in its horizontal and vertical portions to other temporal bone landmarks.

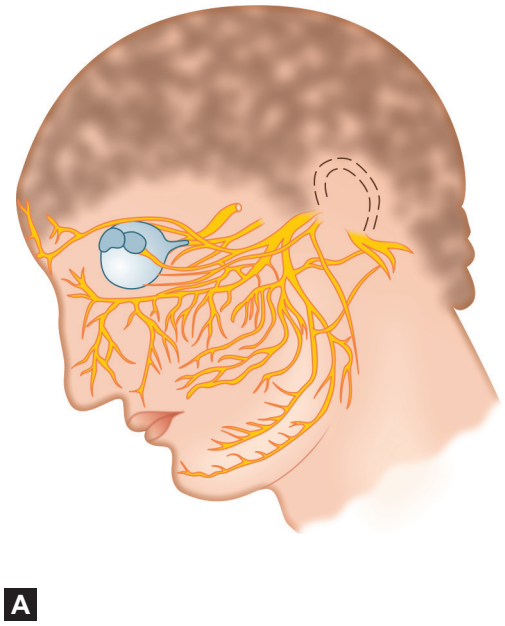

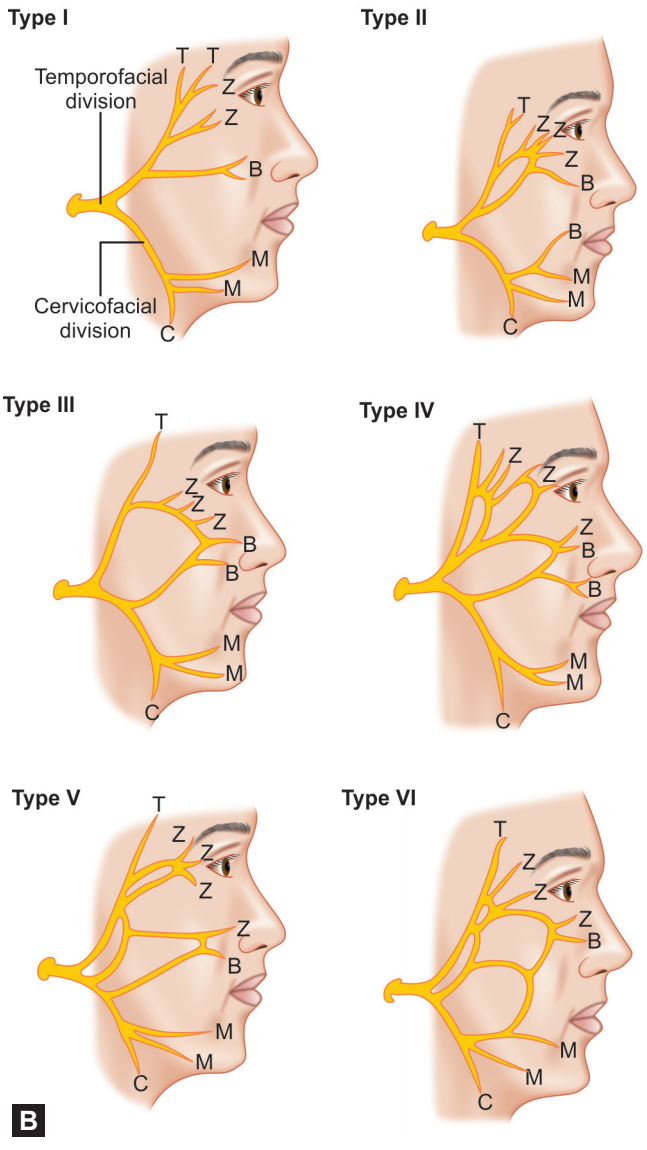

**Figs. 1.3A and B:** (A) The distribution of the facial nerve to muscles of the face after the nerve has exited from the stylomastoid foramen. The extratemporal anatomy of the facial nerve is variable. (B) Common patterns of branching of the extracranial portion of the facial nerve. Type I is seen in 20% of cases; Type II, in 37.5%; Type III in 20%; Type IV, in 15%; Type V, in 15%; and Type VI, in 2.5%, according to Coker and Fisch. (T: Temporal branch; Z: Zygomatic branch; B: Buccal branch; M: Marginal mandibular branch; C: Cervical branch).

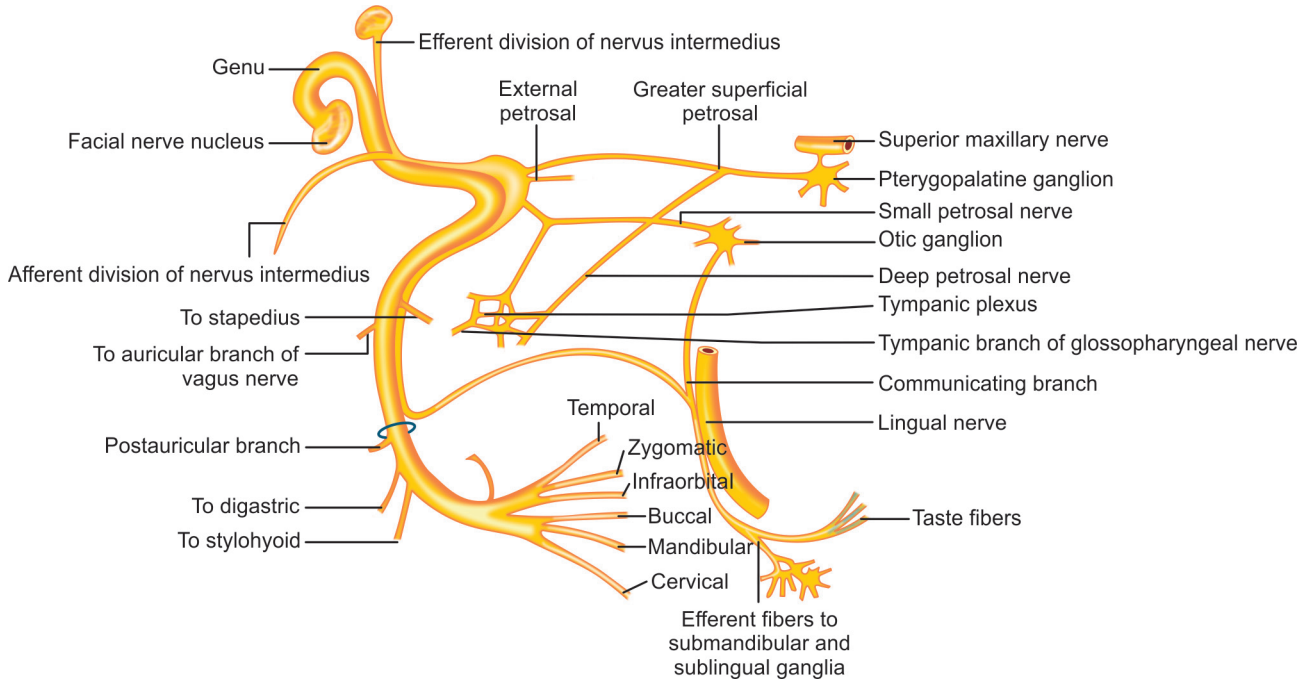

**Fig. 1.4:** Branches of the facial nerve.

and postganglionic axons to the lacrimal glands, nasal glands, and palatine mucosal glands; it also communicates with the lesser petrosal nerve[3]

3. The nerve to the stapedius muscle
4. The chorda tympani nerve, which supplies taste fibers to the anterior two-thirds of the tongue, preganglionic parasympathetic fibers to the submandibular gland, and postganglionic fibers to the submandibular and sublingual glands
5. The posterior auricular branch, which innervates the auricularis posterior, the cranially oriented muscles of the auricle, and the occipital muscles-communicates with the greater auricular nerve, the auricular branch of the vagus nerve, and the lesser occipital nerve[3]
6. The branch to the posterior belly of the digastrics muscle
7. The branch to the stylohyoid muscle
8. The temporal branch that supplies the lateral intrinsic muscle of the auricle, the anterior and superior auricular muscles, the frontalis, the orbicularis oculi, and the corrugator
9. The buccal branch, which innervates the procerus, the zygomaticus major and minor, the levator labii superioris, the levator anguli oris, nasal muscles, the buccinator, and the orbicularis oris
10. The marginal mandibular branch to the risorius muscle and the muscles of the lower lip and chin
11. The cervical branch to the platysma; there are interconnections between the facial nerve and primarily the sensory nerves, including the trigeminal, glossopharyngeal, vagus, and cervical nerves.[4]

The intracranial portion of the facial nerve is supplied by the anterior inferior cerebellar artery. The intrapetrosal portion is supplied by the superficial petrosal branch of the middle meningeal artery and the stylomastoid branch of the posterior auricular artery. The extracranial portion is supplied by the stylomastoid, posterior auricular, superficial temporal, and transverse facial arteries. The anastomosis between the intratemporal branches usually occurs in the upper one-third of the vertical portion.

## EMBRYOLOGY OF THE INTRACRANIAL PORTION OF THE FACIAL NERVE

This discussion includes information on the development of only the extracranial portions of the facial nerve. We encourage the reader to consult other literature for a brief review of the embryology of the intracranial portions,[1] and for new information on differentiation and migration of the facial nerve.[1] This information is very helpful for the purpose of orientation.

*Fertilization through week 4*: The facioacoustic primordium appears during the third week of life. It is attached

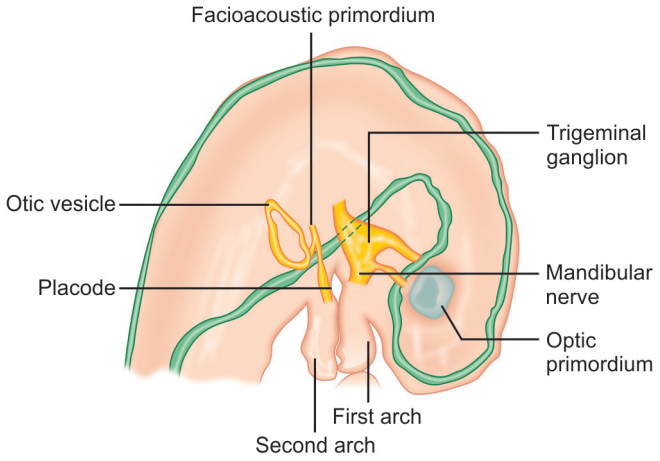

**Fig. 1.5:** A 4.2-mm embryo approximately 3-and-a-half weeks old. The region of the epibranchial placode of the second arch is labeled.

to the metencephalon just rostral to the otic vesicle. It becomes more superficial and rostral as it proceeds ventrally, and it ends adjacent to the deep surface of the epibranchial placode on the dorsal and caudal aspect of the first branchial groove. There are no branches, and the geniculate ganglion is not yet present (Fig. 1.5). During the fourth week, by the time the embryo reaches 4.8 mm in length, the facial nerve splits into two parts. The chorda tympani nerve comes off rostrally, courses ventrally to the first pharyngeal pouch, and enters the mandibular arch. The caudal main trunk terminates in mesenchyme. By the time the embryo reaches 6 mm in length, the nerve approaches the epibranchial placode, and large, dark nuclei mark the development of the geniculate ganglion.[5]

*Weeks 5 and 6*: By the time the embryo has reached 7 mm in length, near the beginning of the fifth week, the mesenchymal concentrations that form the cephalic muscles can be seen in association with their nerves (Fig. 1.6).[6] The geniculate ganglion and the nervus intermedius also appear, although the latter is not always visible as a separate nerve until approximately the seventh week.[5] The geniculate ganglion is lateral and rostral to the VIIIth nerve ganglion. The greater superficial petrosal nerve is present. The chorda tympani is large and enters the mandibular arch; it terminates near a branch of the mandibular nerve, which will become the lingual nerve. By the middle of the fifth week (embryo length: 10 mm), the facial nerve gives off small branches to the posterior digastric premuscle mass. The nerve terminates in mesenchyme.

In the 8-mm embryo, all the cranial nerves except the olfactory and optic nerves are recognizable. All the cranial nerves that carry sensory fibers have prominent ganglia near their points of connection with the brain. These include cranial nerves V, VII, VIII, IX, and X. The primarily efferent cranial nerves (III, IV, VI, and XII) have no external ganglia. In the 8- to 14-mm period, the posterior auricular nerve appears near the chorda tympani. Complete separation of the facial and acoustic nerves is apparent, and a discrete nervus intermedius develops.

By the time the embryo reaches 14 mm in length, the geniculate ganglion and the greater superficial petrosal nerve are well defined, and the epibranchial placode has disappeared. The greater superficial petrosal nerve courses ventrally and rostrally to the lateral aspect of the developing internal carotid artery. Here it joins the deep petrosal nerve and continues as the nerve of the pterygoid canal. It terminates in a group of cells that will become the pterygopalatine ganglion. At 16–17 mm (middle of the sixth week), a branch arises from the ventral aspect of the geniculate ganglion and courses caudally and dorsally to the glossopharyngeal ganglion. The chorda tympani and lingual nerves end near the developing submandibular ganglion. Some facial nerve fibers terminate in the mandibular arch superficially and caudally.

During this period, the superficial layer of the mesenchymal lamina of the second arch spreads to establish four laminae (Fig. 1.7):

1. The occipital lamina (the occipitalis, auricularis posterior, and transverse nuchae muscles)
2. The cervical lamina (the cervical part of the platysma)
3. The mandibular lamina (the depressor labii inferioris, the mentalis, the risorius, the depressor anguli oris, the inferior part of the orbicularis oris, and perhaps the buccinator and the levator anguli oris)
4. The temporal lamina, which spreads during the latter part of this stage (the auricularis superior).

When the embryo is between 10 and 18 mm in length, the deep layer of the second mesenchymal lamina differentiates into the posterior digastrics complex (the stapedius muscle, the posterior belly of the digastric muscle, the digastric tendon, and the stylohyoid muscle).

*Weeks 7 through 9*: By the beginning of the seventh week, the embryo has reached approximately 18 mm in length (Fig. 1.8). The nervus intermedius, which is smaller than the motor root of the facial nerve, passes into the brainstem between the acoustic nerve and the facial nerve motor root. The chorda tympani and lingual nerves unite proximal to the submandibular tympani nerves, and it divides into cranial and caudal branches.

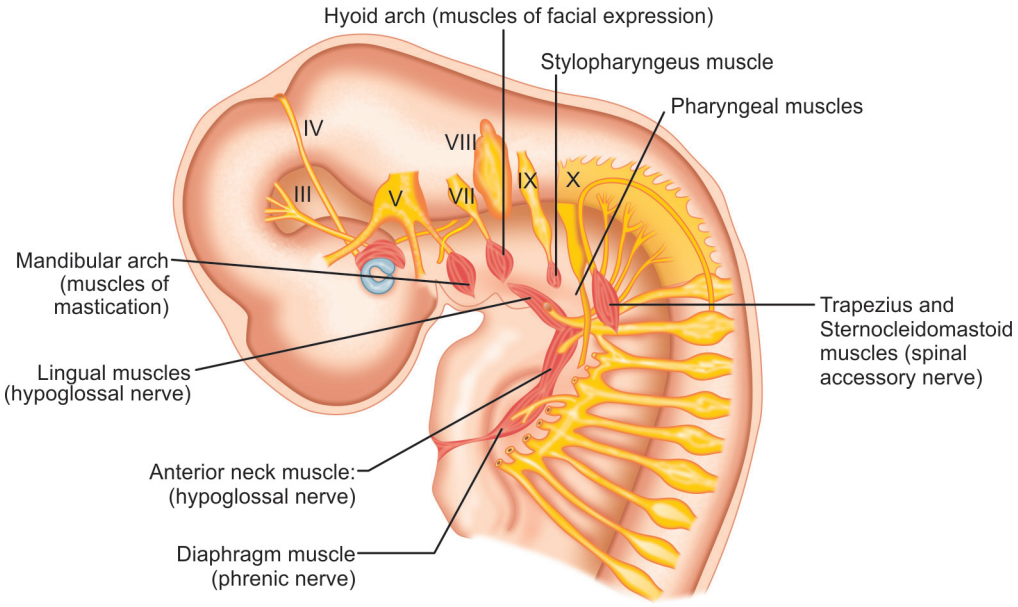

**Fig. 1.6:** Diagram of a 4-and-a-half-week-old embryo illustrating the mesenchymal concentrations that will give rise to the cephalic muscles, as well as the cranial nerves associated with them.

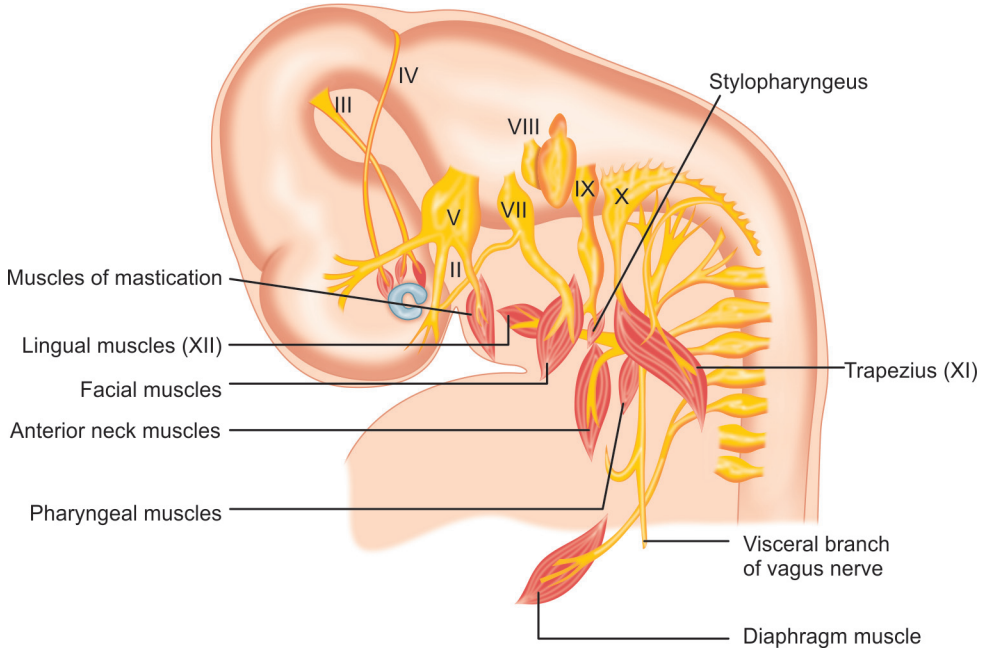

**Fig. 1.7:** A 6-week-old embryo (11 mm) showing further development of the premuscle masses of the cephalic muscles.

The caudal branches communicate with branches of cervical nerves C2 and C3. Several branches are visible in the peripheral portion of the VIIth nerve. The most caudal branches communicate with nerves from the second and third cervical ganglia in a plexus in the second arch. Another portion courses ventrally, terminating deep to the platysma myoblastic lamina. The rest of the branches course to the angle of the mouth, or caudally and superiorly into the mandibular arch. By the time the embryo is 19 mm long, some caudal branches have reached the infraorbital

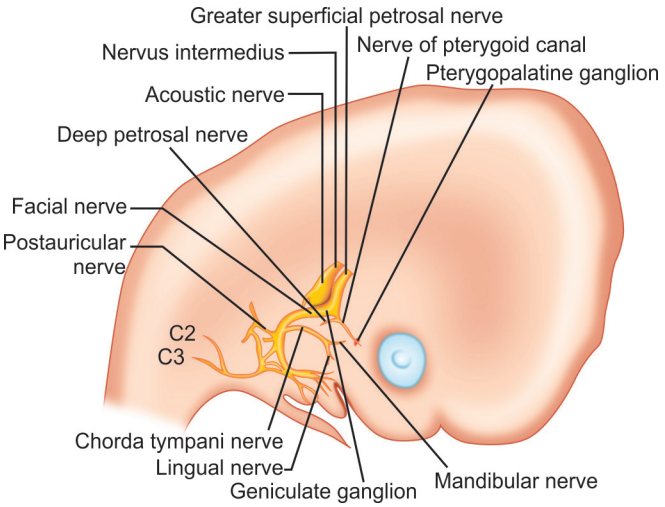

**Fig. 1.8:** The relationship between the facial nerve and parotid primordium at approximately 7 weeks (18 mm).

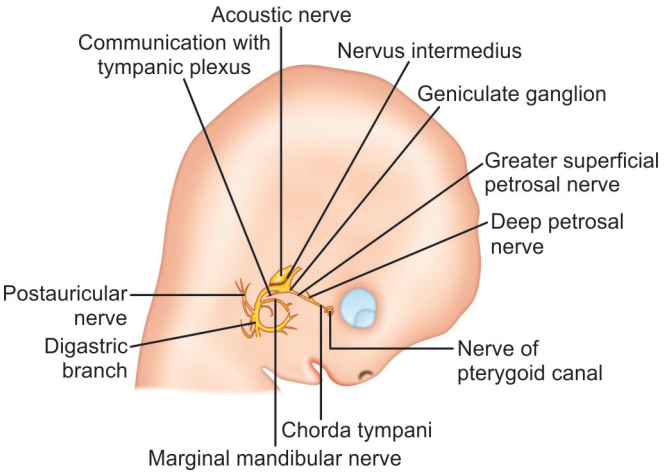

**Fig. 1.9:** By the middle of the 7th week (22 mm), additional branching has occurred. However, the structures of the facial nerve are still anterior with respect to the external auditory meatus, which is in the process of migration from its original location low on the developing embryo.

rim. All of the peripheral branches lie close to the deep surfaces of the myoblastic laminae that will form the facial muscles. Very few fibers course dorsally. The zygomatic and temporal nerves will arise higher in the facial nerve. At 18 mm, the parotid bud is rostral and unbranched, appearing as an evagination from the lateral oral cavity area.

In the 22-mm embryo (middle of the seventh week), the posterior belly of the digastric muscle and the stapedius and stylohyoid muscles are developing (Fig. 1.9). A branch from the geniculate ganglion near the greater superficial petrosal nerve, which developed earlier, is reduced to a communication as the tympanic plexus and the lesser petrosal nerve develop from the IXth cranial nerve. The interanastomoses of the peripheral branches of the facial nerve are visible as separations of the main trunk. A small nerve branch approaches the buccal region superficial to the parotid bud.

Separations between nerve branches increase considerably in number and size by the end of the seventh week (26 mm). By then, the branch to the stapedius muscle is visible. This branch was probably present earlier, but it can be seen only after the branch separates from the main trunk.[5] Peripheral branches course cranially to become the zygomatic and temporal divisions. The buccal, mandibular, and cervical divisions constitute approximately one-half of the peripheral branches. All the peripheral divisions can be identified, but the temporal branches have not yet reached the frontal region. Anastomoses are well established with the infraorbital, buccal, auriculotemporal, and mental branches of the trigeminal nerve. Previously established communications with branches of C2 and C3 have become communications with the greater auricular and transverse cervical nerves. A combined marginal mandibular-cervical branch appears between the time the embryo grows from 20 to 45 mm (seventh through the middle of the eighth week).

The superficial layer of the second-arch mesenchyme differentiates into two more laminae:[4]

1. Infraorbital (zygomaticus major and minor, the levator labii superioris alaeque nasi, the superior part of the orbicularis oris, and possibly the compressor naris, the depressor septi nasi, the orbicularis oculi, the frontalis, the corrugator supercilii, and the procerus)
2. Occipital platysma.

Between 24 and 26 mm, the zygomaticus major, the depressor anguli oris, and the buccinators appear. Between 27 and 45 mm, the frontalis and zygomaticus minor appear. The branch that connects the VIIth cranial nerve with the lesser petrosal nerve (from cranial nerve IX) apparently carries small myelinated fibers that contain interspersed autonomic fibers from the auricular branch of cranial nerve X. In addition, by 26 mm the embryo develops first-order ductules of the parotid primordium, which lies next to the masseter muscle, and several branches of the facial nerve course superficial to it.[7] By 27 mm, second-order ductules appear. At this time, the buccal, marginal mandibular, and cervical nerve branches approach the parotid primordium. By 32 mm (eighth week), third-order

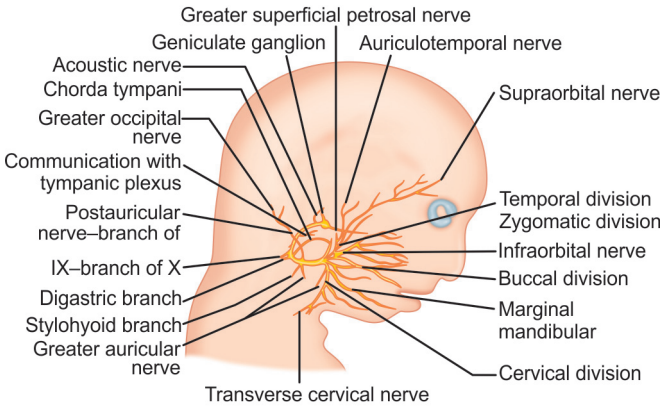

**Fig. 1.10:** During the 11th week (80 mm), extensive branching including communications with other cranial nerves can be seen. The vertical portion of the facial nerve is still anterior with respect to the external auditory meatus (not shown). The vertical portion and main trunk could be injured easily during surgery if the relationship of the auricle to the facial nerve were assumed to be that of an adult.

ductules are present, and the primordium has entered the parotid space. In the 37-mm embryo (8.5 weeks), fourth-order parotid ductules are present, and buccal nerve branches are superficial to the main duct. The temporal, zygomatic, and upper buccal branches are superficial on the parotid primordium. The lower buccal, mandibular, and cervical branches are deeper. The postauricular nerve goes to the occipital region, and a branch to the dorsal aspect of the auricle is present. Although there are no branches to the fused eyelids, yet a branch from the temporal division approaches the frontal region.

During the eighth week, a sulcus develops around the facial nerve, blood vessels, and stapedius muscle on the posterior aspect of the cartilaginous otic capsule. The sulcus is the beginning of the fallopian canal. The orbicularis oris, the levator anguli oris, and the orbicularis oculi also appear at approximately 37 mm.[4] During the ninth week (50–60 mm), the auricularis anterior, the corrugator supercilii, the occipital and mandibular platysma, and the levator labii superioris appear. Also about the ninth week, the laterohyale fuses to the otic capsule to form part of the anterior wall of the fallopian canal and the pyramidal eminence. The segment of the anterior wall of the fallopian canal distal to the laterohyale is formed by Reichert's cartilage. The cranial nerves move closer to their adult relationships.

*Weeks 10 through 15*: During the 58- to 80-mm period, extensive branching of the peripheral portions of the facial nerve occurs (Fig. 1.10). Some divisions reach the midline. Extensive communication with branches of the trigeminal nerve occurs in the perioral and infra-orbital regions. Communications exist between the nervus intermedius and both the VIIIth nerve and the motor root of the VIIth nerve. Despite extensive branching, the facial nerve begins its vertical course while still in the middle ear, and its relationship to the external and middle ear structures is far more anterior than it is in the adult.

During the 11th week (80 mm), the external petrosal nerve arises from the facial nerve distal to the geniculate ganglion and courses with a branch of the middle meningeal artery. Branches also arise from the facial nerve between the stapedius and the chorda tympani nerves. Together, these branches and branches of cranial nerves IX and X provide sensory innervation to the external auditory canal. Branches to the lateral aspects of the eyelids are present, and communication with the zygomaticotemporal nerve has begun to develop. Previous communications with branches of cervical nerves have now become communications with the lesser occipital and transverse cervical nerves. The horizontal portion of the facial nerve can be distinctly seen adjacent to the developing otic capsule. The nasal muscles arc also differentiated at approximately 80 mm.

The relationship between the facial nerve and the parotid gland is about the same at 12 weeks as it was at 7 weeks. However, by the time the embryo reaches 80 mm in length, complicated connections between the superficial and deep portions of the parotid primordium can be seen.[7] At 14 or 15 weeks, the geniculate ganglion is fully developed, and facial nerve relationships to middle ear structures have developed more fully. During this growth period, the facial nerve has remained in association with the mesenchyme, which differentiates into the labyrinth and the mastoid.

*Week 16 through birth*: Between 16 and 20 weeks, the facial nerve, arterioles, venules, and the stapedius muscle lie in a sulcus on the canalicular wall. The mesenchyme in which they are surrounded is differentiating into connective tissue. Although the middle ear continues to enlarge, the facial nerve remains more superficial and anterior in relation to the auricle than it is in the adult. All definitive communications of the facial nerve are established by the 16th week (146 mm).

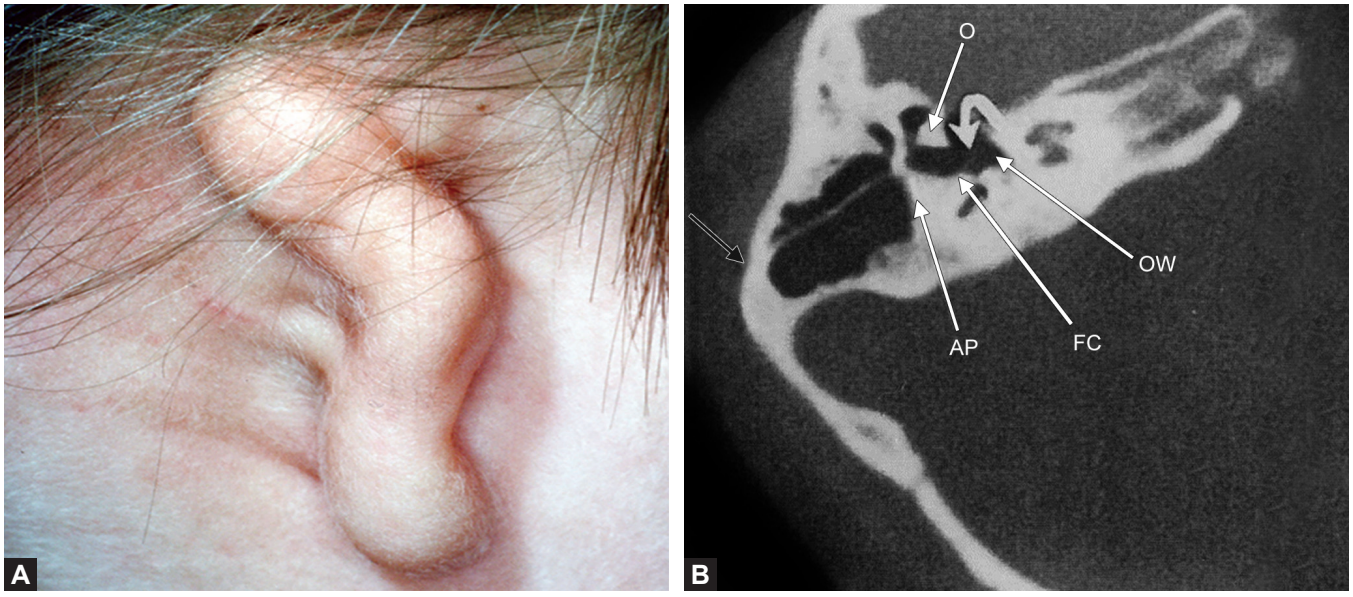
By 26 weeks, ossification has progressed, and growth of the outer layer of periosteal bone has resulted in a partial closure of the sulcus, forming the fallopian

canal. The deep surface is completed first. By 35 weeks, a bony ridge has formed that separates the geniculate ganglion from the epitympanic rim. Late in fetal life, the facial canal in most cases is closed by bone except in the anterior cranial portion, where it remains open to form the facial hiatus along the floor of the middle cranial fossa. However, at least 25% of fallopian canals have this dehiscence; the most common site is adjacent to the oval window.[8] The length of the dehiscence ranges from 0.5 mm to the length of the entire horizontal portion, but they are usually no larger than about 2 × 3 mm. This most common area of dehiscence is probably secondary to the failure of ossification after the stapedial artery (which passes through this area) resorbs prior to birth. The incidence of dehiscence has been reported to be as high as 55%.[9]

By the time of birth, the facial nerve has developed into a complex but generally consistent structure. In an interesting study of the mandibular ramus in stillborns by Sammarco et al.,[10] the authors found that in 17 of 24 facial halves, some or all of the mandibular branches of the cervical facial ramus were below the angle of the mandible. Moreover, 19 of the 24 specimens had 2 or 3 mandibular branches. All mandibular branches were above the mandibular margin as they crossed the facial artery. In 16 specimens, all branches passed over the facial artery; in the other 8, they straddled the facial artery. At birth, the anatomy of the facial nerve approximates that of the adult with the exception of the nerve's exit through the superficially Iocated stylomastoid foramen. Adult anatomy occurs in this region as the mastoid tip develops postnatally.

## CLINICAL APPLICATIONS

In patients with congenital malformations, it is usually possible to determine the fetal age at which developmental arrest occurred. This information allows the surgeon to predict the anatomy of the deformed ear and facial nerve on the basis of their usual embryologic development at the time when the arrest occurred. Moreover, if anomalies are also present in other organ systems (e.g., the kidney), they often reflect interference with development at the same time in fetal life. Hence, when a congenital anomaly of any portion of the ear can be observed visually, radiologically, or surgically, and if the clinician recognizes the fetal age at which normal development ceased in that portion, the physician should be able to predict the position of the facial nerve. If the facial nerve is anomalous, its development is most likely to have been interrupted at the same time that the development of the ear was interrupted, particularly in the case of a middle ear malformation.



**Figs. 1.11A and B:** (A) Appearance of the auricle prior to otoplasty. (B) CT scan revealing absence of the external auditory canal (open arrow), an atresia plate (AP) at the level where the tympanic membrane should be, and the ossicular mass (O). The dehiscent horizontal portion of the facial nerve (curved white arrow) is seen coursing above the oval window (OW) and entering the fallopian canal (FC) at the pyramidal bend.

To test the validity of such predictions, surgical observations were made of 13 ears in 11 patients with congenital malformations.[1,11] We describe one of these cases to illustrate the clinical application of information about facial nerve embryology. The patient was a 6-year-old boy who had been followed by the author since the age of 3 months. His auricle was malformed, and only portions of the helix, lobule, and tragus were recognizable. Computed tomography (CT) revealed the absence of the external auditory canal and the presence of a small middle ear space with an ossicular mass (Figs. 1.11A and B).

The appearance of the auricle placed the time that the defect occurred at approximately the eighth week, and the relationship of the nerve to middle ear structures had been fairly well established. However, because the middle ear was small and not fully formed, it and the vertical portion of the facial nerve appeared to the surgeon to be anteriorly and inferiorly displaced. Moreover, the vertical portion of the nerve coursed more superficially than it does in the normal adult. The nerve coursed through the region where the surgeon planned to construct the new ear canal.

After creating an ear canal and removing the atresia plate, the surgeon identified the moderately malformed ossicles. The malleus and incus were fused, but an incudomallear joint was seen. The stapes was fully developed but immobile, although it was easily manipulated. The horizontal portion of the facial nerve was in a normal position relative to the stapes, but dehiscent. As predicted, the facial nerve and middle ear were more anterior than is the case in a fully developed ear, and the facial nerve coursed anteriorly and laterally more abruptly distal to the pyramidal bend.

If adult relationships are used to gauge the position of the middle ear with respect to the position of the external meatus, the surgeon would enter the middle ear and mastoid region posterior to the vertical portion of the facial nerve and hypoplastic middle ear. Exploration from the point of entry forward would put the facial nerve at risk of injury, especially in light of its abruptly superficial course from the pyramidal bend to the stylomastoid foramen. However, with an understanding of the embryology of the facial nerve, its location can be predicted easily and accurately.

CHAPTER

# Update on Inner Ear Regeneration/Basic Science Update

2

*Judith S Kempfle, Albert SB Edge*

## INTRODUCTION

About 12–17% of the American population has some degree of hearing loss[1] (http://www.nidcd.nih.gov/health/statistics/Pages/quick.aspx), including sensorineural hearing loss (SNHL) in 2–3 out of 1,000 newborns and conductive hearing loss or malformations that affect the outer and middle ear in a large number of children.

To date, no cure is available for SNHL. Sensory cells that are lost do not regenerate. Hearing aids only provide limited effectiveness to children with severe SNHL, and even for children who qualify for a hearing aid, only one fifth of them are compliant.[2] Cochlear implants are effective in children with severe SNHL. Despite all technical advances, however, hearing quality remains far below natural hearing, which complicates speech and language development in these children.

The most common causes of SNHL are the loss of sensory cells and loss or degeneration of spiral ganglion neurons (SGN). Genetic causes are prevalent in children, but a variety of environmental causes also cause loss of sensory cells and neurons. These include noise, trauma, ototoxic drugs, and toxins. Once the cells are lost, the inner ear undergoes rapid degenerative changes and does not recover.[3,4] In order to restore hearing for children before or during speech development, regenerative approaches for hearing loss, in particular medical treatments, would be highly attractive.

## THE FLIPSIDE OF EVOLUTION

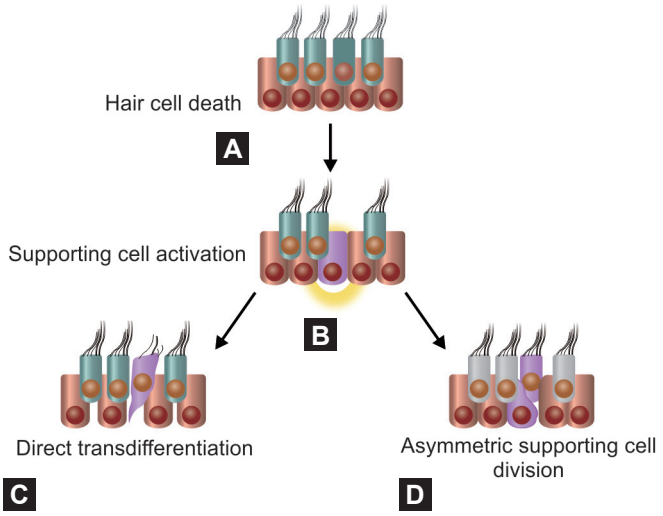
Lower vertebrates replace hair cells after damage. In the vestibular organs of fish and amphibians, vestibular hair cells are produced throughout life, and the overall number of hair cells increases with the growth of the animal.[5,6] In birds, the number of hair cells does not increase while the animal is growing; rather, new cells replace old, dying cells.[7,8] This suggests that the sensory epithelia of lower vertebrates contain mitotic cells that act like stem cells. Mammals, however, do not retain a capacity to replace hair cells after damage. The inability to replace hair cells has been hypothesized to be due to the complex anatomy of the inner ear, as well as a more rigid cytoskeletal structure in the mammal compared to other animals, which prevents proliferation and cell cycle re-entry.[9–11]

Destruction of hair cells with a laser in the lateral line of zebra fish led to massive regeneration of hair cells.[12,13] Similar regeneration was shown in the auditory and vestibular organs of birds after ototoxic or noise damage.[11,14] In all cases, supporting cells are the source of hair cells.

Replacement and regeneration of hair cells occurs by asymmetric division or by direct transdifferentiation. In asymmetric division, a pre-existing supporting cell divides and forms a new hair cell and supporting cell. In direct transdifferentiation, a supporting cell dedifferentiates to redifferentiate into a hair cell, and the replacement takes place without proliferation, thereby depleting the supporting cell pool (Figs. 2.1A to D).[15,16]

## INNER EAR DEVELOPMENT

The developmental processes that lead from the very early stages of inner ear development to the final mature cochlear and vestibular structures could provide clues for designing strategies to regenerate cells of the inner ear.



**Figs. 2.1A to D:** *Hair cell replacement in birds and fish*. After death and disappearance of hair cells in birds or amphibians, supporting cells become activated (A) and turn into hair cells (B) through direct transdifferentiation of one supporting cell into one hair cell (C) or asymmetric division of one supporting cell to become both a hair cell and a supporting cell (D).

In regeneration strategies, the developmental mechanisms can be employed to (re)activate genes and pathways that specify cell fates and cause differentiation into inner ear cell types from stem cells.

Thickening of ectoderm on each side of the neural tube forms the otic placodes and constitutes the first stage in inner ear development. The surrounding tissues help to induce this process with secreted fibroblast growth factors (FGFs). The otic placode invaginates and ultimately closes and forms the otocyst. With continuing development, inner ear morphogenesis separates the otocyst into vestibular and cochlear regions.

The Wnt pathway directs the ectoderm toward an otic fate and specifies the size of the otic placode.[16a] The FGF family is comprised of a number of different secreted growth factors and their receptors (FGFRs). Fibroblast growth factors influence proliferation and differentiation in many tissues. In the inner ear, FGFs are present during otocyst formation and are active in prosensory domain induction to specify neural progenitors and a subset of supporting cells (pillar cells).[17–19] The Notch pathway is active during the earliest induction stages of otic development, and Notch and the members of its canonical pathway are differentially expressed in the otocyst. Recent research suggests that Notch can induce the prosensory stages of development,[20] and pharmacological inhibition of Notch before induction of the prosensory domain leads to a loss of the prosensory area.[21] BMP4 belongs to the TGFb family and is a secreted molecule that plays a key role in signaling for prosensory domain specification, acting along a concentration gradient after release from the surrounding tissues.[22,23] BMP4 is also secreted later in development within the cochlea at different concentration levels, with high concentrations leading to neural cell formation and low concentrations leading to sensory cell formation[24] (J. Kempfle et al., in preparation).

## SENSORY CELL FATE

Precursor cells undergo divisions to give rise to the vestibular and cochlear organs, and this is followed by specification of hair cell, supporting cell, and neuronal fate. Mechanisms that are active during this stage are important for regeneration strategies, since they can be employed to differentiate stem cells into the mature cell types of the inner ear.

Notch, as noted above, is not only important for establishing the prosensory domain but also active during cell fate specification, acting to prevent supporting cells from differentiating into hair cells by a process of lateral inhibition.[25] Notch signaling also cooperates with the Wnt pathway to determine cell fates in the inner ear.[26] The Wnt/β-catenin pathway, which as mentioned above plays a role in development of the prosensory region, also participates in specification of cell fate like the Notch pathway.[27] Other pathways, such as BMP and sonic hedgehog (Shh) also continue to be active during cell fate specification (Fig. 2.2). It is assumed that a gradient of BMP4 exists in the inner ear along a neural-abneural axis, with high concentrations of BMP4 supporting neuron formation and low levels favoring hair cell development.[24] Similarly, high concentrations of Shh also seem to lead to neural differentiation in the ear.[27a]

A key gene for hair cell formation is Atoh1 (Math1). Atoh1 is part of the family of basic helix-loop-helix (bHLH) transcription factors, and it is necessary for hair cell fate but not required for sensory epithelium formation.[28–30]

Overexpression of Atoh1 leads to additional hair cells in nonsensory areas of the inner ear,[28] whereas lack of Atoh1 leads to dying cochlear progenitors and missing hair cells with deafness.[31,32,32a] Stimulating the expression of Atoh1 would be one way to effectively regenerate hair cells but the signaling that leads to its expression remains poorly understood. Interaction of Pax2 and Sox2, and Sox2 with Six1/Eya1, has been implicated in Atoh1 stimulation and the promotion of hair cell fate[33] (J. Kempfle et al., in preparation).

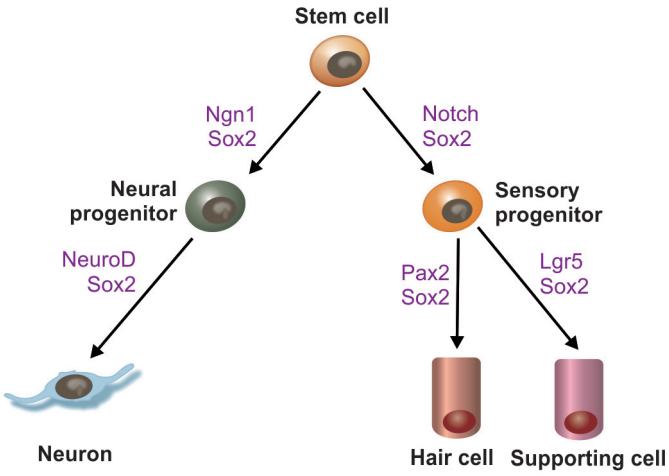


**Fig. 2.2:** *Inner ear cell fate specification*. Development and differentiation of inner ear stem cells follow a stepwise differentiation process from one common stem cell (yellow) into neural (green) or sensory progenitors (orange). Neural progenitors develop into neurons (blue). Sensory progenitors give rise to hair cells (brown) and supporting cells (fuchsia). Crucial factors needed for cell fate and differentiation at the various steps are written in purple.

The fate of cochlear progenitors is directed toward neurons by neurogenin1 (Ngn1). In neural progenitors, Sox2 and Ngn1 interact and activate each other, which leads to subsequent activation of NeuroD and development of SGN.[34] Sox2 is a key gene in conferring stem cell characteristics[35] and plays a critical role in specifying hair cell and supporting cell fate in neural and sensory progenitors. Loss of Sox2 early in development leads to complete loss of the sensory epithelium without development of hair cells and supporting cells.[36] Sox2 is important in continued maintenance of supporting cell fate and while it is ultimately turned off in hair cells and neurons, it continues to be expressed in supporting cells throughout life. Continuous high Sox2 expression may be responsible for the regenerative capacity of supporting cells. Lgr5, which is active in the Wnt pathway, marks a subset of Sox2-positive supporting cells, which have been shown to proliferate and transdifferentiate into hair cells in vivo.[37]

## THE PHANTOM "INNER EAR STEM CELL"

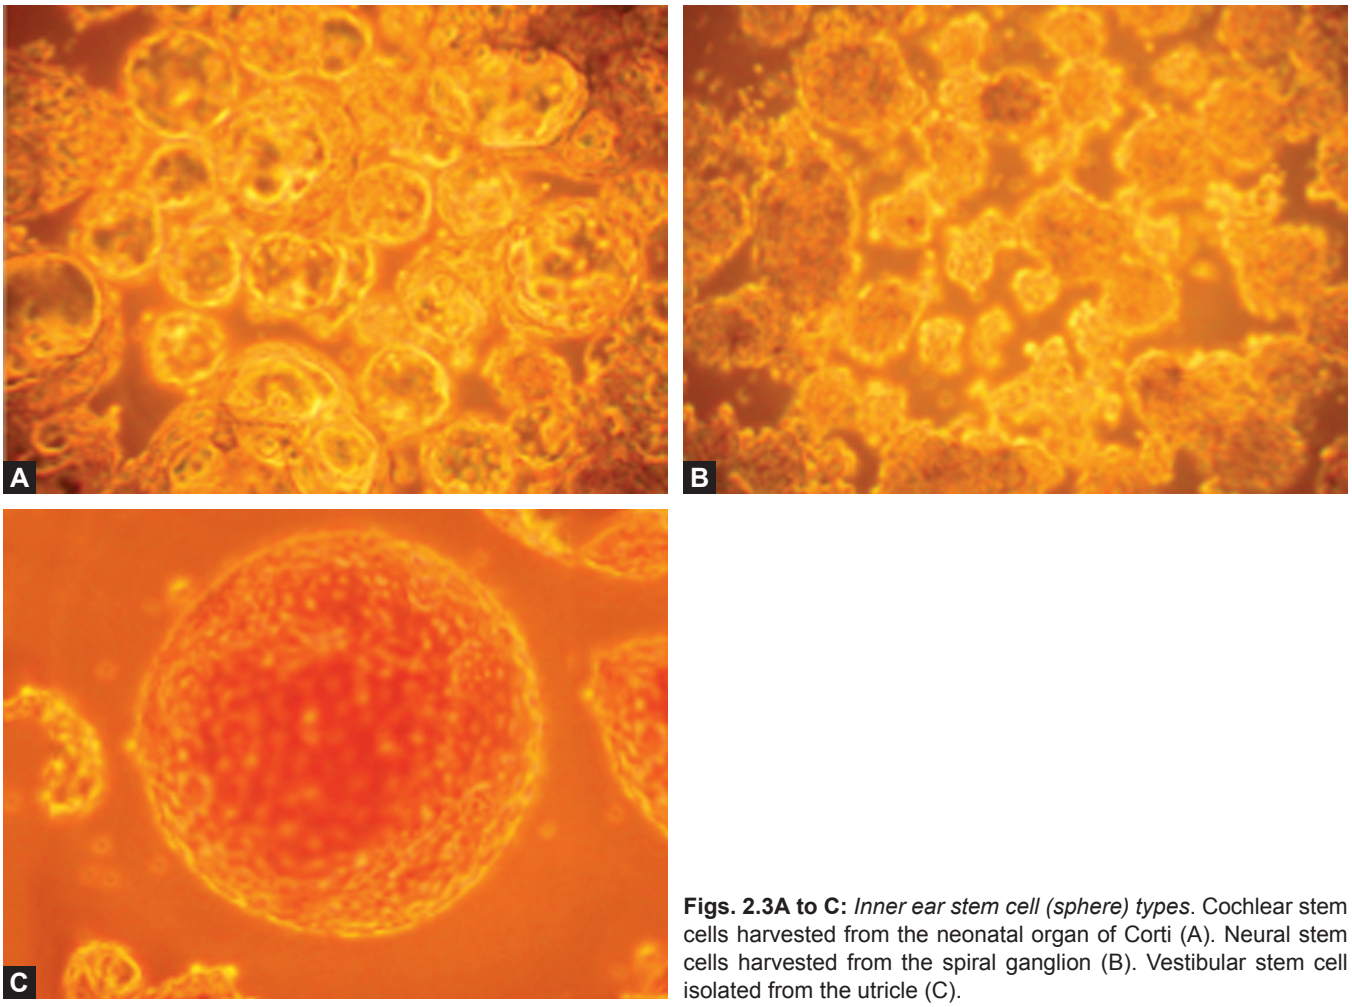
Totipotent embryonic stem cells can renew indefinitely and differentiate into cell types representative of all three germ layers (ectoderm, mesoderm, and endoderm). In postnatal tissue, stem cells with a more limited potential retain the ability to renew their cells and regenerate after damage. These stem cells are pluripotent or multipotent; they remain active throughout life in several organ systems such as blood, skin, and intestine where they replace damaged or old cells. Some organs contain dormant or facultative stem cells with the ability to differentiate after damage to the tissue, whereas other organs such as the brain and heart, which do not repair themselves, may show some turnover, albeit at a very slow rate. Stem cell niches have been discovered in the subventricular zone as well as in the hippocampus in the brain, where neurons are turned over even in the adult.[38] Dormant stem cells may be present in the inner ear.

Tissue isolation from the organ of Corti of neonatal mice has demonstrated cells in the sensory epithelium that undergo cell division, similar to neurospheres harvested from neural tissue, with the addition of growth factors.[39,39a] These spheres can proliferate and increase in number and purity with passage, similar to neural stem cells.[40–42] Expanded spheres contain cells that can give rise to all the cell types of the inner ear similar to the differentiation from the otic placode (Figs. 2.2 and 2.3).

When inner ear stem cells proliferate, they express the stem cell marker, Sox2, similar to the otic placode. Once plated and differentiating, early inner ear progenitors express progenitor markers, Sox2, Musashi, nestin, islet1, and Pax2, similar to those in the brain at early developmental stages. After several days in vitro, the cells downregulate early progenitor markers and begin to express mature neural or sensory cell genes.[41,42]

In the neonatal mouse, such stem cells can be harvested from the organ of Corti (cochlear stem cells), the spiral ganglion (neural stem cells), and the utricle (vestibular stem cells). All of these stem cell types, when put into culture, can proliferate and differentiate into the cell types found in the inner ear. However, only the utricle retains its proliferative qualities until adulthood, whereas the cochlear and neural stem cells lose that ability shortly after birth. Postmortem studies on inner ear tissue of the adult human show limited sphere formation from vestibular cells in vitro, and no sphere formation from cochlear tissue.[43]

In vitro studies have shown that the inner ear harbors cells that may be induced to regenerate hair cells. However, until very recently, it was not known which cells in the ear had stem cell-like capacities. Even though they are not mitotically active in the living animal, supporting cells harvested from neonatal tissue and placed in culture divide and differentiate into hair cells.[16] A subset of supporting cells with stem cell-like properties was



**Figs. 2.3A to C:** *Inner ear stem cell (sphere) types*. Cochlear stem cells harvested from the neonatal organ of Corti (A). Neural stem cells harvested from the spiral ganglion (B). Vestibular stem cell isolated from the utricle (C).

identified: third row of Deiters' cells, inner pillar, and inner border cells, as well as the greater epithelial ridge. All those cells expressed Lgr5, which labels stem cells in the intestine and enhances Wnt pathway activity.[37,44] Wnt signaling plays a role in proliferation and cell fate specification in embryonic development and in stem cells and is highly conserved throughout species. Studies in mice have shown that postnatal supporting cells that express Lgr5 are Wnt dependent.[37] These cells behave as hair cell precursors[37] and are induced to proliferate by Wnt signaling. Future regeneration strategies could thus target supporting cells that express Lgr5.

## REGENERATION AND ITS PITFALLS

Hearing loss or vestibular dysfunctions can be caused by a variety of different factors, such as noise damage, ototoxic substances, trauma, hereditary defects, infectious disease, or aging. Hair cells or neurons that are destroyed cannot be regenerated and treatment options for damage of the inner ear are limited to hearing aids and cochlear implants. Vestibular implants have been tested in monkeys with promising results.[45] Electronic aids could be combined with biologic agents to improve regeneration. A number of recent advances have been made in applying biological methods to repair the inner ear: drug treatment to activate endogenous stem cell-like cells (supporting cells) to proliferate and replace damaged cells,[46] gene transfer with viruses to express genes in remaining cells of the inner ear that lead to regeneration or transdifferentiation into the needed target cell type,[47] and transplantation of stem cells that can replace damaged cells[48,49] (Fig. 2.4).

One obstacle to regenerating the inner ear is the anatomically complex structure of the cochlea and the vestibule. The cells lack planar alignment and are difficult to reach in different compartments of the inner ear.[50] Application of

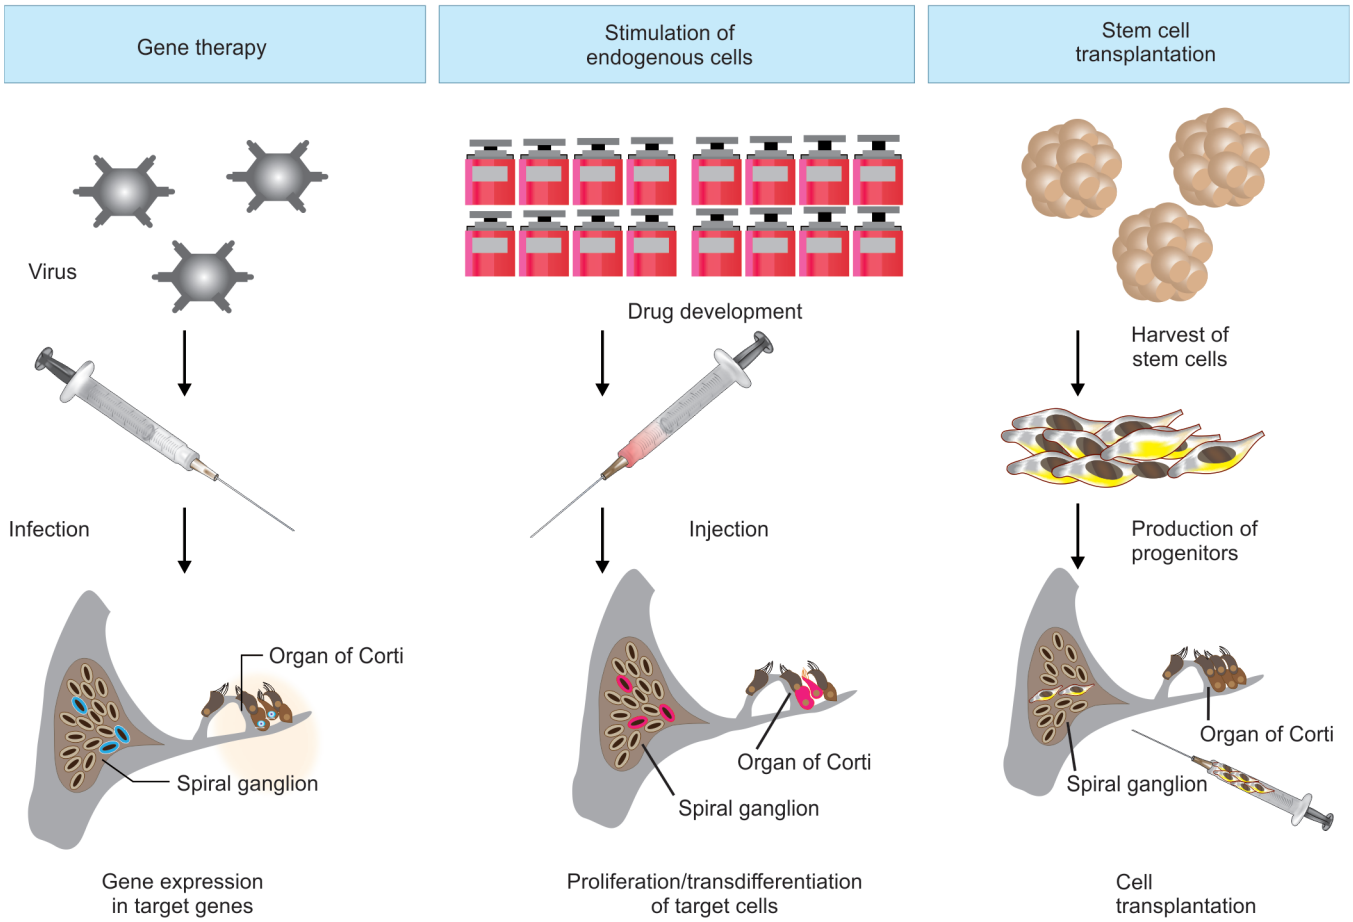


**Fig. 2.4:** *Inner ear regeneration strategies*. Gene therapy: Infection of inner ear target cells with a virus carrying an effector gene. Overexpression of the gene in target cells leads to proliferation or to a switch in cell fate. Stimulation of endogenous cells: Drugs with regenerative potential are injected into the middle ear or directly into the inner ear and activate endogenous cells with regenerative potential (e.g. supporting cells) to transdifferentiate or proliferate. Stem cell transplantation: Embryonic stem cells are differentiated into inner ear cell types and directly injected into the inner ear to replace lost cells.

agents via the middle ear only allows direct access to the basal turn of the cochlea; the spiral ganglion or vestibular organs will require more difficult surgical routes.[51,52]

## TREATMENT WITH GROWTH FACTORS AND DRUGS

Different approaches to the treatment of inner ear dysfunction have involved delivery of protein and small molecule drugs. Neurotrophin-3 (NT3) and brain-derived neurotrophic factor (BDNF) are secreted in the inner ear from early embryonic development to adulthood and are important for survival of neurons. NT3 and BDNF are broadly expressed in the otocyst and are later restricted to the sensory epithelium and then the organ of Corti.[53,54] The receptors for NT3 and BDNF, tyrosine receptor kinases C and B (TrkC, TrkB), respectively, are expressed in the spiral ganglion.[55] Mouse mutants lacking BNDF or NT3 show >80% reduction of SGN.[56,57] Exogenous application of NT3 or BDNF or their agonists in animal models in vitro and in vivo lead to increased neurite outgrowth and survival of SGN.[58–61] The performance of cochlear implants can be compromised by neuronal damage.[62] New techniques including gene therapy with continuous expression of BDNF or NT3 slow release of neurotrophins from polymers, or delivery via coated or filled cochlear implants are under development as a way to treat loss of neurons that result from implantation of the device.[62,63]

In addition to factors used in combination with implants, drug treatment of the inner ear could activate regeneration from cochlear cells after hair cell or neuronal damage. Inhibition of Notch in inner ear stem cells increased hair

cell numbers in vitro.[64] γ-Secretase inhibitors interfere with lateral inhibition and upregulate Atoh1 by inhibiting the Notch pathway. After noise induced hearing loss, application of γ-secretase inhibitors, drugs developed for treatment of Alzheimer's, led to regeneration of hair cells with partial recovery of hearing.[46] Lineage tracing identified supporting cells as the origin of the newly formed hair cells. These supporting cells turned into hair cells by direct transdifferentiation.[46]

## GENE THERAPY

Gene therapy relies on transfer of genes into the cochlea. Different vehicles target different cell types.[50] Viruses, plasmids, and lipid packages have been used as shuttle systems for genes into inner ear cells.[65] Various viral vectors were tried: adenovirus (AV) has a fast onset of gene expression after infection but may only be expressed transiently, as it does not integrate into the host DNA and may cause severe immune reaction or toxicity.[66] Genes delivered with an adeno-associated virus (AAV) are expressed over years in the genome, and AAV has demonstrated very little toxicity, but packaging capacity in AAV is limited. AAV carrying the RPE65 gene was recently applied to the retina in patients with Leber's congenital amaurosis, resulting in partial restoration of vision.[67,68] Lentivirus is less commonly used due to the immune response and toxicity in the inner ear, although it permits long-term expression with high packaging capacity.[50,69] Only 3.4% of clinical trials for gene therapy have used lentivirus (http://www.abedia.com/wiley/vectors.php).

Injection of adenoviruses carrying the Atoh1 gene into the inner ear of rats and mature guinea pigs in vitro and in vivo resulted in additional immature hair cells in nonsensory areas in the ear.[28,69a] Furthermore, adult deafened guinea pigs recovered some hearing after gene therapy with Atoh1-AV, which entered nonsensory cells.[47]

Downregulation of gene expression might be a therapeutic option in the treatment of hereditary diseases. Small interfering RNAs (siRNA), which interfere with transcription by binding to complementary sequences, and microRNAs, which inhibit messenger RNAs at the post-transcriptional level, can be used to inhibit gene expression.[70–72] siRNA to NOX3, which is responsible for production of superoxides in the ear, has been successfully delivered to the inner ear via the transtympanic approach, and inhibition of NOX3 effectively protected hair cells and neurons after ototoxic insult.[73]

## TRANSPLANTATION OF CELLS

Another option for future therapies that would provide alternatives to cochlear implants as well as auditory brainstem implants[74] would be cell replacement in an attempt to rebuild the ear. For such a therapy to be successful requires derivation of fully functional sensory neurons from stem cells, transplantation of neurons into the inner ear, and migration or neurite outgrowth to reinnervate both the cochlea and cochlear nucleus. With a cocktail of secreted neurotrophic molecules, including BMP4, embryonic stem cells were pushed toward a sensory neuron cell fate in vitro.[51] Identification of sensory neuron progenitors indicated that the differentiation programs that define this fate had been at least partially reproduced. After damage of the original neurons in an animal model, transplantation of the neural progenitors was then tested in the animal models by injection into the nerve trunk.[48,51,74a] Progenitors survived in vivo and grew processes that contacted hair cells. They also grew processes into the cochlear nucleus. The formation of functional synapses between hair cell and neurons and in the cochlear nucleus remains to be established, but partial recovery of hearing in the transplanted animal model of auditory neuropathy has been observed.[74a,74b]

## DELIVERY ROUTES TO THE INNER EAR

The major concerns for delivering biological agents into the inner ear are the efficiency and side effects. Several possible means of access for a surgical opening include the round window, accessed from the middle ear though the tympanic membrane, a direct cochleostomy through the lateral wall of the cochlea, and a canalostomy into a semicircular canal. However, the risks of damage to the inner ear including a perilymphatic fistula are high. The least invasive delivery method would be systemic application, as no surgical intervention would be needed, but the efficiency of this approach may be limited by the blood–cochlear barrier[75] and the concentrations of reagents needed to achieve sufficient levels in the perilymph and endolymph may cause systemic side effects such as systemic inflammatory response syndrome (SIRS).[76]

The transtympanic approach provides a safe route for delivery of substances into the middle ear and is commonly used by otologists. To permeate the inner ear in sufficient quantity requires contact with the round window membrane. Large molecules are likely to require an extended time due to lower permeability of the membrane. Several trials have used gelfoam sponges or hyaluronic

acid to increase the time of contact with the round window membrane.[77,78,78a] Alternatively, partial digestion of the membrane with collagenase led to increased entrance of AAV viruses across the membrane into the inner ear. No severe systemic side effects have been reported with either method. Direct application into the inner ear would offer the highest treatment efficiency. Viruses injected into the perilymph can reach the endolymph and target cells.[79,80] Osmotic pumps have achieved long-term delivery.[78,81,82]

## CONCLUSION

Until the introduction of cochlear implant technology some 30 years ago, treatments that would address inner ear dysfunction seemed a remote possibility. Auditory research was a fairly neglected area, but improved understanding of the pathophysiology of SNHL and the discovery of hair cell regeneration in nonmammalian vertebrates provided hope that biological treatments for cellular repair might be possible. Emerging techniques in auditory research and microsurgery allowed for better understanding, but the technologies remain at an early stage of development. The vast improvements and new findings in inner ear research bring regeneration strategies closer, but have yet to enter clinical practice. Gene therapy, small molecules or growth factors, and cell therapy have great promise for both neural and hair cell replacement, but numerous challenges remain. The system is highly resistant to regeneration and the complex anatomy complicates surgical approaches.

Nonetheless, progress in basic inner ear research has been immense and the field is poised for translation of new knowledge into therapies. A mix of bioengineered devices, nanotechnology, and cell therapies is already a reality (e.g. in the cochlear implant), and there is reason for cautious optimism about new treatments for deafness.

CHAPTER

# Impact of Evolution on Eustachian Tube Function and Otitis Media

3

***Charles D Bluestone, J Douglas Swarts, Jeffrey T Laitman***

Otitis media (OM) is a major health-care problem since it is the most frequent diagnosis made by health-care professionals who provide care for infants and children, and is not uncommonly encountered in adults. There is general agreement that the etiology and pathogenesis of middle-ear (ME) disease is multifactorial, but the consequences of human evolutionary history[1] for the presence and prevalence of OM have not been addressed until relatively recently. We have hypothesized that otitis media is most likely a disease that occurs only in humans and is unlikely to be present in other species in the wild.[2] Since hearing loss is associated with ME disease, if animals in the wild developed it they most likely would have been selected out by predation. Normal hearing is essential for survival in the wild.

We also posit that OM in humans is probably a consequence of human evolutionary history, i.e. a side effect of adaptations for bipedalism, the development of a large brain, and speech, producing changes in craniofacial skeleton that underlie the pathogenesis of this unique human disease. In this chapter, we describe these evolutionary events and how their consequences may impact management. Similarly, this evolutionary pathway may also contribute to the occurrence of rhinosinusitis in humans, which is also posited to be present only in humans, and is described in Chapter 27.

## BIPEDALISM, BIG BRAIN, AND BORN TOO SOON

Habitual bipedalism is one of the distinguishing features of hominids when compared with our predecessors, including our nonhuman primate ancestors (Fig. 3.1). Adaptations for bipedality are evident in one of our earliest ancestors, *Ardipithecus ramidus*, who lived > 4 million years ago.[3] There is no consensus on the evolutionary advantages of either walking and running on two legs or knuckle walking as in the great apes over quadrupedal locomotor patterns. But among the hypothesized advantages of bipedality are improved thermoregulation due

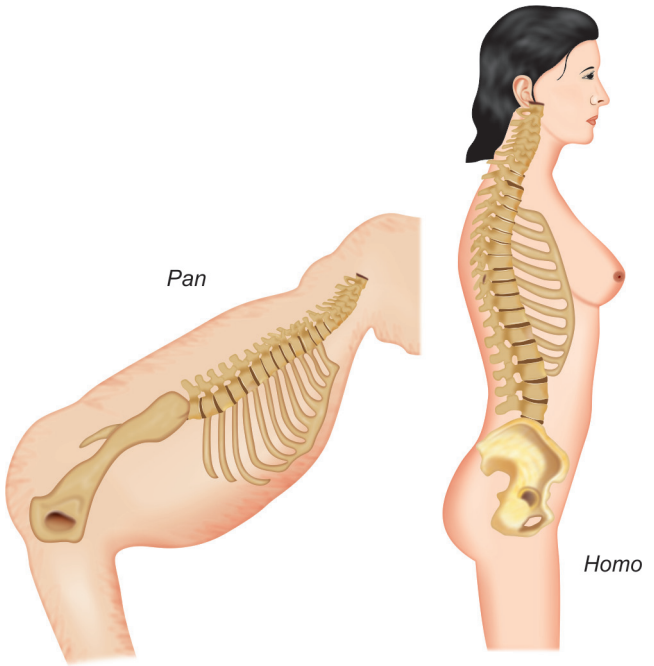

**Fig. 3.1:** Cartoon depicting the locomotive posture of the chimpanzee (*Pan troglodytes*) with that of the human (*Homo sapiens*). With permission from Bluestone and Swarts.[2]

to decreased exposure of the body to sun, ability to carry (including food and infants), the ability to see over the savannah for food and predators, and freeing of the hands, allowing tool- and weapon-making.

On the other hand, there are disadvantages to walking on two legs, such as disorders of the back and lower limb joints, both which are relatively common, but develop after reproductive age. But an even more significant disadvantage arising from bipedality is the constriction of the female pelvic outlet. The narrowing of the outlet is thought to arise as a consequence of the need for osseous support of the abdominal contents and changes that increase biomechanical efficiency in locomotion. For early hominids, these anatomical changes did not impair the delivery of newborns since their brains and bodies were small relative to their mother's size. However, during the subsequent 2 million years the hominid brain doubled in size, such a large increase that humans are born 12 months too early because of the constraints imposed by our big brain on passing through the narrowed pelvic outlet. This sequence of events is well known to anthropologists, as Martin[4] concluded, based on brain development, humans should have a 21 months' gestation period: 9 months in the uterus and 12 months outside the womb. This is illustrated in Figure 3.2 which depicts the relative sizes of the female bony pelvic birth canal to the size of the brain in the chimpanzee and human.[5] Delivery of human newborns through the birth canal is so tight that almost all pregnancies require birth attendants, a situation unique to humans. Anthropologists describe humans as being "secondarily altricial"; some higher mammals, including primates, are mature ("precocious") at birth, whereas others, such as dogs and cats, are "altricial", i.e. relatively helpless at birth. Humans should be precocious at birth but are not.

We previously described, in detail, the comparative anatomic and birthing differences between humans and our primate relatives, and the consequences of being "born too soon" for the ears, nose, and throat.[6] Among these consequences is that the Eustachian tube (ET) is too short and floppy during the first year of life. This structural and functional immaturity, in the context of an immature immune system, helps to explain the high incidence of acute OM in the first year of life, especially now that child day-care attendance exposes these highly susceptible babies to respiratory pathogens. A report from Norway finds recurrent ME infection more prevalent during the first 18 months of life in premature infants when compared with normal term babies. This difference was attributed to gestational age differences, not weight at birth[6]; thus, premature infants are "born way too soon". However, being born too soon does not explain why OM remains common throughout childhood and in some individuals into adulthood.

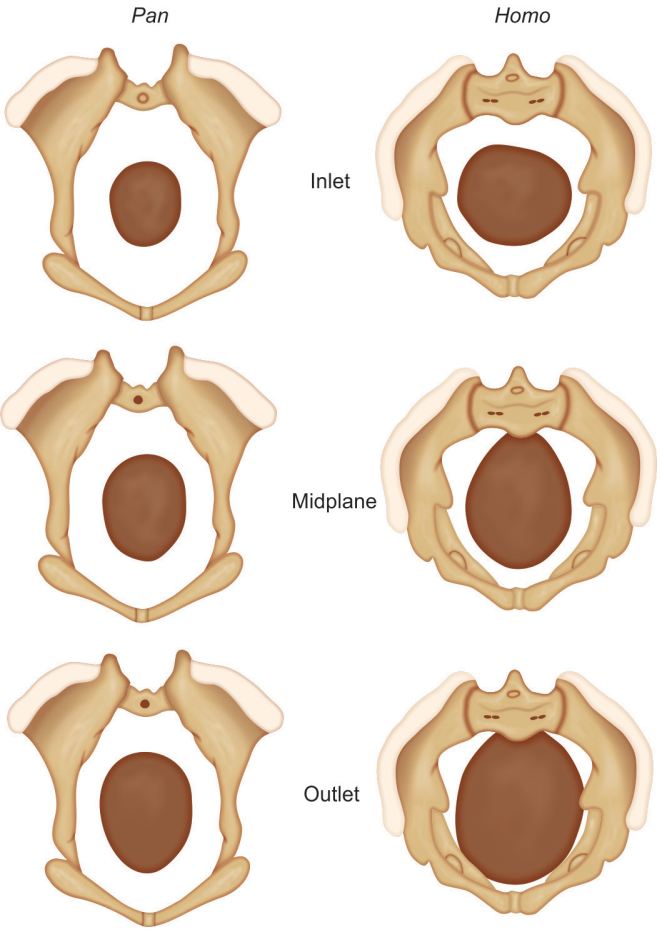

**Fig. 3.2:** Line drawing comparing the pelvic outlet with the brain size (shaded) of *Pan* (chimpanzee) to that of *Homo* (human) at birth. The brain of the chimpanzee easily fits in the relatively large pelvic outlet, but the human brain even at 9 months' gestation has an extremely tight fit. With permission from Bluestone and Swarts.[2]

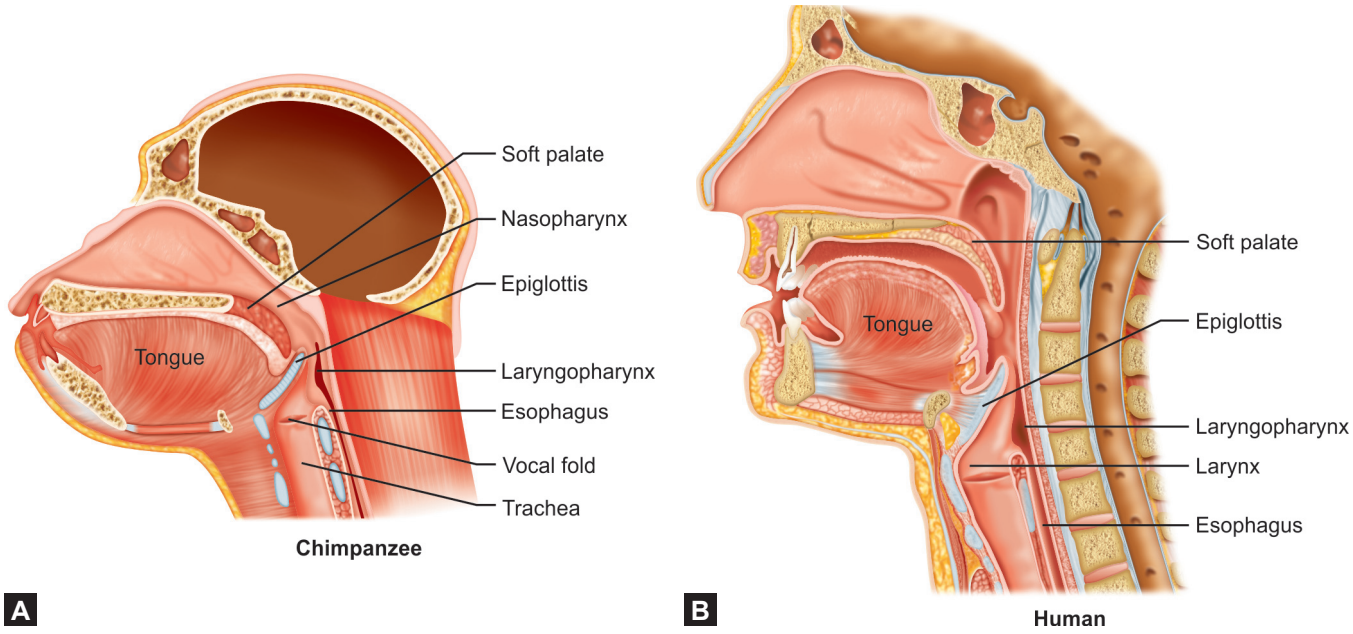
## LOSS OF HUMAN PROGNATHISM

Another important difference of modern humans, when compared with our hominid ancestors and extant nonhuman primates, is facial flattening, or the loss of facial prognathism.[7] This is depicted in Figures 3.3A and B, a human-chimpanzee skull comparison that shows the reduction and repositioning of the maxillofacial complex in the human. Facial flattening, along with descent of the hyoid, contributed to shortening of the palate.[8] We have described these evolutionary adaptations in detail elsewhere.[9] So why have we lost our facial prognathism?

**Figs. 3.3A and B:** Comparison of the facial prognathism in skulls of the chimpanzee (A) and the facial flattening of the human (B).



**Figs. 3.4A and B:** Line drawing in the midsagittal plane comparing the chimpanzee and human showing the shorter palate, an oropharyngeal tongue, a narrower pharynx and a descended larynx (loss of "epiglottic—soft palate lock-up") in the human when compared with the chimpanzee.

## Adaptation for Speech

Another unique adaptation of *Homo sapiens* is that we are the only species that developed speech. During our evolution, in a short 40,000 years, our larynx descended, elongating the supralaryngeal vocal tract that enhanced speech[8] (Figs. 3.4A and B). This adaptation narrowed the pharyngeal airway and shortened the palate, which probably aids in the production of vowels and consonants, but also has consequences for the palatal muscles (described later).

## Cooking

Another possible explanation for our facial flattening is the cooking of food. As described by Wrangham,[10] the earliest evidence of cooking by hominids dates back about 1.8 million years to *Homo erectus*. He hypothesizes that cooking provided the necessary caloric density to meet the energy requirements of our rapidly growing brain. Cooking reduces the need for large masticatory forces releasing the selective pressures on the teeth and musculature, thus allowing a decrease in dental and craniofacial size, i.e.

a smaller maxilla and mandible, in comparison to other hominids. We consider this to be an attractive hypothesis to explain both the increase in human neonatal body and brain size and the loss of facial prognathism.[11]

## EUSTACHIAN TUBE FUNCTION RELATED TO ALTERED MORPHOLOGY OF THE PALATE

We have proposed that the loss of prognathism altered palatal morphology including the muscles of the palate involved in ET function, the tensor veli palatini, and levator veli palatini muscles. These muscles became less effective physiologically than in the nonhuman primate (*Macaca mulatta*).[2] When we compared the tubal function of monkeys and humans, monkey dilatory tubal function was consistently superior.[12] Humans have relatively poor active tubal function. The consequences of poorer tubal function becomes evident during activities that impose nonphysiologic stresses on the ET, such as flying in airplanes and scuba diving, activities in which equalizing ME negative pressure becomes problematic. In contrast, even the application of sudden large negative ME pressures in the monkey were easily equilibrated with a single swallow.

The relatively poor function of the human ET compared with that of the monkey is most likely due to differences in the anatomy of the paratubal muscles. Figure 3.5 is a cross section of the ET from a human temporal bone specimen showing a relatively slim tensor veli palatini muscle attached to the lateral lamina of the tubal cartilage and the relatively large belly of the levator veli palatini muscle as a rounded mass that abuts the inferior portion of the tubal lumen. Despite their genomic similarity and their use as a model for studies of ET physiology and pathophysiology and the pathogenesis of OM, rhesus monkey paratubal muscles are not identical to those of humans.[13] Comparison of the anatomy of these two muscles between the monkey and the human reveals two major differences: first, the monkey tensor veli palatini muscle is bulkier and attaches along the entire length of the cartilaginous ET, whereas in the human this muscle is less robust and only attaches to the midportion of the ET; and second, the belly of the levator palatini muscle is not as prominent and does not impinge on the inferior portion of the tubal lumen in the monkey in contrast to the human condition (Figs. 3.6A and B).

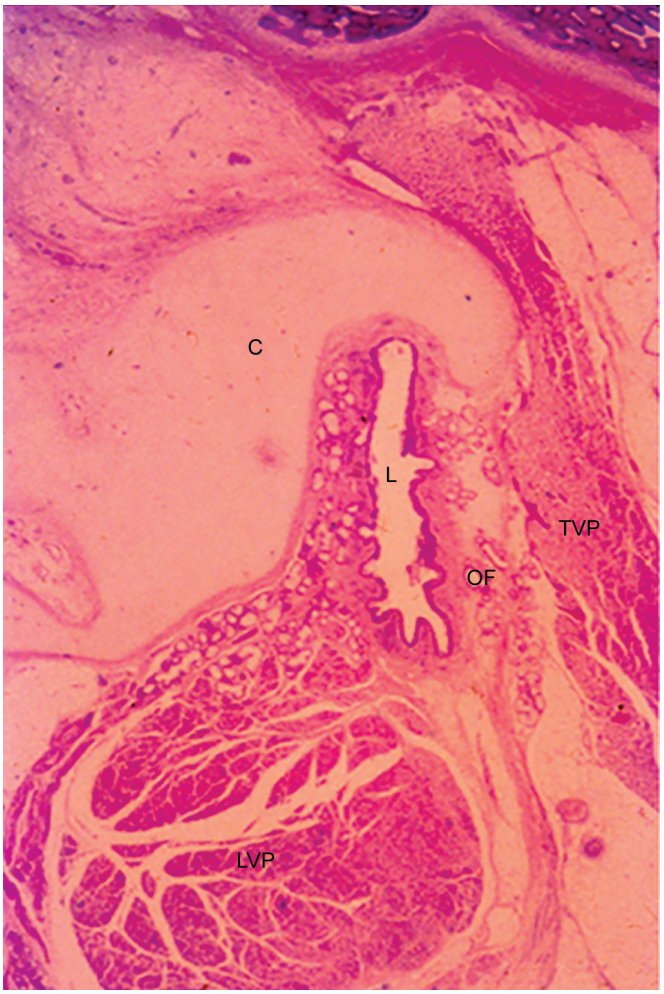


**Fig. 3.5:** Cross section through the midcartilaginous portion of the left human Eustachian tube, showing the robust rounded belly of the levator veli palatini muscle abutting the inferior portion of the tubal lumen, and the rather thin slip of the attachment of the tensor veli palatini to the lateral lamina of the tube. (C: Tubal cartilage; L: Tubal lumen; LVP: Levator veli palatini muscle; OF: Ostmann's fat pad; TVP: Tensor veli palatini muscle).

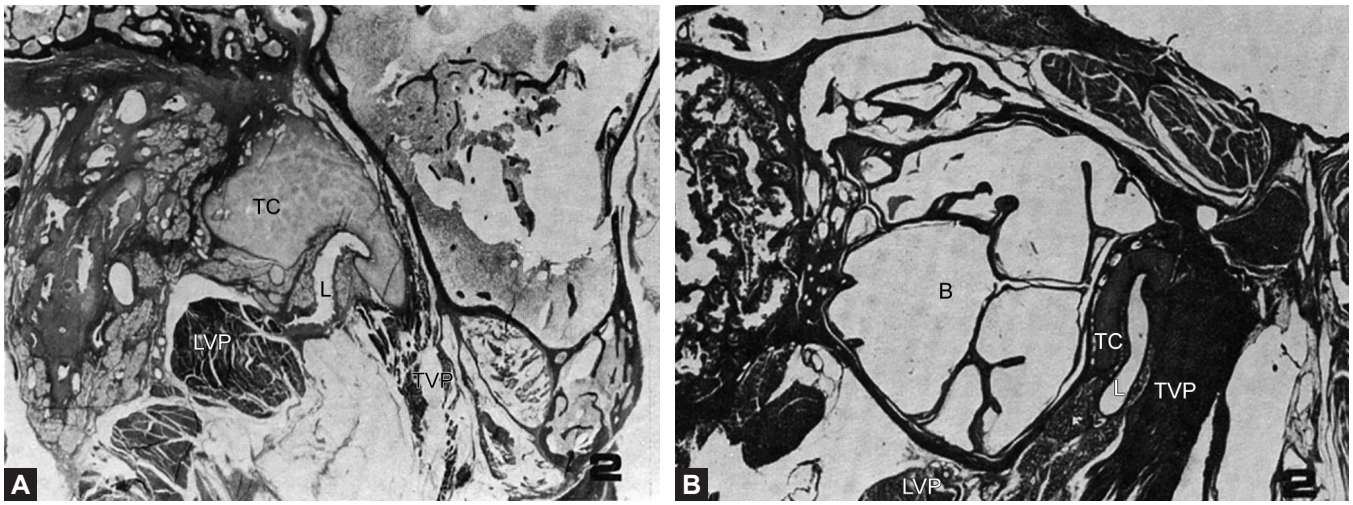
## PATHOGENESIS OF HUMAN OTITIS MEDIA RELATED TO MUSCLES OF THE EUSTACHIAN TUBE

In contrast to the prevalence of OM in humans, especially in infants and young children, we have never observed spontaneous ME disease in the outbred animals (e.g. ferrets and monkeys) used in our laboratory over the past 30 years. Is this remarkable difference in the rate of OM related to the comparatively poor human ET function, a consequence of differences in paratubal muscular anatomy



**Figs. 3.6A and B:** Coronal view of the left Eustachian tube and related structures in the temporal bone specimen from a 13-year-old human female (A) compared with a coronal view of the left Eustachian tube in a temporal bone specimen from a rhesus monkey (B). Note that the levator veli palatini muscle in the human has a rounded belly and closely approximates the inferior portion of the tubal lumen. In the monkey, this muscle is more sparse and there is a distinct separation between the muscle and tubal lumen. Also note, the robust belly of the tensor veli palatini muscle in the monkey compared with the human. (TC: Tubal cartilage; L: Tubal lumen; TVP: Tensor veli palatini muscle; LVP: Levator veli palatini; B: Bulla of monkey). With permission from Doyle and Rood.[13]

in *H. sapiens* as compared with the monkey? Experiments with the monkey in our laboratory undergirded our understanding of the pathogenesis of ME disease in the human.[14] We have successfully created OM in this animal model by inactivating the tensor veli palatini muscle either by severing the tendon at the hamulus of the pterygoid bone or by injecting botulinum toxin into its belly. The consequence of these manipulations is an inability to dilate the ET lumen during swallowing, resulting in a ME effusion. Our conclusion was that a healthy tensor veli palatini muscle is critically important in the prevention of ME disease. We postulated that the monkey's larger tensor veli palatini muscle with a longer insertion on the cartilaginous portion of the ET could explain their excellent tubal function. Furthermore, if tubal inflammation did occur in the monkey its efficient ET function would prevent the development of ME disease. By contrast, since humans have comparatively poor tubal function and are susceptible to upper respiratory tract infections, OM is a common disease. Buchman and colleagues[15] reported that some adult volunteers who had nasal challenge with virus developed ME disease. Why viral infection affected some subjects and not others may be explained by the results of a later study in which adult volunteers who had signs of tubal dysfunction prior to a viral challenge developed more severe dysfunction and ME negative pressure. Subjects with good tubal function before the challenge did not develop OM.[16] We concluded from these observations and experiments that the relative inefficiency of the human tensor veli palatini muscle is a viable explanation for the pathogenesis of ME disease in some individuals, especially under nonphysiologic and inflammator conditions.

Obviously, due to their transient nature, these conditions cannot be invoked to explain why ME disease persists in a subgroup of patients. We have reported that older children and adults with chronic OM with effusion had ET dysfunction characterized by constriction of the lumen as opposed to dilation during swallowing during the forced response test.[17] This observation in the context of experimental electrical stimulation of the monkey paratubal muscles during the forced response test[18] suggests that the observed constriction is most likely due to contraction of the levator veli palatini muscle, which collapses the dilated tubal lumen. This hypothesis has yet to be confirmed, but is currently under investigation in our laboratory.

Eustachian tube constriction has been identified in children with cleft palate. The infant with an unrepaired cleft palate is a natural model of chronic OM with effusion, due to a functional, as opposed to an anatomic, obstruction of the ET. Similarly, surgical clefting of the monkey soft

palate induced OM with effusion that persisted until the cleft had healed.[19] During the interval when the soft palate was clefted, ET function tests revealed constriction of the tubal lumen during swallowing that we now attribute to a dysfunction of the levator veli palatini muscle. We posit that in an effort to prevent OM in these babies, surgical repair of the palate should focus on anchoring the tensor veli palatini muscle at the hamulus and repositioning the levator veli palatini muscle to preclude tubal constriction, as well as correcting their velopharyngeal insufficiency and hypernasal speech.

## OTHER FACTORS INVOLVED IN PATHOGENESIS

The above describes the consequences of our evolutionary history for the pathogenesis of OM in humans; however, the extremely high incidence of OM today cannot be explained solely as a consequence of evolutionary adaptations in humans. Other factors, such as heredity and immunity,[20,21] as well as those derived from living in novel environments (those we are not adapted to) such as a decrease in breast-feeding, smoking in the household, use of pacifiers and very importantly, child day-care attendance, are well known to increase the risk of ME disease. [22]

## SUMMARY AND CONCLUSION

It is well known that the pathogenesis of OM is multifactorial, but the role of evolutionary adaptation on its development has not been addressed until recently. Our hypothesis is that OM is most likely restricted to humans, in contrast to other species in the wild, because the associated hearing loss would have reduced the fitness of affected individuals. The byproducts of two human adaptations may have resulted in an increased prevalence of OM: the interaction of bipedalism with increased brain size, and the loss of facial prognathism, which may have been the result of adaptation for speech or the advent of cooking almost 2 million years. As a consequence of our adaptation for bipedalism, the female pelvic outlet is constricted, which in the context of a rapidly enlarging brain results in humans being born 12 months too soon. Significantly, immature ET structure and function in conjunction with an immature immune system helps to explain the high incidence of OM in the first year of life. But the persistence of ME disease beyond that stage is not explained by "immaturity". The morphology of the palate changed with the adaptations that produced facial flattening, with concomitant effects on the paratubal muscles that affected ET function. These changes resulted in relatively poor human physiologic tubal function in comparison to a nonhuman primate.

# Genetics of Hearing Loss

***Anne BS Giersch***

## INTRODUCTION

The human genome is the complete set of genetic information contained in almost every cell in our bodies. The 3 billion base pairs of DNA that make up our genome are located on the 23 pairs of chromosomes in each cell nucleus and the small mitochondrial chromosome found in the cytoplasmic mitochondria. The genome includes both protein coding and noncoding sequences. The protein coding sequences, which have been most extensively studied, comprise 1–2% of the genome and encode ~22,000 genes. A total of 99.9% of the genome sequence is identical between individuals. That still leaves 0.1% of the genome, or 3 million base pairs, of sequence variation between any two people. The vast majority of this variation is benign and referred to as single-nucleotide polymorphisms (SNPs). However, the concern of this chapter is our understanding of the relatively rare mutations in protein coding genes that cause clinically important traits, in particular, hearing loss.

The genetics of deafness and hearing loss is more complex than perhaps any other medical condition. Hearing impairment is a prime example of how a relatively common medical condition can be caused by a defect at any one of numerous genetic loci. About 60% of hearing loss is thought to have a genetic etiology in developed countries (Fig. 4.1). As modern medicine makes inroads in reducing the environmental causes of hearing loss, such as vaccination programs to combat infectious diseases that can damage the inner ear, the percentage of hearing loss attributed to genetic factors will continue to rise. It should be noted, however, that even the "environmental" causes of hearing loss listed in Figure 4.1 can have a genetic component.

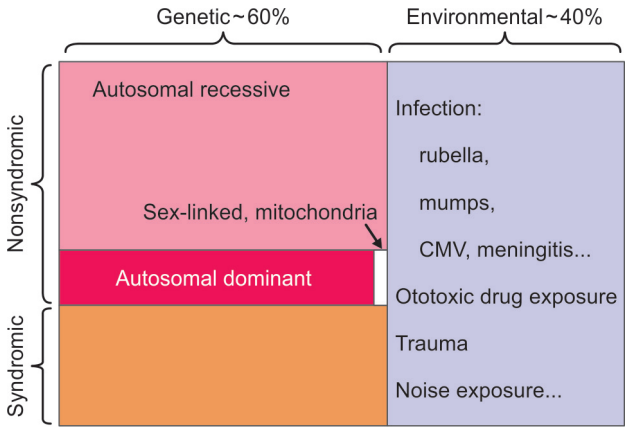

**Fig. 4.1:** Representation of proportion of hearing impairment that has a genetic or environmental cause. Some of the more common environmental causes are listed. Genetic hearing loss is further divided into syndromic, nonsyndromic hearing loss, mitochondrial and sex linked.

For example, genetic background can make an individual more or less sensitive to ototoxic drugs or noise exposure.

Determining the cause of hearing loss can be difficult, in part due to its variability of presentation. It can have a prelingual or postlingual onset. It can be stable or progressive. It can be unilateral or bilateral, conductive or neurosensory, mild or profound. If there is a clear family history of hearing loss, or a known etiologic agent of acquired hearing loss, such as a maternal rubella infection during pregnancy, establishing the cause of hearing loss in a child as genetic or acquired can be quite straightforward. However, often determining the cause of a recently diagnosed hearing loss may require a comprehensive evaluation, especially if there are no obvious culprits. At a minimum, an initial evaluation should include a targeted

patient history including family history and a physical exam, concentrating on key genetic and clinical features of the many forms of syndromic and nonsyndromic hearing loss, discussed in more detail below and in additional chapters.

## SYNDROMIC HEARING LOSS

The genetic causes of hearing impairment are generally divided into two conceptual categories: syndromic and nonsyndromic. Syndromic hearing loss is the association of hearing impairment with other clinical findings, such as retinitis pigmentosa in Usher syndrome, pigmentary anomalies in Waardenburg syndrome, cardiac arrhythmia in Jervell and Lange-Nielsen syndrome, and renal anomalies in Alport syndrome. Over 400 syndromes list hearing loss as a clinical symptom.[1] Sometimes the hearing loss is the most serious component of the syndrome, and sometimes it is of lesser concern in the face of potentially life threatening clinical manifestations. Occasionally, hearing loss is recognized early, but the syndromic nature of the disorder is not appreciated until much later in life. For example, in the Usher syndromes, hearing loss can be present at birth, but the visual deterioration may not begin until the teen years. In Perrault syndrome, which manifests with early onset deafness and ovarian dysgenesis in females, the infertility is frequently unrecognized until delayed puberty is noted. Otologic syndromes will be addressed more fully in a later chapter, but in thinking about inheritance and genetic diagnosis, it is important to keep in mind that without genetic testing it can be difficult to determine clinically if a child has syndromic or nonsyndromic hearing loss. Newborn screening, which will also be addressed in a later chapter, can recognize congenital hearing loss but does not identify the additional clinical symptoms of syndromic disorders.

## NONSYNDROMIC HEARING LOSS

Approximately 70% of hearing loss is nonsyndromic, and can be inherited in an autosomal recessive, autosomal dominant, sex-linked, mitochondrial, or multigenic fashion (Fig. 4.2). It is frequently congenital (present at birth) in which case it should be detected by newborn hearing screening. However, the onset may not be until months or years later. To date, 54 autosomal dominant (DFNA#) loci have been mapped with the affected gene identified at 27 of those loci. Seventy-five autosomal recessive loci (DFNB#) have been mapped, with the causative gene found in 44 loci. Six sex-linked loci (DFN#) have been mapped with the affected gene found in 3 loci.[2]

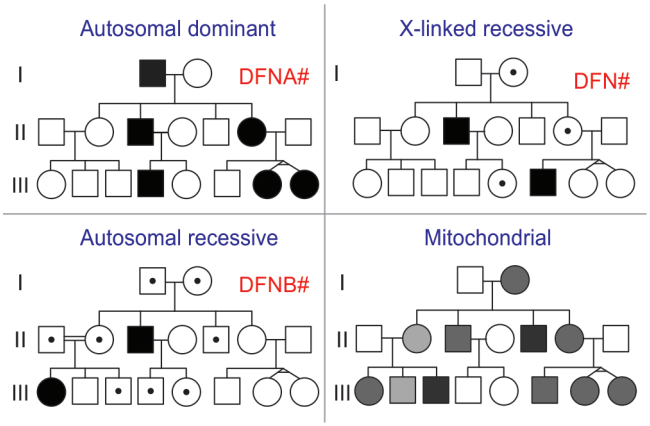

**Fig. 4.2:** A primer on modes of inheritance. In each Figure, generations are listed from oldest (I) to youngest (III) from top to bottom, connected by vertical lines. Males are squares; females are circles. Filled circle/square is an affected individual; open circle/square is unaffected. Shades of gray (mitochondrial) reflect variable degrees of symptom severity. A dot reflects a carrier of a recessive mutation. Matings are connected by horizontal lines. A double horizontal line reflects a consanguineous mating, where the partners are related and thus have an increased risk of both being carriers of the same recessive mutation. Hearing loss disorders with an autosomal dominant mode of inheritance are named DFNA# where the # reflects the order of discovery or report. DFNB# reflects recessive hearing loss. DFN# refers to X-linked hearing loss. In autosomal dominant disorders, a mutation is passed from parent to child and one expects approximately half the offspring to be affected. In autosomal recessive disorders, each parent is a carrier of one mutation and only offspring who receive a mutated gene from both parents manifest the disorder. Approximately 25% of offspring are expected to be affected. In X-linked recessive disorders, generally only males are affected, receiving the mutation from a carrier mother. In mitochondrial disorders, the mitochondrial genome is only passed from mother; thus, while both males and females can be affected, only females pass along the mutation. The variability of phenotype is related to the percentage of mutated mitochondria per cell (heteroplasmy).

Eighty percent of genetic nonsyndromic hearing loss is inherited in an autosomal recessive fashion, making it by far the most common category. About 20% of nonsyndromic hearing loss is inherited in an autosomal dominant manner, and a small percentage has an X chromosome-linked or mitochondrial mode of inheritance. Taking a detailed family history going back three generations as shown in Figure 4.2 may reveal a dominant, X-linked or mitochondrial inheritance pattern, since the hearing impairment will "run in the family". However, in autosomal recessive hearing impairment, which is the most common, both parents can be unaffected carriers and thus have no family history of hearing impairment. In fact, 90% of congenitally deaf babies are born to hearing parents.

The gene most frequently involved in nonsyndromic hearing loss is *GJB2*, which encodes the protein gap junction beta 2, more commonly referred to as connexin 26. This protein functions as a membrane channel, regulating the passage of ions in and out of the cell. The presentation of hearing impairment caused by *GJB2* mutations is somewhat variable, but most frequently profound and prelingual.

Over a hundred different mutations have been identified in this small gene (only one coding exon). Most of the mutations are inherited in a recessive fashion (both alleles are mutated); however, a few dominant mutations have also been noted. Different ethnic populations tend to have different mutations in the gene. Deletion of a G at nucleotide position 35 (c.35delG) is most common among Caucasians, whereas deletion of a C at nucleotide position 235 (c.235delC) is more common in Asians. Because of different carrier rates in different populations, *GJB2* mutations can account for anywhere from 10% to 50% of autosomal recessive nonsyndromic deafness in a given geographical region.

The second most commonly mutated gene in autosomal recessive nonsyndromic hearing loss is *SLC26A4*, accounting for 3–4% of cases. *SLC26A4* encodes the protein pendrin, which is an anion transporter. *SLC26A4* mutations also cause Pendred syndrome, which is associated with developmental abnormalities of the cochlea, sensorineural hearing loss, and diffuse thyroid enlargement (goiter). Because the goiter often does not manifest until later in life, Pendred syndrome is often misdiagnosed as nonsyndromic hearing loss.

Other genes relatively commonly mutated in nonsyndromic hearing impairment are *TMPRSS3*, *CDH23*, *TMC1*, *OTOF*, and *MYO15A*. The frequency of finding one of these genes depends on the population being evaluated, but multiple independent mutations have been identified in each, thus ruling out any common founder effect.

## MITOCHONDRIAL CAUSES OF HEARING LOSS

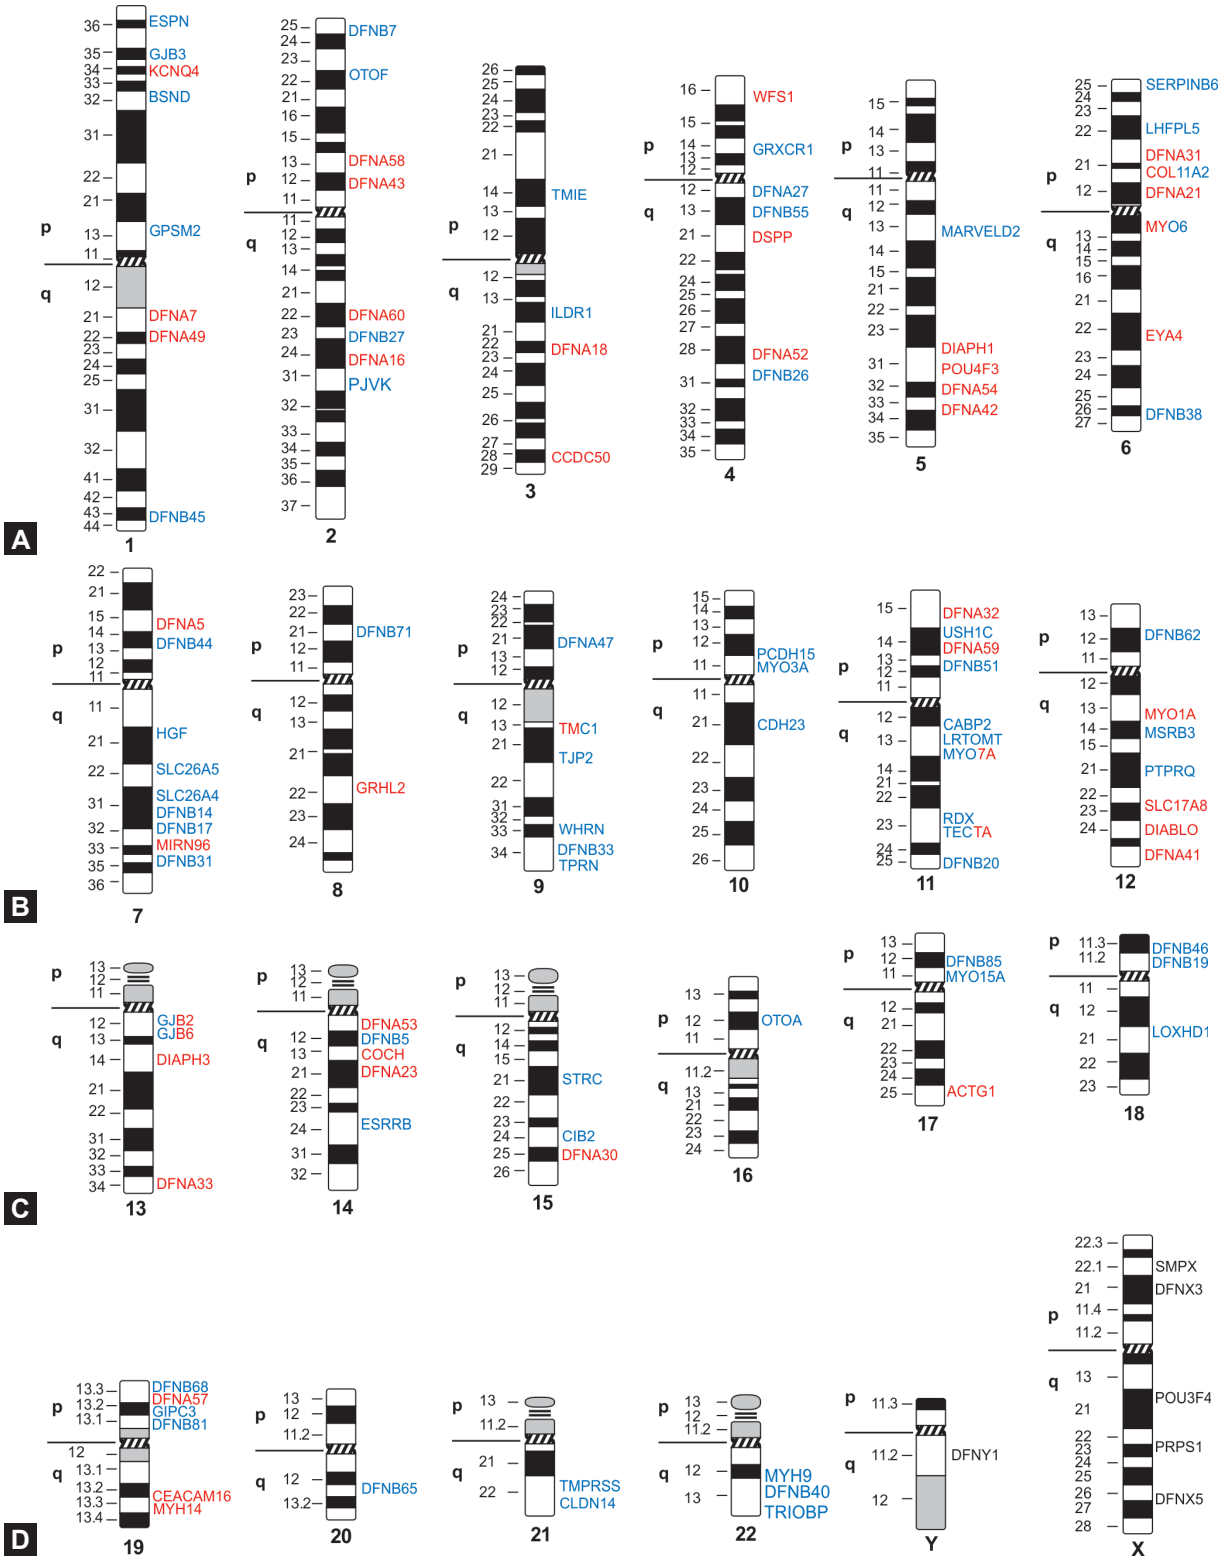
Mitochondrial mutations account for only a small percentage of genetic hearing loss, and have a unique inheritance pattern (Fig. 4.2). The mitochondrion has its own genome and is only inherited from the mother, through the egg. Thus, both males and females can be affected, but only females can pass the mutations along to subsequent generations. In addition, there can be hundreds to thousands of copies of the mitochondrial genome in a cell; usually only some of which carry a mutation (a condition known as heteroplasmy). Depending on the percentage of mutated mitochondria per cell and the cell type(s), which have the most or fewest mutant mitochondria, the presentation of symptoms can vary considerably between individuals, even among members of the same family who presumably have the same mutation.

Mitochondrial mutations can cause either syndromic or nonsyndromic hearing impairment. Among the mitochondrial syndromes in which hearing loss is a component are MERRF (myoclonus, epilepsy and ragged red fibers on muscle biopsy) and MELAS (mitochondrial encephalopathy, lactic acidosis and stroke-like episodes). In both syndromes, hearing loss is variable in presentation and not always present. Nonsyndromic mitochondrial hearing loss can be due to mutations in the mitochondrial *MTTS1* or *MTRNR1* genes. The latter is most commonly associated with aminoglycoside-induced hearing loss, i.e. the patient develops hearing loss only after exposure to aminoglycoside antibiotics.

## IDENTIFICATION OF DEAFNESS GENES

Many genetic disorders are associated with mutations in only one gene. For example, cystic fibrosis is caused by mutations in the *CFTR* gene on chromosome 7, Huntington's disease is caused by expansion of a short repetitive sequence in the *HTT* gene on chromosome 4, and mutations in the *NF1* gene on chromosome 17 cause neurofibromatosis type 1. These are all examples of monogenic disorders—one gene, one disease. Even though Huntington's disease or any of the other monogenic diseases is relatively rare compared to hearing loss, the fact that every case of Huntington disease is caused by a mutation in the same gene aided in the early identification of the disease-causing gene in 1983.[3]

Hearing impairment and deafness, by contrast, shows extreme genetic heterogeneity. Over 125 nonsyndromic deafness loci have been mapped by various means, with the causative gene identified in ~70 of these loci to date. Figures 4.3A to D show the known nonsyndromic hearing loss loci displayed by their map position on the human chromosomes. If the gene has been identified, it is listed. Otherwise, the deafness locus is referred to as DFN#. It would be impossible to also display the more than 400 syndromic loci! Figure 4.3 demonstrates the extreme heterogeneity that is observed in genetic hearing impairment.



**Figs. 4.3A to D:** Nonsyndromic hearing loss loci. The name of the genes that cause nonsyndromic deafness/hearing impairment and their chromosomal loci are indicated. DFNA or DFNB refers to a genetic locus where a hearing disorder has been mapped but the gene has yet to be identified. Red refers to dominant inheritance; blue refers to recessive inheritance; black refers to sex-linked inheritance. A gene that is both blue and red has been shown to cause both dominant and recessive hearing loss, depending on the mutation. For an up-to-date list of genes and loci, *see* the Hereditary Hearing Loss homepage.

## LINKAGE ANALYSIS IN HUMAN PEDIGREES

There are a number of techniques for identifying hearing loss genes. One tactic that has been productive over the past 15 years or so is linkage mapping. Linkage is defined as a tendency for genes close together on the same chromosome to be inherited together through multiple generations; thus, they are physically linked. The further apart two loci are on a chromosome, the higher the likelihood a recombination event will separate them. Linkage analysis begins with a large family, or pedigree, in which hearing loss is clearly inherited, in either a dominant, recessive, or X-linked manner.

Inheritance of the hearing impairment is tracked through the pedigree in conjunction with the inheritance of hundreds of genetic markers mapped to the human genome. Some combination of genetic markers will be inherited more often in the deaf family members than in the hearing family members, i.e. these markers are believed to be linked to the hearing loss. Narrowing in on the linked region can identify a chromosomal locus in which the deafness gene lies. The difficulty lies in the fact that depending on the size of the linked chromosomal region, dozens or even hundreds of genes may reside there. Each of these genes becomes a potential candidate. Sometimes an educated guess can be made as to which gene in the interval might be the culprit, but often a lab will need to sequence many genes before identifying the deafness causing mutation. The first nonsyndromic deafness gene, *GJB2*, was identified in 1997[4] by this method. Many of the other genes displayed in Figure 4.3 were identified by linkage mapping as well.

Using linkage mapping, a large family in which hearing loss segregates will usually yield the smallest genetic interval in which to hunt for the causative gene. However, due to the extreme genetic heterogeneity of hearing impairment, identifying a "deaf family" can be difficult. Deaf people have a tendency to marry deaf people and may have deaf or hearing children. If the individuals in a family are deaf for different genetic reasons, analysis of the segregation of a hearing impairment gene through a pedigree can be confounding and lead to inconclusive results. Figure 4.4 illustrates just such a situation. It is difficult to say if the hearing impairment (filled in figures) segregating through the families shown is recessive or dominant. Sometimes when deaf individuals marry, they have all deaf children or no deaf children. The only firm conclusion a geneticist can make is that there are at least two independent causes of the hereditary hearing loss segregating in the families in Figure 4.4.

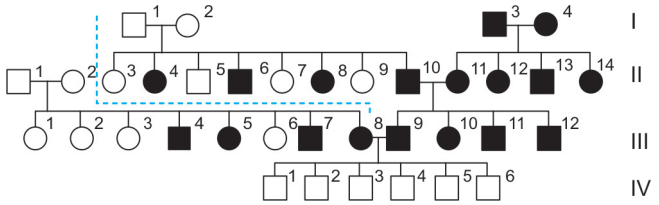


**Fig. 4.4:** Deafness segregating through several families. When deaf individuals (filled in circles/squares) mate with other deaf individuals, their offspring may or may not be deaf, depending on the gene(s) affected in the different families and the mode(s) of inheritance of mutations involved. This example illustrates how difficult it is to do linkage studies in unrelated families.

Because of assortative mating (individuals mating based on a shared phenotype, such as deaf people), many successful linkage studies have begun with isolated populations, where deaf family members are at least partially either physically (e.g. an island or isolated village) or culturally (e.g. religion or language) separated from the general population. This is particularly important for investigations of recessive hearing loss. In recessive disorders, *two* mutated alleles of the same gene must be inherited together to cause the phenotype, so a setting in which some degree of inbreeding occurs (i.e. first cousin marriages) helps to keep the deafness genes "in the family". Figure 4.5 is an example of a family pedigree from the Punjab province in Pakistan in which autosomal recessive deafness segregates. Note that deafness is observed only after genetically related individuals (double horizontal lines, in this example, first cousins) have offspring together.[5] Linkage analysis mapped the gene to chromosome 3 and the responsible gene was eventually identified by sequencing candidate genes in the region as *ILDR1*, immunoglobulin-like domain containing receptor 1, a putative transmembrane receptor.[6]

## MOUSE MODELS

The laboratory mouse has been an invaluable resource for studying mammalian hearing impairment. Unlike humans, the mouse has a short life span, is amenable to experimental manipulation, and, with controlled breeding, can have limited genetic heterogeneity. The physiology of the mouse auditory system is remarkably similar to humans, allowing insights into the morphogenesis and molecular mechanisms of human hearing and hearing

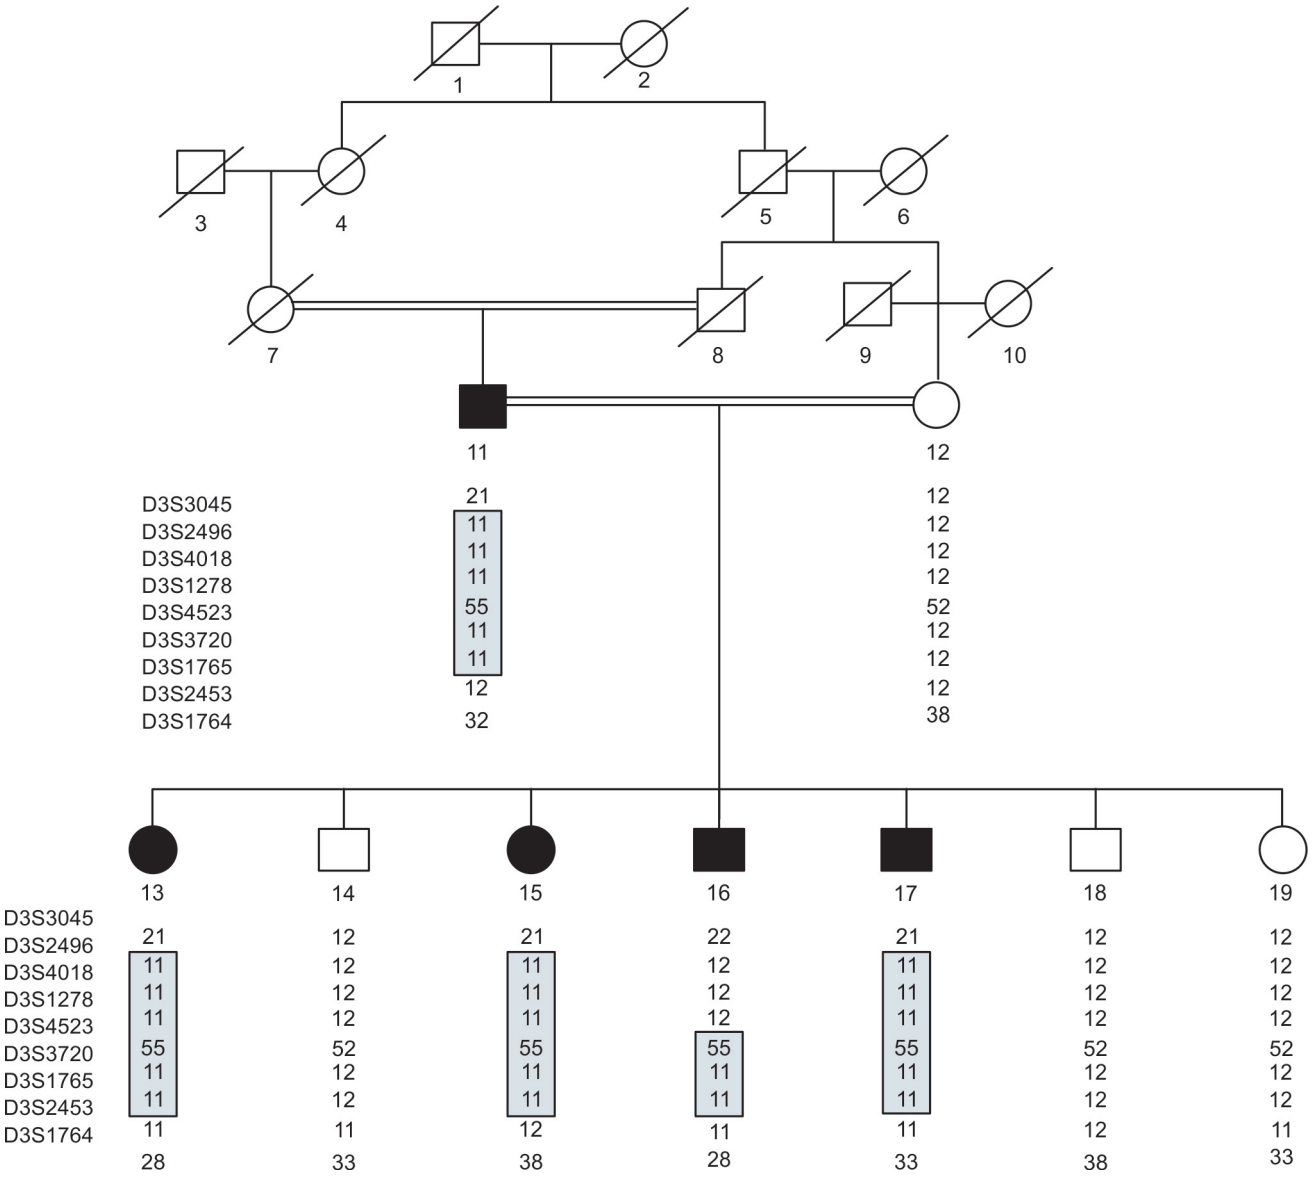

**Fig. 4.5:** Recessive deafness segregating through a Pakistani family from the Punjab region. The deafness locus (DFNB42) was mapped by linkage analysis to chromosome 3q13.31-q22.3 in this large family from an isolated village. Molecular markers linked to chromosome 3 are listed to the left. Marker alleles are listed below each individual. Homozygous regions are boxed. Reproduced from Aslam et al.[5] with permission from John Wiley and Sons.

loss. Combined with the fact that ~99% of human genes have orthologs in mice, these common laboratory animals have played an integral part in our understanding of genetic causes of deafness.

Mouse strains with hearing impairment were first recognized by their vestibular defect. Strains with names like waltzer, whirler, circler, and shaker had an obvious behavioral phenotype that made them a curiosity to mouse breeders. Because of considerable redundancy of function between the cells of the vestibular system and the cochlea, these strains also have hearing loss. Genetic manipulation available in the mouse enabled cloning of the mutant gene in these strains. Study of human pedigrees with hearing impairment demonstrated the same genes also cause human syndromic or nonsyndromic deafness. Table 4.1 lists some examples of such strains, the corresponding mutated gene and human hearing disorder.

Because genetic, histopathological, and molecular studies can be performed on mouse inner ear, much of what we now understand in terms of cochlear pathophysiology

**Table 4.1:** Mouse hearing loss mutants first recognized based on the behavioral phenotype caused by concomitant vestibular defects. Mutations in the human ortholog of each gene ultimately was shown to cause either syndromic or nonsyndromic hearing loss

| *Mouse strain* | *Affected mouse gene* | *Orthologous human hearing disorder* |
|---|---|---|
| Ames waltzer | *Pcdh15* | Usher syndrome type 1D |
| Deaf circler | *Ush1c* | Usher syndrome type 1C |
| Dreidel | *Pou4f3* | DFNA15 |
| Jackson circler | *Ush1g* | Usher syndrome type 1G |
| Jerker | *Espn* | DFNB36 |
| Shaker 1 | *Myo7a* | Usher syndrome type 1B, DFNB2 |
| Shaker 2 | *Myo15a* | DFNB3 |
| Snell's waltzer | *Myo6* | DFNA22 |
| Twister | *Otog* | DFNB18 |
| Waltzer | *Cdh23* | Usher syndrome type ID, DFNB12 |
| Whirler | *Whrn* | Usher syndrome type IID |

comes from mouse studies. For example, the Usher syndrome proteins, some of which are listed in Table 4.1, are now understood to be structural components of the hair cell stereocilia. Mutations in genes responsible for ion transport through the cochlear supporting cells, such as *Gjb2* encoding connexin 26, *Kcnq1* encoding potassium voltage-gated channel Q1, and *Slc26a4*, encoding solute carrier 26a4, have informed our knowledge of cochlear ionic homeostasis. Some mouse models are even teaching us about the middle ear conditions, such as otitis media. The induced mouse mutants Jeff and Junbo both develop otitis media with effusion. The Jeff strain has a mutation in the *Fbxo11* gene; Junbo has a mutation in *Evi1*.[7,8] The mechanism of action of these two genes is still being investigated, but it is clear that a disorder that was previously believed to have a purely infectious etiology can also have an underlying genetic predisposition.

## GENETIC TESTING

Genetic testing is recommended for all newborns identified by newborn hearing screening, once follow-up testing confirms a positive result. Likewise for an older child whose hearing loss may be identified through routine pediatric care or even school-based hearing screening, unless a known nongenetic cause has been identified (e.g. cytomegalovirus infection). Taking a family history of hearing loss may reveal a pattern of inheritance, as described above, but, since the majority of hearing loss is recessive, a negative family history does not rule out genetic hearing loss (absence of evidence is not evidence of absence!). Additional diagnostic testing to assess for a syndrome could proceed in a stepwise fashion—temporal bone imaging to evaluate for enlarged vestibular aqueduct associated with Pendred syndrome, electrocardiogram to assess for long QT interval associated with Jervell and Lange-Nielsen syndrome..., but comprehensive genetic testing can confirm or rule out these syndromes and many others, as well as nonsyndromic hearing loss. Thus, genetic testing can ultimately save time, money, and yield more prognostic information than ordering one test at a time.

The field of clinical genetic testing is evolving at an incredible pace as of this writing, thus the definition of a "comprehensive" genetic test is a moving target. Whole genome or exome sequencing is on the horizon, but not yet routine for hearing impairment. Currently, the most comprehensive genetic tests are conducted by laboratories using massively parallel sequencing to screen gene panels. The panels all include the genes most frequently mutated in the most common syndromic, nonsyndromic, and mitochondrial forms of hearing impairment. Up-to-date clinical genetic testing information can be obtained at the GeneTest website: http://www.genetests.org/. This site lists more than a dozen clinical laboratories around the world that offer testing for panels of hearing loss genes. Other useful web-based resources are listed in Table 4.2.

In the United States, the nationally certified laboratories that offer the largest deafness gene panels are as follows:

- The *OtoGenome* panel—71 genes—Partners Center for Personalized Genomic Medicine affiliated with Harvard Medical School—http://pcpgm.partners.org/lmm/
- The *OtoScope* panel—66 genes—Molecular Otolaryngology and Renal Research Laboratories at the University of Iowa—http://www.healthcare.uiowa.edu/labs/morl/
- The *Hearing Loss Expanded* Panel—56 genes—ARUP Laboratories affiliated with the University of Utah—http://www.aruplab.com/

"Comprehensive" genetic testing sounds ideal, but the reality is that even laboratories that test more than 50 deafness genes are able to report a positive result in fewer than half the cases. There are multiple reasons for a negative result:

1. The patient may not have genetic deafness. Perhaps the hearing loss should in fact be attributed to an infectious, environmental, or toxic exposure

**Table 4.2:** Internet resources to find additional, up-to-date information about genetic hearing loss

| National Center for Biotechnology Information Genetic Test Registry<br>http://www.ncbi.nlm.nih.gov/gtr/ | Maintained by the NIH, the Genetic Testing Registry (GTR) provides a central location for voluntary submission of genetic test information by providers. The overarching goal of the GTR is to advance the public health and research into the genetic basis of health and disease |
| Deafness Variation Database<br>http://deafnessvariationdatabase.com/ | Maintained by the University of Iowa, the Deafness Variation Database provides a guide to genetic variation in genes known to be associated with deafness. It includes all known genetic variants present in any gene that is included on University of Iowa's OtoSCOPE genetic deafness screening platform to facilitate variant analysis |

2. The patient has a very rare form of genetic deafness. Over 130 genetic deafness loci have been mapped and there may be an equal number yet to be unidentified. The causative mutation may lie in one of these many genes that are not on the current test panels
3. The mutation lies in an intron or other extragenic region. Most of the available testing sequences coding exons only, so mutations in an intron or regulatory regions upstream or downstream of a gene may not be sampled
4. A mutation is found but is a VUS—Variant of Unknown clinical Significance.

Once a sequence variant is found in one of the gene panels, it must be assessed as to the likelihood that it is pathogenic or benign. Not all sequence alterations are pathogenic; many are benign variants. There are thousands of polymorphisms throughout the genome that can be found in electronic databases of variants or SNPs. Most laboratories have a list of criteria that must be met before calling a sequence alteration pathogenic. Has it been observed previously, either by the testing laboratory or in the literature, to be associated with hearing loss? Does it alter a highly conserved amino acid or splice site? If there are multiple affected family members, do all the affected family members carry the same mutation(s), while none of the unaffected have it? If these criteria cannot be met, then a novel sequence variant is usually considered a VUS.

When genetic testing results are positive for a pathogenic mutation, it can help inform the prognosis (i.e. whether the hearing loss will worsen), the best intervention (e.g. hearing aids, cochlear implant, and sign language) and recurrence risks to future children and other family members. Furthermore, it can either eliminate the possibility that a syndrome is present, with likely clinical symptoms that have not yet manifested (e.g. adolescent-onset retinitis pigmentosa in Usher syndrome, long QT in JLNS, renal abnormalities in BOR or thyroid abnormalities

in Pendred syndrome), or predict the onset of such features if a test for a syndromic cause is positive. Of individuals with sensorineural hearing loss detected in the newborn period, up to 5% have hearing loss associated with Pendred syndrome and up to 10% have Usher syndrome. Knowing that a child will eventually develop vision problems suggests a course of action in managing the hearing loss. ASL only would be ill advised for a child with Usher syndrome; cochlear implant(s) would be a better choice.

If a child is found to have two recessive mutations, the parents will be tested to confirm they are both carriers. If so, then they have a 25% risk with each subsequent pregnancy of having another child with the same type of hearing loss. This risk may seem too high to some couples. They may opt to not have more children, to have prenatal diagnosis to detect an affected fetus, or to have preimplantation genetic diagnosis of fertilized embryos, to implant only unaffected embryos. Many otolaryngologists may not feel equipped to counsel patients about the implications of their genetic test results, beyond the immediate management of the hearing loss. Genetic counselors are an invaluable resource for interpreting the implications of a genetic diagnosis and conveying that information to a family.

CHAPTER

5

# Otologic Syndromes

***Elizabeth E Cottrill, Adva Buzi, Ken Kazahaya***

## INTRODUCTION

The otologic system is composed of the external, middle, and inner ear including the cochlea and associated vestibular organs. Hence, defects in this system encompass a wide range of anomalies. Patients may present with a wide range of hearing loss, sensory, conductive, or mixed in origin. External ear anomalies are also at times associated with syndromes affecting the otologic system. Vestibular symptoms are less common, but several syndromes are associated with these anomalies. Isolated vestibular syndromes are rare.

The otologic system is involved in many syndromes with over 200 named syndromes associated with hearing impairment. The classification of otologic syndromes into specific categories is difficult as there is a wide range of heterogeneity and overlap in the systems involved. In general, syndromes may be classified as hereditary or nonhereditary. Many syndromes are discovered with initial diagnosis of hearing impairment in a child. Physical appearance, laboratory tests, imaging of the temporal bone, or consultation with other specialists often leads to a specific diagnosis. The following is a review of otologic syndromes most commonly encountered.

## DOMINANT SYNDROMES

### Branchio-Oto-Renal Syndrome

Branchio-oto-renal (BOR) syndrome is characterized by the triad of branchial anomalies, otologic anomalies usually coupled with hearing loss, and renal anomalies. The branchial anomalies often present in the form of cervical fistulas, sinuses, and cysts and renal anomalies range from agenesis to dysplasia. Renal anomalies are found in 25% of individuals.[1] Less common phenotypic findings include lacrimal duct aplasia, short palate, and retrognathia.[1]

#### *Genetics*

There are several implicated genes that are known to cause BOR syndrome. One causative gene is EYA1, the human homologue of the Drosophila eyes absent gene, which is found in approximately 25% of patients with a BOR phenotype.[2] This phenotype is hypothesized to reflect a reduction in the amount of the EYA1 protein.[2] Recently, mutations in two additional genes, SIX1 and SIX5, have also been shown to cause BOR syndrome.[3,4] Both of these newly implicated genes act within the same genetic network as the EYA and PAX genes for regulation of organogenesis during fetal development. Inheritance of BOR syndrome is autosomal dominant, penetrance is nearly 100%, and prevalence is estimated at 1 in 40,000 newborns.[1] BOR affects 2% of profoundly deaf children.[1]

#### *Presentation*

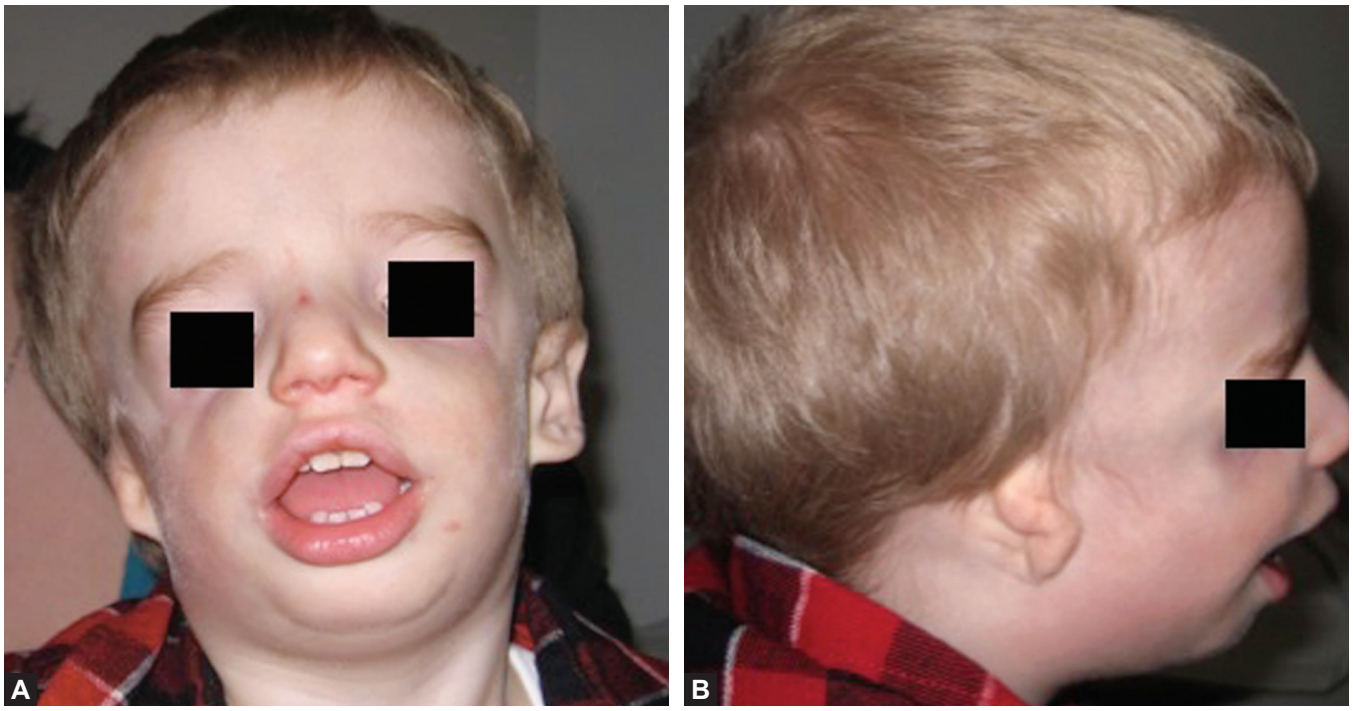
Hearing impairment is the most common feature of BOR syndrome and is reported in almost 90% of affected individuals.[1] Hearing loss in BOR syndrome is most often mixed (50%) but can be selectively conductive (30%) or sensorineural (20%). Hearing loss is severe in one-third of affected individuals and is progressive in one quarter.[1]

Otologic anomalies can involve the external, middle, or inner ear. External ear anomalies include preauricular pits (82%), preauricular tags, auricular malformations (32%), microtia, and external auditory canal narrowing (Fig. 5.1).[5] Middle ear anomalies include various ossicular malformations, facial nerve dehiscence, absence of the oval window, and reduction in size of the middle ear cleft.[5] Inner ear anomalies include cochlear hypoplasia and dysplasia occasionally with enlargement of the cochlear or vestibular aqueducts, or merely hypoplasia of the lateral semicircular canal.[6]

**Fig. 5.1:** Ear findings of a patient with branchio-oto-renal syndrome. Note the presence of a preauricular tag.
*Courtesy*: Lan Krantz, MD, Department of Genetics, Children's Hospital of Philadelphia.

## Treacher Collins Syndrome

Treacher Collins syndrome (TCS), alternatively called mandibulofacial dysostosis (MFD), is characterized by abnormalities of craniofacial development. The obligatory features of the phenotype include antimongoloid palpebral fissures, colobomas, eyelash malformations, molar defects, preauricular hair displacement, micrognathia, and "fishlike" facial features (Figs. 5.2A and B). Patients often also have auricular defects, nasal deformities including choanal atresia, macrostomia, and high arching palate. Patients often have a conductive hearing loss secondary to ossicular fixation.[7]



**Figs. 5.2A and B:** Patient with Treacher Collins syndrome.
*Courtesy*: Craniofacial Clinic, Division of Pediatric Surgery, Children's Hospital of Philadelphia.

### Genetics

Treacher Collins syndrom is inherited in an autosomal dominant fashion with an incidence of 1 in 50,000 live births, and while it has nearly complete penetrance, it has variable phenotypic expression.[8] However, up to 60% of cases do not have a family history and are therefore thought to result from de novo mutations. The causative gene is *TCOF* located on chromosome 5q, which encodes for the protein treacle.[7] During embryologic development, treacle is expressed at peak levels in the first and second branchial arches,[9] and it has been shown that the disease results from interference in the development of these arches.[8, 10] Greater than fifty mutations in the *TCOF* gene have been detected thus far and most appear to result in a truncated protein.

### Presentation

Patients with TCS are often identified at birth. Of note, although developmental anomalies arise bilaterally, they are often not truly symmetric. Mandibulofacial dyso stosis is associated with Pierre Robin sequence and palatal clefting in 35% of cases. Severe obstructive apnea secondary to the micrognathia and glossoptosis often requires surgical intervention.

The external ear is notably deformed in TCS patients. Patients usually present with bilateral microtia or anotia of varying severity with auricular remnants malpositioned.[11] This may be accompanied by stenosis or atresia of the external auditory meatus and, at times, aberrant tympanic membranes. The middle ear may be deformed or absent entirely. The inner ear is usually morphologically normal; however, from a functional standpoint, the pathologic ossicular chain results in a conductive hearing loss. This can be a maximum conductive hearing loss of up to 60 dB; however, the degree of deficit can vary.[11]

## Stickler Syndrome

Stickler syndrome (SS), also known as arthro-ophthalmopathy, is classically defined by the features of myopia, hearing loss, and cleft palate.[12]

### Genetics

Stickler syndrome is a rare autosomal dominant disorder with a preva-lence of 1:10,000,[13] and is caused by mutations in genes encoding proteins that make up type II and XI collagen: COL2A1, COL11A2, and CO11A1.[14,15] Based on the genetic mutation and phenotypically characterized by the particular ocular findings, SS can be broken down into three types. SS type 1 is caused by mutations in COL2A1[14] and the phenotype is characterized by the classic ocular findings with a "membranous" vitreous. SS type 2 is due to mutations in COL11A2 that is not expressed in vitreous,[15] thus making it distinct in that it displays no ocular abnormalities. SS type 3 is caused by mutations in COL11A1,[16] and phenotypically, the vitreous in these patients shows irregularly thickened fiber bundles.[16,17]

### Presentation

Snead and Yates,[17] set forth criteria for the diagnosis of SS that requires (1) congenital vitreous anomaly and (2) any three of myopia with onset before age 6 years, rhegmatogenous retinal detachment or paravascular pigmented lattice degeneration, joint hypermobility, sensorineural hearing loss, or midline clefting. Other manifestations that can be seen, but are not criteria, include midfacial flattening, mandibular hypoplasia, short upturned nose, or a long philtrum. Micrognathia is common, and, if severe, leads to Robin sequence with complete cleft palate (28–65%); however, clefting in SS is more commonly limited to submucous cleft.[18] The ocular findings in SS are the most prevalent feature with most having mypoia[17,18] and many also having vitreoretinal degeneration, retinal detachment, cataract, and blindness.[12] Retinal detachment in adolescence or early adulthood leading to blindness is the most severe ocular complication and affects approximately 50% of individuals with SS.[18]

The hearing loss associated with SS can be conductive, sensorineural, or mixed. If conductive, the loss typically reflects the eustachian tube dysfunction that commonly occurs with palatal clefts. SNHL is more common in older patients and possible mechanisms of pathogenesis include primary neurosensory deficits due to alterations in the pigmented epithelium of the inner ear or abnormalities of inner ear collagen.[18] Computed tomography has not shown gross structural abnormalities. Patients with type 1 SS tend to have either normal hearing or mild loss, whereas at the other end of the spectrum, type 3 patients tend to have moderate-to-severe hearing loss, and patients with SS type 2 fall in between.[13]

## Waardenburg Syndrome

Waardenburg syndrome (WS) is classified under four types with considerable heterogeneity and distinctive

**Fig. 5.3:** Heterochromia in a patient with Waardenburg syndrome. *Courtesy*: John Germiller, Department of Pediatric Otolaryngology, Children's Hospital of Philadelphia.

phenotypic characteristics. WS type 1 is recognized by SNHL, white forelock, pigmentary disturbances of the iris, and dystopia canthorum, a specific displacement of the inner canthi and lacrimal puncti.[19] WS type 2 is distinguished from WS type 1 by the absence of dystopia canthorum. WS type 3, also called Klein-Waardenburg syndrome, is characterized by type 1 features with the addition of hypoplasia or contracture of the upper limbs.[20] WS type 4, also known as Waardenburg–Shah syndrome, involves the association of WS with Hirschsprung disease. Other features often seen include synophrys, broad nasal root, hypoplasia of the alae nasi, patent metopic suture, and a square jaw (Fig. 5.3).[19,20]

### *Genetics*

WS has an aggregate prevalence of 1:10,000–1:20,000.[20] WS type 1, which is the most common type, is caused by mutations in PAX3, a DNA-binding transcription factor expressed in neural crest cells early in development, and mutation results in the absence of strial melanocytes in affected individuals.[21] WS type 2, which is the second most common type, has been associated with mutations in MITF, a transcription factor involved in melanocyte development, in approximately 15% of cases.[21] In addition, mutations in SNAI2, a zinc-finger transcription factor expressed in migratory neural crest cells, have also been shown to cause WS type 2.[22] Similar to WS type 1, PAX3 is the causative gene in WS type 3.[23] Three genes have been implicated in WS type 4: endothelin 3 (EDN3), endothelin receptor B gene (EDNRB), and SOX10.[24,25] It is important to note that although WS types 1 to 3 are inherited as dominant diseases, WS type 4 is autosomal recessive.

### *Presentation*

Classically, the hearing impairment seen in WS is profound, bilateral, and stable over time and is responsible for approximately 2% of profound congenital SNHL.[26] However, it shows considerable variability between and within families. Congenital SNHL is present in 36–66% of cases of WS type 1 versus 57–85% of cases of WS type 2 and is most associated with individuals having pigmentary disturbances of the eyes and skin.[19,20] Audiogram configuration varies, with low-frequency loss being more common. Temporal bone imaging is typically normal, although malformation of the semicircular canals and cochlear hypoplasia can be found.[27]

## Apert Syndrome

Apert syndrome is a rare form of acrocephalosyndactyly involving the cranium, midface, hands, and feet. Manifestations include brachycephaly or acrocephaly, midface hypoplasia and retrusion, and symmetric syndactyly.[28] Also associated is hypertelorism, proptosis, deep fore head, downward sloping palpebral fissures, shallow nasal bridge with a broad nasal root, and bulbous tip (Figs. 5.4A and B).[28] The palate frequently has a high arch and may be cleft.

### *Genetics*

Apert syndrome is inherited in an autosomal dominant pattern with an incidence of 1:200,000 live births.[29] Apert syndrome is caused by a mutation within fibroblast growth factor receptor 2 (FGFR2) located on 10q26 and results in premature closure of calvarial suture lines.[30] Most cases of Apert syndrome arise sporadically through new mutations, although some familial cases with autosomal dominant transmission have been reported.[31]

### *Presentation*

The defects in Apert syndrome are present at birth. While other aspects of Apert syndrome often take priority in terms of treatment, many patients with Apert syndrome have a variety of middle and inner ear anomalies. Middle ear anomalies most often sited are stapes or ossicular chain fixation and middle ear effusions causing conductive hearing loss.[28,32] Inner ear anomalies include dilation of the vestibule, structural anomalies of the cochlea, and semicircular canals.[32] In a 2005 report; Rajenderkumar et al. reviewed 70 cases of Apert syndrome from 1970 to 2003 and found the incidence of congenital hearing loss to be between 3% and 6%, but 56% of patients went on to develop permanent conductive hearing loss by 20 years of life.[32]

## AUTOSOMAL RECESSIVE DISORDERS

### Pendred Syndrome

Pendred syndrome (PS) is an autosomal recessive disorder characterized by bilateral SNHL, often with enlarged vestibular aqueducts, and an iodine organification defect that can lead to thyroid goiter later in life.[33] PS is the most common syndromic form of hereditary sensori neural hearing loss, accounting for approximately 10% of hereditary deafness.[33,34]

#### *Genetics*

Pendred syndrome is autosomal recessive with a prevalence estimated at 7.5–10 per 100,000 individuals.[33] Most cases of PS result from mutations in the SLC26A4 gene that encodes a chloride and iodide transporter known as pendrin that is expressed in the inner ear, thyroid, and kidney.[35] Expression of SLC26A4 has been shown throughout the endolymphatic duct and sac, in distinct areas of the utricle and saccule, and in the external sulcus region within the developing cochlea.[36] Of note, mutations in SLC26A4 also cause a type of nonsyndromic autosomal recessive deafness called DFNB4 in which it is postulated that there may be a degree of residual function in the abnormal pendrin protein. More recently, mutations in the transcription factor FOXI1 have also been shown to cause PS in patients heterozygous for a mutation in SLC26A4.[37]

#### *Presentation*

The hearing loss in PS is usually congenital and severe to profound, although progressive mild-to-moderate SNHL is sometimes seen.[33] Bilateral dilation or enlargement of the vestibular aqueduct (EVA) is common, and may be accompanied by cochlear hypoplasia. A thyroid goiter develops usually in the second decade, although patients often remain euthyroid.[35] Thyroid dysfunction can be shown with a perchlorate discharge test, in which radioactive iodide and perchlorate are administered with a release of >10% radioactivity considered diagnostic for PS; however, the sensitivity of this test is low, making genetic testing the preferred diagnostic method.[34] The hearing impairment is usually prelingual, bilateral, and profound, although it can be progressive.[34] Radiologic studies always show a temporal bone anomaly, either dilated vestibular aqueducts or Mondini dysplasia.[34]

## Jervell and Lange-Nielsen Syndrome

Long QT syndrome can be dominantly or recessively inherited. The dominant disease, called Romano–Ward syndrome, is more common and does not include deafness.[38] The less common and recessive disease is known as Jervell and Lange-Nielsen syndrome (JLNS) and it is characterized by congenital deafness, prolonged QT interval, and syncopal attacks.[38]

### *Genetics*

Jervell and Lange-Nielsen syndrome is genetically heterogeneous with mutations in the KVLQT1 and KCNE1 genes causing defects in subunits of a potassium channel expressed in the heart and inner ear that account for the phenotype.[39] Although the prevalence of JLNS among children with congenital deafness is only 0.21%,[40] it is an important diagnosis to consider because of its cardiac manifestations.

### *Presentation*

Hearing impairment in JLNS is congenital, bilateral, and severe to profound.[39] It is due to changes in endolymph homeostasis caused by malfunction of the ion channel.[39] The prolonged QT interval can lead to ventricular arrhythmias, syncopal episodes, and death in childhood.[40] Importantly, treatment of the long QT interval with β-adrenergic blockers can reduce mortality from 71% to 6%.[40]

## Usher Syndromes

The Usher syndromes (US) are a genetically and clinically heterogeneous group of diseases characterized by sensorineural hearing loss, retinitis pigmentosa with night blindness and gradual vision loss, and often vestibular dysfunction.[41] Three clinical subtypes of US are recognized and are defined according to the severity and onset of the hearing loss, the presence/absence of vestibular dysfunction, and the age at onset of retinitis pigmentosa. The collective prevalence of the US is estimated at 4.4: 100,000 in the United States.[41,42]

### *Genetics*

The Usher syndrome is inherited in an autosomal recessive manner. Numerous genes have been implicated in causing the US and even within each subtype of US there is genetic heterogeneity. The two most common forms are US type 1B and type 2A, which, together, account for 75–s80% of all US.[43] US type 1B accounts for three fourths of US type 1 and is caused by mutations in a myosin gene called MYO7A.[44] US type 2A is the most common of the US overall, and is caused by mutations in a gene, USH2A, which encodes a 1551-amino acid protein named usherin, a putative extracellular matrix molecule.[45] Despite the numerous genes involved, at a basic phenotypic level, the hearing loss in the US is largely attributed to abnormal shape of the auditory hair bundles in the inner ear.

### *Presentation*

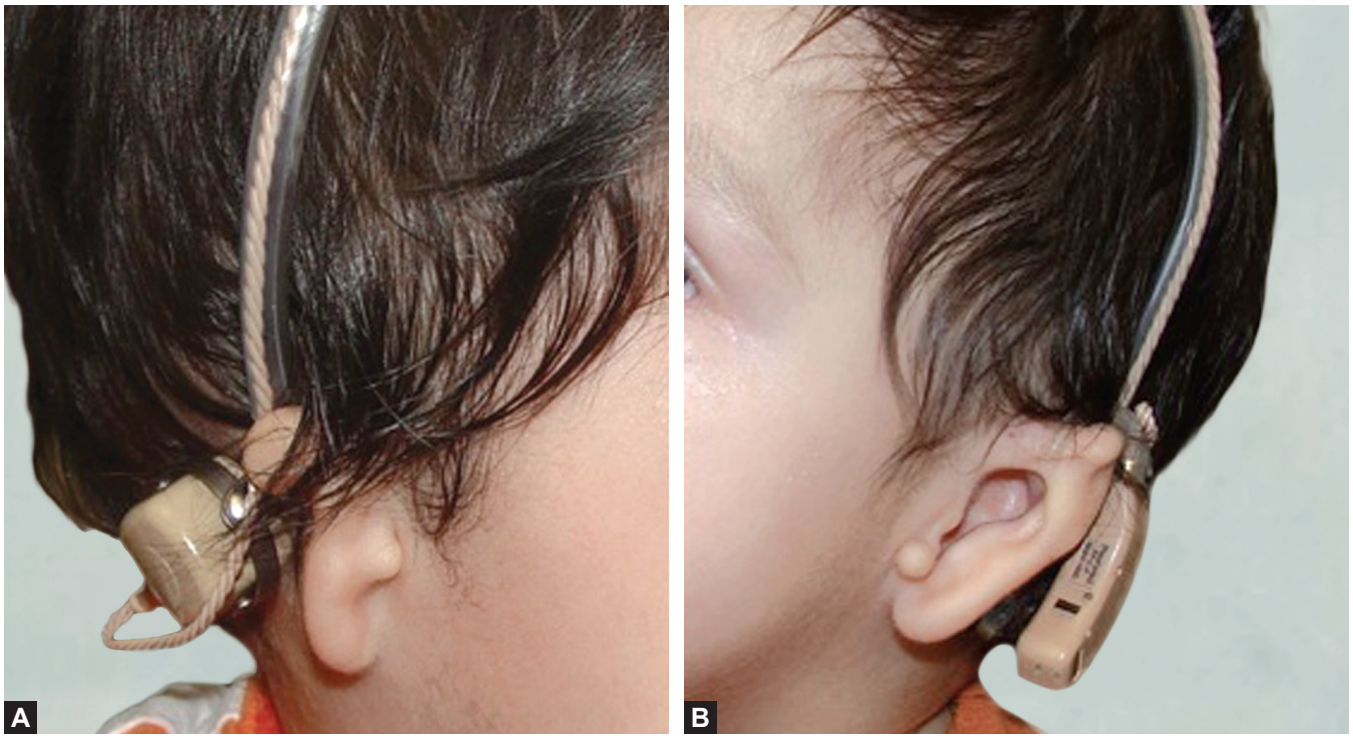
In the United States, US account for between 3% and 6% of congenitally deaf patients and is the cause of approximately 50% of deaf-blindness.[42] Type 1 (USH1) is phenotypically distinguished by the presence of severe-to-profound congenital hearing loss, vestibular dysfunction (bilateral caloric areflexia of the vestibular system), and retinitis pigmentosa that develops in childhood.[42] Type 2 (USH2) is distinguished by moderate-to-severe congenital hearing loss, which can often be treated with hearing aids, no vestibular dysfunction, and retinal degeneration that begins in the third-to-fourth decade;[42] and type 3 (USH3) is characterized by progressive hearing loss, variable vestibular dysfunction, and variable onset of retinitis pigmentosa.[42] Vision loss for each type is progressive and begins with loss of peripheral vision and night blindness.

## Goldenhar Syndrome/ Oculoauriculovertebral Spectrum

Goldenhar syndrome, also known as hemifacial microsomia or oculoauriculovertebral spectrum (OAVS), is composed of a spectrum of malformations involving the first and second branchial arches.[46] The typical presentation includes epibulbar dermoids or lipodermoids, microtia, mandibular hypoplasia, and vertebral anomalies.

### *Genetics*

Goldenhar syndrome appears to be a heterogeneous disease with an incidence of 1 in 5,600 to 26,550 live births.[47] Most cases are sporadic, although there are reports of both autosomal dominant and recessive forms. It exhibits a 3:2 predilection for males and most commonly affects the right ear.[48]



**Figs. 5.5A and B:** Ear findings in patient with Goldenhar syndrome.
*Courtesy*: Craniofacial Clinic, Division of Pediatric Surgery, Children's Hospital of Philadelphia.

### *Presentation*

External ear malformations present in almost all cases of OAVS that range from slightly dysmorphic to absent ears and are usually associated with the involved side of the face (Figs. 5.5A and B).[49] While commonly unilateral, occasionally both ears may be involved.[49] Common minor ear anomalies in these patients include preauricular appendages and pits both of which may be unilateral or bilateral, and have been described in 53–90% of OAVS patients.[49] Reported rates of middle ear anomalies ranges from 67% to 75%[50,51] and include displaced or malformed ossicles that are known to develop from the dorsolateral terminations of the cartilage in the first and second branchial arches. Inner ear alterations are less common and range from agenesis of the inner ear canal to altered cochlear and semicircular canal morphology.[50] Because the most common ear anomalies in the OAVS are external and middle ear abnormalities, secondary conductive hearing loss predominates in these patients,[48] and the degree of hearing loss correlates directly with the level of involvement of structures.[52,53] Although less common, mixed hearing loss with a sensorineural component has been observed, as evidenced by inner ear malformations.[50,52,53] Bilateral profound hearing loss is rare in these patients.

## X-LINKED SYNDROMES

### Alport Syndrome

Alport syndrome is characterized by glomerulonephritis often resulting in progressive renal failure, and a variable degree of sensorineural hearing loss. Patients may also display ophthalmic complications including lenticonus and retinopathy.

### *Genetics*

The underlying defect in Alport syndrome is damaged collagen IV, a key component of basement membranes. Clinical variability among those affected exists secondary to the variety of defects that exist in genes that code for collagen as well as the inconsistency in collagen formation. Several genetic mutations have been attributed to the disease. The most common is found in 85% of patients and consists of a mutation in the COL4A5 gene that results in

an X-linked recessive inheritance pattern of the disease. Autosomal recessive and dominant patterns have also been described, the latter being rare. Males have a more severe form of the disease and often progress to renal failure. Women have variable penetrance depending on the degree of mosaicism.[54]

### *Presentation*

The presenting sign of Alport syndrome is most often hematuria and can be seen as early as infancy, although the renal disease may remain asymptomatic for years. As mentioned, differing mutations in collagen genes have an impact on the severity of disease in patients. In the juvenile form of Alport syndrome, patients may develop renal failure and profound SNHL before the age of 30. In the adult onset form, disease progression does not begin till the age of 30 and hearing loss may be limited to a mild form or late-onset deafness.[54]

Generally, sensorineural hearing loss in Alport syndrome presents in the second decade of life, affects both ears equally, and is progressive in nature. Configurations vary and may be flat across frequencies, downsloping, or "U" shaped and does not usually exceed 70 dB. Speech discrimination scores are generally maintained.[55] Cochlear micromechanics have been faulted for the hearing impairment secondary to histopathologic abnormalities found in the basement membrane of cells in the organ of Corti.[56]

## OTHER SYNDROMES

### Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a congenital disorder in which patients have fragile, brittle bones. Four original forms of OI are described; however, more recently, attempts have been made to expand the classification and include four more forms. Most patients share the common defect in a gene that codes for collagen type I.[57]

### *Genetics*

Mutations of COL1A1 or COL1A2 have been identified as the cause of most forms of OI. Several types have not been associated with a mutation to date. A mutation affecting a glycine residue in either of these genes produces a combination of normal and abnormal collagen resulting in variable expression of the disease. A mutation leading to a premature stop codon in COL1AI results in a milder form of OI in which collagen is formed but at a lesser rate.[57] Most types of OI are inherited in an autosomal dominant manner, although autosomal recessive forms have been described. A high de novo rate is characteristic of the more severe forms of the disease.

### *Presentation*

The main presenting sign of OI is fragile bone. The range of severity is wide and varies from fetal fractures and demise to a mild form without fractures. Other abnormalities with variable expression include blue sclerae, hyperlaxity of ligaments and skin, dentinogenesis imperfecta leading to discoloration of teeth, and hearing impairment.[57]

The hearing impairment associated with OI often does not present until the second to fourth decade of life. At onset, the loss is conductive in nature often progressing to a mixed hearing loss. Rarely, an isolated sensorineural hearing loss exists.[58] The conductive hearing loss in patients with OI is caused by otosclerotic lesions leading to a fixed stapes footplate. The mixed loss results from more extensive otosclerosis involving the cochlea. Ossicular discontinuity may play a part as well. The severity of hearing loss has not been correlated to the severity of bone fragility and a wide variability exists in its presentation among patients.[59]

### Crouzon Syndrome

Crouzon syndrome is part of a family of syndromes referred to as craniofacial dysostosis. Premature craniosynostosis, or fusing of the fibrous sutures of the skull, leads to abnormal cranial and facial features. Crouzon syndrome is estimated to occur in 1 per 65,000 births (Figs. 5.6A and B).[60]

### *Genetics*

Crouzon syndrome is inherited as an autosomal dominant trait. Penetrance is complete, while expression is variable. Sporadic cases are common have been associated with advanced paternal age. A mutation in the gene that codes for FGFR2 has been shown to be the cause of the syndrome.[61] A different variant associated with acanthosis nigricans is linked to a mutation in FGFR3. [62]

### *Presentation*

Patients may show varying cranial deformities secondary to inconsistent craniosynostosis. Patients most often present with brachycephaly resulting from craniosynostosis

**Figs. 5.6A and B:** Patient with Crouzon syndrome.
*Courtesy*: Craniofacial Clinic, Division of Pediatric Surgery, Children's Hospital of Philadelphia.

of the coronal, sagittal, and lambdoid sutures. In addition to cranial deformities, most display hypoplasia of the midface, exorbitism (secondary to decreased bony orbital volume). A high incidence of obstructive sleep apnea and increased intracranial pressure exists in this population. Mental development is generally normal.

External appearance of the ears is usually normal in these patients, but some may show mild abnormalities including low-set ears or abnormal rotation.[63] The prevalence of hearing loss in patients with Crouzon syndrome has been estimated to be around 35%.[64] The hearing loss can be conductive, sensorineural, or mixed in origin Conductive hearing loss often is associated with Eustachian tube dysfunction and associated findings including perforation, chronic otitis media, and retraction. Ossicular chain fixation and external auditory canal atresia have also been described. The sensorineural component of hearing loss is not as well defined and occurs infrequently.

## Down Syndrome

Down syndrome occurs in approximately 1 in 650 births. It is the most common malformation syndrome. A variety of physical signs are associated with this syndrome and patients have a characteristic physical appearance.

### *Pathogenesis*

Down syndrome is the result of an extra copy of the genetic material of chromosome 21. This can be in the form of an extra chromosome from a nondisjunction event or a translocation. Advanced maternal age has been strongly correlated with the risk of manifestation of the syndrome.

### *Presentation*

Physical signs often associated with Down syndrome include brachycephaly, upward slanting palpebral fissures, epicanthic folds, and macroglossia. Patients often display growth retardation as well as mental delay. Hypotonia and joint laxity are also common.

Patients with Down syndrome have distinctive small, low-set auricles and small ear canals. The Eustachian tube is often dysfunctional due to its shape and easy collapsibility. These patients are more prone to problems with chronic otitis media and suffer from other complications resulting from chronic Eustachian tube dysfunction. Historically, a high rate of hearing loss was reported in this population. More recently, aggressive management of chronic ear disease, the most common cause of hearing loss in this population, has shown a great improvement in rates of permanent loss.[65]

## CHARGE Syndrome

CHARGE syndrome was initially described as an association of malformations often identified concurrently. Characteristics include coloboma, heart defects, choanal atresia, growth retardation, genital defects, and ear anomalies. In the past decade, a genetic mutation confirmed the association as a syndrome.[66] The incidence of the syndrome is about 1 in 10,000 births.

### *Pathogenesis*

De novo mutations in CH7 gene are thought to lead to the development of CHARGE syndrome. The gene encodes a protein that deals with chromatin remodeling and likely has an effect on cell-cycle regulation. Rare familial instances have been documented with autosomal dominant inheritance of the syndrome.

### *Presentation*

The characteristics of patients with CHARGE syndrome are often variable and not all patients possess all abnormalities encompassed in the mnemonic attributed to the syndrome. Features seen in the syndrome include unilateral or bilateral colobomas at times associated with microphthalmos, unilateral or bilateral choanal atresia or stenosis, cranial nerve dysfunction, swallowing problems, external and internal ear anomalies, genital anomalies, developmental delay, cardiovascular malformations, growth deficiency, orofacial clefts, and tracheoesophageal fistula.

Patients with CHARGE syndrome display a wide variety of ear anomalies and a high rate of hearing loss. External, middle, and inner ear anomalies have all been described. The external ear, while characteristically hypoplastic and low-set, may present as microtia. Accessory auricles may be present.[67] Moderate-to-profound hearing loss is common among these patients secondary to ossicular anomalies, Eustachian tube dysfunction, and varying inner ear anomalies. Common inner ear anomalies include cochlear dysplasia, semicircular canal aplasia, atresia of the oval window, and cochlear nerve deficiency. Atypical routing of the facial nerve and facial nerve palsies is also common.[68]

## Kabuki Syndrome

Patients with Kabuki syndrome are distinguished by typical facial features, most significant of which include elongated palpebral fissures with lower eyelid eversion, a broad and depressed nasal tip, and large prominent ears. These patients also display a wide variety of musculoskeletal and cardiac anomalies.

### *Pathogenesis*

Two gene mutations have been shown to be associated with Kabuki syndrome: MLL2 (myeloid/lymphoid or mixed-lineage leukemia and KDM6A [lysine (K)-specific demethylase 6A]. The majority of cases are sporadic, although the genes are inherited in an autosomal dominant fashion. The incidence of this rare syndrome is approximately 1 in 32,000 births.[69]

### *Presentation*

Apart from the typical facial features, patients with Kabuki syndrome display postnatal growth retardation and a spectrum of developmental delay. A large percentage of patients also have cleft lip and palate. Cardiac anomalies, skeletal abnormalities, and immunodeficiency are also seen and their presentation varies greatly among patients.[70]

The external ear anomalies displayed in Kabuki syndrome vary. The majority of patients have large, prominent ears or cup ear deformities. Aural atresia and preauricular pits have also been described. It has been estimated that approximately half the patients with Kabuki syndrome will have a hearing impairment. This loss is usually conductive in nature and due to recurrent or chronic otitis media. Sensorineural hearing loss has been reported in rare cases with associated inner ear anomalies ranging from enlarged vestibular aqueduct to complete cochlear aplasia.[71]

## Turner Syndrome

Turner syndrome is marked by the absence of all or part of one X chromosome. Patients are phenotypically female, but have characteristic physical appearances.

### *Pathogenesis*

Turner syndrome, also referred to as gonadal dysgenesis, is caused by complete or partial absence of one X chromosome. The most common karyotype is 45, XO that signifies a complete absence of one X chromosome. Loss of material from the short arm of the X chromosome is thought to result in the common physical signs and symptoms of the syndrome. Turner syndrome occurs in up to 1 in 2000 phenotypically female patients.

### *Presentation*

Patients with Turner syndrome have characteristic physical appearances consisting of short stature with webbed neck, gonadal dysgenesis, and lack of secondary sex characteristics. Patients also have cardiac, renal, and ophthalmologic abnormalities. Cleft palate or other palatal abnormalities are also common.[72]

Externally the ears are most often normal; however, cup ear deformity and low-set ears are described. Eustachian tube dysfunction causing chronic ear disease is common and conductive hearing loss occurs in as many as 70% of patients.[73] Sensorineural hearing loss is less common and is thought to occur in the second or third decade of life and progress slowly. Mid frequency losses as well as a form of early presbycusis with prominence in the higher frequencies have been described. Sensorineural hearing loss has been postulated to be related to the patient's karyotype.[74]

## Nager Syndrome

Nager syndrome is a congenital anomaly syndrome also known as Nager acrofacial dysostosis. Preaxial limb and mandibulofacial anomalies are the predominant features of the syndrome.

### *Pathogenesis*

Recently, Nager syndrome was found to be caused by haploinsufficiency, or inactivation of one of two copies, of the gene SF3B4, a spliceosomal factor.[75] It is a rare condition and is believed to be autosomally inherited. The majority of cases to date have been sporadic.

### *Presentation*

Patients with Nager syndrome have similar facial characteristics as those with TCS. These features include downslanting palpebral fissures, malar hypoplasia, micrognathia, external ear anomalies, and cleft palate. Limb anomalies, including hypoplasia of the radial aspect of the hand especially the thumb, foreshortened forearms, and duplications of the thumbs, are the other common findings in these patients.[76]

Otologic anomalies, including external and middle ear malformations, are noted in the majority of patients with Nager syndrome. Auricular anomalies can range from preauricular pits to anotia with external auditory canal atresia or stenosis. The most commonly encountered form of hearing loss is conductive secondary to chronic otitis media (middle ear disease is ubiquitous in this population), canal atresia or stenosis, and ossicular anomalies. Moderate-to-severe conductive loss is most common. Sensorineural hearing loss is not considered a factor in this syndrome, although some reports show patients with mixed hearing loss. Several reports have shown most patients present with normal inner ear anatomy.[77]

## Velocardiofacial Syndrome

Velocardiofacial syndrome (VCFS), also known as 22q11.2 deletion syndrome, encompasses multiple presentations. All share a common genetic basis: a deletion on the short arm of chromosome 22. The genes affected are involved in pharyngeal arch development, and the phenotypic presentation of this VCFS is secondary to this fact.

### *Pathogenesis*

Several genes have been found to contribute to the phenotypic variability encountered in patients with VCFS. These include TBX1, TBX2, TBX3, and VEGF, all of which are involved in pharyngeal arch development. VCFS affects an estimated 1 of every 4000 newborns. In < 10% of patients, the syndrome is inherited in an autosomal dominant fashion.

### *Presentation*

The presentation of patients with VCFS is diverse. The face in these patients often appears long and hypotonic with narrow palpebral fissures. A squared nasal root with a narrow alar base is seen. Congenital cardiac anomalies are common and can include tetralogy of Fallot, pulmonary artery alterations, and septal defects. Immune deficiency is common secondary to the thymic aplasia (a third arch derivative) and manifests as problems with T-cell-mediated response. Hypocalcemia secondary to decreased parathyroid function is a frequent manifestation. Clefting of the secondary palate can be obvious or can manifest overtly as a submucous cleft. Velopharyngeal insufficiency is common in this population.[78]

Small auricles that at times are morphologically abnormal are often seen in patients with VCFS (Fig. 5.7). Eustachian tube dysfunction leading to chronic otitis media is the main cause of conductive hearing loss in this population. Middle ear anomalies have been reported. Inner ear anomalies with resulting SNHL have also been described in approximately 10% of patients.[79] TBX1 is reported to be important in the development of the inner ear.[80]

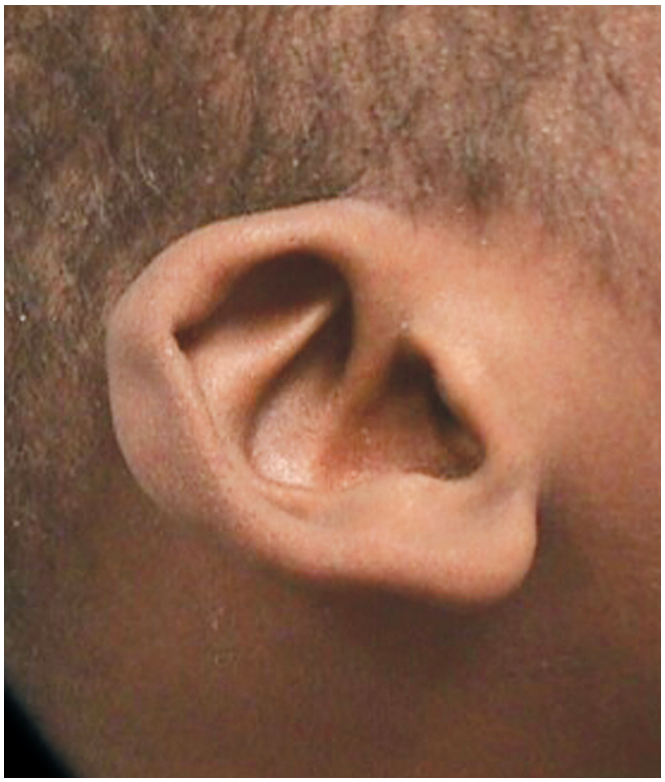


**Fig. 5.7:** Ear findings in patient with velocardiofacial syndrome. *Courtesy*: Lan Krantz, Department of Genetics, Children's Hospital of Philadelphia.

## CONCLUSION

An abundance of syndromes associated with otologic findings exists. These syndromes may affect one or several parts of the otologic system. Management of patients with otologic syndromes is best approached by a multidisciplinary team as many have concomitant anomalies.

CHAPTER

6

# Congenital Hearing Loss

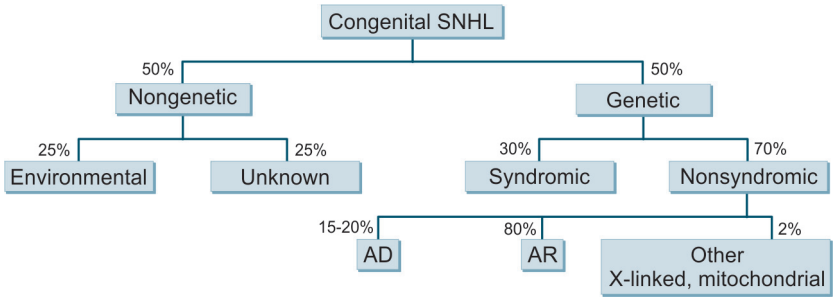
***Gillian R Diercks, Leila A Mankarious***

## INTRODUCTION

Sensorineural hearing loss (SNHL) in the pediatric population is the most common congenital abnormality and the most common sensory disorder, with an estimated incidence of 1.1 per 1000 births.[1] Roughly 20–30% of congenital hearing loss cases are profound (hearing level > 90 dB)[2] and an estimated 30% of children with hearing loss have additional disabilities, such as cognitive impairment.[3] Hearing loss in children can be classified according to the age of onset and etiology. The term "congenital" refers to the age at which hearing loss develops; however, it does not point toward the particular etiology of the sensory deficit.

There are multiple causes for congenital hearing loss, which include genetic, metabolic, infectious, and environmental etiologies (Flowchart 6.1). A total of 50% of SNHL cases have a genetic basis, where 30% are syndromic and associated with other organ system abnormalities, and 70% are nonsyndromic. With the advent of genetic testing, the etiologic distribution likely has not changed; however, the ability to identify a specific diagnosis has improved. Of the nonsyndromic cases, approximately 80% are autosomal recessive, 20% are autosomal dominant, 1% are X-linked, and < 1% demonstrate a mitochondrial pattern of inheritance.[4] Infectious causes including toxoplasmosis, rubella, cytomegalovirus (CMV), herpes simplex, syphilis, and H. influenza type B meningitis once represented the majority of acquired hearing loss cases. With advancements in immunization programs, prenatal and neonatal care, the incidence of infection-associated hearing loss has decreased significantly.[5] However, neonatal intensive care unit (NICU) admissions are becoming increasingly prevalent, and premature infant survival is increasing. As a result, hearing loss associated with hypoxia, hyperbilirubinemia, extracorporeal membrane oxygenation (ECMO), sepsis, and exposure to ototoxic medications, such as aminoglycosides and

**Flowchart 6.1:** Etiologies of congenital hearing loss.



diuretics, is increasing.[6] Other causes of congenital hearing loss include otitis media with effusion, congenital malformation of the external or middle ear, noise exposure, and trauma.[7] The prevalence of childhood hearing loss increases until roughly 6 years of age due to delayed diagnosis and progressive hearing loss associated with genetic or infectious conditions, such as CMV and meningitis.[2]

Hearing loss that occurs early in life is present during the most critical periods for language and social development and may have long-lasting consequences for affected children and their families.[2] Though prelingual hearing loss has an obvious and direct effect on spoken language development, it may also affect indices of academic achievement, impart psychosocial and parental stress, and decrease future employment opportunities.[8,9] Lack of auditory input changes the function of the auditory system, affecting interactions between cortical areas, and may impair cortical development.[10] If hearing is established later in life, after this critical period, complex auditory functions cannot be restored fully, and auditory input may become uncoupled from other sensory modalities.[2]

Prior to initiation of widespread newborn hearing screening, children born with hearing impairment were identified at an average of 1.5–3 years of age, typically due to impaired language development.[11] Because of diminished auditory input during critical developmental periods, most children with hearing loss lagged in their language and other academic skills even after educational support and devices to augment hearing were initiated. In the 1990s, studies demonstrated that early intervention before 6 months of age—a critical period for language development—could substantially improve language acquisition. There was a movement toward early identification of SNHL, resulting in the implementation of universal newborn hearing screening in the United States in 1999, which has been instrumental in the early recognition and interdisciplinary treatment of congenital hearing loss. Fortunately, these interventions, which include speech therapy, amplification, and cochlear implantation, have allowed for improved language outcomes, including reading ability and communication, which improve life opportunities for children with congenital deafness.[2,12]

## EARLY HEARING DETECTION AND INTERVENTION

All infants under the age of 3 months should be screened in accordance with recommendations from the NIH consensus statement in 1993 on early identification of hearing impairment in infants and young children in order to minimize the lasting effects of prolonged auditory deprivation. These recommendations have now been mandated by federal law. In addition, the Joint Committee on Infant Hearing (JCIH), a group of specialists composed of representatives from audiology, otolaryngology, pediatrics, and nursing, has made additional recommendations that infants should be hearing-screened by 1 month of age and intervention should be initiated for those infants who have significant hearing loss by 6 months of age. In addition, neonates who have been in the intensive care unit for more than 5 days should also have auditory brain stem response (ABR) testing as part of their screening so that neural loss is not missed.[13]

## NEWBORN HEARING SCREENING

Newborn testing protocols primarily utilize either automated auditory brain stem response (aABR) to a transient stimulus or an otoacoustic emission (OAE), again after a brief stimulus. Transient-evoked OAEs test over a broad frequency range and distortion-product OAEs evaluate distortion product in response to two pure tones. Both aABR and OAEs have advantages and limitations that are important to be aware of and are reviewed in further detail in a separate chapter (Chapter 14). aABR requires attachment of surface electrodes to the skin to produce a well-defined waveform; thus, recording time is increased in comparison to OAE testing which does not require scalp recording. However, unlike OAE, which only test the function of cochlear outer hair cell function, ABR evaluates proper functioning of both inner and outer hair cells, as well as acoustic neural tracts within the brain. OAEs may miss patients with hearing loss due to isolated inner hair cell dysfunction (auditory neuropathy/auditory dyssynchrony) or central nervous system pathology. Lastly, OAEs are more susceptible to middle ear pathology, external canal collapse, and vernix as well as ambient noise. Audiologic screening of the newborn infant is a rapidly changing and growing field requiring frequent equipment updates. The choice of which screening test to use will be influenced by institutional resources as well as regional differences in audiologic education and training.

Of all neonates screened using aABR, 2–3% "refer" for further evaluation, and of those, repeat testing shows that less than 1% fail. Initial "refer" rates for OAE screening are higher with an initial rate of 5–10% and subsequent

2% on rescreening. Hence, aABR appears to be a more accurate test for screening but has some disadvantages as mentioned above. Once an infant has failed two newborn screens, a diagnostic ABR is obtained that tests both ears even if only one has failed. Audiologic testing in children older than the newborn period is beyond the scope of this chapter and will be reviewed elsewhere.

## ETIOLOGY OF CONGENITAL HEARING LOSS

### Genetic

Up to 50% of congenital hearing loss cases are hereditary, and over 400 forms of genetic deafness have been described.[14] A total of 30% of these cases are syndromic and associated with other organ system abnormalities. The most common syndromes associated with hearing loss include Pendred, Usher, Waardenburg, and Branchio-oto-renal. The remaining 70% of genetic cases are nonsyndromic in which hearing loss is most often sensorineural.[4] The majority of nonsyndromic cases, up to 80%,[4] demonstrate an autosomal recessive pattern of inheritance. While autosomal dominant forms of nonsyndromic hearing loss are often associated with progressive, postlingual deafness, autosomal recessive hearing loss is typically prelingual.[4] Up to 50% of autosomal recessive cases are due to mutations in *GJB2* and/or *GJB6* at the DFNB1 locus, which encode connexin 26 and 30.

While a complete description of all the genetic causes of congenital hearing loss is beyond the scope of this chapter and is described elsewhere in this text, we summarize the most common causes of syndromic and nonsyndromic congenital loss.

### Syndromic

#### *Autosomal Dominant*

*Waardenburg:* This syndrome, characterized by variable degrees of prelingual SNHL and pigmentary changes involving the skin, eyes (heterochromia iridis), and hair (white forelock), is the most common form of autosomal dominant syndromic hearing loss. There are four types of Waardenburg syndrome: WSI, WSII, WSIII, and WSIV. These four disorders are linked by the common feature of melanocyte dysfunction but each has distinguishing features. In WSI, dystopia canthorum, which is lateral displacement of the medial canthus, is present. Patients with WSIII also demonstrate upper limb abnormalities, and patients with WSIV have Hirschsprung disease. WSI and WSIII are associated with mutations in *PAX3*, WSII is associated with mutations in *MITF* and *SNA12*, and WSIV is associated with mutations in *EDNRB*, *EDN3*, and *SOX10*.[14]

*Branchio-Oto-Renal*: This is the second most common form of autosomal dominant syndromic hereditary hearing loss. It is associated with conductive, sensorineural, or mixed hearing loss as well as malformations of the external ear, preauricular pits, branchial cleft fistulas or cysts, and renal abnormalities. It has been associated with mutations in *EYA1* and *SIX1*; there are also a number of hereditary cases in which the genetic mutation has not yet been identified.[14]

*Stickler Syndrome*: This is an autosomal dominant disorder involving mutations in *COL2A1*, *COL11A1*, or *COL11A2*, which are involved in type 2 collagen synthesis. Patients with this syndrome demonstrate SNHL, spondyloepiphyseal dysplasia, cleft palate, and congenital myopia. Because of their myopia, as well as increased risk for retinal detachment, patients with Stickler syndrome require routine ophthalmologic evaluations.[14]

#### *Autosomal Recessive*

*Pendred:* This is the most common form of autosomal recessive syndromic hearing loss. It is associated with congenital severe to profound SNHL as well as temporal bone defects, including Mondini malformation and enlarged vestibular aqueduct. Pendred syndrome is also associated with euthyroid goiter, which develops due to delayed iodine organification. Goiter is not sensitive or specific for the disorder, however. Due to incomplete penetrance, some patients will never develop goiter, and others will not present with goiter until adolescence or adulthood.[4] Most patients with Pendred syndrome are euthyroid with normal thyroid function tests.[15] The perchlorate discharge test is diagnostic. A total of 50% of families with Pendred syndrome demonstrate mutations in *SLC26A4*, a chloride/iodide transporter.[4] This gene is also associated with autosomal nonsyndromic hearing loss at the DFNB4 locus.[14]

*Usher:* This is a common form of autosomal recessive syndromic hearing loss and affects over 50% of deaf and blind

individuals in the United States.[14] It is characterized by SNHL and retinitis pigmentosa, a form of retinal degeneration. There are three forms of Usher syndrome, which are distinguished by the degree of hearing and vestibular impairment. In type 1 (USH1), vestibular dysfunction and severe to profound SNHL are present at birth. Patients with type 2 (USH2) have normal vestibular function, and congenital SNHL may range from mild to severe. In type 3 (USH3), the rarest form of the disease, patients develop progressive hearing loss and vestibular dysfunction. Patients with impaired vestibular function may not meet their motor developmental milestones. Retinal degeneration in patients with Usher syndrome is usually not symptomatic until adolescence; however, electroretinography can identify photoreceptor abnormalities in patients as young as 2 years of age.[14] Therefore, if Usher syndrome is suspected, ongoing ophthalmologic evaluation is critical. It is also important to identify patients with Usher syndrome early, as it may help guide decisions about the most appropriate communication strategies—for example, choosing cochlear implantation over sign language. Multiple genetic mutations have been identified, including *MYO7A*, *USH1C*, *CDH23*, *PCDH15*, *USH1G* for USH1, *USH2A*, *GPR98*, and DFNB31 for USH2, and *USH3A* for USH3.[16]

*Jervell and Lange-Nielsen:* This is the third most common form of syndromic autosomal recessive hearing loss. Affected individuals demonstrate SNHL and the cardiac conduction abnormality of QT interval prolongation, which may result in syncopal episodes and sudden death. In cases with a positive family history of sudden death, sudden infant death syndrome, syncope or QT prolongation, ECG is warranted.[14,15] This syndrome is associated with mutations in *KCNQ1* and *KCNE1*, which together encode a potassium channel important for maintenance of the electrochemical gradient of the inner ear and cardiac myocardium.

### X-linked

*Alport Syndrome:* This syndrome is characterized by progressive bilateral SNHL, typically postlingual, glomerulonephritis that leads to renal failure, and ophthalmologic abnormalities, including anterior lenticonus that results in myopia. Hearing loss usually is not apparent until after the first decade of life; however, Alport syndrome may be diagnosed earlier secondary to its associated ophthalmologic findings. Up to 85% of cases demonstrate an X-linked pattern of inheritance associated with mutations in*COL4A5*, which is associated with type 4 collagen production; autosomal recessive forms of the disease and, rarely, autosomal dominant inheritance have also been described.[14]

### Mitochondrial

*MTRNR1:* A total of 50% of patients with aminoglycoside-related ototoxicity harbor the 12S ribosomal RNA mutation 1555A>G. This gene is also associated with maternally inherited, nonsyndromic hearing loss that is not related to antibiotic exposure.[17] Another significant mutation that puts individuals at risk for SNHL is the *MT-TS1* within mitochondrial tRNA.

## Nonsyndromic

### Autosomal Recessive

*DFNB1:* This locus on chromosome 13q11 has been implicated in autosomal recessive nonprogressive mild to profound SNHL. Mutations in two genes, *GJB2* and/or *GJB6*, have been identified that encode connexin 26 and connexin 30, respectively. Connexin 26 and connexin 30 are gap junction proteins expressed in the cochlea and felt to be important for potassium recirculation and maintenance of an electrochemical gradient.[4] Mutations in *GJB2* have been identified in up to 50% of autosomal recessive, nonsyndromic hearing loss cases. Over 220 mutations in this gene have been identified, which occur in different frequencies across populations.[17] Approximately 1 in 33 US residents of Northern European descent carry a mutation in this gene.[18] The most common mutation, seen in up to 2/3 of cases, is the deletion of guanine at position 35 (35delG). This deletion results in a frame shift mutation and premature termination of protein synthesis.[4] A total of 10–15% of patients with hearing loss have a mutation in only 1 copy of *GJB2*. In these patients, a neighboring gene, *GJB6*, also harbors a mutation. The most common abnormalities in *GJB6* are large deletions that truncate *GJB6* or abolish *GJB2* expression.[17] Patients who are homozygous for a mutation in *GJB6* demonstrate autosomal recessive SNHL, or may develop SNHL if there is also mutation in *GJB2* on the opposite allele.[4]

*OTOF (otoferlin):* This mutation, located at the DFNB9 locus, is associated with nonsyndromic autosomal recessive hearing loss. Up to 50% of cases with mutations in

both *OTOF* alleles demonstrate auditory neuropathy in which OAEs are present in the absence of ABR responses. Testing for this mutation should be considered in cases of suspected auditory neuropathy auditory dyssynchrony.[17]

### X-linked

*DFN3:* In this genetic form of hearing loss, patients exhibit a mixed conductive-SNHL, characteristic inner ear dysplasia, and stapes fixation.[17] Imaging demonstrates dilation of the internal auditory canal with abnormal communication between the subarachnoid space and endolymph. This abnormality is associated with the development of perilymph gusher with disruption of the oval window and is a contraindication to stapedectomy.[4,17] It has been mapped to mutations in the gene *POU3F4*.

## Nongenetic

Approximately 25% of congenital hearing loss cases are acquired secondary to environmental causes such as infection, prematurity, ototoxic exposures, and trauma. In the remaining 25% of cases, the cause of hearing loss is unknown; however, some authors suggest these cases are due to unknown genetic factors.[4] This is not surprising given the complexity of the auditory system and genetic heterogeneity, which make gene identification a challenge.[4] It is likely that whole exome sequencing will become more available over time due to a decrease in cost and a progressive increase in understanding of the identified mutations. In the future, it is likely that a number of the cases with no known cause will be rediagnosed with a specific genetic mutation.

### Perinatal Causes

Low birth weight, asphyxia, hypoxia, and NICU admission are all associated with hearing loss. Additional perinatal risk factors for hearing loss include persistent pulmonary hypertension, respiratory distress syndrome, hyperbilirubinemia, and ECMO. These peri- and neonatal risk factors account for 12.6–18.9% of bilateral profound SNHL cases and prevalence may reflect trends in improved NICU survival.[19] Low birth weight, <1500 g, is the most common risk factor in the NICU population.[19] Neonatal infections, such as sepsis and meningitis, and exposure to ototoxic medications are also associated with increased hearing thresholds.[6]

### Infectious Causes

Prenatal infections secondary to maternal exposure to the TORCH organisms (toxoplasmosis, rubella, CMV, herpes simplex, and syphilis) and viruses, as well as postnatal meningitis from *Neisseria meningitides, Haemophilus influenzae, Streptococcus pneumoniae, Escherichia coli, Listeria monocytogenes, Streptococcus agalactiae,* and *Enterobacter cloacae*, are associated with hearing loss.[14] However, with improved prenatal care and immunization programs, these are becoming increasingly less common.[7,19] Congenital CMV infection, however, may be asymptomatic and remains an important cause of congenital hearing loss.

### Cytomegalovirus

CMV is the most prevalent congenital infection in the United States and the most common cause of acquired (nongenetic) congenital hearing loss, accounting for 10–60% of cases.[20,21] Infection occurs by vertical transmission, which can be intrauterine, intrapartum, or postnatal. Maternal infection may be primary, result from reactivation of a latent infection, or due to reinfection with a different viral strain,[20] and occurs in 2–6% of pregnancies.[22] Postpartum infection is most commonly caused from the breast milk of an infected mother.[20] The worldwide prevalence of congenital CMV infection is 7 per 1000 births. Only 12.7% of infections are symptomatic at birth[23]; infection cannot be identified by clinical examination in the majorty of neonates affected by congenital CMV.[24] Neonates with symptomatic infection exhibit a "blueberry muffin rash", petechiae, intrauterine growth restriction, microcephaly, hepatosplenomegaly and jaundice with associated hyperbilirubinemia, thrombocytopenia, and elevated hepatic transaminases. Over 50% of symptomatic infants develop neurologic sequelae, including SNHL, learning disability, and visual impairment.[25]

A total of 15–65% of affected patients develop hearing loss,[21] including 4.4–10% of patients who are asymptomatic at birth.[20,26] The pattern of hearing loss associated with CMV infection is variable—it may be unilateral or bilateral, delayed in onset, or progressive.[14] Hearing may be normal at birth; therefore, only approximately 50% of congenital CMV-related SNHL is identified by newborn hearing screening.[24,27] The median age at first progression of loss and detection of hearing loss in children affected by congenital CMV is 18 months and 27 months, respectively.[28]

After 3 weeks of age, it is difficult to diagnose if CMV infection is congenital or acquired. While universal screening for congenital CMV is not recommended currently, the development of dried blood spot, urine, and saliva polymerase chain reaction (PCR) amplification assays makes congenital CMV easier to detect and newborn screening a growing possibility.[24,29] PCR is replacing urine viral culture, the previous gold standard, as the most efficient and sensitive method of CMV detection.[20] In particular, PCR of both liquid and dried salivary samples is gaining popularity due to its high rates of sensitivity and specificity, as well as ease of collection, storage, and transport.[20,24] Some authors argue that salivary PCR is now the diagnostic test of choice to detect congenital CMV.[20,24]

Evidence-based recommendations for the management of congenital CMV are limited.[20] Complete blood count (CBC) and liver function tests (LFTs) should be obtained. If hepatic disease is present, coagulation studies should also be ordered.[20] Cranial ultrasounds (CrUSS) should be used to assess for intracerebral calcifications and other abnormalities in all children with confirmed congenital CMV. MRI imaging is reserved for children with symptomatic disease, or as follow-up imaging in patients found to have abnormal CrUSS.[20] All infants with congenital CMV should also undergo an ophthalmologic assessment as well as a baseline audiologic evaluation, which should be repeated every 3–6 months until age three, then annually until age six.

Several trials have demonstrated that early treatment of children with symptomatic congenital CMV with 6 weeks of intravenous ganciclovir at 6 mg/kg dosing twice daily results in hearing improvement or stabilization as well as decreased developmental delay independent of hearing level.[30-32] Currently, antiviral treatment is only recommended for symptomatic newborns (< 30 days) with central nervous system or severe focal organ system involvement.[20] Due to lack of data proving its efficacy, antiviral therapy is not indicated for older patients, patients with asymptomatic disease, or those without CNS involvement. Neonates on ganciclovir treatment are at risk for central venous catheter infections and pancytopenia, requiring weekly monitoring. Additionally, because ganciclovir is renally excreted, patients receiving therapy require weekly testing of creatinine clearance and therapeutic drug levels. Whole blood CMV viral load levels should also be obtained weekly to assess drug efficacy. Valganciclovir, the oral prodrug of ganciclovir, is also being studied; however, there is not yet published data from prospective randomized trials on its efficacy or comparing outcomes to those obtained using ganciclovir therapy, which is the current standard of care.[20,33,34]

### *Metabolic Disorders*

Multiple metabolic disorders are associated with the development of SNHL, and should be considered in children with affected siblings, from consanguineous unions, developmental delay, or dysmorphic features.[6] Metabolic conditions include disorders of amino acid production (phenylketonuria), polysaccharide metabolism and storage (Hurler, Hunter), neurotransmitter metabolism (Canavan disease), mitochondrial metabolism (MELAS, MERRF), and peroxisomes (Refsum, Zellweger syndromes).[6]

### *Other Causes*

Noise exposure, even in utero, is associated with high-frequency hearing loss. Infants born to mothers with occupational noise exposure are at increased risk for SNHL by as much as threefold. After birth, noise-induced hearing loss can result from recreational activities and exposure to fireworks.[6] Head trauma may result in hearing loss due to temporal bone fracture, posttraumatic perilymphatic fistula, or in children with temporal bone abnormalities, such as enlarged vestibular aqueduct. Exposure to ototoxic medications, including aminoglycosides and platinum-based chemotherapeutic agents, as well as radiation, can also lead to hearing deficits.[6]

## MEDICAL EVALUATION

A careful history and physical examination, including objective audiometric data, are the first steps in determining the cause of a child's hearing loss. This information may be sufficient to diagnose the cause of hearing loss or may help direct further diagnostic studies, such as genetic testing or imaging.

### History

A careful history should be obtained to determine maternal and prenatal risk factors, perinatal events and risk factors, and history of environmental exposures (such as to drugs or trauma). A directed history of speech and language development milestones may help determine when hearing loss occurred. The point at which

**Table 6.1:** History taking: Risk factors for congenital and childhood hearing loss

| *Prenatal* | *Examples* |
|---|---|
| Maternal infections | TORCH (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis) |
| Maternal exposure to toxic agents | Aminoglycosides, furosemide, quinine, chloroquine, thalidomide, alcohol, tobacco |
| Maternal metabolic disorders | Diabetes, hypothyroidism |
| *Perinatal* | *Examples* |
| Prematurity | |
| Low birth weight | < 1500 g |
| Hypoxia, low APGAR scores | 0–3 at 5 min; 3–6 at 10 min |
| Hyperbilirubinemia | |
| Sepsis | |
| NICU admission | |
| Extracorporeal membrane oxygenation (ECMO) | |
| Exposure to ototoxic medications | |
| *Postnatal* | *Examples* |
| Viral illness | Varicella, measles, mumps |
| Bacterial meningitis | |
| Otitis media with effusion | |
| Trauma | Head trauma, noise exposure |
| Metabolic disorders | Hypothyroidism, glycogen storage disease |
| Neurodegenerative disorders | |
| Genetic syndrome, other organ system abnormalities | Visual impairment, kidney disease, history of syncope |
| *Family history* | *Examples* |
| First and second degree relatives with hearing loss | |
| Common origin from ethnically distinct areas of the world | Ashkenazi Jews, Japanese |
| Consanguinity | |

Adapted from Lin and Oghalai[7] and Mafong et al.[15]

hearing loss developed, whether it was identified during prenatal screening or occurred in a delayed fashion, may help to determine the etiology; however, it should be noted that some genetic forms of hearing loss, as well as infectious disease-related loss, may be progressive or occur after the postnatal period. Over 400 syndromes associated with congenital hearing loss have been identified involving abnormalities of many other organ systems.[35] Therefore, other system abnormalities should be noted in the history, bearing in mind that collaboration with other specialists may be needed to identify the syndromic causes of hearing loss when present.[7] Identification of syndromic cases is crucial, as it may help guide discussions of prognosis, anticipated complications or involvement of other organ systems, such as in Usher's syndrome, and further management.[15]

Obtaining a detailed family history that includes three generations may help in determining if there is a hereditary basis for the hearing loss and guide confirmatory genetics testing.[14] Table 6.1 summarizes important elements of the history.[6,7]

## Physical Examination

A focused otolaryngologic physical examination of the head and neck should be performed to assess craniofacial

structures and the external and middle ear. Head size and symmetry, maxillary development, jaw size, and facial movement, and other cranial nerve function should be noted. The size, position, and shape of the pinna and external ear, as well as middle ear morphology, should be examined. These may help to identify syndromic features or causes of a conductive hearing loss, such as middle ear effusion, microtia or external canal atresia, branchial cleft pits or fistulae, pigmentary and ocular abnormalities.[6,7]

An important adjunct to the physical examination is the objective data from audiologic evaluations. ABR and auditory-steady state evoked potentials (ASSR) can be measured in neonates to help identify auditory thresholds. In older children, behavioral audiometry, obtained with visual reinforcement, or play audiometry may also be used. OAEs, the absence of which may suggest a cochlear abnormality, may also be useful, though not specific. Nonsyndromic, genetic hearing loss is most commonly sensorineural, while acquired and syndromic hearing loss may be conductive, sensorineural, or mixed.[7]

## DIAGNOSTIC TESTING

### Laboratory Testing

History, physical examination, and audiologic testing are essential components in the workup of congenital hearing loss. The use of further diagnostic studies in the workup of pediatric hearing loss is less clear. When the history and physical examination point toward a specific diagnosis, the decision about which ancillary tests to order can be straightforward. However, when the cause of hearing loss is unknown, the number of studies available is exhaustive. These include ECG and various laboratory tests, such as a CBC, platelets studies, autoimmune tests, such as ANA, ESR, and rheumatoid factor, thyroid function studies, blood urea nitrogen, creatinine, and urinalysis.[15] Routine laboratory testing has a low diagnostic yield, leading some authors to reconsider their use of a comprehensive battery of testing to evaluate children with unexplained SNHL.[15,36] Instead, laboratory testing should be individualized and directed toward a suspected diagnosis.[4]

Most authors, however, agree that all children with profound bilateral hearing loss of unknown etiology should undergo an ECG to evaluate for QT interval prolongation, which is suggestive of Jervell and Lange-Nielsen syndrome, or other conductive abnormalities. Albeit rare, the detection of these cardiac abnormalities could be lifesaving.[15,37] Similarly, if the results for maternal syphilis screens are unknown, venereal disease research laboratory and fluorescent treponemal antibody should be performed to identify cases of asymptomatic neurosyphilis, as initiation of treatment could prevent progression or the development of symptomatic disease.[37] Because congenital CMV infection is another important cause of idiopathic congenital SNHL, and treatments are available, we argue that CMV testing using urine or saliva PCR should be performed in children with nonsyndromic SNHL of unknown etiology within the first 6 months of life.

A summary of ancillary tests and their utility is provided in Table 6.2.

### Radiographic Imaging

Of all the tests used to determine an etiologic diagnosis for congenital hearing loss, high-resolution CT imaging has the highest yield, identifying a cause in up to 26–37% of cases.[15,19] CT imaging is used to evaluate bony anatomy, while MRI allows for visualization of the membranous labyrinth, internal auditory canal, and cortical structures which are essential components of the auditory system.[15] Radiographic imaging may not only identify the specific cause of hearing loss, but also guide appropriate treatment options.[15] For example, in children found to have enlarged vestibular aqueduct and Mondini malformation, Pendred syndrome should be considered and patients should be counseled regarding activity restrictions, as even minor head trauma may result in progressive hearing loss.[15] If internal auditory canal dysplasia is noted, calling the presence of an auditory nerve into question, cochlear implantation should be reconsidered.

### Genetic Testing

In patients who demonstrate no clear etiology for hearing loss based on physical examination and imaging studies, genetic testing can increase the likelihood of identifying a diagnosis.[38] Genetic testing may allow for accurate and early diagnosis, which can help to maximize early intervention strategies to facilitate cognitive development and provide information about prognosis. Identification of syndromic cases before a particular phenotype is exhibited may guide additional testing or interventions.[38] Identification of the genes involved also allows for genetics counseling and risk stratification.[4,38] It may also reduce parental guilt and anxiety.[17]

Over the past several decades, significant advances have been made in the field of genetics, with identification of new genetic targets in SNHL, as well as the development of more cost-effective, efficient methods of genetic

**Table 6.2:** Ancillary studies and associated hearing loss etiologies

| *Diagnostic yield* | *Study* | *Associated etiology of sensorineural hearing loss* | *Cases in which testing may be helpful* |
|---|---|---|---|
| Low | ANA, ESR, RF, anticardiolipin, immunoglobulins, complement studies | Autoimmune hearing loss (juvenile rheumatoid arthritis, lupus) | Other symptoms of autoimmune disease |
| | CBC | Thalassemia, sickle cell trait, leukemia, lymphoma | Clinical suspicion for leukemia or lymphoma based on other findings (prolonged illness, gingival bleeding, bone or joint pain) |
| | Platelet studies | Hereditary macrothrombocytopenia (Fechner syndrome, a variant of Alport syndrome) | Family history of Fechner syndrome (autosomal dominant inheritance pattern) |
| | Glucose | Wolfram syndrome, Alstrom syndrome, diabetes | Maternal inheritance or autosomal recessive pattern of type 2 diabetes or diabetes insipidus, ocular abnormalities, obesity |
| | Urinalysis looking for proteinuria, hematuria | Alport syndrome, metabolic disorders | Personal or family history of Alport syndrome or hematuria |
| | BUN, creatinine | Alport syndrome | History of abnormal urinalysis |
| | Antibody titers | Toxoplasmosis, Rubella, CMV, herpes simplex | Within 3 weeks of birth with maternal history of disease or exposure |
| | Thyroid studies (FT4, T3, TSH, perchlorate test) | Pendred syndrome, cretinism | Goiter, history of hypothyroidism, evidence of Mondini malformation or EVA on imaging |
| Low but intervention may be lifesaving, preserve vision | RPR, FT-ABS | Syphilis | Maternal history is unknown |
| | ECG | Jervell and Lange-Nielsen syndrome | History of syncope, arrhythmias, family history of sudden death. |
| | Ophthalmology consultation | Usher syndrome, Alport syndrome, Cogan's syndrome, Norrie disease, Stickler syndrome, congenital CMV | History of vestibular abnormalities or myopia; family history |
| High | CT Temporal bone | Temporal bone abnormality (EVA, Mondini malformation) | Consider in cases where etiology is unknown |
| | MRI of IAC, brain | Cochlear nerve hypoplasia/aplasia, CPA mass, brain lesion | |
| | Genetic testing | Connexin 26/30 Mutation | |
| | Viral culture or PCR | Cytomegalovirus (CMV) | |

Adapted from Lin and Oghalai.[7] and Mafong et al.[15]

testing. Because *GJB2* is the most common cause of nonsyndromic genetic SNHL, most authors agree that *GJB2* analysis should be the first step in mutation analysis.[4] If genetics testing reveals no or only one copy of a mutation in *GJB2*, analysis of *GJB6* should also be considered.[4,17,38] *SLC26A4* testing should be performed if imaging demonstrates evidence of Mondini dysplasia or enlarged vestibular aqueduct, if hearing loss is progressive, or if a goiter is present.[17] If auditory neuropathy is suspected, *OTOF* should be evaluated.[17] *COCH*, the mutation of which is associated with an autosomal dominant form of hearing loss, should be tested for mutations in cases with progressive hearing loss and vestibular dysfunction.[17] Many genes have also been identified for Usher's syndrome and should be considered for analysis in the presence of an Usher's phenotype.

The methods used for genetic testing are evolving. DNA sequencing, such as with the Sanger method, is the most comprehensive and definitive method of analysis, because it allows for the detection of small deletions and

insertions, as well as point mutations. This method is limited, however, because it may not detect deletions of entire exons or genes, analysis and interpretation are labor intensive, and sequencing is expensive.[4,17,38] Therefore, only the small number of genes responsible for a large proportion of hearing loss, such as *GJB2*, are sequenced to screen for mutations in the routine clinical setting.[38] This limits the number of patients in whom a genetic cause can be identified.

Many genetic forms of hearing loss result in phenotypically similar severe-to-profound hearing loss. Therefore, it is difficult to predict the genetic cause to guide genetic testing. As an increasing number of genes are identified for testing, Sanger sequencing is becoming a less practical option. New DNA sequencing technologies that allow for cost-effective, complete screening of all known deafness genes are being developed.[17,38] Most laboratories currently use solution-based capture, in which DNA probes customized to genomic regions of interest are hybridized to fragmented DNA samples. Fragments that hybridize with the selected probes associated with hearing loss are then sequenced. Gene chip technology, such as the Affymetrix DNA resequencing microarray platform, was previously used; however, sequencing was inaccurate, making interpretation difficult.[17] Next generation sequencing technologies offer improved sequencing accuracy[17] and are being introduced into the market as a diagnostic tool. The clinical utility and interpretation of these assays are more reliable than gene chip testing but are still being investigated. Currently, there are a limited number of laboratories (University of Iowa, OtoSCOPE and Harvard Medical School Laboratory for Molecular Medicine, OtoGenome) in the United States that offer solution-based capture and next generation sequencing for diagnosing SNHL as a diagnostic tool for patient care. They do not offer whole exome sequencing but rather assess patients' DNA for mutations in a limited number of known genes that cause hearing loss. There are many more laboratories that offer testing on a research basis only. This field is rapidly expanding and when a complete genetic screening system is available and affordable, it will allow for genetic testing of patients who fail their universal newborn hearing screen and dramatically increase the number of hearing loss cases with an etiologic diagnosis.[38–40]

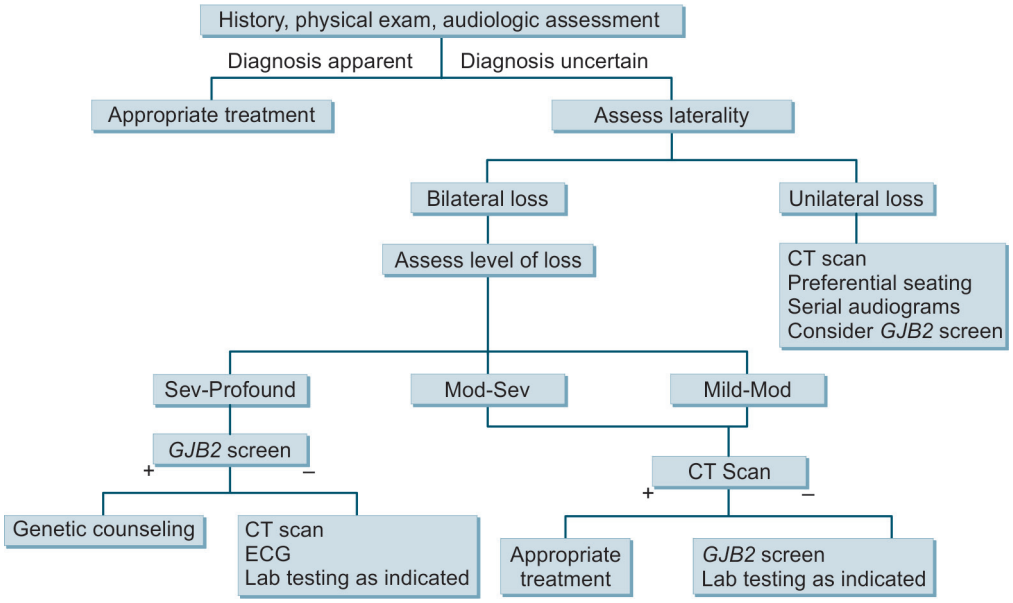
The results of genetics testing should be interpreted with caution—not all mutations are pathogenic and a negative test does not exclude genetic deafness, as discovery of genes associated with congenital hearing loss is ongoing. Results need to be interpreted correctly and communicated clearly to patients and their families. This burden often falls on pediatricians or clinical geneticists with a genetic counseling background.[17] Genetic testing also raises ethical concerns and should not be performed without consent and full disclosure to a child's parent or guardian. Importantly, genetic testing is not necessarily perceived as advantageous, particularly in the deaf community. However, recent surveys indicate that genetic testing for hearing loss is becoming increasingly accepted, in both the hearing and nonhearing communities.[41]

## Testing Algorithms

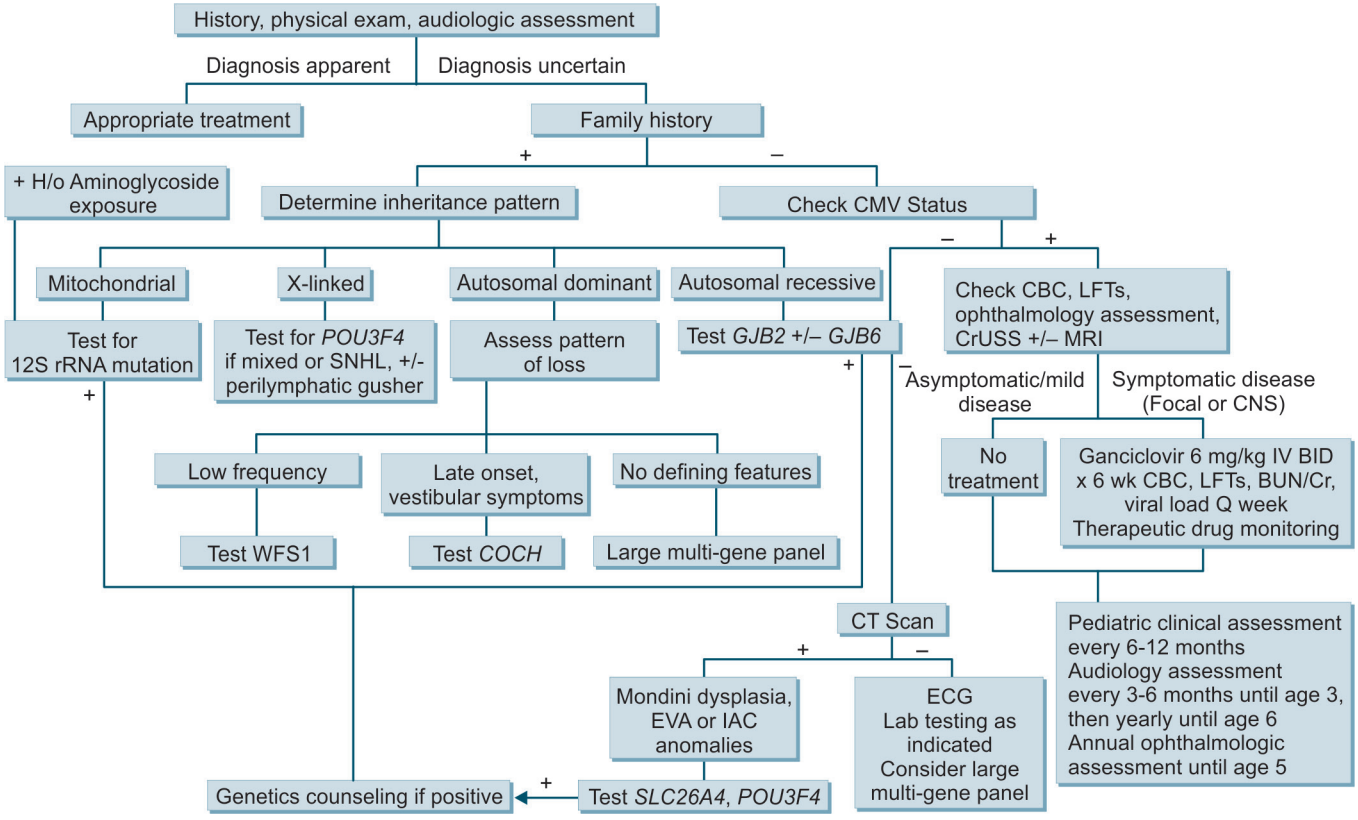
Currently, there is no consensus regarding the battery of tests that should be performed in cases where the cause of hearing loss in unknown. However, evidence-based, cost-effective models have been proposed.[15,37,42] In 2005, Preciado et al. published a sequential diagnostic algorithm tailored to the level of hearing loss in children with bilateral SNHL of unknown etiology; this method was found to be more diagnostically and cost-effective than a simultaneous testing approach.[37] Flowchart 6.2 outlines Preciado's algorithm. In this model, children with unilateral hearing loss should first undergo diagnostic imaging, as this testing provides the highest diagnostic yield. Children with bilateral hearing loss are stratified based on level of impairment—mild-moderate, moderate-severe, severe-profound. Those with mild-moderate and moderate-severe loss first undergo CT imaging, then go on to genetics testing for *GJB2* if imaging workup demonstrates no abnormalities, with additional laboratory testing if indicated. Children with severe-profound loss first undergo *GJB2* testing. If genetics evaluation is negative, they then undergo imaging studies, followed by ECG and additional laboratory testing if indicated.

While Preciado's model is evidence based, it does not take the prevalence of CMV-related nonsyndromic hearing loss into account. Additionally, since 2005 significant progress has been made in the field of hearing loss genetics. New algorithms have also been proposed to guide further genetics testing in cases where *GJB2* testing is negative.[38] In Flowchart 6.3, we provide a sequential diagnostic algorithm which incorporates additional genetic testing and the role of congenital CMV. The cost-effectiveness of this algorithm has not been tested; however, it may increase diagnostic yield over Preciado's algorithm. All patients should undergo a thorough history, physical examination, and audiologic evaluation. If the diagnosis is apparent by history, appropriate treatment should be offered. If not, family history should be considered. If the family history demonstrates

**Flowchart 6.2:** Preciado's sequential diagnostic paradigm, 2005. Adapted from Preciado et al.[37]



**Flowchart 6.3:** Diagnostic algorithm for determining the etiology of congenital hearing loss. Adapted from Preciado et al.[37]; Brown and Rehm[38]; and Kadambari et al.[20] Genetic testing would be indicated if testing for WRS1, COCH and large multi-gene panel were positive.



a particular inheritance pattern this should guide genetics testing. For patients who have no family history, testing for CMV should be initiated within the first 6 months of life. If CMV testing is negative, or if the family history suggests an autosomal recessive inheritance, *GJB2* with or without *GJB6* testing should be performed. For patients who test negative, imaging should be pursued. Further genetics testing should be performed if imaging suggests internal auditory canal dysplasia (*POU3F4*), Mondini malformation, or EVA (*SLC26A4*). In cases where imaging yields no apparent abnormality and the etiology of hearing loss remains unknown, ECG and further laboratory testing (such as urine analysis and syphilis testing) should be considered. Further multigene panel testing may also be performed to identify the presence of less common genetic mutations associated with congenital hearing loss. In children who test positive for CMV, additional studies including CBC, LFTs, an ophthalmologic evaluation and cranial ultrasound should be performed. Children who are symptomatic should receive ganciclovir therapy if they are less than 30 days of age. All children with evidence of CMV, whether symptomatic or asymptomatic, required close follow-up with serial audiograms and ophthalmology evaluations.

## HEARING INTERVENTION

The overriding goal of hearing rehabilitation is to maintain both social and academic integration within society. It is well known that children who are inadequately rehabilitated often lag in both these indices. For patients who have a hearing loss that cannot be corrected with early medical management, hearing intervention is indicated. Infants who have failed a newborn hearing screen and have hearing loss confirmed by follow-up ABR can be fit with hearing aids as early as 3 months of age. There is some difficulty in fitting infants due to the small ear canal size and the inherent masking of near-normal sounds due to the fit of the ear mold. Hence, not all hearing professionals agree that hearing aids are indicated in children with mild hearing loss and very small ear canals. For children with a mild hearing loss of 25 dB or greater in both ears, hearing aids and/or frequency modulation (FM) systems are generally indicated. There is growing evidence that patients with a unilateral loss may also benefit from amplification in the diminished ear[43,44]; however, considerable uncertainty and variability in practice exists among care providers. Research in this area began after multiple studies highlighted academic and language difficulties experienced by children with unilateral hearing impairment. However, not all children with unilateral loss benefit from amplification. Current practice trends appear to be leaning toward a trial of amplification.

The use of hearing aids with or without an FM system for patients with bilateral moderate-to-severe hearing loss is fairly well accepted and little variability exists in recommendations as to the use of auditory rehabilitation. Currently, cochlear implantation is indicated for children who have > 80 dB hearing loss in both ears and can be performed as early as 1 year of age. Cochlear implants can partially restore hearing by directly stimulating surviving hair cells, supporting cells and acoustic nerve fibers. Optimally, cochlear implant candidates should demonstrate favorable anatomy, including a normal cochlea and robust acoustic nerves, and minimal to no cognitive impairment. However, hearing professionals have found a wide array of patient variants that have benefitted from cochlear implants.[45] A full discussion of hearing restoration in the pediatric patient can be found in Chapters 16, 21, 22, and 23.

Many factors are taken into account to determine the optimal hearing restoration plan for each patient. These include but are not limited to performance using a hearing aid, anatomic factors within the cochlea and acoustic nerve, confounding developmental diagnoses that may affect cognitive and/or motor abilities (such as the cognitive delays precluding the ability to develop language, inability to use sign language or expected decline in vision inherent in Usher's syndrome) and the family's belief about the correct form of communication for their child. Infants and children with hearing loss are best served by a multidisciplinary team that includes otolaryngology, speech pathology, audiology, neurology, ophthalmology, genetics, neuropsychology, and social work. Often children need to be followed over time since their developmental status may not be apparent early-on. Families need to be supported, not only to help guide making good clinical decisions for their children, but also because of the added emotional and financial burden of caring for a child with hearing loss. Lastly, members of the deaf community may have expectations about what constitutes the best form of communication for their child, which should be respected by the health-care professional.[46]

CHAPTER

# 7 Embryology and Congenital Abnormalities of the External Ear

*Douglas R Sidell, Daniel I Choo*

## INTRODUCTION

The external ear plays an important role in the overall appearance of the face. Although slight variation in the position, shape, and size of the auricle are seen across populations, auricular abnormalities often distract a viewer's gaze away normal facial anatomy. Several congenital auricular abnormalities have been described, and each is derived from disturbances in the normal development of the external ear. Embryogenesis of the auricle occurs in harmony with the development of other branchial arch derivatives, including the external auditory canal and middle-ear cleft. As a result, auricular abnormalities frequently occur in the setting of abnormalities of the external auditory canal and middle ear. While this is an important consideration for the clinician and surgeon, this chapter deals primarily with the etiology, classification, presentation, and management of auricular abnormalities.

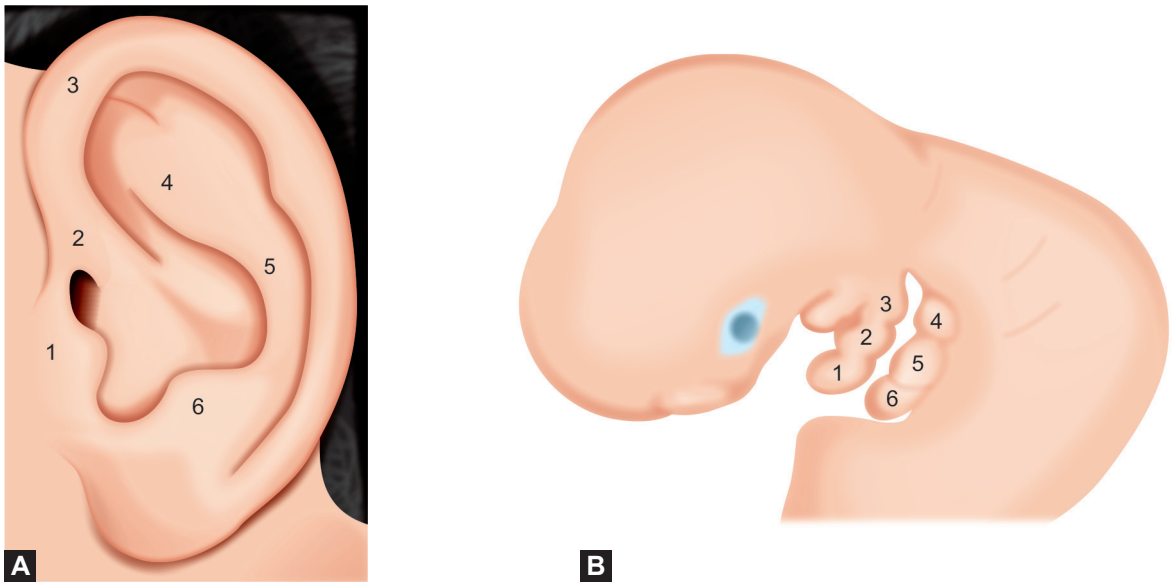
## A BRIEF REVIEW OF EMBRYOLOGY

Otologic development lies on a continuum that begins during the third week of embryogenesis, at which time the auditory placode is recognized as a thickening lateral to the acousticofacial ganglion. During the fifth gestational week, mesenchymal proliferation of the first and second branchial arches produces hillocks that surround a primitive external auditory meatus. The auricle itself is arguably derived from three hillocks that arise from the first arch (hillocks 1–3) and three hillocks that arise from the second arch (hillocks 4–6) (Figs. 7.1A and B). Some authors suggest that the first arch contributes only to the tragus (hillock 1), while the remaining structural components of the auricle (hillocks 2–6) are derived from second-arch mesenchyme.[1,2] Regardless of derivation, most authors would agree that by the end of the sixth gestational week, all hillocks are visible. The six hillocks then merge, achieving a near normal appearance by 17–18 weeks. Over the following 14 weeks, the auricle continues to migrate from its origin adjacent to the primitive pharynx, to its final destination at the lateral aspect of the head.[1] By 8 years of age, the auricle has reached > 95% adult size, yet it continues to enlarge throughout life.[1,2]

Any developmental arrest occurring along the prenatal embryologic continuum will result in varying degrees of auricular abnormalities, each detectable on physical examination. Additionally, some changes to the appearance of the auricle may occur after the majority of embryologic development has been completed. Pliability of the auricle is enhanced by elevated levels of hyaluronic acid under the direct influence of maternal estrogen. As a result, the auricle may be influenced by extrinsic compression prior to delivery but after the greater part of embryologic development.[3–5] This phenomenon is thought to be one mechanism leading to congenital anomalies in which the auricle is completely formed, but has an abnormal shape and appearance. The same principle of increased pliability can also be advantageous in the treatment of such patients.

## HEREDITY OF AURICULAR ABNORMALITIES

A tight association exists between our genetic makeup and embryologic tissue abnormalities. Several genes have been implicated in the normal development of the



**Figs. 7.1A and B:** The auricle itself is arguably derived from three hillocks that arise from the first arch (hillocks 1–3) and three hillocks that arise from the second arch (hillocks 4–6).

pinna, and as such, mutations in these genes may contribute to frank auricular abnormalities. Although some specific mutations have been described in their association with abnormal development of the external ear, the majority of events occur in patients in the absence of an associated syndrome or known genetic abnormality. In contrast, several genes have been implicated in syndrome-associated auricular abnormalities, and may be inherited in an autosomal recessive, dominant, or X-linked pattern. Treacher-Collins syndrome (autosomal dominant), branchio-oto-renal syndrome (autosomal dominant), and oto-palatal-digital syndrome (X-linked) are but a few examples.

## AURICULAR ANATOMY

Auricular abnormalities include subtle variations among the anatomic proportions of an auricle that is otherwise normal; they may also present more obviously, with a complete or partial absence of the external ear. The former category includes abnormalities such as the prominent ear or protruding ear, and represents those variations that are considered to deviate from established esthetic norms. In contrast, more obvious auricular abnormalities, such as those seen in patients with microtia, have a strong genetic influence and are more frequently associated with other otologic abnormalities or genetic syndromes. The specific embryologic influence of the genetic code on various components of auricular development is becoming a topic of increasing interest. A complete understanding of normal anatomic proportions and growth patterns of the auricle are therefore an important element of the pediatric otolaryngologist's practice. Several attempts have been made to classify the esthetic properties of the auricle, and a series of accepted normal values for auricular dimensions has been established and are discussed below. Despite this, the esthetic norms attributed to the auricle have seen changes over time, and differ between races and cultures. As a result, it is important to remember that a single definition of "correct" esthetic proportions does not exist, and each evaluation should be taken in the context of the whole patient.

### Normal Dimensions

The adult auricle ranges in length from approximately 5–6.5 cm, and the width is typically 50–60% of auricular length. Although the ear continues to grow slowly throughout life, the vast majority of both vertical and horizontal growth occurs in the first decade. However, the pediatric auricle grows disproportionately, such that the length of the ear reaches adult measurements prior to the width, and the rapidity of growth is thought to be faster in females.[6] The pediatric auricle reaches 85–90% of adult width within the first year of life, and >95% of predicted width within 10 years. In contrast, the length of the ear is approximately 70–75% of adult length within the first year, reaching >90% of expected adult length within 10 years. [6,7]

### Normal Orientation

The auricle resides on a line approximately one ear-length posterior to the lateral canthus, extending from the level of the brow posterosuperiorly at a 15°–30° angle. The vertical and horizontal position of the ear must be evaluated when considering the individual patient's facial structure and adjacent anatomy. It should be noted that some degree of variability when considering ear position within the individual is also acceptable. The majority of patients have some amount of positional asymmetry between each ear. However, the ability for one to recognize this difference is probably the only factor that brings an acceptable difference into the realm of being abnormal; the definition is thus very subjective.

The normal auriculocephalic angle is crudely defined as the angle between the pinna and the cranium. Although this angle can be acceptably more obtuse when the ear is wide, a normal measurement is described as being < 35°, and may range from 15° to 20° at birth to > 30° during adulthood.[8] As described by Farkas[7] the mean measurement of this angle is 25° in adult men and 21° in adult women.[6,7]

## THE PROMINENT OR ABNORMALLY SHAPED EAR

The true incidence of abnormally shaped ears is likely underestimated, as many abnormalities fall on the less-severe spectrum of auricular deformities and are thus frequently excluded from the literature.[6] The prominent ear is loosely defined as falling outside of the boundaries of the previously described measurements for protrusion. In reality, the presence of a protruding ear reflects abnormalities in the normal folds of the auricle itself, thus manifesting as the composite result of such abnormalities. For example, the antihelical crease is created by the folding of auricle between the helix and scapha, thus placing the helical rim adjacent to the scalp. Loss of the antihelical crease results in an obtuse conchoscaphal angle (> 90°), thereby creating an obtuse auriculocephalic angle and wide or deep conchal bowl. As a result, prominence of the ear can be explained by abnormalities in the development of the antihelix and concha. Other variations in the development of the auricular subunits may occur in conjunction with the prominent ear, or represent unique manifestations that vary from the esthetically accepted normal. Some of these abnormalities may overlap with the definition of microtia, and a list of such auricular abnormalities is presented in Table 7.1.

## PATIENT EVALUATION

Otoplasty for the correction of the protruding or abnormally shaped auricle is the most frequently performed esthetic surgery in the pediatric population. Evaluation of the patient suspected to have auricular prominence must be performed in the context of the individual, using standard measurements only as guidelines during the examination. More importantly, facial structure, auricular symmetry, head shape, and hairline must all be considered during analysis. Because definitions vary greatly among the literature, true prominence is often a matter of opinion.[9] As a result, the decision to intervene is unlikely to be made based on physical findings alone, but instead relies on a discussion between the patient, the family, and the physician. Additionally, nonsurgical interventions have gained increasing popularity over the past two decades. These methods, using external splints, provide a low-risk intervention that may be implemented in the neonatal period.[3]

### Nonsurgical Intervention

Multiple studies exist that demonstrate the ability to nonsurgically mold congenital auricular abnormalities shortly after birth. The first publications formally discussing these techniques originated in the Japanese literature in the 1980s. Several variations in nonsurgical molding have subsequently been described,[10–13] but all techniques rely on external splinting to maintain the normal shape and position of the auricular cartilage during early development. Of the previously mentioned congenital deformities of auricle, the cup ear, prominent ear, and Stahl ear are all amendable to nonsurgical molding.[10] The fundamental efficacy of this process is thought to occur secondary to estrogen-driven increases in the concentration of hyaluronic acid in the extracellular matrix of the auricle in the early days of life.[4,5,14,15] After birth, hyaluronic acid concentrations decline in concert with estrogen concentrations, thereby reducing auricular pliability. Despite the common belief that the ideal window for nonsurgical intervention is during the neonatal period only, some suggest that nonsurgical intervention may take place several weeks after birth. In one of the few prospective studies evaluating nonsurgical correction of the protruding ear, van Wijk and colleagues suggest that the time required for splinting increases proportionally with the age at the time of initiating treatment. The authors conclude that the best chance of success occurs in patients

**Table 7.1:** Auricular abnormalities

| *Auricular abnormality* | *Description* | *Figures* |
|---|---|---|
| Cup ear | Flat antihelix, helical overhang, wide concha, and a deceptively small auricle |  Cup ear |
| Shell ear | Underdeveloped helical rim; often accompanied by poorly defined antihelix |  Shell ear |
| Lop ear | Helical overhang; loss of support of helical rim |  Lop ear |
| Stahl ear | Flat antihelix; inconspicuous superior crus with a horizontal orientation; malformed scaphoid fossa |  Stahl ear |
| Macrotia | Ear size that exceeds normal anatomic proportions; enlargement often limited to superior 1/2 to 1/3 of ear. May have associated effacement of the helical fold | |
| Cryptotia | The superior auricle is buried beneath the skin of the scalp. May be accompanied by an underdeveloped scapha. Also referred to as "pocket ear" or "hidden ear" deformity |  Cryptotia |

who are treated prior to 6 weeks of age. In their study, 132 children (209 ears) were nonsurgically treated, with an average age of 8.8 weeks at the initiation of treatment. Efficacy was shown to deteriorate with age and older children were noted to require longer periods of splinting.[3] Although opinions vary among practitioners, many would agree that noninvasive auricular molding techniques have little applicability after 3 months of age. Additional arguments in favor of early intervention include the lack of manual dexterity, decreased head mobility, and decreased production of sweat during the neonatal period, all contributing to a greater degree of success with regard to maintaining splint placement. Regardless, the decision to attempt nonsurgical molding carries little risk to the patient, and does not preclude later surgical intervention. Skin irritation and difficulty maintaining splint placement are the most frequently encountered risk factors, and permanent sequelae are nearly nonexistent. Recently, commercially available devices for nonsurgical ear molding have become available, and reduce many of the difficulties

associated with splint placement and irritation. In 2010, the United States Food and Drug Association (US FDA) approved the EarWell (Becon Medical Ltd, Naperville, IL), a manufactured external splint with a touted 90% rate of success.[16]

## Surgical Intervention

After the neonatal period, or in patients experiencing unsuccessful nonsurgical intervention, surgical correction of auricular abnormalities is an available option. Timing of surgical intervention is based on our knowledge of auricular development during childhood, the patient's social environment, and parental concern. Waiting to intervene until age 3 allows the ear to reach 85–90% of adult dimensions, whereas operating prior to age 6 obviates exposure to ridicule in the school environment.

The goals of surgery for the protruding ear include the creation of the antihelical fold and reduction of the auriculocephalic angle. Correction of antihelical fold should occur in multiple locations along the length of the ear, and the postauricular crease should not be distorted. Several hundred otoplasty techniques exist; however, satisfaction among patients is relatively high regardless of the technique used. Techniques are often chosen based on the specific characteristics of the defect, the pliability of the cartilage (often more malleable in patients under 5 years of age) and surgeon preference and experience. Because protrusion of the auricle (unlike microtia) is frequently bilateral, the procedure should begin with correction of the most involved ear first. The second ear can then be corrected while maintaining symmetry with the first. If unilateral surgery is performed, discrete abnormalities in the less-involved auricle may become more noticeable, and patients often return for correction of the second ear. As a result, in the setting of a protruding ear that is predominantly unilateral, patient satisfaction is often enhanced when bilateral surgery is performed. The surgical technique most commonly employed for the correction of the protruding ear is the placement of horizontal mattress sutures on the posterior auricle as described by Mustarde.[18–19] This allows for the precise recreation of the antihelical fold. Reduction of the auriculomastoid angle and correction of the antihelix can also be performed if necessary by means of a conchal setback technique as described by Furnas.[20] This method draws the ear posteriorly by suturing the conchal cartilage to mastoid periosteum and fascia, and may improve esthetic results in select patients. Finally, elements of cartilage sculpting, suturing, and conchal setback are combined in the Farrior technique. This method involves using a "graduated approach" to achieve a customized outcome for the unique abnormalities of each ear. The simplest interventions are used first, and the ear is repetitively evaluated intraoperatively until the desired outcome is achieved.[21]

Similar to the protruding ear, cup ear deformity and Stahl ear deformity are both amendable to surgical correction. Stahl ear deformity is the result of a normal quantity of abnormally shaped cartilage that results in an inconspicuous superior crus with a horizontal orientation and a flat antihelix. Cup ear deformity is also frequently described interchangeably with lop-ear deformity. The cup ear deformity is notable for a flat antihelix, helical overhang, wide concha, and a deceptively small appearance of the auricle. Several surgical techniques exist for the correction of each abnormality, and involve cartilage scoring and suturing techniques as well as excision and grafting methods.[17,21,22]

Major complications following otoplasty are relatively rare, and include hematoma, wound infection, tissue necrosis, and keloid formation. Minor complications include persistent or recurrent protrusion, small ulcerations and the development of Herpes zoster infection.[21]

# MICROTIA

Significant variability exists among the definition of microtia within the literature. For the purposes of this chapter, microtia will be used to describe abnormalities of the external ear in which a component of the auricle is absent or small; the most extreme end of this spectrum being anotia, or complete absence of the auricle.

## Epidemiology

Luquetti and colleagues reviewed the epidemiology of microtia and determined that the reported prevalence varies from approximately 0.8–4 individuals per 10,000 births.[23] The heterogeneity in prevalence estimates is speculated to occur due to differences in inclusion criteria between studies, and due also to variations in the definition of microtia among researchers. Mild cases of microtia may be misclassified or not brought to clinical attention, thus impacting incidence and prevalence figures. It is agreed upon that males are more frequently diagnosed, and nonsyndromic microtia is thought to be unilateral in 70–90% of patients.[24] The right ear is more frequently affected for unknown reasons.[25]

## Genetics

The genetic complexities that are associated with the development of the external ear have become an area of expanding research over the past decade. Scientific advances in genetics research have allowed for the development of novel animal models, controlled human genetics studies, and subsequent investigations into single-gene disorders that are associated with microtia. Research has thus amassed in strong support of the genetic influence on microtia development.

Microtia may occur in isolation or in the setting of a syndrome or disorder. Inheritance patterns in familial microtia or syndromic patients with microtia are thought to be primarily Mendelian, and several genes have been identified in this setting. In support of this genetic basis for microtia, several syndromes with single-gene abnormalities are known to exist in conjunction with microtia, such as *EYA1* mutations in patients with branchio-otic syndrome. Additional syndromes having strong associations with microtia include Treacher-Collins syndrome, Miller syndrome, and the oculo-auriculo-vertebral spectrum.[23,26,27] To date, >20 syndromes associated with microtia have been reported, with varying incidences of auricular abnormalities among them. Although a detailed discussion of the genetic influences of microtia is beyond the scope of this chapter, to the interested reader we recommend "Microtia: Embryology and Genetics" by Daniella Luquetti and colleagues, for a more comprehensive discussion on the subject.[23]

In contrast to syndrome-associated microtia, sporadic cases are more likely to be due to multiple genetic abnormalities and/or environmental influences. Although the exact etiology of microtia is unknown, several environmental risk factors have been identified. Some of the more established risks include maternal acute illness, congenital rubella, low birth weight, higher parity, and maternal diabetes mellitus. In addition, medications such as thalidomide and retinoids have also been linked to the development of microtia.[23,28,29] Evidence has also been established in support of other risk factors leading to the development of microtia. Of these, living at high altitude, neural crest disruptions and vascular compromise to developing tissue have been cited as potential contributing events.[26,29–31]

**Table 7.2:** Weerda classification system for microtia

| Second-degree dysplasia:<br>Some structures present | A. Cup Ear deformity type III<br>B. Mini ear |
| Third-degree dysplasia:<br>No recognizable structures present | A. Unilateral<br>B. Bilateral<br>C. Anotia |

## Classification

With the broad spectrum of auricular abnormalities that accompany the diagnosis of microtia comes a multitude of classification systems developed to better categorize this phenomenon. Although several systems exist, the most commonly cited classification systems include the Weerda classification system (Table 7.2) and the Marx classification system (Table 7.3).[32,33] The Weerda classification system provides several terms that are frequently used in the diagnosis of microtia, yet the complexity of this system has been seen as a limitation to use in the clinical setting. In contrast, the Marx system is more simplified, and is possibly the most frequently employed classification system to date. Other systems have been described, and base their classification on physical characteristics, management approaches, or for specific research purposes.[23,34] Ultimately, when considering the complexities of embryologic development, all systems may be criticized as oversimplified.

## Clinical Presentation and Management

The clinical presentation of microtia can exist anywhere along the continuum between a small pinna with all structures present, to complete absence of the auricle. When considering treatment options, several important

**Table 7.3:** Marx classification system for microtia

| | |
|---|---|
| Grade I | Abnormal (small) auricle. All landmarks present and identifiable |
| Grade II | Abnormal auricle. Some landmarks absent |
| Grade III | Small auricular tag or anotia |

elements of the history and physical examination must be considered. The clinical setting and patient presentation will often be dictated by the severity of microtia and the presence or absence of an associated syndrome. Patients with severe microtia or syndrome-associated microtia are frequently brought to clinical attention during the neonatal period. When microtia is first diagnosed, a thorough history and physical examination with possible genetic analysis is warranted to evaluate for the presence of an associated syndrome. Syndromic patients may have other, more life-threatening organ system abnormalities that warrant early treatment. Notably, the treatment of other congenital systemic abnormalities almost always takes precedence over microtia repair. Other important considerations include the presence or absence of canal atresia, the hearing status of the patient, and the specific desires of the patient and parent. Canal atresia may influence hearing status, hearing rehabilitation options, and surgical planning strategies. If hearing loss is present, hearing rehabilitation or alternative communication modalities should be instituted prior to 6 months of age to maintain age-appropriate developmental milestones and to prevent speech and language delay. Lastly, patient and parent wishes are important to elucidate during the initial consultation and during ongoing patient visits. Microtia alone is not a life-threatening process, and although auricular abnormalities are associated with a known social stigma, the decision to treat and the timing of treatment are ultimately up to the parent and/or patient to decide. Regardless of an often-early presentation, the timing of microtia repair is commonly delayed until early childhood. This is frequently performed prior to the beginning of grade school but after the contralateral auricle (if unilateral microtia) has had an opportunity to grow to a near-adult size. Patients are often 5–6 years of age at the time of repair.

Although the origins of auricular reconstruction date back to 600 BC, modern microtia repair using cartilage grafting did not arise until the 1920s. Today, auricular reconstruction is frequently performed in 2–4 stages using autologous cartilage or semisynthetic biomaterials. Alternatively, anchored prostheses are occasionally used in a smaller subset of patients. Advances in prosthetics have resulted in the ability to create several prosthetic options that are realistic and difficult to recognize by the casual observer. Unfortunately, the use of prosthetic devices requires the removal of all remaining soft tissue remnants of the auricle, and frequently precludes future staged auricular reconstruction if the patient comes to desire this approach. In addition, due to the activity of school-age children, prosthetic anchoring methods are often inadequate. The risk of peer-based ridicule in the event that the prosthesis becomes dislodged or torn-free during sports or activities is often an overwhelming consideration that leads young patients away from this treatment option.

## Staged Surgical Reconstruction

Staged microtia repair requires the implantation of cartilage autograft or a synthetic allograft framework that is subsequently elevated from the lateral aspect of the head in subsequent stages. Two of the most frequently employed methods of surgical reconstruction include the Brent Technique[35,36] and the Nagata Technique.[37] Both methods use costal cartilaginous grafts in a staged approach to recreate the natural appearance of the auricle. Results vary among physicians; however, results likely coincide with the frequency by which the surgeon performs the technique. Regardless, a life-like auricle is a highly complex anatomic structure, and therefore difficult to recreate with precision. If one were to consider the results of all surgeons the majority of outcomes would likely be considered adequate rather than excellent, and primarily serve the purpose of redirecting the casual observer from the once-absent auricle to other features of the face. For this reason, a realistic understanding should be established between the parent/patient and surgeon preoperatively with regard to the specific outcomes expected and desired. Fortunately, the vast majority of patients are satisfied with their outcome, and microtia surgery can be a very rewarding experience.

Preoperative measurements are essential in ensuring an acceptable cosmetic outcome. Measurements taken from the contralateral ear can serve as a template for microtia repair. The use of X-ray film or transparent plastic is often used to create this template. In addition, the use of facial landmarks is important when establishing normal auricular position. This is exceedingly important in the patient with bilateral microtia. Patients and families should be counseled preoperatively that due to the frequently low hairline ipsilateral to microtia repair, a hair-bearing auricle may require further cosmetic hair-removal treatment following auricular reconstruction.

Both the Brent and Nagata techniques use contralateral cartilage, often from the synchondroses of the 6th, 7th,

and 8th ribs. Dissection is performed in the subcutaneous plane, with judicious use of cautery in young patients and patients with atresia so as to reduce the risk of cautery-induced injury to the facial nerve. One final consideration is the timing of atresia repair in the patient with external auditory canal atresia. This is frequently performed either prior to or immediately after the creation of the postauricular sulcus. These patients present a unique challenge in that the position of the auricle may not align appropriately with the position of the external auditory canal after atresia repair. For this reason, slight refinement in position of the pinna may be required after reconstruction of the external canal.

## The Brent Technique

The Brent technique has been modified and perfected over the past three decades, and is one of the most commonly employed techniques used for auricular reconstruction to date. This technique involves the use of costal cartilage auricular reconstruction using a four-stage procedure:

Stage 1: The appropriate position for the ear to be reconstructed is marked using the previously described template. Rib is harvested from the contralateral 6th–8th ribs. An auricle is created by carving the synchondrosis of the 6th and 7th ribs to resemble an antihelix and triangular fossa. The 8th rib is then sutured to this structure to replicate the helix. A judicious skin pocket is then dissected to receive the carved structure and provide vascular supply to the auricular graft. Excess subcutaneous fat is removed during this stage, and hair follicles associated with the skin flap may be transected at this stage. Some prefer to bank a small piece of cartilage for use during tragal reconstruction (stage 4), and a piece of cartilage for to serve as a wedge to improve auricular projection (stage 3).

Stage 2: The second stage involves creation of a lobule, and is performed between 4 and 6 months following stage 1. A malformed lobule is commonly present in grade 3 microtia patients, and this tissue is used if available. Transposition of the lobule requires exposure of the inferior aspect of the previously buried cartilage framework; suturing the lobule to the base of the framework contributes to a more natural appearance.

Stage 3: The third stage involves the elevation of the previously buried auricle to create a postauricular sulcus. This is generally performed 4–6 months following lobule transposition. A marginal incision is created extending from the attachment site of the lobule to the helical root. Dissection is then performed between the cartilage graft and the underlying periosteum. A thinned full-thickness skin graft is then placed over the postauricular sulcus. At this stage, the previously banked wedge of cartilage (stage 1) may be placed deep to the skin graft and sutured in place to increase auricular projection. The skin graft harvest site is often from the low-midline abdomen and sutured in place using a chromic suture. A bolster is placed over the graft site and removed after 7–10 days.

Stage 4: Tragal reconstruction is performed following elevation of the auricle. This stage is occasionally skipped by the patient who is happy with their reconstruction, and does not want to undergo further surgery. Otherwise, tragal reconstruction requires the use of cartilage placed in a pocket anterior to the external auditory meatus. This cartilage graft may be harvested from the contralateral ear as a composite graft, or previously banked cartilage (stage 1) may be used if adequate and available.

## The Nagata Technique

In 1996, Nagata presented a modified technique for microtia repair. Although similarities exist between the Nagata and Brent techniques, there are several important differences. The Nagata technique is classically described as a two-stage procedure and is recommended for patients 9 years of age and older to allow for adequate cartilage size:

Stage 1: The first stage requires rib harvest in a similar fashion as that described by Brent. The rib cartilage framework incorporates a tragal component and is buried in a subcutaneous pocket. The lobule is also transposed during this stage.

Stage 2: After approximately 6 months, the buried cartilaginous construct is elevated using a small, elliptical, or crescent-shaped piece of costal cartilage as a posterior wedge. This is harvested via the patient's previous incision site. To obviate the necessity for a second rib harvest, some prefer to harvest and bank cartilage during stage 1 if adequate skin coverage is possible. Posterior coverage is accomplished using a temporoparietal facial flap rather than skin grafting.

## Microtia Repair Complications

The majority of patients have acceptable outcomes following microtia repair and are satisfied with their

result. However, follow-up and communication with the patient are essential to maintain acceptable outcomes. Complications, when they occur, can often be managed conservatively if identified early. One of the more common major complications includes skin necrosis, either with or without a coinciding infection. This may be due to intraoperative damage to the subdermal plexus, or secondary to fluid collection (hematoma, abscess, or seroma) at the operative site. In addition, secondary or primary infection occurring at the operative site may lead to skin loss or cartilage breakdown. Management of soft tissue complications includes treating infection when present and conservative debridement of skin and cartilage when necessary. Many wounds will heal by secondary intention. Rarely, revision surgery with skin grafting is required. Additional complications include the formation of keloids or hypertrophic scars at the incision site, cartilage migration, or improper sizing or orientation of the auricle itself. Lastly, one must also consider the risks of donor-site complications and donor-site morbidity when performing costal cartilage grafting. The risk of pneumothorax when harvesting rib cartilage is a potential complication leading to intraoperative ventilator difficulty and the requirement for a chest tube. Postoperatively, atelectasis or immobility associated with chest wall pain at the donor site is not uncommon.

## FUTURE DIRECTIONS

The management of auricular abnormalities is a demanding but rewarding discipline with a high level of patient and provider satisfaction. As the diagnosis and treatment of this patient population is continuously enhanced by modern techniques and technology, this high level of satisfaction is expected to persist. Promising improvements in our understanding of congenital auricular abnormalities and their genetic origins is expected to result in exciting changes to our current classification systems and management strategies. Likewise, advances in material science and tissue engineering are also likely to prove promising in their application to auricular reconstruction.

CHAPTER

8

# Congenital Aural Atresia

***Dane M Barrett, Bradley W Kesser***

## INTRODUCTION

Congenital aural atresia (CAA) is a rare condition resulting from malformation of the first and second branchial arch derivatives. The severity of this condition ranges from ear canal stenosis to complete atresia of the external auditory canal and middle ear structures. The more severe form of atresia, osseous atresia, is more frequently found than the milder membranous atresia. The reported incidence of aural atresia is one in every 10,000–20,000 live births. Males are affected more commonly than females, with the right ear more commonly affected than the left. Unilateral atresia has a higher incidence than bilateral atresia with studies reporting a three- to sevenfold difference.[1-3]

CAA may be found in isolation, in association with other external and middle ear deformities, or as part of a spectrum of congenital disorders such as Treacher Collins syndrome or Goldenhar/hemifacial microsomia. Microtia is the most common external deformity associated with aural atresia. The severity of the microtia tends to correlate with the severity of the middle ear deformity.[4] Of the middle ear deformities, fusion of the malleus and incus bones is the most frequently occurring malformation. The stapes footplate, which has dual origin from the second branchial arch and the otic capsule, is typically normal.[5,6] Cochlear function is also usually normal, though there is a higher incidence of inner ear abnormalities in the atresia population compared to the general population, as high as 22% in one study.[7] The facial nerve can also be affected by abnormal temporal bone embryogenesis, and while it can be found in a normal position, the nerve often lies more lateral and anterior than normal, and can take a more acute angle at the second genu.

As noted, CAA can be an associated malformation in certain syndromes. Approximately 10% of patients with CAA have an associated named syndrome including Treacher Collins, Goldenhar, hemifacial microsomia, branchio-oto-renal syndrome, de Grouchy syndrome, and Crouzon syndrome. Of the sporadic cases, 5% are due to genetic transmission but are nonsyndromic. Abnormalities of chromosome 18 have been identified in one group (de Grouchy syndrome) of atresia patients.[8] CAA may also be associated with kidney and spine problems, and facial weakness.

Evaluation and management of aural atresia poses a significant set of challenges to the otolaryngologist, and several factors must be taken into consideration. Of paramount importance is the provision of adequate hearing habilitation to support normal speech and language development. This issue is especially critical in children with bilateral atresia, although children with unilateral atresia, perhaps a more subtle disability, may also need services and habilitation.[9] These factors include not only decisions regarding the need for amplification, but also decisions regarding how to ensure the best possible scholastic environment for children to succeed in the school setting.

Surgery to open the ear canal and restore the natural sound conducting mechanism of the ear canal, eardrum, and middle ear may be an option for some families, in carefully selected candidates. If a surgical approach is chosen, the timing of surgical repair in coordination with repair of microtia must also be taken into account. This chapter reviews the concepts needed to meet the unique challenges faced in managing the patient with aural atresia.

## EMBRYOLOGY

Development of the ear is a complex process of cellular migration and differentiation into mature structures beginning in utero and continuing after birth. Development of both the ear canal and middle ear may arrest at any point resulting in a spectrum of malformations. Knowledge of the normal embryologic development of the temporal bone, specifically the external auditory canal and middle ear, is vital to understanding the pathogenesis of aural atresia, allowing the surgeon to anticipate the abnormal position of anatomic structures and avoid unnecessary injury during surgery. The inner ear has a completely separate embryologic anlagen (otic placode) than the outer and middle ear (branchial apparatus). The implication is that most (but certainly not all) children with CAA have normal cochlear function and normal bone conduction thresholds. For a detailed discussion of the embryology of the ear, the reader is referred to Chapter 1 of this section.

## EVALUATION

Aural atresia is frequently recognized at birth due to its association with microtia and other craniofacial malformations. Newborn hearing screening should identify the associated hearing loss and refer the infant for further testing. However, some children with only minor or no other congenital anomalies may escape detection until school age. Auditory evaluation including auditory brainstem response (ABR) testing with air and bone conduction thresholds should be performed as soon as feasible. Toddlers and older children can be tested behaviorally with visual reinforced audiometry (VRA; ages 1–3) and conditioned play audiometry (CPA; ages 3–6). Many states in the United States have a 1–3–6 goal for their newborn hearing screening program—identify by 1 month, confirm by 3 months, intervene by 6 months.

After a complete hearing evaluation, decisions can be made among the patient, the family, and hearing healthcare professionals regarding hearing habilitation and amplification. For children with more complex abnormalities, a cohesive multidisciplinary treatment plan should be instituted and may include referrals to plastic surgery, genetics, developmental pediatrics, and speech and language pathology to maximize the possibility for a good outcome for each patient.

### History and Physical Examination

A full history and physical examination should be the focus of the initial evaluation. There are multiple scenarios in which the patient will present to the otologist. The patient may be sent to the otologist shortly after birth when the CAA is recognized in conjunction with microtia or after identification by newborn hearing screening; as an older child as a referral from a plastic surgeon intending to perform microtia repair; as a child referred from the pediatrician or school after failing a hearing screening examination; or as a referral from another clinician who has noted canal stenosis. Patients may even occasionally present as an adult if they did not have the problem addressed in childhood. Regardless of presentation, the patient should be assessed for syndromic conditions as well as additional nonsyndromic anomalies. This assessment should entail a thorough prenatal, birth, postnataly and family history. History taking should also include an evaluation of possible psychosocial issues. Assessment of cognitive abilities, speech and language delays, developmental milestones, and behavioral problems will aid in the formation of a comprehensive therapeutic plan.

A careful physical examination of the head and neck should be performed with an emphasis on craniofacial development. All derivative structures of the first and second branchial arches should be carefully examined. Close inspection of the mandible and hemiface with palpation should be performed to assess for the presence of hemifacial microsomia, maxillary or mandibular hypoplasia. A thorough oral cavity examination is necessary to evaluate the palate and other intraoral structures.

Following examination of the other head and neck systems, attention may then turn to the otologic portion. Beginning with the external ear, the auricle is evaluated to determine the degree of microtia present. The integrity and function of each division of the facial nerve should be carefully assessed as facial nerve dysfunction has been associated with microtia and aural atresia.[7,10] The mastoid tip, condyle, and zygomatic arch should be palpated to estimate the size of the mastoid and temporal bone, which can aid in surgical planning. Under binocular microscopy, the size and caliber of the ear canal, if present, presence of a tympanic membrane, and appearance of the ossicles should be assessed. In patients with unilateral atresia, the unaffected side also warrants thorough evaluation.

The patient may also present with a draining or moist ear. Aural drainage in the setting of ear canal stenosis should alert the clinician to the possibility of an ear canal cholesteatoma—skin trapped in a stenotic canal. Such drainage demands more careful evaluation—possible examination and cleaning under anesthesia and/or computed tomography (CT) imaging. Congenital middle ear cholesteatoma in patients with CAA is extremely rare.[11]

Finally, the focus of the examination should be shifted to nonotolaryngologic systems. Due to frequent association of neurologic, cardiac, renal, skeletal, and urologic anomalies, these systems should be reviewed and assessed. Unrelated conditions such as hemangioma, umbilical and inguinal hernia, and anemia can also be found on rare occasions.[12]

### *Audiometric Data*

Assessment of cochlear function in patients with CAA should be obtained as early as possible. Ideally, ABR testing should be performed within the first few weeks to months of life in children with both unilateral and bilateral atresia. If early assessment is not possible, behavioral audiometry using VRA or CPA, or even standard audiometry depending on age may be performed. In bilateral atresia, the masking dilemma may confound standard audiometric results; bone conduction thresholds for individual ears may be assessed through sensorineural acuity level (SAL) testing. Using bone conduction ABR testing, detection of a wave I response in either ear corresponds with a functional auditory nerve confirming cochlear function.[13]

Accurate assessment of cochlear function in patients with bilateral atresia prevents future errors such as operating on an only hearing ear or in an ear with little possibility of a good hearing outcome. In either case, amplification in children with bilateral atresia should occur in the first 3–4 weeks of life, at least within the first 3–4 months. Early amplification is paramount to maximizing speech and language development in patients with bilateral CAA.

A more lenient approach may be taken with patients with unilateral atresia if the contralateral ear has normal hearing. It is critical to determine that the contralateral ear is functioning well and to monitor the hearing in the normal ear with routine follow-up testing. By traditional standards, these patients do not necessarily require amplification. The data are unclear how helpful amplification is for children with unilateral CAA, although certainly amplification is strongly recommended in children with unilateral sensorineural hearing loss (SNHL).[14,15] Whether or not the patient has unilateral or bilateral atresia, it is important to detect any additional hearing loss not otherwise explained by atresia, and provide the patient with the option of at least a short-term amplification solution while a long-term treatment plan is formulated.

### *Radiologic Data*

Radiographic assessment of CAA can provide valuable anatomic information that is not only beneficial for diagnostic purposes, but also important for determination of surgical candidacy, surgical planning, and prediction of outcomes. High-resolution computed tomography of the temporal bone with thin sections (minimum 1 mm sections) is the study of choice. Projections in the axial and coronal planes are necessary for complete evaluation of the inner ear and middle ear structures. The incus, malleus, incudostapedial joint, stapes, and round window are typically best seen on axial sections. The oval window, height of the tegmen, vestibule, distance between atretic plate and malleus–incus complex, and connection of the malleus to the atretic plate are better seen on coronal sections. For a full evaluation of the facial nerve, from internal auditory canal to stylomastoid foramen, both projections are important.

If audiometric data have confirmed normal cochlear function and no other indication for radiographic evaluation exists (acute facial palsy, otorrhea with concern for cholesteatoma), imaging of the temporal bone can typically be deferred until the patient is 5–6 years of age, the time when atresia surgery is considered. The rationale for this delay is to avoid unnecessary radiation exposure until the child is near the age in which surgical intervention is considered. Older children receive overall less total body radiation exposure. In addition, patient cooperation is unlikely in younger children necessitating sedation for an adequate study. Finally, a majority of patients with CAA who go on to develop cholesteatoma do not do so until after the age of 3.[16] Therefore, in the vast majority of cases, it is prudent to delay radiographic imaging until the patient is older, more cooperative, and will receive less total body radiation.

Once the imaging study has been performed, it is important to systematically assess the auditory pathway. The status of the inner ear should be evaluated to ensure there are no associated inner ear malformations. Next, the middle ear and mastoid should be evaluated. Extent of temporal bone pneumatization, size and status of the middle ear cavity, position/height of the tegmen, thickness of the bony atretic plate as well as the soft tissue component are well delineated by CT and are important components for surgical planning (Fig. 8.1). Patients with dysplastic inner ear structures, poor pneumatization and/or hypoplastic middle ear cleft, or low-lying tegmen (Fig. 8.2) are typically poor surgical candidates (*see* classification below).

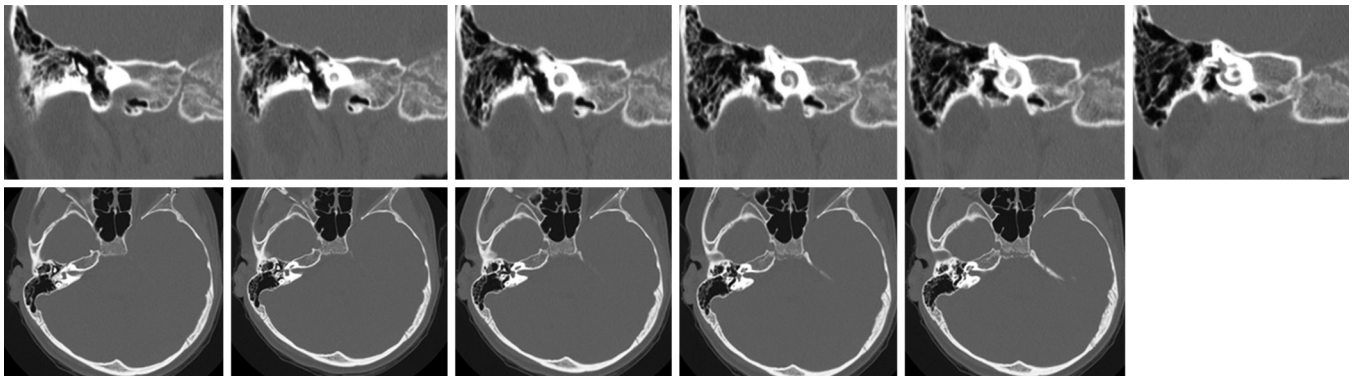

**Fig. 8.1:** Series of coronal and axial high-resolution CT scans of the temporal bone. Good candidate for atresiaplasty. On coronal imaging, note good height of tegmen, well-aerated middle ear and mastoid, fused malleus–incus, incudostapedial joint intact, stapes better seen on axial sections, oval window open, good distance between malleus–incus complex and atretic plate. On axial imaging, incudostapedial joint nicely imaged, stapes present, oval window open, fused malleus–incus, well-aerated mastoid and middle ear.

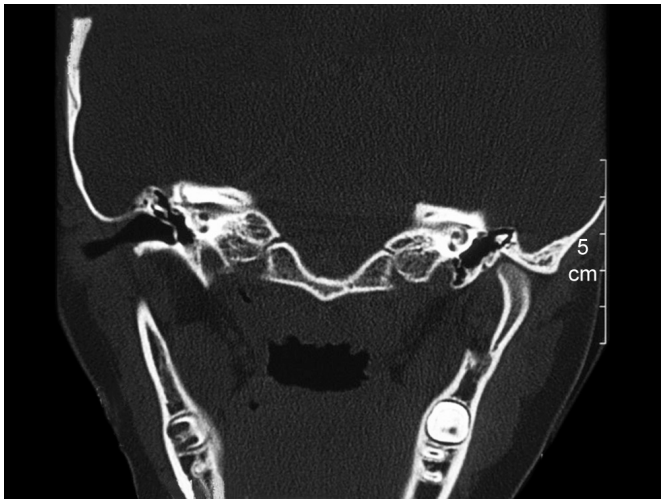

**Fig. 8.2:** Not a good candidate for left atresia surgery—tegmen too low.

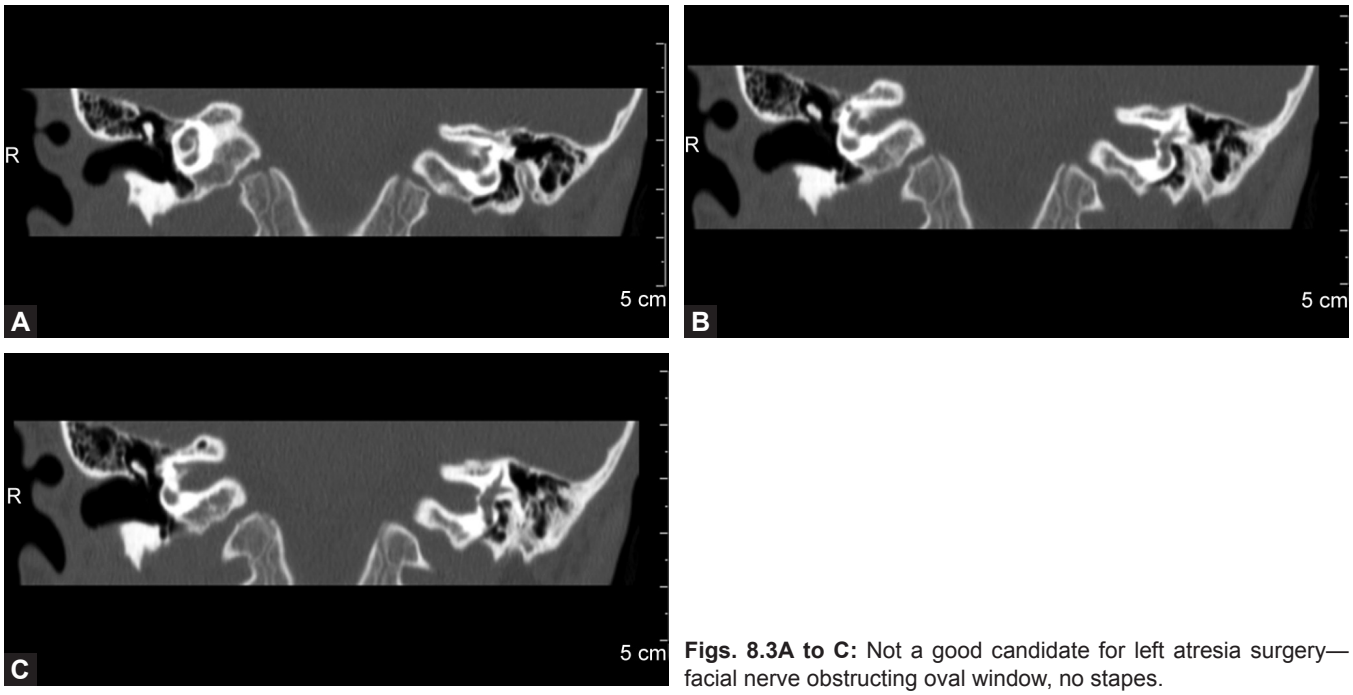
The status of the ossicles, particularly the stapes, is also very important. The presence of a normal stapes, stapes footplate, and oval window must be ensured if atresiaplasty is being considered. Although stapes fixation can only be determined intraoperatively, if immobile, stapes surgery with or without ossicular reconstruction should be performed at a later date. Finally, the course of the facial nerve should be analyzed with particular attention to the relationship of the horizontal portion to the stapes footplate and location in the mastoid segment. CT may help anticipate any potential obstruction of the stapes footplate due to an aberrant facial nerve (Figs. 8.3A to C).

If a patient with an atretic ear complains of pain and/or drainage, this may be indicative of a developing or progressing cholesteatoma and should prompt immediate imaging. Patients with congenital aural stenosis are at significant risk of harboring a cholesteatoma (up to 14% according to Ishimoto et al.[17]). Among patients with aural stenosis who have canal diameters of 3 mm or less, 50% will develop cholesteatoma.[16] As such, patients with severe canal stenosis precluding adequate in-office cleaning should be imaged around 4–5 years regardless of symptomatology to ensure that there is no cholesteatoma. If cholesteatoma is discovered, congenital or otherwise, surgical management to eradicate disease and create a safe ear is mandatory.

## Classification Systems

As innovation and advancement in atresia surgery have progressed, the development of classification systems has been important in guiding therapeutic decision making. These systems help characterize the severity of the malformation as well as stratify patients who would do well with surgical repair versus those who would be better served with conservative management or other options for amplification. More recently, there has been emphasis on honing classification schemes so they not only determine surgical candidacy but also predict surgical outcomes.[18] Many systems have developed over the years, which utilize a variety of different parameters including examination findings, radiographic results, and intraoperative observations. The two predominant grading systems, the De la Cruz classification system and the Jahrsdoerfer classification system, rely primarily on CT scan findings. These will be reviewed briefly as well as the predominant classification system for microtia.



**Figs. 8.3A to C:** Not a good candidate for left atresia surgery—facial nerve obstructing oval window, no stapes.

The De la Cruz system is a modification of an earlier system initially proposed by Altmann in 1955.[1] Altmann divided patients into three groups based on their anatomical variations. De la Cruz altered this system dividing abnormalities of the external and middle ear into major and minor categories based on CT scan findings. Patients who have normal mastoid pneumatization, a normal oval window, footplate and inner ear, as well as a good facial nerve–footplate relationship are determined to have minor malformations. These patients are deemed to have a good possibility of obtaining serviceable hearing after atresiaplasty. Patients with abnormalities in any of the above structures are deemed to have major malformations and would be better served with conservative management.

The Jahrsdoerfer grading system assigns a point to each normal appearing anatomic structure in the middle ear seen on the high-resolution temporal bone CT scan, with a point for the degree of microtia and two points awarded for a normal stapes bone (Table 8.1).[19] Each affected ear is thus given a score of 1–10. Using this scale, Shonka et al. showed that a score of 7 or higher corresponded with an 89% chance of achieving good hearing results (speech reception threshold [SRT] ≤30 dB HL), while ears scoring 6 or less had a 45% chance of achieving good hearing results.[20] Shonka also found that, when evaluating individual anatomical features alone, poor middle ear aeration was the only feature predictive of poor audiometric outcome.[20] In cases of bilateral atresia, the surgeon may be less rigid in selection of surgical candidates.

**Table 8.1:** Jahrsdoerfer grading scale

| *Parameters* | *Points* |
|---|---|
| Stapes present | 2 |
| Oval window open | 1 |
| Middle ear space | 1 |
| Facial nerve | 1 |
| Malleus–incus complex | 1 |
| Mastoid pneumatized | 1 |
| Incus-stapes connection | 1 |
| Round window | 1 |
| Appearance external ear | 1 |
| Total available points | 10 |

Jahrsdoerfer et al.[19]

Classification of microtia is considered separately from CAA. Grade I microtia corresponds to a smaller than normal auricle that is otherwise normal with all anatomic subunits. Patients with deficient or absent anatomic subunits are categorized as Grade II. In Grade III, the auricle has a classic "peanut" appearance with only remnant soft tissue, or there is complete anotia. Interestingly, Ishimoto et al. compared the relationship of hearing levels in microtic ears with temporal bone anomalies using the

Jahrsdoerfer scale. He found that hearing level in microtic ears correlated with oval window and round window formation, as well as ossicular development; hearing levels, however, did not correlate with severity of microtia, middle ear aeration, or facial nerve aberration.[17]

## MANAGEMENT

Initial management of children with aural atresia is focused on parental reassurance, establishing a multidisciplinary team, and addressing the possible need for hearing amplification. In establishing a long-term treatment plan, the primary options include (1) observation with behavioral strategies (e.g. preferential seating in class); (2) assistive listening device, e.g. Frequency modulated (FM) system; (3) amplification (bone conducting or bone-anchored hearing devices); and (4) atresia repair (canaloplasty). These options are not mutually exclusive, and it is important for the parents and/or patient to understand the risks and benefits associated with each. Additionally, the need for speech and language therapy and other resources should be discussed with the family. Traditionally, management considerations for children with unilateral atresia have been somewhat different from children with bilateral atresia. Where present, these differences will be highlighted in the following sections.

### Observation

Observation implies that no intervention is made toward hearing rehabilitation. This option, along with its consequences of possible speech and language delays and psychosocial problems should be discussed. Nonetheless, observation without amplification is only practical in children with unilateral atresia with a normal hearing contralateral ear. In general, these patients will most likely develop normally from a speech, language, and intellectual standpoint. Preferential seating in school for these children is a must. The use of hearing aids in children with unilateral atresia is gaining more support in the literature; however, until recently, it has not been recommended. This is primarily due to poor patient compliance in young children. Nevertheless, close monitoring of academic progress in children with unilateral CAA is essential, as unilateral hearing loss in children can be a barrier to scholastic success.[21-23] Serial audiometric evaluation is also important to ensure normal functioning of the contralateral ear. Observation in children with bilateral atresia is not recommended.

### Amplification

Early hearing amplification for children with bilateral aural atresia is essential for optimizing speech and language development. In patients with complete atresia of the canal, a bone conducting hearing aid should be used within 3–4 weeks of age. Bone conduction hearing aids deliver auditory stimuli transcutaneously through the scalp using a headband apparatus with a bone conduction oscillator situated behind the ear. These systems are relatively inexpensive and can be utilized within the first several weeks of life. The major drawbacks for conventional bone conduction hearing aids include discomfort from constant pressure of the steel spring, the ability for the transducer to easily shift over the head, poor esthetics, and relatively poor sound quality due to attenuation of high frequency sounds by the skin. Softer headbands have been developed in attempts to minimize patient discomfort and maximize usage. Children with canal stenosis without atresia and relatively normal pinna development can typically be fitted with air conduction aids that are more comfortable and discreet.

Adults with unilateral CAA can be offered a trial of a hearing aid if it can be fitted or a bone conducting device. Adults are more likely to accept hearing aids than younger children with unilateral atresia as the perceived benefits gained from binaural hearing generally outweigh the nuisance of wearing a device.

#### *Bone-Anchored Hearing Aids*

The development of bone-anchored hearing aids (BAHAs) has been a significant advance in the management of conductive hearing loss, and is a viable alternative to atresiaplasty. BAHA systems have a vibrational transducer coupled directly to the skull via a titanium implant. The primary indications for BAHA include patients with a pure tone average (PTA) bone conduction threshold of 45 dB HL or less, and a speech discrimination score of 60% or better using a phonetically balanced word list.[24] The US Food and Drug Administration has approved these devices for children 5 years and older when cortical bone reaches the appropriate thickness to accept an implant. Under local or general anesthesia, the titanium implant/abutment is implanted behind the ear in the hair-bearing scalp. Following surgery, 3–6 months are typically allowed for healing and osseointegration before the sound processor is connected.

This osseointegrated coupling is much more effective than conventional, transcutaneous bone conducting

hearing aids. BAHA provides enhanced sound quality and is more efficient in sound energy transmission offering a 10–15 dB improvement over bone conducting aids.[18,25] In fact, review articles have shown that speech recognition and discrimination scores for BAHAs are significantly better compared to conventional bone conducting aids.[26,27]

There are several disadvantages to the BAHA. It is more expensive than bone conducting aids and requires a minor operation, often under general anesthesia. Compared with atresiaplasty, BAHA commits the patient to an appliance that is vulnerable to mechanical failure. Local wound infections can occur at the site of the abutment, which must be frequently cleaned. There is also the possibility of repeat surgery if the abutment does not osseointegrate. Finally, placement of the abutment may preclude the child from future microtia repair, but careful coordination between plastic microtia surgeon and otologic BAHA surgeon should allow a BAHA to be placed along with conventional microtia repair.

There is a paucity of data comparing BAHA directly to atresiaplasty. BAHA remains a reasonable alternative to atresiaplasty, especially in patients who are poor surgical candidates. In patients who are good surgical candidates, they are as likely to have good results regardless of which intervention is selected. Therefore, it is important to thoroughly discuss the risks and benefits of both atresia surgery and BAHA surgery, highlighting quality of life issues surrounding dependence on a device and difference in degree of risk between both procedures.[18] Hearing outcomes with the BAHA tend to be more reliable.[28,29]

## Surgery

Surgical repair of the atretic ear is a viable option in appropriately selected patients. The primary goals of surgery include correction of the air–bone gap (ABG), creation of a "safe" well-epithelialized canal, and maintenance of canal patency. The operation must not only be successful, but remain so over a long period of time. Even with meticulous technique, late onset hearing loss and even the need for revision surgery may occur.[30]

### *Patient Selection*

The key components in considering elective atresiaplasty include audiometric data demonstrating normal cochlear function in the atretic ear and a high-resolution CT scan of the temporal bone demonstrating favorable anatomy. Children with dysplastic or hypoplastic inner ear structures are poor surgical candidates and should be directed toward amplification. Secondary to inner ear development, assessment of the development of the middle ear cleft, ossicles, oval and round windows, as well as assessment of the facial nerve course and mastoid pneumatization have a profound impact on surgical management. A well-pneumatized mastoid and middle ear cleft increases the likelihood of surgical success. Identifiable ossicles as well as good oval window/footplate/facial nerve relationship are ideal. On the other hand, poor pneumatization of the mastoid is one of the most common causes of inoperability in a patient with CAA. An anteriorly displaced facial nerve can restrict the field of dissection and increases the possibility of facial nerve injury. The facial nerve may also overlie the oval window preventing ossicular reconstruction thus preventing hearing improvement.

In patients with the most favourable anatomy, the decision to operate becomes more difficult. Historically, otologists only operated in cases of surgical need, such as bilateral CAA, acute facial nerve paralysis, cholesteatoma, or otorrhea. The surgical option would be deferred until adulthood so that the patient could make an informed decision based on the risks and benefits of atresia surgery.

Given the well-documented academic difficulties of a subset of children with unilateral SNHL,[22] surgeons have offered atresia surgery to patients with unilateral CAA to overcome the problems of sound localization and difficulty hearing in background noise. Preliminary data indicate that after surgery, patients are able to hear better in background noise.[31] More research is needed to clarify the ability of patients to "use their new ear" in tests of sound localization and binaural hearing after atresia surgery. Of course, only those patients with favorable anatomy should be selected for unilateral atresia repair.

### *Timing of Surgery*

As the majority of CAA patients also present with microtia, the timing of surgery must take into account both reconstructive procedures. Auricular reconstruction typically relies on autologous rib cartilage as the substrate for microtia repair. Rib cartilage does not reach adequate size for auricular reconstruction until the child is 5-8 years old.[32] Once of appropriate age, rib graft auricular reconstruction precedes atresia repair to avoid disruption of surgical planes as well as the blood supply needed to maintain viability of the cartilage graft and local flaps. Atresiaplasty is generally delayed at least 3 months following the final stage of microtia repair.

### Alternative Techniques

In recent years, more plastic surgeons have been opting to use the Medpor® implant (Stryker, Kalamazoo, MI) covered with a vascularized temporoparietal fascia flap in lieu of autologous cartilage for auricular reconstruction.[33] Medpor is a porous high-density polyethylene, which is a well tolerated implant compared to earlier alloplastic materials. Use of Medpor avoids the risk of pneumothorax and provides more flexibility in the timing and traditional sequence of surgery. Current recommendations are for atresia surgery to precede Medpor microtia repair because exposure of the implant during an atresia operation would greatly jeopardize the viability of the implant. The operation can also be done at an earlier age. Roberson et al. performed atresiaplasty prior to microtia repair with an average age of 4.2 years, with comparable results to traditional atresia repair with autologous rib cartilage.[34] Other novel techniques have been attempted, including atresiaplasty at the time of elevation of the cartilage framework.[35]

### Surgical Approach

Each surgical step must be done meticulously to gain acceptable hearing results. Accurate identification and use of anatomic landmarks is vital to ensuring a safe dissection and avoidance of the facial nerve and inner ear structures.

There are two general approaches in atresia surgery, the anterior approach and the mastoid approach. The transmastoid approach involves drilling through mastoid air cells to reach the atretic plate,[36] while in the anterior approach, the bone directly posterior to the temporomandibular joint (TMJ) is drilled to reach the atretic plate.[3,37] The anterior approach creates a more natural ear canal with care taken to minimize opening of mastoid air cells, and carries less risk of a draining ear. The basics of this approach will be reviewed briefly.

### Patient Preparation

General anesthesia is induced, and the patient is placed supine with the head turned away (standard otologic positioning). The arm ipsilateral to the operated ear is tucked loosely on an arm board in preparation for future skin graft harvest. The postauricular area is shaved and a local anesthetic is instilled into the postauricular skin. Electrodes for continuous facial nerve monitoring are placed, reducing the risk for intraoperative facial nerve injury. Muscle relaxants other than short-acting paralytics for induction should not be used; this must be communicated to the anesthesiologist.

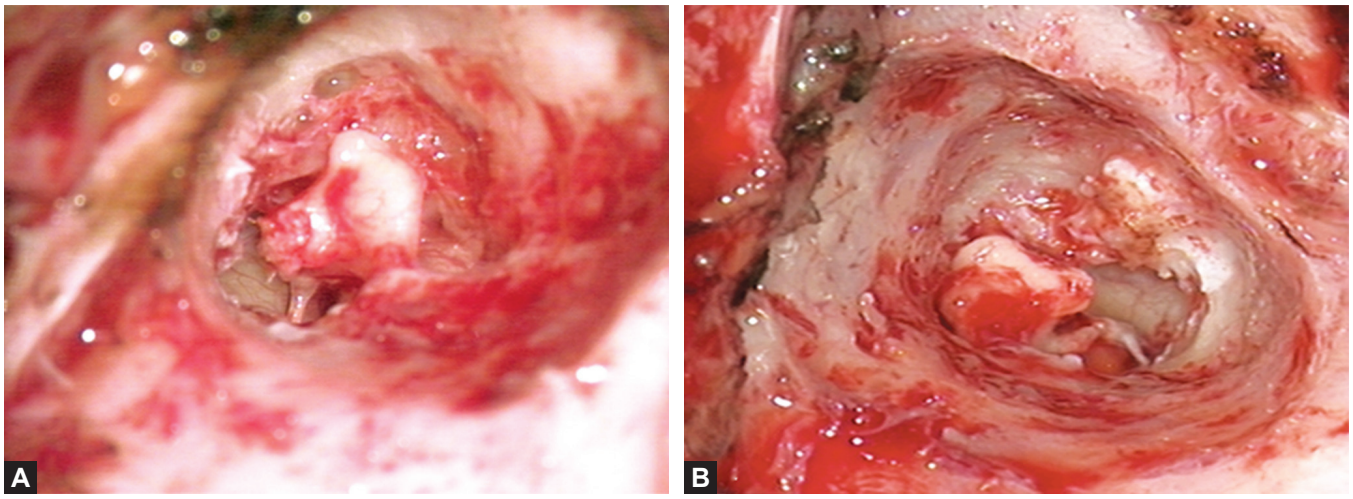
### Exposure and Dissection

A postauricular incision is made to the level of the temporalis fascia and a quarter-sized piece of fascia is harvested and set aside. A T-shaped incision is made in the periosteum with the superior–inferior limb made anteriorly along the posterior rim of the glenoid fossa. The periosteal flap is elevated until the linea temporalis, cribriform area, and posterior edge of the glenoid fossa are exposed. If there is remnant tympanic bone, drilling begins at the cribriform area. If no remnant tympanic bone is present, the junction of the linea temporalis and posterior rim of the glenoid fossa is used as the site of initial drilling. Drilling proceeds anterior and superior to identify the tegmen. The tegmen is followed medially to the epitympanum. Exposure of the temporomandibular joint and mastoid air cells is avoided. This approach minimizes the risk of injury to an aberrantly oriented anterior and lateral facial nerve.

Upon entry into the epitympanum, the ossicular mass is identified. Atretic bone is carefully removed with diamond micro drills and microsurgical instruments. Drilling of the ossicular mass should be avoided to reduce the risk of a high frequency SNHL. Once the ossicular mass is freed from atretic bone, ossicular chain and stapes footplate mobility are assessed (Figs. 8.4A and B). Reconstruction may be done with the patient's own ossicular chain, or a partial or total prosthesis if needed depending on anatomy. In general, reconstruction with an ossicular prosthesis results in about a 10 dB loss in the PTA and SRT.[38] If the stapes footplate is not mobile, stapes surgery should be deferred to a later date. The canal is widened to a diameter of 12 mm, which is purposely larger than the average canal size of 9 mm. This compensates for the natural contraction that occurs during the healing process.

### Grafting

The ipsilateral arm is exposed and a split thickness skin graft is taken from the nonhair bearing upper arm. The graft is harvested with a dermatome set for a thickness of 0.005–0.006 in. The skin graft is washed of blood and cut to 4 × 5 cm. If the ossicular chain is intact and mobile, the dehydrated fascia graft is trimmed to the appropriate size and draped over the ossicular mass with 1–2 mm of graft extending up onto the canal wall in all dimensions (Fig. 8.5).



**Figs. 8.4A and B:** Intraoperative view of canal with fused malleus–incus complex in the middle ear: (A) left ear and (B) right ear.

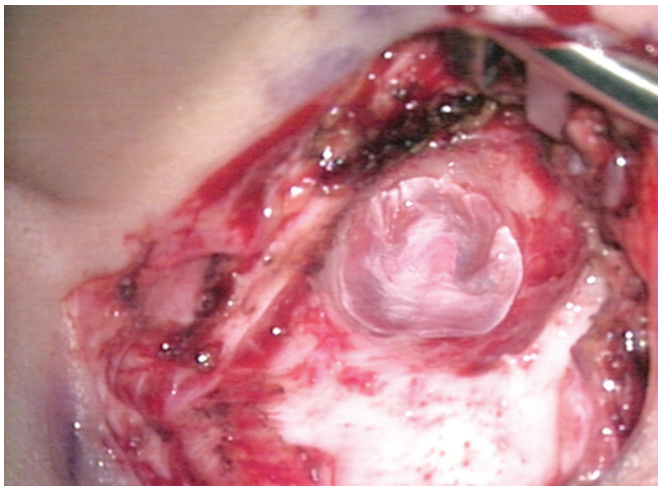


**Fig. 8.5:** Intraoperative view of the fascia graft draped over the fused malleus–incus (left ear).

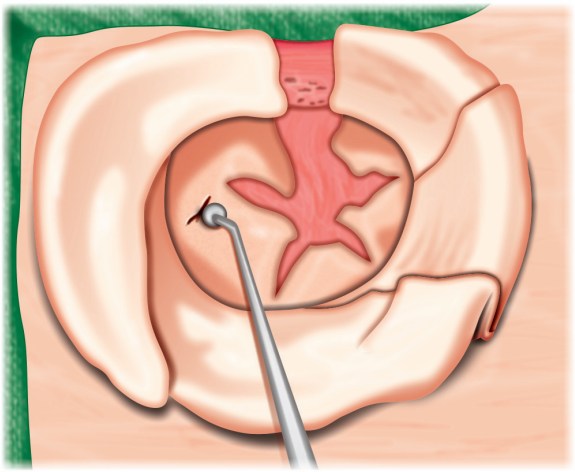

**Fig. 8.6:** Schematic drawing of the placement of notched ends of the split thickness skin graft.

The skin graft is notched at the medial end so that each notch comes together to cover completely the temporalis fascia. The graft is also circumferentially positioned so that it covers the bone of the canal; the edges should meet anteriorly (Fig. 8.6). The purpose of this is to prevent epithelial growth into the mastoid air cells. A 0.04 in. silastic disk is fashioned and placed over the skin graft and fascia to hold the fascia and skin grafts in place. Four to five wicks are delivered down into the ear canal standing on end and hydrated with ototopical antibiotic drops that when hydrated, expand and hold the skin graft against the bony canal (Fig. 8.7). Excess lateral skin is draped over the hydrated wicks.

### *Meatoplasty*

An anteriorly based conchal skin flap is created, and the underlying soft tissue and cartilage are excised creating the meatus (Fig. 8.8). The skin flap is delivered through the meatus and sutured to periosteum at the glenoid fossa, creating the anterior–lateral canal wall. The mastoid periosteal flap and postauricular incision are closed with absorbable suture. The skin graft is then delivered laterally through the meatus and sutured to the native conchal bowl skin. The remaining lateral canal is packed with additional wicks soaked with ototopical antibiotic drops. A mastoid dressing is applied and the skin graft donor site is dressed.[2]

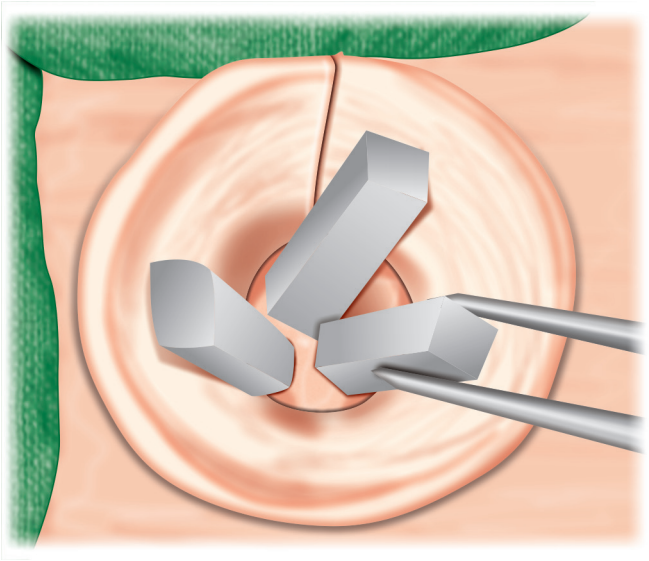

**Fig. 8.7:** Schematic drawing of the placement of the wicks in the bony canal.

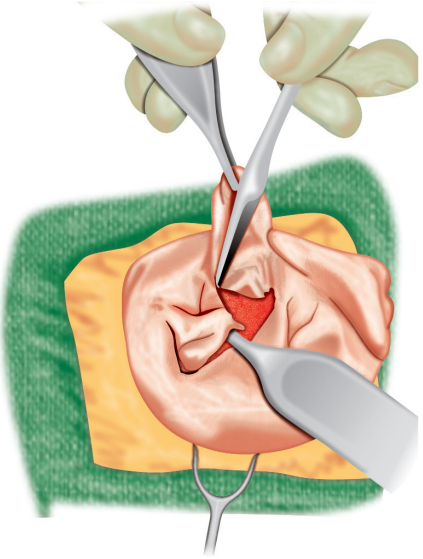

**Fig. 8.8:** Schematic drawing of the anteriorly based conchal skin flap that will serve as the anterior-lateral canal wall.

### *Postoperative Care*

The mastoid and arm dressings are removed on the first postoperative day. The patient is discharged home with instructions to apply antibiotic ointment to the postauricular incision and on a cotton ball that is placed over the meatus and changed daily. The packing and remaining absorbable skin sutures are removed at the 1-week postoperative visit. At the first postoperative visit, corticosteroid antibiotic drops are given to use twice daily for 1 week and strict dry ear precautions should be followed. The ear canal is otherwise exposed. At the 1-month postoperative visit, the ear canal is debrided of sloughed epithelium and an audiogram is obtained to evaluate postoperative results. Assuming no postoperative complications, dry ear precautions are relaxed, and follow-up is scheduled for annual or biannual canal debridement.

### *Complications*

Complications can be minimized with proper patient selection, good surgical technique, close follow-up, and patient adherence to postoperative instructions. The most commonly seen complications are graft lateralization, mucosalization with a moist ear, meatal stenosis, and high-frequency SNHL. The incidence of these complications ranges anywhere from 3% to 26% depending on the report.[6,30] Facial nerve palsy is much less frequent, with an incidence of <0.1%.[39] Salivary fistula and canal cholesteatoma are two very rare complications, but should be suspected in a draining postoperative ear.[40]

### *Outcomes*

The two most important factors in achieving consistently good hearing outcomes in atresia surgery are careful preoperative selection of patients and meticulous surgical technique at each step of the operation. With favorable anatomy and careful technique, postoperative hearing results can reach in the normal or near-normal range (SRT ≤ 30 dB HL) in 80–90% at 1 month.[20]

There is a paucity of data on long-term hearing results after this operation, but Lambert examined the stability of hearing results after atresia surgery and found that almost two-thirds of patients maintained an SRT < 30 dB HL for the longer follow-up (> 1 year; mean, 2.8 years); about one-third required a revision procedure.[41] Similarly, De la Cruz reported a long-term (> 6 months) ABG of 30 dB or less in 51% of primary cases and 39% of revisions.[6]

Even if the hearing deteriorates, a conventional hearing aid can be worn in the new canal many times to bring the air conduction thresholds into the normal range.

## CONCLUSION

Bilateral CAA requires relatively prompt evaluation to determine bone conduction thresholds, with intervention

aimed at bypassing the atretic ear canals through bone conduction hearing devices. In most patients with bilateral atresia, normal speech and language development an progress with the appropriate use of resources including amplification and speech therapy.

Unilateral CAA requires close monitoring of the nonatretic ear to ensure normal hearing with close attention to speech and language progress and performance in the school setting. Resources to help children with unilateral CAA include preferential seating in class, individualized education programs, FM systems, amplification, and surgery.[9] The decision to amplify is made among the family and hearing health-care professionals. Surgery can be undertaken in both unilateral and bilateral CAA after careful evaluation of the audiologic and radiologic data.

Meticulous surgical technique can bring air conduction thresholds in patients with CAA to the normal or near-normal ranges. Further research is needed to determine the long-term stability of these audiometric results and whether children with unilateral CAA can "use" their new ear in tests of binaural hearing.

CHAPTER

# 9 Management of Children with Inner Ear Malformations

*Levent Sennaroglu, Esra Yücel, Gonca Sennaroglu, Burce Ozgen*

## INTRODUCTION

Inner ear malformations may account for up to 20% of congenital hearing loss cases based on temporal bone computed tomography (CT). The majority of these children who have an associated bilateral severe to profound hearing loss are cochlear implant (CI) candidates. However, those cases with severe malformations may require special surgical approaches to facilitate implant placement, making clinical decisions challenging.

Although inner ear malformations have been traditionally separated into five groups,[1–3] recent findings suggest that inner ear malformations can also be classified into eight distinct groups.

## COMPLETE LABYRINTHINE APLASIA (MICHEL DEFORMITY)

### Definition and Radiology

Labyrinthine aplasia is the absence of the cochlea, vestibule, semicircular canals (SCCs), and vestibular and cochlear aqueducts (Fig. 9.1). The petrous bone is reported to be hypoplastic, whereas the otic capsule may be hypoplastic or aplastic.[4] In the majority of patients, the internal auditory canal (IAC) is abnormal, consisting only of the facial canal, although the labyrinthine, tympanic, and mastoid segments of the facial nerve can be seen in the temporal bone. However, in a portion of patients, it may not be possible to observe the facial canal in the temporal bone even though there is no facial paralysis. The middle ear ossicles are usually present.

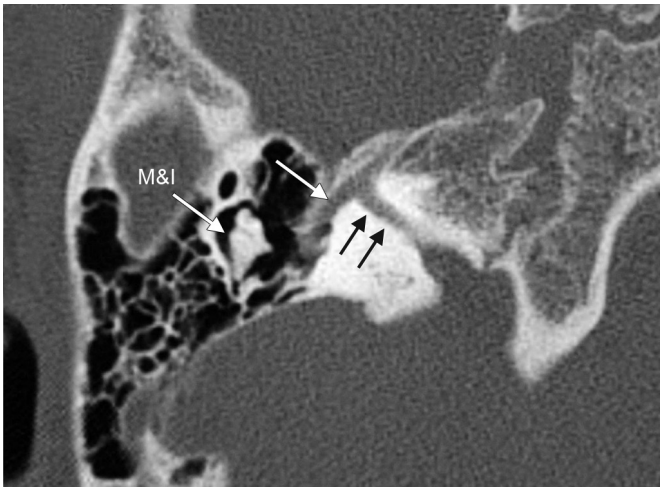

**Fig. 9.1:** Axial CT image of a patient with labyrinthine aplasia demonstrates a hypoplastic otic capsule with complete absence of the inner ear structures. The facial canal with the labyrinthine (black arrows) and tympanic (white arrow) segments is well visualized.

### Audiological Findings

Audiological examination reveals either no response at all or profound sensorineural hearing loss (SNHL) at 125, 250, and 500 Hz at the upper limits of the audiometer. The latter finding demonstrates that this is not true hearing, but rather vibrotactile sensations. This can also be appreciated in cases of children with a rudimentary otocyst and cochlear aplasia.

### Management

As there is no inner ear development, it is not possible to perform CI surgery in these children. Auditory brainstem

implantation (ABI), in which the electrode is placed into the lateral recess to directly stimulate the cochlear nuclei, is thus the only surgical option for hearing habilitation. Although translabyrinthine, retrosigmoid and retrolabyrinthine approaches can be used for ABI surgery, the retrosigmoid approach is preferred in children.[5] The temporal bone is much smaller in children of 2–3 years of age when compared to that of an adult. As a result, the translabyrinthine approach provides a much more limited surgical exposure than the retrosigmoid approach. In addition, drilling the temporal bone with a translabyrinthine approach to expose the brainstem requires longer surgical times compared to retrosigmoid craniotomy. Therefore, we favor the latter approach for ABI surgery in children.

Based on the findings in 48 children who have undergone ABI surgery in Hacettepe University, there is no real correlation between the type of inner ear malformation and the development of the cochlear nuclei. Even in the absence of an inner ear, the cochlear nuclei may be developed and it may be possible to obtain electrically evoked far-field responses of the upstream auditory pathways (electrical auditory brainstem response) during ABI surgery. Unfortunately, there is no way of preoperatively determining whether the cochlear nuclei are present and functional in children with labyrinthine aplasia based on current magnetic resonance imaging (MRI) techniques and evoked response testing methods. Indeed, children with labyrinthine aplasia have demonstrated hearing benefits that mimic those of children with other inner ear pathologies who underwent ABI surgery.

## RUDIMENTARY OTOCYST

### Definition and Radiology

A rudimentary otocyst consists of incomplete millimeter-sized representations of the otic capsule (round or ovoid in shape) without an IAC (Fig. 9.2). Sometimes parts of the SCCs may be present. This pathology falls somewhere between a Michel deformity and common cavity (CC) in the spectrum of inner ear anomalies. In Michel deformity, there is no inner ear development, while in CC, there is an ovoid or round cystic space instead of a separate cochlea and vestibule. The CC is usually similar in size to cochlea/vestibule and it communicates with the cerebellopontine cistern via the IAC. The rudimentary otocyst is a few millimeters in size and does not communicate with the subarachnoid space via an intact IAC.

Audiological findings are similar to those found in complete labyrinthine aplasia.

**Fig. 9.2:** A rudimentary otocyst is seen with a small ovoid structure (black arrow) that has no communication with the cerebellopontine angle.

### Management

The fact that there is no connection between the otocyst and the brainstem is a contraindication to CI surgery. As a result, these patients are candidates for ABI.

## COCHLEAR APLASIA

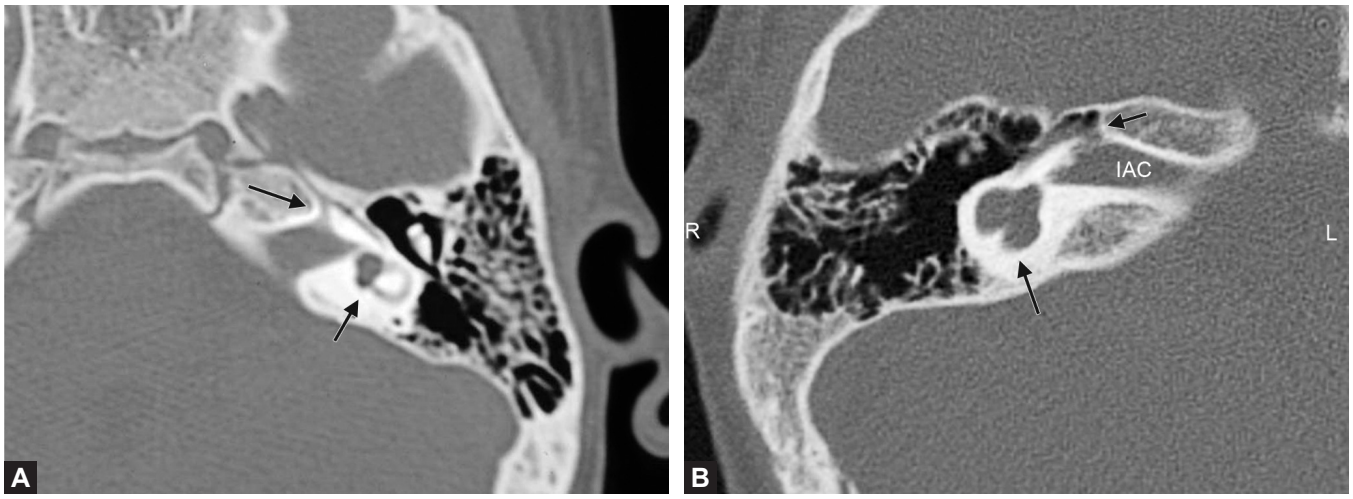
### Definition and Radiology

Cochlear aplasia is simply described as the absence of the cochlea. The accompanying vestibular system may be normal (Fig. 9.3A) or it may have an enlarged vestibule (Fig. 9.3B).[1] The labyrinthine segment of the facial nerve is anteriorly displaced and usually occupies the normal location of the cochlea. It is essential to distinguish cochlear aplasia with a dilated vestibule (CADV) from CC. If the cochleovestibular nerve (CVN) is present, cochlear implantation can be done in CC. However, CI surgery should not be done in CADV. The challenge is that in some patients, it is very difficult to distinguish between these entities. Detailed differences between the two pathologies are described in more detail in the section on CC.

It has been observed that cochlear aplasia with normal labyrinth is symmetric, with similar features found in different patients. The etiology is most likely genetic. Given the asymmetric development of CADV, this pathology may be genetic or environmental.

### Audiological Findings

In a typical audiologic evaluation, these patients will have no response at all or profound hearing loss at low



**Figs. 9.3A and B:** Cochlear aplasia with normal (A) and dilated (B) vestibule (thick arrow). Note the facial canal (thin arrow) in each case.

frequencies. Collectively, these findings in complete labyrinthine aplasia, otocyst deformity and cochlear aplasia demonstrates that profound hearing loss at low frequencies is purely a vibrotactile response and should not be interpreted as hearing in CI candidates with other pathologies.

### Management

As there is no inner ear development, ABI is the only feasible surgical option to provide hearing sensations in children with cochlear aplasia.

## COMMON CAVITY

### Definition and Radiology

A CC is defined as a single chamber (ovoid or round in shape) representing the cochlea and vestibule (Fig. 9.4). Theoretically, this structure has cochlear and vestibular neural structures. The IAC usually enters the cavity at its center, with the SCCs or their rudimentary parts accompanying the CC. Cases with vestibular dilatation are occasionally termed as "vestibular common cavity"; however, this is not a correct term.

As noted above, it is very important to differentiate between cochlear aplasia with vestibular dilatation (CAVD) and CC. In contrast to a CC (Fig. 9.4), which is described above, CAVD (Fig. 9.3B) usually has a vestibule and SCCs whose external outline resembles the normal labyrinth. The vestibule is at its expected location at the posterolateral

**Fig. 9.4:** Common cavity anomaly represented with an ovoid single structure (CC). Note that the IAC is present and is extending to the midportion of the CC. The facial canal (white arrow) has aberrant course. (IAC: Internal auditory canal; CC: Common cavity).

portion of the IAC fundus. The accompanying SCCs may be enlarged or normal. A CC (Fig. 9.4), on the other hand, is an ovoid or round structure. SCCs or their rudimentary parts may accompany a CC. The IAC usually enters the cavity at its center. The location of a CC may be anterior or posterior to the normal location of the labyrinth. It is very important to differentiate these malformations from each other, because cochlear implantation in a CC may result in acoustic stimulation, but in CAVD, CI will fail with no functional stimulation. In spite of these factors, it may sometimes be difficult to differentiate between the two malformations.

An otocyst deformity is a more primitive malformation than the CC deformity. There is a rudimentary cystic ovoid or round structure that is a few millimeters in dimensions without any internal auditory canal development.

## Audiological Findings

These patients can have detectable hearing thresholds only at low frequencies and at the maximum limits of the audiometer.

## Management

The presence of a CVN is important when discussing management options with the family. High-resolution 3 T MRI with oblique views (either direct or reformats) of the internal auditory canal should demonstrate the presence of a CVN before cochlear implantation. At the present time, there is no test to determine the amount of cochlear fibers in the CVN.[5] If a behavioral audiometric response or language development is present with hearing aid use, a meaningful population of cochlear fibers is assumed to exist and the patient is a candidate for CI. The surgical approach is via a transmastoid labyrinthotomy as described by McElveen.[6] After canal up mastoidectomy, air cells are removed to identify the CC. Originally the position of the labyrinthotomy was best described in the lateral SCC; however, experience in our department has shown that any position along the cavity allows for safe entry into the CC. Therefore, a labyrinthotomy location at the periphery of the CC, away from the facial nerve, is preferred. A straight (nonmodiolar hugging) electrode is preferred, resulting in a lateral position of the electrode. A precurved electrode will have the contacts located medially and may not stimulate the periphery of the CC efficiently.

Postoperative X-rays should demonstrate circular shaped electrode placement that follows the internal curvature of the CC. If there is a cerebrospinal fluid (CSF) gusher, the X-ray should be taken intraoperatively. The presence of a CSF gusher confirms a wide connection between the CC and the IAC. If the electrode is in the IAC, it should be repositioned.

In patients with a very narrow or long IAC where the presence of cochlear fibers is questionable, an ABI may be a more appropriate option from the outset. Additionally, if there is no CVN demonstrable by MRI, ABI is indicated.

The exact location of the neural distribution is not precisely known in CC. Therefore, audiological outcomes cannot be predicted precisely before CI surgery. Initially, the family should be informed that if there is very limited progress with CI, ABI should be done on the contralateral side to provide the best possible hearing stimulation to the child. This decision should be done as early as possible.

## Electrode Choice

Because the exact location of neural tissue in CC is unpredictable, electrodes with contacts on both sides or full ring electrodes should be used. Precurved electrodes with contacts facing the modiolar side will coil within the open lumen of the CC and not likely stimulate the neural elements found along the lateral wall. In case of a CSF gusher, an electrode with a cork type silicon stopper (not available in the United States) may be advantageous in controlling the CSF leakage. The length of the electrode can be calculated by measuring the diameter of the CC and using the formula $2\pi r$ to estimate the perimeter. This roughly determines the length of the electrode that will make one full turn inside the CC.

Beltrame et al.[7] described a special electrode for CI surgery in the setting of a CC. This electrode has a non-stimulating tip which is inserted into one labyrinthotomy and then delivered through a second labyrinthotomy with a microhook.

# INCOMPLETE PARTITION OF THE COCHLEA

## Definition and Radiology

This is a group of cochlear malformations where the external dimensions of the cochlea are similar to that of a normal cochlea but the internal architecture is deficient. Based on our experience at Hacettepe University, incomplete partition of the cochlea accounts for 41% of inner ear malformations. These cases can be further divided into three different types of incomplete partition cases according to the defect in the modiolus and the interscalar septa.

### *Incomplete Partition Type I*

This type was described as a "cystic cochleovestibular malformation" in 2002 by Sennaroglu and Saatci.[3] These represent approximately 20% of inner ear malformations. In this group, the cochlea lacks the entire modiolus and interscalar septa (Fig. 9.5A), giving the appearance of an empty cystic structure. IP-I type cochlea has been reported

to have external dimensions (height and length) similar to normal cases.[8] It is accompanied by an enlarged, dilated vestibule (Fig. 9.5B). Vestibular aqueduct enlargement is very rare. Due to maldevelopment of the cochlear aperture (CA) and absence of the modiolus, there is a defect between the IAC and the cochlea (Fig. 9.5C), and CSF may completely fill the cochlea. The cochlea is located in its usual location in the anterolateral part of the fundus of the IAC.

*Audiological findings*: The majority of IP-I patients have severe to profound SNHL. Hearing aids are rarely sufficient to support oral language development, and virtually all patients with IP-I benefit from CI surgery for hearing habilitation. At Hacettepe University, 35 patients with IP-I have undergone CI surgery. In our patient population, only three patients could use hearing aids unilaterally. Specifically, these children used the hearing aid on the side with moderate-to-severe hearing loss and had profound hearing loss in their contralateral ear.

As it is possible to have cochlear nerve (CN) aplasia in IP-I, some patients may not be a candidate for CI surgery. Four patients with IP-I at our institution have undergone successful ABI surgery.

*Management*: If a patient is diagnosed with bilateral moderate HL, HA can be used for rehabilitation. However, we have not had experience with this as none of the patients have had any residual hearing. For patients with asymmetrical hearing loss (i.e. one side with moderate hearing loss and the other side with profound hearing loss), the best option is to use bimodal stimulation, with a hearing aid on the side with moderate hearing loss and a CI on the contralateral side with profound hearing loss.

It is very important to demonstrate the cochlear nerve with MRI in order for a patient to be a candidate for CI. If the CN is present, then a CI should be pursued, otherwise ABI surgery is preferred.

Two variations may complicate CI surgery in patients with IP-I.

*Gusher*: Although this does not occur in every IP-I patient, the cochlea may be filled with CSF because of the defect between the cochlea and the IAC. In some cases, there may be an egress of CSF as soon as the cochleostomy is made. It is very important to properly seal the leak or the patient will be prone to recurrent meningitis. The surgeon who is operating on patients with an elevated risk of gusher should adopt the principle that it is essential to fully control the gusher prior to completing the surgery. Recent electrodes with a cork type stopper have been used to facilitate this principle. Less severe leakage of CSF, known as oozing, can be usually managed by simply packing the cochleostomy with soft tissue. There are several options for managing and avoiding a CSF gusher:

1. Small cochleostomy: The size of the cochleostomy can be made small enough such that the electrode fits tightly and there is minimal space to place soft tissue around the cochleostomy. This technique, however, may not be effective in controlling the CSF leakage around the electrode
2. Large cochleostomy: The size of the cochleostomy is larger (approximately twice the size of the electrode), and pieces of soft tissue can be placed inside the cochleostomy around the electrode. Although seemingly paradoxical, this is more effective than a small cochleostomy
3. Electrode with a cork type stopper: This electrode has a progressive conical shape and is much more effective at controlling CSF leak than the standard silicon ring at the end of the electrode. This electrode is not yet available in the United States. To make it more effective, it may be passed through a piece of soft tissue prior to insertion into the cochleostomy. Ideally, the cochleostomy should be circular but in reality there may be irregularities. The soft tissue therefore serves the purpose of filling these irregularities around the cochleostomy

   Even with this newer type of electrode, surgical manipulations are sometimes necessary to completely control CSF leakage. Again, the surgeon should not leave the operating room without complete control of the leak. If CSF continues to ooze around the electrode, there will be an increased risk of recurrent meningitis. If full control of the leakage is not accomplished, subtotal petrosectomy (as described below) is the next reasonable option
4. Subtotal petrosectomy: This technique includes complete removal of the skin, blind sac closure of the ear canal, obliteration of the cavity with fat and plugging the Eustachian tube in addition to the procedures mentioned above. By plugging the Eustachian tube the procedure provides additional protection against meningitis. However, it should be emphasized that if the leakage is not fully controlled, complications may still occur

   Once a subtotal petrosectomy is done in a child with a CI, it is very difficult to check the condition of the ear.

MRI cannot be done because of the CI without magnet removal or in cases where the device is approved for 1.5 T MRI scanning with the magnet in place. High-resolution CT cannot differentiate between the fat obliteration and CSF coming from the leakage. If high CSF pressures produce a fistula at the oval window, it may not be possible to detect such a defect. Therefore, we prefer proper control of the leak at the cochleostomy, leaving the ear canal and tympanic membrane intact. During follow-up, any abnormality in the tympanic membrane may alert the surgeon to a CSF leakage. In that situation endaural exploration of the middle ear may be necessary.

5. Continuous lumbar drainage (CLD): In patients with severe CSF leakage, 4–5 days of CLD diverts the CSF from the site and allows for better healing of the cochleostomy site to promote healing. It should be considered in patients with severe CSF leakage.

Electrode choice: We do not know the exact location of the neural tissue in the cochlea. Therefore, electrodes with contacts on the modiolar side may not produce the desired effect. Electrodes with contacts on both sides or full rings may provide better stimulation. In addition, an electrode with cork-type silicon stopper may stop CSF leakage more efficiently.

Postoperatively, these patients should have an X-ray to demonstrate the position of the electrode. If there is severe gusher, the X-ray should be taken in the operating theater. If the X-ray demonstrates that the electrode is in the IAC, the electrode must be repositioned. Electrodes that are modiolar hugging may have a higher likelihood of facial or cochlear nerve damage when they are being removed from IAC for repositioning.

*Facial nerve anomaly*: As there is abnormal development of the labyrinth, the facial nerve may have an abnormal course. As such, the facial recess approach may not provide sufficient exposure for round window insertion. In this situation, an additional transcanal approach may be necessary. This has been done in 3 patients (out of 35) in our department. In cases where this is not possible, subtotal petrosectomy (where the skin is totally removed and the bony external auditory canal is taken down) may provide a better view of the landmarks.

Auditory brainstem implantation: The ABI is indicated in IP-I patients with aplastic CN. Four patients with IP-I and aplastic CN have received the ABI in our department.

Meningitis in IP-I: Meningitis can occur in IP-I patients even prior to their CI surgery or in their nonoperated ear. High CSF pressure filling the cochlea disrupts often thin stapes footplate, leading to a CSF fistula at the oval window and meningitis. Several cases of this have been reported in the literature.[1,9–11]

Usually, these children have recurrent meningitis and high-resolution computed tomography (HRCT) reveals a small opacity in the oval window area. Imaging will also reveal whether the middle ear and mastoid are full of CSF. All patients with IP-I and recurrent meningitis who have normal tympanic membranes but fluid filling the middle ear and mastoid should have an exploration of the middle ear with special attention to the stapes footplate.

It is interesting to note that meningitis is often reported in IP-I cases. IP-III cases almost always have a CSF gusher during CI surgery or stapedotomy but meningitis is very rarely reported in these patients.[1,9] This is most likely due to the fact that the stapes footplate is thicker at birth in these patients and thus it is less likely to develop a defect caused by high CSF pressure.

Management: Meningitis in IP-I necessitates an endaural exploration of the middle ear. Usually, there is a cystic structure of variable size originating from the stapes footplate. It is better to keep the stapes in place and insert a large piece of fascia or muscle tissue through the defect into the vestibule, using the stapes to keep the soft tissue in place. Tissue glue is then used after soft tissue placement to further anchor the tissue. In some cases, it may be necessary to remove the stapes and obliterate the defect with more pieces of fascia and bony tissue. The incus can be inserted into the oval window and may provide a tight seal if all else fails.

### *Incomplete Partition Type II*

In a type II cochlear malformation, the apical part of the modiolus is defective but the basal part is anatomically normal (Fig. 9.5D). This is the type of cochlear anomaly that was originally described by Carlo Mondini and together with a minimally dilated vestibule and a large vestibular aqueduct (LVA; Fig. 9.5D) constitutes the triad of the Mondini deformity. The authors, together with Phelps et al.[9] and Lo,[12] stress the importance of using this particular name only if the above mentioned triad of malformations is present. The apical part of the modiolus and the corresponding interscalar septa are defective. This gives the apex of the cochlea a cystic appearance due to the confluence of middle and apical turns. The external dimensions of the cochlea (height and diameter) are not different from that seen in normal cases.[8] As this study

pointed out, it is not correct to define this anomaly as a cochlea with 1.5 turns.[8] This description should only be used for cochlear hypoplasia.

*Audiological findings*: These patients do not have a characteristic hearing level, as their audiometric threshold testing varies from normal to profound. The hearing loss can be symmetric or asymmetric. The most characteristic audiological finding is the air–bone gap particularly present at low frequencies. Govaerts et al.[13] indicated that the conductive component could not be explained by middle ear impedance problems, such as effusion. Tympanometry is normal in the absence of otitis media and acoustic reflexes are generally present. The cause of the air–bone gap in these children is likely due to a "third window" effect from the large vestibular aqueduct, and can resemble the audiometric findings in superior canal dehiscence syndrome.

These patients can experience progressive hearing loss throughout their lifetime. At birth, they may have normal hearing but usually there is progressive hearing loss over time. The LVA transmits the high CSF pressure to the inner ear and may cause progressive hair cell damage. Pulsation seen during the surgery when the cochleostomy is created demonstrates the high intracochlear pressure transmitted by LVA. Head trauma may exacerbate this hearing loss and these children are advised to avoid head trauma as much as possible. Sudden hearing loss can also be seen. Because of the progressive nature of the hearing loss, these patients usually have good language development. Papsin[14] also reported that children with incomplete partition are typically implanted older than other cases for the aforementioned reason.

*Management*: At a young age, these patients may have near normal hearing and usually do not require amplification initially. With progressive hearing loss, they become candidates for hearing aid. Usually the progression in hearing loss continues, ultimately creating a need for CI at some point in the future. What causes this progression remains unknown. A role for head trauma has been suggested, and these patients are advised to avoid trauma by wearing helmets when playing sports and avoiding contact sports completely.

During surgery, a facial recess approach was successfully used in all 47 patients who underwent CI surgery at Hacettepe University. This standard approach could be used in all patients because the cochlea and labyrinth had normal external dimensions. As a result, the facial nerve does not typically have an abnormal course that would prevent using the facial recess approach.

Out of 47 patients operated on in our department, 22 patients had no CSF leakage, 19 patients had CSF oozing, and 6 patients had a gusher. The majority had strong pulsation at the time of cochleostomy, likely explaining the progressive nature of the hearing loss. Head trauma may cause increase in CSF pressure resulting in progressive or sudden HL.

A gusher is more common in IP-I or IP-III, but it may occur in IP-II as well. This observation demonstrates that there is a defect in the modiolus. A LVA cannot explain CSF leakage. The cochleostomy should be closed completely because there is a risk of recurrent meningitis if CSF leakage persists around the electrode in the cochleostomy.

*Electrode choice*: The basal part of the modiolus is normal. All kinds of electrodes (modiolar hugging, straight) can be used. Because of the risk of CSF leakage and sometimes a severe gusher, electrodes with cork type stopper may be advantageous. The surgeon must be prepared to use the measures as described in the IP-I section to manage the CSF gusher.

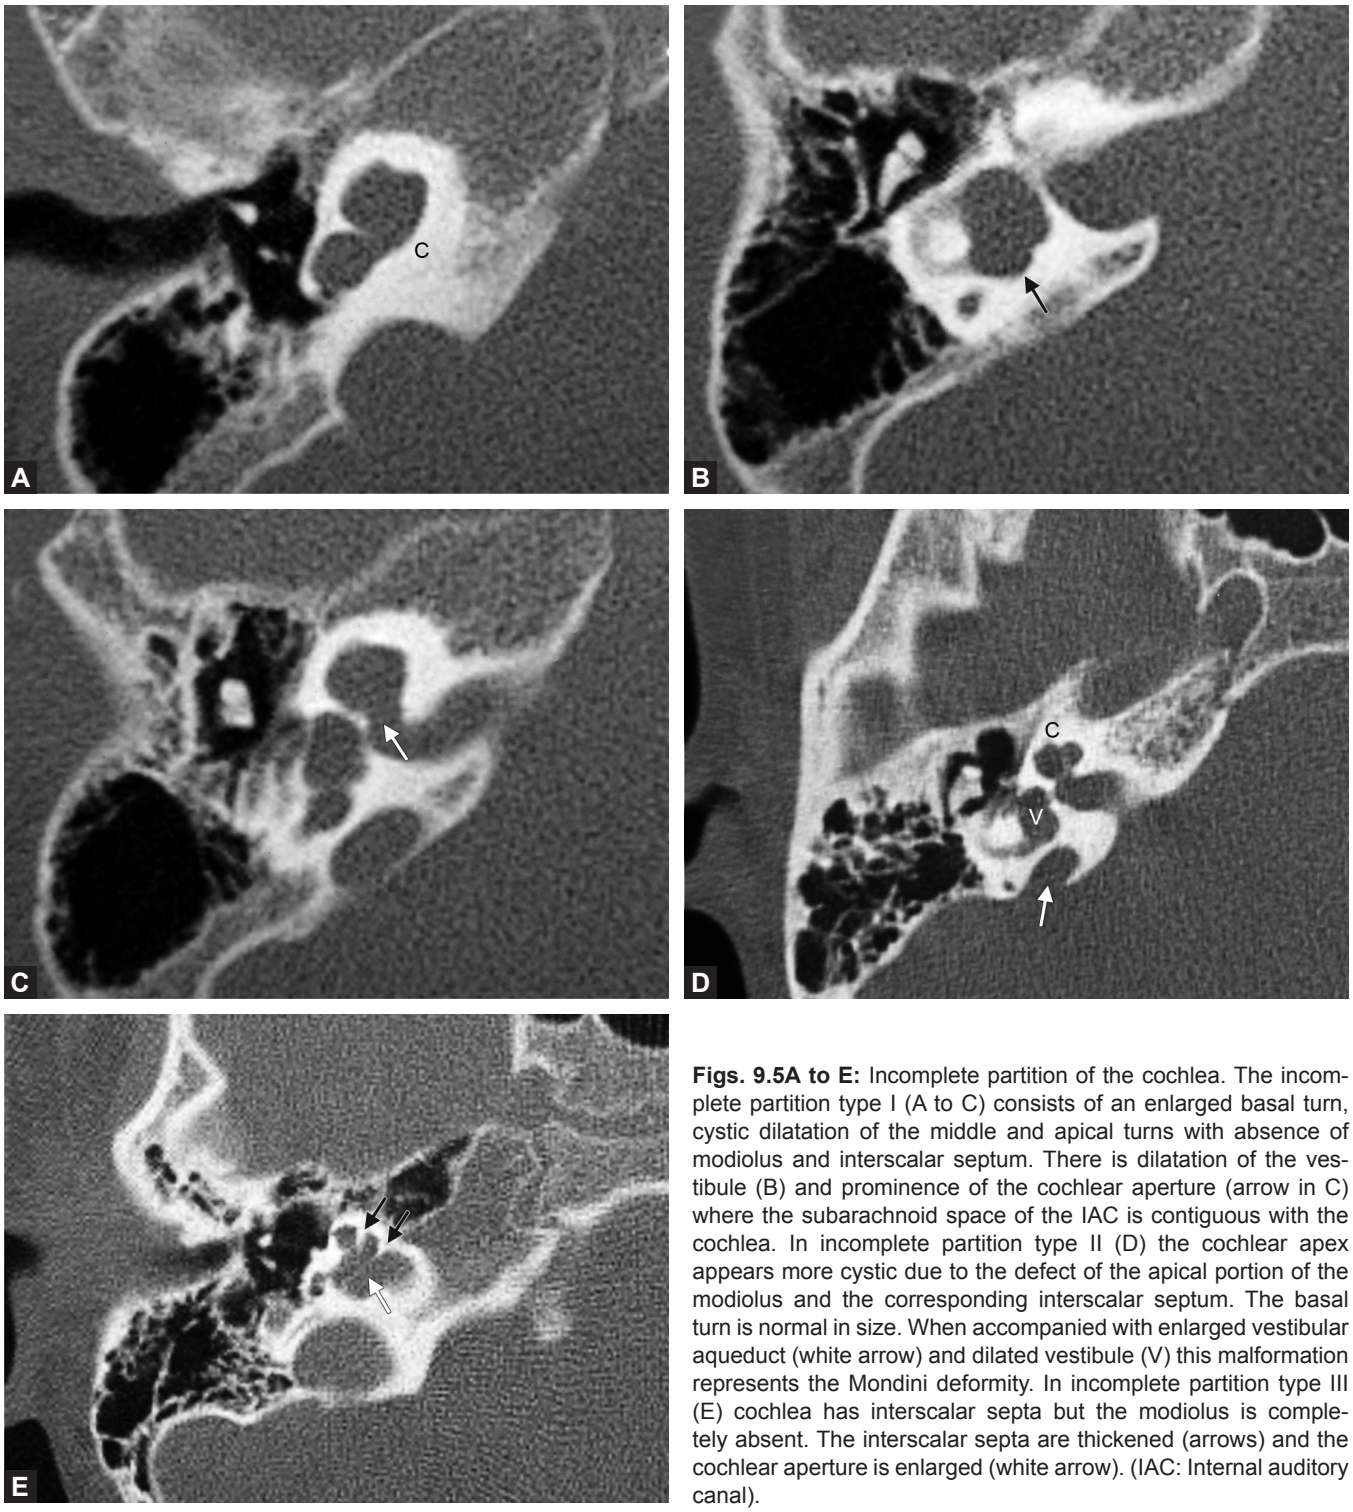
An X-ray can be taken after surgery, as there is a low risk for the electrode to enter the IAC.

### *Incomplete Partition Type III*

The cochlea in incomplete partition type III (IP-III) has an interscalar septa but the modiolus is completely absent (Fig. 9.5E). IP-III cochlear malformation is the type of anomaly present in X-linked deafness, which was described by Nance et al.[15] for the first time in 1971. Phelps et al.[16]described the HRCT findings associated with this condition for the first time, and this characteristic deformity was included under the category of incomplete partition deformities for the first time by Sennaroglu et al. in 2006.[17]

This anomaly is the rarest form of incomplete partition cases. According to the radiological database in Hacettepe University Department of Otolaryngology, IP-III constitutes 2% of the inner ear malformation group.

*Radiology*: Phelps et al.[16] reported that there is a bulbous IAC, incomplete separation of the coils of the cochlea from the internal auditory canal and widened first and second parts of the intratemporal facial nerve canal with a less acute angle between them. Talbot and Wilson[18] later added that the modiolus is absent and there is a more medial origin of the vestibular aqueduct with varying degrees of dilatation.



**Figs. 9.5A to E:** Incomplete partition of the cochlea. The incomplete partition type I (A to C) consists of an enlarged basal turn, cystic dilatation of the middle and apical turns with absence of modiolus and interscalar septum. There is dilatation of the vestibule (B) and prominence of the cochlear aperture (arrow in C) where the subarachnoid space of the IAC is contiguous with the cochlea. In incomplete partition type II (D) the cochlear apex appears more cystic due to the defect of the apical portion of the modiolus and the corresponding interscalar septum. The basal turn is normal in size. When accompanied with enlarged vestibular aqueduct (white arrow) and dilated vestibule (V) this malformation represents the Mondini deformity. In incomplete partition type III (E) cochlea has interscalar septa but the modiolus is completely absent. The interscalar septa are thickened (arrows) and the cochlear aperture is enlarged (white arrow). (IAC: Internal auditory canal).

In addition, Sennaroglu et al.[19] reported that in this deformity the interscalar septa are present but the modiolus is completely absent (Figs. 9.6A to F). The cochlea is located directly at the lateral end of the internal auditory canal instead of its usual anterolateral position. This gives the cochlea a characteristic appearance. From an earlier

study, the external dimensions of the cochlea (height and diameter) were found to be similar to the normal cochlea.[17] Apart from these features it was reported that the labyrinthine segment of the facial nerve has a more superior position in relation to cochlea;[19] the labyrinthine segment is located almost above the cochlea. If the axial sections are followed from top to bottom, the first structure that is identified in these cases is the labyrinthine segment of the facial nerve. In addition, there is a much thinner otic capsule around the cochlea and vestibule. The interscalar septum appears to be thicker than normal.

*Audiological findings*: There may be two types of hearing loss associated with this malformation.

Mixed-type hearing loss: The SNHL component is most likely due to the modiolar defect, whereas the conductive component may be due to stapedial fixation or third window phenomenon. The air–bone gap usually involves high frequencies as well as low frequencies. Snik et al.[20] suggest that the air–bone gap is associated with a third window phenomenon. They reported that because of the congenital malformation, the audiovestibular system functioned more effectively than it normally would, thus leading to better bone conduction levels. Their study revealed that audiological studies were in accordance with pure SNHL and air–bone gap in the audiogram did not signify a conductive hearing loss component.

Profound SNHL: The severity of this type of hearing loss may vary. It is most likely due to the absence of the modiolus, and in this situation, CI surgery is the primary means of restoring hearing.

*Management*: Mixed hearing loss gives the impression of stapedial fixation. Stapedotomy results in a severe gusher and further SNHL, and thus should be avoided. Patients with severe HL are candidates for CI.

Because of the absent modiolous during the surgery of IP-III, two serious problems may occur:

1. Gusher: These patients may have severe gusher during surgery, because of the large defect between the cochlea and the IAC. If it is not properly sealed, the postoperative CSF leakage may lead to recurrent meningitis. Ideally, the size of the cochleostomy should be slightly larger than the electrode in order to allow for soft tissue to be placed around the electrode. Passing the electrode through a tiny piece of fascia and inserting this together with the electrode may further improve the seal at the cochleostomy site

   An electrode with a "cork" type stopper (standard electrode 25 mm) provides for proper sealing of the cochleostomy (to prevent CSF fistula postoperatively) and also makes one full turn around the cochlea.
2. Electrode misplacement into the IAC: Because of the defective modiolus, electrodes with complete rings or contact surface on both sides may provide better stimulation. The probability of the longer electrodes entering the IAC is more than the shorter electrodes. Therefore, an electrode with full rings or contact surfaces on both sides, which will make only one turn around, the cochlea appears to be sufficient.

*Electrode choice*: Modiolar hugging electrodes have a tendency to go toward the center of the cochlea. As there is no modiolus in IP-III, this may result in misplacement into the IAC. The fact that the cochlea is located directly at the lateral end of the IAC rather than the usual anterolateral position may facilitate displacement of the electrode into the IAC during insertion. Longer electrodes may also be misplaced into the IAC. If a modiolar hugging electrode is used and postoperative X-ray demonstrates that the electrode is inside of the IAC, the facial nerve may be damaged when the electrode is removed. Thus, straight electrodes that are 25 mm in length and provide one full turn around the cochlea are preferable.

An X-ray should be taken in the surgery to confirm placement of the electrode. If the electrode is discovered to be in the IAC, it should be repositioned during surgery.

As mentioned before, spontaneous CSF leakage through the oval window is more frequently seen and reported in IP-I, even though both IP-I and IP-III are associated with high volume CSF leakage on cochleostomy. This may be secondary to the thicker stapes footplate that is present in IP-III.

## HYPOPLASIA

### Radiology and Definition

Cochlear hypoplasia represents a group of cochlear malformations in which the dimensions are less than those of a normal cochlea with internal architecture deformities. In cochlear hypoplasia, there is clear differentiation between the cochlea and vestibule and both of these structures occupy their respective locations relative to the IAC. In this regards, they are different than the rudimentary otocyst and CC. In smaller cochlea, it is usually difficult to count the number of turns with CT and/or MRI. But the

definition "cochlea with 1.5 turns" should be used for hypoplasia (particularly type III), rather than for IP-II cochlea. According to radiologic and histopathologic literature, as well as our own radiological data, four different types of cochlear hypoplasia can be identified:

- Type I (bud-like cochlea): The cochlea is like a small bud, round or ovoid in shape, arising from the IAC (Fig. 9.6A). Internal architecture is severely deformed; no modiolus or interscalar septa can be identified
- Type II (cystic hypoplastic cochlea): The cochlea is smaller in its dimensions with no modiolus and interscalar septa, but its external architecture is normal (Figs. 9.6B and C). There is a wide connection with the IAC. The vestibular aqueduct may be enlarged and the vestibule may be dilated (Fig. 9.6C). In this type of hypoplasia, gusher and unintentional entry of the CI electrode into IAC is possible
- Type III (cochlea with <2 turns): The cochlea has a short modiolus and the overall length of the interscalar septa is reduced, resulting in fewer turns (i.e. <2 turns). The internal (modiolus, interscalar septa) and external architecture are similar to that of a normal cochlea, but the dimensions are smaller and number of turns are fewer (Fig. 9.6D). The vestibule and the SCCs are hypoplastic. The CA may be hypoplastic or aplastic (Fig. 9.6D)
- Type IV (cochlea with hypoplastic middle and apical turns): The cochlea has a basal turn which is nearly normal in size and appearance; however, the middle and apical turns are severely hypoplastic and located anterior and medially rather than in their normal central position (Figs. 9.6E and F). The labyrinthine segment of the facial nerve may be located anterior to the cochlea rather than in its usual location.

## Audiological Findings

These patients will present with a range of thresholds on audiometric testing. Decision-making about the amplification options may be difficult, particularly in patients with a hypoplastic cochlear nerve. Patients with mild to moderate hearing loss can be habilitated with hearing aids and have near normal to normal language development. The majority of cochlear hypoplasia patients have severe profound hearing loss where a CI would be a reasonable option.

Some patients have CA aplasia with cochlear nerve aplasia and thus, an ABI would be the best hearing facilitative option. Other patients with cochlear hypoplasia have hypoplastic cochlear nerves. The best option in these cases is to use CI in the better-developed side or the side that is more suitable to CI surgery. If there is limited hearing and language development, an ABI should be considered for the contralateral side.

Some cases of hypoplasia (particularly hypoplasia type IV) may have mixed hearing loss in which the conductive component is due to stapedial fixation.

## Management

### *Cases with Mixed Type of Hearing Loss*

These patients may benefit from stapedotomy. This can be done in childhood if the family is motivated and can result in enhanced oral language development with or without hearing aid usage.

### *Cochlear Implantation*

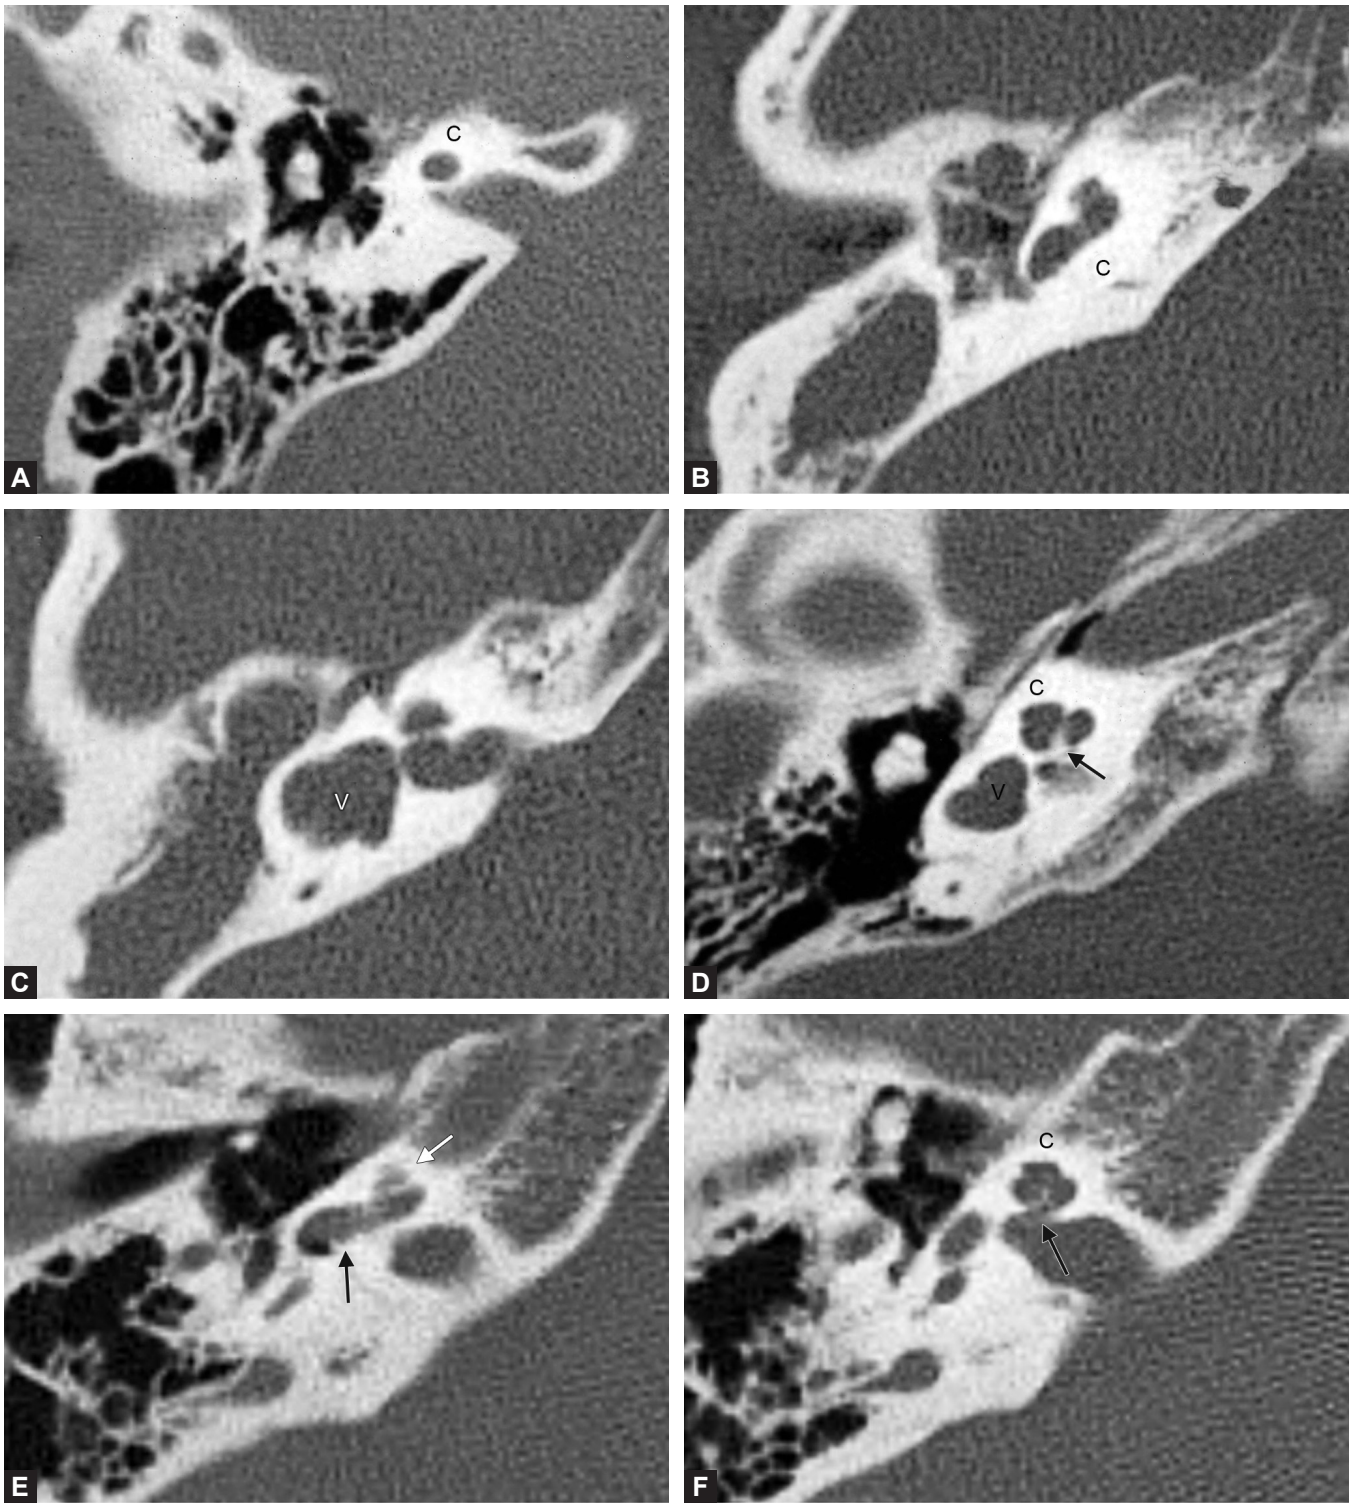
A transmastoid facial recess approach can be used in the majority of these patients. During surgery, facial nerve malposition is to be expected because of labyrinthine abnormalities. We have noticed that if the lateral SCC is not developed properly, the facial nerve may be in an unusual location. In one patient, e.g. we found that the facial nerve was already dehiscent and lying in the area of the facial recess.

If the cochlea is small, the promontory may not have the usual protuberance and it may be difficult to visualize the promontory and round window through the facial recess. In these situations, an additional transcanal approach may be necessary to provide better access to the hypoplastic cochlea.

## Electrode Choice

As the cochlea is smaller than normal, the length and cross-sectional area of the cochlear duct are smaller when compared to that of a normal cochlea. Thinner and shorter electrodes should, therefore, be used. A standard electrode may be too large for the cochlea and it may not be possible to obtain a full insertion.

Hypoplasia type II has the possibility of CSF leakage. A short electrode with a stopper type silicon ring may be used along with other measures for managing a CSF gusher. Because of the possibility that a full insertion may not be obtained, a shorter version of the electrode (19 mm) with a cork type silicon stopper is useful for cochlear implantation in a hypoplastic cochlea (particularly type II).



**Figs. 9.6A to F:** Cochlear hypoplasia can be seen in four types. Type I (A) anomaly is a 'bud like' cochlea where a very small round/ovoid structure is seen instead of a fully developed cochlea. Type II hypoplastic cochlea (B and C) is small in size with no modiolus and interscalar septa. The vestibule may be enlarged (C).Type III cochlear hypoplasia (D) has a short modiolus with shortened interscalar septa. The internal and external architecture however is similar to a normal cochlea. Cochlear aperture is aplastic (black arrow). Type IV cochlear hypoplasia (E and F) is diagnosed when the cochlea has a normal basal turn (black arrow) but hypoplastic middle and apical turns (white arrow).

It should be noted that the anatomy is particularly distorted in type I. Even though CI can be successfully placed into a hypoplastic cochlea, limited language development is expected. During the initial consent, the family should be informed that ABI surgery will most likely be required on the contralateral side in future.

### Auditory Brainstem Implantation

Auditory brainstem implantation (ABI) is indicated for patients with aplastic CA and cochlear nerve aplasia. As indicated before, if the child does not demonstrate significant improvement with CI, ABI should be considered as soon as possible on the contralateral side.

## LARGE VESTIBULAR AQUEDUCT

This describes the presence of an enlarged vestibular aqueduct (i.e. the midpoint between posterior labyrinth and operculum is >1.5 mm) in the presence of a normal cochlea, vestibule, and SCC (Figs. 9.7A and B).

Audiological presentation and management is similar to that of IP-II.

## COCHLEAR APERTURE ABNORMALITIES

### Definition and Radiology

The CA, cochlear fossette, or cochlear nerve canal transmits the cochlear nerve from the IAC to the cochlea. This can be visualized in the midmodiolar view as well as coronal sections on HRCT (Fig. 9.8A).

The CA is considered hypoplastic if there is a narrow opening between the cochlea and IAC (Fig. 9.8B), with a width of <1.4 mm.[21] The CA is considered to be aplastic when the canal is completely replaced by bone or there is no canal on midmodiolar view (Fig. 9.8C).

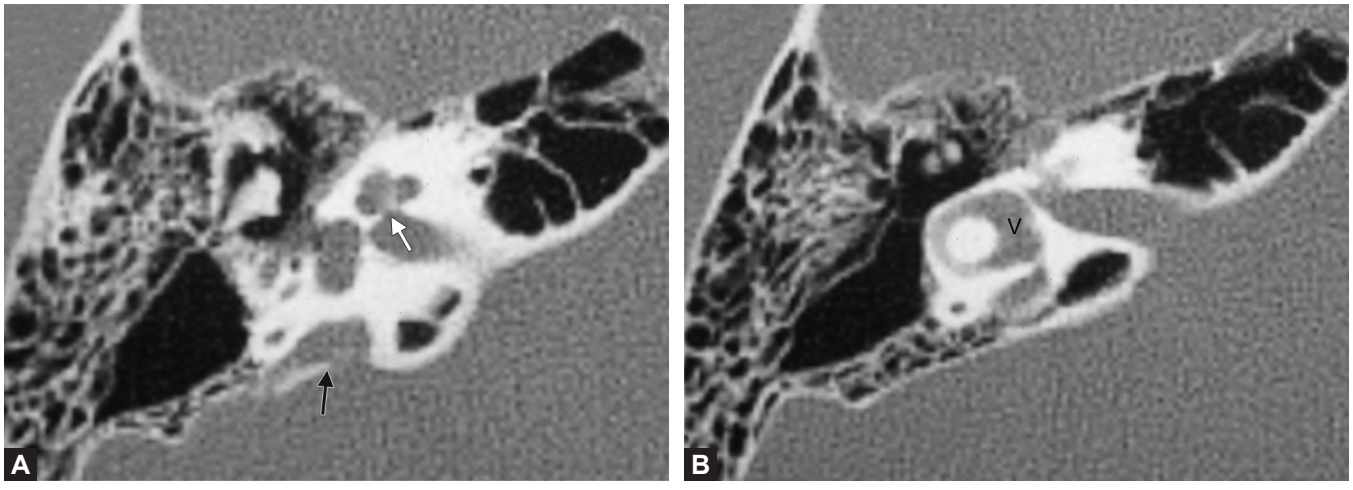
When the CA is aplastic, the cochlear nerve is typically aplastic as well. In situations where the CA is hypoplastic the nerve may be hypoplastic or aplastic.

CA hypoplasia and aplasia usually accompanies cochlear hypoplasia, but it is also possible to see this anomaly in an otherwise normal cochlea.

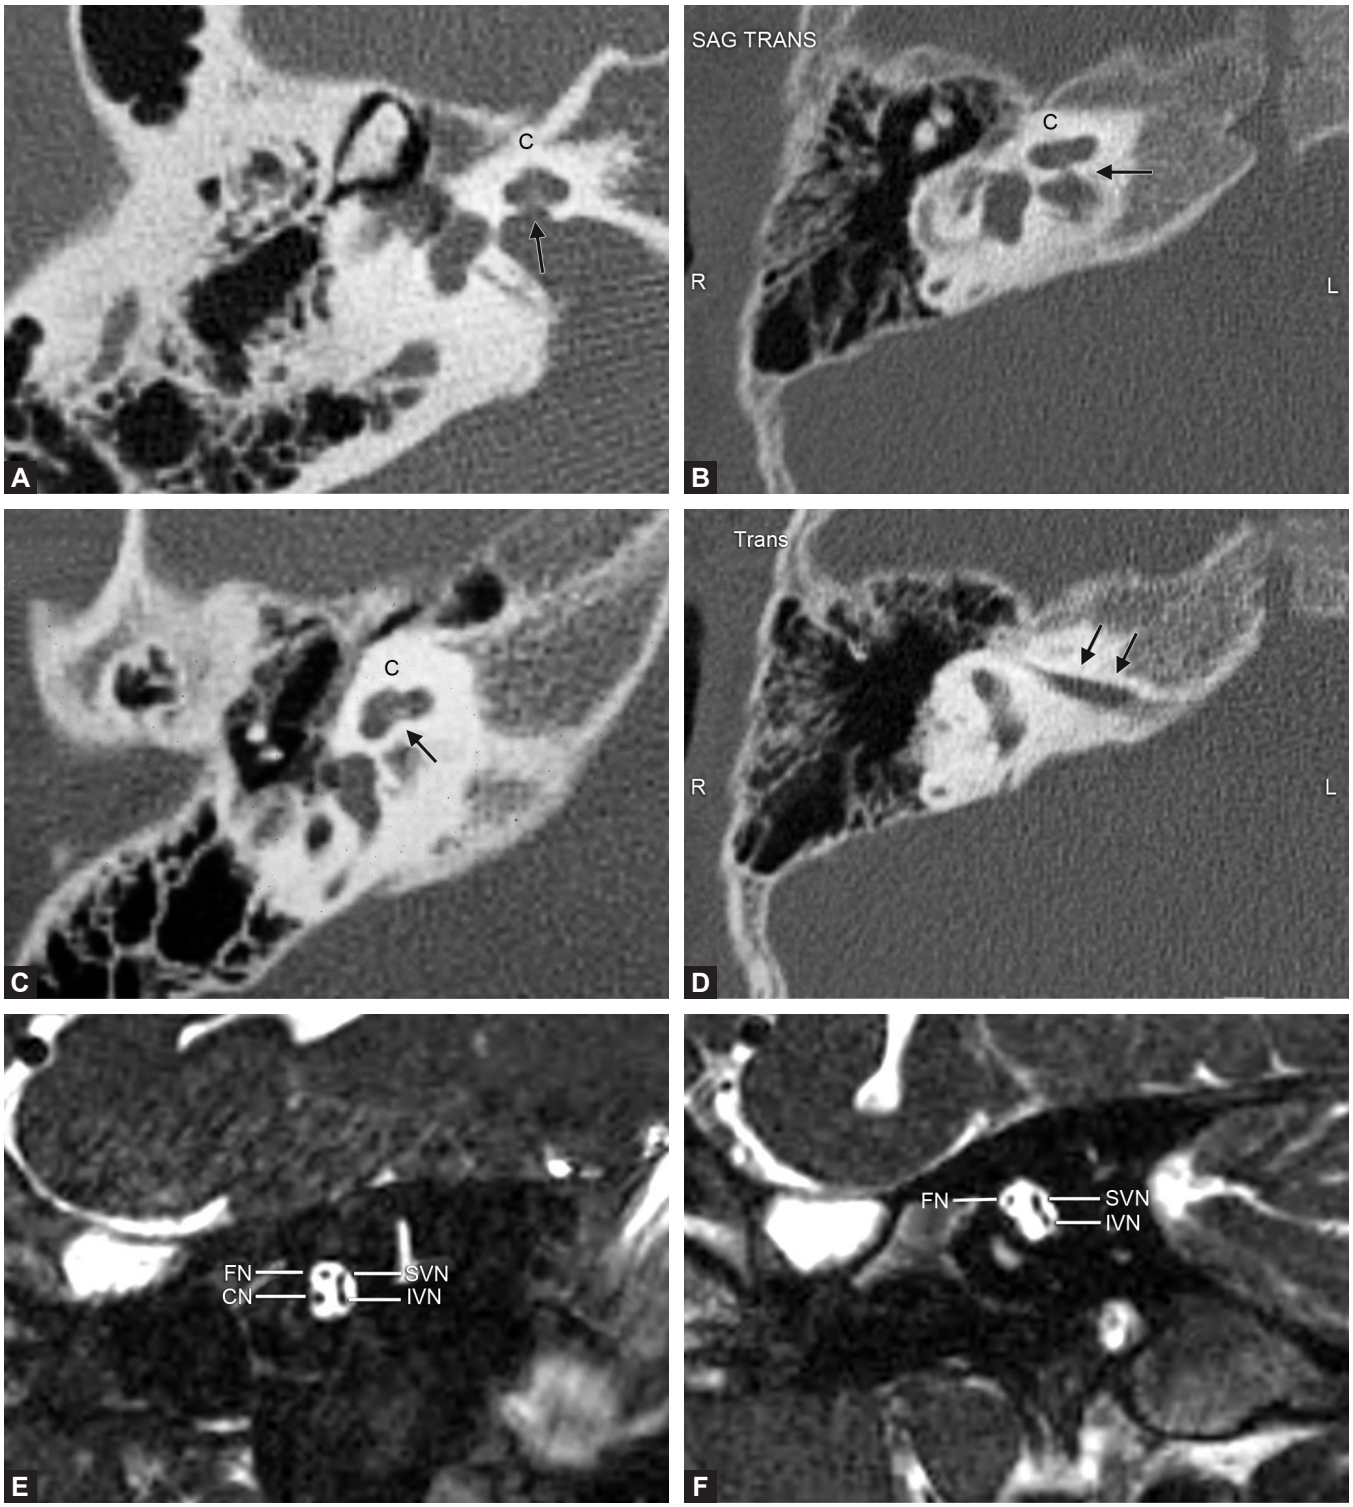
CA abnormalities may be accompanied by a narrow IAC on HRCT. The IAC is considered narrow if the width of the midpoint of the IAC is <2.5 mm (Fig. 9.8D), and can accompany other malformations or with a normal cochlea. In cases of narrow IAC, there is a possibility that the cochlear nerve is aplastic or hypoplastic and therefore imaging with MRI should be obtained. Axial and sagittal oblique high T2-weighted images (i.e. CISS and FIESTA) should be carefully investigated to determine whether CN aplasia or hypoplasia is present. On sagittal oblique MR sections, four distinct nerves can be visualized in the IAC (Fig. 9.8E). In CN aplasia, no nerve can be identified in the anterior-inferior part of the IAC (Fig. 9.8F).

### Audiological Findings

Severe to profound SNHL is usually present. As the cochlea is normal, otoacoustic emissions (OAE) may be present and the child may pass newborn hearing screening if far field auditory evoked responses are not measured. Their hearing loss is typically discovered later



**Figs. 9.7A and B:** A large vestibular aqueduct case has a dilated vestibular aqueduct (A) (black arrow) with normal appearing cochlea (white arrow) and vestibule (B).



**Figs. 9.8A to F:** Normal appearance of the cochlear aperture (arrow) on a transvers CT section from the midmodiolar level (A). Narrowing of the cochlear aperture (arrow) consistent with hypoplasia of the aperture (B). Complete obliteration of the canal (arrow) diagnostic of cochlear aperture aplasia (C). Narrow IAC (arrows) (D). Sagittal oblique MRI of the temporal bone showing a normal size cochlear nerve on the right (E) and absence of the cochlear nerve on the left (F). (FN: Facial nerve; CN: Cochlear nerve; SVN: Superior vestibular nerve; IVN: Inferior vestibular nerve; IAC: Internal auditory canal).

on in childhood based on the family's concerns of lack of sound awareness and language development. If the newborn screening protocol involves OAE and automated ABR, this malformation can be diagnosed during infancy. Diagnostic audiological evaluation will reveal profound hearing loss.

### Management

Hearing aids usually do not provide sufficient amplification in patients with CA hypoplasia and aplasia. In patients with bilateral hypoplastic CA with hypoplastic cochlear nerve, hearing aid trial is necessary. If this does not provide adequate functional hearing, these patients usually become candidates for CI. The family should be counseled that if CI does not provide sufficient hearing in terms of auditory perception, contralateral ABI may be necessary to achieve improved audiologic and language outcomes.

In CA aplasia, ABI is indicated as first-line therapy.

## RESULTS OF IMPLANTATION IN INNER EAR MALFORMATIONS

### Cochlear Implantation

It is difficult to assess audiological results across cohorts from different institutions according to the classification system presented here. Papsin[14] reported that patients with incomplete partition had consistently higher scores than other groups on both open-set and closed-set word testing postoperatively. Children with narrow IACs or cochlear canals performed significantly worse than children with normal caliber IACs and cochlear canals. Additionally, children with hypoplastic cochlea and CC also had worse outcomes. Wermeskerken et al.[22] reported that the ability to develop open-set speech perception in incomplete partition cases is similar to patients with normal anatomy after an average follow-up period of 2 years. Eisenman et al.[23] reported that children with severe malformations performed more poorly than those with mild malformations. Their results indicated that children with malformed cochleae demonstrate significant improvements in their speech recognition skills with a CI in comparison with their preoperative performance with hearing aids. But, the rate of postimplantation improvement was slower than that of children with radiographically normal cochleae. After 2 years there was no difference. Berrettini et al.[24] reported that out of four IP-I cases, two had good results. They concluded that the results of CI in IP-I are variable, but in many cases satisfactory, and are mainly related to the surgical placement of the electrode and residual neural nerve fibers.

Because of the progressive nature of hearing loss, hearing and language outcome with CI is the best in IP-II and LVA groups. In patients at Hacettepe University after 3 years of CI use, we have seen that IP-II and LVA patients have no statistically significant differences in the Meaningful Auditory Integration Scale (MAIS), pattern perception or sentence recognition tests as compared to their age-matched peer controls. Both groups of patients develop spoken language (expressive and receptive) with an increasing rate similar to their peers.

The majority of IP-I and CC patients show significant improvement on postoperative test scores and therefore benefit from CI. Out of six patients at our institution with CC, one patient had excellent word recognition abilities with the CI. The remaining four patients had moderate development, and one patient showed unsatisfactory development. After CI, 70% of IP-I patients had sentence recognition between 70% and100%, whereas 20% of these patients could not complete the test. Children who had at least 70% sentence recognition were also able to develop spoken language by using only auditory inputs. However, in order to develop syntactic elements of spoken language, these patients needed intensive formal therapy programs and visual cues such as speech reading, symbols, and pictures.

Fifty percent of the children with hypoplastic cochlea were able to obtain open set discrimination scores with CI. They developed spoken language similar to other children who underwent cochlear implantation. The remaining 50% of patients with hypoplastic cochlear nerve or type I hypoplasia had insufficient audiologic development and were only able to detect some environmental sounds and differentiate and imitate the pattern changes in words. Some of these patients went on to receive an ABI in their contralateral ear.

### Auditory Brainstem Implantation

There are a limited number of articles regarding the outcomes of ABI in children. Colletti L[25] reported the initial auditory results of ABI in children. All of the 14 prelingually deafened children in this study developed environmental sound awareness, detection of instrumental sounds and lip-reading enhancement after ABI surgery. Three

prelingual children achieved bisyllabic word recognition as well understanding of simple commands. Eisenberg et al.[26] reported the results of a 3-year-old boy who received an ABI 1 year before. They concluded that his audiological results were at the median of the range shown for a small sample of CI children implanted at a similar age. Goffi-Gomez et al.[27] reported their ABI experience in three children with inner ear malformations. All of the patients use their device daily with improvement in their auditory skills. Similarly, Choi et al.[28] reported that in their experience with nontumor patients, all of the children demonstrated an improvement in auditory performance. In our preliminary report with 11 children,[29] we indicated that six children gained basic audiologic functions, were able to recognize and discriminate sounds and could identify environmental sounds such as a doorbell and telephone ring by the third month of ABI use. In the consensus statement written by Sennaroglu et al.,[30] it was indicated that the minimum age at implantation should be between 1 and 1.5 years old and that additional handicaps decreased the likelihood of favorable audiological outcomes with ABI in children.

At the present time, 48 children with various inner ear malformations have received an ABI in Hacettepe University. When the long terms results are analyzed, it may be evident that it is possible to obtain closed and open set discrimination scores with ABI. Of children with more than 1 year of ABI use, 18 patients had 100% pattern discrimination and the remaining 11 patients had scores between 33% and 96%. In terms of multisyllabic words, 11 patients had 100% discrimination score, 8 patients had scores between 25% and 92%. Twelve patients achieved open-set scores above 50%, with two patients achieving 100%.

When different malformations were taken into consideration, patients with CC or cochlear aplasia had the best hearing thresholds with ABI. When we examined the influence of the type of malformation on audiological and language outcomes, again we found that patients with CC deformity have the best scores in all tests. Additionally, patients with CVN identified on MRI were found to have better hearing thresholds than patients with CVN agenesia.

CHAPTER

# Diagnostic Approach to Common Pediatric Otologic Problems

10

*Adrian L James, Sharon L Cushing, Blake C Papsin*

## INTRODUCTION

Otologic diagnosis aims to identify the relevant features required to establish accurate diagnosis, to assess the severity of the problem and to determine the appropriate timeline for treatment. Ear problems in young children present specific difficulties to the clinician in this regard: not only is the narrow ear canal more difficult to inspect, the child may be unable to provide any description of their symptoms or to cooperate with examination. Furthermore, some pediatric otologic conditions exist or progress in relative silence and may only be discovered incidentally during routine examination or audiometry. A robust diagnostic approach is needed in order to identify these conditions and determine which need further management.

The aim of this chapter is to outline the diagnostic approach to assessment of a child presenting to an otolaryngology clinic with an ear-related problem. Emphasis is given to the differences between the assessment of children and adults, and to the common symptoms and signs that indicate an otologic problem. Considerations for the effective examination and investigation of the child's ear are described. More detailed description of the specific presenting and diagnostic features of these conditions can be found in relevant chapters throughout this volume.

## DIFFERENCES BETWEEN THE APPROACH TO ADULT AND PEDIATRIC OTOLOGIC DIAGNOSIS

Fundamental differences distinguish children from adults in the presentation and diagnosis of otologic disorders. In keeping with other pediatric conditions, the history of the presenting complaint is typically not obtained from the patient but from the parent, potentially leading to misinterpretation of the nature or severity of problems. This difficulty is compounded by seemingly greater tolerance, or less awareness, by children of some symptoms, notably hearing loss. This is particularly true if the onset of such symptoms occurs before the acquisition of the necessary language skills to communicate them. As an example, before newborn hearing screening, profound unilateral congenital hearing loss would often not be identified until most children were over 5 years of age.[1]

In addition to the difficulty of ascertaining symptoms correctly, complete examination and testing can be limited by the child's ability to cooperate. The tympanic membrane cannot be assessed easily when a child is resisting examination and moving, and inflammation cannot be assessed reliably during crying: just as the face becomes red in a crying baby, so does the eardrum! Wax obstruction provides an additional challenge, as tolerance of removal may be limited. Audiometric assessment has to be modified according to the child's stage of development (*see* Chapter 14), with behavioral testing typically not possible until after 9 months of age. Only limited assessment of vestibular function is practical under 4 years of age and sedation or anesthesia typically required for diagnostic imaging up to age around 6 (for CT) to 8 years (for MRI).

Finally, a different spectrum of otologic problems is seen in children from adults with initial presentation of congenital anomalies, and differing acquired pathologies.

Profound prelingual hearing loss provides very specific diagnostic and therapeutic priorities. Acute otitis media (AOM) and otitis media with effusion are much more common, yet classic otologic and neuro-otologic conditions such as otosclerosis, glomus jugulare, Meniere's disease, and acoustic neuroma are very rarely seen in children. Thus, a diagnostic approach specific to conditions of childhood is required. Tips to facilitate general assessment of the child's ear are described below, followed by important aspects of specific presenting complaints.

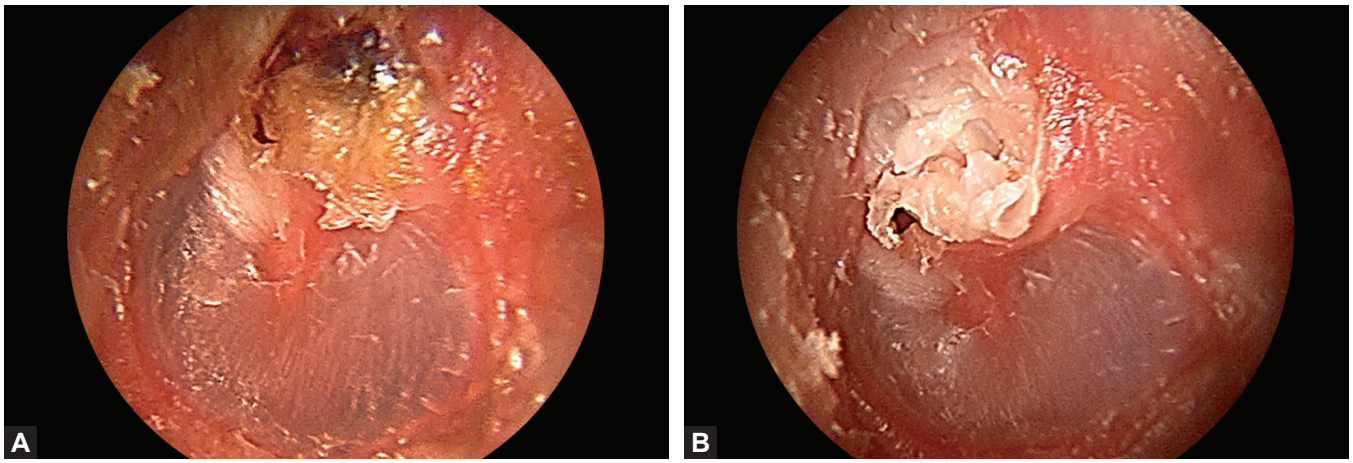
## EXAMINATION OF THE EAR IN A YOUNG CHILD

- Take care not to hurt the child: this may preclude subsequent assessment
- Position the child sitting sideways on the lap of their guardian
- Ask them to embrace the child with one hand holding the child's head to their chest, and the other hand to hold the child's arms to their side, as demonstrated in Figure 10.1. This comforting stable position restrains the child with the ear canal rotated up into an optimal position for examination
- First inspect the external ear for any dysmorphisms including preauricular sinus anterosuperior to the root of the helix or, much less commonly, first branchial sinus anteroinferior to the lobule. Consider checking sites of previous surgical incisions
- An outstanding ear with swelling or redness over the mastoid suggests mastoiditis.[2] This will be tender, but if possible, check for fluctuance that may require drainage, or alternatively for an inflamed postauricular lymph node that will have a more well-defined edge
- Look through the otoscope while positioning it in the ear canal so as to keep it within the lumen and avoid trauma—the bony meatus is sensitive. With care, it may be possible to navigate around wax, so as not to push it into the meatus and obstruct the view. Note the diameter and length of the meatus. In comparison with the tympanic membrane, a false fundus is featureless and laterally placed. Note the presence of wax obstruction, foreign body, purulent secretions, or meatal skin infection
- Always begin with the larger otoscopic speculum that provides a better view. Small speculae are only necessary in a particularly narrow meatus (e.g. neonates or Down syndrome) or to see around wax.

**Fig. 10.1:** This comforting stable position restrains the child with the ear canal rotated up into an optimal position for examination.

### Assessment of the Tympanic Membrane

- Use a systematic approach to examine the entire tympanic membrane. The pars flaccida must be inspected for the presence of retraction or cholesteatoma (Figs. 10.2A and B) and the anterosuperior quadrant must be inspected for an underlying congenital cholesteatoma (Fig. 10.3). Perforation or retraction may involve any part of the pars tensa. The example in Figure 10.4 shows a perforation as well as myringosclerosis that can be distinguished from cholesteatoma by its sharper edge and brighter and more superficial whiteness. Assess for prominent vascularity implying inflammation from infection and the presence of an effusion that may look purulent, suggesting AOM (Fig. 10.5). A serous or mucoid effusion without inflammation implies OME (Fig. 10.6)
- A retracted tympanic membrane requires careful assessment as shown in Figures 10.7A to D. Features to look for in a retraction include the following:
  - Are the limits of the retraction visible?
  - Is desquamated keratin trapped within the retraction?
  - Is there any sign of infection or granulation associated with the retraction?
  - Does the reaction involve any of the ossicles? Which ossicles, and how much contact is there? Is there any ossicular erosion?
  - Does the retraction remain adherent to middle ear structures during pneumatic otoscopy or Valsalva maneuver?



**Figs. 10.2A and B:** Cholesteatoma arising from the pars flaccida of left ear. (A) Cholesteatoma is visible under the anterosuperior quadrant of the pars tensa anterior to the malleus handle. The origin of the cholesteatoma from retraction of the pars flaccida is obscured by dry keratin debris that has the misleading appearance of cerumen. (B) After removal of the dry keratin plug, the pars flaccida defect containing moist white keratin debris is clearly visible. This demonstrates the importance of cleaning and examining the pars flaccida area carefully.

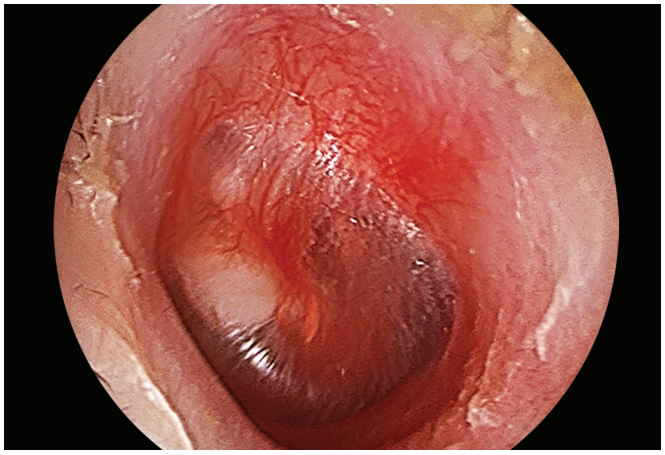


**Fig. 10.3:** Congenital cholesteatoma of the left ear. A rounded white 'pearl' of cholesteatoma is present under the anterosuperior quadrant of a normal tympanic membrane. This area can be partially obscured by the curvature of the ear canal so must be inspected carefully in children.

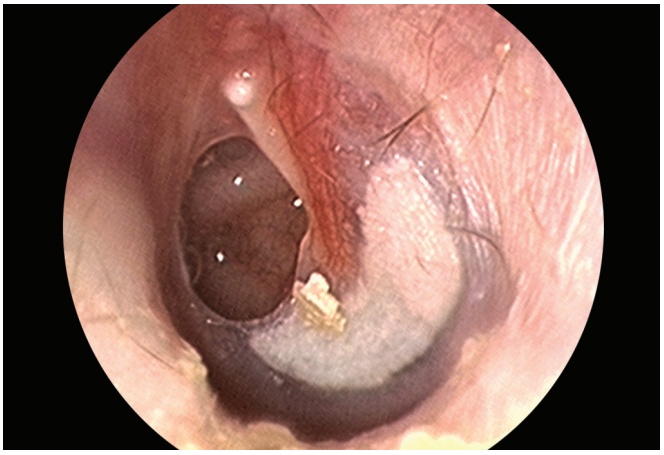

**Fig. 10.4:** Perforation of the anterosuperior quadrant of the right eardrum. There is no sign of infection as the ear is clean and the middle ear mucosa not inflamed. Myringosclerosis is present in much of the remaining pars tensa.

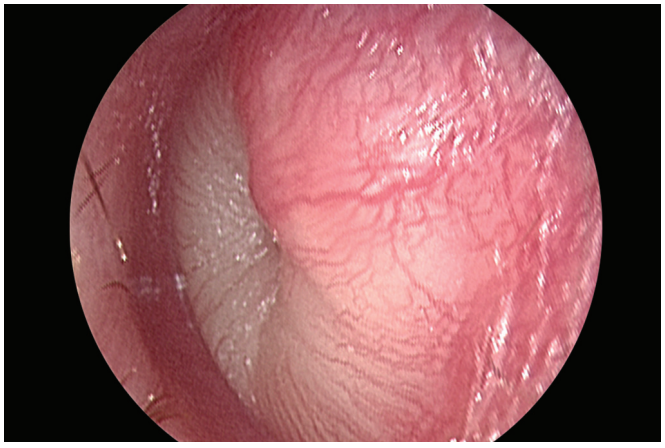

**Fig. 10.5:** Acute otitis media of the left ear. The tympanic membrane is bulging under pressure from a purulent middle ear effusion. Prominent vessels and erythema indicate acute inflammation.

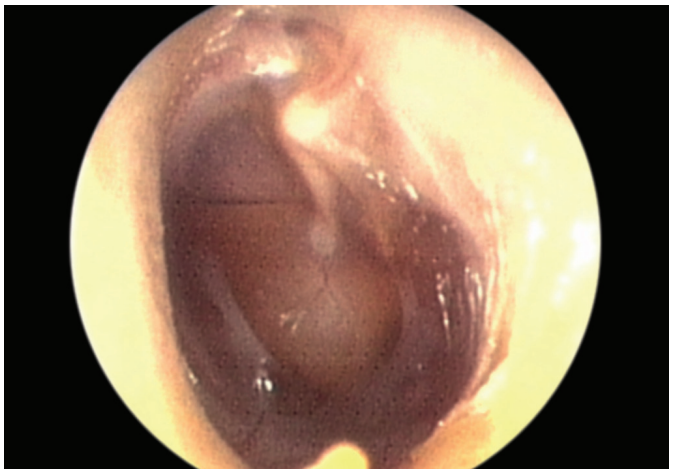

**Fig. 10.6:** Otitis media with effusion of the left ear. A serous middle ear effusion can be identified with certainty in this ear because of the clearly delineated air-fluid level anterior to the handle of the malleus. This allows the subtle difference in color between the air and fluid filled areas to be appreciated.

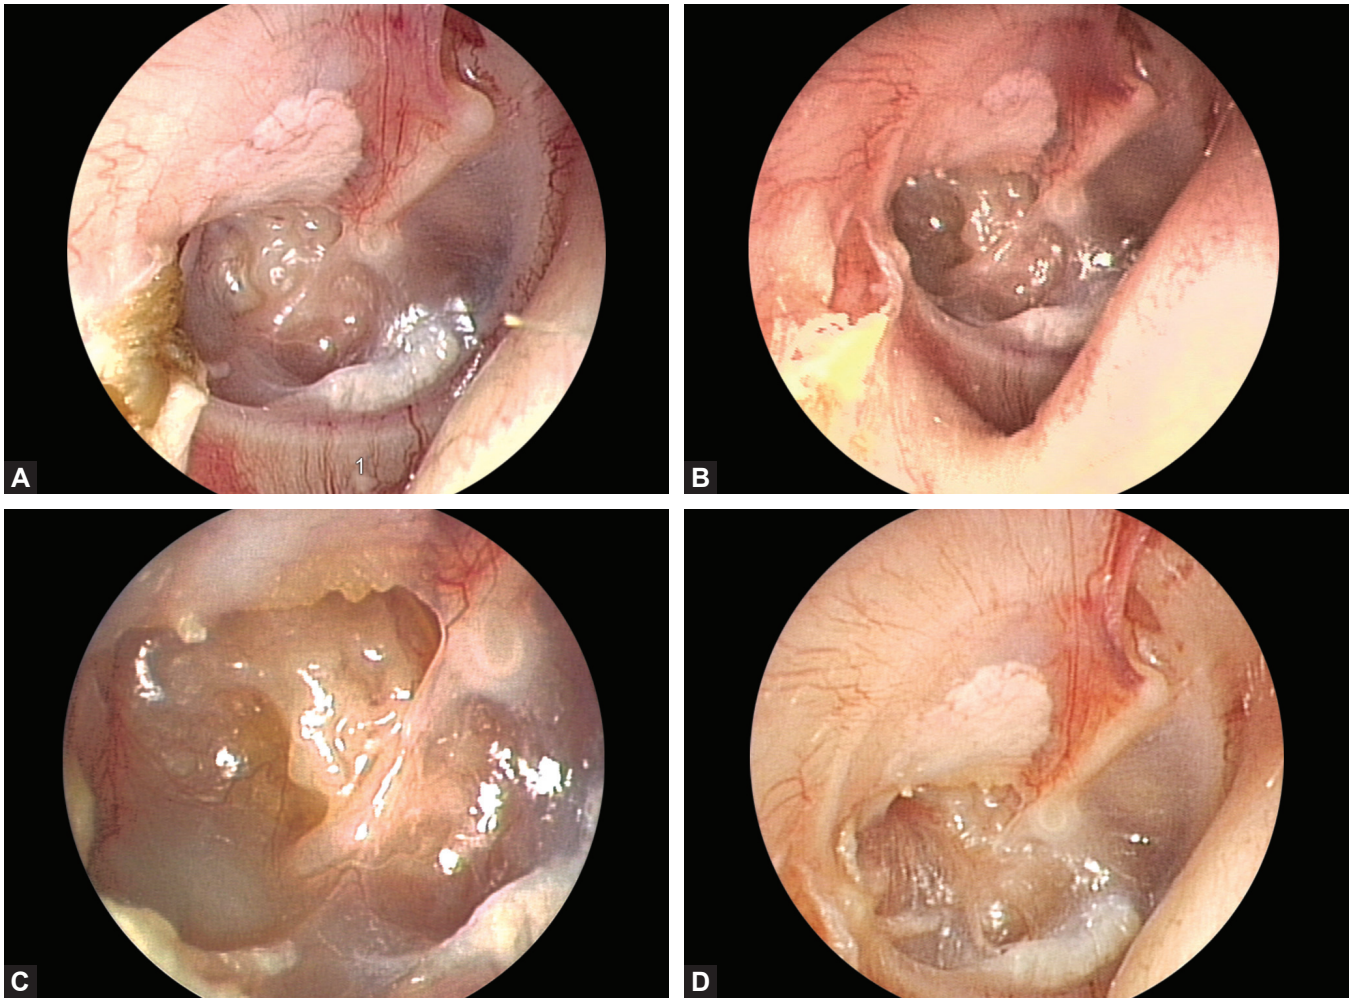
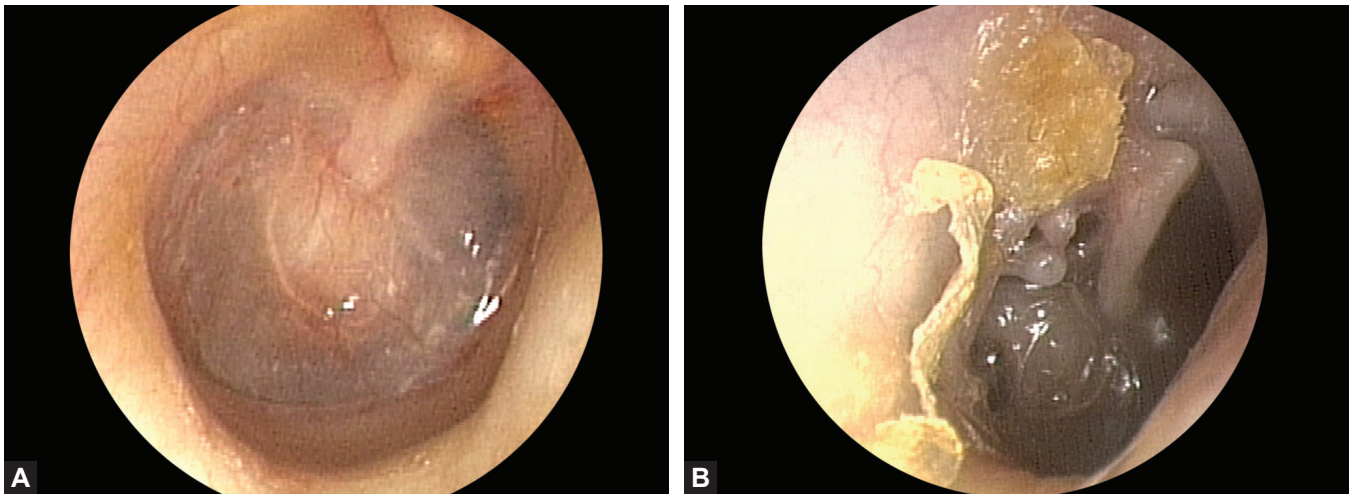


**Figs. 10.7A to D:** Otoendoscopic images of a right tympanic membrane at different stages of assessment. (A) First inspection shows pars tensa retraction that looks potentially adherent to promontory (centrally) and the jugular bulb (posteroinferiorly). The limits of the retraction in the retrotympanum are not visible and a trail of accumulating keratin indicates a risk that cholesteatoma may be forming. (B) Debridement of the keratin reveals erosion of the meatal skin that can lead to granulation tissue formation. (C) The wide-angle view from the endoscope placed closer to the eardrum shows the retrotympanic retraction is clean. An angled scope could be used to assess the hidden area superiorly. (D) Valsalva maneuver inflates the retraction elevating it off the jugular bulb, but the eardrum remains partially adherent to the promontory.



**Figs. 10.8A and B:** Retraction of the right tympanic membrane in two different ears, showing limitations of staging systems. (A) The pars tensa is touching the promontory. This is classified as Sade stage 4 if the retraction remains adherent to the promontory on pneumatic otoscopy or Valsalva, or stage 3 if not adherent. The response to pneumatic otoscopy or Valsalva maneuver may be inconsistent between observers or different days. (B) In addition to contact with the promontory, this pars tensa is draped around the long process of incus and stapes. The long process of incus is partially eroded and barely in contact with the stapes and the posterior limit of the retraction is not visible. Keratin is accumulating on the adjacent canal wall implying impairment of normal migration. Despite these concerning features, this retraction would also be classified as Sade stage 3 or 4. The diagnosis of progressing tympanic membrane retraction cannot rely upon use of staging systems alone.

  - A drawing or written description can be used to record the status of tympanic retraction. Staging systems are widely used for recording the status of tympanic membrane retraction but the established systems have poor reliability, inadequate sensitivity for noting clinically relevant changes and no correlation with hearing level or indication for treatment.[3] As demonstrated in Figures 10.8A and B, endoscopic photo-documentation is thought to provide a more accurate record.
- Inspection is enhanced by the stereoscopic view with a microscope and by otoendoscopy which can reveal the limits of the anterior recess and retracted areas
- A pneumatic attachment is recommended by many for the assessment of tympanic membrane mobility. This can be difficult in children. The ability of a clinician to identify a middle ear effusion is enhanced equally by pneumatic otoscopy or tympanometry.[4,5]

## Cleaning the Ear Canal

The view must be sufficiently clean to allow inspection of the entire tympanic membrane.[6] Irrigation or mechanical debridement with head light or microscope can be used according to the tolerance of the child:

- *Irrigation*: Usually avoided in the presence of tympanic membrane perforation or retraction, tympanostomy tube or foreign body. Safer than mechanical cleaning on a child that cannot keep still. May leave traces of debris or water that impair accurate inspection
- *Mechanical debridement*: Only feasible if the child keeps still voluntarily or is small enough to be appropriately restrained. Avoid poking the bony meatus or tympanic membrane, as this is usually painful. Suction can be distressingly noisy to children, so the wax curette, alligator forceps, or cotton wool on an applicator are preferable tools when possible. To help keep young children still, an assistant can cradle the head and a parent asked to hold the hands and chest within reassuring sight of the child. Infants may be swaddled effectively
- Complete assessment requires visualization of the entire tympanic membrane. If not possible a repeat visit should be scheduled. Regular application of a ceruminolytic may facilitate cleaning at subsequent follow-up[6]
- General anesthesia may be required to allow sufficient cleaning to make an accurate diagnosis. When possible this should be combined with other interventions that may be necessary such as tube insertion, or in cases where cooperation may be limited, auditory brainstem response testing and hearing aid mold fitting. If however the diagnosis is sufficiently obvious,

it may be more appropriate to proceed directly to surgical treatment so as to avoid the delay and inconvenience of an additional anesthetic (e.g. in management of cholesteatoma).

### General Examination

Examination includes assessment of the general demeanor and health of the child, as well as the remainder of the otolaryngologic examination (including the other ear!). Status of the nose is of particular relevance because of the association between adenoid hypertrophy and otitis media. Flexible nasendoscopy can be tolerated even by young children and should be favored over lateral radiographs for adenoid assessment when possible as it will provide a three-dimensional assessment of the adenoid relative to the Eustachian tube orifice and also facilitate identification of a submucous cleft palate. A bifid uvula or cleft palate may indicate predisposition to middle ear disease, which is even greater when the lip is also cleft.[7]

## PRESENTING FEATURES OF OTOLOGIC CONDITIONS

### Hearing Loss

When assessing hearing loss in children, two important differences from adults must be considered. First that the presentation may be relatively silent as the child may be unaware of the deficit, and second that sound deprivation has irreversible effects on development of auditory neural pathways and consequently speech and language development. The assessment of hearing ability in neonates and young infants relies on the use of objective tests (such as otoacoustic emissions and auditory brainstem response testing) which are used in newborn hearing screening to identify congenital hearing loss as early as possible.[8]

In older children, it is important to ask the parents about severity and time course of hearing loss. Reports that the child can hear but does not "listen" may be indicative of a mild or unilateral hearing loss. Secondary effects of hearing loss on speech and language development, behavior and socialization, and school performance may give important indications of the magnitude of the hearing problem.

While the physician is able to gain a basic impression of hearing and speech ability during conversation with the parent and child, tuning fork tests and informal tests of hearing such as whispering at fixed distances have been shown to have poor reliability in children.[9,10] In order to determine hearing thresholds and to distinguish between conductive and sensory or neural causes, there is no substitute for appropriate audiological tests, especially when conducted by an audiologist experienced in working with children.

When hearing or listening impairment seems out of proportion to audiometric thresholds, disorders beyond the ear should be considered. These include auditory neuropathy spectrum disorder (identified by absent auditory brainstem response in the presence of normal otoacoustic emissions or cochlear microphonic), central auditory processing disorder (for which psychometric tests can be completed), or behavioral disorders (such as autism).

### Otorrhea

Discharge from the ear is indicative of infection, except in rare circumstances such as the clear watery leak of cerebrospinal fluid following temporal bone trauma. The approach to diagnosis aims to distinguish between acute and chronic middle ear infections and otitis externa. History of the complaint is very important as it may not be possible to clear the ear canal sufficiently in a child to make the diagnosis from inspection of the eardrum—at least at the first visit.

Age at presentation gives important diagnostic clues: during infancy AOM with perforation is most likely, in older children chronic suppurative otitis media (CSOM) is most likely (from tympanic membrane perforation or cholesteatoma). Otitis externa seems to be less common than in adults. It is important to elicit a description of the nature of the discharge and how it differs from wax so as not to misinterpret the parental description. Foul smelling discharge is more typical of CSOM, particularly cholesteatoma. Management can be facilitated by understanding whether the infection was provoked by water exposure (e.g. when swimming) or by an upper respiratory tract infection, or whether it occurred spontaneously.

Attention to associated symptoms and timing may help distinguish recurrent acute infections from intermittently discharging chronic infection. It is essential to determine whether otorrhea occurs with or after otalgia. Acute otitis externa occurs with pain and some discharge. If otorrhea occurs after pain, or indeed if

pain subsides when otorrhea starts, AOM should be suspected. Otorrhea without pain or fever is typical of CSOM, cholesteatoma or chronic otitis externa.

Middle ear infection does not always cause sufficient otorrhea to be noticed by the parent or child, even when the tympanic membrane is disrupted.[11] To make an accurate diagnosis, it is vitally important that the entire tympanic membrane is inspected carefully, looking for evidence of infection, perforation, or cholesteatoma. A narrow opening into a pars flaccida cholesteatoma can be missed easily, particularly when partially obscured by waxy keratin debris or pus. If the eardrum cannot be adequately seen after cleaning the canal as thoroughly as can be tolerated, follow-up should be booked to check the child's ear again. Delay in the diagnosis of cholesteatoma may lead to irreversible hearing loss from ossicular erosion and other complications.

## Otalgia

In children, otalgia is most commonly caused by AOM, but diagnosis is not always simple. As outlined in guidelines from the American Academy of Pediatrics[12] accurate diagnosis of AOM can be surprisingly difficult and there is often some degree of uncertainty. A carefully taken history can help to distinguish AOM from the many causes of referred otalgia (Table 10.1).

AOM is most common around 12 months when the infant is too young to describe the cause of his or her distress. At this age, many babies cry out at night, and also may be teething (increased drooling may indicate this cause of otalgia). A short history of distress associated with inflammation of the tympanic membrane and a middle ear effusion are required to make the diagnosis.[12]

**Table 10.1:** Some important causes of otalgia in children

| | | |
|---|---|---|
| - Acute otitis media | | |
| - Acute otitis externa | | |
| - Referred otalgia | - Dental | - Teething |
| | | - Molar abscess |
| | | - Braces |
| | - Tonsils | - Tonsillitis |
| | | - Tonsillectomy |
| | - Temporomandibular joint dysfunction | |
| - Neoplasia | | |
| - (Malingering/attention seeking) | | |

These appearances are not always as clearly seen as in Figure 10.4. The presence of fever, acute otorrhea, and history of a recent cold make the diagnosis more certain. AOM is less common in older children, but diagnosis may be easier to make if a history of otalgia and ipsilateral hearing loss is provided. The degree of certainty of diagnosis, severity of symptoms, age of the child, and frequency of episodes are important criteria to consider when planning treatment.

The presence of otalgia with a normal tympanic membrane and ear canal implies a referred cause.[13] As summarized in Table 10.1, potential dental and oropharyngeal causes must be assessed. Rarely neoplasia may present with otalgia, so caution and thorough assessment must be completed before entertaining the relatively rare diagnosis of a functional cause.

## Facial Palsy

Assessment of facial nerve palsy in children follows the same principles as in adults. Thorough assessment of the ear is important as facial palsy may have an otologic cause such as a complication of AOM, active CSOM, or temporal bone trauma.[14] Presentation with swelling in front of the ear may also be secondary to spread of suppurative middle ear disease, and not imply a parotid cause.

## Headache

Headache is not a typical feature of pediatric ear disease. When associated with suppurative middle ear disease (i.e. AOM, CSOM, and cholesteatoma) it is critically important to consider the possibility of intracranial complications. Children can appear surprisingly well with an intracranial abscess. A contrast-enhanced CT scan may be necessary to make this diagnosis (Figs. 10.9A and B).

## Vertigo and Imbalance

The diagnostic approach to disorders of balance in children aims to distinguish vestibular from other causes. The first challenge is to identify the problem as many children cannot articulate the feeling or sense of vertigo and are often initially thought to be clumsy and uncoordinated. Some may even be misdiagnosed with a behavioral abnormality. Their symptoms can go unrecognized or misdiagnosed for years. Their presentation is variable and depending on the cause can include ataxia,

**Figs. 10.9A and B:** Coronal CT scans of a temporal lobe abscess from cholesteatoma. (A) Using settings optimized for bone, this image shows somewhat rounded soft tissue swelling under the tegmen tympani consistent with cholesteatoma. Without intravenous contrast, the adjacent brain appears normal. (B) The contrast-enhanced scan reveals a large temporal lobe abscess. Contrast material is important in the diagnostic approach for suppurative intracranial complications with CT.

headache, visual disturbances, hearing loss, otalgia, and otorrhea. Other important symptoms include, oscillopsia, drop attacks without loss of consciousness, lateropulsion (sensation of being pushed to one side), and vegetative symptoms (nausea, emesis, and malaise). Learning disabilities can sometimes be a presenting complaint due to poor dynamic visual acuity secondary to deficiency of the vestibulo-ocular reflex. Children with congenital or acquired severe deficits of vestibular function may not experience vertigo but rather have balance deficits that go unrecognized. This is particularly common in children with profound sensorineural hearing loss (SNHL).[15]

Despite such variable presentation, the four focused questions shown in Table 10.2 help to differentiate the pathology in most cases.[16]

Full diagnostic assessment requires examination of static and dynamic imbalance and visual acuity. As outlined in Table 10.3, a large range of testing is feasible in children and may reveal the diagnosis without recourse to more invasive tests of vestibular end-organ function such as vestibular-evoked myogenic potentials and caloric testing. For example, pre- and postrotatory nystagmus can be evoked by rotating the child while seated on a rotating office stool (with the parent if needed to hold a young child) to assess the vestibulo-ocular reflex. Developmental reflexes should be tested when examining infants: floppiness and lack of head control can be early signs of vestibular impairment.

### Tinnitus

When children report noises in their ears, it is appropriate to assess severity and type. Questioning should aim to distinguish between objective causes such as popping or clicking that may imply Eustachian tube dysfunction or, rarely, myoclonus, and pulsatile tinnitus that may imply a vascular cause, from the subjective ringing or humming tinnitus which is more commonly troublesome to adults.[17] Assessment must also consider symptomatology of the patulous Eustachian tube that includes autophony and intrusive sensation of breath sounds in the ear. Chronic sniffing can induce tympanic membrane retraction via a patulous Eustachian tube.[18]

### Hyperacusis

As it is common for young children to find loud noises unpleasant, it is important to determine whether the severity of intrusion into everyday life is sufficient to justify a diagnosis of hyperacusis and supportive therapy.[19,20]

## INVESTIGATIONS FOR PEDIATRIC EAR PROBLEMS

### Audiology

The importance of appropriate audiological assessment of the child with otologic conditions has been emphasized above. Further details can be found in Chapter 14.

**Table 10.2:** Diagnostic approach to assessment of pediatric balance disorders, using four sets of questions. The characteristic answers to these questions indicate likely diagnoses[16]

| | |
|---|---|
| 1. "How does it feel?" | |
| Light headed/faintness | Anxiety |
| | Orthostatic hypotension |
| Whirling/spinning | Peripheral vestibular disorder |
| 2. "What makes it worse?" | |
| Moving | Peripheral vestibular disorder |
| Rolling/bending/look up | Benign positional vertigo |
| Straining | Perilymph fistula |
| 3. "How many episodes and how often?" | |
| Multiple; seconds to minutes | Benign positional vertigo |
| | Benign paroxysmal vertigo of childhood |
| Multiple; >20 minutes to hours | Vestibular migraine |
| | Meniere's syndrome |
| Single; hours to days | Labyrinthitis/vestibular neuritis |
| 4. "Any associated symptoms/problems?" | |
| Change in awareness | Seizure disorder |
| Preceding event | Ototoxic medication |
| | Head/ear trauma |
| Other diagnoses | Otologic disease |
| | Autoimmune disorder |
| | Cardiac disorder<br>Postural orthostatic tachycardia syndrome (POTS) |
| Family history | Migraine |
| | Hearing loss |

## Microbiology

Currently, culture of otorrhea or pus from the middle ear space is generally only helpful for diagnosis when antibiotic resistance is suspected, e.g. after failure of first-line treatment.

## Diagnostic Imaging

Diagnostic imaging can be appropriate as part of the diagnostic approach to otologic conditions. The decision to obtain imaging must be balanced by the need for sedation or general anesthesia in younger children (normally up to the age of around 6–8 years), and by awareness of the long-term impact of irradiation on the developing brain and vulnerable soft tissues such as the lens and thyroid in young people. Use of CT in young children should be reserved to situations in which the results may have sufficient impact on clinical decision making, and not simply to satisfy the diagnostic curiosity of the physician or parent.

Imaging should be considered as part of the diagnostic approach when neoplasia of the temporal bone is suspected (such as histiocytosis or rhabdomyosarcoma) for assessing vascular anomalies (especially prior to surgical intervention) and for assessment of facial nerve palsy if persistent or from temporal bone fracture. SNHL and cholesteatoma are more common reasons to consider diagnostic imaging so are discussed in more detail.

### *Sensorineural Hearing Loss*

At our institution, MRI is now favored over CT as a single imaging modality as it reveals intracranial diagnoses (congenital cytomegalovirus infection, hyperbilirubinemia), cochlear nerve anomalies (congenital aplasia), and intracochlear anomalies (incomplete partition; obliterative labyrinthitis) more clearly than CT and without

**Table 10.3:** Clinical tests of vestibular function for assessment of imbalance in children

| | | |
|---|---|---|
| Static imbalance tests | | |
| Eye movements | | |
| | Spontaneous nystagmus | Vestibular disorder |
| | Pressure-induced nystagmus* | Labyrinthine fistula |
| | Gaze-evoked nystagmus | Central nervous system disorder |
| Dynamic imbalance tests | | |
| Dix–Hallpike maneuver | | |
| | Rotatory nystagmus | Benign positional vertigo |
| Vestibulo-ocular reflex assessment | | |
| | Head thrust test | Vestibulo-ocular reflex anomaly: |
| | | Loss of stationary gaze |
| | | Corrective saccade |
| | Head shake maneuver | Post head shake nystagmus |
| | Dynamic visual acuity | |
| | Rotary chair testing | |
| Vestibulospinal testing | | |
| | Romberg and sharpened Romberg | |
| | Past pointing | |
| | Fukuda stepping test | |
| Gait and gross motor function | | |

*Pressure can be transmitted by tragal compression, impedance testing (Hennebert's sign), or loud sound (Tullio phenomenon).

irradiation. It is important to remember that MRI has restricted utility after cochlear implantation. CT may still be appropriate prior to cochlear implantation to assess candidacy with cochlear nerve hypoplasia or labyrinthitis ossificans and for surgical planning with syndromic anatomical anomalies.

Recent guidelines suggest that CT is not indicated for sudden SNHL in adults.[21] However, it is a more sensitive test than MRI for identifying enlarged vestibular aqueduct that is a common cause of sudden progression of hearing loss in children.[22] In conjunction with MRI, it is useful for identifying cochlear nerve hypoplasia by revealing the diameter of the cochlear nerve canal at the base of the cochlea, and also after meningitis for distinguishing between cochlear ossification or fibrosis when MRI reveals obliterative labyrinthitis.

### *Cholesteatoma*

In most centers, CT is the standard imaging modality in the setting of suspected cholesteatoma despite the fact that it has unreliable sensitivity and specificity for making a diagnosis of cholesteatoma. Keratin accumulation within cholesteatoma is indistinguishable from granulation tissue or effusions, though a convex soft-tissue to air interface is highly suggestive of cholesteatoma. Discharge of purulent contents out of a cholesteatoma sack can leave an air containing space yielding a false negative scan. Bone erosion (e.g. of scutum or incus) may be caused by small retraction pockets, thus providing a false positive scan. The role of CT is not so much in making the diagnosis as in surgical planning, revealing the potential limits of the disease in relation to the patient's anatomy and opportunities for surgical access. Rare complications of cholesteatoma can be revealed (e.g. canal fistula or intracranial pathology) as well as anatomical variations that might predispose to surgical complications (e.g. course of the facial nerve and venous sinuses).

With MRI, non-echo planar diffusion weighted imaging has good sensitivity and specificity for identifying larger cholesteatomas.[23,24] Current resolution and lack of contrast between bone and air limit the utility of MRI in surgical planning, but it can be helpful when diagnosis is in doubt, or to diagnose more extensive occult residual cholesteatoma after previous surgery.

### *Conductive Hearing Loss with a Normal Tympanic Membrane*

CT may help to identify an occult congenital cholesteatoma in the medial epitympanum, more commonly when the hearing loss is unilateral and the child has previously passed newborn hearing screening. CT may also reveal the nature of congenital ossicular fixation and help guide decision-making regarding ossiculoplasty. In cases where such lesions are suspected, a direct coronal CT scan best illustrates the status of the stapes footplate.

### *Complications of Suppurative Middle Ear Disease*

A contrast-enhanced CT scan of the brain must be considered when AOM, CSOM, or cholesteatoma are associated with headache or drowsiness (*see* Figs. 10.9A and B). Fever and malaise are atypical features of CSOM and cholesteatoma and should also raise concern for suppurative intracranial complications.

## Blood Tests and Other Investigations

Blood samples may be difficult to obtain in children and generally do not play a large role in the diagnostic approach to chronic otologic problems of childhood. Testing for genetic mutations is likely to offer more definitive diagnostic testing in the near future and currently has increasing utility in the diagnosis of SNHL. The implementation of more widespread perinatal screening tests is reducing the need for some tests (e.g. congenital hypothyroidism as a cause of hearing loss). Renal function tests can be considered in hearing loss (e.g. Alport's in which SNHL can be associated with deteriorating renal function later in older boys, or branchio-oto-renal syndrome associated with branchial and preauricular sinuses). Thyroid function testing can be considered in the presence of a goiter with SNHL (Pendred's syndrome) but children with this condition are usually euthyroid.

ECG should be considered in assessment of profound bilateral congenital SNHL as a long QT interval is associated with sudden death in Jervell and Lange-Nielsen syndrome. Children with hearing loss should have regular tests of visual acuity to ensure they have no additional sensory impairment. As outlined above, children with imbalance or severe/profound SNHL should have an assessment of vestibular and balance function.

## KEY POINTS

Assessment of pediatric ear problems is made more difficult by the limited history that may be available from the patient and limitations in the degree of cooperation that may be possible with examination and testing.

A thorough diagnostic approach requires the following:

- Careful history taking
- Examination of the entire tympanic membrane
- Debriding the ear canal and drum as necessary
- Collaboration with pediatric audiology
- Being alert to opportunities for early diagnosis for optimum outcome, especially in prelingual hearing loss and also cholesteatoma.

CHAPTER

11

# Clinical Examination of the Ear

***Cuneyt M Alper, Michael S Cohen***

## INTRODUCTION

The clinical examination of the ear in the pediatric population can be challenging. While teenagers and adults tend to be similar both anatomically and behaviorally, the examination of infants and toddlers requires unique skill and experience in order to obtain a complete examination and make an appropriate diagnosis. The appearances of normal and pathologic disease states may not differ dramatically between children and adults; however, there are often substantial differences in medical history, risk factors, and clinical presentation that may alter the interpretation and management of similar conditions, all of which can impact the clinical outcome.

History is often provided by parents or other caregivers, and as such, the reporting of symptoms can be influenced significantly by the exposure, perceptions, knowledge, interpretation, and quality of life impact on the historian. For example, crying may or may not be a manifestation of ear pain, and, if present, could have any number of causes, none of which would be easily verified or differentiated in infants or young children. Some symptoms such as hearing loss or vertigo may not be noticed by others, and tinnitus would only be known if the child is old enough to perceive and express it.

The difficulties inherent in assessing pediatric otologic problems delineated above only increase the importance of the otologic examination. On the other hand, physical examination, and especially otologic examination, has distinct challenges in the pediatric population. The ear canal is narrow in infants and young children, and may be unusually narrow in a syndromic child. It may be difficult to visualize the ear drum without cleaning the ear canal, which may be very challenging or even impossible in the office. Children with anatomic, cognitive or behavioral limitations require skill and experience in approaching, examining, and testing.

Moreover, the general medical practice climate today emphasizes productivity, resulting in pressure to spend less time with each patient in clinic as well as a higher proportion of scheduled surgeries per patient encounter. These effects may be more pronounced for pediatric otolaryngologists due to the high volume nature of the specialty. Books and training encourage a complete and thorough history taking and physical examination; however, practice pressures "correct" such unrealistic intentions and one of the skills that is often expected to be acquired quickly by both trainees and junior faculty is the ability to spend the shortest amount of time in obtaining a focused history and physical examination while meeting the targeted billing requirements. This creates a conflict between productivity and being able to acquire the necessary elements for decision making while also avoiding assessment errors and medical-legal liability. Therefore, unfortunately today's training should include acquiring fast, efficient, and safe assessment skills. In general, teaching a focused and efficient history taking and physical examination demands a more thorough and complete assessment to be done by the teacher in order to judge and correct what was done by the trainee. Clinicians in training institutions experience the same productivity pressures as any other practitioner, which can limit this critical didactic relationship. Instead, under the present circumstances the teacher often has to rely much more on what the "efficient" trainee gathers, and limit him or herself to verifying some of the most crucial elements.

A similar relationship has become widespread between physicians and mid-level providers, and the same limitations and dangers exist when nurse practitioners and/or physician assistants see patients first, or even on their own.

All of these challenges heighten the importance of other training modalities and materials including books, visual training materials, and special educational activities that do not have the pressure on productivity.

This chapter intends to serve the purpose of providing the important elements helpful or even perhaps crucial in the examination of the ear in the pediatric population. The scope of this chapter does not include medical history as a separate section, which is covered in the previous chapters; however, some relevant elements are mentioned where appropriate.

## FACILITIES AND ENVIRONMENT

### Waiting Room

Otologic problems in children are assessed and managed by a variety of health care professionals in a variety of settings (emergency department, urgent care, family medicine, pediatrician, internist, otolaryngologist, pediatric otolaryngologist). In most cases, a child will be seen in an environment that is only for children. A clinic dedicated to pediatric otologic problems is extremely rare, and does not exist in most centers; therefore, a broad spectrum of pediatric and/or pediatric ENT problems may be seen in the same clinic. Desire to increase or to keep up with decreased reimbursements have created an environment of fast-paced short turnover clinic visits, eroding the patient/parent satisfaction with increase in potential for errors. On the other hand, this planned rapid pace is often not realistic, resulting in prolonged waiting periods up to 1–2 hours past the scheduled appointment. Besides the fact that in an adult clinic the patient is alone or sometimes with just one or two companions, a child always comes with minimum one or two parents and often even more relatives of various ages. These factors all increase the importance of the capacity and conditions of the waiting room. It is extremely important to accommodate this load of waiting people, with adequate space and seating as well as features to keep them busy and less annoyed with a wait. Having toys in a waiting room helps to keep the children busy; however, maintaining the cleanliness of toys can be challenging. Attractive toys in the waiting room or even age appropriate toys given to each child can quickly become fomites, even with the intention of cleaning after use. Instead, solid and easily cleaned stationary toys can be supplemented with visual entertainment options (Fig. 11.1). It is important to have a staff periodically clean the commonly touched surfaces throughout the day, not only at the end of the clinic, for sanitation and also to reassure waiting families of their cleanliness (Fig. 11.2). Similarly, there should be adequate hand sanitization stations in the waiting area with warnings to use hand cleaning before and after touching toys or common surfaces. Ideally, two or more TV monitors targeting different age groups would serve the best. A simple practice is engaging waiting children with coloring pages that can continue to occupy their attention when they

**Fig. 11.1:** Waiting room should be spacious with adequate seating.

**Fig. 11.2:** Toys or items attracting children should have surfaces that can be easily cleaned and sanitized.

continue to wait in the examination rooms. Parents should be encouraged to bring children's favorite toys, which is usually the habit anyway. Recently, these toys are being replaced by portable small electronic game consoles, tablets or smart phones with games or videos, that set invisible chains in keeping patients in their seats.

## Room and Setup

An examination room that meets the needs for children with ear problems should have minimum standard furniture and equipment. The layout and quality of these may vary; however, here are some preferences for practical reasons. One layout that this author finds useful is having the physician stool on wheels in one corner of the room, in between the treatment cabinet and the desk with computer and drawers with documentation and information binders, and the examination chair facing the physician corner (Fig. 11.3). This layout allows the rotation of the examination chair 180° to reach both ears for otoscopy or manipulation, while for a right-handed otologist to easily access the drawers with instruments, material or suction on the right and the desk with the PC and monitor and paperwork on the left. The physician faces both the patient with or without the parent keeping the patient on the lap and the parents or other companions that sit on the other side of the computer table. At the other corner of the room on the other side of the treatment cabinet is the best place for the floor standing microscope or the endoscope tower (Fig. 11.4). On the other side of the microscope an examination table is placed so that the microscope can serve both the patients on the table and on the examination chair (Fig. 11.5). It may not be possible due to the cost or necessary to equip every room with an endoscope tower; however, if there are one or more dedicated endoscope rooms, the remaining rooms, i.e. most of the rooms, can be equipped with a microscope (Fig. 11.6). This setting naturally is describing an environment best for pediatric otologic examination, and may be different for the examination rooms that have a varying weight of need for ear examination. In a handy location, a wall dispenser of various size otoscope speculums should be placed.

Walls can have child friendly posters, as well as pictures or drawings of ears and other relevant anatomical structures. A set of normal and abnormal examination pictures and with a ventilation tube, as well as illustration of the entire ear and related structures from pinna to ear canal, tympanic membrane (TM), middle ear (ME), mastoid, Eustachian tube (ET), nasopharynx, and adenoids is very useful when describing physiology, pathophysiology, and intended treatment options to the patient and the parents.

## Necessary Instruments

The treatment cabinet is an essential element of the examination room (Fig. 11.7). Cabinets may have mounted charging docks on top, as well as containers for frequently used items such as tongue depressors. Drawers should be dedicated to 4×4 and 1×1 gauze, cotton balls, wicks, culture

**Fig. 11.3:** Physician stool is at one corner of the room, in between the treatment cabinet and the desk with computer and drawers with documentation and information binders, and the examination chair faces the physician's stool.

**Fig. 11.4:** The other corner of the room on the other side of the treatment cabinet is the best place for the floor standing microscope or the endoscope tower. Two sizes of papoose are shown used to restrain children if needed for procedures.

**Fig. 11.5:** Microscope can serve both the patients on the table and on the examination chair.

**Fig. 11.6:** Dedicated endoscope rooms may have both the endoscope tower and microscope.

swabs, curettes, additional nondisposable speculum sizes, adequate number of 3, 5, 7 suctions, alligators, right angle picks, and tuning forks (Fig. 11.8). A headlight, Brunning's or Siegel's otoscope sets, Frenzel's glasses, packing material and other equipment, and material that are relatively rarely needed may be kept in a storage room available for all examination rooms.

In addition to the standard commonly used speculum sizes 3, 4, 5, there should be extra-small and extra-large speculums available (Fig. 11.9).The handheld otoscope brand that is most widely available and used in the market is Welch Allyn (Fig. 11.10). The wall dispenser holds the more commonly used sizes of 3, 4, and 5.

The reusable otoscope speculum set that comes with the handheld otoscope has sizes 2, 3, 4, 5, and 9 mm. (Fig. 11.11). These specula are a little thicker; therefore, while the inner diameter is the same, one may achieve a better seal with a speculum in this set. The 9 mm is used when there is a very large canal or using in postmeatoplasty canal-wall-down ear cleaning. The same manufacturer offers SofSpec Extra Comfort Reusable Otoscope Specula. These come as 3, 5, and 7 mm for Pneumatic, Operating and Consulting Otoscopes. The brand has introduced the MacroView Otoscope that comes with the set of Four Reusable Ear Specula for Diagnostic and MacroView Otoscopes of sizes 2.5, 3, 4, and 5 mm. Additional sizes of 2.75 and 4.25 mm speculum are also available to be used for the Diagnostic and MacroView Otoscopes. In addition, for manipulation under microscope, additional small (2, 1.5, 1 mm) and large size (5.5, 6, 6.5, 7, 7.5, 8 mm) metal speculums should be available.

Ear examination often requires cleaning of the external auditory canal (EAC), which is may be a difficult task because of the narrow canal and frequently noncompliant and constantly moving child. In addition, not having proper instruments handy makes this task harder. A set of different sizes of curettes are essential (Fig. 11.12). Round and oval shaped serrated and nonserrated curettes are commonly used in practice. Wire curettes are preferred by some physicians. This author prefers the slightly angled serrated oval-shaped curettes, finding them less traumatic and more effective in loosening and dragging the cerumen out. There should be extra small curettes that can go through the very small speculum sizes as well. Keeping these relatively rarely used specula and curettes separately allows for finding them easily when needed.

## FIRST CONTACT

Physical examination of the ear starts with the first contact with a patient. While the clinician starts the inspection with this first contact, it may or may not be an eye contact, based on the child. Even for children as young as a few months of age, the initial contact and interaction with the clinician has a tremendous effect on realizing the full potential of that patient–clinician encounter. When child's age and cognitive abilities permit, the clinician has to explore the potential path and methods to achieve the goal of developing the most productive and efficient interaction with the child and the family.

A simple first step is displaying a smiling face. A smile is an expression of friendliness universal across cultures

**Fig. 11.7:** Cabinets may have mounted charging docks and containers for frequently used items such as tongue depressors. Drawers are dedicated to gauze, cotton balls, wicks, culture swabs, curettes, additional nondisposable speculums, suctions, alligators, right angle picks, and tuning forks.

**Fig. 11.8:** Cabinet top and drawers are utilized based on the design and preferences of the physicians.

**Fig. 11.9:** Additional extra-small and extra-large speculums should be available.

**Fig. 11.10:** Commonly used pair of otoscopes with pneumatic and surgical heads with disposable or rechargeable batteries are standard tools in clinic.

**Fig. 11.11:** Surgical otoscope head comes with reusable speculum set of sizes 2, 3, 4, 5, and 9 mm. Suitable for most manipulations in wide variety of ear canal sizes.

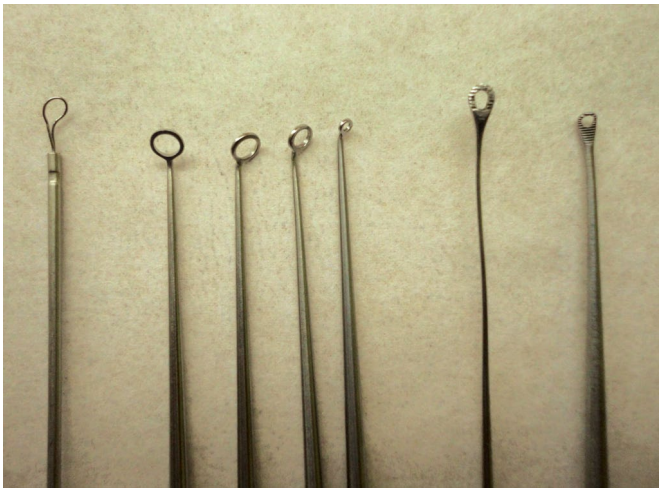

**Fig. 11.12:** A wide range of round and oval shaped serrated and nonserrated or wire curettes should be available in cabinets in each room.

that can ease the interactions to follow. Directing the attention first to the child before the parents and establishing and maintaining friendly contact with the child as long as possible will be very useful throughout the visit and in the future visits. Shaking hands with the patient, in addition to the parents may display the child's importance in the clinician's eye. Hand hygiene may be deferred to just before picking up the instruments and initiating contact with the child for the examination. The child's response to the clinician's attempt to establish contact, will tell a lot to the clinician about the child's character, cognitive and maturity level, past experience with other physicians and the mood that he/she is in at that time. From this starting point, it is the clinician's skill that takes this interaction as far ahead as possible.

There is no single path or method to follow after the initial contact. Clinicians that develop a rich repertoire of interaction scenarios and have the flexibility to change and adapt to the evolving situation will be able to achieve a more efficient and complete physical examination. Gradual introduction of instruments will be useful. Most children are familiar with the handheld otoscope, with good or bad past memories. Especially if the reaction of the child indicates unpleasant previous experience with the otoscope, extra patience and effort with soft and reassuring tones should be attempted.

## INSPECTION

The physical examination starts with inspection of the child. Child's posture, walk, response to sounds and commands, and age appropriate speech and language gives clues on the status of the inner ear. The shape of the head and face may indicate craniofacial malformation, an association or a specific syndrome. Facial asymmetry can be musculoskeletal or neuromuscular, and the latter may give information on the status of the facial nerve. Nystagmus is often not obvious, but the chief complaint and history of present illness would direct the attention of the clinician to the spontaneous nystagmus.

**Fig. 11.13:** Normal auricle.

Inspecting the head also reveals information on the shape and position of the auricle (Fig. 11.13). Periauricular areas need to be inspected for signs of swelling or previous surgery scars. Ecchymotic discoloration over the mastoid process, termed Battle sign, may reflect a skull base fracture. Depression over the mastoid cortex may indicate

a previous mastoidectomy. Asymmetrical protrusion or downward displacement of one pinna would bring attention to postauricular or supra-auricular swelling or abscess and possible mastoiditis. Subperiosteal abscess from acute otitis media (OM) and mastoiditis is more likely to develop more superior to the canal and push the auricle more inferiorly in infants.[1]

Examination of the mouth and palate may reveal cleft palate or submucous cleft both of which predispose the child to otitis media.[2] Bifid uvula may also be associated with increased incidence of ME effusion.[3]

## PALPATION

Palpation of the head and periauricular areas is an essential phase of the initial examination primarily because of being the first contact between the child and the physician for the purpose of examination. Therefore, initial touch should be gentle and not look or feel like part of the examination. To serve the purpose, caressing the head, hair, and cheek should precede the gradual approach to the auricle. It should not be difficult to imagine how annoying it may be to have a stranger touching you first on the auricle with an instant pull and concurrent insertion of the otoscope speculum. This is even more important for children with autism, mental retardation, or cerebral palsy.

Tenderness or swelling around the auricle may be from external otitis or mastoiditis. While the former has circumferential findings, mastoiditis affects the posterior and superior parts of the postauricular region the most. Hematoma of the auricle presents a management emergency.

## OTOSCOPY

Otoscopy is an essential part of the clinical examination of ear. Good visualization provides information on the EAC, TM, and the ME. Findings also provide very important clues on the previous status and history of the conditions in the TM and the ME. A number of methods have been utilized to visualize the EAC, TM, and ME.[4] The tools and techniques aim to straighten the ear canal for direct view, to push away the EAC hair and soft tissues to widen the field of view, to protect the EAC skin from direct contact with and avoid trauma or pain from the instruments used to clean the EAC, to seal the EAC for pneumatic manipulation and change of the EAC pressure to better assess the status and conditions of TM and ME, and to magnify the view for more accurate assessment.

Historically, magnification was not an inherent part of the otoscopic examination. Direct inspection using a head mirror with or without a speculum is still common practice in developing countries. Currently, the handheld otoscope is the standard tool for the otoscopic examination. Otoscope components include a removable speculum, a head into which the speculum fits, a light source coaxial to the line of sight, a magnifying lens opposite to the tip of the speculum, and a hand piece that usually contains a disposable or rechargeable battery.

Otoscopes are used either as closed or open systems. Closed systems allow pneumatic otoscopy, i.e. changing the external ear canal pressure to move the TM. Open systems (or closed systems that can be opened) allow insertion of instruments through the head and the speculum.

Direct visualization of the entire TM with an otoscope often requires straightening of the ear canal. This is achieved by a gentle tug of the pinna in the posterosuperior direction. Only a gentle pull is adequate to get the ear canal angle straightened. Pulling of the auricle with greater than necessary force is not uncommon especially in trainees, resulting in patient discomfort and even pain. A trainee may not realize how uncomfortable this could be. On the other hand, failure to adequately straighten the canal results in using the speculum itself onto the canal to correct the view resulting in discomfort or pain.

Various other otoscope types are available, such as with a larger and rectangular lens, or teaching otoscopes with sidearm viewer, and pocketscopes with smaller lenses. The MacroView Otoscope (Wellch-Allyn) provides approximately twice the field of view and 30% greater magnification than a traditional otoscope. On the other hand, this otoscope is limited to two standard speculum sizes that may hinder the ability to achieve a seal in various size ear canals.

### External Auditory Canal

Discharge from the external ear canal may be obvious on direct inspection or apparent only with otoscopy. Suctioning the ear is unpleasant for the patient and can rarely be done without restraint in very young children. With acute otorrhea in the presence of a ventilation tube, the physician may elect not to get a culture or suction that could alienate a child, and instead consider waiting for the likely favorable response to the course of ear drops. In the case of chronic otorrhea or when there is also otalgia, especially in the absence of known ventilation tube or a perforation, it is necessary to visualize the TM after a good

cleaning with suction. When an older child who cannot be restrained adamantly refuses to be suctioned, alternatives such as drying the otorrhea with a cotton swab may be beneficial.

Swimmers ear can be quite challenging to manage. If the ear canal is completely closed with edema and debris, and there is significant pain, the only way to relatively rapidly help to relieve symptoms is a prolonged and patient cleaning through the bottleneck formed by the middle and outer part of the EAC, remove some of the debris and otorrhea trapped medially and place a wick for sustained delivery of eardrops. This requires cooperation of the child, and otologist's patient reassurance and extremely careful manipulation to sustain the process.

One important finding to note with respect to inflammatory EAC narrowing is fullness and soft, fluctuant bulging of the superior and posterior canal. A subperiosteal abscess formed by eroding through the mastoid cortex may extend from the lateral surface of the mastoid into the canal. Another mechanism for the sagging ear canal is, especially in infants and young children, the development of subperiosteal abscess by extending of pus from the ME into the superior part of the canal where there is no annulus at the notch of Rivinus and extending laterally between the tympanomastoid and tympanosquamous sutures onto the lateral surface of mastoid. A negative CT scan may be misleading, and in this case even there is a subperiosteal abscess that needs to be drained, and a ventilation tube is placed, this mechanism does not definitively warrant mastoidectomy.

Bloody otorrhea in an ear with a history of tubes is almost always related to reactive granuloma formation that responds very well to the antibiotic and steroid combination ear drops. In the absence of history of tube or trauma, bloody otorrhea or polypoid granulation tissue on the TM should alarm the otologist of concerning pathologies including cholesteatoma and neoplasm.

A common EAC problem is cerumen within the ear canal. For optimal visualization of the TM, one study found that cleaning of cerumen was necessary in about a third of young patients.[5] In a child without otologic complaints, if the visible part of the TM appears to be normal and mobile, cleaning of cerumen may not be necessary each time. History of otorrhea, hearing loss, speech delay should all be good enough reasons to remove cerumen for complete visualization of the TM. When not possible, normal tympanometry suggests normal ME function. When not visualized or normal ME status cannot be verified, use of cerumenolytic ear drops or irrigation of the ear canal may be an option. As a principle, neither should be used when an intact TM cannot be verified. Irrigation is relatively commonly used in adult primary care settings, however, rarely in children. TM perforation has been reported with jet irrigation, warranting caution, and gentle irrigation.[6] This author does not remember performing or ordering an ear canal irrigation on a child for over a decade. Instead, removing with a curette is preferred. When intact TM can be verified, use of carbamide peroxide in glycerol (Debrox) over several days to weeks may be an option.

Foreign bodies in the ear canal are often challenging. Most children with a foreign body in the EAC are under 4 years old. Often the otoscopist sees the child after unsuccessful and traumatizing attempts at removal. Prior to any attempt, an effort should be made to assess whether TM is intact and the degree of hearing loss is expected from the foreign body impaction. Removal should be attempted when all the potentially necessary instruments are available. A number of EAC foreign bodies including commonly seen global objects can be removed with a right angle pick with a tiny tip that can get around the object without hurting the canal and drag the object after hooking on or into the object.

Canal wall down cavities require periodic cleaning and should be done by an otologist familiar with the postsurgical anatomy of the patient. This may require prolonged cleaning of the cerumen and debris layer by layer patiently to avoid cavity infections.

Trauma to the EAC could involve just the canal or an underlying head trauma would require relevant attention and workup. Often cleaning attempts traumatize the canal resulting in bleeding and concern on the site of the injury. Cleaning the canal immediately following trauma is for verification of the status of TM and mostly done for documentation purposes. Otherwise, it is quite unpleasant to try to examine and clean a child's recently injured EAC, and therefore, this may be postponed.

## Tympanic Membrane

Inspection of the TM should focus on position, color, degree of translucency, and mobility. Position and size of the light reflex may give more information on the position and the shape of the TM than what is behind. A smooth TM has a single somewhat triangular light reflex wherever the TM is perpendicular to the light source and the eye. The light reflex may not be present due to not having a perpendicular surface area anywhere on the TM.

An absent light reflex may also be due to the absence of a smooth surface from residue or debris remnants on the TM, or due to a thickened, inflamed, or scarred TM. When present, in addition to the observation of change in the position and shape of the light reflex with pneumatic otoscopy, the static shape and position may provide some information on the TM and ME. A bulging TM with a concave surface would have a smaller than usual, even a pinpoint reflex, shifted to a different place on the TM, even to the posterosuperior quadrant. The TM may potentially have more than one light reflex at more than one site of bulging TM. A retracted TM may have a broader light reflex, depending on the degree of retraction, if there is still a distinct area that is perpendicular, compared to the other sites on the TM. Multiple or broken light reflex sites indicate irregular TM surface with possible retraction pockets. As the TM gets atrophic and gradually dimeric, more of the light goes through the TM and not reflected, and the light reflex may disappear.

The TM is naturally slanted medially from posterosuperior to anteroinferior. This may be perceived as retraction of the TM; however, this judgment needs to be based on TM mobility with positive and negative EAC pressure and TM's position referenced to the anchor points. In most quadrants the reference points are either umbo or somewhere along the TM attachment on the manubrium and annulus (except notch of Rivinus where there is no annulus). If the TM fibers are medially positioned in between the central and peripheral anchor points, TM can be described as retracted. Retracted TM does not always imply significant negative pressure, since sequelae from previous infections, ET dysfunction, OM or trauma may weaken the TM structure, resulting in medially positioned TM even with a very mild negative pressure, or adhesion to a surface in the ME may keep the TM in the retracted position in the absence of negative ME pressure. When the TM is retracted, the umbo is typically medially displaced, the manubrium becomes more horizontal and the lateral process of the manubrium becomes more prominent.[7] On the other hand, these changes including more horizontal angle of the manubrium are sometimes present without negative ME pressure, as sequelae of previous infections and effusion and possibly secondary to the shortened tensor tympani tendon.

Bulging of the TM should also be defined as its position relative to the anchor points on the annulus and the manubrium. It is stated that the natural position of the TM is slightly bulging, based on a number of histology slides showing the cross section of the TM not as conical but as slightly bulging outward, displaying doubly curved "seagull" shape.[8] In a normally functioning ET, there is a physiologic reason to have slightly positive pressure at rest giving this appearance. Slightly bulging TM may be physiologic with buildup of gasses in the ME with the changes in breathing and gas consumption during going to sleep and waking up. Change in blood gas composition can result in transmucosal gas exchange into the ME, especially with the changes in rapidly exchanging gases such as carbon dioxide, but this typically does not last long. A patulous ET can result in fluctuating fullness, synchronous with breathing, but this condition is rare in children. Sneezing or nose blowing may open the ET and deliver a gas bolus to keep the TM bulging until it leaks back out passively or gets absorbed to the blood. More commonly, a screaming child may appear to have a bulging and congested appearance masquerading as otitis.

There is varying degree of vascularity of the TM, but normal vascularity comes from the superior part of the EAC where the vascular strip is between the tympanomastoid and tympanosquamous sutures, reaching the TM at the notch of Rivinus on the pars flaccida region of the TM and extend inferiorly along the manubrium. Seeing blood vessels at various density and engorgement may be normal (Fig. 11.14). Hyperemia of the TM should be defined when the TM is red where there are no apparent blood vessels.

Occasionally, there may be one or more bullous lesions on the TM. This could be without a bulging TM

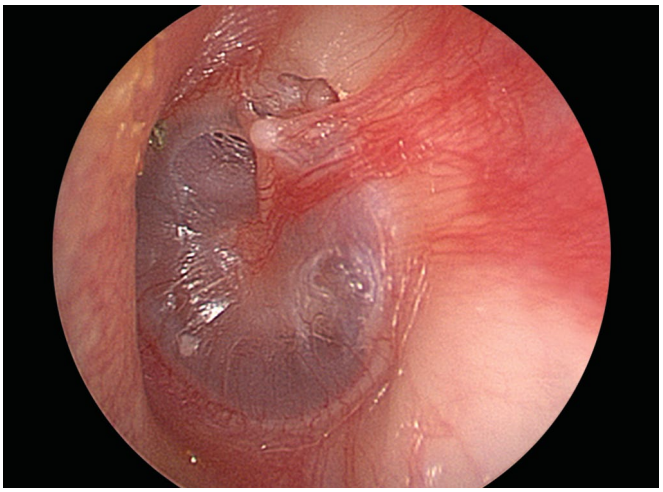

**Fig. 11.14:** Prominent but normal vascularity coming down from superior part of the external auditory canal and extending onto the tympanic membrane along the manubrium. This ear has shallow pars flaccida retraction pocket and some areas of mild atrophy and scarring.

with purulent looking effusion behind, but rather quite painful inflammation of the TM, called bullous myringitis.[9] Bullous lesions on the TM may develop during the perforation of the TM. Sometimes, perforation does not occur instantly through all three layers, but pus may pass through the mucosa and middle layer and for a period of time may dissect the epidermal layer filling underneath as a bulla, just before perforating through this last layer.

Acute OM may present itself with true bulging of the TM. Fullness of the TM is initially apparent in the posterosuperior portion of the parts tensa and the pars flaccida, because these two areas are the most compliant parts of the TM.[10] One other underlying reason for isolated pars flaccida and posterosuperior quadrant bulging should be kept in mind, especially when the rest of the TM does not appear to be bulging or inflamed. A number of mucosal folds and membranes around the ossicles divide ME and attic space into compartments.[11] Rarely, the two small isthmuses between the epitympanum and mesotympanum get blocked with the inflammatory tissues, and purulent effusion trapped above these isthmuses manifests itself as selective bulging of the pars flaccida and posterosuperior quadrant. This presentation may be as severe and worrisome as aditus ad antrum block, presenting with coalescent mastoiditis and its complications. A ventilation tube would not be adequate, since it would not provide drainage of the entrapped pus in the epitympanum and mastoid.

Assessment of EAC and TM trauma should focus on ruling out temporal bone fracture, potential facial paralysis, sensorineural or conductive hearing loss, CSF or perilymph otorrhea, and presence or absence of TM perforation. Assessment of the size and edges of TM perforation may result in need for early intervention, if the edges of the perforation appear to be inverted or displaced unevenly, reducing the chance of spontaneous healing and bringing the risk of cholesteatoma formation.

## Pneumatic Otoscopy

Pneumatic otoscopy should be considered the standard in otoscopic examination.[12] Although not currently widely used by most practitioners, and not even by the majority of otolaryngologists, there is growing awareness and expanding utilization especially among younger physicians.

The TM is semitranslucent and minimally transparent under normal conditions with a degree of normal individual variability (Fig. 11.15). TM thickness and histology or changes resulting from the present or past abnormal

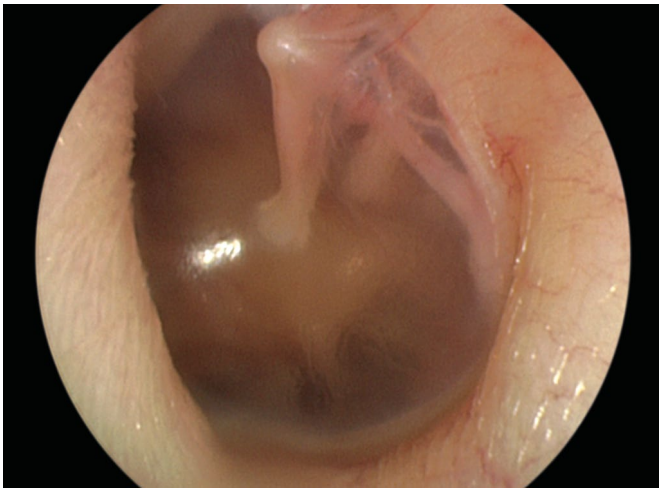

**Fig. 11.15:** Tympanic membrane with normal color, semitranslucency and minimal transparency.

conditions of the TM or the ME impact the translucency and transparency. Pneumatic otoscopy allows assessment of the status of TM and the ME while changing the pressure in the sealed EAC with a squeezable bulb.[13,14]

Misuse of pneumatic otoscopy and resulting misdiagnosis of the ME status is not rare. The most common error is failure to recognize the inability to change the EAC pressure in both negative and positive direction by squeezing and releasing the bulb, resulting in the misdiagnosis of immobile TM, and effusion or infection behind the TM. In order to prevent this error, an otologist should be aware of several important technical details:

1. Choosing the right size speculum is the initial step. While one may get better with experience in guessing the correct size, there are only three commonly used specula 3, 4, and 5 designated by the inner diameter in mm. When it is noticed that the initial choice is not the best for the ear canal, one should not hesitate to change the speculum size. While most pediatric group patients can be examined with a good seal with these three sizes, one should be aware that large ear canals limit the ability to perform pneumatic otoscopy. There is a need for alternative instruments that could get a seal in a larger EAC. For the large ear canals, the Siegel or Brunning speculum set used with microscope is the best option. If not available, tympanometry may be needed to assess the TM mobility
2. Failure to achieve a seal in the ear canal and otoscope head system may be due to suboptimal coupling of the speculum or the lens with the otoscope head. The best method to test the seal of the system is to squeeze the bulb when the tip of the speculum is digitally

**Fig. 11.16:** Otoscope handle grabbed in the palm with the opposing four fingers provide a steady grip. The thumb holds the bulb against the upper part of the otoscope handle while the other hand pulls the pinna gently to straighten the ear canal and keeps the head steady.

occluded.[15] Performing this simple test immediately after inserting the speculum into the otoscope head is a good practice. Especially when using a number of different handheld otoscopes in a number of clinic rooms in various clinical settings, one may run into otoscope heads that do not seal well or at all. Bent otoscope heads and/or worn out or loose lens caps should be repaired or replaced in order to achieve the most basic otoscopic examination standard: pneumatic otoscopy with an otoscope head that can seal. The clinician should be vigilant in checking and demanding this basic otoscopic examination standard in every clinical examination setting

3. There are many ways to hold the otoscope handle and bulb. Of those, this author feels that having the handle grabbed in the palm with the opposing four fingers provides the most steady grip. The thumb holds the bulb against the upper part of the otoscope handle (Fig. 11.16), making the other hand available to pull the pinna gently posterosuperiorly to straighten the ear canal, and to help keep the head steady
4. It is best to insert the otoscope to an ear canal with the bulb half squeezed by the thumb. This half squeezed bulb allows changing the EAC pressure in both positive and negative directions.[8] This is in contrast to earlier teaching to insert the speculum and apply positive pressure after achieving a seal, and after momentarily breaking the seal, releasing the bulb for negative pressure.[13] A concern regarding this teaching is that if the bulb is squeezed after the establishment of the seal, the only possible direction of pressure change is toward positive pressure. If there is negative ME pressure during the examination to start with, and especially if there is significant retraction, squeezing the bulb will result in little medial movement, if any. Furthermore, release of the bulb will not have any effect on pulling the TM more lateral than its original position, resulting in the misdiagnosis of ME effusion, when there is actually only negative ME pressure without effusion.

Pneumatic otoscopy provides extremely valuable and often irreplaceable information regarding the presence or absence of effusion, degree and severity of retraction, atelectasis or retraction pocket, TM perforation and patency of a ventilation tube. For all these conditions, the ability to move the TM by changing EAC pressure is used as the criteria for diagnosis.

One of the common manifestations of chronic and recurrent otitis media and perhaps underlying ET dysfunction is TM retraction, retraction pocket, and/or atelectasis. The retraction pocket or state of retracted or atelectatic TM may be temporary due to the negative ME pressure or more permanent from adhesions of the TM into the ME structures. However, this is usually from some histological changes in the structure of the TM with loosening and weakening of the elastic fibers or partial or complete loss of them. This usually irreversible process may stop progressing in childhood or in adulthood. In the examination of the ear, it is important to have multiple assessments, especially after a cold or allergy exacerbation or an airplane flight to see the ear in its worst condition, and to see if it is improving on its own in time. Keeping track of potential progression and whether there is chronic or intermittent formation of effusion is critical in management.

Pneumatic otoscopy is the clinical method to determine if TM is retracted because of mild or significant negative pressure, whether the retraction is generalized or localized, whether part or entire TM is collapsed on the promontory, or enveloping around the long process of incus and incudostapedial joint, whether any small or large part of the TM that is in contact with the promontory or ossicles, whether there is adhesion, and to be able to see, if there is keratin debris building up within a retraction pocket in an invisible but retractable depth. There should be caution for applying controlled and slowly changed pressure in order to prevent perforation at an atrophic segment of the TM.

Discoloration of the TM may indicate the status of the ME. A general hyperemia with inflammatory appearance, especially with purulent looking effusion and bulging TM, is consistent with acute OM. However, differentiation is not that straightforward, and diagnosis of OM is not based solely on the TM appearance. Still, a clear serous effusion or an amber-colored effusion is more likely consistent with an OM with effusion. Mucoid or mucopurulent effusion without bulging is rather a harder call with respect to acuity of the process. Also, it is also not rare to find ME filled and TM slightly bulging when the child is happily playing in your clinic and even parents are reporting that their child is sleeping well.

## Diagnosis of ME Effusion

Erythema of the TM has been considered a criterion for diagnosis of OM. In a crying baby, visualizing a bulging and red ear drum often leads to this diagnosis. However, these findings may merely be from crying caused by the physical examination itself. Pneumatic otoscopy is a valuable tool to see if the ME is aerated. Even though myringitis, an early phase of OM, is a possibility when erythema is present without an effusion, this condition is rare. When TM mobility is normal, OM diagnosis and administration of any treatment should be avoided. While pneumatic otoscopy is considered invaluable in differentiating the presence and absence of ME effusion, this diagnosis is not simple. Skill and experience is necessary to have a high level of certainty. Even most experienced otologists feel some degree of uncertainty with some ears. TMs are never categorically “mobile” or ”immobile”.

When an otoscopy clearly shows an air fluid level, pneumatic otoscopy does not seem necessary. On the other hand, TMs do not always demonstrate normal translucency, and instead may have thickness from inflammation or myringosclerosis or just scars. It is not rare to have geographic irregular distribution of thick and thin areas or scar bands that may resemble an air fluid level, or air bubbles within the fluid. Changing of the TM position with pneumatic otoscopy usually shifts the air fluid level or position of the air bubbles and verifies the presence of effusion.

Thin, retracted, and deformed TMs that touch the promontory may pose a diagnostic challenge. The whitish surface may often be confused with effusion and even sometimes with a cholesteatoma. The meniscus of fluid at the edges of interface between the surfaces may look like

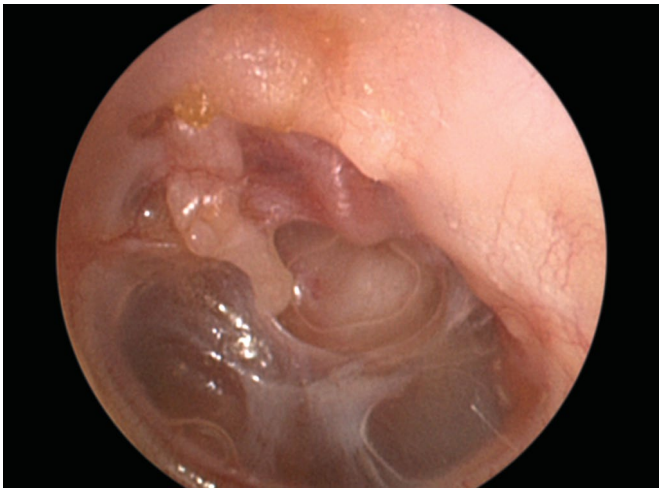

**Fig. 11.17:** A retracted tympanic membrane with atrophic and tympanosclerotic areas. Posterosuperior part is touching the promontory, displaying a round meniscus of fluid at the contact surface, while middle ear is essentially filled with air.

an effusion, but it is caused by a drop of fluid that is often not more than the normal moisture on the mucosa itself (Fig. 11.17). Pulling the TM off of the promontory in part or completely with pneumatic otoscopy will change the size of touching interface area, and cause the meniscus to disappear.

When ME effusion is suspected, several details are critical for diagnosis. In addition to picking the right size speculum and making sure that there is a good coupling and seal between the lens, head, speculum, and ear canal and starting with slightly squeezed bulb, the otoscopist should get used to changing the bulb volume only slightly. If there is a good seal, only a slight squeeze and release should be adequate to move the TM with normal ME pressure, in both directions. Inexperienced otoscopists are more likely to make large pressure changes with the bulb, which may become a habit. Uncontrolled and uncalculated pressure applications lead to significant patient discomfort. If the patient is a child, this contact, which is typically the initial step in the examination, could result in an early loss of chance to build a calm interaction. One reason that feeds this habit is not paying attention to or being able to get a seal with the otoscope. In order to move the TM when there is not a good seal there must be large volume swings in the bulb. When there is no seal, the extent of TM movement is determined by the degree of leak relative to the volume change achieved with the bulb. However, if there is no seal, one cannot get a good feeling of how much bulb movement corresponds to how much normal TM mobility. Having the habit of

performing unsealed otoscopic examinations hinders the necessary experience in developing the sense of normal and abnormal movement of the TM.

First of all, it should be realized that the volume change with maximum displacement of a normal TM from the most retracted to most bulging position is only about 0.2–0.3 mL.[16] Therefore, when the ME pressure is normal, and the TM is in its neutral position, all it is needed to appreciate this degree of displacement is a minimal change in the bulb volume. The pressure required to move a normal TM with normal ME pressure ranged between 10 and 15 mm of water.[17] However, the pressure needed to move the TM when there is ME effusion ranged from 40 to 160, depending on the quality of effusion. Although TM did not move at 200 mm pressure when there was ME effusion, examiners often used excessive pressures up to 500–1000 mm.[17,18] It is the otoscopists skill and experience that develop over years to realize the disproportional degree of volume change in the bulb to move the TM, translating to the confirmation of presence of ME effusion. After reaching the maximum degree of displacement, added displacement will only result in pain and reactive movement of the head that increases the risk of ear canal trauma from the speculum edge. It is the inexperienced otoscopist that results in traumatic pressure of the speculum on the ear canal or pain even bleeding. Role of control of movement, and its impact on accuracy of examination and/or pain will be discussed later in the chapter.

Second, one can always move the TM to a certain degree with exaggerated pressures. Uncontrolled volume swings with the bulb may therefore give the false impression of mobile TM. Theoretically, fluid is non-compressible, and when ME and mastoid cell system is completely filled with fluid, there should be no movement of the TM whatsoever. However, in reality, there is always some degree of movement in the EAC/TM appearance with increased pressure swings. This is usually not a false perception. There are many potential spaces for displacement within the ME cleft that can allow for TM mobility even in the setting of effusion. These may include the presence of some air in the ME/mastoid cell system, displacement of intravascular fluids, compression of the tensor tympani muscle in the semicanal, displacement of fluid in the ET, and compliance of the EAC in young infants.[1] In fact, in the presence of ME effusion, the degree of mobility of TM may even be referenced to the compliance of the EAC soft tissues, and in the absence of effusion, expect much more movement with pressure swings compared to the ear canal tissues. This is equivalent to the admittance with tympanometry at 250 Hz that happens due to the compliance of the EAC and that disappears at 1000 Hz.

An especially important detail with respect to the TM mobility and presence of effusion is the appearance of vascularity on the TM. Positive EAC pressure that exceeds the capillary perfusion would lead to blanching of the TM. Similarly, negative EAC pressure results in engorgement of the vasculature resulting in overall reddening. These changes can be observed in a normal TM; however, this is much more pronounced in the TM with effusion. The key is to notice if the blanching and engorgement of the blood vessels is present at the onset of TM mobility. If there is air with normal ME pressure behind the TM, any significant blanching or engorgement will not be present until the TM reaches the extent of its mobile range as determined by its tissue properties. If, on the other hand, there is effusion filling the ME/mastoid cell system, the blanching and engorgement will be observed before or at the onset of movement of the TM. If this blanching or engorgement happens in one direction only at the onset of a pressure change, the ME pressure can be determined. That is, if the TM blanches with positive pressure only, there is likely negative ME pressure, and vice versa. When an effect is seen with both positive and negative pressure, this suggests a stiff TM and effusion filled ME.

## Otoscopy with Surgical Head

Standard closed head otoscopes can admit an instrument by sliding the lens off to the side, allowing the otoscopist to clean cerumen, suction, or remove a foreign body, still utilizing the lens magnification. However, this approach limits the insertion and manipulation angle, making instrumentation challenging. Handheld otoscopes with a surgical head have a small central lens that rotates which allows instrumentation at a much broader range of angles. It is best to have a second separate handheld otoscope with a surgical head next to a standard otoscope available for each patient encounter. In the presence of cerumen occlusion in the canal, it is often necessary to switch back and forth the otoscopes with the pneumatic and surgical heads, until the full or at least adequate inspection of the TM is possible. It is especially important to have these two handhelds right by the patient when examining and cleaning a restrained child. For a skilled otologist, it is the restraint that annoys both the child and the parents, more than the instrumentation, most of the time. Needing to

change the head on the same handpiece back and forth may lead to frustration of the patient/parent as well as the otologist.

## Otomicroscopy

Microscopes have been used in otological surgery since they were first introduced in the1940s. Use of them in the clinical setting is more recent. However, the binocular microscope is now considered an essential part of clinical examination of the ear. While otomicroscopy is widely used in the clinical examination of adults, it is relatively more rarely used in pediatric practice. There are a number of reasons for this, from cost to lack of necessary training and skill, to the perception that it is not necessary or easy to use in the pediatric population. For many pediatric otolaryngology practices, having a microscope in every office room may be cost-prohibitive.

Microscopic examination requires a relatively steady head. This limits the likelihood of success for routine otomicroscopy in most young children. If needed, some degree of restraining is often required. Routine use of microscopes in the assessment of every patient also reduces the efficiency in the clinic flow, even if stabilizing the head or restraining was not necessary. Microscopic examination takes some time with laying the child on an examination table or reclining the chair and positioning, if needs to be done on both ears sometimes needing to go around or having the patient lay on the opposite direction, depending on the setup of the room.

For most pediatric examinations, visualizing the TM routinely under microscope is not necessary. For many practitioners, most manipulations in the ear canal can be performed competently without using a microscope. On the other hand, a microscope must be available for challenging cases and evaluation of complex otologic conditions. The microscope frees both hands for handling instruments more carefully and sometimes use of two concurrent instruments.

## Pneumatic Otomicroscopy

Microscopic examination is superior to otoscopy in visualization of the landmarks and specific sites and pathologies in detail; however, pneumatic otoscopy is superior to the microscope in assessing ME pressure and TM mobility and identifying the presence or absence of ME effusion.

Specific instruments used with microscope will allow for pneumatic otomicroscopy. Otoscope sets, called Brunning or Siegel, have heads with pneumatic bulb attachment and broad series of speculum sizes that allows seal of the EAC and observe with the microscope through the nonmagnifying glass on the head (Fig. 11.18). Sets also have glasses with magnifying heads that were more commonly used in the era of head mirrors, before handheld otoscopes were available or widely used. Ideal visualization of the TM can be achieved using the microscope with the pneumatic head set sealing the EAC. Naturally, there are limitations as stated earlier for the microscope, where in young children steady head position for sustained stable viewing angle and focus may not be easy or possible (Fig. 11.19).

**Fig. 11.18:** Pneumatic otomicroscopy is performed with sets that have heads with pneumatic bulb attachment and broad series of speculum sizes that allow seal of the external auditory canal.

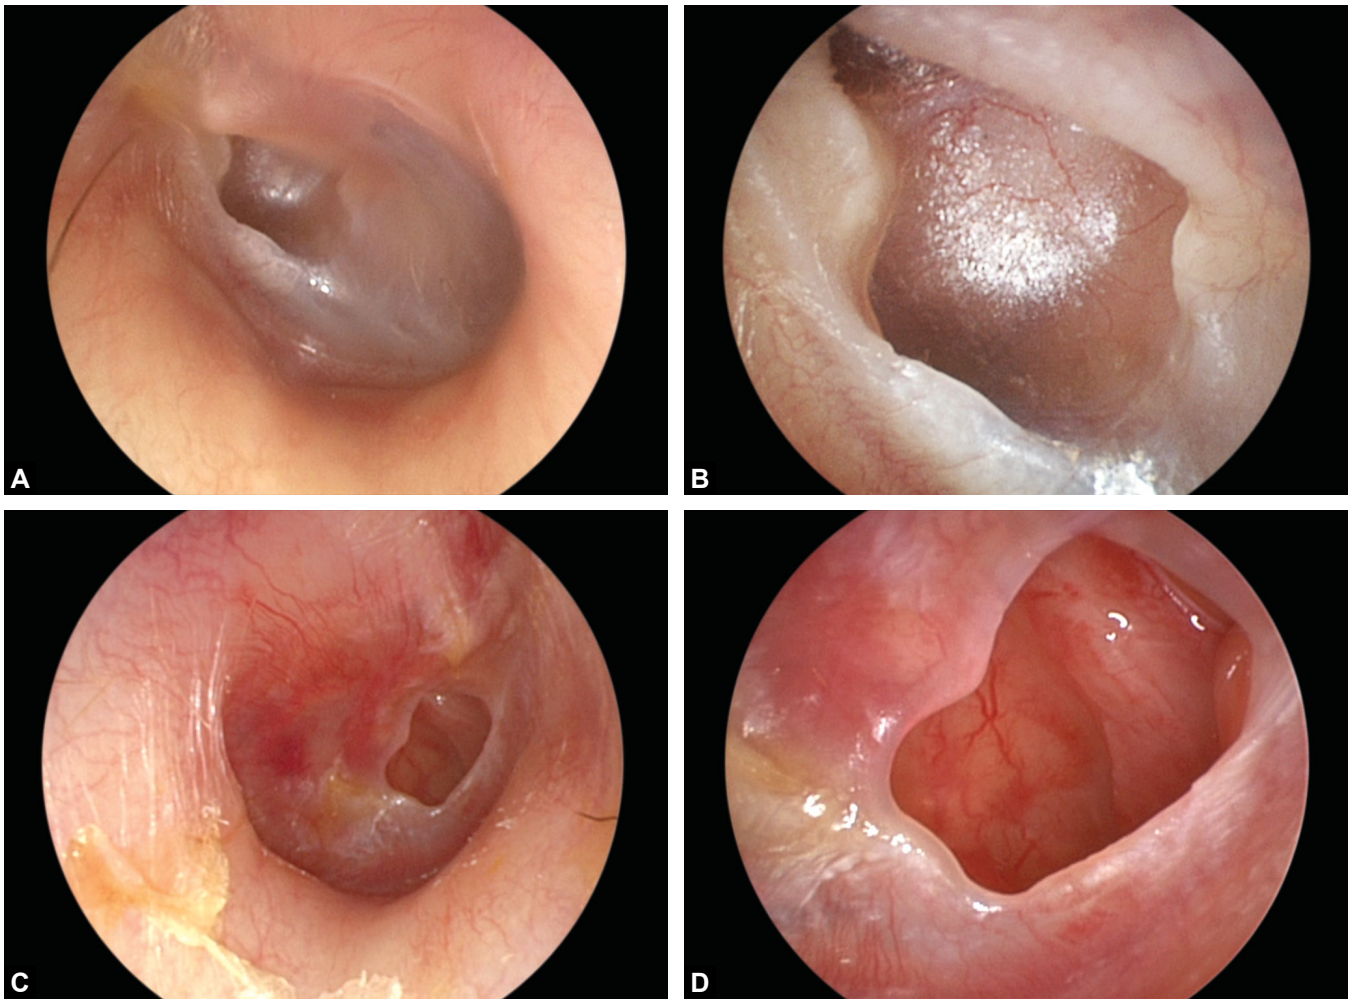
**Fig. 11.19:** A small child sitting on the mother's lap can have manipulation under microscope.

## Otoendoscopy

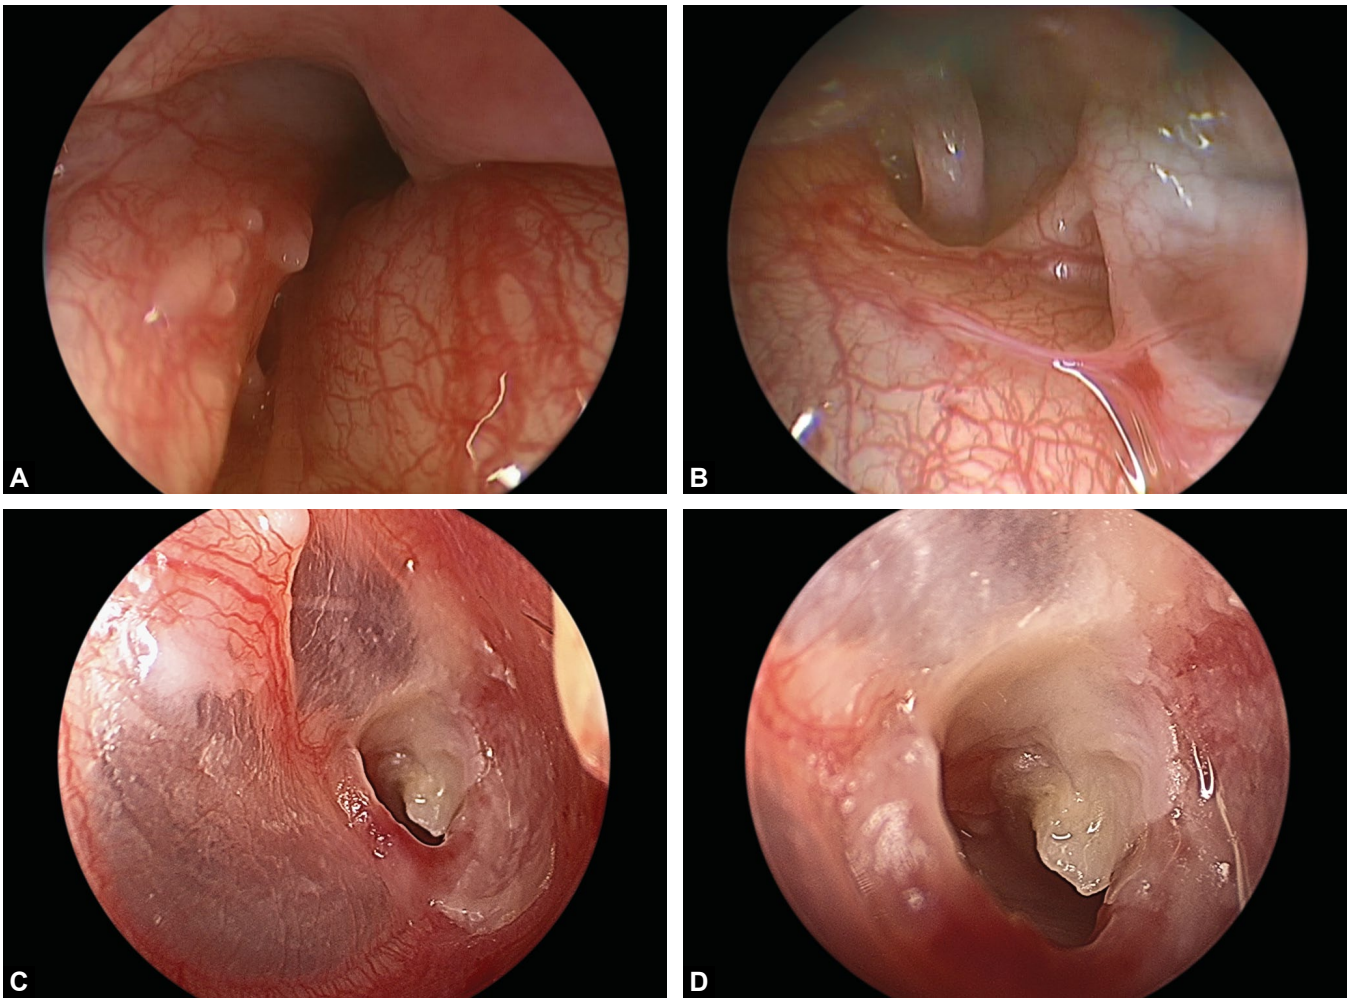
Endoscopy has been applied to otologic surgery for some time. Use of endoscopes in the clinical examination of the ear can be limited, especially in the pediatric population. On the other hand, with a cooperative child, examination of the depth of a retraction pocket or to assess the ME sites that are not directly visible to the microscopic examination may be extremely useful in assessing the ear and the decision making in the management of complex otologic problems (Figs. 11.20A to D).

Patient selection is critical, and the issues related to instrument handling and precautions to prevent trauma and restraint apply to the endoscopic examination of the ear in the office setting. As a rule, otoendoscopy should be used with extreme caution in a child that requires restraining. In an older cooperative child, turning the face of the patient to the monitor brings his attention to the condition of his ears, and enhances the acceptance of any proposed treatment by the patient and the parents tremendously.

Endoscope sizes and the degree of the angled ones vary. In the office a 0° telescope should be preferred, and 30° or 70° telescopes should be reserved for experienced hands on extremely cooperative children (Figs. 11.21A to D). In the absence of specific ear endoscopes, 2.7 mm nasal endoscopes may be used for the same purpose. Technology is rapidly changing and a number of medical instrument manufacturers are developing and marketing smaller and smaller endoscopes with various angles. Currently, decreasing the size below 2 mm seems to decrease the image quality considerably. Short, 6 cm otoendoscopes are excellent for diagnostic imaging, but leave little room for a second instrument if needed. Longer scopes from 16 to 20 cm are more suited to this purpose, but again must



**Figs. 11.20A to D:** Endoscope allows a closer look at a tympanic membrane retraction pocket (A); to visualize potential deeper extension (B); or a perforation (C) to assess better the condition of the middle ear (D).



**Figs. 11.21A to D:** A 70° endoscope visualizing the Eustachian tube orifice (A) and oval window with posterior crus of the stapes (B) A 0° telescope enhances the visualization of the tympanic membrane perforation (C) and skin ingrowth onto the promontory (D).

only be attempted in highly cooperative older patients. Examiners should be aware that heat from the endoscope may result in vertigo due to a caloric response.

## HANDLING OF THE INSTRUMENTS

When there is no need for instrumentation, the examiner's free hand is used for straightening the EAC. When speculum is used with a microscope and when manipulation is planned with the other hand, straightening the ear canal becomes an issue. Common practice is to push the speculum onto the canal to keep the broad visualization of the desired site. However, this can be uncomfortable and could suddenly trigger a series of reactions from more movement to expressing the feeling of pain to crying or even refusal of further examination or manipulation. It is therefore important to reduce the pressure applied on the ear canal by the speculum in addition to the other used instruments.

One technique to straighten the canal when a speculum is inserted without using the other hand is using the third finger to retract the auricle. While the first two fingers hold the speculum, the third is extended under the speculum into the concha and the pinna is stretched gently to achieve the same effect as pulling the pinna with the other hand. It is even more comfortable, because rather than pulling on the helix the tension is placed directly on the concha, which is better tolerated. A right-handed person examining the right ear holds the speculum with the first two fingers of the left hand, and the third finger is brought into the concha and flexed toward the palm to retract in a posterosuperior direction and achieve

**Fig. 11.22:** A right-handed person examining the right ear holding the speculum between the first two fingers of the left hand flexing the third finger placed in the concha in the posterosuperior direction.

**Fig. 11.23:** A right-handed person examining the left ear holding the speculum between the first two fingers while the third finger extends posterior to the speculum pushing the concha in the posterosuperior direction.

an improved directional view (Fig. 11.22). For the same person that examines the left ear, the third finger goes between the speculum and the palm, but this time, instead of flexing, it pushes the pinna in cranial direction, which practically pushes the pinna in the posterosuperior direction (Fig. 11.23).

## Precautions Regarding Instrumentation

Instrumentation in the EACs of infants and children is always challenging. Gentle use of instruments is essential. In an older individual, if any move hurts, the otologist may apologize and continue more carefully. In a small child, there may be no second chance other than going downhill with restraint. However, typically, restraining brings need for more restraining on future examinations. Therefore, ideal pediatric examination is without restraining, when possible. This is impossible for certain ages, presentations and past history of restrained or painful examinations, but the possibility of examination and manipulation without restraint should always be kept in mind and explored. On the other hand otologist should always be prepared for a sudden movement. There is no excuse for a significant iatrogenic trauma in the hands of an otologist caused by a sudden movement when the instrument is in the ear canal. Even most minor trauma can be avoided by an experienced otologist with certain precautions and well developed reflexes.

The best precaution to avoid trauma during an examination of instrumentation of a child's ear is developing a good relationship with the child, if possible. Sometimes, conversation and explaining of what is going to happen and how it is going to be done may make difference even in very young children as young as 2 or 3 years old. Effort should be made to explain that a sudden movement could result in pain, knowing that you cannot rely on this explanation to prevent a movement when pain is experienced. However, often it is the fear of unknown or pain that results in movement. And main goal of such conversation is to reduce the fear. Asking the child to tell you if/when he/she feels any pain coupled with assuring the child that if there is pain you promise to stop doing what you are doing may help reducing the chance of prepain movement.

Next precaution is a specific way of handling the instruments, to have less chance of inadvertent trauma if there is a sudden movement. Focusing into the view inside the speculum reduces the awareness of the movements of the head and the rest of the body. Head movement is not easily noticed when someone is looking at the TM through the otoscope, especially when the other eye is closed. A nonrestrained hand could reach up and pull the otologist's hand or worse, push or hit the instrument of the hand holding it and make an instrument further get inserted into the canal.

In order to trigger the trained reflex of pulling the instrument out of the EAC, there is a need for input. Visual input needs to be used when possible. Keeping both eyes open, even looking through the otoscope with one eye

constantly gives a feedback. Having the hand that holds the speculum or the otoscope touch somewhere on the head when possible will give tactile clue on movement and initiate the reflex to adjust the position or angle or pull out the instrument. The third and probably most important precaution is related to the instrument holding hand. The best technical precaution is to use the hand or fingers as a stopper, keeping stable the distance between the tip of the instrument and the anchor point where the tip of one finger or some part of the hand. When the instrument holding hand is anchored to the edge of the speculum which is lodged in the ear, any movement of the head will not only be felt instantly with the instrument hand, triggering the subcortical/spinal level reflexes, but will move the instrument hand concurrently. Anchoring primarily helps reducing the risk of inadvertent medial movement of the tip but not necessarily prevent rotational movement that could potentially traumatize the sides, i.e. the EAC.

The anchoring practice is essential in general for steady otological surgery, and can be applied to handling of most instruments during surgical manipulation, but it also provides an office technique for less risk for pain and trauma. For most instruments, while the first two fingers (for alligator/scissor group, first and third) are used to hold the instrument, the third (or the second for the alligator/scissor group) usually reaches to the shaft of the instrument for steady handling. The fourth finger can touch the edge of the speculum, and the fifth finger can touch the head, if possible (Figs. 11.24 and 11.25) using these two points to anchor and use as a stopper. Sometimes, using the other hand holding the speculum for the point of anchor may be an option.

Adding an extra stabilizing factor is possible by laying the shaft of the instrument to the edge of the speculum. This technique not only makes the hand and instrument steadier but also results in the movement of instrument concurrently with the speculum when the head of the child moves. On the other hand, this does not necessarily eliminate the risk, and on contrary can increase the lateral rotational movement at the axis of where it is anchored, if the concurrent rotational adjustment of the hand position lags the head's rotational movement, there may be a higher chance of trauma on the side walls.

Similar precautions are applicable to the use of an endoscope in the clinical setting. The diameter and the length of endoscopes may bring varying degree of difficulties. In general, while handling an endoscope in the ear, precaution to rest the second hand that does not hold the endoscope head and camera broadly on the head next to the ear and use the fingertips of that hand to stabilize the endoscope shaft close to the EAC entrance and use the fingers as stopper to prevent any sudden medial displacement with any move is essential.

**Fig. 11.24:** For handling a curette or a similar instrument, while the first two fingers are used to hold the instrument, the third usually reaches to the shaft of the instrument for steady handling, the fourth finger can touch the edge of the speculum, and the fifth finger can touch the head, if possible using these two points to anchor and use as a stopper.

**Fig. 11.25:** For handling an alligator or a similar instrument, first and third finger are used to hold the instrument, the second usually reaches to the shaft of the instrument for steady handling, the fourth finger can touch the edge of the speculum, and the fifth finger can touch the head, if possible using these two points to anchor and use as a stopper.

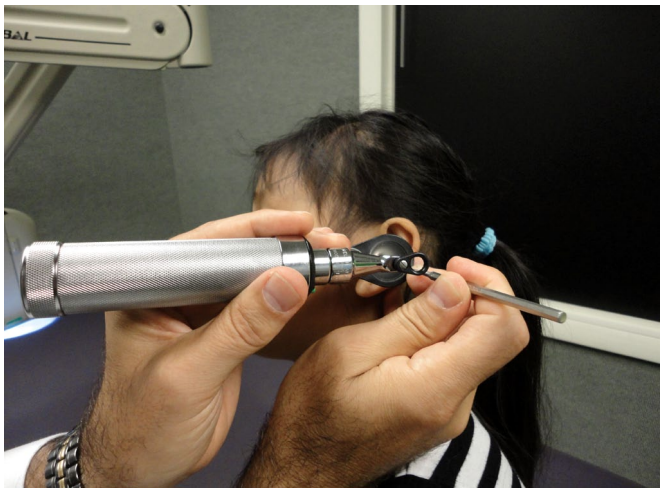


**Fig. 11.26:** When possible from simple examination to all manipulations should be attempted with the child is sitting freely on the examination chair.

**Fig. 11.27:** Most short and simple manipulations can be performed on the parent's lap.

## TO RESTRAIN OR NOT TO RESTRAIN A CHILD

The best restraint is the avoidance of restraint. The more a child is restrained, the more he/she will try to move, get upset, or cry. In the very young, restraining may be unavoidable. In an older child, when possible, all manipulations, starting from the simple examination, should be attempted when the child is sitting freely in the examination chair (Fig. 11.26). All children want to be in control. Starting from the toddlers and preschool age, all children would like to be in charge of what they are doing and what is to be done to them. A practitioner dealing with children should be aware of this and acknowledge it as much as possible. Going the extra length in unrestrained manipulation is only possible with an empathetic and patient approach.

Children should be explained at age appropriate length or detail why the intended manipulation needs to be done and how it is going to be done. If a potentially painful procedure is intended, condition that could cause pain, specifically, their movement should be explained to enforce their effort to stay steady. Their verbal consent needs to be obtained. This assent is not always necessarily a clear verbal approval, but often rather a silent or passive acceptance.

The next option is to not necessarily physically restrain, but to be prepared to restrain with any movement, if that would happen. This requires someone, preferably a family member, being physically close and prepared to hold, if needed. Naturally, the critical differentiation is whether the manipulation can possibly be completed without any restraint throughout the process. If there is such a possibility, it is important to be ready to help stabilizing any potential movement immediately, if that would occur, without a constant tight restraint. The clinician should have a good estimation of the reliability of the family member or other staff in their ability to achieve this task.

If on the other hand, due to the type and extent of manipulation one definitely expects a movement, holding the child tight a little late just when it is needed could limit the unavoidable drama. This applies especially for the short duration of manipulations. Stopping after a very short restraint may reduce the child's reaction. However, when a prolonged, potentially annoying or painful or risky manipulation is planned, and because of the age or the level of cooperation, compliance with this without a restraint is not a possibility, the otologist should plan the best condition of restraint for all these variables. Of the options, when possible, utilizing the parents' help should be prioritized. From the age when restraining is essential, i.e. from newborn period to the age that child thinks sitting on the lap of one of the parents is still acceptable, this option should be tried (Fig. 11.27). The best holding position is having the hand that the head is going to be turned toward, to turn and hold the head against the chest of the parent while the other arm and hand holds or covers both arms of the child over the belly holding the upper body against the chest of the parent (Fig. 11.28). This position is often necessary for even simple otoscopic examination

**Fig. 11.28:** Younger children may gently be restrained on mother's lap by turning and holding the head against the chest while the other arm and hand holds or covers both arms of the child over the belly.

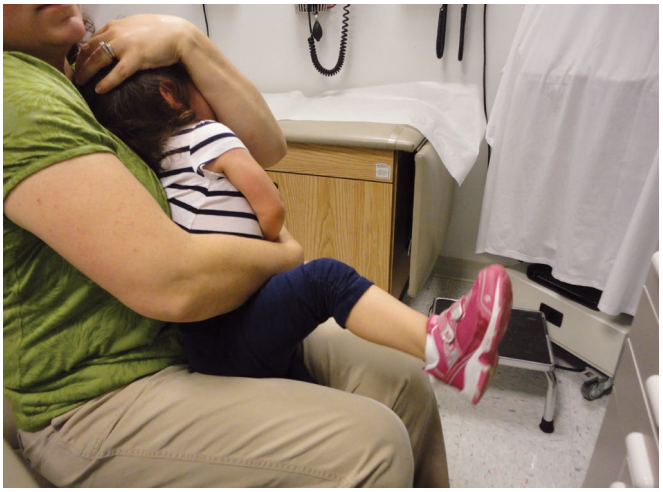

**Fig. 11.29:** When a child starts to move, their legs may need to be restrained between the legs of the parent.

that does not need any manipulation for the infants and most toddlers. For babies, this grasp and stabilization is sufficient, however, for older kids, or the ones that have constantly moving legs, placing the child's legs between the parents' and holding the entire body tight could be necessary (Fig. 11.29). When parents can get good hold of the child, most kids under 4–5 can be restrained like this. This position can always be supplemented with a helper whose role is to help hold the child's head.

Simple otoscopic examination may be performed in a child as young as 2 with the child sitting alone on the examination chair, and it is best to offer the child this option and see if he/she is able to comply. Most young kids may choose to stay where they are, either the seat next to their parent or their lap, but it is always a great start if they agree to come and sit on the examination chair. This, if the examination part goes well, is the first step for unrestrained manipulation, when needed. The second prerequisite in those conditions is good communication. Explaining what is going to happen, and have them accept what you are going to do is essential to build and retain the trust that the child may start to feel in the otologist. In those circumstances, when there is no restraint, instead of hiding, instrument tips should be shown to the child. They are typically afraid of needles or other sharp objects. The curette is the most commonly utilized instrument in the office setting. In this author's experience, most children accept a trial of the use of a curette when they closely see the tip of the instrument and feel it on their skin. Although not as easy, alligator tips can be shown so that they understand that they are not scissors, like what they resemble, and that they are for holding tiny things.

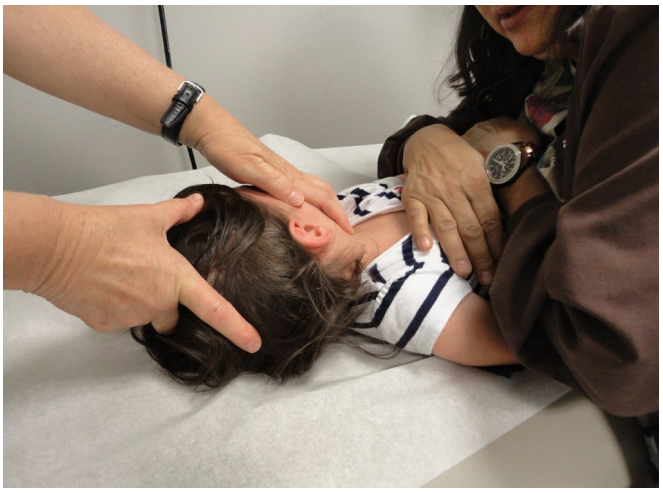

**Fig. 11.30:** A common method of restraining is while one holds the shoulders and below, the other focused on stabilizing the head.

For a prolonged manipulation or work close the TM, in infants, or in young or noncompliant children, restraining on the examination table is more effective and safe. In order to reduce the time under restraint, the otologist should gather all the necessary instruments and material including handheld otoscopes with pneumatic and surgical heads, curettes, gauze, suction, if needed, and extra specula with different sizes. When restraining on a table, a minimum of two helpers should be used. The patient's lower body is stabilized by one, and the head by the other (Fig. 11.30). Arms and shoulders can be held

**Figs. 11.31A and B:** One other restraining technique may eliminate the need for the second helper (A); however, it is not rare to need help to control the legs of the child (B).

by the lower body person who should lean over the child with their body (Figs. 11.31A and B). If the lower body person cannot handle arms shoulders and legs altogether, a third person takes over the legs, pressing the knees on the table, not allowing legs to gain leverage from the table to move the entire body.

When the additional helpers are not available or reliable, swaddling the entire body of baby with a sheet is an option, leaving the head uncovered so that the single helper can control the head. Papoose boards with at least two sizes should be available. These boards have broad Velcro bands that stabilize each section of the body separately for most effective restraint (Fig. 11.32). In noncooperative children older than 3 or 4, who must have the restrained assessment and/or manipulation, the papoose is very useful.

For older or noncooperative children who are strong, the otologist should decide whether or not safe stabilization is possible. It should be realized that, even with the adequate number of helpers, a strong older child may find a way to have a sudden movement that may be adequate to cause significant pain or trauma.

It is crucial to talk with the family members in detail with the greatest sensitivity and empathy. The otologist should develop a high level of skill in assessing the thoughts and concerns of the parents. While the child's level of cooperation is a critical factor, the attitude of the family is of equal importance. There is a need to identify the main decision maker in the family. It is important to explain the reason for restraining, which is performing the procedure in a painless and safe way, with the clarification

**Fig. 11.32:** When there is a need for prolonged and precise manipulation a papoose may need to be utilized.

that despite the restraining there may be a small risk that pain or trauma may occur. Parents should be aware that at any point they can ask that the procedure is stopped, and also that the otologist may choose to abandon the task when he/she feels that it is no longer possible to complete the intended task, or when continued restraint can no longer be justified. The otologist should be confident enough to abandon manipulation without feeling embarrassed or concerned about being seen as incapable when it is clear that the planned manipulation cannot be achieved.

The comprehension and past experience of the parents, and their past interactions and comfort with the otologist dictate the degree of counseling required.

When families seem overly anxious about any pain or risk, or hint toward medico-legal consequences of such outcomes this may end up shifting the threshold for performing a procedure in the clinic. Whatever the reason, the otologist should respect the decision of parents, and seek alternative options, including examination of ears under anesthesia. If parents do agree to proceed, it is best to ask if they prefer to be in the room. If they are in the room, which should be encouraged unless they strongly prefer to leave, their status of continued acceptance and approval of the ongoing restraint should constantly be monitored.

### Children with Very Narrow Canals

Children and babies with very narrow canals, such as most newborns and most children with Down syndrome bring unusual difficulties in the clinical examination. When this child is referred to a specialty clinic, the question may be a simple one, like whether or not there is an ear infection or effusion, since, typically no one has ever seen the TM before. Preparation for the ear examination starts with preparing the parents. They should understand that answering this simple question may take 5–20 minutes of cleaning under restraint, and even after this prolonged struggle, an answer may not be given with full confidence. But, despite these, every effort should be made to safely and patiently clean the ear canal. All the tools including two handheld otoscopes with very small curettes that can pass through the 3 mm speculum should be placed next to the head. If 2 mm speculum is needed, #3 Fr. suction may work better.

### Children with Cognitive Limitations

Older children with cognitive impairments due to autism, Down syndrome or other syndromes, mental retardation, or cerebral palsy create challenges in the clinical examination of the ear. Sometimes, it is impossible to perform a safe and adequate examination of these children in the clinic. However, it is possible for a hasty approach or impatience to make the examination more difficult or impossible.

The initial step in an encounter with such a child is to stay at a distance and establish trust. By the age that they present to our clinic, such patients have typically been examined by a large number of people with white coats, and it is likely that they did not like most of them. Prolonged conversation between the physician and the parents may allow the child to feel less threatened, seeing the peaceful interaction that is going on. During this period, the physician should assess the child's reactions and gather information about risk or chance of aggressive behavior, the child's past experiences with the ear examination, the child's tolerance and parental expectations and acceptance regarding the pending examination.

This should be followed by the gentle and slow approach to the child, holding his or her hands, and then touching his or her head, constantly talking to the child with a calming voice. Laying one or both hands on the head, close to the ear and keeping it there and well before inserting the otoscope speculum, touching with the fingers, all on and around the pinna usually prevents a big or sudden reaction at first contact. If there is a risk for sudden movement, it would be better to have a family member to be on the other side, gently holding and comforting the child. It must be kept in mind that, sometimes for some reason, the child may react to you, the otoscopist, and if that seems to be the case, one should not take it personally, and explore the possibility of having another person attempt the examination.

Sometimes, from the beginning or well ahead in the examination, it may become apparent that the tasks in the clinical setting will not be achieved, and that restraining may not be an option. Alternatives, including getting a tympanogram, and abandoning the attempt to visualize or clean an ear if there is a reasonable tympanometric curve, or planning to perform this examination or manipulation under sedation or anesthesia should be introduced.

## VISUALIZATION, VIEWING, SHARING, AND DOCUMENTING

Many physical examination tools or instruments for the ear have not changed for decades. The microscope has been used in otologic care for > 70 years, and have been used in office examination of the ear for > 40 years. Endoscopes are relatively new to the outpatient clinics, and even more so to the pediatric clinics. However, viewing the microscopic and endoscopic images in the clinic with a monitor is quite a recent technological advancement. This technology allows the parents to see and better understand the problem, compare one ear to the other or to other reference images, watch any manipulation, and develop a trust (or sometimes distrust) with what they see happening. Images are more and more becoming part of the electronic medical records, allowing direct comparisons of the

conditions, the change in the conditions with time, and the effect of treatment. Photo or video documentation provides an opportunity for medico-legal protection and also brings the risk of being scrutinized. Whether or not we like it, electronic image documentation is not going away, rather its applications continue to broaden. Moreover, having and utilizing these tools in the clinical examination has already become a quality marker and a marketing tool, creating a pressure on providers to expand their technological armamentarium.

## CONCLUSION

Clinical examination of the ear in childhood presents unique differences and difficulties in recognizing, examining, testing, diagnosing, deciding on the clinical management options, and conducting them in the clinic. Other than the surgical and technical difficulties, there are many other important differences that distinguish health-care professionals who assess and take care of ear diseases in children. Assessment and management of acute and chronic ear diseases in children should be done by health-care professionals who are familiar, experienced, and skilled at managing these differences and difficulties in the pediatric population.

CHAPTER

# 12

# Pediatric Temporal Bone Imaging

*Nikhila Raol, Michael S Cohen, Robert Liu, Hugh D Curtin, Paul A Caruso*

## INTRODUCTION

While imaging in otolaryngology is invaluable in helping with diagnosis and with delineation of surgical anatomy, several considerations are needed when considering imaging in a child. Radiation risks and the need for sedation are among the most critical issues that differ between obtaining radiographic studies in children and adults. This chapter discusses some of the salient points about imaging of the temporal bone in the pediatric population, as well as outline how to decide which type of imaging is preferred based on clinical presentation. Lastly, it will describe how to interpret the studies and how to use them appropriately to help in making a diagnosis.

The initial portion will discuss the various types of imaging used and considerations specific to each type.

The clinical portion is arranged by clinical scenario in alphabetical order and includes:

- Congenital aural atresia and external auditory canal stenosis
- The infected ear
  - The nondraining ear
  - The draining ear
- Facial nerve paresis
- Hearing loss
- Masses, pits, and cysts
- Tinnitus
- Vertigo.

## PART I: IMAGING MODALITIES

Computed tomography (CT) and magnetic resonance imaging (MRI) are the two workhorses of imaging of the temporal bone. The standard technique and protocols most often used for imaging of the temporal bone are first presented. Special considerations for both modalities are then reviewed.

### Computed Tomography

#### *Routine CT Temporal Bone Technique*

The anatomy and pathology of the temporal bone involve small structures; resolution is thus highly important. Collimation is of optimal importance to achieve high resolution.

We routinely use a collimator of 0.6 mm and most commercially available units can be collimated to at least 1 mm. Collimation wider than 1 mm is not usually used, as the resolution is often insufficient.

IV contrast is used for evaluation of vascular pathology, e.g. dissection, for tumors, and may be considered for some types of infections such as coalescent mastoiditis or evaluation for abscesses, but is not routinely used for evaluations for otomastoiditis or hearing loss.

#### *MDCT Reformats*

Multidetector CT (MDCT) provides shorter acquisition times, decrease in tube current load, and improved spatial resolution.[1] Short acquisition is useful in temporal bone imaging in order to reduce motion artifact and in particular in children who require sedation or are imaged postprandially without pharmacologic sedation. Although the radiation dose with multidetector scanners in high-quality mode remains an issue compared with single detector scanners, the improved spatial resolution allows

for high-quality reformats that essentially obviates the need for rescanning the patient in a second coronal plane.[1]

Reformats may, moreover, be obtained in sagittal or oblique planes to improve the detection of pathology in specific clinical settings such as superior semicircular canal (SSCC) dehiscence as discussed below in this chapter under the indication of vertigo and dizziness.

### *Stenver Reformat*

Similar to the method explained above, for making the standard axial and coronal images, the 0.6 mm raw data are brought up on the console viewer in three orthogonal planes: axial, coronal, and sagittal. As above, the technologist scrolls through the sagittal plane until a view of the lateral semicircular canal is obtained represented by the two "dots" of the anterior and posterior limbs. The axial plane is then established by connecting the two dots. The technologist then scrolls through the axial data set until an image of the summit of the SSCC is viewed. The Stenver reformats are then made by tracing a line perpendicular to the long axis of the summit of the SSCC at 0.6 × 0.5 mm intervals. This plane is effectively perpendicular to the roof of the SSCC and displays the roof of the SSCC in cross section.

### *Poschl Reformat*

Similar to the method explained above, for making the standard axial and coronal images, the 0.6 mm raw data are brought up on the console viewer in three orthogonal planes: axial, coronal, and sagittal. As above, the technologist scrolls through the sagittal plane until a view of the lateral semicircular canal is obtained represented by the two "dots" of the anterior and posterior limbs. The axial plane is then established by connecting the two dots. The technologist then scrolls through the axial data set until an image of the summit of the SSCC is viewed. The Poschl reformats are then made by tracing a line parallel to the long axis of the summit of the SSCC at 0.6 × 0.5 mm intervals. The line must be made as parallel as possible to the axis of the summit of the SSCC. A slight obliquity may spuriously obscure a dehiscence by volume averaging with the temporal bone on either side of the summit of the SSCC (Figs. 12.1A to D).

## Cone Beam CT

Cone beam CT is a relatively new technique that uses ultralow dose mA and a cone beam of radiation to scan the entire volume of interest. In the temporal bone, it has the advantages of low-dose imaging, including sparing of the eyes and lenses, and improved resolution of certain structures such as the ossicles, modiolus, and vestibular aqueduct. Cone beam CT, however, requires the patient to be seated and allows for only one ear at a time to be imaged, which may be a concern in infants or young children who may cooperate for imaging for only a short period of time.

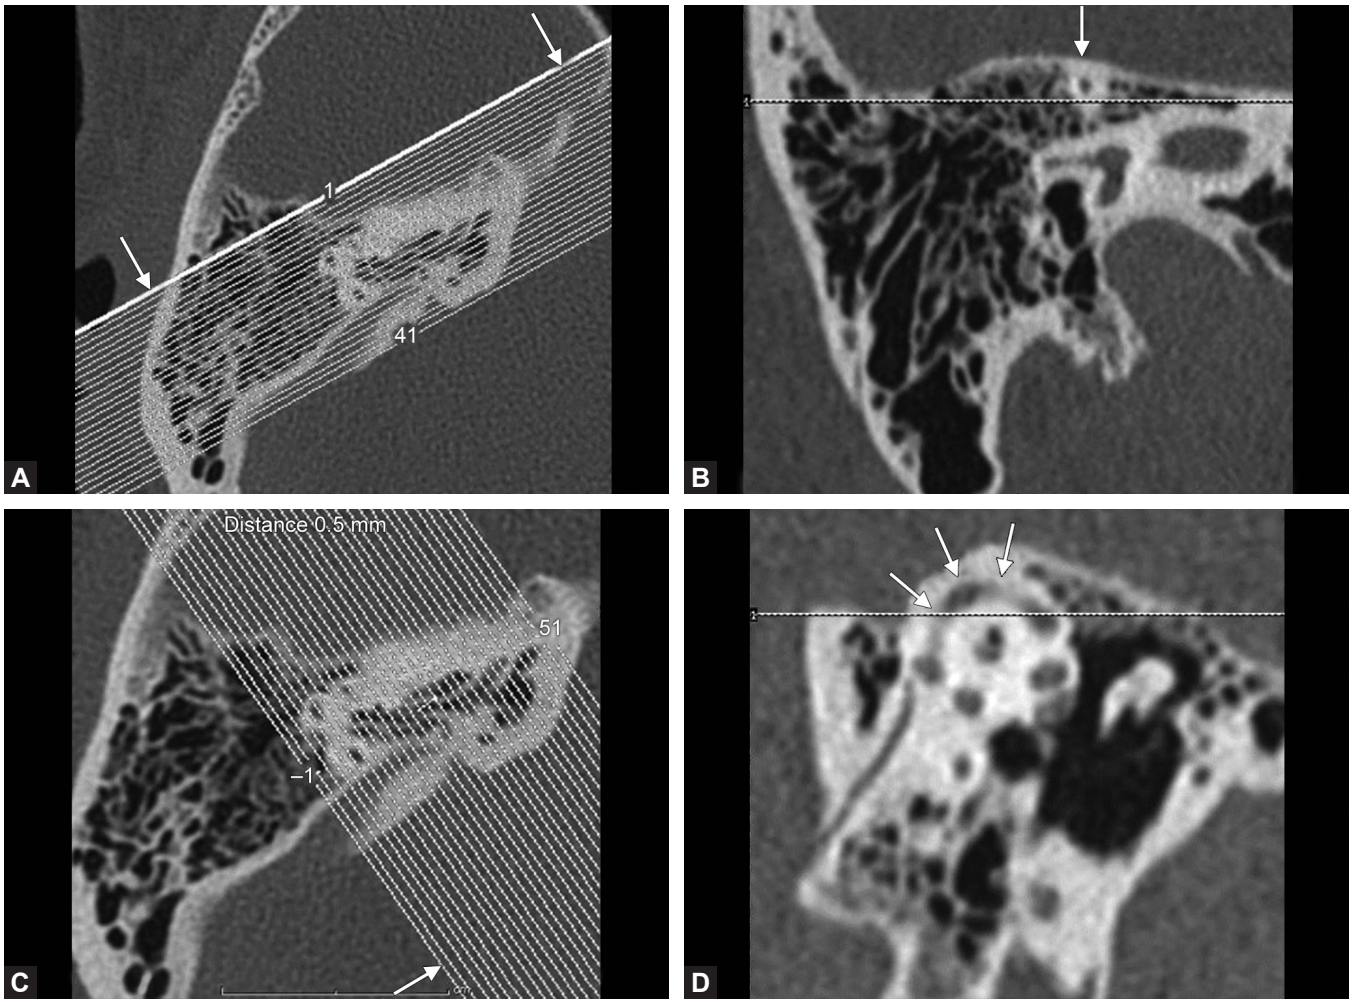
## Radiation Dose Reduction Techniques and Considerations for Pediatric Patients

Compared with most radiography procedures, CT examinations deliver higher radiation dose to patients. The quantity $CTDI_{vol}$ (Volume CT Dose Index) is currently used in CT dosimetry.[2] When a scan is prescribed, the scanner displays the $CTDI_{vol}$ in mGy on the console. However, the dose displayed is not the true dose for the specific patient under examination. Instead, the $CTDI_{vol}$ represents the average dose in the central section of a standardized phantom scanned with the selected protocol.[2a] The head phantom is a cylinder with a diameter of 16 cm and a height of 15 cm.

The effective dose E is used to assess the radiation detriment from partial-body irradiation (e.g. irradiation of only the head or only the abdomen). The effective dose is a weighted sum of the doses to all exposed tissues. $E = \Sigma(w_t \times H_t)$, where $H_t$ is the equivalent dose to a specific tissue and $w_t$ is the weight factor representing the relative radiosensitivity of that tissue. The unit of effective dose is sievert (Sv). The effective dose for a typical CT examination of the temporal bone is about 1 mSv (i.e. 1/1000 Sv). In comparison, the average effective dose from cosmic rays, radioisotopes in the soil, radon, etc., is about 3.11 mSv per year in the United States. The effective dose can be estimated from the dose-length product ($DLP = CTDI_{vol} \times$ scan length), which is also displayed on the CT scanner console. The effective dose for a head study in mSv is approximately 0.0021 × DLP (mGy cm) and approximately 0.0067 × DLP (mGy cm) for a 1-year-old patient.[2]

### *Radiation Risks*

Biological effect of radiation is either deterministic or stochastic. The deterministic effect will not occur unless a threshold dose is exceeded. However, the stochastic effects may occur at any dose level and the probability of occurrence increases with dose linearly according to the linear-nonthreshold dose–response model.[3]



**Figs. 12.1A to D:** Stenver and Poschl reformats in a patient with normal hearing AD. In (A), an axial source image is used as a reference to prescribe a set of 2D reformats that runs parallel to the long axis of the temporal bone in the standard Stenver topographic plane. This reformat runs perpendicular to the axis of the superior semicircular canal and thus provides a clear view of the roof of the superior semicircular canal [single white arrow in (B)]. In (B), the roof of the superior semicircular canal is intact. In (C), a similar axial slice is used to prescribe a set of 2D reformats that run perpendicular to the long axis of the petrous temporal bone in the standard Poschl plane (D). These reformats provide a view of the superior semicircular canal from posterior to anterior (three short white arrows).

For CT of temporal bone, the primary concern for deterministic effect is the dose to the lens. The minimum dose required to produce a progressive cataract is about 2 Gy in a single exposure.[4] If the lens is in the direct X-ray beam, the dose to the lens from CT of temporal bone is in the range of 0.03–0.06 Gy, but it could be as high as 0.13 Gy. If the patient is positioned in such a way that the lens is outside of the direct X-ray beam, the dose is in the order of 0.003 Gy.[5] Although the typical dose to the lens from a single CT scan is much lower than the threshold value for cataract, multiple nonoptimized scans in a short time with the lens in the X-ray beam can result in a lens dose close to the threshold. Every effort should be made to keep the lens outside of direct X-ray beam if it is possible.

Stochastic effects include carcinogenesis and the induction of genetic mutations. Children are inherently more sensitive to radiation because they have more dividing cells and radiation acts on dividing cells. Also, children have more time to express a cancer than do adults.[6]

## *Factors Influencing the Patient Dose*

The CT scanning protocols should be optimized such that the quality of images is sufficient for diagnosis and the patient dose is kept as low as reasonably achievable. To get the best balance of the image quality and patient dose, it is important to understand the effects of imaging parameters on the dose and imaging quality.

Patient dose depends on three group factors: equipment related factors, patient related factors, and application related factors.

The factors in the first group include X-ray beam filtration, X-ray beam collimation, system geometry, and detector efficiency. Although users do not have control of most of these factors, it is important to understand that the *Z*-axis dose efficiency is reduced when the total X-ray beam width becomes very small for MDCT due to the need to keep the beam penumbra out of any detector row.

The dose is strongly dependent on patient size. If the same technique is used to image the heads of an average adult and a newborn, the dose to the newborn is significantly higher.

Imaging parameters such as kVp, mAs (the product of the tube current and the time in seconds per rotation), and pitch (the table travel per rotation divided by the total X-ray beam width) are selected by the operator.

If all other parameters are fixed, the patient dose is proportional to the effective *mAs* which is defined as the *mAs* (*mA* × seconds per rotation) divided by the pitch.

The dependency of dose to *kVp* is more complicated. In general, the dose increases as a power function of kVp ($D \sim kVp^p$) if all other parameters are fixed. The value of $p$ is in the order of 2–3 depending on the type of the scanner.

### *Image Quality*

Image quality is characterized by spatial resolution, contrast resolution, image noise, and other quantities. It is difficult to use a single variable to characterize completely the quality of an image. However, in practice, image noise has been widely used to judge the CT image quality since the detectability of low contrast objects is strongly dependent on the contrast to noise ratio. The standard deviation of an ROI in the image is usually used to represent the noise. In CT, for a given reconstruction kernel, the noise is primarily due to the fluctuation of the X-ray photons reaching the detector. The noise is approximately inversely proportional to the square root of patient dose. To reduce the noise by a factor of 2, dose must be increased by a factor of 4. In general, image quality is better when the patient dose is increased.

### *Strategy for Dose Reduction*

To optimize the CT technique, the image quality required for the specific indication is assessed based on the radiologist's experience. The imaging parameters are then selected based on the patient size and organ type under examination such that the required image quality is achieved while the patient dose is kept as low as possible. Weight or age-based pediatric protocols should be established and special attention should be paid to children under age 2 because their heads are small and under rapid development.

## Magnetic Resonance Imaging

### *Routine Technique*

The standard MRI protocol for evaluation of the temporal bone in adults is detailed below for a 1.5 T magnet:

- The patient is placed in the supine position in the head coil
- Sagittal T1, axial T2, axial FLAIR, and axial DWI images are obtained through the whole brain
- Axial T1-weighted images are obtained through the temporal bone from the arcuate eminence through the mastoid
- Axial CISS (Siemens) or 3D Fiesta (GE) images are obtained through the internal auditory canals (IACs) and pons and are considered key sequences in evaluating children for sensorineural hearing loss (SNHL)
- Gadolinium is then administered
- Axial T1-weighted images are obtained through the whole brain, and high-resolution images are obtained through the temporal bones.

### *Additional Considerations*

Coronal high-resolution T1-weighted images may be useful for more detailed imaging of the temporal bone; the indications for the use of this sequence are reviewed in the indications section of this chapter.

### *MRA*

The most common indication for MRA is in the evaluation for tinnitus. For this indication, MRA is used to evaluate for dural arteriovenous fistulae, aneurysms, vasculopathies such as fibromuscular dysplasia, or arteriovenous malformations.

### *Safety Considerations*

Standard MRI safety considerations obtain in the temporal bone and the reader is referred to publications that list the safety of various prostheses.[7] For those institutions with a busy otology service, the issue of MR compatibility of stapes prostheses, total ossicular reconstruction prostheses (TORPs) and partial ossicular reconstruction

prostheses (PORPs) may arise. These prostheses are listed as well in the standard MRI safety references. Most stapes prostheses do not deflect significantly in a 1.5 T unit.

### *Plain Film Radiography*

Plain film radiographs have limited application to imaging of the temporal bone. A plain radiograph in the Stenver projection, however, may be used for intraoperative or postoperative confirmation of position of a cochlear implant lead. Plain films are used mostly for intraoperative verification of placement of cochlear prostheses. We favor the Stenver projection for this evaluation. The patient is placed in a 45° obliquity contralateral to the implanted ear that places the implanted ear in a position parallel to the film and then in 15° Townes projection. For example, if the left ear has been implanted, the radiographer would turn the head 45° to the right, with the film behind the head of the patient, and shoot a single radiograph with the beam tilted 15° inferiorly toward the patient (Fig. 12.4). Familiarity with this projection and with the proper position of a cochlear implant is one of the few instances in current imaging where plain film radiography is critical as the intraoperative assessment is often made while the patient is still anesthetized on the OR table.

### *Ultrasound*

US may be used for evaluation of periauricular cystic lesions such as first pharyngeal arch anomalies or ultrasound guided biopsies of periauricular lesions.

### *PET*

PET or PET/CT may be used for assessment of temporal bone masses or nodal metastases.

## PART II: REFERRALS AND IMAGING STRATEGIES

This part of the chapter is organized according to the major clinical indications for which a child may be referred for temporal bone imaging. The indications are listed in alphabetical order below. For each clinical indication, the following points are addressed:

- What is the pertinent clinical background?
- What is the first imaging modality of choice?
- What are the clinical questions that the imaging needs to address?
- What is your approach to the interpretation of the imaging?

## Congenital Aural Atresia and External Auditory Canal Stenosis

### *Clinical Background*

Children with congenital aural atresia (CAA) and external auditory canal stenosis (EACS) are often diagnosed just after birth, as this condition precludes examination of the ear and is often accompanied by some degree of microtia. In fact, in only about 5% of cases is atresia noted without coexistent microtia.[8] EACS may present later in childhood due to recurrent bouts of otitis externa or problems with cerumen impaction. Unilateral atresia is more common than bilateral atresia, and bony atresia is more common than membranous.[9]

While CAA and EACS are most common sporadic in nature, they have been described as part of a spectrum of numerous hereditary conditions, including mandibulofacial dysostoses such as Treacher-Collins' syndrome and Nager's syndrome, where associated abnormalities of the mandible are present; branchio-oto-renal (BOR) syndrome, where preauricular pits or cysts, as well as branchial cleft cysts or sinuses are often visible; CHARGE syndrome, where concurrent airway may occur; and facial clefting syndromes, such as Bixler's syndrome, where cleft lip and palate may be present.[10] Vigilance in recognizing the presence of a possible syndrome may lead help with surgical decision making as well as allow for multidisciplinary treatment of patients, both from a clinical perspective and from a radiographic and anesthestic perspective, with regards to safety.

### *Imaging Modality of Choice*

Noncontrast CT scan of the temporal bone

### *Clinical Questions*

- How pneumatized and large are the mastoid and middle ear cavity (MEC)?
- Is the facial nerve at risk for injury?
- Are the oval window and stapes normal?
- Are the inner ear structures normal, i.e. what is the risk of acoustic injury to the inner ear during surgery?
- What is the status of the ossicular chain?
- Is there an associated syndrome or evidence of other extra-auricular malformation that may affect the patient's prognosis?

In cases of aural atresia, imaging plays a primary role in surgical decision making. Multiple studies have demonstrated improved outcomes with atresiaplasty in patients

who score higher on the Jahrsdoerfer criteria,[11] where aspects such as presence of stapes, middle ear and mastoid aeration, facial nerve position, and status of round, and oval windows are given a certain number of points. A similar modified grading system expands on these criteria and again higher scores indicated more favorable outcomes.[12] Patients who are not good candidates by these grading schemes would likely have improved hearing outcomes with bone-anchored hearing aid (BAHA) placement. Imaging may also help to identify underlying genetic abnormalities and find other anomalies that may need to be addressed prior to or at the time of atresiaplasty.

### *Interpretation*

For surgical planning, the pneumatization of the mastoid and MEC should be determined. Evaluate the course of CN VII, paying particular attention to segments that may be aberrant. The AP distance from the posterior margin of the glenoid fossa to the descending portion of the facial nerve should be noted because this space is where the surgically created external auditory canal will pass. Evaluate the status of the middle ear, including the oval window and stapes, as well as possible fusion of the malleus and incus, which is commonly seen. Describe the appearance of the inner ear and the IAC.

The thickness of the skull should be noted, in case a BAHA is a better option. This is typically placed 5 cm posterior to the atretic canal (Figs. 12.2A and B).

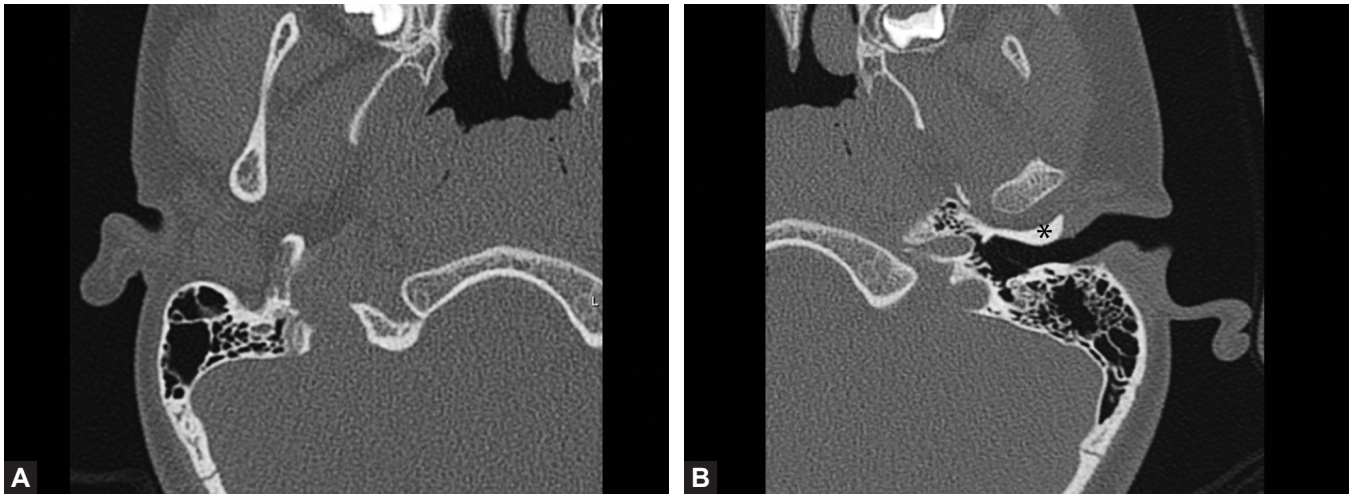
For evaluation of other possible genetic issues, the extra-auricular elements of the scan should be studied. Craniosynostosis may suggest a syndrome such as Apert of Crouzon's syndrome. BOR syndrome may be suggested by presence of cysts/fistulas/sinus tracts in the periauricular region. Zygomatic deficiency and mandibular abnormalities are frequency seen in syndromes affecting the first branchial arch, such as mandibulofacial dysostoses or oculo-auriculo-vertebral syndrome. Orbital abnormalities may be present in syndromes such as CHARGE, BOR, of OAV. Choanal atresia can also suggest CHARGE syndrome, and abnormalities in the maxilla or palate may indicate a clefting syndrome.

## The Infected Ear

There are various presentations of children with an infected ear. These can be divided into the nondraining ear and the draining ear.

### *The Nondraining Ear*

Clinical Background: Children with acute otitis media (AOM) often present with fever, fussiness, possible lethargy, and otalgia. The tympanic membrane (TM) will be bulging and erythematous, indicating the presence of a purulent effusion. In cases of AOM complicated by mastoiditis, a proptotic pinna may be noted, as well as postauricular tenderness or fluctuance, if a subperiosteal abscess has developed. Facial nerve paralysis can also



**Figs. 12.2A and B:** External auditory canal stenosis in a 6-year-old girl with congenital aural dysplasia AD. The right temporal bone (A) is malformed: the external auditory canal has not developed and no aerated passage is seen between the skin and the middle ear cavity compared to the normal aerated left external auditory canal in (B). The tympanic portion of the temporal bone [asterisk (*) in B on the normal side] has not formed. The mastoid is aerated but hypoplastic on the dysplastic side (A).

present in these cases of acute infection. Depending on the extent of clinical suspicion, further workup with imaging may be warranted to determine if surgery is indicated.

### *Imaging Modality of Choice*

- For evaluation of intratemporal complications and initial evaluation for extent of infection: Noncontrast CT temporal bone
- For evaluation of extratemporal complications: MRI brain with gadolinium.

### *Clinical Questions*

- Are there intratemporal (local auricular) complications of AOM such as coalescent mastoiditis, osseous erosion, facial nerve involvement, or suppurative labyrinthitis?
- Are there extratemporal complications of AOM such as sigmoid sinus thrombosis, epidural abscess, or meningitis?

### *Interpretation*

Intratemporal complications should be initially evaluated. Inspect the osseous margins of the mastoid for evidence of demineralization (bone window) and for subperiosteal abscess (soft tissue window) that may reflect a coalescent mastoiditis. Inspect the osseous margins of the facial nerve canal for demineralization that would suggest inflammatory dehiscence. Although dehiscence cannot be definitively determined unless seen intraoperatively, knowledge of possible nerve exposure is helpful for surgical planning. Evaluate for erosion of the walls of the membranous labyrinth that would suggest a suppurative labyrinthitis. Evaluate for middle ear and mastoid opacification, which may suggest AOM or cholesteatoma.

Next, evaluate for extratemporal sequelae of AOM. Inspect the margins of the MEC and mastoid for evidence of epidural or Bezold abscess. Evaluate the transverse and sigmoid sinus for evidence of thrombosis. Evaluate the meninges for evidence of meningitis. Here again, an MRI would be a more sensitive modality (Figs. 12.3A to D).

## *The Draining Ear*

Clinical Background: Children with a draining ear may present with symptoms of acute infection, such as those listed above, or they may present with chronic drainage, with or without otalgia. If the history suggests that the patient initially had an AOM and drainage subsequently began with improvement in symptoms, it is likely that the patient developed a perforation with allowed for drainage. In those cases, imaging is not necessarily indicated, as long as treatment with antibiotics (topical ± systemic) is being continued. If symptoms are not improving, imaging would be indicated to evaluate for those things listed above.

If the patient presents with findings of external auditory canal (EAC) edema with pain on external manipulation, otitis externa is the likely diagnosis. In these situations, imaging is not typically indicated unless the patient is not improving with topical antibiotics, pain is out of proportion to examination, or new symptoms, such as facial weakness, appear. These should make one suspect malignant or necrotizing otitis externa (MOE/NOE), which includes osteomyelitis and may require a prolonged course of IV antibiotics. This would be rare in the pediatric population, as this disease is more commonly seen in diabetics and others with some degree of immunosuppression (i.e. HIV).

A chronically draining ear due to chronic otitis media (COM) can be divided into two main categories: active COM, when the ear demonstrates active inflammation with purulent otorrhea, and inactive COM, where the ear is not constantly draining but bouts of reactivation may occur.[13] Physical examination is paramount in guiding management and need for imaging. Any of the following may be present in COM: TM perforation, retraction, or atelectasis; ossicular chain erosion, middle ear inflammation resulting in granulation tissue and/or adhesions; and cholesteatoma.[13]

### *Imaging Modality of Choice*

- Noncontrast CT of the temporal bone.

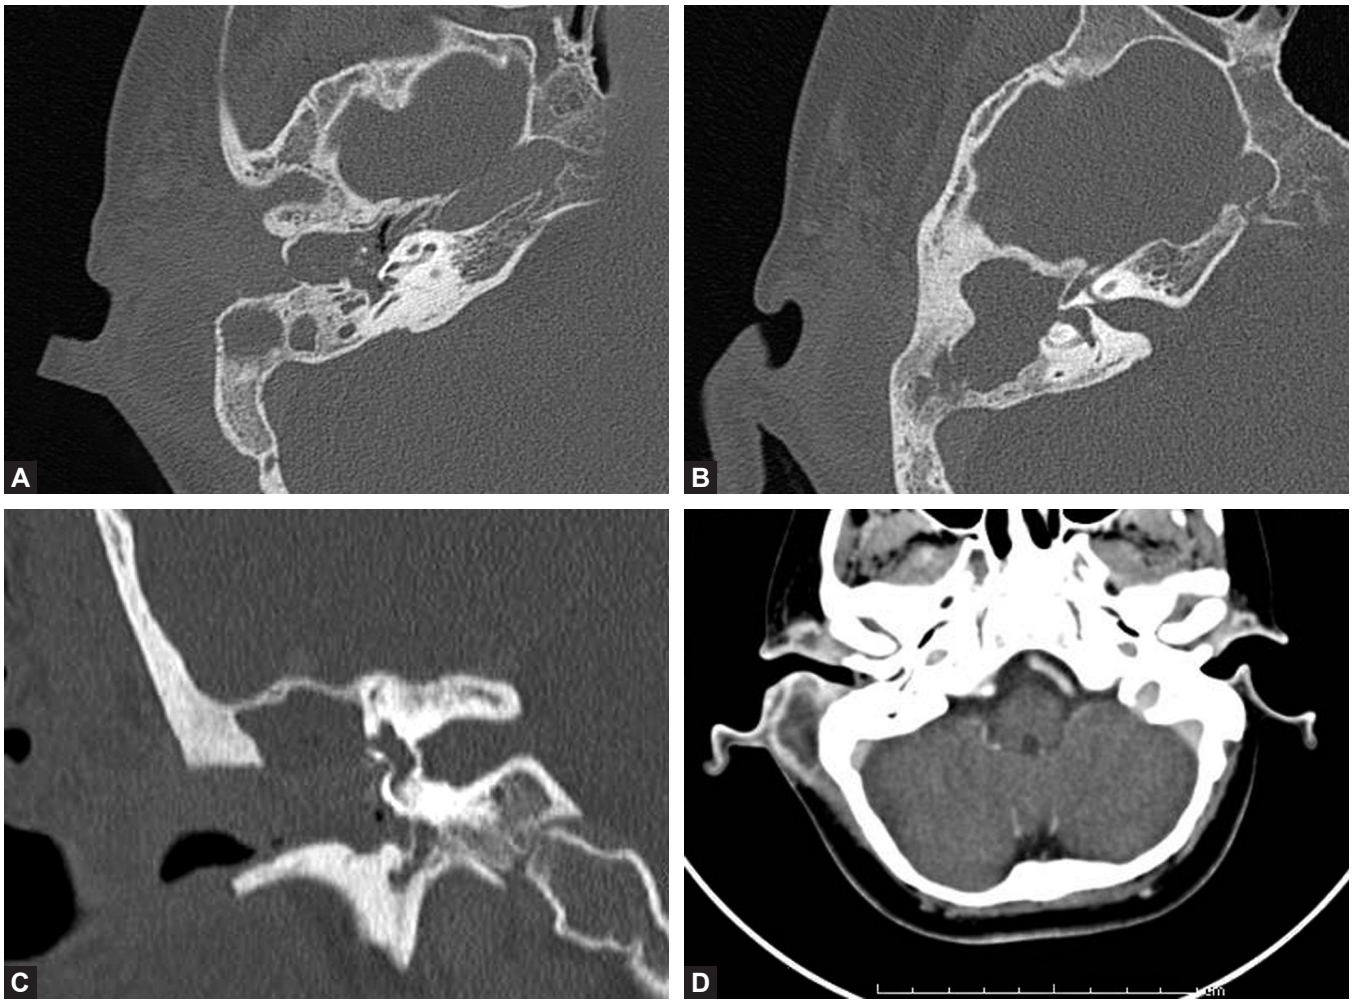
### *Clinical Questions*

When NOE is suspected, the following should be addressed:

- Is there bony involvement or inflammation that extends into the soft tissues inferior to the EAC that would suggest NOE?
- What is the extent and severity of infection?
- Are there any sequelae of infection, such as possible facial nerve involvement?

While the diagnosis of COM ± cholesteatoma is a clinical one, imaging will help answer many questions necessary for surgical planning. In the setting of cholesteatoma, imaging should address the following:

- Is the cholesteatoma limited to the attic or is there further involvement of the mastoid?



**Figs. 12.3A to D:** Coalescent mastoiditis in a 12-year-old boy presenting with draining ear and otalgia, AD. Axial CT images (A and B), coronal reformat (C), and axial postcontrast image (D) show subtotal opacification of the external auditory canal middle ear cavity and mastoid. The walls of the MEC and mastoid are expanded and bulge laterally into the EAC suspicious for a cholesteatoma. The ossicles are markedly eroded. The MEC lesion has eroded through the lateral wall of the lateral semicircular canal. Labyrinthitis ossificans have developed in the basal turn of the cochlea. A rim enhancing subperiosteal abscess has erupted developed from the lateral wall of the mastoid. (MEC: Middle ear cavity).

- Is the mastoid well-pneumatized and aerated?
- Is there ossicular chain erosion?
- Is there dehiscence of major landmarks and structures, such as the facial nerve, tegmen, or lateral semicircular canal?
- Is there external auditory canal erosion?

When cholesteatoma is not present but chronic drainage and/or perforation, retraction, or atelectasis of the TM is the primary issue, imaging should address the following:

- Is the mastoid well-pneumatized and aerated?
- What is the size of the mastoid?
- Is there ossicular chain erosion?

### *Interpretation*

If NOE is the primary concern, the auricle and periauricular soft tissues should be evaluated for signs of edema and fat stranding, suggesting infection. Inflammation extending inferior to the EAC may indicated NOE. Assess the severity of opacification of the EAC. The coronal soft tissue images are keys in evaluating for cartilage involvement that is the site of origin of NOE. Particularly in children, the canal should be evaluated for presence of a foreign body.[14] Bony erosion suggests NOE and may indicate the need for long-term parenteral antibiotics. If there is evidence of skull base

erosion and osteomyelitis, an MRI should be considered to evaluate for intracranial involvement, e.g. abscess or sinus thrombosis.[15]

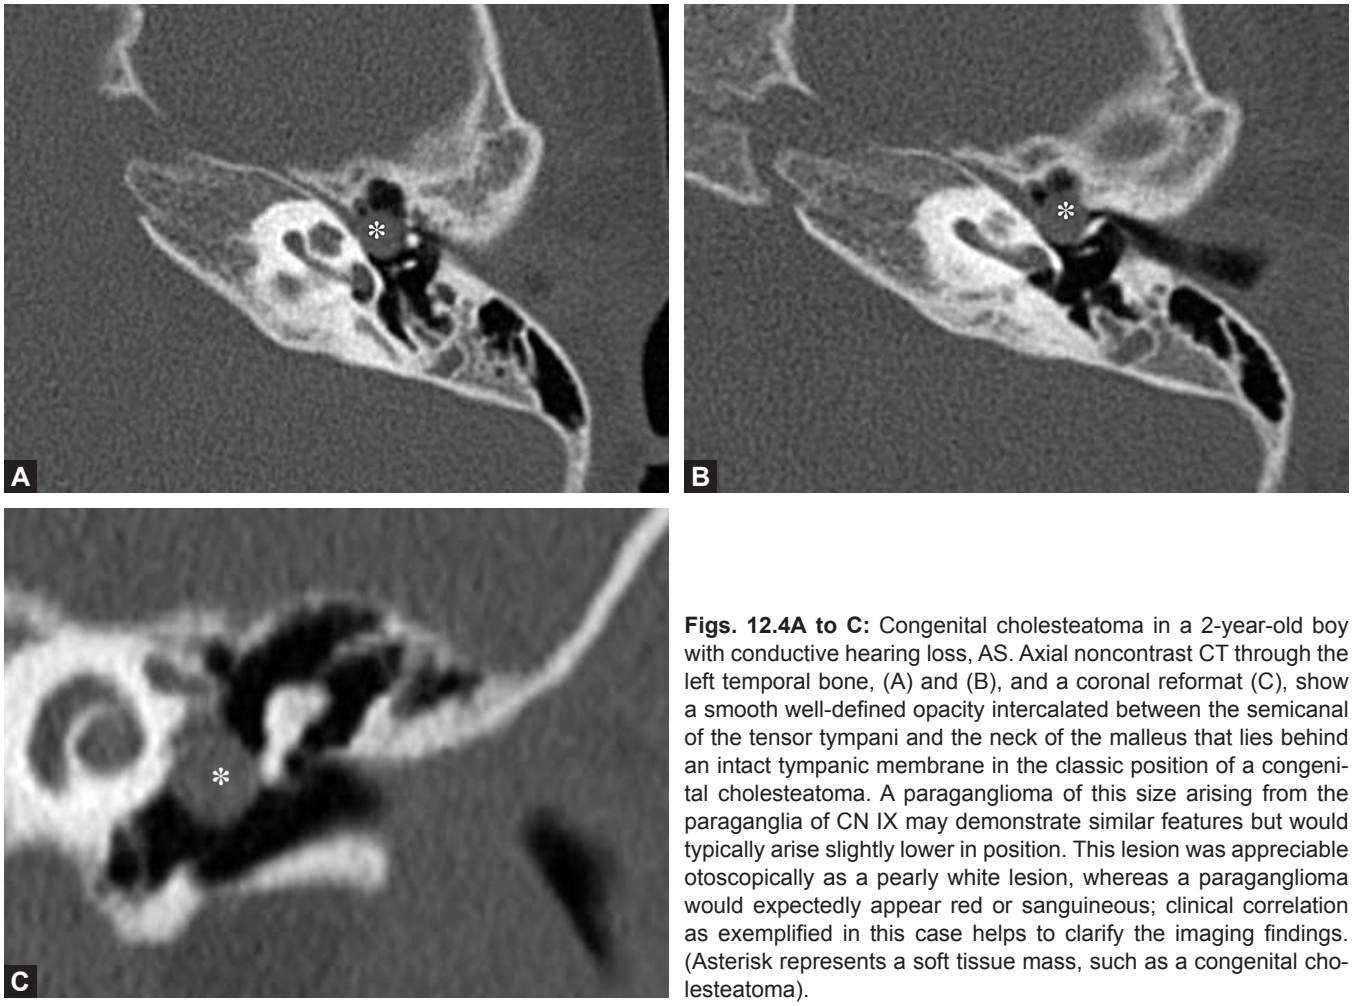
In the case of suspected cholesteatoma or chronic otomastoiditis, the EAC can first be inspected for erosion, as posterior canal wall erosion will likely imply that a canal wall down procedure is needed. Examine for signs of cholesteatoma, including blunting of the scutum, soft tissue in the epitympanum/middle ear/mastoid, and ossicular chain erosion. Be sure to differentiate between a sclerotic mastoid, which has few air cells, and an opacified mastoid, which has air cells that appear to be filled with fluid or soft tissue. Look for surgical landmines, including a high-riding jugular bulb, an anterior sigmoid sinus, a low-lying mastoid tegmen, horizontal semicircular canal dehiscence/fistula, or facial nerve dehiscence (Figs. 12.4 and 12.5).

## Facial Nerve Paresis

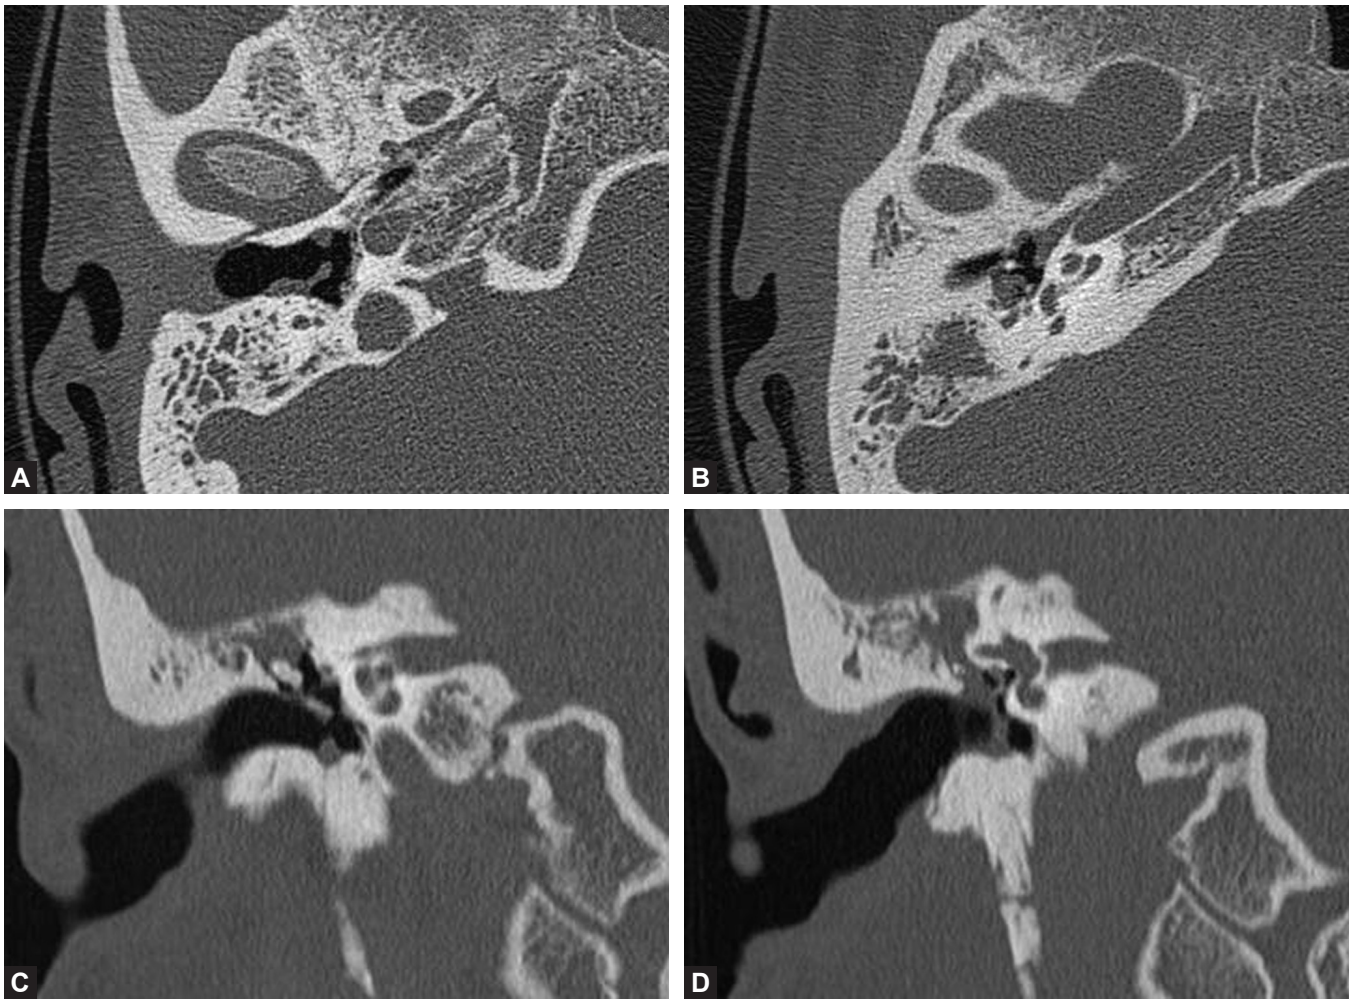
### *Clinical Background*

Children may present with facial paresis or paralysis in a number of different circumstances:

1. Congenital (including Mobius' syndrome, Goldenhar's syndrome, in utero thalidomide exposure)
2. Post-traumatic (including traumatic forceps delivery)
3. Infectious (including AOM, Lyme's disease, Ramsey Hunt's syndrome)
4. Neoplastic (including tumors of parotid, temporal bone, brain)
5. Bell's palsy
6. Iatrogenic (including after parotidectomy, otologic surgery)
7. Melkersson–Rosenthal's syndrome (recurrent facial palsy, orofacial swelling, and fissured tongue).



**Figs. 12.4A to C:** Congenital cholesteatoma in a 2-year-old boy with conductive hearing loss, AS. Axial noncontrast CT through the left temporal bone, (A) and (B), and a coronal reformat (C), show a smooth well-defined opacity intercalated between the semicanal of the tensor tympani and the neck of the malleus that lies behind an intact tympanic membrane in the classic position of a congenital cholesteatoma. A paraganglioma of this size arising from the paraganglia of CN IX may demonstrate similar features but would typically arise slightly lower in position. This lesion was appreciable otoscopically as a pearly white lesion, whereas a paraganglioma would expectedly appear red or sanguineous; clinical correlation as exemplified in this case helps to clarify the imaging findings. (Asterisk represents a soft tissue mass, such as a congenital cholesteatoma).



**Figs. 12.5A to D:** Acquired cholesteatoma in a 12-year-old boy presenting with draining ear and otalgia, AD. Axial CT images (A and B), coronal reformat (C), and axial postcontrast image (D) show subtotal opacification of the external auditory canal middle ear cavity and mastoid. The walls of the MEC and mastoid are expanded and bulge laterally into the EAC suspicious for a cholesteatoma. The ossicles are markedly eroded. The MEC lesion has eroded through the lateral wall of the lateral semicircular canal. Labyrinthitis ossificans have developed in the basal turn of the cochlea. A rim enhancing subperiosteal abscess has erupted developed from the lateral wall of the mastoid. (EAC: External auditory canal; MEC: Middle ear cavity).

In evaluating congenital facial nerve paralysis, other abnormalities may be noted on physical examination, including hemifacial microsomia, additional cranial nerve and neurologic abnormalities, and other systemic issues such as ocular abnormalities or thoracic issues.[16] Post-traumatic injury at birth, such as forceps-assisted delivery or compression by the maternal pelvic outlet, typically has a favorable outcome, but if symptoms persist, other causes, including neoplastic or neurologic etiologies, should be entertained and worked up.[17] With regards to other trauma, such as a temporal bone fracture, presence of sudden onset indicates direct nerve injury, which would push one toward surgical management. Delayed onset suggests edema and may lead the clinician down a different management algorithm. For infectious etiologies, clinical history is paramount, with special attention given to onset, fever, otalgia, otorrhea, exposure/travel, bug bites, etc. In addition, physical examination may demonstrate lesions (vesicles, target lesions from bug bite), other coexisting cranial nerve anomalies (i.e. CN VI or VIII), etc. Neoplastic causes may present with gradual or sudden onset facial nerve weakness, palpable masses, other cranial nerve involvement, and pain. Lastly, while Bell's palsy is a frequently utilized diagnosis, presence of other abnormalities or questionable history should prompt the clinician to consider other etiologies.

### *Imaging Modality of Choice*

- In the post-traumatic setting: Noncontrast CT scan of the temporal bone
- In the non-post-traumatic setting: MRI of brain with gadolinium.

### *Clinical Questions*

The role of imaging in facial nerve paresis varies based on etiology, but should essentially assess the following:

- Congenital: Is the nerve absent or hypoplastic?
- Post-traumatic: Does the fracture occur along the course of the facial nerve?
- Infectious: Is there evidence of otitis media or mastoiditis?
- Neoplastic: Are there any lesions along the course of the facial nerve?

In the case of iatrogenic facial nerve paresis following otologic surgery, imaging may identify where the injury occurred in order to guide further management.

### *Interpretation*

In the setting of post-traumatic facial nerve injury, look for any site of bony disruption of the fallopian canal or free-floating bone fragments along the course of the facial nerve that may be impinging on the nerve. The fallopian canal is most narrow at the labyrinthine segment, and would therefore be the most likely site of compression.

When nontraumatic facial nerve paresis exists, MRI may demonstrate findings such as a brainstem tumor, a demyelinating plaque, facial nerve hypoplasia or aplasia, or abnormal enhancement and/or nodularity along the course of the facial nerve. The parotid gland should also be evaluated to ensure that a tumor affecting the extratemporal portion of the facial nerve is not being missed.

## Hearing Loss

### *Clinical Background*

In children, hearing loss should be thought of from two perspectives: congenital vs. acquired, and sensorineural vs. conductive. When a child presents for hearing loss due to a failed newborn hearing screen, he/she has typically also had a sedated ABR to confirm hearing loss. Once middle ear disease has been ruled out, syndromic and nonsyndromic causes for SNHL are worked up, including but not limited to congenital CMV infection, Usher's syndrome, Jervell and Lange-Nielsen's syndrome, congenital Rubella, and Alport syndrome. Imaging in the process of workup will help elucidate aplasia or hypoplasia of the cochlear nerve, as well as identify other possible temporal bone abnormalities. In addition, imaging may help predict whether the hearing loss may worsen, for example, as in enlarged vestibular aqueduct.

In the case of acquired asymmetric or sudden SNHL in pediatric patients, the incidence and etiologies are not as well documented, but causes may include viral (including EBV, CMV), EVA, ototoxicity, noise exposure, and nonorganic causes.[18] Neoplasms, such as a cerebellopontine angle (CPA) tumor, and inflammatory disorders can be ruled out with imaging. Asymmetric hearing loss is defined as a difference between the two ears in hearing thresholds (>10 dB in three consecutive frequencies or 15 dB in two consecutive frequencies) or a difference in word recognition scores (>15 points difference).

In children who present with an audiogram demonstrating conductive hearing loss (CHL), a good history will provide many clues as to the etiology, including duration that the hearing loss has been present, recurrent infections, history of head trauma, and family history of hearing loss or otologic surgery. Physical examination may also give clues, including middle ear effusion, perforation, retraction, and hyper- or hypomobile TM. Imaging may be indicated if an obvious cause of hearing loss cannot be found on examination.

### *Imaging Modality of Choice*

- For sensorineural hearing loss: MRI of the brain with gadolinium with fine cuts through the IACs (can detect nerve aplasia/hypoplasia) +/- Noncontrast CT scan of the temporal bone (bony abnormalities, including cochlear dysplasias)
- For sensorineural hearing loss for which cochlear implantation is being planned: Noncontrast CT scan of the temporal bone
- For conductive hearing loss: Noncontrast CT scan of the temporal bone.

### *Clinical Questions*

For congenital SNHL:

- Is the cochlear nerve absent or hypoplastic?
- Is the cochlear fossette narrow?
- Is there evidence of an enlarged vestibular aqueduct?
- Is the cochlea properly formed?
- Is the vestibular system properly formed?

For acquired SNHL:

- Is there a cochlear or retrocochlear (CN VIII, brainstem, auditory cortex) lesion?

For CHL:

- Are the external auditory canal, TM, middle ear space, and ossicles normal?
- Is there evidence of otospongiosis or Paget's disease?

### *Interpretation*

For SNHL, inspect the cochlea and inner ear for evidence of dysplasia, abnormal elevated signal on the T1-weighted images that may suggest hemorrhage, abnormal enhancement that may be seen in labyrinthitis, or loss of signal in the membranous labyrinth that may reflect labyrinthitis (ossificans). Trace the cochlear nerve from the cochlear fossette to the brain stem, to identify an abnormal nodule that may represent a schwannoma, abnormal enhancement that may suggest a leptomeningeal process investing CN VIII, and for intactness/presence of the nerve. Hypoplasia or aplasia of the nerve is contraindication to implantation. Look at the IAC and CPA cistern for a mass.

Check the whole brain images for any evidence of disorder of myelination, malformation such as a Chiari I, meningitis, or CNS hypotension or hypertension.[19–24]

For preoperative planning for cochlear implantation in a patient with SNHL, begin by inspecting the thickness of the skull 4–5 cm posterior and superior to the spine of Henle, as this is where the receiver-stimulator portion of the device will be positioned. In children, the bone is often quite thin, and may not allow for drilling of a well in which to place portion of the implant, or may result in dural exposure (intentionally) if a well is drilled. Evaluate the pneumatization of the mastoid, as underpneumatization will likely result in a most challenging mastoidectomy. Also examine the pneumatization of the facial recess and describe the position of the facial nerve with respect to the recess. An aberrant or dehiscent nerve or a laterally positioned posterior genu may lead to injury, and require an alternate approach to the MEC. Check aeration of the middle ear and near the area of the round window niche to determine how difficult electrode insertion may be.

Evaluate the inner ear for evidence of malformation that may reduce the efficacy of the implant or make insertion more challenging. Cochlear malformation may require modification of electrode insertion techniques. Inner ear malformations may raise the risk of meningitis. Labyrinthitis ossificans (LOs) that may be a sequela of prior meningitis may limit the ability of the surgeon to advance the electrode.[25,26] If there is evidence of LO, an MRI should be performed to determine better the caliber of the membranous labyrinth. Evaluate the cochlear fossette (bony canal for CN VIII at the base of the cochlea) for evidence of stenosis that may herald a hypoplastic nerve or dysplasia that may increase the risk for CSF gusher. Check the otic capsule for evidence of otospongiosis or, e.g., Paget's disease that may increase the risk of facial nerve stimulation from the electrode.[27] Evaluate the temporal bone for evidence of COM. Active COM should be addressed prior to placement of the cochlear implant. Again, evaluate the position of the jugular bulb, sigmoid sinus, and mastoid tegmen.

For CHL, EAC narrowing should first be noted. The TM, if visible, may demonstrate perforation, retraction, or thickening. The middle ear space should be evaluated for opacification, which may indicate granulation tissue, cholesteatoma, or a mass. The ossicular chain should be evaluated for possible erosion/discontinuity/fusion. Signs of otosclerosis (otospongiosis) or Paget's disease may be seen at the oval window niche.

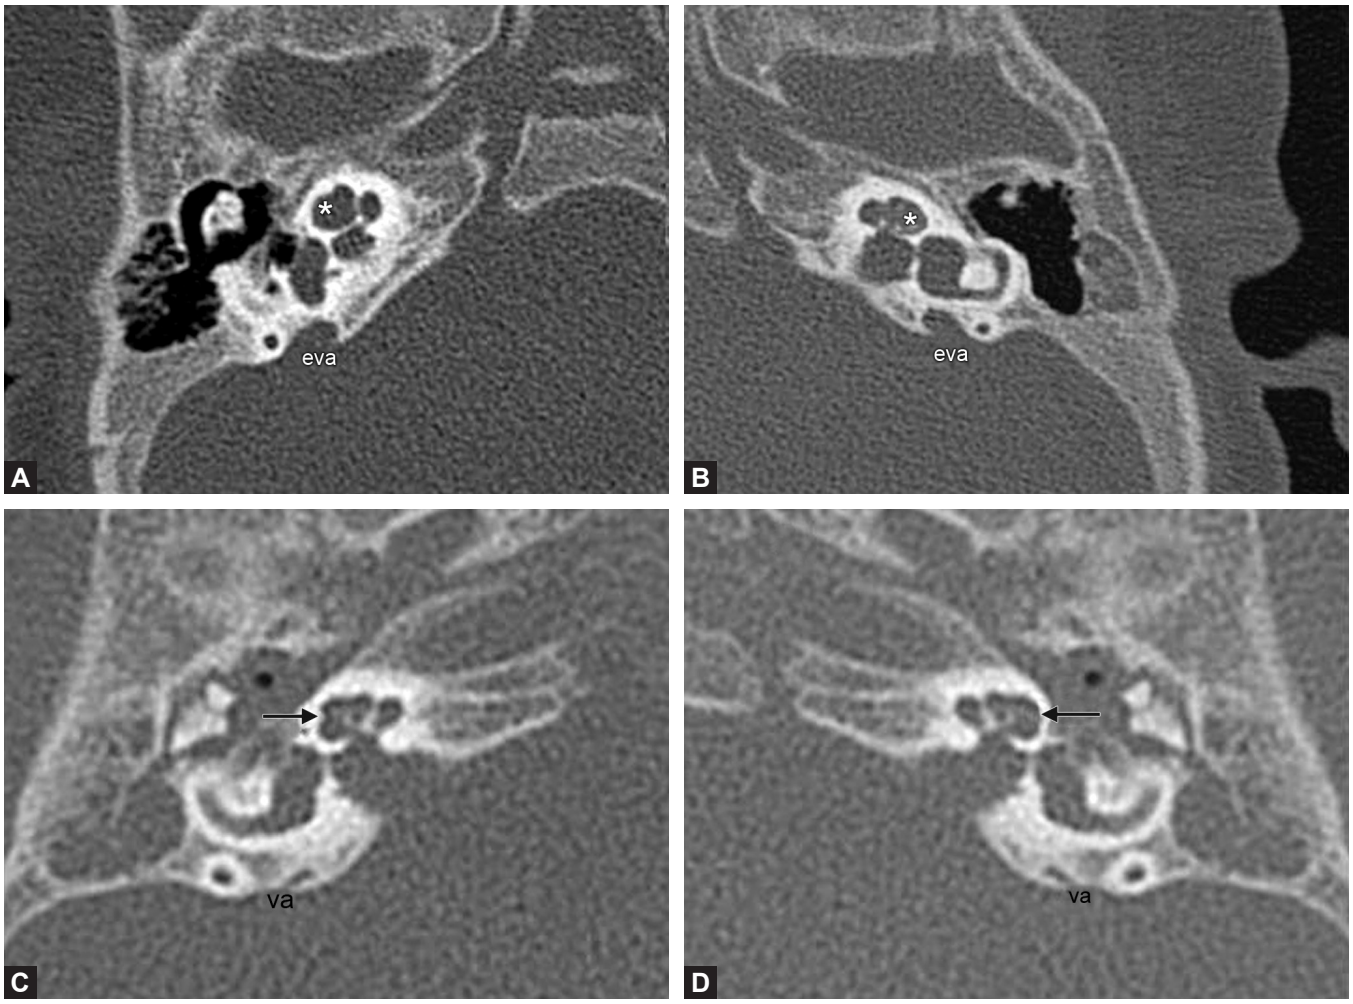
Evaluate the inner ear for evidence of inner ear abnormalities that may produce CHL such as SSCC dehiscence, enlarged vestibular aqueduct, or lateral semicircular canal dysplasia.[28–30] If the standard coronal and axial reformats do not clearly demonstrate intactness of the roof of the SSCC, Stenver and Poschl reformats are used (as described in PART I above) for evaluation for dehiscence of the SSCC (Figs. 12.6A to D).

## Masses, Pits, and Cysts

### *Clinical Background*

Children may present with a variety of lesions in and around the ear. For external lesions, such as preauricular or EAC lesions, accompanying history may include fluctuation in size of a mass, drainage, history of infection, and hearing loss. For lesions that are retrotympanic, accompanying history may include hearing loss, aural fullness, pulsatile tinnitus, and otalgia. Physical examination should note the following:

- Auricular masses: Where is it located in relationship to the tragus? Is there a pit at the skin or is it completely subcutaneous? Are there other masses in the region? Masses in this region may include a preauricular pit/cyst, a first branchial cleft cyst, a parotid tumor, or lymphadenopathy
- EAC masses: Is it soft tissue or bony? Is it unilateral or bilateral? Is it obstructing the TM? Masses in this region may include canal cholesteatoma, exostoses, osteoma, papilloma, or other neoplasm



**Figs. 12.6A to D:** Bilateral cochlear dysplasias and enlarged vestibular aqueducts (EVAs) in 4-month-old boy with bilateral sensorineural hearing loss (SNHL). Axial CT of the temporal bone of the right ear, (A), and left ear, (B), in a child with SNHL are contrasted with the temporal bone CT from an near age matched child with normal hearing (despite bilateral ear effusions) in (C) and (D) (where (C) and (D) are both mirror images of the same left ear replicated for ease of comparison). (A) and (B) are the abnormal right and left ears show bilateral cochlear dysplasias reflected by blunting of the cochlea at the junction of the first and second turns as indicated by the asterisk (*) and in conspicuity of the modioli. Compare the contour of these dysplastic cochleae to the normal sharp angle at the junction of the first and second turns as seen in the normal comparison ears marked by the black arrows. In (A) and (B), the vestibular aqueducts 'eva' are markedly enlarged compared to the normal vestibular aqueducts "va" in (C) and (D).

- Retrotympanic masses: Is it pearly white in nature? Is it vascular appearing or red in nature? Masses in this region may include cholesteatoma, a high riding jugular bulb, glomus tympanicum (paraganglioma), or an aberrant carotid artery.

## *Imaging Modality of Choice*

- Initial imaging to evaluate for possible mass: CT scan of temporal bone with contrast
- Adjunct imaging for soft tissue evaluation: MRI head and neck with gadolinium.

## *Clinical Questions*

- Auricular/EAC masses: When a clear cut diagnosis of a simple preauricular pit is made, imaging is not necessarily needed. However, if there is question of a branchial cleft cyst or neoplasm, imaging can help delineate any tract that may be present, as well as help evaluate the extent of a neoplasm, including nodal metastases
- Retrotympanic masses: Imaging should help determine if the mass is simply a soft tissue lesion or a vascular lesion. In addition, the extent of the mass can be evaluated

### *Interpretation*

For a retrotympanic mass, describe the anatomic relations of the lesion. For a lesion centered in the middle ear/mastoid, determine if there is tegmen erosion or involvement of the middle cranial fossa. Determine the relationship of the mass to cranial nerves VII, IX, X, and XI. Evaluate for involvement of the ossicles, TM, carotid artery, and Eustachian tube orifice. Some of the major clinical considerations are listed below.

For an auricular mass center around the external auditory meatus, erosion of the temporal squamosa or middle cranial fossa should be noted. Evidence of bony erosion, inferior/anterior involvement of the parotid gland, medial extent with or without TM/middle ear involvement, and posterior involvement of mastoid cavity should all be evaluated and noted. Nodal involvement should also be determined.

## Tinnitus

### *Clinical Background*

Children do not typically complain of tinnitus unless elucidated by the parent, but the incidence ranges from 13% to 53%, with a higher incidence in the adolescent population often due to noise exposure. [31] The tinnitus must be separated into pulsatile and nonpulsatile, and accompanying symptoms may include hearing loss, aural fullness, and otalgia. Pertinent physical examination includes otoscopy and auscultation in the periauricular region to evaluate for bruits/blood flow that may indicate a vascular cause.

On otoscopy, fluttering of the TM may be seen in middle ear myoclonus, while a dehiscent jugular bulb may present with tinnitus that extinguishes with turning the head toward the side of the tinnitus. Other causes of pulsatile tinnitus include an arteriovenous malformation, benign intracranial hypertension, or a heart murmur. Imaging can help determine if a vascular lesion is the cause of the pulsatile tinnitus.

In nonpulsatile tinnitus, the quality (pitch, volume) and location (unilateral vs. bilateral) should be determined. In rare instances, imaging may be indicated in unilateral nonpulsatile tinnitus without an identifiable cause to evaluate for a CPA tumor.

### *Imaging Modality of Choice*

- For nonpulsatile tinnitus: MRI of the brain with gadolinium
- For pulsatile tinnitus: MRI/MRA of the brain with gadolinium

### *Clinical Questions*

- Is there a temporal bone lesion present?
- Is the lesion vascular?
- Is the lesion destructive or expanding?
- Is the lesion central or peripheral?

### *Interpretation*

Inspect the external auditory canal and mastoid for evidence of inflammation that may be associated with tinnitus. Check the temporomandibular joint for evidence of degenerative disease that has been reported as a cause of tinnitus.[32]

Evaluate the middle ear for evidence of inflammation such as serous otitis or lesion such as a paraganglioma, hemangioma, or meningioma. Otospongiosis that may cause pulsatile tinnitus from increased blood flow to the promontory may occasionally be seen (if it is florid) as abnormal enhancement or signal abnormality on the CISS, 3D Fiesta, or DRIVE sequence but cannot be excluded by MRI. If any evidence is present to suggest this, CT scan of the temporal bone should be performed as an adjunct study.

Search for a vascular cause that may require review of the noncontrast enhanced CISS, DRIVE, or 3D Fiesta sequence, the contrast enhanced MRI, and the MRA. This search may be divided into arterial causes (carotid artery stenosis, atherosclerosis, aneurysm, aberrancy, persistent stapedial artery), venous causes (dural sinus stenosis/diverticula, dehiscent jugular bulb), vascular impingement (i.e. AICA on CN VIII), and arteriovenous malformations and dural arteriovenous fistulas.

Evidence of inner ear abnormalities, including labyrinthitis and dysplasia, and IAC/CPA cistern tumors should be evaluated.

Evaluate the brain images for evidence of pseudotumor cerebri, Chiari I malformation, or lesion of the fifth or seventh nerves that may be associated with middle ear myoclonus or for a lesion of the triangle of Guillain–Mollaret such as a demyelinating plaque, that may be associated with palatal or middle ear myoclonus.[33–36]

## Dizziness/Vertigo

### *Clinical Background*

In children, a number of etiologies may lead to vertigo, but it is overall a rarely reported symptom. History should help elucidate the cause, as the diagnosis is typically made clinically and does not usually require imaging. Once it is determined that the patient has true vertigo, the timing of the vertigo, as well as presence of hearing loss, should

be categorized. Meniere's disease (episodic vertigo with hearing loss), labyrinthitis (persistent vertigo with hearing loss), benign paroxysmal positional vertigo (episodic vertigo, no hearing loss), and vestibular neuritis (persistent vertigo, no hearing loss) can all be quickly diagnosed with this history. In addition, physical examination may suggest a third window phenomenon (+Hennebert sign, Tullio phenomenon) or middle ear effusion, which can cause episodic vertigo.

In the pediatric population, other causes include peripheral vestibulopathy due to inner ear structural anomalies, such as EVA, migraines, motor/developmental disorders (cerebral palsy, mitochondrial myopathy), CNS structural lesions (Chiari I malformation), and psychogenic vertigo.[37] Vestibular testing is indicated prior to imaging. If history, physical examination, and testing indicate a possible structural or inflammatory cause, imaging is useful.

### *Imaging Modality of Choice*

- If central cause is suspected (i.e. stroke and tumor): MRI of the temporal bone with gadolinium
- If possible third window (SSCC, perilymphatic fistula from cholesteatoma) is suspected: Noncontrast CT scan of the temporal bone.

### *Clinical Questions*

- Is there a central cause (tumor, Chiari I) that may be the source?
- Is there evidence of labyrinthitis?
- Is there evidence of EVA or a 3rd window (perilymphatic fistula, SSCC)?

### *Interpretation*

Check the cerebellum, brain stem, and the supratentorium for evidence of infarct (especially the vestibular nuclei in the medulla), disorder of myelination, malformation such as a Chiari I, or for evidence of neurodegeneration such as spinocerebellar ataxia. In children this component of the evaluation should include a search for evidence of neurodegenerative disorders such as Friedrich ataxia, mitochondrial disorder, or inherited disorder of myelination such as Fabry disease.[38] Check CN VIII, the IAC, and the CPA cistern for evidence of tumor. Abnormal enhancement of CN VIII may confirm nerve pathology such as neuritis or leptomeningeal disease. Evaluate the membranous labyrinth for evidence of labyrinthitis. Lastly, if a CT is done, evaluate for SSCC or perilymphatic fistula if CT is available.

## CONCLUSION

For imaging of the temporal bone in children, CT and MRI of the temporal bone and/or brain are the modalities best suited for the pediatric population. The determination of the modality of choice depends on the clinical indication for the imaging study and the clinical questions that need to be addressed, the age of the patient, and the growing concern for morbidities associated with radiation and sedation, all of which need to be weighed when deciding on the best approach to imaging.

CHAPTER

# 13

# Histopathology of the Temporal Bone

*Felipe Santos, Alicia M Quesnel, Joseph B Nadol Jr*

## INTRODUCTION

A detailed understanding of the macroscopic to microscopic anatomy of the temporal bone is essential to the otologic surgeon. This understanding is derived from exposure to the three dimension relationships in dissections conducted in the temporal bone laboratory, the study of radiographic imaging including CT and MRI in normal and pathologic disease states and a knowledge base of otopathology specimens that provide an understanding of anatomic relations at the cellular level. This chapter is not a comprehensive overview but rather highlights anatomic correlates from histopathology that inform clinical and surgical decision making. For a comprehensive review of otopathology and temporal bone anatomy, the reader is referred to other texts including Schuknecht's Pathology of the ear, 3rd edn[1] and Anatomy of the temporal bone with surgical implications, 2nd edn.[2]

## MIDDLE EAR AND MASTOID

### The Middle Ear

The tympanic cavity is a mucosal lined space aerated by the Eustachian tube (ET). It houses the ossicular chain. The jugular bulb comprises much of the floor of the tympanic cavity. Along the anterior wall is the carotid canal that can be dehiscent (Fig. 13.1). The roof or tegmen tympani separates the middle ear from the middle fossa floor. The medial wall consists of the sinus tympani, round window, and oval window niche. The dimensions of the middle ear are variable. At term, the antrum and tympanic cavity approximate adult size.

Laterally, the tympanic membrane separates the external ear canal from the middle ear. The tympanic membrane is separated into a pars flaccida and a pars tensa. The tympanic membrane consists of three layers: (1) a lateral epithelial layer, (2) a middle fibrous layer (pars propria), and (3) a medial mucosal layer. The pars propria of the pars flaccida consists of fewer elastic fibers and does not have fibrous tissue arranged in inner circular and outer radial strata like the pars tensa.

The ossicles of the middle ear are the malleus, incus, and stapes. They transmit sound from the tympanic membrane to the inner ear. They are derived from the first and second branchial arches and assume their adult

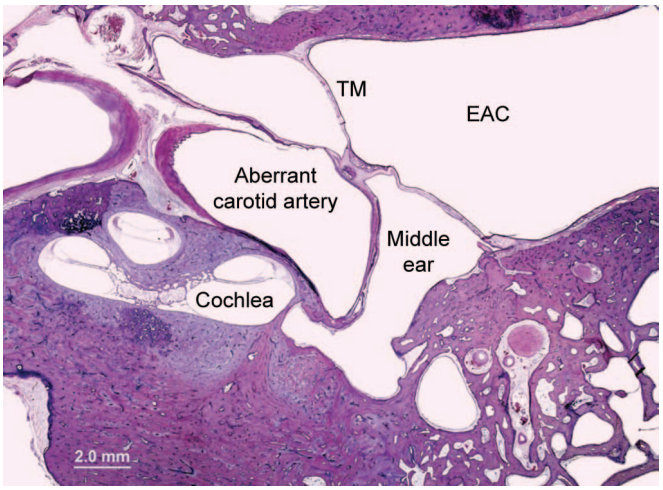

**Fig. 13.1:** A dehiscent carotid canal along the anterior tympanic wall. Tympanostomy tube placement in the anterior inferior quadrant could result in catastrophic hemorrhage. (TM: Tympanic membrane; EAC: External auditory canal).[1] (Courtesy of F Linthicum, House Ear Institute, Los Angeles, CA).

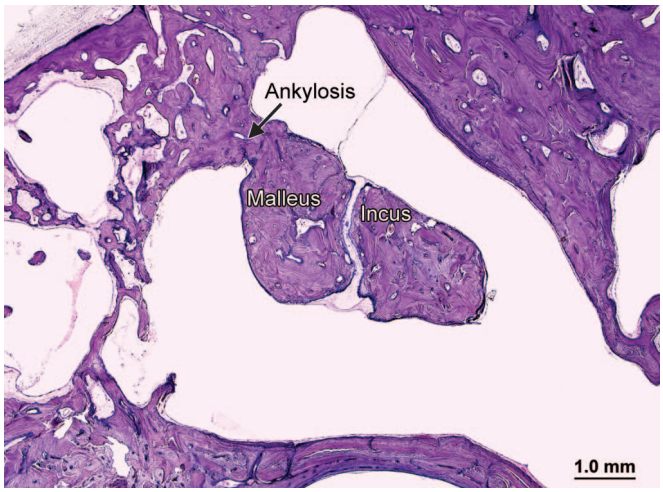

**Fig. 13.2:** Malleus ankylosis can result in conductive hearing loss. The head of the malleus is fixed to the epitympanum.

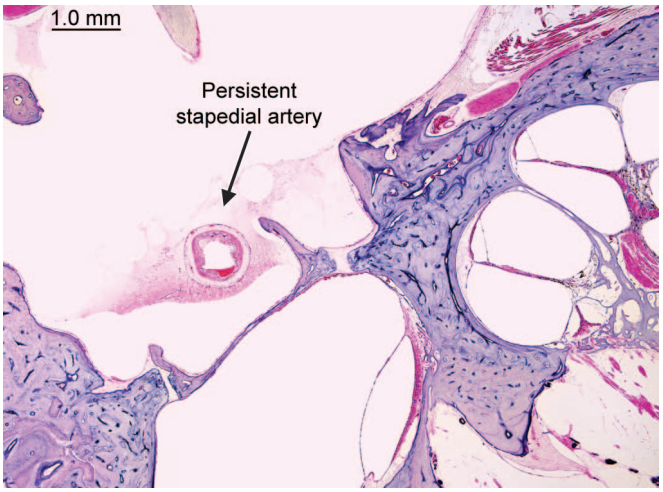

**Fig. 13.3:** A persistent stapedial artery.

configuration by the 20th week of gestation. The malleus consists of a head, neck, lateral process, anterior process, and manubrium. The anterior malleal ligament defines the axis of rotation of the ossicles with the posterior incudal ligament. The malleus is held in place by five ligaments in addition to the tensor tympani tendon, incudomalleal joint, and tympanic membrane. The head of the malleus can ankylose to the epitympanum, resulting in a conductive hearing loss (Fig. 13.2).

The incus consists of a body, short process, long process, and lenticular process. The incudostapedial joint is a diarthrodial articulation. The incus is held in place by the posterior incudal ligament and the medial and lateral incudomalleal ligaments. The incus and malleus have a marrow space that usually regresses following infancy. The ossicles may be pneumatized; this can make them more susceptible to fracture with manipulation.

The stapes consists of a head, footplate, and two crura. The crura are separated by the obturator foramen. This can be closed by a mucous membrane or traversed by a persistent stapedial artery. A persistent stapedial artery is a remnant of the normal embryonic hyoid artery that originates off the internal carotid artery (Fig. 13.3). The stapediovestibular articulation is a syndesmosis. Congenital stapes fixation, characterized by a nonprogressive conductive hearing loss without tinnitus or vertigo, represents roughly one third of ossicular malformations.

## Mastoid

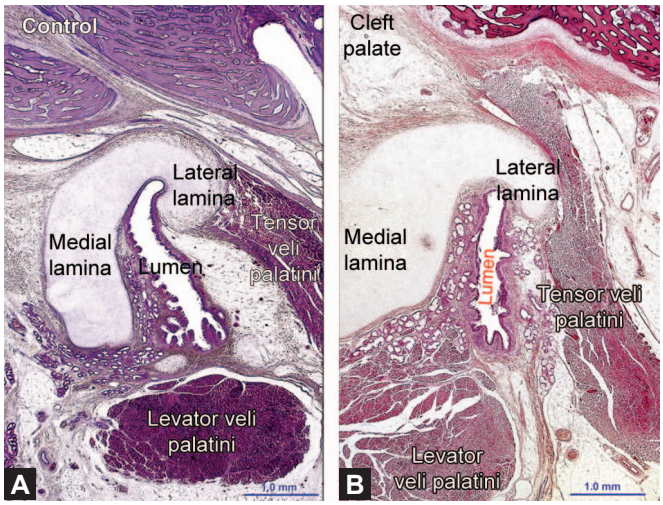
The temporal bone can be divided into different regions, areas, and tracts of pneumatization. The mastoid region is incompletely pneumatized at birth. Diploic bone and marrow are replaced during pneumatization. The mastoid continues to grow for 5–10 years postnatally. As the mastoid grows the tip descends, leaving the stylomastoid foramen in a more protected medial and inferior position to the external auditory canal than at birth. The facial nerve is consequently more susceptible to injury in the mastoid segment in younger patients.

## Eustachian Tube

The ET enables ventilation of the middle ear by communication with the aerodigestive tract. It extends from the lateral nasopharyngeal wall to the medial mesotympanum. The inferomedial portion is cartilaginous and the superolateral portion of the tube is comprised of a bony channel. The ET is closed at rest and three muscles coordinate opening of the pharyngeal end of the ET: tensor veli palatini, levator veli palatini, and salpingopharyngeus.[3] The reader is referred to Chapter 3 for further detail. Cleft palate results in ET dysfunction and anatomical abnormalities of the cartilaginous ET can be seen on histopathology (Figs. 13.4A and B). These histologic differences likely contribute to insufficient opening of the ET and insufficient ventilation of the middle ear cavity.[4] Children born with cleft palate invariably develop recurrent serous effusions, recurrent acute otitis media, and/or chronic otitis media as a result of the poor ventilation of the middle ear cavity.

# THE INNER EAR

The major structures of the inner ear include the cochlea, utricle, saccule, three semicircular canals, endolymphatic



**Figs. 13.4A and B:** Comparison of Eustachian tube orifice anatomy in a normal case and a patient with cleft palate. (A) The normal anatomy of the Eustachian tube orifice on a temporal bone specimen sectioned in the vertical plane. (B) A specimen from a patient with cleft palate is notable for the decreased volume of the lateral cartilaginous lamina, the comparative immaturity of the cartilage, and the straight rather than curved lumen of the Eustachian tube.[1] *Courtesy*: Dr I Sando, University of Pittsburgh School of Medicine, Pittsburgh, PA.

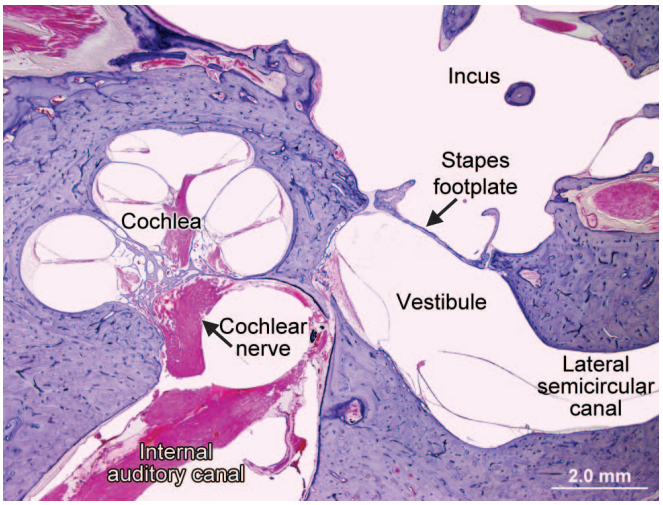


**Fig. 13.5:** Normal anatomy. In a horizontal section through a hematoxylin- and eosin-stained temporal bone at the midmodiolar plane, the size, spatial relationship, and structure of the bony and membranous parts of the cochlea, saccule, utricle, and lateral and posterior semicircular canals can be seen.

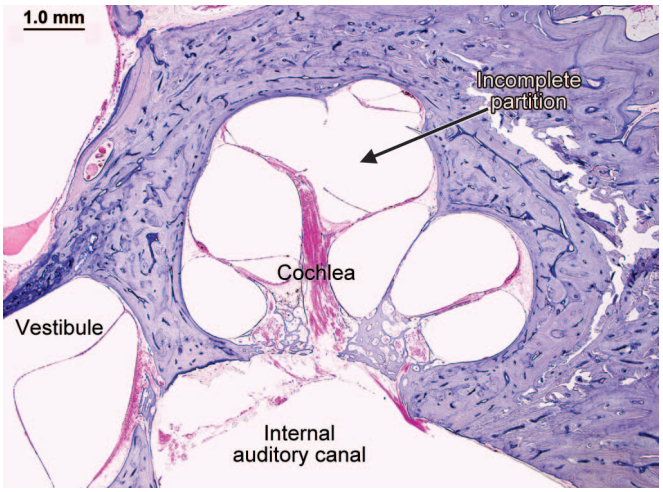

**Fig. 13.6:** Incomplete partition type II. This was previously called the Mondini malformation when associated with an enlarged vestibular aqueduct.

sac, and vestibular aqueduct (Fig. 13.5). The bony labyrinth is fully formed by 22 weeks' gestational age and the inner ear is adult size at that point. The otic capsule bone is formed by endochondral, endosteal and periosteal bone. By 8 weeks' gestation, a cartilaginous model of the otic capsule is formed by mesenchymal condensation.[5,6] Ossification of the cartilage proceeds at multiple ossification centers throughout the petrous bone, and ultimately results in dense otic capsule bone with some remaining cartilaginous islands. These islands are termed "globuli interossei" and are seen in the normal pediatric and adult otic capsule bone (Fig. 13.5). The modiolus is the central bony structure of the cochlea where the spiral ganglion neurons are located, and develops separately from the otic capsule bone. The modiolus is derived from membranous bone, which undergoes ossification between gestational weeks 20–25.[6]

The membranous labyrinth refers to the soft tissue structures, including neural elements, located within the bony labyrinth. The membranous portion of the cochlea includes three fluid filled spaces. The scala tympani and scala vestibuli contain perilymph and communicate at the helicotrema. The scala media, also called the cochlear duct, contains endolymph and is where the organ of Corti resides. The scala media and scala vestibuli are separated by Reissner's membrane. The scala media and scala tympani are separated by the basilar membrane. Deficiencies in the interscalar septae result in cochlear malformations (Fig. 13.6).

The cellular components of the organ of Corti, such as the inner hair cell, outer hair cells, and supporting cells, as well as the stria vascularis, spiral ligament, basilar membrane and Reissner's membrane, are easily examined with light microscopy on a human temporal bone specimen (Fig. 13.7). In temporal bones from patients with

sensorineural hearing loss, there is typically a histopathologic abnormality that can explain the sensorineural hearing loss. The most common abnormalities found include loss of spiral ganglion neurons, loss of outer hair cells and/or inner hair cells, abnormalities of the stria vascularis, and loss of supporting cells. The histopathologic findings in two syndromes with sensorineural hearing loss, Alport's syndrome (Figs. 13.8A and B) and Usher's type I (Fig. 13.9), are shown.

The five vestibular end organs include the saccule, utricle, and three semicircular canals. The vestibular sensory epithelia are located in the macula of the saccule and utricle, and in the cristae of the semicircular canals. There are two types of vestibular hair cells, both with stereocilia and a kinocilium. Type I cells are flask shaped and innervated by an afferent fiber only, and type II are cylindrical and have both afferent and efferent fibers.[8]

The vestibular aqueduct is a bony channel that extends from the posterior fossa to the vestibule. It contains the endolymphatic duct, which terminates at the endolymphatic sac on the surface of the posterior fossa dura. The congenital malformation in which the vestibular aqueduct is enlarged can result in sensorineural, conductive, or mixed hearing loss (Fig. 13.10).

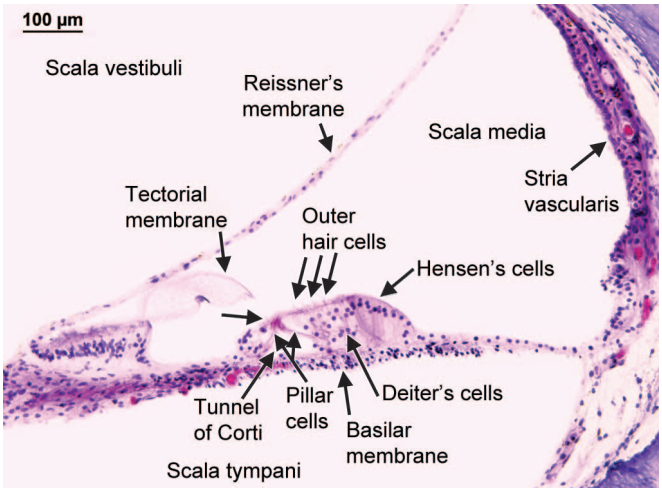

**Fig. 13.7:** The cochlear duct with organ of Corti shown at high power magnification.

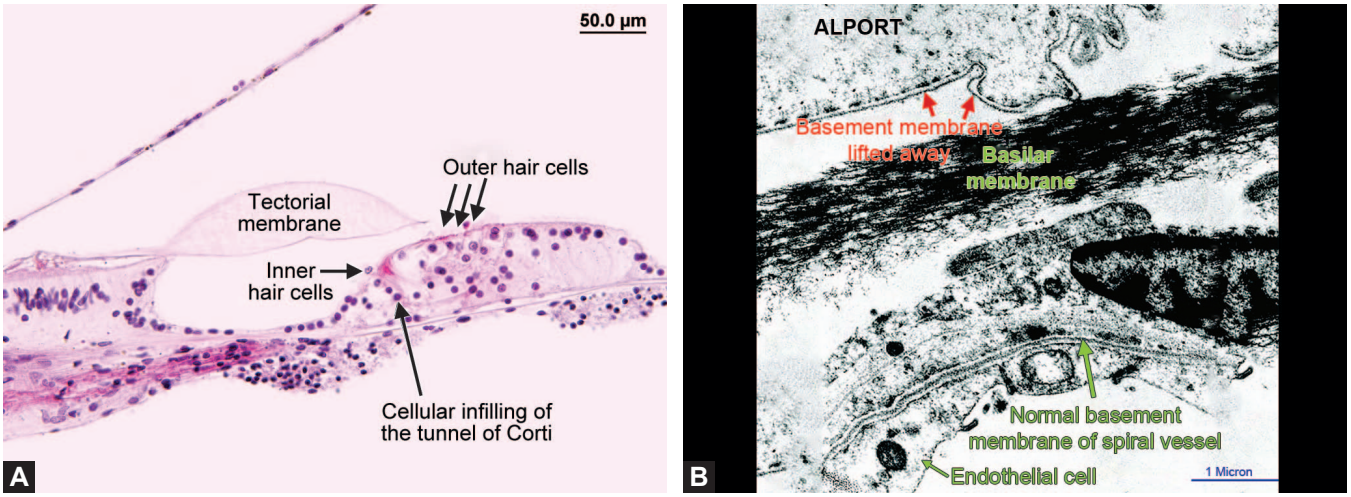
## THE FACIAL NERVE

All the neural connections of the facial nerve are established by the 17th week of gestation. The bony covering of the facial nerve (fallopian canal) is complete by term. Dehiscences, particularly in the tympanic segment of the facial nerve and over the geniculate ganglion in the middle fossa, are a common variant of normal. The facial nerve may be more susceptible to iatrogenic injury or disease in these areas as a result of this normal variant (Fig. 13.11).

The intratemporal segments of the facial nerve include the labyrinthine, tympanic, and mastoid segments. The nerve follows a circuitous but constant course in the temporal bone. After the facial nerve exists the internal auditory canal the facial nerve makes its first abrupt posterior turn (first genu) distal to the geniculate ganglion.



**Figs. 13.8A and B:** Alport's syndrome is due to a mutation in the gene that codes for alpha 5 type IV collagen, most commonly X-linked inheritance, and causes glomerular nephritis, sensorineural hearing loss, and ocular abnormalities. The histopathologic findings include (1) absence of the space of Nuel, the space between the outer pillar cell and first outer hair cell in the organ of Corti due to cells obliterating this area (A) and (2) separation of the basement membrane from the basilar membrane in the organ of Corti (B).[1]

The tympanic segment then runs parallel to the petrous ridge above the oval window and makes its second turn (second genu) inferiorly at the sinus tympani. This marks the beginning of the mastoid (or vertical) segment that exits the temporal bone at the stylomastoid foramen. The chorda tympani nerve originates from the mastoid segment near the pyramidal eminence. In infants the chorda tympani may divide distal to the stylomastoid foramen and enter in its own canal.

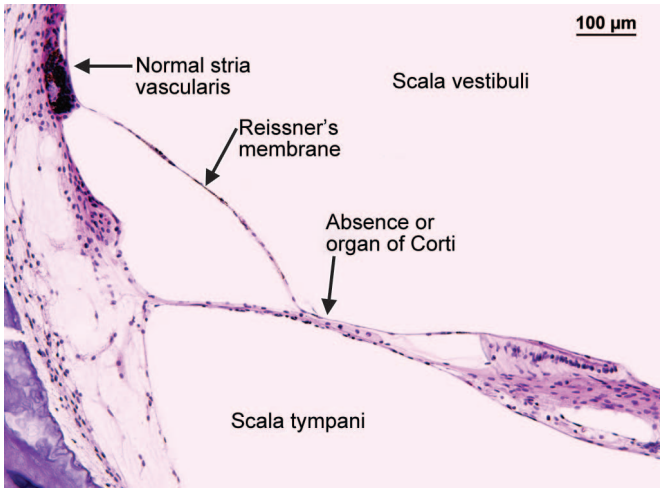


**Fig. 13.9:** Usher's syndrome type I is an autosomal recessive syndrome characterized by congenital profound sensorineural hearing loss and blindness from retinitis pigmentosa. The human temporal bone pathology is notable for complete degeneration of the organ of Corti throughout the cochlea, with the exception of disorganized mounds of cells at the apices.

While uncommon, there are variations in the course of the facial nerve. These include (a) a tympanic segment anterior and inferior to the oval window,[9] (b) a tympanic segment anterior to both the oval and round window membrane,[10] and (c) tripartitions and bifurcations in the tympanic and/or mastoid segments (Fig. 13.12).

## Vascular Anatomy

The course of the carotid artery within the temporal bone is of significant importance to the otologic surgeon. The carotid courses through the petrous bone in a bony canal of 0.5 mm thickness.[11] Up to 1% of carotid arteries may be dehiscent in this area. An aberrant internal carotid artery traverses over the cochlear promontory and results from an enlarged inferior tympanic artery providing the principal blood supply to the intracranial carotid artery. An anomalous course of the carotid or aneurysm may be seen as a pulsating mass along the anterior part of the tympanic membrane.

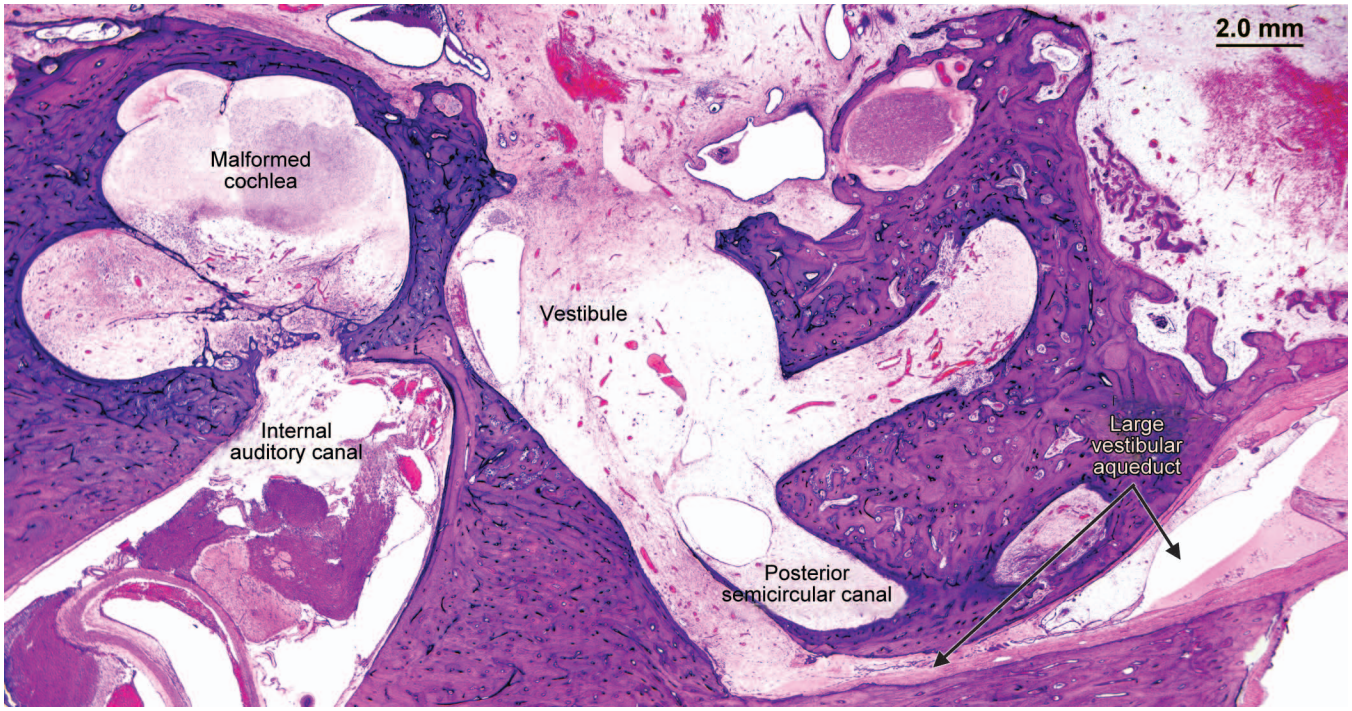

**Fig. 13.10:** Large vestibular aqueduct. This case demonstrates a large vestibular aqueduct, as well as a cochlear malformation with incomplete partition. There was an intense cellular inflammatory process with mature granulation tissue and fibrous tissue filling the cochlea, middle ear, vestibule, and semicircular canals, possibly the result of prior surgery and cochlear implantation.

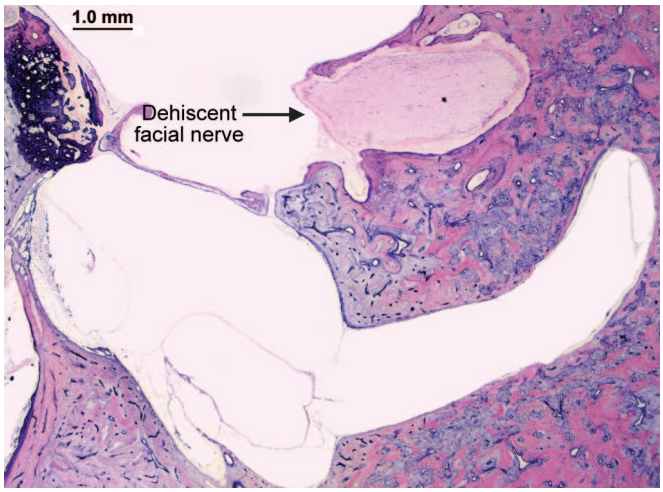

**Fig. 13.11:** Dehiscent tympanic segment of the facial nerve.

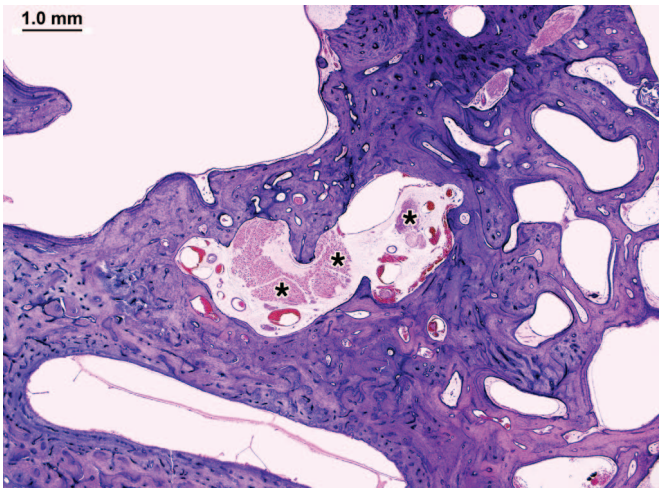

**Fig. 13.12:** Anomalous partitions (indicated by asterisks) of the vertical segment of the facial nerve.

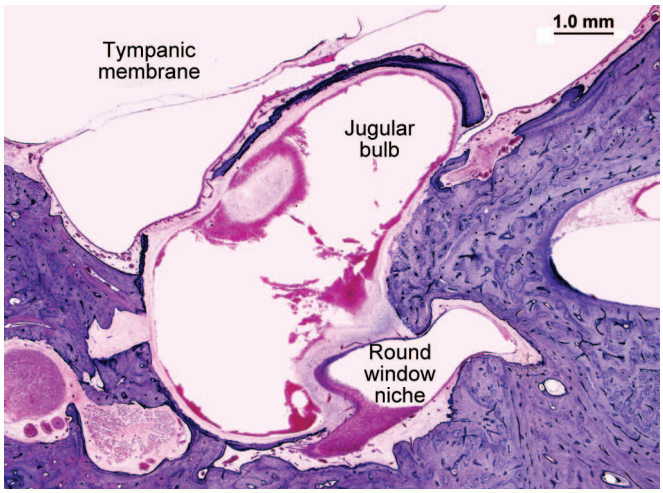

**Fig. 13.13:** A high jugular bulb may preclude an adequate view of the round window membrane during cochlear implant surgery or susceptible to injury with insertion of a tympanostomy tube or elevation of a tympanomeatal flap.

The jugular bulb is variable in position. It may be high in the middle ear and may be seen above the tympanic annulus encroaching the round window membrane. The jugular bulb may be dehiscent in up to 7% of cases[12] (Fig. 13.13).

CHAPTER

# Newborn Hearing Screening and Audiologic Considerations for Children

14

***Barbara S Herrmann***

## BACKGROUND

Newborn hearing screening is now considered the standard of care in the United States and most developed countries because of the adverse consequences of undetected hearing loss on the linguistic, cognitive, and emotional development of a child. The importance of early identification of hearing loss was recognized by many individuals in the 1950s and 1960s, most prominently by Marion Downs who attempted to institute a behavioral observation based method of screening in the late 1960s.[1] These programs, based on a newborn's startle reaction to various sounds, proved costly due to the variability of newborn behavior. Many infants with normal hearing were referred for more testing and infants with hearing loss were missed. As interest in the early identification of hearing loss grew, the Joint Committee on Infant Hearing (JCIH) was formed in late 1969 composed of representatives from professions involving children and hearing, audiology, otolaryngology, pediatrics, and nursing. After thorough review of existing screening programs, the status of the current clinical techniques available and promising research being started, the Committee published its first statement in 1971.[2] In this statement, it recognized the urgent need for early detection of hearing impairment but could not justify the mass screening of all newborns because of the lack of appropriate test procedures.

As a result, a high-risk approach for identification of congenital hearing loss was suggested in which those infants with factors associated with congenital hearing loss in their medical or family history were identified at birth and enrolled to be tested repeatedly during the first 5 years of life.[2,3] This approach was mandated first in Massachusetts in 1977 and subsequently in other states. Over the next 15 years, studies on childhood deafness, however, indicated that the high-risk approach was ineffective in lowering the age of identification of hearing loss, which remained at an average of 2.5 years in developed countries, for two reasons: (1) 50% of all children born with hearing loss did not have an identifiable risk factor and (2) the high lost to follow-up rate for repeated testing on those children identified with risk factors.[4,5]

During the same time period, physiologic methods of testing hearing that did not rely on a behavioral reaction to sound began to be developed that eventually enabled the accurate testing and diagnosis of hearing loss in the infant. Auditory-evoked response testing using the auditory brainstem response (ABR) began to be used to measure the hearing sensitivity of infants who were at least 30 weeks' gestational age in the late 1970s and early 1980s.[6] Recording the synchronized neural firing from the auditory nerve and central auditory system to brief sounds, the ABR is currently considered the gold standard technique for the measurement of hearing sensitivity in infants.[7] As the testing of infants became possible, the ABR began to be used to screen infant hearing in the survivors of neonatal intensive care units (NICUs) who were recognized as having a higher incidence of hearing loss than well babies. With the successful application of ABR in infant hearing screening, instruments were developed that could be used by individuals with minimal training and knowledge of infant hearing,[8] thus lowering the cost and making more fiscally possible universal screening of all infants. In parallel, another physiologic response from ears with near normal hearing, otoacoustic emissions (OAEs), was also discovered[9] and applied in infant hearing screening.[10]

Newborn hearing screening programs began to be instituted in many NICUs and also in some well-baby nurseries, most notably the Rhode Island Project.[10] The surgeon general, C. Everett Koop, took interest in infant hearing and issued a challenge in 1988 that by the year 2000, all children with hearing loss be identified by 12 months of age, a challenge incorporated in the Health and Human services Healthy People 2000 report.[11] A consensus conference sponsored by the National Institutes of Health on the topic of infant hearing in 1993 concluded with the recommendation that all infants should be screened for hearing loss before discharge from the hospital.[12] This recommendation generated some controversy, most notably sparked by an opinion article by Bess and Paradise in 1994.[13] This article challenged the need for newborn hearing screening based on the lack of data showing the identification before the age of 2.5 years resulted in better outcomes for children than those identified later. This challenge prompted not only controversy but a series of studies, especially by Yoshinaga-Itano and colleagues that tracked the language development of children identified and starting early intervention for hearing loss at different ages.[14,15] These studies consistently indicated that better language outcomes were associated with earlier identification and intervention and that children identified later had a consistent deficit in language that persisted. With this additional evidence, barriers to the clinical implementation of universal newborn hearing screening (UNHS) began to fall, most notably by the endorsement of UNHS by the American Academy of Pediatrics. By 2000 the Joint Committee statement stated "Given the … empirical evidence to date, the JCIH considers that accepted public health criteria have been met to justify implementation of UNHS"[16] with a recommendation that infants not passing the hearing screening be evaluated and diagnosed by 3 months of age and intervention begun by 6 months of age.

This growing body of evidence supported the push in many states to institute statewide infant hearing screening. The first state to mandate newborn hearing screening was Hawaii in 1991, followed quickly by Rhode Island. Over the next two decades, all states and US Territories instituted statewide programs either by legislative action or gubernatorial action. Data from these programs are now compiled by the Centers of Disease Control (CDC) through the Early Hearing Detection and Intervention (EHDI) program.[17] In 2010, 98% of all births in the United States (3,881,046 infants) were screened for hearing loss; 98% of those infants passed the screening. Of the infants not passing the screening, 68% had been evaluated by 3 months of age with an estimated prevalence of congenital sensorineural hearing loss of 1.6 per 1000 births (range 0–4.6). Similar efforts in other developed countries have resulted in newborn hearing screening worldwide.

## SCREENING TECHNIQUES

There are two currently accepted newborn hearing screening techniques using a physiologic response to a sound: (1) the auditory-evoked response using either the ABR or, more recently, the auditory steady-state response (ASSR) and (2) evoked OAEs using either transient-evoked otoacoustic emissions (TEOAEs) or distortion product otoacoustic emissions (DPOAEs). Each of the techniques has its supporters and heated controversy has surrounded discussions regarding which is the better technique to use. Commercially available equipment has been developed for each of the response metrics and how each of these responses can be recorded is detailed elsewhere. Neither of these techniques measures the psychophysical perception of a sound as does the behavioral response, but both require that portions of the auditory system be intact for the responses to be present.

### Auditory-Evoked Responses

The ABR has been used in newborn hearing screening for the longest period of time with the first automated ABR infant hearing screener available in 1985.[8] The ABR reflects synchronized neural electrical activity that is elicited by a transient sound and recorded using surface electrodes on the head.[18] The response is extracted from the ongoing activity of the brain using signal processing techniques, most commonly signal-averaging of the ongoing electroencephalic activity for time window of 10–20 ms after many presentations of either frequency-limited toneburst signals or broadband click signals. Since the presence of the ABR requires the function of the auditory periphery (including the inner and outer hair cells, and auditory nerve) and of the central auditory pathways (up through the level of the upper brainstem), it is a metric of the physiologic integrity of much of the auditory system. For this reason, the ABR is considered the standard technique for the measurement of hearing loss in infants.[7] Most ABR screening instruments use a low-intensity broadband click.

The ASSR is a different auditory-evoked potential that has been more recently developed and is now currently being applied to newborn hearing screening.[19] ASSR analyzes the electroencephalic activity to frequency and amplitude modulated tonal signals with respect to peak detection in the spectral domain as opposed to the amplitude and latency in the time domain used in recording the ABR. Though promising for a more frequency specific measure of auditory screening, the ASSR is 10 times smaller than the ABR, making it more difficult to detect <30 dB HL even in normal hearing individuals. It is also more prone to false detection of artifact as response because of its use of the spectral domain analysis rather than time waveform analysis. The amplitude of the ASSR increases proportionally with the amplitude and frequency modulation of the tonal signals; however, with increased modulation the frequency specificity is similar to that achieved with the toneburst signals of the ABR.

### Otoacoustic Emissions

OAEs are low-intensity sounds that are emitted primarily by healthy normal ears. OAEs are elicited by transient broadband clicks, TEOAEs by the distortion generated in a healthy ear by two tones of different frequencies (DPOAEs).[20] Both TEOAEs and DPOAEs are present in healthy, normal ears and in ears with tonal sensitivity thresholds of 30 dB HL or better. Both are usually detected using spectral analysis of averaged waveforms. TEOAEs and DPOAEs are believed to be generated by the outer hair cells of the organ of Corti, though perhaps not by the same mechanism. Since the outer hair cells are frequently the first to be damaged by conditions causing peripheral hearing loss, OAEs are usually present in ears with normal peripheral hearing and are absent in those with hearing loss >30 dB HL. Thus, OAEs are considered an appropriate metric for identifying infants with hearing loss.

As the clinical application of OAEs increased, it was discovered that a small number of infants (and adults) have present TEOAEs or DPOAEs, and do not have ABRs to low-intensity sounds. These infants and some older individuals have been categorized as having auditory neuropathy/dys-synchrony[21,22] and the damage to the peripheral ear (either to the inner hair cells, the inner hair cell and nerve synaptic junction or to the auditory nerve itself) is sufficient to prevent spoken language development due to poor speech perception. A study of temporal bones from infants who did not pass an ABR infant hearing screening indicated a small number of specimens had present outer hair cells in some areas of the basilar membrane where inner hair cells were absent.[23] Animal models of similar cochlear damage consistently have present OAEs but absent ABRs. Thus although the majority of infants with hearing loss will not have OAEs, a small proportion, estimated to be about 1 in 12,000 births,[24] will pass an OAE newborn hearing screen but not have sufficient hearing to develop speech and language. Because of this issue, the JCIH recommends that ABR be used in the NICU population where the prevalence of auditory neuropathy/dyschrony is greater than in the well-baby nursery.[25]

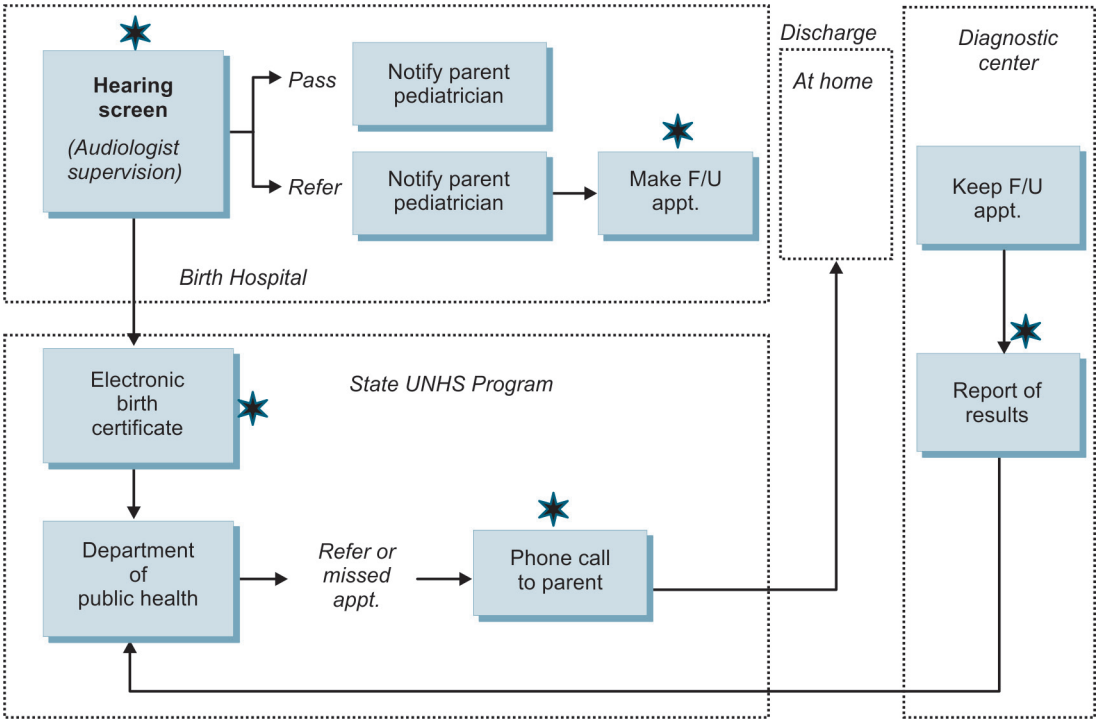
## IMPORTANT CONSIDERATIONS IN UNHS PROGRAM DESIGN

### Overall Design

The success of a newborn hearing screening program depends heavily upon the design and supervision of its implementation. Most states have detailed guidelines regarding the requisite components of a program that include screening personnel, equipment maintenance and calibration, documentation of results within the hospital and to the state, communication to parents and families, and linkage to the follow-up evaluations[26] website that follow the guidelines set out by the JCIH. Each of these components is necessary to have a comprehensive program and the flow of information from one segment to another is critical to the effectiveness of the program. Without careful consideration of overall design, it is not uncommon for many infants to be screened, but because of ineffective monitoring those infants are not diagnosed in a timely manner and consequently do not receive intervention in the initial year of life.

The goal of newborn hearing screening is to identify neonates with hearing loss that will be detrimental to speech and language development, diagnose the hearing loss, and begin appropriate intervention. Flowchart 14.1 illustrates the flow of the UNHS newborn hearing screening program in the state of Massachusetts. The structure of this particular program has resulted in one of the lowest lost to follow-up rates in the country. Screening programs are in birth hospitals and required to be associated with an audiologist for supervision and training (thus providing the nursery with a knowledge base regarding hearing). Hearing is screened in the nursery before discharge from the hospital and the outcome is either pass or refer

**Flowchart 14.1:** Flowchart of universal hearing screening program in the state of Massachusetts as an example of a closed-loop system that helps to minimize the number of infants who do not pass but do not receive a full diagnostic evaluation. Key elements of this system are highlighted by stars and include an audiology supervised hearing screen in the birth hospital, the scheduling of a diagnostic appointment before discharge from the birth hospital, entry of the screening outcome into an electronic birth certificate, contacting the parent after hospital discharge and report of diagnostic evaluation results to the centralized state department tracking the hearing screening of infants in the state.



(did not pass). Results are documented in the medical record and given to the parents verbally and by means of an informational handout containing results and basic information about the importance of hearing to the development of speech. The documentation in the record is transmitted through the discharge summary to the infant's pediatrician. In addition, the results are entered into the electronic birth certificate (EBC) that is maintained by the state's Department of Public Health (DPH). This electronic entry to the birth certificate begins a parallel system of monitoring for completion of the follow-up evaluation and intervention. Infants who do not pass their hearing screening are required to be scheduled for a full diagnostic evaluation at a DPH approved center before discharge from the hospital. This requirement enters the child and family into an audiology diagnostic system making a link between the nursery and the diagnostic follow-up. The usual time between discharge and the follow-up appointment is 3–4 weeks. The DPH department for UNHS screens the EBC data at regular intervals, identifies those infants not passing the screening, contacts the parents after discharge to encourage them to keep the appointment, and provides any assistance necessary. At the completion of the diagnostic evaluation with AER, the diagnostic center submits a data form to the state detailing the results of that evaluation. The DPH links the completion of follow-up diagnosis to the child's UNHS outcome and, if hearing loss is present, links the screening and diagnostic outcome to the state's Early Intervention Department. Babies who do not come to their diagnostic appointments are reported via the same system as a missed appointment, at which point the state again reaches out to the parent (in parallel to the diagnostic center).

In Massachusetts, this closed-loop system from newborn hearing screening to diagnosis and subsequently intervention has resulted in a consistently low rate of lost to follow-up (infants not receiving further testing, diagnosis, and intervention). This low lost to follow-up rate is in contrast to many states that do not directly schedule follow-up appointments before discharge from the nursery nor have established a parallel system of monitoring via the EBC to a state database. Figure 14.1

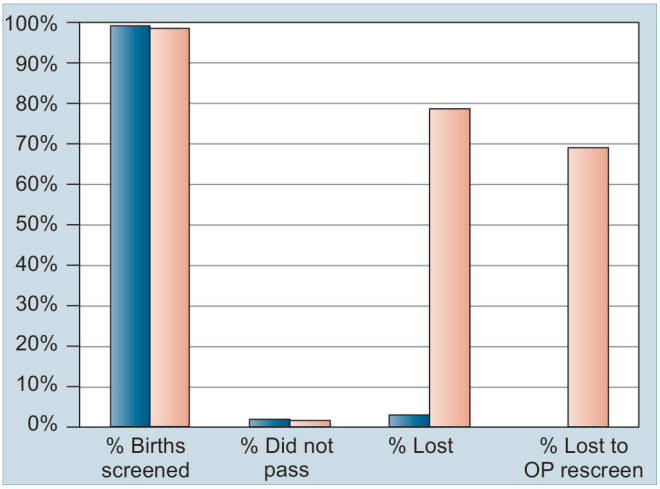


**Fig. 14.1:** Comparison of newborn screening data from Massachusetts (blue) and Texas (brown) which have different program designs. While the states have similar statistics for the percentage of infants screened and the percentage of infants not passing, the states differ greatly with respect to the number of infants not passing the screening that are lost to follow-up for a full diagnostic evaluation. Interestingly, the majority of the infants lost in Texas are lost to an outpatient rescreen; in Massachusetts all screening is done in the birth hospital before discharge and the appointment for the full diagnostic evaluation is made before discharge.

illustrates the lost to follow-up rate reported to the CDC in 2010[27] of two states over the last 10 years, Massachusetts and Texas. Texas does not have direct entry into an EBC for tracking of infants needing services nor a direct link to follow-up through scheduling a diagnostic appointment before discharge. These two elements are very effective in decreasing the lost to follow-up rate that the CDC reported to range from 2.9% to 86.1% and averages 39.3% over the entire country in 2010.

The design of a newborn screening program will also depend upon the health service system that is in place. For instance, in countries with a centralized national health service such as Belgium, newborn hearing screening has been incorporated into the first well baby visit by a visiting nurse in the home about 2 weeks after birth. The screening outcomes are entered and tracked as part of the well-baby health services including the diagnostic evaluations, again creating a closed-loop system that decreases infants who are lost to follow-up.[28]

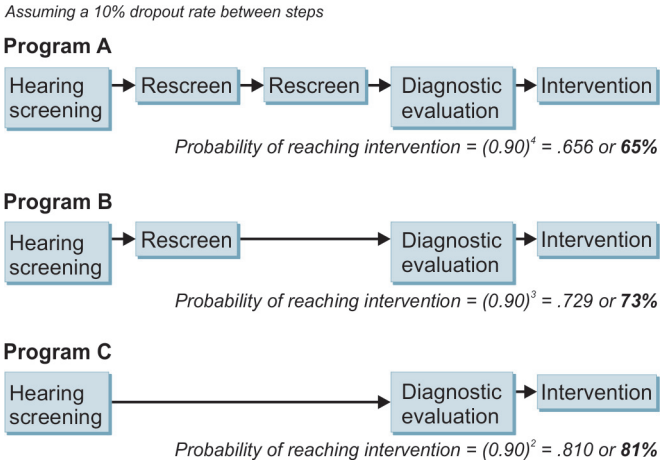
## Multiple Hearing Screens

Within the overall design of the UNHS program are decisions regarding the number of hearing screens before referring an infant for diagnostic testing. As newborn hearing screening programs were being implemented there was significant focus on reducing the number of infants referred for further testing. This concern has merit because of the increased cost in health dollars and the increased anxiety of parents with the additional testing for each referral. Hence, the sensitivity and specificity of a newborn hearing screening technique was critical in lowering cost.[13,29] Some individuals approached lowering the referral rate by rescreening infants who did not pass their initial hearing screening with the argument that reuse of the less expensive screening would eliminate those infants who may not have passed their initial hearing screenings because of a temporary hearing loss at a lower cost than the full evaluation.[10] In many places, this approach resulted in one or more in hospital screens followed by an outpatient screen before referral for diagnostic testing. There are several problems with this approach.

The first problem is that the use of several steps before referral to diagnostic testing increases the probability that the child will be lost to follow-up. If the probability of dropout before follow-up testing is a constant for each step in the design of a UNHS program, then the probability that a baby with hearing loss that does not pass an initial hearing screening makes it through the process to intervention is the product of the probabilities of dropout at each step. Flowchart 14.2 illustrates this principle. Assuming a dropout rate of 10% at each step, the program with the fewest number of steps will have the lowest probability of dropout for the entire program. Using rescreens, especially those scheduled as outpatients only increases the probability of lost to follow-up.

Second, repeated hearing screens increase the chance of a false pass due to the probability of repeated statistical testing.[25] Regardless of the screening technique chosen, all of the automated hearing screening instruments use a statistical test for detection of the response such as an F-test or the calculation of a Likelihood Ratio. Repetition of any statistical test increases the chance of a false identification of significance, which in this application means a response to sound is detected when it does not exist. Hence, repeat screenings only increase the chance of a false result. It is interesting, however, that humans tend to believe the outcome of the screen when it is the one that is secretly hoped for, that is, all testing is stopped when the infant passes a screening even after seven to eight screens that did not pass. For some reason, after multiple tests referring the child, the nursery staff believes the pass outcome.

**Flowchart 14.2:** This flowchart illustrates that increasing the number of steps between hearing screening and intervention increases the probability that the infant will be lost. The calculation illustrated is the overall probability of being lost as the product of the probability of dropout at every stage of the protocol.



Third, mild hearing losses are more likely to be identified with an initial hearing screen in the nursery if the screening is not repeated. Reports are beginning to surface indicating that some screening practices are missing babies with milder but permanent hearing loss.[30] Most screening instruments are set to detect infants whose hearing sensitivity in the 750–4000 Hz range is 30 dB HL or poorer. (For this reason, ABR instruments usually use a stimulus level of 35 dB HL). Some infants have hearing thresholds of 20–30 dB HL and the response detection techniques used are less likely to pass these ears. However, there is an increased likelihood of passing with repeated screens. Additionally, measures of acoustic reflectance[31] have indicated that all infants are born with some middle-ear fluid and most likely vary in the speed by which this fluid is cleared and by the amount of hearing loss, if any, that is caused by the fluid. In normal hearing infants, the fluid does not usually cause a change in hearing sensitivity sufficient to cause the infant not to pass the hearing screening. Infants with hearing sensitivity in the marginal or grey area of 20–30 dB may not pass the initial hearing screen because of a small decrease in hearing sensitivity caused by fluid pushes their thresholds into the range where they do not pass. Once the fluid has cleared, however, this infant with marginal hearing is more likely to pass the hearing screening. An example of this situation is shown in Figure 14.2. This infant did not pass the newborn hearing screening in either ear in the nursery. A diagnostic ABR evaluation at 4 weeks of age estimated the audiogram shown. A repeat recording of the ABR to a 35 dB HL click at the time of the diagnostic evaluation is also shown (the same stimulus used in the newborn hearings screening). The ABR is clearly present and would have been detected upon rescreen. Fortunately for this child, however, the use of a single screen referred this infant for full evaluation that diagnosed the marginal loss and prompted the continued follow-up of this child audiologically, medically, and educationally.

Finally, there is a perception that repeated hearing screenings somehow lower a family's anxiety over the failure to pass a newborn screening without giving any further information about a baby's hearing. A study verifying this perception has not been reported. It is not uncommon, however, for parents whose children have referred on repeated hearing screens to wonder why the definitive diagnostic test was done sooner to give them better information about their child.

## Cross-Disciplinary Collaboration

An important aspect of successful UNHS programs is the cooperation of professionals from several disciplines with the newborn and family to smoothly identify, diagnose, and begin intervention for congenital hearing loss. Beginning with nursery personnel including nursing, screening personnel, and neonatologists/pediatricians, the list of cooperating disciplines grows to include audiologists, otolaryngologists, speech-language pathologists, and educators. For this reason, all these disciplines are represented on the JCIH. Additional services for those diagnosed with hearing loss may also include genetics, ophthalmology, family counseling, and developmental pediatrics. To aid coordination of the contributions of each of these disciplines, the JCIH has described the role of each in contributing to the overall care of the child and support of the family in preventing the difficulties associated with untreated hearing loss in children.[25] Since these professionals often are in different institutions or minimally in different departments, it requires additional effort to coordinate all aspects of the program and support the baby and family in each phase of identification, diagnosis, and intervention.

## The Role of the Otolaryngologist

Pertinent to this chapter is the role of the otolaryngologist. Besides providing support and being a resource to a UNHS

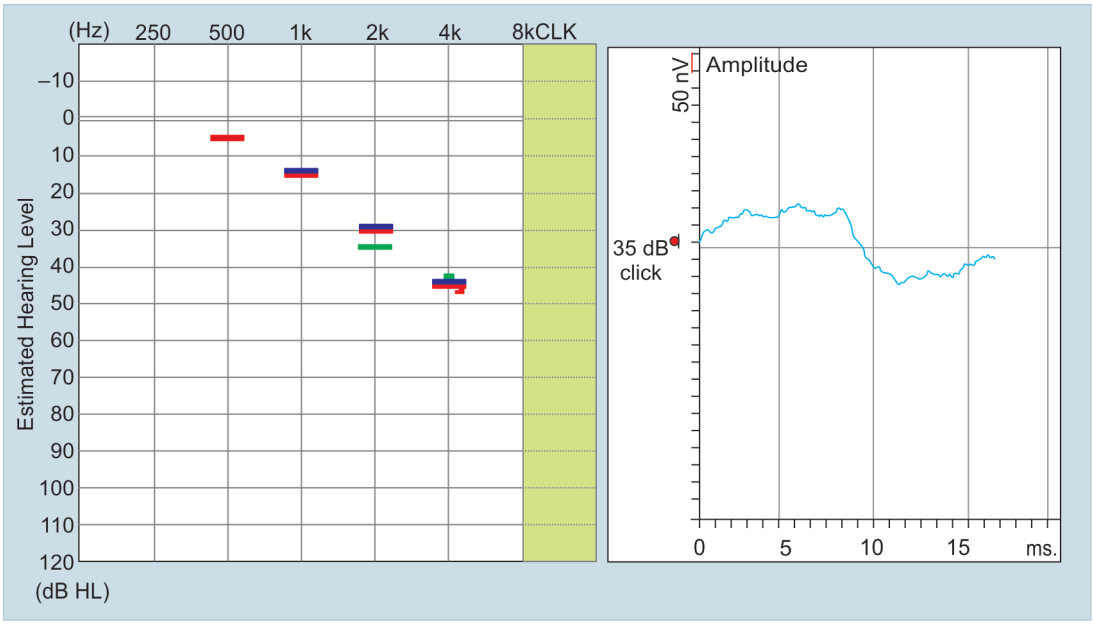


**Fig. 14.2:** Results of the diagnostic evaluation for an infant who did not pass the newborn hearing screening in a single-screen program and was found to have mild hearing loss when evaluated at 4 weeks of age. On the left is the measured hearing threshold sensitivity (red: right ear; blue: left ear; green: unmasked bone) using ABR (shown on the audiogram). On the right is the ABR response to a 35 dB HL click recorded at the full diagnostic evaluation. The clear presence of this response 4 weeks later suggests that the child may have had a slightly greater loss at birth perhaps due to middle-ear fluid which had cleared by 4 weeks of age. This child may have passed a rescreen.

program, the JCIH defines the role of the otolaryngologist in UNHS as the physician who is responsible for the comprehensive head and neck examination and the assessment of structural abnormalities that may be identified on examination or via imaging. The otolaryngologist determines the etiology of the hearing loss, identifies the risk indicators for progressive loss including syndromes associated with hearing loss and other disorders of the head and neck, and determines the need for medical or surgical intervention of ear disease resulting in conductive and sensorineural hearing loss. In addition, the otolaryngologist works with their audiology colleagues in determining the use of appropriate assistive technology such as amplification or cochlear implantation.[25]

## OUTCOMES FOR NEWBORN HEARING SCREENING

As mentioned at the beginning of the chapter, the outcomes of UNHS across the country have been tabulated by the EDHI program of the CDC for over 10 years.[27] Outcomes are tabulated in accordance to the recommendations of the JCIH for number of babies screened, number receiving diagnostic evaluations and also calculates the overall prevalence of congenital hearing loss identified through UNHS (currently 1.6 per 1000 births). These numbers show that most babies in the United States are screened for hearing loss, though the lost to follow-up rate varies drastically from 2.9% to 86.1%, with a national average of 38%. As demonstrated by the Massachusetts UNHS program, this problem is often solved by better design of the overall program and the use of state resources to track those infants who do not follow-through.

Within a single program, outcomes of a UNHS screening program and of the results of follow-up evaluation are the best way to monitor the quality of the program. Figure 14.3 gives an example of the statistics of a newborn hearing screening program over a 1-year period. You can see on this chart that the overall refer rate is calculated each month (with a cumulative total for the program calculated across the months monitored). The results of the follow-up testing on refers are also tabulated. By tracking these statistics, one can monitor any unusual change in referrals beyond the expected rate and address any issues such as equipment problems, need for retraining in a timely manner, need to tighten the linkage to follow-up, etc. Tracking these statistics over years can also highlight any issues or concerns and set expectations.

**Fig. 14.3:** Sample statistics tracking the performance of a newborn hearing screening program over 1 year.

**Table 14.1:** Risk indicators for delayed-onset or progressive hearing loss from the Joint Committee on Infant Hearing 2007 Statement[25]

| |
|---|
| • Caregiver concerns regarding speech, language, hearing or developmental delay |
| • Family history of childhood hearing loss |
| • Neonatal intensive care unit stay of more than 5 days or any of the following: ECMO, assisted ventilation, exposure to ototoxic medications or loop diuretics and hyperbilirubinemia requiring exchange transfusion |
| • In utero infections such as CMV, herpes, rubella, syphilis and toxoplasmosis |
| • Craniofacial anomalies including those involving the pinna, ear canal, ear tags, ear pits and temporal bone anomalies |
| • Physical findings such as white forelock, that are associated with a syndrome known to included sensorineural or permanent conductive hearing loss |
| • Syndromes associated with hearing loss or progressive loss such as neurofibromatosis, osteoporosis and Usher syndrome; other frequently identified syndromes include Waardenburg, Alport, Pendred and Jerveil and Lange-Nielsen |
| • Neurodegenerative disorders such as Hunter syndrome or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome |
| • Culture-positive postnatal infections associated with sensorineural hearing loss including confirmed bacterial and viral meningitis |
| • Head trauma, especially basal skull/temporal bone fractures requiring hospitalization |
| • Chemotherapy |

(CMV: Cytomegalovirus; ECMO: Extracorporeal membrane oxygenation).

The most important outcome for UNHS is, of course, the original motivation of preventing the speech and language delays associated with later diagnosis in children with hearing loss. Larger studies of these outcomes are beginning to be reported and are showing the expected effect; that is, identification and intervention of hearing loss before 6 months of age does result in better speech and language outcomes for children.[32,33]

## AFTER NEWBORN SCREENING: OTHER AUDIOLOGIC CONSIDERATIONS FOR CHILDREN

Concern regarding hearing loss in children does not end with newborn hearing screening. Though the exact numbers are not known, timely identification of late-onset hearing loss is the next challenge after UNHS with the same cooperation of disciplines (otolaryngology, pediatrics, audiology, education, rehabilitation) as with newborns. Currently the JCIH[25] addresses this issue through the identification of risk indicators (Table 14.1) for delayed onset of loss and through the monitoring of speech and language skill development for those infants who do not have any identifiable risk indicators for delayed-onset loss. The ideal place for identification of risk indicators and monitoring speech and language is through the medical home of the child, the pediatrician/primary physician within the periodic visits recommended by the AAP. Once referred and diagnosed, the entry into intervention is again the goal to minimize the effects on speech and language and later on education.

The techniques used to test children as they grow change with development of the skills available for response. These differences have been well catalogued and described in many sources including the JCIH statements.[20,25,34] For infants 0–6 months, case history, ABR, OAEs, and tympanometry are recommended components of a diagnostic evaluation. By a developmental age of 6 months, the child is capable of being conditioned to look for a toy or other reinforcing item when hearing a sound using a technique called visual reinforcement audiometry (VRA) for both tonal signals and speech detection. When the child's conditioned response is reliable, VRA replaces ABR for the measurement of hearing threshold sensitivity. By 3 years of age, most typically developing children will play a game such as putting a block in a bucket (play audiometry) to measure hearing threshold; by 5, most typically developing children are capable of raising their hand to a tone with the same reliability as an adult. As children develop spoken language, they become capable of doing tests of speech perception that provide insight into the distortion caused by a hearing loss that complements the information provided by measures of hearing threshold sensitivity.

Suffice it to say, hearing can be tested at any age. Diagnosis and intervention as early as possible will always be in the best interest of the child. Coordination of care and support of families through the process will result in the best outcomes for a child. This process starts with newborn hearing screening and continues through the development of the child and into the adult years. The evidence continues to show that the earliest detection and intervention of hearing loss helps to reduce and even prevent the linguistic, emotional, and cognitive impact that accompanies late-identified hearing loss.

CHAPTER

# Speech and Language Evaluations of Children with Hearing Loss

15

*Kathleen M Lehnert, Deborah S Grammer, Howard W Francis*

## INTRODUCTION

As the framework by which ideas are organized for exchange between people[1] language is important to the socialization of children, their successful engagement in education, and prospects for a productive adulthood. Access to the phonemes or basic units of speech is made possible by the frequency, temporal and intensity coding of the cochlea and central auditory pathway.[2,3] By representing the unique acoustic characteristics of each phoneme, the normal auditory system enables the discernment, recognition, and production of meaningful speech sounds that allow the developing child to illicit human reaction and influence behavior (Table. 15.1).[4,5] In turn, the child's evolving understanding of the world and its expectations are influenced by information received and decoded by the auditory system. An important determinant of long-term success, literacy is also dependent on the ability to decipher phonemes.[6,7] Hearing deficits therefore pose a significant threat to the normal development of language with implications that extend to educational achievement and long-term life opportunities.[8,9]

If the use of spoken language is the treatment goal for a child with hearing loss then access to the speech spectrum must be facilitated using appropriate hearing instruments or devices such as hearing aids and cochlear implants. The evaluation and mitigation of hearing loss without understanding its downstream effects on the child's language milestones, however, limits the development of an appropriate rehabilitation strategy and the ability to monitor outcomes. Whereas the clarity of speech production is often the most obvious manifestation of a hearing deficit, the first priority is to optimize receptive language through early and appropriate intervention,[8–10] so as to fortify the foundation for further language development

**Table 15.1:** Frequency distribution of important speech and language information

| *Frequencies* | *Important speech and language features* | *Communication examples* |
|---|---|---|
| 4,000 Hz | • Grammatical morphemes | • Plural markers (e.g. cat**s** and watch**es**), possessive markers (e.g. mommy**'s**), verb tenses (e.g. trie**s**, walk**ed** ) |
| 2,000 Hz | • Key frequency for speech intelligibility | • Bursts of acoustic energy for plosives (p, b, t, d, k, and g) and affricates (ch and j)<br>• Stridency for continuant sounds (s, z, sh, zh, f, and v) |
| 1,000 Hz | • Suprasegmentals<br>• Vowel discrimination | • Stress, rate and intonation and inflection |
| 500 Hz | • Voice tones<br>• Nasality information | • Differentiation between male, female and child voices<br>• Nasal sound information for /m/, /n/, and /ng/ |
| 250 Hz | • Suprasegmentals<br>• Nasal murmur | • Stress, rate and intonation and inflection<br>• Resonance of the nasal pathways for the nasal sounds |

Information from Ling.[5]

including more fluent speech and good reading skills.[11] Speech and language abilities should be evaluated by a speech-language pathologist (SLP) who has extensive experience and training in hearing loss, management of hearing aids, and management of cochlear implants. A team approach is necessary, however, to effect an optimal rehabilitation strategy and should include close cooperation with an audiologist, otolaryngologist, and educator. Other professionals with special training in auditory rehabilitation, such as teachers of the deaf, are also valuable members of the rehabilitation team, as are parents, the primary teacher of every child. Speech and language skills are evaluated in order to develop a plan for rehabilitation and monitoring. This chapter addresses the purpose of the speech and language evaluation along with the implications of intervention for children with hearing loss.

## THE SPEECH AND LANGUAGE EVALUATION PROCESS

Given the long-term objective of achieving age-appropriate speech and language abilities, tests standardized on typically developing children with normal hearing are used to gauge progress toward this goal.[12] The instruments listed in Table 15.2 are typically used to evaluate the speech and language abilities of children with hearing loss. For a young child, parent report measures are used in conjunction with norm referenced standardized assessments to fully capture the child's speech and language abilities across environments that the clinician may not have the ability to observe. Clinician-directed norm-referenced tests where the child responds to targeted language test stimuli are primarily utilized in older children, however.

Information is first gathered from parents, clinicians, and teachers in order to select appropriate assessments that can be used to characterize the child's unique communication profile. The SLP prepares for the evaluation by reviewing pertinent case history and other available documentation, including audiological reports, previous speech and language assessments, psycho-educational assessments, gross motor and fine motor assessments (i.e. physical therapy and occupational therapy), and education-related documents such as the Individualized Family Service Plan (i.e. special education services for infants and toddlers) or Individualized Education Plan (i.e. special education services for school age children). If possible, it is helpful to directly communicate with providers who are currently working with the child including SLP, audiologist, psychologist, early interventionist, classroom teacher, physical therapist, and occupational therapist. Additionally, the parents and/or guardians are interviewed regarding communication history and current communication behaviors.

Depending on the child's age, assessments are given to evaluate speech articulation and language abilities in the areas of form, content, and use.[13] Form of language comprises syntax, morphology, and phonology. These components provide the structure of language. Syntax specifies how words are organized in sentences. For example, noun–verb agreement or a descriptive word precedes the object of a sentence. Morphology consists of morphemes that are the smallest units of meaning within a word. If one adds an "s" to a noun, e.g., the meaning of the noun changes from singular to plural. In this example, the noun and the grammatical marker "s" are each considered morphemes. Phonology is the sound system of our language. The system is comprised of many individual phonemes or speech sounds that can be manipulated to create words. Content of language refers to the meaning of words and sentences to include nouns, verbs, adjectives, adverbs, concepts, synonyms, antonyms, idioms, and figurative language. Receptive vocabulary is the child's knowledge of word meanings while its counterpart, expressive vocabulary, comprises words that the child uses to impart meaning. A language user who has a strong semantic knowledge base understands and uses a variety of words that are rich in meaning to convey a message. Pragmatics is the social use of language and thereby influences all the other aspects of language. All the above aspects of language are used simultaneously to produce meaningful communication in an effortless manner. Speech articulation abilities overlay how the intended verbal message is communicated intelligibly.

Table 15.1 describes where speech sounds fall across the frequency spectrum.[4] Without sufficient access, gaps in speech perception will be evident and therefore weak or uneven speech and language abilities will be exhibited. Vowels carry 90% of the energy during speech production, whereas consonants account for only 10% of speech energy. However, 90% of the information needed to perceive the differences between speech sounds is carried by consonants.[4] Consonant perception and speech understanding are therefore quite vulnerable to hearing deficits, which predominantly affect the high frequencies (Table 15.1). Hearing at 4000 Hz, e.g. is critical for "s"

and "z" grammatical markers that are necessary for the development of plurals, possessives, and some verb tenses. Even mild to moderate high frequency hearing losses can significantly alter normal acquisition of receptive and productive language.

Expressive language develops through listening and manifest as verbalizations that evolve with both receptive language and oral motor coordination. Babies begin speech sound production by vocalizing and crying. These sounds evolve over the next year through exploration of fine motor movements of the vocal tract and further refinement of their oral motor development that shape vocalization to approximate speech sounds that are heard daily.[14–17] For example, the child progresses through a series of babble stages, which precede the production of the first words (Table 15.3). Subsequent production of speech sounds is shown in Table 15.4, reflecting development of oral motor skills and expanding expressive vocabulary.[17] An understanding of these early stages of articulation and phonological skill acquisition is critical to the early detection of abnormal language development before large deficits occur. When there is a delay in the production of early vocalizations, speech sounds or the achievement of appropriate milestones then a number of causes should be considered and ruled out including hearing loss, cognitive learning disorder, and oral motor deficits.

In the case of hearing loss, early intervention with hearing aids or cochlear implants can provide adequate speech input that helps to guide this normal construction and progression of both receptive and expressive language. Appropriate intervention should not, however, await the appearance of deficits in normal speech and language development. In the setting of moderate to severe and progressive hearing loss, the use of a hearing aid may initially be accompanied by normal development of speech and language. The appearance of a plateau or regression of development should prompt strong consideration of cochlear implantation and enhanced rehabilitation.

**Table 15.3:** Pre-linguistic phonological development

| *Babbling stage* | *Examples of associated verbal behaviors* |
|---|---|
| Phonation *(Ages birth to 1 month)* | Crying, coughing, and sneezing; sounds of pleasure |
| Cooing and Gooing *(Ages 2-3 months)* | Vowels and consonant-like sounds produced in the back of the throat; back vowels (i.e. oo, aw, ah) and velar productions (i.e. k and g); responds vocally to speech of others |
| Exploration/Expansion *(Ages 4-6 months)* | Begins babbling using strings of consonants and vowels (CV syllables) varying in pitch and intonation patterns; experiments with speech sounds and verbalization; imitation begins to emerge; squeals with excitement; vocalizes displeasure with intonation; makes non-speech sounds such as raspberries |
| Canonical Babbling *(Ages 7-9 months)* | Engages in vocal play; babbles in reduplicated patterns (i.e. babababa, mamamama); imitates reflexive vocalizations such as coughing and "raspberries"; produces distinct intonation patterns like adult speech; produces a greater variety of speech sounds using lips and tongue |
| Variegated Babbling *(Ages 10-12 months)* | Becomes more imitative of adult speech sounds; continues to use CV syllables in babble; begins to combine a variety of CV syllables resulting in jargon (e.g. "ba-mu-gee-da"); practices words known with inflection; produces adult-like vocalizations including intonation, prosody and rhythm |

## DEVELOPING INTERVENTION GOALS AND MEASURING PROGRESS

The characterization of speech and language delay guides intervention. The results of speech and language assessments are shared with the parents and an evaluation report is generated containing test scores and their interpretation along with narrative describing areas of strengths and weaknesses. Annual evaluations establish a trajectory of improvement of these delays allowing for adjustments of treatment strategy toward further narrowing speech and language. Information from the initial assessment is used as a starting point for establishing intervention goals, making therapeutic recommendations and tracking the development of speech and language skills. Frequency and duration of therapy are driven by the severity of the child's language delays. To monitor speech and language growth more carefully and to modify short-term therapy goals, evaluations can be performed at 6-month intervals or at the therapist's discretion. The clinician should always refer to the administration rules for each specific test regarding time intervals allowed for subsequent testing.

The tracking of speech and language progress on at least an annual basis is necessary in order to monitor expected language growth. In children with hearing aids or cochlear implants, the rate of language growth should be similar to that of a child with normal hearing. Therefore, at least 12 months growth of language should be demonstrated in a 12-month period of time, i.e. month-for-month language growth in a period of one year.[18] Given this growth rate, the goal for a child who received hearing aids or cochlear implants in infancy, is to achieve language-age equivalent scores that are commensurate with the child's hearing age (i.e. length of time with enhanced hearing within the speech spectrum) on all test measures.[12] Not all children may achieve the month-for-month language growth goal, however. Factors that may affect growth rate include age of implantation, cognitive abilities, parental involvement, socioeconomic status, or inadequate intervention services.[8,9]

## THERAPEUTIC CONSIDERATIONS

Once diagnosed and provided with appropriate sensory input through a listening device, the goal of therapy should be to advance the child through the natural language milestones experienced by normal hearing children. Infant and toddler intervention should occur within a natural play environment. Additional emphasis should be placed on coaching and guiding for parents and caregivers how to implement strategies and techniques that facilitate listening and spoken language acquisition. Behaviors that promote language development at home should also be taught, modeled, and reinforced.[8,11,19] Commitment to a longitudinal rehabilitation program consisting of frequent sessions with the child, including the parent or guardian, is therefore critical to achieving rehabilitation goals.

The auditory hierarchy of detection, discrimination, identification, and comprehension serves as a framework for developing intervention goals for children with hearing loss.[20] Each of the levels along the hierarchy builds upon

*Age in years at which 90% achieve mastery.

the previous level (e.g. you have to be able to detect before you can discriminate). The time spent on each of the levels is dependent on the child's language and learning abilities and it may require the clinician to adjust by moving up and down the hierarchy as different auditory stimuli along the continuum of speech elements (e.g. syllables, words, phrases, sentences, and connected discourse) are worked on.[20] Therapy should not, however, be fragmented but rather comprehensive so that the skills of audition, language, speech, and cognition are being integrated concurrently.[12]

Both didactic instruction and incidental learning have a role in the speech and language therapy of children with hearing loss.[21] During didactic instruction, a teacher or therapist uses a planned structured activity in order to teach specific information and language structures in a systematic way. Older children with hearing loss require some direct teaching of new language concepts and terminology using this approach. As much as 90% of what we know, however, is learned incidentally.[4] For example, we learn how to interact socially by observing and overhearing language through everyday conversations within the home, age-appropriate slang used in peer interactions, and new concepts from listening to the radio or television. A child with hearing loss, however, has more difficulty casually hearing what people are saying or being aware of conversations around them.[5] Because the child with hearing loss does not tune in readily, they may seem distracted or disconnected from events and conversations. Therefore, social rules, novel vocabulary, and language structures often need to be taught directly.

## FINAL THOUGHTS

Speech and language assessments that are administered by a qualified speech and language pathologist provide valuable information that determines the peaks and valleys in the speech and language abilities of children with hearing loss who use hearing aids or cochlear implants. The information gathered from the assessment will assist in determining speech and language growth between assessment intervals, assist with the development of therapy goals, and obtain an understanding of language strengths and weaknesses as they impact the child's performance in the classroom and day-to-day interactions. It is imperative that strong parental involvement, intensive individualized intervention, in addition to appropriate educational placement, take place in order for the child to make the expected language growth. The ultimate outcome for children with hearing loss who have access to the sounds of language via sensory devices is to obtain speech and a language ability commensurate with their hearing peers. Parents who take an active role in their child's educational and therapeutic programming help to attain the best outcomes. The speech language pathologist partners with the parents in guiding them to be the primary language facilitator and advocate for their child.

CHAPTER

# 16

# Amplification and Classroom Management

*Lynne A Davis, Christine Carter*

## HEARING LOSS

Hearing loss is the result of cellular dysfunction, structural anomalies, and/or interference of mechanical function by pathology in the ear or auditory pathways. The effect of these anatomical changes is a reduction in the loudness and clarity of auditory stimuli and interference with the brain's ability to spatially organize sound in the environment.[1,2] When the anatomy or physiological response of the body to medical treatment prevents recovery of normal function, the goal of intervention is to maximize the amount of information; the pathways are capable of transmitting and to reduce environmental competition. This may be achieved by using a combination of amplification, auditory encoding devices (such as cochlear implants), assistive listening devices, and management of room acoustics and noise sources. The intervention and combination of devices used is dependent on the degree and configuration of the hearing loss and the age of the patient.

### Effects on Development

Children are particularly susceptible to the life-long detrimental effects of hearing loss. In hearing families and communities, spoken language is the basis of communication. Oral languages rely on the use of complex systems of sound organization for the purpose of encoding meaning. It is the mode by which children in hearing communities are taught by their elders about the world around them and learn about the intricacies of social interactions and relationships within society. When a child has restricted access to the speech sounds at the base of the language, incomplete development of language may result and limit the child's cognitive development.[3,4]

The critical language learning period of the young brain is finite. Early access to auditory stimuli is necessary for the development of the cortical areas governing fundamental auditory processing skills.[3] The brain is most plastic within the first few years of life. After 4 years of age, elimination of extraneous neurons from receptive sensory areas begins. After 7 years of age, the P1 cortical auditory evoked potentials (associated with auditory cortical maturation) no longer achieves normal levels despite introduction of auditory stimulation in congenitally deaf children. Early identification and intervention are crucial in ensuring that adequate acoustic stimulation is received to maximize the developmental potential of the brain.

## SPEECH AND LANGUAGE ACCESS

Adequate hearing sensitivity, in at least one ear, is essential to maintain access to the spectral and temporal fluctuations of speech over distance for normal development of oral language. The loudness of conversation level speech at one meter's distance naturally fluctuates between 55 and 65 dB HL. For every doubling of distance, the loudness decreases by 6 dB. For every halving of distance, the volume increases by 6 dB. A young infant, cradled in a parent's arms, receives the parent's "conversation level" speech at levels fluctuating between 67 and 77 dB HL. For infants with no worse than moderate hearing loss, these levels provide at least some access to the components of speech needed for the initial stages of cortical development. As infants grow, however, their position in relation to their caregivers quickly begins to change. By 1 month of age, they are increasingly placed in portable car seats or baby carriers. By 3 months of age, they become heavier and are placed

on play mats or in play pens located >1 m away. Around 8 months of age children may be crawling across the room, and by 1 year of age they may toddle out the door. When hearing loss is present, small changes in distance may drastically affect a child's access to sound. Amplification of sound may be necessary to ensure adequate and stable access at all times. Significantly better language development occurs when amplification is introduced by 6 months of age when chronic hearing loss is present.[4]

## Amplification

A hearing aid is a device that is composed of microphones, a sound processor, an amplifier, and a speaker. It is used to amplify sounds from the environment and deliver the amplified sound to an ear. The amount of amplification at each frequency is dependent on the selected fitting algorithm, the volume level of the incoming sound, and the amount of hearing threshold decrease at each frequency. The goal of the amplification is to improve access to softer levels of auditory information input.

Decision making in the implementation of amplification in young children revolves around the amount and frequency configuration of the hearing loss, hearing levels in the better ear, the structure of the affected ears, and the gross motor skills of the child. There are no age restrictions on how young an infant may be when beginning use of amplification.[5] Ears, however, must be large enough to allow for the introduction of amplified sound. The curvature of the pinna and the size of the external auditory canal rapidly grow over the course of the first few years of life. An ear mold is a soft plastic insert that is formed to fit the child's ear. It serves as an adapter piece to route amplified sound into the ear canal. The mechanical components of the hearing aid are housed in a small device that sits over the top and behind the ear. An acoustic seal must be maintained to prevent the amplified sound from being detected and reamplified by the microphones of the system. As the child grows, new ear molds are created. The use of ear molds and behind-the-ear style amplification allows for continued access to sound without the need for sending the hearing aid in to the manufacturer repeatedly for re-casing as the ear grows.

In cases where the size of the ear may prevent the use of an ear mold for an extended period of time, and the hearing loss is primarily conductive in nature, a bone-conduction hearing aid may be employed to provide sound directly to the patient's cochleae. A bone conduction hearing aid transmits amplified sound through an oscillator. The device is coupled to the patient's head by snapping it onto a headband or by snapping the device onto a transcutaneous metal post that has been surgically implanted in the patient's skull.

Gross motor development may influence the age of introduction to amplification and the use of monaural amplification that alternates between the ears. Small hands like to grasp, and mouths are the most common portal of exploration. It is frequently easier to introduce amplification as a part of the body prior to the development of aimed intent. Amplification may therefore be provided before neck control is adequate to maintain the head in a position that does not distort the external ear and break the acoustic seal with the ear mold. Hearing aids may be used on one ear alone and alternated between the ears depending on the head position at any given time to ensure that each side experiences stimulation.

The goal of intervention is to maximize the amount of information the auditory pathways are capable of transmitting with the purpose of improving expressive and receptive speech and language. A child needs only one hearing ear in order to learn oral language. In cases of asymmetric hearing loss, amplification may be recommended for the ear with better speech recognition capacity. Amplification of a significantly poorer side can adversely affect the better hearing ear. Children are frequently unable to adjust their positioning within an environment and young children are frequently unable to competently determine when or if amplification may provide any benefit. Amplification of a significantly poorer ear can adversely affect performance in noise and interfere with localization ability.[2,6,7]

Amplification devices do not correct the underlying anatomical weaknesses that cause hearing loss. Alterations in structural orientation or physical characteristics within the ear and cochlea result in the loss of frequency tuning specificity and spectral smearing.[1] Loss of inner hair cells may prevent transmission of the signal to the nerve or result in only partial transmission to the nerve. In cases of neural agenesis, the nerve may not be present or sufficient to transmit complex spectral and timing information to the brain.

## Cochlear and Brainstem Implants

Cochlear and brainstem implants provide an option for encoding sound into controlled electrical signals. These devices employ an external sound processor that uses microphones to receive sounds from the environments.

Sounds are then analyzed and encoded based on spectral and timing information. The code is sent through a headpiece to a surgically implanted internal device. The receiver stimulator of the internal component generates controlled electrical impulses that are transmitted along an electrode array to stimulate neural components within the auditory system. This provides a method of enabling highly impaired systems to have access to sound.

Functional outcomes (or word understanding ability) of implantation cannot be guaranteed and the reduced redundancy of spectral information provided by these devices may not be sufficient to provide normal language acquisition without extensive therapy and support services. Implants are reserved for patients with such severe hearing deficits that either technological restrictions prevent adequate stimulation through acoustic amplification or the level of cellular dysfunction severely limits transmission of acoustically presented information in the better ear.

### Limits of Sound Processors (CI and HA)

The complex array of tuning characteristics in the ear allow the cochlea to encode frequency, intensity, and timing characteristics of an incoming signal with a degree of precision we are as of yet unable to replicate. Hearing aids and implant sound processors are restricted by the limitations of their components. Due to standing sound pressure vibrations/fluctuations in the environment, there is an intensity level below which the vibrations on the microphone diaphragm are not amplified. Signal processing within these devices is reliant on pattern recognizers that selectively amplify or encode fluctuating sounds and suppress steady-state, nonfluctuating sounds. Pattern recognizers are unable to determine which fluctuating sounds and/or which person speaking is important in relation to other sounds in the environment. All fluctuating sounds in the environment are therefore amplified.

## HEARING IN DIFFICULT LISTENING SITUATIONS—THE CLASSROOM

Even hearing aids and cochlear implants that are functioning optimally provide reduced benefit in difficult listening situations. Such situations are those where background noise, reverberation, and/or distance from the sound source are involved. The most typical difficult listening environment for children with hearing loss is the classroom. From preschool through higher education individuals with hearing loss encounter classrooms that are far from ideal listening environments.[8]

Classrooms are difficult listening environments for children with hearing loss, because most are large spaces with many hard, acoustically reflective surfaces. Classrooms also have both internal and external sources of noise that compete with the desired signal. Internal noise sources in classrooms include heating and cooling systems, computers and other equipment, as well as staff and students. External noise sources vary with classroom location but may include human and vehicle traffic going past the room and sound from abutting rooms that carries through walls and ductwork. When audiologists describe a listening situation, they use the term "signal-to-noise ratio" (S/N) to indicate how quiet or noisy the situation is. If the desired signal is louder than the noise/interference, then the S/N is positive by the number of decibels the signal intensity exceeds that of the noise. Conversely, if the noise is more intense than the desired signal, the S/N is negative by the number of decibels the noise exceeds that of the signal. Studies have shown that the poorest, most negative S/N are found in classrooms with the youngest students.[9] People with normal hearing can understand speech in a classroom with a S/N of –6 dB, where the noise is 6 dB more intense than the speech. People with hearing loss typically require an S/N of +12 to +20 dB to understand, and people with normal hearing do at an S/N of 0 dB.[10] Typical classrooms in the United States have been found to have S/N ranging from –6 to 0 dB. These S/N jeopardize the ability of children with hearing loss to access the school curriculum completely.[8]

### Noise Management in Classrooms

Although hearing aids and cochlear implants make many sounds audible for children with hearing loss, they do little, if anything, to improve S/N.[11] To ensure good access to speech in classrooms professionals need to evaluate each classroom for noise levels, ease of listening, and teacher's habitual location during instruction. If a classroom is found to be acoustically poor, there are several options for improving its acoustics. One option is making nonelectronic changes, including putting rubber covers on desk and chair legs, adding carpets and drapes, and installing acoustic panels on the classroom walls. If such changes do not result in an adequate acoustic environment, use of specialized equipment may be needed.[12] The most likely equipment for this purpose in schools is some version of an FM system (Figs. 16.1A to C). When using an FM system,

**Figs. 16.1A to C:** An FM system with a "boot" receiver attached to a hearing aid (A) and an independent ear level receiver (B). The microphone and transmitter are worn by the teacher and may be clipped to clothing (C) or worn as a headset. Room and desktop style speakers are also available.

teachers wear a microphone/transmitter that sends the teacher's voice directly to a receiver. The receiver may be in a set of loudspeakers in the classroom, a personal receiver attached to a hearing aid or cochlear implant, or a receiver integrated into a hearing aid or cochlear implant processor. FM systems using speakers can result in S/N of up to +12 dB if installed and used properly.[11] Personal FM systems can do even better, yielding S/N of between +20 and +25 dB.[11] FM systems can transmit their signals over a variety of available channels to avoid having signals bleed through walls to neighboring classrooms.[13] Many school districts have a contract with a manufacturer to provide FM equipment for any students who need the technology to hear their best in the classroom.

An alternative technology for improving S/N in classrooms is called a "loop system". In loop systems wiring is installed, typically either under carpeting or around the perimeter of the room near the ceiling. Speech from the teachers' microphones is converted to an electromagnetic signal transmitted through the room wiring. Students then typically pick up the electromagnetic signal using telecoils incorporated in their hearing aids or cochlear implants. A limitation of loop systems can be variable signal strength depending on location and orientation of the students' telecoils with respect to the room wiring.

Given the level of general use of technology in today's classrooms, children with hearing aids and/or cochlear implants often need hardware for auditory access to

computers and other equipment. A variety of cables and specialized hardware are available for connecting to a wide range of electronic devices. Audiologists can help to identify hardware that may be helpful for students with hearing loss.

## Additional Factors in the Classroom

Access to appropriate education and the full range of classroom activities for children with hearing loss can be affected by many other factors in addition to classroom acoustics. These include teaching style (traditional, learning groups, etc.), room setup, language skills of the children, availability of a skilled interpreter for students who communicate using sign language, and availability of real time captioning and/or note-takers in secondary education, among others.[14] In their coursework general educators typically receive little information on meeting the needs of students with hearing loss. That makes it important for some professional to be responsible for evaluating classroom, teacher, and student characteristics prior to placement of children with hearing loss in any educational setting. This professional will most likely be an audiologist or a teacher of the deaf/hard of hearing.

In most parts of the United States, there are regional education agencies that provide specialty services such as audiology. In those parts of the country all schools have access to audiologists who provide all of the services mentioned above. In other states, although there are no regional educational agencies, many school districts employ audiologists who can provide such services. In still other states, there are few audiologists employed in schools, and there is no regional structure, so it is more difficult to locate an appropriate professional to evaluate the classroom, teacher, and student to ensure good access to the curriculum.

The goal of evaluating child, teacher, and classroom characteristics for each child with a hearing loss being served by schools is an important one. Hearing loss varies widely in type and degree, and there can be no "one size fits all" approach to classroom management for children with hearing loss. In general it is good to provide all of the intervention needed for each child but no more than is needed for the child to achieve success in school. This means that some children with hearing loss will require only an evaluation of characteristics and needs and preferential seating close to the teacher's location while instructing the class. By the third grade most students with hearing loss can identify the best location in a classroom for hearing and understanding. Some students with hearing loss will need some level of technology and/or supplemental services. Still others may be best served in a specialized educational placement more separate from the general education classroom. Many students with hearing loss will benefit from personnel who can support their social development as well.[15] Finding the right level of support for children with hearing loss is best accomplished by a team of professionals that includes teachers, including teachers of the deaf/hard of hearing, audiologists, psychologists, and speech-language pathologists.[16]

## Role of the Speech-Language Pathologist

While availability of audiologists in the schools varies greatly across the country, almost all schools employ speech-language pathologists. These professionals play an important role in schools for children with hearing loss. Speech-language pathologists evaluate children's communication skills, including both language and speech; they are aware of the effect of teaching style and the importance of multimodality teaching for students with hearing loss; they understand the effects of a poor acoustic environment on learning; and they may have some familiarity with FM systems. Speech-language pathologists can provide vital preteaching of vocabulary that is unfamiliar to children with hearing loss. Then they can supplement classroom content by giving children with hearing loss more chance to use new vocabulary and concepts, and they can post-teach any crucial concepts the children may have missed during the units. Children with hearing loss are also served well by having an adult mentor in school, and in many cases, speech-language pathologists are a good choice for this role.[16] They or school nurses are good choices for the person who keeps spare batteries for younger children using hearing aids in school. Additionally, speech-language pathologists, school counselors, and school social workers can all help with the social aspects in schools. Additionally, children with hearing loss may need support in making friends in the school setting and in meeting other children with hearing loss, and speech-language pathologists, school counselors, and school social workers can all help with the social aspects of the educational setting.

## SUMMARY

Serving the hearing and educational needs of children with hearing loss depends on early appropriate amplification or implantation and communication intervention. This needs to be followed by good access to school curriculum. Such access requires individual evaluation of the needs of the children and characteristics of the classrooms and teachers to ensure that hearing loss is not a barrier to full preparation for a successful adult life.

CHAPTER

# Multidisciplinary Evaluation of the Pediatric Cochlear Implant Candidate

17

***Margaret Winter***

Cochlear implantation has without question positively impacted the lives of many deaf persons, often providing the only avenue through which spoken language can be used and understood. The majority of adult implant users have communicated through spoken language most of their lives, having had either normal hearing at some point or hearing loss that could be reasonably well addressed through use of conventional amplification. For them, cochlear implants provide better access to sound such that they can continue to communicate, now more easily, as they always have. For older children and teenagers who already communicate through listening and speaking, candidacy criteria and benefits of the device are much the same as for adults. For very young children, however, the implant is the tool through which they learn to listen, to discriminate speech sounds, to understand words and sentences, and to develop spoken language. There is a narrow time window of opportunity in which optimal success is likely to be achieved, and multiple other factors impact a young child's ability to be successful as well. It is unfortunately the case that not all deaf children are candidates for cochlear implantation, and not all deaf children are good candidates where the goal is the development of spoken language. It is essential to keep in mind that the main aim of all those who work with deaf and hard of hearing children should be development of effective communication skills through which a child will succeed socially and educationally. Therefore, careful consideration of the most effective means of communication is an essential element of a candidacy evaluation of a prelingually deaf child.

## THE COCHLEAR IMPLANT TEAM

Pediatric candidacy is best evaluated by a team of professionals who can consider multiple aspects of a child's development and potential to benefit from the device. At a minimum, most teams consist of the surgeon, audiologist, and speech-language pathologist. Additional professionals who contribute greatly to candidacy decisions include a psychologist, social worker, and educators. The psychologist and social worker may be part of an in-house team, or they may be called upon to consult where concerns about a child's cognition or behavior exist or where families may need assistance with practical issues such as applications for social supports, transportation, food, and lodging. An educator may also be part of the in-house team, and the child's teachers and other educational and therapy personnel should always be included in the candidacy evaluation, since even with multiple office appointments the in-house team may not have a clear picture of a child's function in school, parent compliance, consistency of device use, and other factors that teachers will have observed on a regular basis.

In some programs or in some circumstances (e.g. abnormal cochlear anatomy), the surgeon chooses the device. In others, the family makes the selection. Where the child is a determined to be a candidate for a cochlear implant in either ear, the team together with parents will determine whether one or both ears should be implanted. The surgeon or parents may have a preference regarding simultaneous or sequential bilateral implantation.

The surgeon may be the first professional to see a potential candidate, or the child may be referred to the surgeon by the audiologist who has already demonstrated that the child has a qualifying hearing loss and cannot derive sufficient benefit from amplification to develop or maintain development of auditory skills. The surgeon will provide the otologic evaluation and order and interpret imaging. The surgeon may determine that the child is not a candidate medically, in which case the evaluation need not proceed except for parent counseling. If the child is a candidate medically, the surgeon is urged not to make an immediate determination of candidacy without input from all members of the team, since so many factors figure into success with cochlear implantation. The surgeon should provide information regarding risks of the procedure, assume ultimate responsibility for confirming that appropriate vaccinations have been received, and provide reassurance to families fearful of surgery. The surgeon can also be very helpful in explaining or clarifying realistic expectations and emphasizing the importance of parents' role in the habilitation process postimplant. The surgeon should communicate with the programming audiologist immediately after surgery if there were irregularities in the procedure, such as a partial insertion of the electrode array, that may affect the way the audiologist is able to program the device.

The audiologist is responsible for determining the child's unaided hearing loss and benefit from hearing aids. Ideally, children tested at birth under newborn hearing screening programs will have received amplification and early intervention within the first few months of life and their benefit and progress with amplification will be continually tracked before they are candidates for implantation. Unfortunately, not all children presenting as potential cochlear implant candidates have had the benefit of early identification or timely referral to the implant center. Audiologic assessments of pediatric cochlear implant candidates will depend on the child's age, development, and listening experience.

A test battery approach is essential to the most complete understanding of a young infant's hearing abilities. Auditory brainstem response (ABR) and otoacoustic emissions (OAE) testing are the most useful tools for a baby who cannot yet participate in behavioral threshold testing procedures. As the primary measures, they enable the audiologist to identify the type and degree of hearing loss and to make a close estimate of hearing thresholds across the speech frequency spectrum, sufficient to select and fit appropriate amplification. Because these tests are measures of physiologic functions of the auditory system but are not hearing tests per se, it is wise for audiologists also to observe the infant's responses using behavioral observation audiometry (BOA). While not a threshold procedure, BOA allows the child's responses to calibrated sounds to be observed, and responses should make sense with ABR and OAE results. If, for instance, a child startles to loud sound or clearly responds repeatedly to voice or other calibrated stimuli despite an absent ABR response, results of the ABR should be reevaluated.

ABR, OAE, and acoustic reflex measurements in combination are the most sensitive indicators of auditory neuropathy spectrum disorder (ANSD). In ANSD[1] children have normal outer hair cell function, so OAEs are typically present but the children have abnormal hearing nerve function resulting in absent ABRs and absent acoustic reflexes. The exact nature of the disorder is not yet clearly understood. Research indicates that abnormal function of the inner hair cells or dyssynchrony in the firing of the auditory nerve may be responsible. Risk factors include a history of high bilirubin treated by blood transfusion and certain genetic conditions.[2,3] ABR thresholds in ANSD are not necessarily reflective of a child's ability to respond to sound, and often behavioral testing reveals audiometric findings significantly different from what the ABR suggested. Present OAEs usually are consistent with, at most, mild hearing loss, but in ANSD the actual hearing handicap can range from mild to profound even when OAEs are present and robust.

Visual reinforcement audiometry (VRA) is used for behavioral audiologic assessment of older infants and toddlers who are able to sit unsupported and turn toward the source of a stimulus. VRA yields pure tone thresholds to unmasked air and bone conduction stimuli and speech awareness thresholds to voice. As such, it provides more complete information than ABR, but ABR can and should be used to confirm behavioral thresholds where there is any question of reliability.

Between ages 2 and 3 years, typically developing children can learn to perform conditioned play audiometry (CPA). CPA requires the child to wait for a stimulus, then perform a task such as dropping a block into a container or putting a peg into a pegboard as soon as he or she hears the sound. He or she can be taught to ignore masking noise so that an asymmetrical loss can be accurately measured through masked air and bone conduction tests. At this stage, a child who uses spoken language can repeat words

or point to pictures on demand so that a speech reception threshold and a speech discrimination score can be obtained.

Children with developmental delays should be assessed using procedures appropriate for their developmental age rather than their chronological age. The ability of a child to perform some type of conditioned response assists the audiologist in fine-tuning amplification and will be extremely helpful in programming the cochlear implant speech processor if the child receives an implant. If a child is unable to perform any type of conditioned response, challenges in programming will be greater.

A hearing aid trial of 3–6 months, combined with appropriate therapeutic intervention, is generally required unless the child is at risk for cochlear ossification, in which case the hearing aid requirement is waived. The audiologist will assess the appropriateness of the hearing aid fitting through both real-ear and behavioral threshold measures and will assess benefit of amplification through speech perception measures in the auditory-only condition. If hearing aids are not adequately addressing the hearing loss, a trial of more effective amplification may be necessary. For children with ANSD, speech perception measures are especially important, since aided detection thresholds may be deceptive in reflecting the true benefit of amplification.

For young infants who have not yet developed speech, speech perception is usually assessed using parent report scales. Numerous standardized speech perception measures can be used with older children across the age-range who are developmentally able to point to pictures or repeat words or sentences. Tests range in complexity from assessments of pattern perception to comprehension and recall of short passages delivered in the presence of background noise or competing speech.

The speech pathologist assesses the child's overall communication ability, including receptive and expressive language and fundamental speech skills. There are two main goals of the evaluation: to determine whether hearing loss is a factor in any speech or language delay, therefore suggesting stronger likelihood that a cochlear implant would be a benefit, and to establish baseline performance that will guide postimplant therapy and serve as a marker for future progress. As with speech perception testing, the assessments may consist of parent-report instruments or standardized tests requiring the child to point to pictures, respond to instructions, or demonstrate spontaneous language.

With very young children, the speech language pathologist's direct interaction with the child establishes the child's communicative intent, which may be linguistic (words or signs) or prelinguistic (gestures, vocalizations, eye contact). It is important to assess not only the child's auditory-oral skills, if they exist, but also his or her skills in whatever communication mode he or she may be using, such as sign. The evaluation would not be reflective of a deaf child's communication ability if he or she is fluent in sign but is assessed only in terms of his or her oral language facility. Similarly, the speech pathologist should take into account language models in the home; children whose home language is different from his or her instructional language may be fully bilingual, partially bilingual, or may be delayed in both languages such that neither provides a completely effective communication strategy. For comprehensive coverage of the speech language pathologist's role in the evaluation process, see Ambrose et al. (2009).[4]

There is necessarily some overlap in speech perception testing and speech language evaluation for older children, because some aspects of speech perception testing depend upon the child's vocabulary and oral language development. But results of the combination of the two types of assessments can contribute to a greater understanding of a child's skill and potential to benefit from implantation. Speech perception testing is performed in the auditory-only condition, whereas speech language evaluation involves face-to-face communication. A child may have good ability to repeat single words and even sentences but test poorly on overall language measures such as oral expression, grammar, and semantics. Or the child may score well on speech language measures because he or she has made exceptionally good use of even minimal residual hearing but score poorly on speech perception measures where visual cues are not available. It is essential that the testing protocols are truly evaluating a child's abilities, not just pointing to what a child cannot do. Even carefully selected, age-appropriate tests may not achieve this goal if individual differences are not considered. For testing of a child with a developmental delay, measures must be based on their developmental age rather than their chronological age. If a child is unable or unwilling to perform a required task on the most basic of tests, the result should be documented as such, but the clinician can and should probe further to determine what the child actually can do, perhaps with suggestions from parents. Informal assessment can be extremely valuable in determining how stimulable a child may be for development of speech, language, listening, and learning.

An in-house educator or educational counselor can help parents to better understand the individual family service plan (IFSP) and individual education program (IEP) processes, whereby children with hearing loss can access educational services appropriate to their specific needs. A majority of children who receive cochlear implants will require special education, itinerant deaf and hard of hearing assistance, accommodations in the general education classroom, or a combination of these. Families unfamiliar with the IFSP and IEP processes may not yet know how services are established or how they may request them for their children, or that they themselves are indeed an integral part of the IFSP or IEP team.

Inclusion of the child's teachers and speech language or auditory therapists in the candidacy evaluation process helps the in-house team to acquire information about the child's current learning environment and services as well as the options available should the child receive a cochlear implant. A self-contained class for 2-year-olds where American Sign Language is the exclusive mode of communication may be appropriate for the child prior to implantation but will be inadequate after implantation, even if the family goal is to maintain sign skills as well as develop oral language skills. Where a child is in transition between early start services and center-based services, it is important for the implant team to communicate with educational personnel about the intent to provide a cochlear implant so they can make suitable choices for placement.

The psychologist may play a broad role on the implant team, performing cognitive and psychosocial assessments with the pediatric candidate, identifying behaviors of concern, and counseling families with regard to their questions, concerns, and expectations. An interview with parents helps to document parental understanding of their child's hearing loss and the cochlear implant process. Parents and grandparents and in some cases the candidate may be at odds with each other over a variety of issues, including acceptance of the hearing loss, custody issues, fears of surgery, and philosophical differences regarding implantation of young children who cannot yet consent to the procedure. The psychologist can help clarify these issues and present strategies for cooperative decision making, thereby laying a firmer groundwork for success whether or not the child receives cochlear implants.

Direct contact with the child helps the psychologist gain an understanding of the child's general developmental level, communication skills or communicative intent, and interaction with parents. Standardized measures of intelligence can document performance on specific tasks and compare skill levels with those of typically hearing children of the same age, although care should be taken to consider the demands made by the particular tasks on the deaf child's language and auditory skills.

The combination of all assessments enables the cochlear implant team to determine the likely degree to which hearing loss has impacted the child's ability to develop listening, language, and speech production skills and to make informed judgments as to the potential benefits of implantation. A child who has reasonably good access to the speech spectrum with hearing aids but who has developed minimal oral language skills may not be receiving adequate support at home, may be in an inappropriate educational placement, may lack access to effective auditory/oral therapy services, or may for reasons unknown be unable to decode the information from amplification. Any or all of these factors may impact success with a cochlear implant. Conversely a child who has minimal access to auditory information and who has nonetheless developed spoken language skills may reasonably be expected to make good use of information from an implant. Results of the team evaluations inform candidacy decisions and may influence the kinds of supports that need to be put in place to maximize benefit from implantation.

Finally, it is important to note that although they do not perform formal assessments, parents are an integral part of the cochlear implant team. Parental observation of their children's developing communication skills, understanding of successful intervention strategies they can practice at home, and their awareness of likely outcomes with implantation are critical to their child's success. Parents invariably want the best for their child but may not always have the knowledge necessary to provide good language and literacy models at home and advocate for appropriate services at school. The potential of parents as effective teachers can be an important consideration in determining a child's candidacy. The professional members of the implant team can be instrumental in helping parents recognize their value as the most important controllable factor in their children's success.

## CANDIDACY CRITERIA

It is safe to say that the goal of the majority of parents seeking cochlear implantation for their children is the development of functional oral language skills. In some

cases, parents understand that their particular child may be unlikely to learn to listen and speak but wish to proceed with cochlear implantation for whatever other benefits it may provide. Often, these families still remain hopeful that despite poor odds their child may be the exception and will learn to speak. Candidacy decisions depend in part on the goals and expectations of the parents and the criteria set by a specific program. In some cases, a child may not be considered as a candidate in one program but will be a candidate in another. Careful counseling is essential so that parents will understand whether or not their child is a candidate in that particular program, or is not medically a candidate and it could be unwise or dangerous to seek implantation at another center. For families whose children are not candidates, further counseling is imperative to help them pursue other appropriate services or devices that will assist them to develop their most functional communication skills.

Although there are specific, Food and Drug Administration (FDA)-approved criteria for cochlear implantation in young children, over the 25 or so years multichannel cochlear implants have been approved for children the now-conventional applications have outpaced these official criteria. For example, the FDA lists the minimum age for implantation as 12 months, but many clinics in the United States and abroad routinely implant children at significantly younger ages. There is no specific FDA endorsement of bilateral cochlear implantation, but it is now the standard of care for appropriate candidates. Officially, the qualifying degree of hearing loss recognized by the FDA is bilaterally severe to profound, but especially now that bilateral implantation is so common, it has become common as well to provide a cochlear implant for an ear with severe hearing loss where the opposite ear has sufficient residual hearing to continue to benefit from a hearing aid. Technological advances in electrode design and surgical technique are making it possible for successful preservation of low frequency hearing, and new sound processor circuitry combines both acoustic amplification and electrical stimulation to accommodate both aidable residual hearing and absence thereof. It is, then, most common for cochlear implant programs to consider basic criteria through the lens of research findings as well as their own clinical experience.

## Age Considerations

It is well documented that where the goal of implantation is the development of spoken language skills, the best candidates are very young children with minimal length of auditory deprivation,[5] or children who have been successful in developing at least some oral language skills through the use of amplification.[6]

Early identified, early implanted children have been shown to develop speech and language similar to that of children with normal hearing.[7] Though by no means a guarantee of success, these two factors are important predictors of optimal outcomes. Numerous studies have shown that auditory plasticity in children is at its peak only through the infant and toddler years, after which the brain's ability to make the most effective use of new auditory information is significantly reduced.[8] It is generally considered that in good candidates, a reasonable goal for auditory/oral skill development is parallel progress with typically hearing children; that is, children with cochlear implants may be expected to achieve a year's growth in a year's time. In early identified, early implanted children, the age-language gap is minimal, auditory plasticity is at its peak, and age-appropriate oral language milestones may be attained. By contrast, a child who has access to sound for the first time through a cochlear implant at age 5 is 5 years behind in auditory/oral development, and may remain so even with excellent auditory benefit from the implant. An age-language gap of 5 years by age 5 is significant, as the child enters school; the same age-language gap of 5 years by age 11 results in that child's inability to access age-appropriate educational information if he or she has not also developed language through other modalities.

This is not to say that school-age children cannot be good cochlear implant candidates. Children who have had sufficient residual hearing to derive significant, if inadequate, benefit from hearing aids and who have developed spoken language as a functional mode of communication can do well with cochlear implants at any age. Children who demonstrate progression of hearing loss are best implanted before their language development begins to slow and their speech production is affected. Children with sudden loss of hearing are usually excellent candidates.[9] Where a child is old enough to understand the procedures, he or she must be given a voice in the decision making, since children who are not in agreement to proceed with implantation can and will refuse to wear the device. It can be extremely helpful to provide fearful children with contact information for others their age who have had successful experience with their implants. In many cases, children who are initially

reluctant to go forward become enthusiastic about the process once they have been reassured by peers in their same situation.

Children of school age who have minimal auditory experience and have not yet developed spoken language skills may receive more limited benefit from cochlear implantation. There are certainly exceptions, and a benefit of the team approach to assessing candidacy is that each child is considered from multiple perspectives. Important questions to be addressed include whether the child has fully developed communication through another modality such as sign language, through which he or she has been able to achieve educationally. In many hearing families, parents have not learned to sign fluently themselves, thus limiting the ability of their child to engage fully in conversational exchanges at home. These children are not only behind in their oral language experience but there is a significant age-language gap in sign skills as well, which impacts reading, writing, and other academic achievement. Fully developed sign skills may provide a good bridge to learning oral language skills; severely delayed sign skills may not, and the therapy efforts necessary to maximize benefit from a cochlear implant may take away from time more productively spent speeding sign language development. In some cases, parents who are disappointed when their children are not able to learn to listen and speak blame the child because parents lack understanding of complexities of oral language development under these circumstances. This does not mean that school-age children with little auditory experience should never receive cochlear implants. It means that an implant should not be provided without extensive family counseling that stresses a full understanding of the importance of language development and of the reduced likelihood that oral language will become the child's primary communication mode. The exclusive focus for such children should not be auditory/oral therapy. It may well be possible for a late-implanted child with no previous auditory experience to develop functional spoken language skills; it is more likely that with appropriate supports implanted children from this population will always rely mainly on visual language but may also benefit from the auditory information they receive from the implant in terms of sound awareness, speech-reading, and even closed-set speech perception. Without appropriate supports and without full parental understanding of appropriate expectations, children from this population may eventually become nonusers and may be no better off in terms of communication skills than they were before implantation.

Consideration of implantation of children with developmental delays should follow the same guidelines as with older, nonverbal children. While there may indeed be benefits to children with cognitive delays or behavioral disorders, careful assessment of the child's current communication strategies and extensive counseling regarding expectations are essential. Children with developmental delays may derive speech perception benefit from cochlear implantation or may benefit in ways not specifically linguistic, such as improved attention or a general sense of connection to the environment. Benefit from cochlear implantation depends on the type and severity of the developmental delay. The stronger possibility that oral language as a primary or even functional communication mode may not be a realistic goal should be part of the discussion with parents.

While it is not clear why cochlear implants are effective for children with what appears to be a dyssynchrony disorder, a considerable body of literature documents the benefits of cochlear implantation for at least some children with ANSD.[10] Success may depend in part upon coexisting conditions that are more common in children with ANSD than in the general population as well as on the type of auditory neuropathy. When ANSD is a result of cochlear nerve deficiency, outcomes may be poor and preoperative imaging may be critical to predicting reasonable benefit. As is the case for children with the much more common cochlear deafness, children with ANSD who are found to be cochlear implant candidates are best implanted as soon as it can be documented that progress with hearing aids is insufficient or has plateaued or declined, and the same educational and therapeutic supports must be in place for optimal progress to occur.

## Degree of Hearing Loss and Benefit from Amplification

In common practice one of the biggest changes in candidacy criteria is in the degree of qualifying hearing loss. Whereas in 1990, only children with bilateral profound loss and little to no benefit from hearing aids could receive a cochlear implant, it is common now to see implantation of children with much more residual hearing.[11] Qualifying hearing loss may include severe to profound loss in at least the high frequencies (with perhaps even moderate loss in the lows), even when hearing loss in the opposite ear is better and receives good benefit from amplification. For very young children in whom oral language progress cannot yet be measured, more reliance may be placed on hearing threshold levels with appropriately fit

amplification. If aided thresholds in the ear under consideration are outside the long-term average speech spectrum, an implant may be considered with the reasonable expectation that detection levels with the implant will be significantly improved, and, with auditory therapy from an experienced provider, speech and oral language skills will improve significantly as well. For older children with measurable speech perception, clinics may not have a fixed score criterion; rather, the speech perception scores may be one aspect of the determination of how well the child is able to use his or her residual hearing. In school and in social situations, some potential candidates may be seen to do surprisingly well in spite of the severity of their hearing loss; in reality, these children may be working extraordinarily hard to do as well as they do and would be greatly helped by better access to speech information.

## Other Considerations

Care should be taken not to adhere so closely to a set of candidacy criteria that extenuating circumstances are not considered. A child who has poor speech and oral language development and little to no sign skill might, at age 8, not be considered a cochlear implant candidate in some programs. If a diagnosis of Usher syndrome is made; however, the picture changes in that as the child loses his vision he will be unable to use visual forms of language. Provision of cochlear implants and intensive auditory therapy may yet be this child's best avenue for communication. A 17-year-old prelingually deaf young person with minimal benefit from hearing aids, who will not have the option under her current medical coverage to pursue cochlear implantation after age 18, might be considered for a cochlear implant for reasons other than development of spoken language as a primary communication mode. If she is about to complete school and has developed language through another modality, she will not be adversely affected educationally as she learns to make the most of the information the implant provides, even if it is limited. A center's established candidacy criteria should serve as a flexible framework through which decisions are made that lead to best enhancement of communication skills.

## Bilateral Cochlear Implantation

Research and clinical experience support benefits of bilateral implantation, which include improvements in a child's ability to localize and to understand speech in noisy environments.[12,13] As noted above, children who receive simultaneous bilateral cochlear implants are more likely to develop approximately equal skills with each implant than children who receives implants years apart. There are numerous good reasons for beginning with one ear and implanting the second ear at a later date, but the longer the interval between surgeries the less likely skills will be equal between the two ears. While it may seem logical to both implant users and their parents that success with the first implant will automatically lead to success with a second, this often proves not to be the case. Factors that influence success with a second implant include, in addition to length of time between surgeries, the history of hearing aid use and benefit on the second ear, and the speech/language benefit with the first device.

In cases of unilateral implantation, most programs strongly recommend their recipients continue to use amplification on the opposite ear for whatever benefit it may provide. Where there is little residual hearing, children eventually may chose to stop wearing the hearing aid. Thousands of children received only one implant in the 1990s, and many of them are now expressing interest in a second device. Extensive counseling is necessary to help them understand possible and likely outcomes, which can include improved detection without discrimination ability, closed set discrimination only, or open set discrimination approximating the ability of the opposite ear. Consistent use of, and benefit from, amplification contributes strongly to the development of auditory skills after receipt of an implant in the second ear.

## Auditory Brainstem Implants

A relatively small number of deaf children are born without auditory nerves or cochleae. In some cases, an auditory nerve appears to be present, if not normal, on imaging but cochlear implants provide minimal to no benefit. Until recently, there were no options for providing functional auditory stimulation to these children.

The auditory brainstem implant (ABI) was developed for use by teens and adults with neurofibromatosis type 2 (NF2), who have had bilateral acoustic neuromas removed. The surgery usually renders them unable to use cochlear implants. The ABI consists of an electrode array on a small paddle that is surgically placed over the cochlear nucleus in the brainstem.[14] At this time, the ABI is approved by the USFDA only for NF2 patients, but prelingually deaf children have been implanted at centers outside the United States.[15,16] Studies show that some of these children develop auditory and speech perception skills that fall

in the lower range of performance scores achieved by children with cochlear implants.[17,18] Test results using the Categories of Auditory Performance inventory with children implanted by Vittorio Colletti in Verona, Italy, indicate that the best outcomes are seen in children who have normal cognition, compared with children with multiple disabilities that include cognitive delay.[19]

The FDA has recently granted several cochlear implant programs in the United States permission to conduct clinical trials of the safety and efficacy of auditory brainstem implantation of prelingually deaf children. The general criteria for ABIs in this population include severe hypoplasia of the cochleae, agenesis of the auditory nerves, and severe cochlear nerve deficiency.

## AFTER IMPLANTATION

Although it is the audiologist who programs the cochlear implant processor after implant surgery, the job of the team as a whole is not over. Programming cannot be effectively performed in a vacuum; the audiologist depends on information from the child's family, therapists and teachers to know if programming is effective or if there are indications that changes should be made. The appropriateness of the child's educational program and auditory therapy are crucial to maximizing success. Postimplant assessments beginning with the same measures performed preoperatively, graduating to more complex measures as the child progresses, help to guide interventions in therapy and education. Where the child is making month for month progress, the outlook is excellent and parents and providers of service can be assured that strategies being employed are effective. Where the age-language gap is widening, results of assessments enable the team to know when additional supports, strategic changes, or new communication modes should be explored. The child's success in communication and academic achievement continues to be a team effort.

# Otitis Media

*David H Chi, Dennis J Kitsko*

## INTRODUCTION

Otitis media (OM) is one of the most common infectious diseases in children, particularly in younger children. Approximately 30–35% of all visits for acute illness in the primary care setting in the first 5 years of life are for middle ear disease. Up to 40% of total office visits at 4–5 years of age will result in the diagnosis of some middle ear problem. This includes approximately 10% of children who present at well-child visits and are without any subjective complaint.[1] Studies have shown that nearly half of all antibiotics prescribed in children < 10 years old were for OM.[2] The financial burden for medical and surgical intervention for OM is estimated at $5 billion yearly in the United States alone.[3] But perhaps the impact on the day-to-day lives of families is far greater than any monetary figure. It can be associated with speech, language, and balance difficulties, which can contribute to further learning problems. The parental burden of dealing with a fussy, irritable child who is sleeping poorly can be very frustrating. Also, parents may be forced to miss multiple days of work as day-care settings frequently will forbid children with high fevers to attend; this is in addition to the time missed from work for physician visits.

For the sake of clarity, the following terms and their definitions will be used in this chapter. "Otitis media" will refer to nonspecific inflammation within the middle ear space. "Acute otitis media (AOM)" will refer to acute infection of fluid within the middle ear space, with associated otalgia and an erythematous or bulging tympanic membrane (TM). "Otitis media with effusion (OME)" will be defined as fluid collection in the middle ear space in the absence of signs of acute infection mentioned above. Finally, "middle ear effusion (MEE)" will refer generally to fluid in the middle ear space, whether this fluid is associated with acute infection or not.

## EPIDEMIOLOGY

### Acute Otitis Media

The vast majority of children will have at least one episode of AOM in childhood. Approximately 62% of infants will have AOM by 12 months of age, with this number rising to 84% at 3 years of age, and 95% by age 7. After age 7, children are much less likely to develop AOM.[1] Many children will have recurrent episodes of AOM as well. Up to 20% of infants will have three episodes by their first birthday, and by age 7, 75% of children will have had at least three episodes.

### Otitis Media with Effusion

Determining the incidence of OME is much more difficult because many children will present without any complaints. Furthermore, many episodes of AOM will "become" OME as ear pain and TM erythema and bulging resolve but MEE remains. Identifying the onset and interval to resolution of OME is challenging, as it requires very short observation intervals. This is particularly true given that approximately 65% of OME episodes will resolve in 1 month.[4] Casselbrant et al. found a 53–61% incidence of OME in 2- to 6-year-old day-care children followed monthly with pneumatic otoscopy and tympanometry.

This number dropped to 22% in 5- to 12-year-old school children.[4,5] Lous and Fiellau-Nikolajsen reported a similar 26% incidence in 7-year-olds that they followed for 1 year.[6]

Multiple studies in various countries have looked at the point prevalence of MEE, which includes both AOM and OME, with a great variety of ranges from 1% to 40%. Given the variability in race, sample sizes, age ranges, number of screenings, and screening tools, it is very difficult to generalize these incidence data in a meaningful way. What is clear, though, is that almost all children develop MEE at some point during the first 3 years of life.[7,8]

## Risk Factors for OM

### *Age*

The highest incidence of AOM occurs between 6 and 11 months of age.[9] The incidence decreases yearly after that with the exception of a small bump at 5–6 years of age, correlating with school entry. It is much less common in children 7 years or older. In school-aged children, obesity has also been shown to be a risk factor for AOM.[10] The risk of persistent effusion after AOM also is greatest in the infant and toddler and decrease with age.[11]

### *Prematurity/Low Birth Weight*

There is controversy as to whether OM is more prevalent in premature infants, with conflicting evidence. Gravel et al.[12] and Alho et al.[13] looked at AOM and MEE, respectively, and found no difference between full-term infants and premature or low birth weight infants. Engel,[14] however, did show a higher prevalence of OME in this high-risk population compared with full-term infants. More recently, Bentdal et al.[15] also found a higher relative risk of AOM in premature infants <33 weeks' gestational age (relative risk of 1.37) than full-term infants. They did not find a corresponding tendency in children with low birth weight.

### *Race*

Native Americans and Alaskan and Canadian Inuits have been shown to have a high incidence of OM, particularly OM with chronic otorrhea and/or perforation.[16–18] This is felt to be due to abnormalities of both the anatomic position of the bony Eustachian tube (ET) as well as poor ET function. Hispanic children may also have an increased incidence of OM compared with Caucasian-American children.[19] Early studies indicated that African-Americans had a lower incidence of OM than Caucasian-Americans, but more recent studies have showed an equal incidence up to age 2.[20,21]

### *Gender*

Multiple studies have shown no gender difference between in OME.[22,23] Gender and AOM, however, is less well defined. Some studies report a higher incidence in males versus females,[11] while others show no gender difference.[19]

### *Genetics/Family History*

Family history is clearly a risk factor for recurrent OM. Twin studies of OM show a heritability of 45–64% in males and 74–79% in females.[24–26] Down syndrome, craniofacial abnormalities, and cleft palate are also risk factors for OM. In fact, almost all children with unrepaired cleft palate under the age of 2 years will have OM.

### *Season*

Both AOM and OME are more common in the fall and winter months, paralleling the increase in upper respiratory infections (URIs). It has been shown both in the laboratory and clinically that viral URI predisposes to ET dysfunction and subsequently to OM.[27,28]

### *Day Care*

Day care is perhaps one of the greatest risk factors for AOM and OME, with an odds ratio of at least two reported in more than one study.[29,30] This is most likely related to the increased risk of URI, particularly in the winter months, associated with close contact with a large number of children. In fact, OM incidence is related not only to day-care attendance, but also to the number of children in the day care, with smaller settings experiencing less OM. Having older siblings is also a risk factor for OM, most likely related to increased URI exposure, as with the day-care setting. In fact, Paradise et al. combined number of older siblings and day-care attendance into a "child exposure index" and found correlation with MEE duration.[21]

### *Smoking/Air Pollution*

Multiple studies have shown an association between passive smoke exposure and increased risk of both recurrent AOM and persistent OME. In fact, one study measuring serum cotinine (a metabolite of nicotine) showed a 38% increase in MEE and prolonged OM in those children with

elevated levels.[31] Residential air pollution has also been shown to be a modest risk factor for OM with a relative risk of 1.1–1.3.[32]

### *Breastfeeding*

Breastfeeding is known to have a protective effect against OM versus bottle feeding. The mechanism is not completely clear, but may be related to the immunologic benefit of breast milk, particularly the immunoglobulin secretory IgA. The ideal duration of breastfeeding is less clear. There is evidence that breastfeeding for 6 months leads to a twofold decrease in the rates of AOM and OME.[33] There is also evidence to suggest that that this provides prolonged protection from OM up to 3 years of age. It is unclear whether breastfeeding well beyond 6 months of age offers additional protection.

### *Pacifier Use*

Pacifier use is also a risk factor for OM, with a 10–15% increase in the number of OM episodes in those children who used pacifiers, depending on age.[34] Counseling parents to limit pacifier use resulted in a 29% decrease in AOM from 7–18 months of age.[35] There is evidence to suggest, however, that pacifier use in children <6 months of age does not increase the risk of OM.[36]

### *Atopy/Allergy*

It has long been thought that there may be a connection between OM and atopy/allergy. Current literature does support a link with OME. Allergic patients have an increased risk of both unilateral and bilateral OME as well as a higher degree of hearing impairment with OME than nonallergic patients.[37–39] Interestingly, however, nasal mucosal swelling (as measured by acoustic rhinometry), nasal eosinophilia, asthma, and eczema have not been correlated with OME.[40]

## ANATOMY AND PATHOPHYSIOLOGY

The anatomic structures involved in regulating the middle ear system include the mastoid cavity, the middle ear cavity, the ET, and the nose/nasopharynx, and palate. The ET is perhaps the most important of these structures, particularly as it relates to the development of AOM and OME. The ET serves three important functions physiologically: (1) pressure regulation/ventilation and equilibration to atmospheric pressure, (2) protection of the middle ear from pathogens ascending from the nasopharynx via a gas cushion, and (3) clearance of secretions from the middle ear. The origin of middle ear disease is poor ET function, and inability to regulate pressure. In infants, the ET is shorter and more horizontal than in an adult, and this is one anatomic factor that leads to poor pressure regulation.

ET dysfunction may occur spontaneously, particularly in infants, but is more commonly associated with antecedent events that cause either anatomic or, more commonly, functional obstruction. Anatomic causes include enlarged adenoids, nasal polyposis, foreign body, or tumor. Functional obstruction is associated with inflammation within the nasal cavity and nasopharynx, most commonly from a viral URI in children. Other causes include allergic rhinitis and gastroesophageal reflux disease (GERD). This inflammation leads to edema around the ET orifice, which is located in the nasopharynx, and subsequent inability of the ET to open in its usual passive fashion to regulate pressure. As negative pressure builds, secretions and pathogens can be aspirated from the nasopharynx into the middle ear space, creating MEE. This fluid may persist and not become infected, resulting in OME. If, however, the fluid becomes infected, either with viruses or more commonly bacteria, an AOM develops.

Certain populations have a much higher incidence of ET dysfunction and, subsequently, OM. Anatomically, those children with craniofacial abnormalities, Down syndrome, and cleft palate may have persistent ET dysfunction and difficulties with OM throughout their lives. Immunocompromised children are also at increased risk—this includes those with primary ciliary dyskinesia, immunoglobulin deficiencies, T- or B-cell defects, chemotherapy, or HIV.

## Microbiology

### *Bacteriology*

The most common bacteria isolated in AOM are *Haemophilus influenza* (35–50%) and *Streptococcus pneumoniae* (25–40%). It was hoped that the introduction of the conjugate pneumococcal vaccine PCV7 in 2000 would dramatically decrease the number of episodes of AOM, but the decrease has been reported at a modest 7.8%, with an increase in the number of nonvaccine serotypes and *Haemophilus* infections.[41–43] *Moraxella catarrhalis* is the third most common bacteria (3–20%) isolated, followed by Group A *Streptococcus* and *Staphylococcus aureus* (1–10%).

Also, although neonates and infants usually have the same bacteriologic pattern as older children, gram negatives such as *E. coli*, *Klebsiella*, and *Pseudomonas* are seen with a higher frequency. Anaerobic bacteria such as *Peptostreptococcus, Fusobacterium, and Bacteroides* are more commonly seen in chronic suppurative OM (persistent drainage via a tympanostomy tube or perforation) and in cases of cholesteatoma. A myriad of other bacteria have been recovered from the middle ear in rare cases, including *Mycoplasma*, *Mycobacterium tuberculosis*, Group B *Streptococcus* species, and *Neisseria* and *Chlamydia* species.

Cultures in OME more commonly do not grow bacteria, and this "sterile" culture occurs about a third of the time. Another third of the cultures will grow the three most common AOM bacteria (*S. pneumonia*, *H. influenza*, and *M. catarrhalis*), with *Haemophilus* being the most common. The final third is composed of nonpathogenic bacteria such as the normal skin bacterium *Staphylococcus epidermidis*, as well as viruses.[44]

More recently, the role of bacterial biofilms in the pathogenesis of OM has been debated. A biofilm occurs when a community of bacteria interact together to surround themselves with a polysaccharide matrix, which protects them from a host's immune response. Because of its low metabolic rate, it is also resistant to antimicrobial therapy. Initially, it was thought that biofilms only existed on hard surfaces such as teeth and tympanostomy tubes. But research has shown that biofilms can also be found in the middle ear.[45] These biofilms were identified in 48% of patients undergoing tympanostomy tube insertion even in the face of negative middle ear fluid cultures. Biofilms have also been found in the nasopharynx in children with OM. This suggests that these biofilms may act as a bacterial reservoir for repeated OM via the ET, and may help to explain why adenoidectomy benefits some patients with OM. At this point, the existence of biofilms cannot be disputed. Their exact role in the pathogenesis of OM, particularly as it relates to treatment strategies, has yet to be clearly defined.

### *Virology*

Before the advent of polymerase chain reaction (PCR), the incidence of viral AOM was unknown and largely underestimated, because isolating viruses in culture was technically challenging. Currently, it is thought that viruses alone account for about 20% of episodes of AOM and are present in about 20–30% of fluid in OME. Rhinovirus and respiratory syncytial virus (RSV) are the most common, but influenza, parainfluenza, and adenovirus are also seen.[46] The role of viruses in OM extends beyond their role in the middle ear directly. Viral URIs are often the events that are precursors to episodes of OM. In one study, 70% of episodes of OM were associated with a viral URI, and viruses were isolated from MEE in 77% of these cases.[47] This suggests that mixed bacterial and viral OM is common and perhaps viruses "set up" the middle ear space for bacterial infection, similar to the pathogenesis of sinusitis.

## DIAGNOSIS

### History

The most recent guidelines released from the American Academy of Pediatrics/American Academy of Family Physicians outline the diagnosis of otitis media based on moderate to severe bulging of the TM or new onset of otorrhea not due to acute otitis externa. Alternatively, diagnosis is based on mild bulging of the TM and recent (< 48 hr) onset of ear pain or intense erythema of the TM.[48] Common symptoms of AOM include ear pulling, poor sleep, fever, and irritability, although some children may have no symptoms. OME, as previously mentioned, is the presence of fluid in the middle ear without acute inflammation. This can be more challenging to diagnose and is often not accompanied by any symptoms, particularly in young children. If symptoms are present, the most common ones include hearing loss, fullness, otalgia (especially at night), and imbalance.

### Physical Examination

Physical examination findings of acute inflammation in AOM include a bulging TM (Fig. 18.1), erythema of the TM, or otorrhea associated with spontaneous perforation. The TM may be thickened and dull and purulence may be visualized through the TM. Caution must be taken when assessing redness of the drum, however and the presence of fluid must be confirmed. One study showed the predictive value of redness of the TM alone to be only 7%, and hyperemia of the TM alone is a very common normal finding, particularly in a crying child.[49] OME usually is seen as opacification of the TM with abnormal color, typically pink, yellow, amber, or blue (Fig. 18.2). Bubbles or air-fluid interfaces may be visible and the TM may be in a neutral or retracted position. Pneumatic otoscopy is a critical part of the otoscopic examination, particularly when determining if MEE is present. This involves the application of positive and negative pressure to the TM.

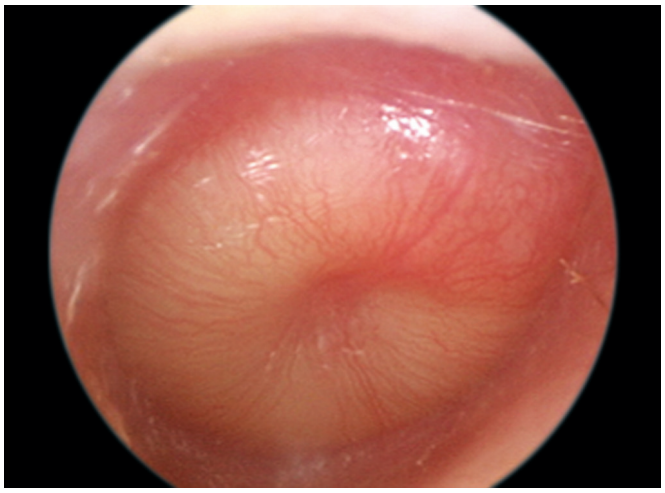

**Fig. 18.1:** Otoscopic examination of acute otitis media.

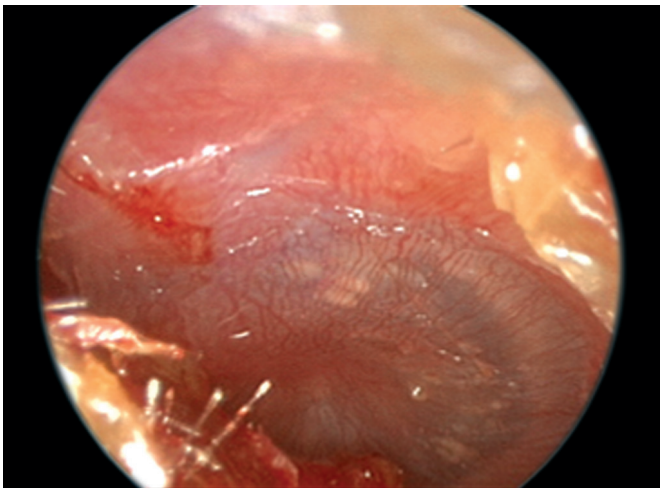

**Fig. 18.2:** Otoscopic examination of otitis media with effusion.

To properly perform pneumatic otoscopy, the largest speculum that adequately fits in the ear canal should be used and an airtight seal must be created within the cartilaginous ear canal. Decreased or absent mobility of the TM is suggestive of fluid and may be used to confirm MEE and OME. Other sources of poor mobility include scarring (myringosclerosis) or thickening of the TM, and obviously a perforation or tympanostomy tube will prohibit mobility. Myringosclerosis is seen as white plaques within the TM, and commonly occurs in a horseshoe pattern centrally around the pars tensa portion of the TM. This occurs with long-standing ear disease, either with or without the previous presence of a tympanostomy tube. Retraction, or atelectasis, of the TM is another common otoscopic finding, and may be associated with OME. In severe cases, hearing loss associated with ossicular chain erosion or cholesteatoma formation can occur. If available, binocular microscopy can also be a valuable tool in examining the TM and assessing for the presence of MEE. One recent study showed an 88% sensitivity and 89% specificity for binocular microscopy in identifying MEE, compared with 68% and 81%, respectively, for pneumatic otoscopy.[50] Obviously, binocular microscopy will not be available in all diagnostic settings and may not be practical in every patient, particularly young children, therefore pneumatic otoscopy remains the gold standard for identifying MEE.

## Ancillary Testing

Immittance testing, or tympanometry, is an audiologic tool that can also be useful in diagnosing MEE. It is particularly useful is young children, those with small ear canals, and those patients in which an airtight seal cannot be obtained for pneumatic otoscopy. Tympanometry involves placing a probe in the ear canal with an airtight seal. The probe emits a tone, and a curve is obtained by plotting the immittance of the middle ear as a function of pressure in the ear canal. A normal, or type A, tympanogram will have a sharp peak, which usually will occur near zero mm water pressure. A flat, or type B tympanogram, is classically associated with MEE, as compliance of the drum is poor. Other sources of flat tympanograms, however, include presence of a tympanostomy tube, or a false positive if a seal is not created with the probe. A type C tympanogram occurs when a peak is obtained, but this peak occurs at a pressure of –150 or greater. This suggests high negative pressure, or a vacuum type effect, in the middle ear, and is much less specific in diagnosing MEE. Tympanometry is highly sensitive, with ranges around 80–90% reported in multiple studies, but its specificity is much lower, reportedly as low as 47%.[50] It is particularly poor in children < 1 year of age, and this may be due to the increased compliance of the ear canal is infants. This can be overcome to some degree by using a 1000 Hz probe tone instead of the usual 226 Hz tone. The role of other supplementary testing, including acoustic reflectometry and ultrasound, is less well defined and not readily available in most physicians' offices.

## Disease Prevention

Modification of the environmental risk factors previously mentioned, such as encouraging breast feeding in the first few months of life and avoiding passive smoke exposure as well as the use of pacifiers, are simple measures that can decrease the incidence of OM. There is only weak evidence that substances such as xylitol and the probiotic bacteria

Lactobacillus prevent OM, and there are not enough supporting data to recommend using the on a routine basis. The role of allergy and GERD in the pathogenesis of OM has not yet been clearly defined, but there is certainly evidence to support their involvement in ear disease. Treating allergy and GERD in those patients who are symptomatic may help prevent further episodes of OM, but there is no clear evidence that treating every child with OM is necessary and it is not routinely recommended. Antibiotic prophylaxis has been shown to prevent AOM, but is largely discouraged because it promotes the emergence of resistant bacteria. The benefit of antibiotic prophylaxis is also small, with nearly a year of antibiotic necessary to prevent only one episode of AOM.

The development of vaccines aimed at the most common causes of OM holds promise. As mentioned previously, the pneumococcal vaccine PCV7 was released in the United States in 2000. Unfortunately, there was only an 8% decrease in total OM episodes with this vaccination, and an increase in nonserotype pneumococcal and *Haemophilus* bacteriology. The true benefit is greater in those patients with recurrent AOM, with a 20% decrease in number of episodes and concomitant 20% decrease in number of children requiring tympanostomy tube placement. It has also resulted in a greater than 80% decrease in invasive pneumococcal disease.[43] More recently, an updated PCV13 vaccine has been released, and it remains to be seen whether this will have a larger impact on total number of AOM episodes. The 23-valent pneumococcal polysaccharide vaccine Pneumovax covers about 90% of pneumococcal infections, but is not efficacious in children <2 years of age, marginalizing its role in preventing OM. Research is ongoing to develop vaccines for nontypeable *Haemophilus* and *Moraxella*.[51,52] The role of maternal immunization with pneumococcal vaccines is also being studied with promising results.[53]

As previously stated, the role of viruses in OM, both directly and indirectly, is significant. The development of viral vaccines has also shown to have a role in decreasing the number of episodes of AOM. The inactivated influenza vaccine reduced the incidence of AOM during flu season by 35%, although the largest benefit is gained in children older than 2, and the efficacy may diminish after 1 year.[54] It does appear that the intranasal live-attenuated influenza vaccine is superior to its inactivated counterpart.[55] Currently, the influenza vaccine is the only viral vaccine that is commercially available for the prevention of OM, but research is ongoing to develop other viral vaccines for OM, with particular attention to RSV.

## MEDICAL TREATMENT OF ACUTE OTITIS MEDIA

There has been controversy for quite some time about the need for antibiotic therapy in all cases of AOM. It has been shown that only a 12% increase in resolution rate was observed in children who received antibiotics versus clinical observation at 2–7 days.[56] Furthermore, the incidence of meningitis, mastoiditis, and other suppurative complications are similar in those treated with antibiotics versus observation (0.17% vs. 0.59%, respectively). In fact, routine antibiotic usage may select out for more invasive, resistant bacteria. A scientific review of the best available studies was performed and new guidelines from the American Academy of Pediatrics and American Academy of Family Physicians were introduced in 2004.[48] This was the first set of guidelines from these academies that included observation as initial management in certain cases of AOM. The factors that are used to determine initial treatment include age, certainty of diagnosis, severity of illness and reliability of the caregiver/follow-up were the factors used to create this recommendation (Table 18.1). Certain diagnosis meets the three criteria mentioned previously in this chapter. Severe illness was defined as severe otalgia or fever >39°C (102.2°F).

### Observation

By definition, the "observation option" refers to observation for a period of 48–72 hours, and limiting management to symptomatic relief. This includes particularly the management of pain, another recommendation from the committee. The most important initial factor in determining whether observation is even an option in a child is the reliability of the caregiver. This not only relates to assurance of follow-up, but also their ability to recognize worsening severity of illness and be able to provide them with prompt access to medical care if necessary. If there are serious concerns with any of these factors, then a physician may choose to initially treat a child with antibiotics empirically. When observation is chosen, a strategy should be in place to ensure that some follow-up occurs. This may include a scheduled clinic or phone follow-up, a parent-initiated visit if there is no improvement at 48–72 hours, or a safety-net antibiotic prescription given to parents to fill if there is no improvement in 48–72 hours. Other exclusion criteria for the observation option include immunodeficiency, genetic abnormalities, craniofacial anomalies, underlying persistent OME, and AOM in the past 30 days.

**Table 18.1:** Criteria for initial antibacterial-agent treatment or observation in children with AOM

| *Age* | *Certain diagnosis* | *Uncertain diagnosis* |
|---|---|---|
| < 6 months | Antibacterial therapy | Antibacterial therapy |
| 6 months to 2 years | Antibacterial therapy | Antibacterial therapy if severe illness; observation option* if nonsevere illness |
| ≥ 2 years | Antibacterial therapy if severe illness; observation option* if nonsevere illness | Observation option* |

*Observation is an appropriate option only when follow-up can be ensured and antibacterial agents started if symptoms persist or worsen. Nonsevere illness is mild otalgia and fever <39°C in the past 24 hours. Severe illness is moderate to severe otalgia or fever ≥ 39°C. A certain diagnosis of AOM meets all three criteria: (1) rapid onset, (2) signs of MEE, and (3) signs and symptoms of middle-ear inflammation.

Adapted from AAP/AAFP Subcommittee Guidelines on Management of Acute Otitis Media, Recommendation 3a, Pediatrics. 2004;113(5):1451-65.

All children under the age of 6 months should receive initial antibiotic therapy for AOM, regardless of certainty of diagnosis or severity of illness. The reason for this is the concern for serious infection in this very young age group and the diagnostic challenge in assessing worsening symptoms or signs of progression to suppurative complications. In children age 6 months to 2 years, initial antibiotic therapy should be instituted if there is a certain diagnosis, or if there is an uncertain diagnosis in the presence of severe illness. If the diagnosis is uncertain and there is nonsevere illness, then observation is an option. This was based on the suggestion in the literature of an increased rate of failure of watchful waiting in this age range. In children greater than age 2, observation is an option even in the presence of a certain diagnosis of AOM, as long as the patient has nonsevere illness. Initial antibiotic therapy should be instituted in the presence of severe illness (Table 18.1).

Although these guidelines are widely accepted, further research may give us a clearer picture of which patients should be treated initially and which can be observed. There have been problems cited with the studies that were used to show high spontaneous resolution rates in AOM. The definition of AOM may have included criteria that allowed inclusion of patients with OME, the antibiotics may have been inappropriate or at an insufficient dosage, and the sickest children and those < 2 years old may have been excluded/underrepresented.[57] All of these factors would make antibiotic therapy appear less efficacious. Another challenge is getting parents to agree to observation, which can be difficult particular given the empiric historic use in AOM. Practitioners have also not universally accepted this into their practice, and one study showed that although 83% of physicians felt observation was a reasonable practice, it was used in only a median of 15% of practices.[58]

## Initial Antibiotic Therapy

The initial antibiotic for an uncomplicated, nonrecurrent AOM is amoxicillin (Table 18.2). Amoxicillin has been shown to be effective against the most common AOM organisms, particularly *S. pneumoniae* and non-Beta lactamase producing *H. influenzae*. The dosage recommendation is the high dose 80–90 mg/kg/day versus the standard 40 mg/kg/day. This higher dose has been shown to be more effective, particularly against the increasing intermediate and highly resistant strains of *S. pneumoniae* that have emerged. In addition, amoxicillin is cost-effective and easy to take, with a low incidence of side effects. In patients with severe illness (severe otalgia or temp > 39°C), or the recommendation is high-dose amoxicillin (90 mg/kg/day)/clavulanate (6.4 mg/kg/day). The challenge in determining appropriate initial antibiotic therapy is the changing landscape of the bacteriology of AOM. Nearly 50% of *H. influenzae* and 100% of *M. catarrhalis* are Beta-lactamase producing, and therefore resistant to amoxicillin alone. But there is also evidence to suggest that AOM caused by these bacteria are more likely to resolve spontaneously, and the combination of *S. pneumoniae* and amoxicillin-sensitive *H. influenzae* still represent the majority of AOM pathogens.

In penicillin-allergic patients without type I hypersensitivity, cefdinir, cefpodoxime, or cefuroxime can be used. Azithromycin or clarithromycin are alternatives in those patients with type I hypersensitivity, although studies suggest increasing resistance rates to these macrolide antibiotics. Other possibilities include erythromycin/sulfisoxazole or trimethoprim/sulfamethoxazole. Clindamycin is also effective if the pathogen is resistant to *S. pneumoniae*. In the case of severe illness or the inability of the patient to tolerate oral medication, intramuscular

**Table 18.2:** AAP/AAFP therapy options for AOM in varying clinical circumstances

| |
|---|
| *At diagnosis when observation is not an option* |
| Recommended: Amoxicillin 80–90 mg/kg/day |
| Alternative for penicillin allergy: Non-type I: cefdinir, cefuroxime, cefpodoxime; Type I: azithromycin, clarithromycin |
| *Clinically defined failure of observation option after 48–72 hours* |
| Recommended: Amoxicillin 80–90 mg/kg/day |
| Alternative for penicillin allergy: Non-type I: cefdinir, cefuroxime, cefpodoxime; Type I: azithromycin, clarithromycin |
| *Clinically defined failure of initial antibiotic treatment after 48–72 hours* |
| Recommended: Amoxicillin/clavulanate (90 mg/kg/day of amoxicillin component, with 6.4 mg/kg/day of clavulanate) |
| Alternative for penicillin allergy: Non-type I: ceftriaxone – 3 days; type I: clindamycin |
| If symptoms are severe (temperature > 39°C and/or severe otalgia) |
| *At diagnosis when observation is not an option* |
| Recommended: Amoxicillin/clavulanate (90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate) |
| Alternative for penicillin allergy: Ceftriaxone – 1 or 3 days |
| *Clinically defined failure of observation option after 48–72 hours* |
| Recommended: Amoxicillin/clavulanate (90 mg/kg/day of amoxicillin with 6.4 mg/kg/d of clavulanate) |
| Alternative for penicillin allergy: Ceftriaxone 1 or 3 days |
| *Clinically defined failure of initial antibiotic treatment after 48–72 hours* |
| Recommended: Ceftriaxone 3 days |
| Alternative for penicillin allergy: Tympanocentesis and clindamycin |

Adapted from Pichichero and Casey.[41]

**Table 18.3:** Consistency of guidelines for acute otitis media

| | |
|---|---|
| All recommend as first line | Amoxicillin, mostly at 80–90 mg/kg/day |
| All recommend as second line | Amoxicillin/clavulanate, mostly "ES" 80–90 mg/kg/day |
| Some recommend as second line | Cefdinir 14 mg/kg/day<br>Cefprozil 30 mg/kg/day<br>Cefuroxime axetil 30 mg/kg/day<br>Cefpodoxime 10 mg/kg/day<br>Ceftriaxone 50 mg/kg/day |
| Not recommended by any guideline: Unless pathogen known to be sensitive; patient had severe allergic reaction to penicillin or amoxicillin; or combined with another antibiotic that is effective against additional organisms | Azithromycin<br>Clarithromycin<br>Trimethoprim/sulfamethoxazole<br>Erythromycin/sulfisoxazole<br>Cefaclor<br>Loracarbef<br>Cefixime<br>Ceftibuten<br>Clindamycin |

Adapted from Pichichero and Casey.[41]

ceftriaxone is also an option. The above protocols are designed not only for patients who are treated initially, but also for those in whom the observation option has failed after 48–72 hours. Table 18.3 outlines antibiotic guidelines from a combination of the AAP/AAFP and CDC guidelines.

The optimal duration of therapy for AOM is not completely certain. Evidence suggests fewer treatment failures in younger children with a standard 10-day course, and the current recommendation is 10 days in children <6 years old. A 5- to 7-day course may be appropriate in

children older than 6 years of age without severe disease. Specific antibiotics have been approved for shorter courses even in younger children. Cefdinir and cefpodoxime have been approved for 5-day courses, and azithromycin has been approved for 1-, 3-, and 5-day courses. A recent study showed, however, that high dose amoxicillin/clavulanic acid for 10 days was superior to a 5-day course of cefdinir in the treatment of AOM.[59]

## Antibiotics for Treatment Failures

When initial antibiotic therapy fails, the patient should be started on high-dose amoxicillin/clavulanate if there is no allergy. If they have failed this therapy already, consideration to alternatives such as cefdinir, cefpodoxime, and cefuroxime can be considered. A 3-day course of intramuscular ceftriaxone can also be considered. In those type I penicillin hypersensitivity patients, clindamycin is also an option because of its high (up to 95%) success against highly resistant *S. pneumoniae*.[60] Finally, in the severely ill patient, tympanocentesis can be performed to make a bacteriologic diagnosis for culture-directed therapy.

## Nonantibiotic Therapies

### *Analgesics*

As mentioned previously, the symptomatic management of pain with analgesics is important in patients with AOM, regardless whether or not they receive antibiotic therapy. Multiple options exist, with acetaminophen and ibuprofen the most common and very effective. Topical analgesia with benzocaine has also shown to be effective, though the benefits are very short lasting.[61] Narcotic analgesics such as codeine and its derivatives can also be used, but must be used cautiously particularly in younger children. Lethargy from the narcotic may mask the worsening symptoms of suppurative complications, and respiratory depression is also a side effect that needs to be monitored.

### *Corticosteroids*

Although some small studies have shown short-term benefit with oral or intranasal steroid, the benefits have been marginal. A larger study showed no benefit with oral steroid over antibiotic alone, and steroids are not routinely recommended in AOM.[62]

### *Antihistamines and Decongestants*

Both large individual studies and meta-analysis of studies have shown no benefit in terms of early cure, symptom resolution, duration of effusion, or prevention of complication or surgery with antihistamines or decongestants.[56] They are not routinely recommended in AOM.

### *Alternative Therapies*

Homeopathy, acupuncture, chiropractic treatment, and nutritional supplements have all been used for AOM but there are no data suggesting a beneficial effect of these therapies. These alternative therapies are not currently recommended for AOM.

# MEDICAL MANAGEMENT OF OTITIS MEDIA WITH EFFUSION

## Observation

OME is common in children both with URIs and after AOM, and fluid may persist up to 1 month after an acute episode of AOM in 50% of cases. In a child without speech, language, or learning delays, observation of fluid is recommended for up to 3 months. If a child is at-risk or OME persists beyond 3 months, audiologic evaluation should be obtained. If the child's hearing is normal (<20 dB), continued watchful waiting is recommended. If there is a moderate or worse conductive hearing loss (>40 dB) then surgical intervention is recommended. When the hearing falls in the mild conductive hearing loss range (21–39 dB), the duration and particularly the severity of symptoms related to the hearing loss must be addressed. If there is parental or teacher concern about the child's hearing, surgical intervention may be considered. Otherwise, observation in 3–6 month intervals should occur until the fluid resolves, language delays occur, or structural abnormalities of the eardrum are observed. These recommendations are from the AAP/AAFP clinical practice guidelines for OME, also published in 2004.[63]

## Medical Therapy

Very little evidence exists to support the use of any medical therapy to shorten the duration of OME. The 2004 guidelines conclude that antihistamines and decongestants are ineffective in treating OME and they do not recommend their use, particularly from a risk/benefit standpoint. Antibiotics and corticosteroids are also not recommended. Although there may be short-term benefit to both antibiotics and steroids, these benefits become nonsignificant within several weeks of stopping them. In addition, their side effect profiles lead to a less than optimal risk/benefit ratio. Autoinflation of the ET, described by Politzer, has been shown to have limited short-term benefit

in very small studies, but adherence to the procedure can be difficult in children. No definitive recommendation has been made regarding autoinflation but because of the low cost and absence of adverse effects it may be a reasonable option to consider while awaiting resolution of effusion.[64]

## SURGICAL TREATMENT OF AOM AND OME

### Myringotomy/Tympanocentesis

Myringotomy, or an incision in the eardrum, may temporarily relieve pressure associated with an AOM and allow culture for bacteriology, but has not been shown to be as effective as antibiotic therapy, does not decrease duration of effusion, and does not prevent recurrent AOM. It also has been shown to be ineffective in the long-term management of chronic OME. Therefore, there is little role for myringotomy alone in OM.

### Myringotomy with Pressure Equalization Tube Placement

Myringotomy with pressure equalization tube (PET) placement is the first-line surgical therapy for recurrent AOM, complicated AOM, as well as chronic OME.[63] Children are in general considered candidates for PET placement if they have 3–4 episodes of AOM in 6 months or 4–6 episodes in 1 year. Recently updated guidelines from the American Academy of Otolaryngology also require the presence of effusion at initial visit prior to recommendation of PET placement in recurrent AOM, as well as preoperative audiologic evaluation in all patients prior to PET placement.[65] Studies show that PETs reduce the frequency of AOM episodes by 56% and decrease the duration of OM.[66,67] Although OM can still occur with a PET in place in the form of otorrhea, many of these episodes are not accompanied by any symptoms and can be treated with ototopical antibiotic drops without oral antibiotics. PET placement is also considered in a complicated AOM episode, meaning AOM with mastoiditis, labyrinthitis, facial nerve paralysis, or other complication. The Academy guidelines do not apply to children who have multiple antibiotic allergies/intolerances, immunosuppression or those at risk for, or already with developmental delays.

PET placement is also the most common initial surgical intervention in chronic OME. Indications for intervention, however, are somewhat more controversial. As mentioned previously, hearing loss, particularly as it relates to speech, language, or learning delays is usually the primary factor in determining whether PET placement is necessary. In a child with speech or language delays, particularly those at-risk patients such as those with genetic abnormalities or other developmental delays, prompt PET placement is indicated. Otherwise, OME is observed for 3 months for spontaneous resolution. If the fluid persists and audiologic evaluation reveals moderate hearing loss (>40 dB) or speech or language delays develop, then PET placement is indicated at this time. In the face of a normal audiogram, observation is recommended at 3–6 month intervals until resolution occurs, significant hearing loss develops, or structural damage of the TM is identified—if any of this occurs, PET placement should be considered. In the face of a mild (21–40 dB) hearing loss, a discussion with parents is necessary and either (1) PET can be placed or (2) close observation at 3-month interval scan be continued.

The average length of time a PET stays in place is reported to be between 1 and 2 years. There is minor variation related to the type and model of tube inserted, but most will remain in place for at least 12 months. Postoperative tube otorrhea is common and can be decreased by using saline rinses intraoperatively, a single dose of antibiotic/steroid eardrops intraoperatively, or more prolonged eardrops therapy.[68] An episode of tube otorrhea after the postoperative period is also not uncommon—it may occur spontaneously but is commonly associated with a URI or water exposure. Younger children have otorrhea more commonly associated with URIs, and the typical sinonasal bacteria (*S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*) are usually cultured. In older children, otorrhea is more likely to occur with water exposure, particularly with swimming, and the most common bacterial pathogens are *Pseudomonas* and *S. aureus*. Topical antibiotic therapy has been shown to be at least as effective as and perhaps more effective than oral antibiotics. Oral antibiotics are usually reserved for those patients with severe systemic symptomatology or those that have failed initial topical therapy. Aural toilet (i.e. suctioning) can also help to clear the ear canal and allow the eardrops easier access to the middle ear space. This is even more important in those cases with acutely inflamed, edematous, and narrow ear canals. Chronic or recurrent otorrhea is a rarer problem that can be more difficult to manage. If a patient has failed both topical and oral antibiotic culture-directed therapy in the presence of repeated aural toilet, then consideration can be given to a variety of adjuvant therapies. This could include tube replacement, adenoidectomy, tube removal, intravenous antibiotic therapy, and mastoidectomy. Particularly in those patients with long-standing chronic otorrhea, a CT scan can also be considered to evaluate for the presence of cholesteatoma.

There are other less frequently seen sequelae of PETs. Early extrusion may occur, usually in the setting of an acute otorrhea episode. A tube may become blocked with cerumen, dried blood or dried mucus—this can often be cleared either with ototopical drops or manually in the office setting. Persistent perforation may occur after PET extrusion, with myringoplasty or tympanoplasty necessary to close the hole. A PET may not extrude spontaneously and be retained in the TM – this can be monitored but may eventually need to be removed in the operative setting. Myringosclerosis (scarring of the TM), atrophy of the TM at the prior PET site, and retraction pockets can also occur after tube extrusion. Although these TM abnormalities can also occur without prior PET placement, they have been shown to be more common after PETs.

## Adenoidectomy

25% of children who have had PETs will have a relapse of OM when the tubes extrude or become obstructed.[69] In those instances where repeated PET placement is indicated, there is a role for adenoidectomy, as it decreases by 50% the need for further surgeries (i.e. a 3rd set of PETs). The groups that benefit the most from adenoidectomy are those with chronic OME who are older than age 4 and those with recurrent AOM older than age 2 with a prior history of extruded PETs.[70] Interestingly, the benefit from adenoid removal is independent from the size of the adenoid tissue, suggesting that not only adenoid size, but chronic inflammation, contributes to OM. This may be related to biofilms, but the exact role of biofilms in this setting has yet to be completely elucidated.[71] Adenoidectomy with myringotomy alone was equivalent to PET placement alone in older children, but this is not recommended routinely because it is more invasive than PET placement alone. Adenoidectomy is not recommended routinely with a first set of PETs unless an indication such as chronic adenoiditis or chronic sinusitis coexists.[63] Tonsillectomy is not recommended in the treatment of either AOM or OME, as it has shown very limited evidence of benefit and poses significantly higher risks.

# COMPLICATIONS OF AOM

## Extracranial

### *Acute Mastoiditis*

Acute mastoiditis describes acute infection and inflammation within the mastoid cavity with bony destruction of the architecture of the air cells, or "coalescence". Clinically, the child would have postauricular edema, erythema, and tenderness in the setting of an AOM. There is commonly protrusion of the pinna as well. A CT scan can confirm the presence of coalescence. Management is controversial, but IV antibiotic therapy alone is often the initial choice. If the child shows no improvement within 48 hours, the surgical options include myringotomy ± PET placement and/or simple mastoidectomy. Another management strategy that is commonly employed is to do a myringotomy and PET insertion initially along with IV antibiotics, with mastoidectomy performed if there is no improvement in 48 hours.

### *Subperiosteal and Bezold's Abscesses*

These occur when an acute mastoiditis erodes through the cortical bone either adjacent to the lateral surface of the mastoid cortex (subperiosteal) or through the mastoid tip into the neck (Bezold's sign). This can most commonly via direct bony erosion but may also occur hematogenously through mastoid emissary vessels. Purulence collects in these areas, with resultant fluctuance and erythema. Again, a CT scan can confirm the presence of an abscess and its precise location (Fig. 18.3). Management in these cases includes myringotomy ± PET placement with incision and drainage of the abscess alone or in combination with simple mastoidectomy.

### *Petrous Apicitis (Gradenigo's Syndrome)*

Petrous apicitis occurs when infection spreads from the middle ear and mastoid medially to the petrous portion of the temporal bone, either directly or hematogenously via vascular channels. The classic triad in petrous apicitis is

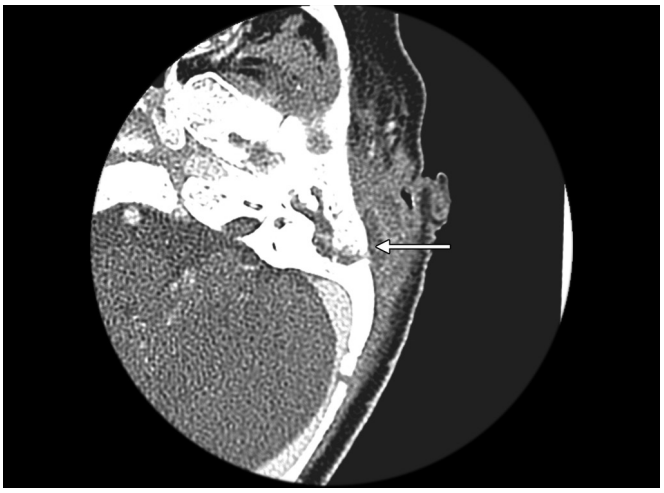

**Fig. 18.3:** Axial CT scan showing acute left mastoiditis with cortical bony erosion and subperiosteal abscess (arrow).

otitis/otorrhea, retrobulbar pain/headache, and abducens nerve (cranial nerve VI) palsy. CT or MRI can usually confirm the diagnosis, and initial management with IV antibiotic therapy alone is often successful.[72] Petrous apicoectomy, typically via a transmastoid approach, is usually reserved for antibiotic failures or infections with complications.

### *Labyrinthitis*

This occurs when inflammation in the middle ear spreads to the labyrinth, which includes the cochlea and semicircular canals. This may be via direct bacterial spread (suppurative labyrinthitis), but is also commonly caused by inflammatory mediators in the absence of the organisms themselves (serous labyrinthitis). Transmission can occur at the oval or round windows, or via microscopic bony labyrinthine defects. The diagnosis is made clinically with acute debilitating vertigo and sensorineural hearing loss in the setting of an AOM. MRI, although not necessary, will also show labyrinthine involvement. IV antibiotics are recommended initially to both treat the infection and try to prevent meningitis. Conversely, labyrinthitis can also be a complication of meningitis – this is in part due to a normal communication channel between the extracranial labyrinth and intracranial meninges, the cochlear aqueduct. Myringotomy ± PET placement drains the fluid and allows for culture-directed therapy, and otherwise vertiginous symptoms are managed in the usual fashion. Serous and suppurative labyrinthitis are treated similarly from a medical standpoint and it is very difficult to distinguish them acutely. In general, however, serous labyrinthitis presents with milder vestibulocochlear symptoms than suppurative labyrinthitis and labyrinthine function is more likely to return in serous labyrinthitis.

### *Facial Nerve Paresis/Paralysis*

The horizontal portion of the facial nerve runs through the middle ear space, and when AOM affects the facial nerve, either through the tiny vascular channels in the normal bony canal or directly secondary to dehiscence of the nerve, facial palsy can occur. This can be a partial weakness (paresis) or complete weakness (paralysis), although more commonly it is partial. Management includes IV antibiotic therapy and wide-field myringotomy versus myringotomy with PET, with culture-directed therapy. A CT scan may be considered to rule out other intracranial or other extracranial involvement. More aggressive intervention is rarely indicated.

## Intracranial

### *Meningitis/Otitic Hydrocephalus*

Bacterial meningitis is the most common intracranial complication of AOM. Transmission of disease from the middle ear can be due to hematogenous spread or directly, via the oval and round windows, cochlear aqueduct, or other bony defects. Symptoms include high fever, altered level of consciousness, vomiting, and neck stiffness. There may be papilledema, Kernig's and Brudzinski's signs, bulging fontanelles, or cranial neuropathies on physical examination. Lumbar puncture is performed to confirm the diagnosis. CT or MRI is usually performed up front to exclude tumor and mass effect, but also may be used to look for other complications. Broad-spectrum antibiotic therapy with myringotomy ± PET for culture is the treatment. Audiologic evaluation of these patients is recommended when neurologic status improves, as sensorineural hearing loss is very common, particularly with pneumococcal meningitis.

Although hydrocephalus is a common finding in bacterial meningitis, another entity has been described known as otitic hydrocephalus. Lumbar puncture demonstrates high CSF opening pressure with normal cytology, thereby excluding meningitis. The pathophysiology is thought to be due to nonobstructing thrombus of the transverse sinus, and MRI is useful to demonstrate the presence of a thrombus. Management includes antibiotic treatment of the underlying AOM, and supportive measures to decrease intracranial pressure.

### *Sigmoid Sinus Thrombosis*

This occurs when a septic thrombus occurs in the sigmoid dural sinus, usually as a result of direct extension of infection from the mastoid cavity. Clinically, it may present with "picket-fence" spiking fevers, headache, and photophobia. Abducens palsy as well as swelling and tenderness over the mastoid process (Greisinger's sign) have also been described. Either CT with contrast or MRI ± venography can make the diagnosis (Fig. 18.4). Management includes IV antibiotic therapy and PET placement ± mastoidectomy. If the choice to perform mastoidectomy is made, the bone directly over the sigmoid sinus should be decompressed. Surgical thrombectomy and anticoagulation are both controversial without strong evidence to support their benefit. This, combined with literature suggesting that recanalization usually occurs spontaneously in 4–6 weeks, suggests that a more conservative approach may be appropriate.[73]

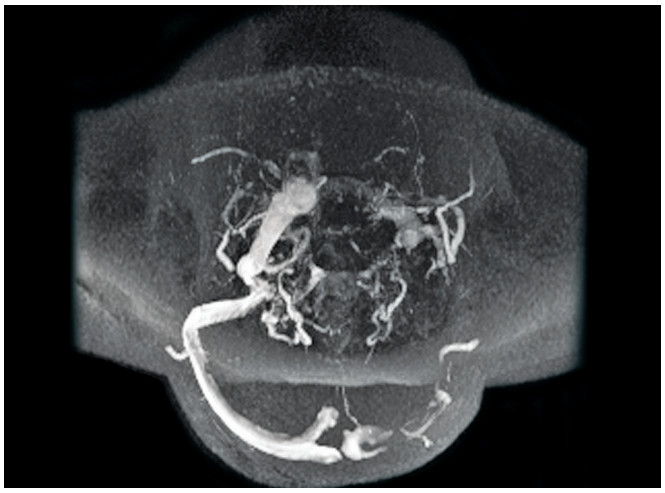

**Fig. 18.4:** MR-venogram showing thrombosis of the left transverse sinus, sigmoid sinus, and internal jugular vein. Comparison can be made to the normal right venous anatomy.

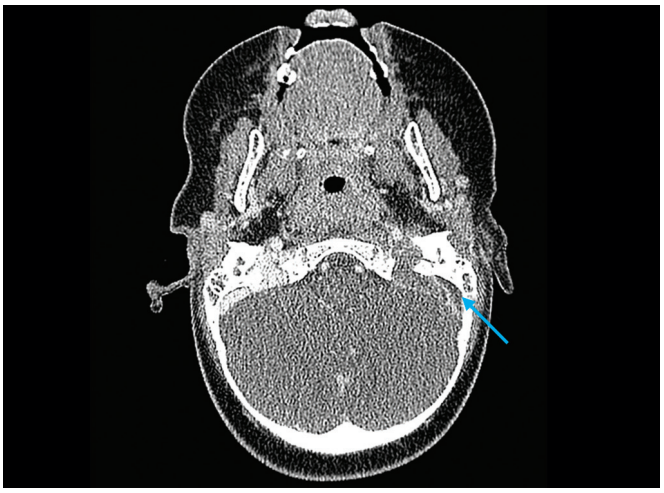

**Fig. 18.5:** Axial CT scan showing epidural abscess (arrow) adjacent to a thrombosed left sigmoid sinus.

### *Intracranial Abscesses (Epidural, Subdural, and Brain Abscesses)*

Intracranial abscesses are defined by the space that they occupy within the cranium. An epidural abscess is located between the bone and the dura mater, a subdural abscess is between the dura and arachnoid maters, and a brain abscess is located intraparenchymally. The mortality associated with subdural and particularly brain abscess is much higher than with epidural abscess. MRI is the imaging study of choice for these abscesses, but most can also be detected with contrast-enhanced CT.

Many epidural abscesses can be managed with IV antibiotic alone, close clinical observation, and interval imaging studies (CT or MRI) for comparison. When an epidural abscess is present in continuity with mastoiditis or sigmoid sinus thrombosis (Fig. 18.5), it may be decompressed via a transmastoid approach. If there is no improvement with antibiotic therapy, or if neurologic status deteriorates surgical drainage either via craniotomy or burr holes, should be performed.

Subdural abscesses tend to spread rapidly through the subdural space, partially contributing to their more aggressive clinical picture. Symptoms include fever, altered mental status, and headache. Neurosurgical drainage is always indicated, while otolaryngologic intervention should be performed if the patient is stable and deferred if the patient is unstable. Other measures to decrease cerebral edema should also be undertaken, as well as seizure prophylaxis.

Brain abscess is a catastrophic complication of AOM, with a reported mortality of as high as 50%.[74] Signs and symptoms may include fever, altered mental status, seizure, and focal neurologic deficits. These focal deficits depend on where within the brain parenchyma the abscess is located. The disease can have an indolent course, making diagnosis all the more difficult. Management is similar to that of subdural abscess.

CHAPTER

19

# Cholesteatoma

***Kenneth M Grundfast, Jessica Levi***

## INTRODUCTION

The otologic disorder characterized by keratinizing epithelium within the middle ear, cholesteatoma, was first described in 1829 by Cruveilhier.[1] The term "cholesteatoma" was coined by Müller in 1838 to describe this disorder because he thought that the visible mass within the middle ear was comprised of cholesterin and fat.[2] A more apt name would be a keratoma as suggested by Schuknecht but, despite many attempts to refer to the otologic disorder as a keratoma, the word cholesteatoma remains the descriptor of choice even though the keratin mass does not contain cholesterol. The contemporary definition of cholesteatoma is the presence of abnormal squamous epithelial growth medial to the tympanic membrane (TM), typically in the middle ear or mastoid. Cholesteatoma is histologically indistinguishable from a sebaceous cyst or a keratoma lined by stratified squamous epithelium that can occur anywhere in the body. Cholesteatoma is usually found in the middle ear or mastoid, but can be found anywhere in the pneumatized temporal bone. When cholesteatoma has not been detected or treated in an early stage, it can expand, destroying adjacent tissues including bone and the adjacent TM. This may result in TM perforation, otorrhea, hearing loss, semicircular canal fistula, vertigo, labyrinthitis, meningitis, and facial paresis. Congenital cholesteatoma is believed to be the result of an error in embryogenesis typically presenting as a well circumscribed cyst in the anterosuperior quadrant of the middle ear medial to an intact TM. Congenital cholesteatoma can be especially destructive because it often goes undetected for many years and tends to occur in a well pneumatized temporal bone so that the cholesteatoma can infiltrate the many air cells that are present throughout the temporal bone. In contrast to the congenital cholesteatoma that is not a sequela of chronic otitis media, acquired cholesteatoma develops in an ear that has had multiple ear infections and either an eardrum retraction pocket or a perforated eardrum; acquired cholesteatoma tends to occur in a temporal bone that has become sclerotic because of the chronic osteitis that accompanies the many infections and inflammatory processes that are typical of chronic otitis media.

## EPIDEMIOLOGY

Based on a retrospective study, the mean annual incidence of cholesteatoma is 9.2 per 100,000 persons of all ages.[3] Congenital cholesteatoma accounts for 1–5% of cholesteatoma in most published series[4] and is therefore encountered less commonly than acquired cholesteatoma. Recent studies indicate that cholesteatoma may occur more commonly than previously had been known; cholesteatoma was observed in 36% of cadaver temporal bones from patients with otitis media (OM) who had TM perforations and in 4% of temporal bones without TM perforations.[5]

There is no known predisposing factor for congenital cholesteatoma though congenital cholesteatoma seems to be more common in boys by a 3:1 ratio.[6] They are bilateral in 4%.[3] The average age at diagnosis is 4–5 years old.[7] For acquired cholesteatoma, a history of recurrent acute otitis media (AOM) or less often, chronic otitis media with effusion (OME), may predispose one to cholesteatoma

formation. The incidence of acquired cholesteatoma has been decreasing, likely because physicians are better able to recognize and treat the precursors to cholesteatoma formation such as chronic OM and eardrum retraction pockets. Patients who are syndromic or have craniofacial abnormalities may also be at increased risk for formation of acquired cholesteatoma as are patients with a family history of cholesteatoma.[8,9]

## PATHOGENESIS

The two main types of cholesteatoma, congenital and acquired, have very different modes of pathogenesis.

*Congenital*: The original definition of congenital cholesteatoma states that the cholesteatoma develops medial to an intact, normal appearing TM in a child with no history of middle ear disease[10] (Fig. 19.1). However, that original definition of congenital cholesteatoma now seems to be too restrictive and no longer entirely accurate. Nearly all children have a history of at least one episode of OM. Also, congenital cholesteatoma may be overlooked until it has expanded to the point of tympanic membrane perforation with resulting granulation and otorrhea, so that a congenital cholesteatoma that has gone undetected for many years may, at the time of discovery, appear much like an acquired cholesteatoma. Further, because of the typical location in the anterosuperior quadrant and in proximity to the Eustachian tube (ET), in some cases congenital cholesteatoma can cause OME, complicating the diagnosis further.[7] In fact, recent evidence has suggested that congenital cholesteatoma occurs during a time of inflammation.[11] Furthermore, Koltai et al. have shown congenital cholesteatoma can often progress rapidly and behave like acquired cholesteatoma.[12] Most experts accept cholesteatoma as congenital if it occurs in a child with an intact TM and no prior history of otologic surgery.[13] Clues that a cholesteatoma was congenital, especially in the setting of TM rupture are: (1) well pneumatized mastoid visualized on CT scan of the temporal bones (2) location of the nidus of cholesteatoma primarily in the anterior superior mesotympanum and the anterior epitympanum rather that the posterior mesotympanum and fossa incudis.

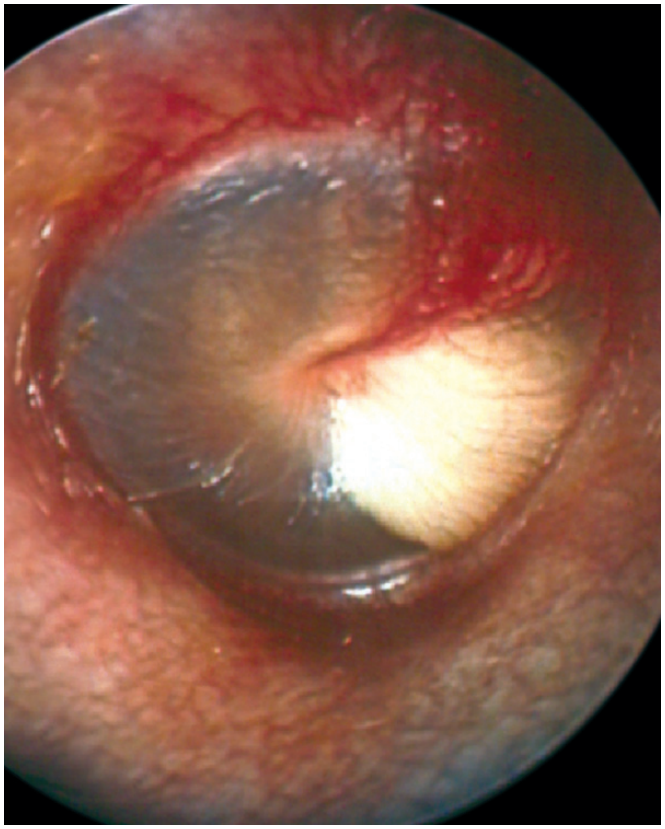

**Fig. 19.1:** Congenital cholesteatoma.

Congenital cholesteatoma is generally identified before the age of 5 and, as mentioned above, usually is located in the anterior-superior quadrant (anterior mesotympanum), and, more specifically, located near the handle of the malleus or the tensor tympani tendon.[14] A congenital cholesteatoma can also be located elsewhere. In a report by Potsic, 18% of congenital cholesteatomas confined to one quadrant were somewhere other than the anterior superior quadrant.[7] In fact, in 50% of cases, they were located in more than one quadrant.[7] There are multiple theories regarding the development of congenital cholesteatoma, the most widely held of which is failure of involution of epithelial rests in the middle ear during embryologic development. Michaels[15] found epithelial cells along the anterosuperior wall of the developing middle ear cleft during weeks 10–33 of gestation and suggested it was these cells that cause cholesteatoma if they do not involute. Other theories include microperforations in the TM that become seeded by epithelium or contamination from the amniotic fluid. Some authors believe epithelial migration or metaplasia may be the source of congenital cholesteatoma.[16]

*Acquired*: Acquired cholesteatoma can be considered to be a sequela of repeated episodes of AOM or OME and often begin as a focal retraction pocket in the posterior superior quadrant of the eardrum (Fig. 19.2). Retraction pockets usually develop in patients with longstanding ET dysfunction and negative middle ear pressure. The pars

flacida and the posterior-superior quadrant are especially prone to retraction pockets. Sites of prior (extruded) tympanostomy tubes are also at risk for retraction pocket formation. Patients with cleft palate are particularly prone to development of this type of cholesteatoma.[17]

The posterior mesotympanum is the second most common location for primary acquired cholesteatoma followed by the anterior epitympanum.[18] Generally, the pocket develops between the pars flaccida of the TM and the neck of the malleus (Prussak's space). The pocket deepens medially and the naturally shed epithelium develops a different migratory pattern. This epithelium can then become trapped and keratin accumulates, forming a cholesteatoma.[19] The cholesteatoma typically expands posteriorly, lateral to the body of the incus. They can also extend to the floor of Prussak's space into the posterior space of von Troeltsch (a pouch lying between the TM and the posterior malleal fold) to enter the middle ear. As this process continues, the sac enlarges and contacts bone, eroding the lateral wall of the epitympanum (scutum).[20] The cholesteatoma continues to grow posteriorly and can enter the aditus ad antrum and then the mastoid. It is in this way that the cholesteatoma can expose the lateral semicircular canal/otic capsule or erode the tegmen tympani (skull base).

**Fig. 19.2:** Acquired cholesteatoma.

Some believe that acquired cholesteatoma can form from abnormal epithelial cell invasion of the pars flacida via basal lamina disruptions.[21,22] Many authors have shown alterations in epithelial cell markers within the cells of a cholesteatoma,[23,24] which would support this theory. Alternatively, based on work by Wendt in Germany in 1873, Sadé found epithelial cells were pluripotent and could become keratinizing in response to inflammation.[25] Thus, cholesteatoma could form from previously normal columnar middle ear mucosa, which underwent metaplasia (this theory is less accepted however).

Cholesteatoma can also form as a result of tympanostomy tube placement or other perforation in the eardrum (such as due to acute suppurative OM or barotrauma).[26] Weiss found epithelial cells could migrate along a surface by a process that he called "contact guidance".[27] This migration helps explain how epithelial cells move to the middle ear from the surface of the TM to create a cholesteatoma. Cholesteatoma that occurs as a result of some sort of "injury" to the TM are referred to as secondary acquired cholesteatoma.

Regardless of the type, the squamous epithelium of the cholesteatoma is metabolically active and has the potential to erode bone. This bone erosion can occur either by constant pressure creating bony remodeling[28] or by enzymatic activity such as collagenase[29,30] or by enhancing native osteoclastic activity.[31]

## SIGNS/SYMPTOMS

Patients with acquired cholesteatoma usually present with a chronically draining ear.[32] Typically, this is not painful. The otorrhea is generally persistent despite multiple courses of ototopical drops or oral antibiotics. It becomes malodorous when it is infected via an upper respiratory infection or external contamination. Patients may also present with hearing loss (usually due to ossicular chain erosion, most commonly the incus). The extent of the hearing loss is determined by the location of the cholesteatoma and the degree of erosion of the ossicles. Children who have undergone any otologic surgery in the past should be monitored with serial audiograms; any new onset hearing loss should prompt investigation for iatrogenic cholesteatoma.

In some patients, the first sign of a cholesteatoma is drainage from the ear and an aural polyp that can be seen on ear examination. In fact, an aural polyp in a child's chronically draining ear should be considered to be a cholesteatoma until proven otherwise. Children may also present with deep retraction pockets or granulation tissue on the surface of the TM. Retraction pockets are shallow when the full extent can be visualized on otoscopy. The retraction pockets that are most ominous and should be considered to be possible incipient cholesteatoma are those in which the cephalad extent of the retraction pocket cannot be seen on examination with an otomicroscope. When white keratin debris can be seen within the depth of a posterior superior eardrum retraction pocket of indeterminate depth, then this can be considered to be an acquired cholesteatoma.

Dizziness is an uncommon symptom associated with cholesteatoma and may indicate late stage disease. It can occur with lateral semicircular canal erosion or erosion of the stapes footplate. Rarely, cholesteatoma can first become manifest when a complication such as brain abscess or a central nervous system complication has occurred. Pain, headache, or bloody otorrhea may herald some of these complications and should warrant prompt evaluation.

In contrast to the natural history of acquired cholesteatoma, the child with a congenital cholesteatoma that is in early stages of development may manifest few or no symptoms. The affected ear may have a normal otoscopic appearance early in life (Table 19.1). Having said this, early diagnosis of a congenital cholesteatoma can be made by a primary care physician who is a skilled otoscopist and sees on routine physical examination a faint whitish mass medial to an intact eardrum in a child who has had a minimal history of ear problems. As a congenital cholesteatoma enlarges within the mesotympanum, the otoscopic findings become more discernible and, around age three to four years, the diagnosis becomes more apparent when the whitish yellow mass within the middle ear can be seen relatively easily. For children with congenital cholesteatoma, eardrum perforation, ear drainage, and hearing loss usually do not occur until around 5 years of age.

**Table 19.1:** Two kinds of cholesteatoma

| | *Congenital* | *Acquired* |
|---|---|---|
| Age at detection | Average = 3 years<br>Can be 30 years | Average = 8 years |
| Earliest phase | Small sphere medial to intact eardrum | Shallow eardrum retraction |
| Location | Anterior/superior | Posterior/superior |
| Mastoid | Well aerated | Sclerotic, poorly pneumatized |

Cholesteatoma located outside of the middle ear, such as perigeniculate or petrous apex, is more likely to present with progressive facial nerve paralysis or a sensorineural hearing loss.

## DIAGNOSIS AND TESTS

Otomicroscopic examination is the key to diagnosis of cholesteatoma in children. Pneumatic otoscopy is particularly important and can help differentiate cholesteatoma from other ear disorders (see below). Congenital cholesteatoma generally appears as a whitish mass medial to an intact TM. When the pneumatic otoscope is applied, positive pressure forces the eardrum to be pressed onto the surface of a congenital cholesteatoma, making it appear larger (concentrically). When the pneumatic pressure is released, the circular whitish mass appears smaller than when the eardrum was pressed against the mass with the pneumatic otoscope.[14]

The first sign of a developing acquired cholesteatoma is a retraction pocket that does not evert on pneumatic otoscopy.[14] Because most cholesteatomas present later, beyond the retraction pocket stage, the most common sign of an acquired cholesteatoma on examination is granulation tissue or a trail of squamous debris within an eardrum retraction pocket. There is also often granulation tissue in the ear canal and middle ear, and frequently a TM perforation. Pneumatic otoscopy can also help diagnose a labyrinthine fistula, which can result from advanced cholesteatoma (the patient will have vertigo and/or nystagmus with the positive air pressure).

Any child with suspected or known cholesteatoma should have a hearing test. There is a difference in effect on hearing between congenital and acquired cholesteatoma. During early stages, the child with a congenital cholesteatoma can have normal hearing because the cholesteatoma almost always originates near the neck of the malleus and grows toward the anterior mesotympanum and epitympanum, and away from the adjacent ossicles.[14] Having said this, the child with a congenital cholesteatoma that has enlarged into the protympanum can develop ET obstruction leading to OME that causes conductive hearing loss. In these cases, the visualization of the small middle ear mass is obscured by the effusion

and it may go undetected until a myringotomy is done in the ear for the purpose of inserting a tympanostomy tube. In general, a conductive deficit in excess of 35 dB (with a 60 dB maximum) indicates ossicular discontinuity, usually secondary to erosion of the long process of the incus. Potsic found the ossicular chain was involved in 43% of cases of congenital cholesteatoma.[7] The hearing can be normal in some cases as when the cholesteatoma is small or the cholesteatoma itself transmits sound to the stapes.[32] Thus, for the child with a congenital cholesteatoma, hearing impairment may or may not be apparent. In the child with acquired cholesteatoma, hearing impairment often occurs early as the cholesteatoma is developing because the retraction pocket (that is so often the precursor to the cholesteatoma) usually overlies the incudostapedial joint. Therefore, erosion of the incus occurs commonly and this is frequently associated with a mild conductive hearing loss with air/bone gap of approximately 10–15 dB. If a child is too young to cooperate for behavioral audiologic testing, then auditory brainstem response testing can be helpful especially if the child is going to have surgery and there is a need to document hearing threshold in the affected ear.

For children with cholesteatoma, the best outcome is typically achieved with early identification by the primary care physician during routine otoscopic examination. In its earliest stages, congenital cholesteatoma will appear as a faint round or oval whitish mass medial to the anterior-superior quadrant of an intact eardrum. Therefore, pediatricians and family physicians are encouraged to be suspicious of any whitish mass in the middle ear that could be the early sign of an enlarging congenital cholesteatoma and refer appropriately. Having said this, there are various conditions that can be associated with detectable whitish areas in the eardrum and it is advantageous for any physician who examines the eardrums of children to know about the conditions that cause the appearance of whitish eardrum abnormalities that can be seen with an otoscope. Certainly hyaline deposits within the eardrum known as myringosclerosis appear as white densities easily visible in the eardrum. Myringosclerosis can be considered a sequela of OM and often can be seen in children with a history of frequent ear infections or persistent middle ear effusion and in children who have had insertion of tympanostomy tubes in their ears. These eardrum blemishes typically have irregular borders and can be seen to move with the eardrum when positive and negative pressure is applied with a pneumatic otoscope. There are three easy ways to differentiate the otoscopic findings in a child who has myringosclerosis from the findings in a child who has a middle ear mass:

1. *Color*: Myringosclerosis is bright white, cholesteatoma is faint whitish yellow
2. *Borders*: Myringosclerosis has patchy, irregular borders; cholesteatoma has a faint blurred, usually rounded, regular border
3. *Appearance with applied positive and negative pressure*: Myringosclerosis size does not change; cholesteatoma appears to get larger with applied positive pressure and seems to get smaller with negative pressure.

*First, the borders of a whitish density*: When a pneumatic otoscope is used the whitish mass that is a congenital cholesteatoma will appear to enlarge as positive pressure applied with the bulb on the otoscope presses the eardrum against the spherical mass in the middle ear but then seems to get smaller as the eardrum moves laterally, away from the middle ear mass as the pressure is released on the bulb of the otoscope and the eardrum lifts off the middle ear mass. In contrast, the findings are different in the eardrum of a child with whitish areas in the eardrum that are areas of myringosclerosis. In the case of myringosclerosis, the whitish patch moves with the eardrum, neither enlarging nor getting smaller with pneumatic otoscopy. In a child who has had chronic OM and has developed an atrophic flaccid retracted eardrum, the eardrum may rest on the promontory of the middle ear that is actually the basal turn of the cochlea and appear to be a round whitish mass suspicious for cholesteatoma. The perception of cholesteatoma in the middle ear that is actually a flaccid eardrum resting on the whitish round promontory of the middle ear can be differentiated from a middle ear cholesteatoma with adept use of a pneumatic otoscope, because the promontory of the middle ear is located inferior to the umbo of the malleus and a spherical middle ear cholesteatoma is usually located in the anterior-superior quadrant of the middle ear and the promontory of the middle ear is bony hard when palpated with a fine instrument wrapped in cotton while a cholesteatoma mass is soft and can be indented with gentle pressure applied to a small blunt instrument such as a calcium alginate fiber-tipped aluminum applicator (Table 19.2).

In early stages of acquired cholesteatoma, a primary care physician may observe a retraction pocket within the posterior-superior quadrant of the eardrum. An adept otoscopist with excellent diagnostic acumen will use the pneumatic otoscope to assess mobility of the eardrum and will begin to be suspicious if a retraction pocket in

**Table 19.2:** Differential diagnosis of whitish eardrum masses

| | *Myringosclerosis* | *Congenital cholesteatoma* | *Promontory* |
|---|---|---|---|
| Color | Bright white | Dull white/yellow | White or pink |
| Border | Irregular | Distinct | Distinct |
| Number of eardrum opacities | Many | One | One |
| Pneumatic otoscopy | Same size with + and – pressure | Larger with + pressure, smaller with – pressure | No change with pressure, or larger with + pressure |
| Location | Anywhere | Anterior to malleus | Central |
| History of Otitis Media/ETD/ Ear tubes | Yes | No | Yes |

the posterior-superior quadrant of the eardrum becomes adherent to the lenticular process of the incus and cannot be everted with negative pressure applied when pressure that indents the bulb of the pneumatic otoscope is released. This inability to evert a topographic indentation in the eardrum located in the posterior superior quadrant of the eardrum should be considered to be a finding that raises suspicion for presence of a developing cholesteatoma and should prompt the primary care physician to refer the child to an otolaryngologist for evaluation.

Imaging, such as CT or MRI, may be helpful in determining the size and anatomic location of cholesteatoma. Plain radiographs will generally only show a very large cholesteatoma and therefore are not useful. High resolution (≤1 mm slice thickness) CT scan of the temporal bones in the axial and coronal planes is the modality of choice because this imaging study can identify a small cholesteatoma in addition to any bony erosion that may have been caused by the cholesteatoma. This modality is also often helpful in determining the extent of disease, particularly mastoid involvement, which can be helpful in surgical planning.[14] Children with congenital cholesteatoma often have well-aerated mastoids, while those with acquired cholesteatoma usually have mastoid opacification. CT scans are particularly useful to evaluate for complications related to cholesteatoma. Ossicular destruction, erosion of the bone covering the facial nerve, dehiscence of the tegmen, and erosion of the horizontal semicircular canal can all be seen on CT, allowing for appropriate surgical planning.

One limitation of CT is that radiographically cholesteatoma is difficult to distinguish from fluid or granulation tissue. Preliminary studies have demonstrated some ability to distinguish these tissues types using diffusion weighted MRI.[33] MRI is superior to CT in detecting residual or recurrent cholesteatoma behind an intact TM graft. In addition, for some complications, MRI is superior such as evaluation of dural involvement, subdural or epidural abscess, encephalocele, sigmoid sinus thrombosis, or inflammation around the facial nerve.

The characteristic MRI appearance of cholesteatoma is slightly higher intensity than CSF on T1-weighted images and high signal intensity on T2-weighted images. Fat will have high T1 signal and low T2 signal and effusions will have low T1 and high T2 signals. Cholesterol granuloma can appear similar to cholesteatoma but will demonstrate capsular enhancement.

Some surgeons will operate on a cholesteatoma without a CT scan, particularly if the cholesteatoma is small, but many otologic surgeons do routinely obtain a CT prior to cholesteatoma for surgical planning purposes, and especially if the child has manifested worrisome symptoms such as vertigo or facial paralysis.

## COMPLICATIONS

Complications of cholesteatoma include eardrum perforation, secondary infections, hearing loss (conductive or less commonly, sensorineural), or vertigo. Secondary infections can be due to middle ear disease or water exposure. Infection can be caused by *Pseudomonas aeruginosa*, *Proteus* species, *Bacteroides*, or *Peptococcus-Peptostreptococcus*.[34,35] When otorrhea associated with cholesteatoma is malodorous, it is due to these secondary infections. Conductive hearing loss is common and is mostly due to incus erosion, but involvement of any of the ossicles can cause this type of hearing loss. Blockage of the ET can also cause a conductive hearing loss due to OM. Less commonly, patients have a sensorineural loss (in about 1%), usually secondary to a labyrinthine fistula. Cranial nerve involvement is also uncommon, but usually affects the 7th nerve and rarely the 8th. Facial paralysis can develop suddenly with a newly infected cholesteatoma or over time with gradual expansion of a cholesteatoma.

Cholesteatoma can erode semicircular canal otic capsule bone resulting in a labyrinthine fistula and this has been reported to occur in up to 10% of patients with

cholesteatoma.[36] A child with a labyrinthine fistula typically will have vertigo and/or nystagmus on pneumatic otoscopy (positive fistula test). They are less likely to present with sensorineural hearing loss, though this can happen as well. The horizontal canal is the most common site for a labyrinthine fistula. Patients with a fistula are at risk for suppurative labyrinthitis and subsequent profound hearing loss.

Cholesteatoma can erode through the boundaries of the mastoid resulting in intracranial complications such as meningitis, brain abscess compression of the temporal lobe, or venous thrombosis. Infection may also extend along the sternocleidomastoid muscle create a neck abscess (Bezold's abscess). Serious complications occur in <1% of patients. Any patient with cholesteatoma and spiking fevers, headaches or new pain, should undergo a CT scan to evaluate for impending complications.

## TREATMENT

Unless there is evidence of infection such as purulent drainage or erythema in the postauricular area, there is no need to prescribe antibiotics for a child with known or suspected cholesteatoma. Ototopicals, in the form of drops, will surround the cholesteatoma and can often penetrate just beyond the surface, but are not able to eradicate completely an infection especially if there is erythema of the skin of the ear canal and the postauricular soft tissues. In some cases, an acquired cholesteatoma can be managed with periodic otomicroscope examination, and debridement of an eardrum retraction pocket. Operating on a noninfected cholesteatoma is preferable and therefore ototopicals are often used in preparation for surgery.

Surgery is the mainstay of therapy for cholesteatoma; without removal, the cholesteatoma will continue to enlarge. The goals of surgery are to remove the cholesteatoma and provide a safe dry ear while also managing any complications that may have occurred. The secondary goal is for hearing preservation or restoration. In some cases, the goal of a first surgical procedure will be removal of cholesteatoma and ossicular reconstruction to improve hearing is best deferred to a second surgical procedure. The outcome of surgery is based in large part on the extent of disease.

The risks associated with surgery for cholesteatoma include hearing loss, facial nerve injury, taste disturbance, dizziness, cerebrospinal fluid leak, and eardrum perforation.[32] Permanent facial nerve palsy occurs in <1%. The facial nerve can be injured at the pyramidal turn when drilling the mastoid or the horizontal portion can be injured with dissection in the middle ear. Many authors use intraoperative facial nerve monitoring, though it is not proven that this reduces the risk of permanent injury. Facial nerve monitoring may be particularly helpful in cases where imaging shows altered facial nerve anatomy, revision cases, or patients who have had prior facial palsies. Delayed palsies usually recover over a period of weeks. Acute palsies may require reoperation with decompression of the facial nerve after any effects of local anesthetic have worn off.

Dizziness can occur with any middle ear surgery, but in cases where there is a labyrinthine fistula, the incidence is increased. Labyrinthine fistulas pose a unique set of problems. Generally, the desquamated epithelium is removed and the matrix is left intact on the lateral semicircular canal. Some authors recommend a canal-wall-down mastoidectomy at this point. Others advocate for removing the matrix and covering the defect with fascia. It is unclear if removing the matrix increases the risk for postoperative hearing loss.

Other complications can include graft failure or perichondritis. Graft failure occurs in 10-15% of cases, resulting in a TM perforation, which may require an additional procedure. Perichondritis of the conchal or auricular cartilage can also occur.

The only contraindication is a patient who is too sick to undergo surgery. Care must be taken in patients with cholesteatoma in an only hearing ear, but generally, the risks associated with leaving it in place are greater than the risk of additional hearing loss with surgical removal.

## SURGERY

To a certain extent, surgery for congenital cholesteatoma is differs from surgery for acquired cholesteatoma because of the anatomic sites where these types of cholesteatoma typically originate. The key to achieving success in surgery for cholesteatoma is knowing where to expect persistent disease and using a surgical approach that is most likely to expose these anatomic sites. Accordingly, the otologic surgeon should plan to gain access to the site where cholesteatoma is most likely to have begun to develop and where the cholesteatoma is most likely to be hidden from view during surgery. There are many clues to differentiating congenital from acquired cholesteatoma, but simply put those patients with cholesteatoma anterior to the malleus, with minimal history of OM and with a well aerated mastoid on CT scan are most likely to have congenital cholesteatoma.

## Congenital

A small congenital cholesteatoma that is detected early in a child's life usually can be removed, in toto, via a transcanal or a postauricular approach depending on location of the cholesteatoma and preference of the surgeon. In these cases, the small spherical or ovoid mass that is encased in a "matrix" can be fully exposed with a properly designed tympanomeatal flap and teased out of the mesotympanum, intact, using small instruments such as a ball probe or a "whirlybird". If the eardrum is torn during the dissection, it can be repaired with a fascia graft. Many variations of middle ear exploration have been described including one by Levi et al. in which two incisions are made in the TM itself around the cholesteatoma sac, rather than raising a full tympanomeatal flap.[37] These approaches are often appropriate for congenital cholesteatoma; in a review of 172 patients with congenital cholesteatoma, the mastoid was involved only in 23%.[7]

The most common site for congenital cholesteatoma to persist after surgery is anterior to the malleus in the area sometimes referred to as "the cog". To remove a congenital cholesteatoma that extends in a cephalad direction >2–3 mm beyond the level of the scutum the mastoid must be drilled in order to completely remove the cholesteatoma and enable the cog area to be visually inspected. Most experts recommend a complete mastoidectomy though some will perform only an atticotomy. Advances in instrumentation and surgical techniques have led some surgeons to utilize endoscopic surgery removal of these lesions without mastoidectomy. Regardless, the focus needs to be on good exposure of the anterior epitympanum. If a CT scan suggests that cholesteatoma is in the cog area anterior to the head of the malleus or if dissection of a cholesteatoma in the mesotympanum is showing that the cholesteatoma extends anterior and cephalad to the neck of the malleus, then it is advisable to remove the incus and head of the malleus so that the anterior epitympanum (cog) can be carefully inspected. Usually the incus can be sculpted and reinserted in the ear as an incus interposition ossiculoplasty to restore ossicular continuity and maintain or restore good hearing. There is no need to plan second look surgery for all children who have had surgery to remove a congenital cholesteatoma especially if the cholesteatoma is relatively small and contained within a matrix. However, if cholesteatoma is large and the matrix is disrupted before or during surgery and the cholesteatoma has had to be removed piecemeal then risk of persistence of cholesteatoma is higher and it might be advisable to plan a second look surgery to be done 6 months after the initial surgery. Further, whenever the surgeon cannot be sure that all cholesteatoma has been removed, then ossicular reconstruction can be deferred to a second surgery that should be done around 6 months after the initial surgery.

## Acquired

In patients with early acquired cholesteatoma that is developing in a shallow retraction pocket, a simple approach to management is to excise the eardrum retraction pocket. This can be done under mask anesthesia with a cup forceps. Indications for excision of a retraction pocket include the following: when the retraction pocket is progressively deepening or it is indenting the lenticular process or there is granulation tissue forming in the pocket. These are all signs of a developing cholesteatoma and therefore must be addressed. One of three things will happen after a retraction pocket is excised: (1) the ear drum heals normally (this is most common), (2) the ear drum heals but the retraction recurs, or (3) the ear drum does not heal at all, leaving a perforation. If there is a permanent perforation this can be repaired at a later time when there is no longer a risk for cholesteatoma formation. Any patient with a shallow retraction pocket needs to be monitored carefully because the retraction pocket can deepen and progress to develop into a cholesteatoma. Retraction pockets that have been excised must be monitored carefully as well to look for any recurrence before a large cholesteatoma forms. Long-standing retraction pockets lose some elasticity and thus may not revert to a neutral position. Deeper retraction pockets, particularly those adhering to the ossicles, must be resected and replaced with a TM graft. Each surgeon has a different threshold for the various treatment options.

A cholesteatoma that extends beyond the middle ear into the fossa incudus generally requires a mastoidectomy for complete removal. Before the advent of the surgical microscope and the drill, cholesteatoma was typically treated with exteriorization without complete removal. This way of managing cholesteatoma minimized operative morbidity such as facial paralysis, profound sensorineural hearing loss, and dural tears, but often left the patient with a chronically draining ear and progressive hearing loss. During the 1950s and 60s, William and Howard House's Otologic Medical Group introduced canal-wall-up (CWU) and other less extensive procedures to treat certain types of cholesteatoma.

Depending on the size and location of a cholesteatoma an atticotomy rather than complete mastoidectomy may suffice for removing or exteriorizing a cholesteatoma. The usual growth pattern of a cholesteatoma is to extend from the middle ear to the epitympanum and attic and then the mastoid air cells. Thus, there are cases where the lateral wall of the epitympanum (scutum), and cholesteatoma sacs are removed without further entrance into the mastoid air cells.

When a cholesteatoma extends beyond the attic, a complete mastoidectomy must be performed. Generally, the mastoidectomy procedure is performed with postauricular and endaural incisions, but some surgeons prefer an "inside out" approach where bone is removed through the ear canal and the attic is progressively enlarged, essentially starting with an atticotomy.

There are two main types of mastoidectomy: CWU and canal wall down. In CWU mastoidectomy, the posterior portion of the external auditory canal is preserved. Often this requires drilling of the facial recess (a small area bounded by the chorda tympani and facial nerve) to obtain the best access to the cholesteatoma. In a canal-wall-down procedure, the posterior portion of the external auditory canal is drilled down to the level of the vertical facial nerve, marsupializing the mastoid into the external ear canal and leaving one large cavity. Canal-wall-down mastoidectomies often require a meatoplasty to enlarge the external auditory meatus. The meatoplasty facilitates future examination and cleaning of the mastoid bowl. While a canal-wall-down mastoidectomy affords superior access to the cholesteatoma taking down the canal wall is not always necessary.

The most common location for persistent disease in acquired cholesteatoma is between the incus and the facial nerve (medial to the incus). Therefore, the incus often must be removed to visualize the space between the body of the incus and the horizontal portion of the facial nerve just anterior to the second genu of the nerve. As mentioned above, if the incus has to be removed in order to inspect the sites where cholesteatoma is most likely to be present, then the incus can be sculpted and reinserted in the ear sitting atop the stapes capitulum and medial to the umbo of the malleus.

Most experts advocate performing a canal-wall-up procedure when possible. Such procedures have the advantage of maintaining a normal appearance (no large meatoplasty), with easier ability to fit hearing aids and less chronic care. Unfortunately, these patients may be at higher risk of persistent or recurrent disease and therefore may require additional future surgery. Canal-wall-down procedures usually do not require a second look procedure but do require a lifetime of care and yearly cleanings. Osborn et al. suggest the superior hearing outcomes and ease of care in CWU procedures outweighs the possible need for repeat operations (often performed in CWU procedures) in most children with cholesteatoma.[38]

Some patients who undergo a CWU procedure require a planned second look procedure 6 months to 1 year after their initial operation. This is done to examine the surgical site for any residual cholesteatoma and eradicate it prior to formation of a large cholesteatoma. Following CWU procedures, recurrent or residual cholesteatoma can hide medial to an intact eardrum or skin overlying the mastoid cavity.[14] Second look procedures are performed in patients with a large extent of disease at the initial surgery or with disease in difficult areas to eradicate (such as the sinus tympani). Second look procedures are also often done in children with large congenital cholesteatoma that adhere to many middle ear structures. Recent literature has suggested diffusion weighted MRI can effectively differentiate cholesteatoma from scar tissue, granulation and fluid and therefore may represent an alternative to second look procedures in the future. Many otologists also use a second look procedure to perform an ossicular chain reconstruction (OCR) (discussed later).

Canal-wall-down mastoidectomies usually only require one surgery. They afford better visualization of most cholesteatoma, and are thus regarded by many as "safer", especially in inexperienced hands or in patients with very extensive disease. Sometimes the true extent of disease is only realized in the operating room, thus the determination between CWU and canal wall down is made intraoperatively. Any patient undergoing a CWU mastoidectomy should be counseled regarding the possibility of a canal-wall-down procedure, in case there are unexpected findings in the operating room.

Other groups that may deserve canal-wall-down procedures include those patients that are not available to for regular follow-up and disease monitoring. Recurrence in someone with a canal-wall-down defect is more apparent and easier to treat than in someone with a prior CWU surgery. Patients with cholesteatoma that has caused damage to the posterior external auditory canal or those who had prior, failed CWU procedures also may warrant canal-wall-down procedures. Some people also advocate canal-wall-down procedures in patients with ongoing

poor ET function and poorly pneumatized middle ear and mastoids.[39] An only hearing hear may be a relative contraindication to a CWU mastoidectomy.

Special consideration should be given to patients with labyrinthine fistula or facial nerve paralysis. Often, patients with labyrinthine fistulas require canal-wall-down procedures, particularly in an only hearing ear. In these cases, some of the matrix is left in place over the fistula so as not to expose the labyrinth. They can be monitored for cholesteatoma growth via the common cavity. However, in cases where there is a normal contralateral ear, a small fistula, and a large mastoid, the posterior ear canal can be left intact. The matrix is then removed from the lateral semicircular canal and the fistula is patched with fascia. In cases of facial paralysis, a facial recess approach is needed to expose the horizontal and vertical portions of the nerve. Decompressing the nerve may be necessary but the sheath should not be opened.

A radical mastoidectomy is rarely indicated in benign disease such as cholesteatoma unless there is persistent disease around the ET or round window, which the clinician is unable to eradicate after multiple attempts. It is performed by drilling down the posterior ear canal, eliminating the middle ear space and ossicles, and plugging the ET. There is no attempt to preserve hearing.

Cholesteatoma located in other areas, such as the perigeniculate area or petrous apex, require other procedures. In these cases, combinations of the transmastoid, middle cranial fossa, and/or the transsphenoidal approach may be necessary.

## OSSICULAR CHAIN RECONSTRUCTION

The secondary goal of any cholesteatoma surgery is hearing preservation or reconstruction. Many times the cholesteatoma involves the ossicular chain. Because the disease process can be so aggressive and have such serious complications, even seemingly normal structures may need to be removed to allow eradication of disease. Initial hearing results may be worse than preoperative hearing levels, but with a subsequent OCR they are often quite good. Most consider air–bone gaps < 30 dB as an acceptable outcome after OCR. The OCR can be performed at the time of the cholesteatoma resection if it is certain the cholesteatoma has been completely removed and does not involve the ossicles or it can be performed at a later date. If the cholesteatoma is extensive and located at multiple sites in the mesotympanum, epitympanum, mastoid air cells, so that even after careful dissection you cannot be sure that there isn't some cholesteatoma left behind, a second look is recommended. By delaying the OCR to the second look, the reconstruction is not put at risk. That is, if there is any residual cholesteatoma after the first surgery, this can grow to invade or disrupt portions of an ossicular reconstruction In addition, parents are likely to be compliant with the recommendation for second look surgery if they understand that a goal of the second surgical procedure will be improvement in hearing and the best chance for sustained good hearing is when the ossicular reconstruction is done after all cholesteatoma has been removed from the ear. In summary, if there is concern for residual cholesteatoma (such as in the sinus tympani) or there was extensive cholesteatoma at the time of the initial surgery, ossicular reconstruction should be delayed 6–12 months as part of a second look procedure.

Cholesteatoma on the lateral surface of the incus can often be dissected free without removal of the incus, but involvement of the medial surface usually necessitates removal. Cholesteatoma that extends medial to the head of the malleus usually requires both the incus and head of the malleus to be removed (this is often seen with congenital cholesteatoma). Any disease near the stapes should be dissected with the utmost care to avoid footplate dislocation and sensorineural hearing loss. Cholesteatoma on the footplate of the stapes often is difficult to remove and therefore some may be left behind. Aggressive dissection on the footplate can result in sensorineural hearing loss or dizziness and often it is prudent to defer complete removal to a second look procedure, with OCR at that time. Often at the second look, residual cholesteatoma on the footplate will have formed a small keratin pearl which is easier to remove. The ossicles can be reconstructed with bone, cartilage, or prosthetic material. Adhesions can be prevented by placing silastic sheeting over the promontory at the time of the first surgery.

## PROGNOSIS

Timing for the first postoperative visit varies widely depending on surgeon preference and the surgery performed. Some surgeons see their patients on postoperative day 1 to remove the dressing themselves. These patients are often admitted to the hospital overnight for observation. Others wait as long as 3 or 4 weeks before the first postoperative office visit. If a wick is placed at the time of surgery it is generally removed in 5–10 days after surgery. Open cavities

require variable amounts of cleaning over the first few weeks after surgery and most patients are seen in the office every 2–3 weeks. Full epithelialization does not usually occur before 12 weeks. Once the mastoid bowl is healed, the patient should return at least every 6–12 months for cleaning. Follow up should be continued indefinitely as cholesteatoma can recur years later. Kuo et al. found the mean detection time for recidivism was 10.4 years after the initial surgery.[40]

Eradication of cholesteatoma is almost always possible. This may require multiple procedures, however. Congenital cholesteatoma tends to recur less than acquired. Small, well-encapsulated cholesteatoma of either type generally does not recur.[32] Looking at children with congenital cholesteatoma, Potsic and colleagues found recurrence was increased when the extent of disease increased from one quadrant to two or more and increased even further when the ossicles were involved.[7]

The recurrence for acquired cholesteatoma may be as high as 50%.[41] Factors that predispose a patient to recurrence include children younger than 8 years old, or those with ET dysfunction, ossicular chain damage or large cholesteatoma.[42] The facial recess and sinus tympani can be difficult areas to access surgically and thus are often the site of recurrence. In congenital cholesteatoma, recurrence is usually located near the cog.

Canal-wall-down procedures may have a lower recurrence rate than those in CWU (5–10% vs. up to 40%), though it can be difficult to tell if this represents recurrence or merely persistence of disease.[43] On the other hand, Shirazi found similar rates regardless of the procedure performed.[44]

Hearing outcome is largely dependent on whether there is ossicular chain damage, especially to the stapes superstructure, and preoperative hearing levels.[45] Cholesteatoma is a common cause of permanent conductive hearing loss. Death from intracranial complications of cholesteatoma is uncommon and decreasing in incidence because of earlier recognition, more timely surgical intervention, and better antibiotic therapy.

Children should be followed carefully after surgery to monitor for recurrence that can occur many years later. Small pieces of cholesteatoma left behind at the first surgery can grow into larger cholesteatoma (residual disease). ET dysfunction, which may predispose a patient to the first cholesteatoma, may still be present, predisposing to a second one. A patient should undergo otologic and audiologic examination frequently and there should be a low threshold for obtaining a CT scan if recurrence is suspected. Patients who undergo canal-wall-down procedures generally need to be followed for life to ensure the mastoid bowl does not accumulate debris. Patients with a new TM perforation or a newly draining ear should be suspected of having a cholesteatoma. Any unexplained decrease in hearing or new ear drainage should prompt evaluation for recurrence.

## FUTURE

We are just beginning to understand the role of biofilms in many head and neck diseases. In cholesteatoma, there is some evidence that biofilm formation contributes to the erosive nature of cholesteatoma, but the evidence is still limited.[46] With improved perinatal imaging techniques the pathophysiology of cholesteatoma may be elucidated further. In the future, diffusion weighted MRI may aid in diagnosing cholesteatoma at the outset or even monitoring for recurrent disease. Use of otoendoscopes may aid in better eradication with first surgeries, leading to less need for second look procedures or even canal-wall-down mastoidectomies.

# Auditory Neuropathy Spectrum Disorder (ANSD)

*L Ashleigh Greenwood, Thierry G Morlet*

## INTRODUCTION

Auditory neuropathy spectrum disorder (ANSD) is an increasingly recognized hearing disorder with a variety of behavioral presentations, ranging from mild difficulty hearing in background noise to profound hearing loss.[1,2] Unlike traditional sensorineural hearing loss (SNHL), where dysfunction stems initially from damaged or absent outer hair cells, ANSD is characterized by the dysfunction of the inner hair cells, the auditory nerve, or the synaptic region connecting the inner hair cells to the auditory nerve.[2–8] Approximately 1 in 10 cases of identified SNHL are ANSD.[9,10] Often the exact etiology of ANSD remains unknown and genetic testing is unyielding. Predicting the appropriate course of intervention is difficult in infants and young children who are unable to offer behavioral information regarding their sound awareness. Even when hearing thresholds are finally identified in the younger population they are usually not reflective of true speech understanding abilities. In addition, those with ANSD who seem to function successfully in quiet often struggle greatly when listening to speech in the presence of background noise.[1,6,11,12] The wide variety in behavioral presentation also makes speech and language development extremely difficult to predict in infants and children. Frequent assessment of behavioral hearing, combined with periodic speech and language evaluations, seem to be the current gold standard to determine the most appropriate course of intervention on a case-by-case basis. Electrophysiologic assessment beyond the level of the auditory brainstem response (ABR), such as the cortical auditory-evoked potential (CAEP), may also prove to be useful in predicting speech and language outcomes in small children.[13] It is important to gain a better understanding of speech and language outcomes in each individual child, so that the most appropriate form of intervention may be selected, to help the child develop normal speech and language skills.

## PHYSIOLOGY OF ANSD

SNHL is a term that most otolaryngologists are familiar with identifying and most audiologists are familiar with treating, whether it is with hearing aids, speech therapy and/or cochlear implantation. Hearing evaluations were quite routine until the 1990s when hearing professionals began to question why some of their "Deaf" patients could respond to sound. The first report on auditory neuropathy was published in 1996,[6] which described 10 patients with dys-synchronous ABRs and present otoacoustic emissions (OAEs). Soon after Berlin et al.[9] discovered that 1–2% of hearing impaired children in schools for the Deaf in the United States had present OAEs and 10–12% had partial OAEs, indicating normal outer hair cell function in "Deaf" patients. Similar studies confirmed these numbers.[14] A more recent report of ANSD in an "at-risk" population of newborns found that around 5% of patients diagnosed with hearing loss were confirmed to have ANSD.[15] Thus, began the investigation into the physiology of ANSD and consequently the naming of the disorder.

One possible etiology for ANSD involves a dysfunction or absence of the inner hair cells within the cochlea. One row of inner hair cells lies medially within the organ of Corti in the cochlea and totals ~3000 at birth.[16] The inner hair cells are sensory cells responsible for transforming

mechanical energy from the traveling wave in the organ of Corti via stereocilia activation, to chemical signals, to electrical impulses that stimulate type I auditory nerve fibers. In some cases of ANSD, the inner hair cells are damaged or absent at birth.[3] There may also be a problem of the chemical neurotransmitters within the inner hair cells in those with ANSD, resulting in dys-synchronous firing of the auditory nerve. A mutation in the *GJB2* gene (coding for the connexin 26 protein) results in a presynaptic form of ANSD.[17] These patients may present with perception of sound but often have a difficult time understanding the meaning of a message due to the intermittent information traveling from the auditory nerve to the brain. Since the connexin 26 protein inefficiently processes potassium in these patients, inner cell death is inevitable and over time will destroy outer hair cells as well, leading to the "loss" of once present OAEs.[18] A mutation in the otoferlin (*OTOF*) gene also results in a dysfunction of the inner hair cells,[7] and auditory information cannot be appropriately transmitted to the auditory nerve. In these cases, outer hair cell function is preserved, and ABRs will be absent.[7]

Finally, the auditory nerve and/or brainstem auditory pathway nuclei may be dysfunctional in cases of ANSD. Children with cochlear nerve aplasia or hypoplastic nerves, gene mutations resulting in auditory neuron dysfunction, and disorders such as hyperbilirubinemia or progressive demyelinating disorders, will present with a hearing loss that is consistent with ANSD. There have been many cases of cochlear nerve aplasia, both unilaterally and bilaterally, which constitute a form of ANSD where the outer hair cells are working yet there is no behavioral perception of sound.[19] In other cases, magnetic resonance imaging (MRI) has revealed small but present cochlear nerves. This creates cases of ANSD with present and functioning outer hair cells, absent or grossly abnormal ABRs with the presence of a cochlear microphonic (CM), while the remaining nerve fibers deliver some incomplete sound information to the brain. A lack of the protein pejvakin results in a dysfunction in the neurons along the afferent auditory pathways in the brainstem.[20] This higher-up nerve dysfunction results in grossly abnormal ABRs, with intact cochlear hair cell function.[20] Hyperbilirubinemia, one of the biggest risk factors for SNHL and ANSD, has also been identified as a cause for destruction of auditory nuclei in the brainstem and auditory pathway neurons.[21] There are also true auditory neuropathies associated with demyelination of neurons in the brain, such as in Pelizaeus–Merzbacher disease (PMD). Those with PMD have normal neuronal connections in the brain; however, a mutation in the *PLP1* gene leads to abnormal myelination of the neurons which eventually leads to a progressive degeneration around the cortical nerve fibers.[22] Patients with PMD have absent or grossly abnormal ABRs in the presence of normal outer hair cell function, yet they are able to understand speech and language (depending on their level of cognition), though they have difficulty hearing in background noise.

## CLINICAL PRESENTATION OF ANSD

"Spectrum" was appropriately added to the title of auditory neuropathy in 2008,[23] and for good reason. The range of behavioral hearing in this disorder is vast and is inevitably different with every case. Often once behavioral hearing thresholds are obtained, they do not reflect the true ability of the patient to understand speech and language. For example, a patient with ANSD may have a sound awareness threshold in the mild hearing loss range, yet may have no ability to repeat a word spoken to them in quiet when visual cues are denied. From experience testing many children with ANSD in our clinic, we have observed some to exhibit pure-tone hearing thresholds in the moderate hearing loss range, and when presented with narrowband noise, their thresholds may improve to a mild hearing loss range. This may indicate that as more of the nerve fibers are stimulated, the better their sound awareness becomes. But we must be careful when interpreting thresholds with this disorder as they almost always indicate only a level of sound awareness and not speech understanding capabilities. The ability of patients with ANSD to understand speech in quiet and speech in the presence of background noise is still often severely impaired implying that the pure-tone audiogram is not indicative of the ability to understand and develop speech and language.

There are a few instances where, based on etiology, speech perception and speech development can be predicted. For example, those identified genetically with certain otoferlin mutations may initially present with OAEs and profound hearing loss.[4] These patients will not develop speech and language without the intervention of a cochlear implant and intense speech and language therapy. On the contrary, patients identified with unilateral cochlear nerve aplasia usually develop speech and language normally with their unaffected ear. They may require some mild intervention, e.g. the use of a frequency modulation (FM) system in the nonaffected ear, to help them in the classroom, and the extremes of using a hearing aid or cochlear implant are not necessary.

**Table 20.1:** Triaging auditory neuropathy spectrum disorder

| | *Tympanometry* | *MEMRs* | *OAEs* | *ABR* |
|---|---|---|---|---|
| Normal hearing | Type A—normal | Present | Present | Present |
| Sensorineural hearing loss | Type A—normal | Elevated or absent | Absent | Present according to degree of hearing loss |
| ANSD | Type A—normal | Elevated or absent | Present initially may become absent over time | Grossly abnormal or absent |

(ABR: Auditory brainstem response; ANSD: Auditory neuropathy spectrum disorder; MEMRs: Middle ear muscle reflexes; OAEs: Otoacoustic emissions).

Unfortunately, most of the time the etiology of the ANSD is unknown, and it is impossible to predict how an infant or small child perceives sound and consequently how they will develop speech and language. This gives foundation for frequent speech and language evaluations, performed by speech-language pathologists, throughout the first few years of life. By monitoring speech and language development, at a certain point it will become clear as to whether or not the child will develop speech and language, and if intervention is needed. If the child exhibits some sound awareness (i.e. looking when the dog barks) he or she may seem to have appropriate receptive language skills at a very young age. As the child becomes older, the speech and language evaluations will monitor this progress and determine if both receptive and expressive language skills are emerging appropriately per their age range.

If speech and language development does not seem to be progressing as the parents would like, intervention may be warranted. The first form of intervention for ANSD is an FM system, hearing aids, or both used together. An FM system and hearing aids may be more useful for children with ANSD who are able to understand speech and language in quiet, but struggle in background noise.[24] The most extreme form of intervention would be cochlear implantation. In cases where the VIIIth nerve is absent on the MRI, and the absence is confirmed by no ABR, no behavioral response (whenever possible) and no cortical response, cochlear implants are not warranted. There have been approximately five cases in our clinic over the past few years where the VIIIth nerve appears absent on the MRI; however, there is evidence of some neural synchrony on the ABR and/or some behavioral responses to sound with functional sound perception. These rare cases reinforce the need for the cross-check principle[25] not only within the realm of audiology, but also between disciplines, when managing and making recommendations for children with ANSD.

## AUDIOLOGIC ASSESSMENT

A full audiologic evaluation is the best way to differentiate an individual with ANSD from an individual with SNHL, and it can aid in determining his or her ability to understand and produce speech. Specifically, there are three tests within the audiologic evaluation that can diagnose definitively the presence of ANSD: middle ear muscle reflex (MEMR) assessment, OAE assessment, and an ABR evaluation. The results of this "triage" of tests can rule out or confirm the presence of ANSD.[1] A quick reference for these tests and their outcomes in normal hearing patients, those with SNHL, and those with ANSD can be found in Table 20.1.

### Acoustic Immittance

Audiologists, much like otolaryngologists, evaluate middle ear function first and foremost. Audiologists use acoustic immittance to investigate tympanic membrane movement via tympanometry, to determine the presence of normal middle ear function. In the presence of normal middle ear function, i.e. no fluid or middle ear disease, an MEMR threshold search can be performed. MEMRs are evaluated by using a probe attached to the tympanometer to create a pressure tight cavity in the ear canal. Once a seal has been obtained a series of loud beeps (up to 110 dB HL) are presented to the ear. The middle ear mechanically transmits the signal into the inner ear, and then the VIIIth nerve sends the signal to the cochlear nucleus in the medulla. The signal is then transmitted to the ipsilateral and contralateral superior olivary complex which is where the VIIth cranial nerve nuclei are located. A branch of the VIIth nerve connects efferently to the stapedius muscle in the middle ear space. If the VIIth nerve nuclei has enough stimulation (i.e. the sound is loud enough), it will trigger a reflexive contraction in the stapedius muscle. The contraction of the stapedius muscle slightly stiffens the motion of the bones in the middle ear, which lessens

the transduction of sound into the inner ear. Present MEMRs indicate that the VIIth and VIIIth nerves are intact but also that IHCs are functional. In patients with ANSD, the MEMRs will be absent, or in some cases, can be present yet extremely elevated in threshold.[26,27] This is due to the site(s) of lesion in ANSD, indicating a breakdown in the transmission of the auditory signal beyond typical outer hair cell (sensory) hearing loss. However, the MEMR will be absent or elevated in those with traditional severe to profound SNHL, therefore relying on acoustic reflexes alone to determine the presence of ANSD is not possible.

## Otoacoustic Emissions

In addition to evaluating MEMRs, audiologists also evaluate outer hair cell function via assessment of OAEs.[28] These OAEs are the by-product of the contractile properties of the outer hair cells. These properties play a crucial role in amplification and of fine frequency discrimination of sounds reaching the cochlea.[29] When the outer hair cells are present and functioning appropriately, an OAE can be elicited. In patients with ANSD, since the outer hair cells are usually unaffected, OAEs are present. In some cases, OAEs will become absent with time due to over amplification from the use of high-power hearing aids. In those patients with traditional SNHL, OAEs will be absent in the frequency range where more than a mild hearing loss is present. Baffling to many audiologists before the discovery of ANSD were patients with severe to profound hearing loss with present OAEs. Therefore, one hallmark of ANSD is the presence of OAEs with a moderate, severe, or profound hearing loss.

## Auditory Brainstem Response

The final piece of information necessary to make a diagnosis of ANSD is the ABR. This electrophysiologic evaluation requires the use of noninvasive electrodes attached to the head to measure electrical activity along the auditory brainstem, indicating sounds are reaching specific nuclei. This procedure can be performed on patients while they are awake if they are able to be still. In most instances, the ABR is performed on sedated infants or small children who are difficult to test behaviorally. The ABR can be used to estimate frequency-specific hearing thresholds by presenting toneburst stimuli to each ear via insert earphones. To rule out the presence of ANSD, click stimuli are presented to each ear using two different polarities, rarefaction and condensation, to ensure a true neural

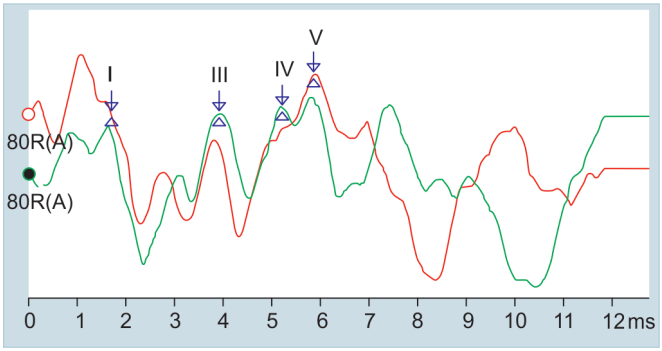

**Fig. 20.1:** An ABR in an individual with normal hearing recorded with both rarefaction (green waveform) and condensation (red waveform) polarities. (ABR: Auditory brainstem response).

response. In those with normal hearing, a normal ABR will reveal the presence and repeatability of waves I–V, when both polarities are overlapping (Fig. 20.1). Those with ANSD have an absent or atypical neural response represented by the ABR. They exhibit what appears to be a mirror image of waveforms when using the rarefaction and condensation polarities, instead of repeatable waves I–V. This mirror image is created by the CM, the gross electrical potential from all of the hair cells in the cochlea, triggered by the simple movement of the traveling wave along the basilar membrane. When the polarities are reversed, the electrical signal from the hair cells in the cochlea will follow the change in stimulus polarity, and the CM will invert. In the past, many audiologists would only use one polarity and run it twice to check for repeatability of morphology. Often the CM can "ring", and if only one polarity is used, a cochlear response may be mistaken for waves I–V. Therefore, it is absolutely pertinent to run two different polarities at high intensities to investigate if there is a true neural response from the auditory nerve and brainstem, or if there is just a response originating from the cochlea.[30] In ANSD, the CM varies in amplitude and duration. It can ring for several milliseconds or be much shorter as shown in Figure 20.2.

## Additional Electrophysiologic Assessment

Several investigators[31] are currently examining cortical auditory function in infants and young children diagnosed with ANSD to better understand cortical maturation, using CAEPs. Present CAEP responses, indicated by a positivity around 80–100 ms (P1) and a negativity around 200 ms (N2), indicate that sound is reaching the primary auditory cortex in the temporal lobe. In addition to identifying

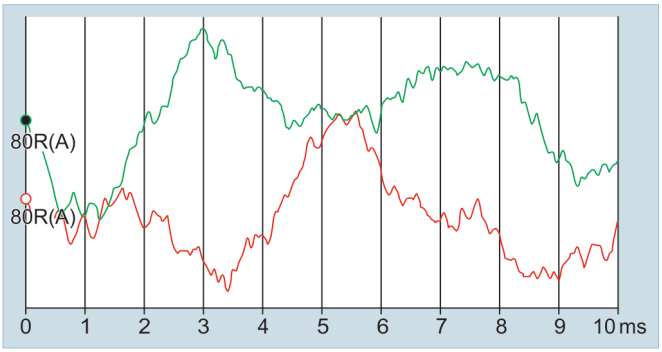

**Fig. 20.2:** An ABR in an individual with ANSD, with only a small cochlear microphonic (CM) and no neural response. (ABR: Auditory brainstem response; ANSD: Auditory neuropathy spectrum disorder).

the presence or absence of a response, the latency of P1/N2 also provides useful information in relation to the processing of the auditory signal in the cortex. The more delayed the latency of P1/N2, the longer it takes for an auditory signal to reach the primary auditory cortex, and therefore the more severely impaired the auditory pathway is presumed to be. Many children with ANSD have been observed to have a present P1/N2 response, although it is delayed in about one third of children.[31] In our laboratory, we have seen 18 children with ANSD for CAEP testing, in which 10 had present CAEPs bilaterally, and 6 had present CAEPs in only one ear, for a total of 89% of children with ANSD exhibiting a present cortical response. Please see Table 20.2 for a further breakdown of CAEPs in our ANSD population. Some investigators[31] are also beginning to investigate cortical auditory development in children fitted with hearing aids or cochlear implants. Speech and language development is almost impossible to predict in children with ANSD, unless a clear site of lesion can be identified and confirmed by behavioral testing, as in cases where the MRI reveals the absence of a cochlear nerve, or genetics testing reveals a specific genetic mutation. In most cases, etiology is unknown and therefore predicting sound perception and speech-language development is impossible. Cardon and Sharma[31] have found, using CAEPs, that the latency of P1 postcochlear implant correlates positively to speech perception measures, i.e. the more delayed in latency the P1 is, the more delayed speech and language perception appears. Through their research, Cardon and Sharma[31] have demonstrated that using CAEPs can provide clinical utility in helping to predict speech and language outcomes in the ANSD population. The CAEP may one day prove significant in predicting the best means of intervention for a child with ANSD based on the presence and latency of the P1/N2 response. Future research is geared in this direction.

## Behavioral Audiologic Evaluation

The staple of audiologic behavioral testing is the audiogram, which uses behavioral responses to map out perception of hearing. A listener is asked to raise their hand or press a button when they "hear the beep", which is usually a simple, single frequency, pure-tone stimuli delivered in a noiseless environment. The presentations are reduced in intensity until the listener can only detect the sound reliably about 50% of the time, therefore obtaining a threshold of hearing. Pure-tone perception is obtained in the low pitches, beginning usually with 250 Hz, up to the high pitches, around 8000 Hz. Ultrahigh frequencies can also be assessed, up to 20,000 Hz. Most patients with SNHL will exhibit an increase in hearing threshold at the frequencies where hearing loss, or cochlear damage, is present. The audiogram is a reliable tool for these patients and usually correlates well with speech understanding.[32] However, for those with ANSD, the audiogram may reflect sound awareness, but does usually not reflect the true ability to understand speech. In theory pure-tone stimuli only stimulate one frequency that may only stimulate one or a few inner hair cells, which concurrently may only stimulate a few nerve fibers. As long as some of those inner hair cells and nerve fibers are working, the tone will be perceived. However, if there is not a complete ability of the inner hair cells or the auditory nerve to capture rapid fluctuations in pitch and intensity, such as in conversational speech, an individual with ANSD might be able to perceive that someone is talking, but will not be able to understand what is being said. Therefore, the audiogram in patients with ANSD should be used in conjunction with other means of speech perception, such as word recognition in quiet and word recognition in background noise.

Word recognition is usually performed in the clinic by audiologists in order to make a comparable comparison to the audiogram. This is a simple task wherein the audiologist presents a list of 25 one-syllable words in quiet, at a clearly audible level, to each ear to get a percent correct score. Word recognition and the audiogram should reflect one another in those with normal hearing. If a patient is identified with SNHL, the words will be presented at a level that will still be clearly audible to them, and if the sound is not so loud that it is distorted, their scores are usually good in quiet. In patients who have ANSD, more often they perform

**Table 20.2:** CAEPs in ANSD

| *Subject ID* | *Age (years)* | *ABR* | *CAEP* | *Delayed P1* | *Delayed N2* | *Abnormal morphology* | *Reduced amplitude* | *Speech development* |
|---|---|---|---|---|---|---|---|---|
| 1 | 9.6 | Absent | Bilateral | Yes | Yes | No | Yes | Age appropriate |
| 2 | 2.2 | Absent | No response | N/A | N/A | N/A | N/A | Delayed |
| 3 | 5.4 | Absent | Right ear only | No | No | No | No | Delayed |
| 4 | 8.6 | Abnormal | Bilateral | Yes | No | Yes | Yes | Delayed |
| 5 | 0.9 | Absent | Bilateral | Yes | Yes | No | Yes | In progress |
| 6 | 0.5 | Abnormal | Bilateral | Yes | Yes | Yes | Yes | In progress |
| 7 | 5.1 | Absent | Left ear only | No | No | No | No | Age appropriate |
| 8 | 1.1 | Absent | Right ear only | No | No | No | No | Delayed |
| 9 | 0.6 | Abnormal | Bilateral | Yes | No | No | No | Delayed |
| 10 | 9.9 | Absent | Left ear only | Yes | Yes | No | Yes | Delayed |
| 11 | 10.4 | Absent | No response | N/A | N/A | N/A | N/A | Delayed |
| 12 | 1.6 | Absent | Bilateral | Yes | Yes | Yes | Yes | Delayed |
| 13 | 1.5 | Absent | Left ear only | Yes | Yes | No | No | Delayed |
| 14 | 0.8 | Absent-left ear; present in the right ear | Right ear only | Absent | Yes | Yes | Yes | Delayed |
| 15 | 6.7 | Abnormal | Bilateral | Yes | Yes | Yes | Yes | Delayed |
| 16 | 4.8 | Absent | Bilateral | No | No | No | No | Delayed |
| 17 | 1.2 | Absent | Bilateral | Yes | Yes | No | No | In progress |
| 18 | 1.4 | Absent | Bilateral | Yes | Yes | Yes | Yes | Delayed |

(ANSD: Auditory neuropathy spectrum disorder; CAEPs: Cortical auditory-evoked potentials).

much worse on word recognition than their audiogram would suggest.[6,12] There are a few patients, however, that will still excel with word recognition, as long as the words are presented in quiet. When speech is presented to the listener in noise, word recognition becomes much harder and almost impossible for those with ANSD.

### Speech Language Evaluation

The variation in clinical presentation of hearing loss in ANSD leads to difficulties predicting speech and language development in infants and young children. Due to earlier identification with newborn hearing screenings, more and more infants are being identified with ANSD shortly after birth. Therefore, the challenge lies in determining if and how these children will develop speech and language skills. Parents are encouraged to have an early baseline speech and language evaluation. Usually these evaluations will consist of parental interviews and observation of the child in the evaluation session. Based on the findings of this initial evaluation, the speech language pathologist will recommend periodic evaluations to track the progress the child is making. The speech language evaluations in the first 18 months of life are the most pivotal in indicating if the child will develop speech and language without any type of intervention.

## ETIOLOGY OF ANSD

### Genetic Links

Manchaiah and colleagues[33] provided an excellent review of the genetic causes of ANSD, and Sininger[10] estimates that up to 40% of ANSD cases may be due to genetic dysfunction. Many nonsyndromic mutations have been reported on in the literature and have a phenotype consistent with ANSD, including otoferlin (DFNB9), pejvakin (DFNB59), and connexin 26 (GJB2). A clinical presentation of ANSD can also be found in many well-known hereditary syndromes involving neurological degeneration, such as Friedreich ataxia, Charcot–Marie–Tooth (CMT) disease, and PMD. Please see an earlier section for more information on these syndromes.

There are a few nonsyndromic mutations that are well reported on in the literature. The protein otoferlin is expressed in the inner hair cells within the cochlea, and when a mutation occurs, the inner hair cells become dysfunctional,[7,33] therefore, impeding a clean chemical signal from reaching the auditory nerve.

### Risk Factors

There are many risk factors and red-flags for infants and children with ANSD. In our experience, and in the literature, two of the biggest red-flags when investigating the presence of ANSD is a birth history including a stay in the neonatal intensive care unit (NICU) and prematurity.[1,10] An estimated 3 out of 1000 infants admitted to the NICU are at risk for being identified with ANSD.[10] There are many reasons a child may be transferred to the NICU after birth, and many of those have been identified in the literature as risk factors for ANSD: low birth weight, brain trauma including anoxia, exchange transfusions, respiratory distress and/or artificial ventilation, ototoxic drugs, and anemia.[1]

One of the two most common risk factors for children identified with ANSD is a history of hyperbilirubinemia.[1,10] The accumulation of bilirubin in children with jaundice has been shown to have a detrimental effect on the auditory nuclei in the brainstem as well as some parts of the auditory nerve.[21] The other most common risk factor for children identified with ANSD is a positive family history of hearing loss.[10] Berlin and colleagues[1] report that approximately 16% of their 260 patients with ANSD have a genetic link, while Sininger[10] estimates up to 44% of children have a positive family history of hearing loss. Although there is a discrepancy in these numbers, it is important to understand that family history of hearing loss should be explored. It is important to note that approximately 38.5% of children identified with ANSD have no accompanying risk factors and a normal birth history.[1] If there is no family history of hearing loss or acquired trauma in these cases, it is almost impossible to determine the etiology of their ANSD.

## MANAGEMENT OF ANSD

Since the behavioral presentation of ANSD varies greatly from one case to the next, the first step in managing this disorder involves close monitoring of the child's hearing and speech abilities. Routine audiologic assessment is crucial in monitoring the degree of sound awareness in those with ANSD, especially in infants. With an increase in newborn hearing screenings, ANSD is able to be identified in infancy, provided the correct protocol of OAEs and ABRs are used, yet infants are unable to indicate what they are hearing and comprehending. Serial audiograms are important in monitoring an infant's sound awareness and localization abilities, as they develop over the first few years of life. However, the meaningfulness of an

infant or child's level of sound awareness is extremely important to assess, and should be frequently monitored via speech and language evaluations. Receptive and expressive language abilities can be explored via routine parental questionnaires beginning in infancy, and through speech and language evaluations as the child ages. The key is to focus on the amount of progress the infant or child is making from one speech and language evaluation to the next. Progress in both expressive and receptive speech and language skills will be the biggest predictor of how and how fast to move forward with intervention for these children.

### Working in an Interdisciplinary Team

At the same time serial audiologic evaluations and speech and language evaluations are occurring, it is often pertinent to involve other areas of medicine, to obtain the full picture of the child and their diagnosis of ANSD. Usually imaging studies are the first course of action recommended by otolaryngologists to investigate possible malformations as the etiology for ANSD. A consultation with a genetic counselor is usually beneficial to find hereditary or nonhereditary mutations or associated syndromes that may be associated with ANSD, such as GJB2-related deafness. An ophthalmology referral is also helpful to rule out any visual problems in the child and to rule out any comorbid progressive disorders, such as Ushers syndrome. A neurology consultation is useful in investigating overall brain function and to investigate the presence of other neuropathies in the body in very young infants and children that may or may not be apparent. A vestibular evaluation is also helpful to assess balance function and to help decide the preferred side for cochlear implantation.

## INTERVENTION

Most children with ANSD will require some sort of intervention in order to develop expressive and receptive speech and language skills. Berlin and colleagues[1] reported that only 5% of their 260 patients with ANSD developed normal speech and language skills without any type of intervention. All children with ANSD who are not showing expected progression of speech and language skills will go through a trial period of amplification, before moving on to more complex interventions such as cochlear implantation.

### Cued Speech

For some parents of children with mild forms of ANSD, the first recommended strategy is to incorporate cued speech into the child's life. Cued speech involves differentiation between phonemes that are similar in appearance by using hand gestures around the face and mouth. It differs from American Sign Language (ASL) in that it is not a language in itself, but rather a manual assistant for any spoken language. Similar to ASL, it does require a certain amount of training to learn the different hand gestures. Cued speech may be beneficial for children who have a milder form of ANSD, with good speech perception in quiet and also in children pre/post cochlear implantation.

### Frequency Modulation Systems and Hearing Aids

Frequency modulation (FM) systems are useful for children who have a milder form of ANSD. Since ANSD is generally a problem of clarity, not volume, the FM system is ideal in providing a clean signal directly to the ear. The FM system consists of a microphone, worn by a speaker, and a receiver, worn by the individual with ANSD. The FM system does not overly amplify the voice of the speaker, but instead allows the message to be clearly transmitted to the individual with ANSD, overcoming background noise. The preferred form of FM system for these children is a personal FM, in which an ear-level receiver is worn by the child. In a classroom, the teacher's voice would transmit through the microphone to the receiver placed at the child's ear. The FM system is especially beneficial in situations with background noise, such as a full classroom. Some children with ANSD benefit from hearing aids paired with an FM system. Most of the time the hearing aids have a mild amount of gain (amplification) in conjunction with the FM system sending a speakers voice directly to the ear. In our experience, about 9% of children with ANSD are successful communicators with an FM system, hearing aids, or both. This is comparable to the literature, which estimates that 15% are successful with traditional amplification.[1]

More commonly, children with ANSD have elevated sound detection thresholds in conjunction with an unclear auditory signal. In these cases, the FM system alone is not enough and amplification is also required for the child to make meaning of sounds and conversation. We recommend the use of a trial period of amplification with loaner hearing aids, as 15% of ANSD patients will benefit from HA.[1] In our clinic, 9% of our ANSD patients who tried hearing aids reported the successful use of hearing aids to develop speech and language. The benefit of the trial period of amplification is to see if hearing aids and FM alone will provide a clear enough auditory signal for the child to

develop speech and language successfully. The hearing aids will be set initially with a very low output. If the low output does not seem to be enough to help the child with sound awareness, and the child is tolerating the hearing aids, then the volume will be increased. Again speech and language development and parental observation will be the most important predictors of success with the hearing aids. A speech and language evaluation should be obtained before and after hearing aid use, to monitor for any help the hearing aids may be providing for the child. After a short trial period with hearing aids, if progress is noted on the speech and language evaluation, and parental observation indicates the child is benefiting from the use of the hearing aids, the child may continue to wear them. Their speech and language development will be closely monitored to assure they are making the appropriate amount of progress in speech development with hearing aids alone. If the child plateaus in speech and language development with hearing aid use, then more aggressive options may be pursued at that point. If the child fit initially with hearing aids is not tolerating them, and little to no progress is made between speech and language evaluations, then the option of a cochlear implant may be more rapidly pursued. While hearing aids may be an option for some children with ANSD, in our clinic, 83% of children who tried hearing aids saw no progression in speech and language development. This is why we do not recommend an extensive hearing aid trial and a few months are usually sufficient to attest the tolerance and progress or lack of thereof in terms of speech and language development.

## Cochlear Implants

The most extreme form of intervention for a child with ANSD would be cochlear implantation. In many cases of unknown etiology, or in the presence of small or dyssynchronous nerve firing, the cochlear implant will send a unified electrical signal to the auditory nerve and provide enough sound for a child to develop speech and language. Once a trial period with hearing aids is exhausted, and speech and language is not developing age-appropriately, a cochlear implant may be recommended. Cochlear implants are a successful means of intervention for many children with ANSD, who do not show improvement with the use of hearing aids.[34,35] Berlin and colleagues[1] estimate that 85% of children who have been implanted showed successful improvement in speech comprehension and language acquisition, while slow progress was observed in 2%, uncertainty in 4% and lack of data in the remaining children because they were recently implanted at the time of the study. So far in our clinic, the majority of children who have been implanted, and for whom follow-up data are available, are also successful users in terms of speech and language development.

The cochlear implant consists of an internal device, an external device, and a sound processor. The internal device contains an electrode array that is inserted into the cochlea. The electrode array bypasses any dysfunction of the inner hair cells and/or the junction between the inner hair cells and the auditory nerve in those with ANSD. The unified electrical signal from the electrode array placed in the cochlea is also believed to better synchronize a dyssynchronous signal in those with ANSD.[36] In children with typical SNHL, the sooner the child can be implanted, the better chance the child will have to gain age appropriate speech, language, and auditory skills. The same is true for children with ANSD. Recent research has shown that children with ANSD implanted at an earlier age have better cortical maturity than children with ANSD implanted at a later age.[31] However, the age at implantation in ANSD varies greatly because of the uncertainty of a specific child outcome.

## Auditory Verbal Therapy

Auditory verbal therapy (AVT) is a crucial step in developing age-appropriate speech and language skills once a child has been implanted. AVT is a type of aural rehabilitation that does not focus on the end product of articulation, but rather emphasizes the pragmatics of language. The child is enriched in language during a therapy session, with the end goal being some form of meaningful communication between the therapist and the child. After receiving a cochlear implant, AVT is mandatory in most centers, so the child learns to listen with the cochlear implant and eventually develops speech and language using the implant. After a few years of AVT, the typically developing child with ANSD using a cochlear implant will graduate from therapy as a successful listener and communicator. AVT is usually not recommended before implantation because the lack of visual cues impairs the child's understanding.

# CONCLUSION

It is estimated that 10% of individuals who present with SNHL loss have ANSD.[9,10] The physiologic dysfunction of ANSD appears to be in the inner hair cells, the synaptic

region connecting the inner hair cells to the auditory nerve, or the auditory nerve itself.[2–8] The gold standard for identifying ANSD clinically is to use a "triage" of tests: OAEs, MEMRs, and ABRs.[1] Unlike traditional SNHL, pure-tone audiograms may not yield a complete picture of functional hearing abilities in those with ANSD, and may indicate more of a sound detection level. Many patients with ANSD will have great functional difficulty listening in background noise.[1,6,11,12] The best tool to measure progression of speech and language development, especially in children and infants with ANSD, are routine speech and language evaluations. The progress made between each speech and language evaluation is pertinent in determining the best course of intervention, in order to develop age appropriate speech and language skills: no intervention, FM system, hearing aids in conjunction with an FM system, or a cochlear implant. Future research is directed at better predicting speech and language outcomes in children with ANSD, using CAEPs.[13]

## CASE STUDIES

### Case Study 1—Susie

Susie began struggling academically, at the age of 7 years, and was referred for a hearing assessment for suspected ANSD. Medical history was significant for many risk factors, including extreme prematurity at 28 weeks' gestation and a prolonged stay in the NICU where ototoxic medications were administered for infection. She required some ventilation assistance after birth for an unknown length of time, and she developed severe jaundice which was treated with phototherapy. Susie reportedly passed her newborn hearing screening in both ears. Upon meeting Susie, she was very friendly and appeared to have age-appropriate articulation. Her audiologic evaluation revealed absent ipsilateral and contralateral MEMRs in the right ear, and partially present yet elevated MEMRs in the left ear. She had partial OAEs bilaterally. Her audiogram showed mild hearing loss in the low to mid frequencies, steeply sloping to a moderately severe hearing loss in the high frequencies; configuration was symmetrical bilaterally. Her word recognition was good in quiet and in noise. Susie's ABR revealed a present CM and some neural synchrony, as indicated by a possible delayed wave V, bilaterally. Due to her elevated/absent MEMRs, partially present OAEs, and grossly abnormal ABR with a present CM, Susie was confirmed to have ANSD. Susie went on to receive a speech and language evaluation that revealed some expressive and receptive speech and language delays, and the fact that Susie relied heavily on lip reading. Susie was fit with bilateral low-gain amplification paired with an FM system. She initially adapted to the amplification well, and used the hearing aids during school and outside of school. After a few months, she no longer tolerated the hearing aids and stopped wearing them. She continues to wear the FM system in school. She is making slow but steady progress academically. Her teachers and her family report that she has "good" and "bad" hearing days, and this is reflected in her ability to retain information. Susie was monitored periodically, every 6 months, and her ANSD remained essentially stable, with good perception of speech in quiet and fair perception of speech in background noise. Susie is certainly the exception when it comes to perceiving speech in background noise. Due to her success with speech perception and her slow but steady academic gain, Susie was not referred for a cochlear implant and was encouraged to continue to use her FM system.

### Case Study 2—Sammy

Sammy was also a late ANSD identification, arriving to our clinic at 5 years of age. Sammy had a history of ongoing ear infections and an active personality, making him difficult to evaluate behaviorally. He reportedly passed his newborn hearing screening in both ears. Around 18 months of age he began to present with some developmental delays and received speech language therapy, occupational therapy, and physical therapy. An MRI study at that time revealed a decrease in myelination in the sensory areas of the brain. A second MRI at 3 years of age indicated a normal amount of myelination and no further concerns for developmental delays. However, speech and language skills did not seem to progress as hoped. Sammy was taken for an audiologic evaluation at an ENT clinic at the age of 4, where he demonstrated normal perception of pure-tones bilaterally. He was unable to picture point for a given word without visualization of the audiologist's mouth. He was referred for a sedated ABR at a local hospital. First, his OAEs were evaluated and were partially present bilaterally. His ABR revealed no neural response at equipment limits of 99 dB nHL with a small CM that reversed with a change in polarity. Due to partially present OAEs and a grossly abnormal ABR with a present CM, Sammy was confirmed to have ANSD. Sammy arrived at our facility at the age of 5 for a CAEP evaluation. The CAEP evaluation revealed present cortical responses with fairly age appropriate latencies bilaterally, with a stronger response in the left ear. Sammy was recommended to have a trial period with hearing aids and an FM system, and his family was also

recommended to implement the use of cued speech. Sammy immediately showed benefit when wearing the hearing aids and requested to wear them daily. A speech language re-evaluation approximately 1 year post hearing aid use revealed some improvement in receptive and expressive speech and language development, although he was still classified as delayed. His articulation had also improved, though he was very difficult to understand to those unfamiliar with him. Sammy continued to be monitored at our clinic every 6 months.

Just before Sammy turned 6, he returned to our clinic for a CAEP evaluation. His parents expressed great concern that his speech and language development had plateaued. They were also deeply concerned that Sammy was not making friends in school due to his inability to communicate effectively. His CAEP evaluation showed a drastic decrease in cortical responses, and a subsequent speech and language evaluation revealed a heavy reliance on facial cues to understand a spoken message. The family was referred to the cochlear implant team for evaluation for candidacy at that time. When Sammy was 6.3 years of age, he received a unilateral cochlear implant. At this time he is mainstreamed in school and is receiving intensive AVT, both in school and outside of school. He is learning to adjust to his implant and he utilizes his amplification on the ear without the implant. Sammy's most recent speech and language evaluation revealed some progress when listening for speech and language with his cochlear implant. However, he will require continued intensive AVT in order to develop age-appropriate speech and language skills, without visual cues.

## Case Study 3—Abby

Abby was referred to our clinic at 6 weeks of age for an audiologic evaluation, due to three prior failed newborn hearing screenings. Abby had no birth complications, no risk factors for ANSD, was born full term, and had no family history of hearing loss. Her parents reported at the time of the ABR that she was startling to loud sounds in the home. Her audiologic evaluation revealed absent MEMRs and partially present OAEs bilaterally. Abby's ABR revealed a robust CM with no neural synchrony, bilaterally, and she was officially diagnosed with ANSD. At 5 months of age, Abby had her first audiometric evaluation in the sound booth, which revealed a speech awareness threshold in the mild/moderate hearing loss range. Abby was referred for genetic testing at that time, for which the otoferlin mutation was negative. She was referred to the cochlear implant team for evaluation for candidacy.

At 10 months of age, Abby was fit with bilateral low-gain amplification. Another booth test again revealed sound awareness in the moderate hearing loss range. At that time, Abby had imaging performed (CT and MRI) that revealed no anomalies in the brain or auditory system. Her first speech and language evaluation was performed at 1 year of age, and revealed a severe expressive and receptive language delay. Abby continued to be monitored periodically with hearing evaluations, which revealed no benefit with the hearing aids. Her parents reported that her hearing seemed to fluctuate, and that she had "good hearing days and bad hearing days". They noticed no difference in her hearing with her hearing aids on. At 18 months, Abby received her right cochlear implant. Immediately after activation, Abby received AVT both in the home and also through our clinic. She made great strides in speech and language acquisition in such a short amount of time that her parents decided to implant her other ear at 2.5 years of age. Abby continues to be enrolled in AVT in our clinic, and she receives AVT in school. She is in a mainstream preschool and continues to make strides in her speech and language skills.

CHAPTER

# Osseointegrated Implants and Implantable Hearing Aids in the Pediatric Patient

21

*Nikhila Raol, Michael S Cohen*

## INTRODUCTION

Osseointegration is defined as a process whereby clinically nonsymptomatic rigid fixation of alloplastic materials is achieved, and maintained, in bone during functional loading.[1] Osseointegrated implants were first used in otolaryngology in the extraoral setting at Sahlgren's Hospital, Sweden, in 1977.[1] In this setting, bone-anchored hearing aids (BAHA) were fastened to a skin-penetrating attachment. The success was noted to be about 98% in 389 cases, with a success rate of 85% in irradiated bone and nearly 100% in nonirradiated bone, at a follow-up of up to 5 years.[2] In 1996, use of the BAHA in the United States was approved by the Food and Drug Administration.[3] Since that time, routine use has been established in patients with bilateral conductive hearing loss who cannot tolerate traditional hearing aids, single-sided deafness, and congenital ear anomalies with hearing loss. Several types of osseointegrated devices now exist, including the Sophono, SoundBite, or Sonitus, and the Vibrant Soundbridge (VSB). Successful utilization of the BAHA in the pediatric population began in 1983, and FDA approval for the device was established for children over the age of 5 in 1996. This chapter discusses the use of osseointegrated implants in the pediatric population.

## CRITERION FOR IMPLANTABLE HEARING AID PLACEMENT

Indications for bone-anchored hearing device in the pediatric population include (1) congenital aural atresia, (2) congenital microtia, (3) chronic suppurative otitis media, (4) persistent otitis media with effusion, (5) chronic otitis externa, (6) unilateral profound hearing loss, (7) unilateral mixed hearing loss, (8) failure with conventional aids, and (9) trauma to the ear (i.e. traumatic ossicular discontinuity).[4] Mounting evidence suggests that children with unilateral profound sensorineural hearing loss, which presents in 0.1–3% of the pediatric population, get significant benefit from BAHA placement; FDA approval for this indication came in 2002. Implantation is only approved in the pediatric population, however, for age 5 years and over, primarily due to the thought that this would allow for adequate skull thickness to be present (at least 3 mm). However, no consensus exists for the minimum age requirement, and children as young as 14 months old have been successfully implanted.[5] Younger age of implantation has been associated with increased perioperative complications due to thin calvarial bone, such as necessitation of multiple drilling sites[6] and incomplete insertion of fixtures with failure of osseointegration.[7] Exposure of dura mater and/or sigmoid sinus is common, occurring in up to 70.5% of pediatric BAHA cases.[6] Granström has used bone augmentation with expanded polytetrafluoroethylene membranes in children with limited bone thickness (< 2.5 mm) without complications.[8]

### Bone-Anchored Hearing Aids

Prior to the development of the BAHA, children were offered the conventional bone conduction hearing aid. A vibrator attached a headband or in an eyeglass frame was used to conduct sound to the bone (Fig. 21.1). However, the discomfort caused by the pressure needed

**Fig. 21.1:** The transcutaneous BAHA Softband in a young child, not yet old enough for percutaneous BAHA application.

for sound conduction as well as the sound distortion that occurred due to soft tissue interference prior to reaching the bone made this a less than ideal method for hearing amplification. The BAHA transmits sound energy directly to the cochlea from the external transducer without the damping effect of the intervening soft tissue. This allows for a 10–20 dB HL decrease in audiometric thresholds. When combined with the decrease in discomfort and the cosmetically less conspicuous nature of the BAHA, this leads to increased compliance and ultimately improved outcomes for hearing impaired children.[9]

The Cochlear Baha is comprised of three parts: an osseointegrated titanium fixture (screw), which is implanted surgically in the postauricular calvarium, a percutaneous titanium abutment, and an external sound processor. The sound processor transduces vibrations from air to bone with corresponding intensity, via the percutaneous abutment and implanted fixture. This generates a frequency dependent elastic deformity of the bone cortex.[10] Audiometric criteria for BAHA implantation, as well as the type of hearing aid to be used, are defined by BC thresholds (measured at 0.5, 1, 2 and 3 kHz). A Baha Divino or Baha BP100 can be used for BC thresholds ≤45 dB HL, a Baha Intenso can be proposed for BC thresholds ≤55 dB HL, and a Baha Cordelle II is indicated for BC thresholds ≤65 dB HL with speech discrimination by BC ≥60%. Bilateral BAHA is indicated when the right BC is equal to the left BC with a mean maximum difference <10 dB. BAHA is indicated for single-sided deafness when BC thresholds of the healthy ear are ≤20 dB.[10] In 2009, Oticon introduced the Ponto bone-anchored hearing aid system, similar in composition (three parts) to the original Cochlear Baha. An additional feature of this system is the 10° inclination available for patients with problems due to the skin abutment.

## *Surgical Procedure*

Traditionally in children, a two-stage surgery has been used for BAHA placement. In the first stage, the titanium fixture is implanted into the skull in the superior postauricular region. In the initial description of the procedure, this was done via a U-shaped incision. However, since the 1990s, the linear incision technique has been used, ameliorating the need for a skin flap and therefore avoiding the risk of flap necrosis. After allowing 4–6 months for osseointegration to occur, the second stage is performed, where a skin graft/pedicled flap is placed, along with soft tissue reduction and abutment placement. This allows for a decrease in the skin complications of the procedure. Sleeper fixtures may also be implanted at the time of the first surgery to use in the case of extrusion of the first implant. One stage surgery has been proposed, similar to the procedure in adults, with a three-sided U-shaped incision or, now more commonly, with a linear incision. Studies have shown favorable outcomes for the properly selected patients, including Roman in 1996 without any increase in complication rate,[10] and Tietze and Papsin in 2001, for children over the age of 9 years where at least a 4 mm implant can be used.[9] In addition, excellent outcomes have been shown by Kohan in 2008, who proposed implantation of both a screw and a dormant safety fixture in a single stage after preoperative CT demonstrated adequate thickness of bone,[11] and the Nijmegan group in 2011, who found that children over the age of 10 years did well with two-stage or single-stage surgery via a linear incision.[12]

## *Outcomes and Complications*

The most common complication in pediatric BAHA practice is the periabutment soft tissue reaction, characterized by Holgers et al.[13] (Table 21.1).

An older study by Tjellstrom demonstrated reaction-free penetration in 64% of cases, but this number has improved significantly, with reaction-free outcomes seen in 84–92% of patients.[1,9] This is likely due to improved handling of the soft tissue around the abutment, with skin graft placement if needed at the penetration site. While the exact causative factor in skin reactions is unclear, multiple etiologies have been proposed. Khwaja et al. showed that

**Table 21.1:** Classification of skin reactions

| | |
|---|---|
| 0 | No irritation |
| 1 | |
| 2 | Slight redness |
| 3 | |
| 4 | Red and moist tissue, no granulation tissue |
| 5 | |
| 6 | Red and moist tissue with granulation tissue |
| 7 | |
| 8 | Revision of skin penetration necessary |

From Holgers et al.[13]

keratin may be the culprit, as they were able to demonstrate a foreign body reaction to keratin and keratinocytes at the titanium-bone interface.[14]

Dental implant studies have suggested that microleakage of bacteria between the implant and abutment may be a causative factor,[15–17] while biofilm has been found on implants with failure of osseointegration.[18] The recently-released Cochlear DermaLock abutments have a hydroxylapatite coating on the medial portion of the abutment that is designed to adhere to the surrounding soft-tissue envelope, theoretically decreasing the risk of wound complications. Long-term data on this new abutment design are forthcoming.

Retention of osseointegrated fixtures has been shown to be quite high in both the adult and pediatric population. While fixture survival rates are 90–100% in adults, recent studies have shown pediatric fixture survival rates to be 71–95%.[9] McDermott et al. reported a 14% rate of fixture loss, with a significant trend in children younger than 5 years.[19] A surgical revision rate of 22% and extrusion rate of 5.8% was noted by Granström, with greater skin flap revision needed between 6 and 12 years of age.[8] Zeitoun et al. demonstrated a failure rate of 11.2% of fixtures.[7] Ida et al. identified a complication rate of 46%, with complication assigned to any child requiring revision in the operating room. An 8% extrusion rate was noted, with trauma and infection being the most common causes for extrusion. In addition, longer follow-up, staged procedure, and presence of a craniofacial syndrome were all associated with complications.[3]

Single-stage procedures have become increasingly popular in the pediatric population. Davids et al. demonstrated that two-stage BAHA implantation with a prolonged interval between stages leads to increased survival of implants in children 5 years and younger when compared to older children.[5] However, Ali et al. showed no failure of osseointegration in their study of 30 children who were all implanted in a single-stage fashion, 7 of whom were under 5 years of age.[20] Maximum follow-up was 8 years for these patients. Improvement in audiometric thresholds from preimplantation has been noted to be significant, with thresholds dropping as low as 0–20 dB with a speech discrimination of 100% at 40 dB.[20]

Lowering of audiometric thresholds when compared to conventional bone conduction hearing aids has also been shown; studies by Tietze et al. and Stevenson et al. have shown approximately a 5 dB lowering of the threshold in the speaking range on 0.5–4 kHz. In addition, multiple additional studies have demonstrated subjective improvement in sound quality and speech using patient/parent questionnaires.[21–23]

Increasing literature about the benefit of BAHA implantation for unilateral profound sensorineural hearing loss has shown benefit in adults, with Hol et al. demonstrating improved ability to understand speech in noise and a lifted head-shadow effect,[24] but the pediatric literature remains limited. A study by Christensen et al. demonstrated significant benefit, using the Hearing in Noise Test (HINT) and Children's Home Inventory for Listening Difficulties (CHILD) questionnaires. Preimplant HINT mean scores at the speech-noise ratio were 42%, 76%, and 95% at 0, 5, and 10 dB, respectively, while postimplant HINT mean scores improved to 82%, 97%, and 99%. CHILD scores also improved for both patients and parents. While all ages of implanted children received benefit, the greatest benefits were seen in the teenage group.[25]

## Transcutaneous Bone-Anchored Hearing Device

Sophono developed the Alpha 1 hearing device in 2006 as an alternative to the traditional percutaneous cochlear Baha, and the device received FDA approval in 2011. The indications for implantation are essentially the same as those for the Baha, but the Sophono implant is indicated for patients with bone conduction up to 45 dB, while Baha can be implanted in patients with bone conduction up to 65 dB. The advantages of the device include absence of a percutaneous abutment, minimal skin complications, and lack of need for long-term wound care. A relative contraindication is a patient who might need serial MRI scans. The Sophono Alpha 2 was also recently introduced in 2013, with small enhancements from the Alpha 1.

The Alpha 1 consists of a surgically implanted internal plate that contains two magnets imperviously sealed in a titanium case. The external sound processor has a bone oscillator and uses a metal disk and spacer shim to magnetically couple to the internal portion and deliver auditory signal through the closed skin. The surgery is a single stage procedure that can be performed under local or general anesthesia (Figs. 21.2A and B). Four weeks are given between implantation and placement of external bone vibrating audio processor.[26]

Evidence of effectiveness is limited, but in a series of over 100 patients, including children over 5 years and adults, data suggest that the best outcomes are for patients with conductive hearing loss or single-sided deafness. The only noted complication was skin redness from pressure that was seen in about 4% of patients. This resolved with slight force reduction of the base plates. Early audiometric data in this study shows an average hearing gain in a free field pure tone audiogram of 31.2 ± 8.1 dB, and the suprathreshold speech perception at 65 dB to increase from 12.9% to 72.1% following implantation. The sound attenuation caused by the intact, thinned skin has been measured to be about 10 dB when compared to direct bone coupling (Baha).[27]

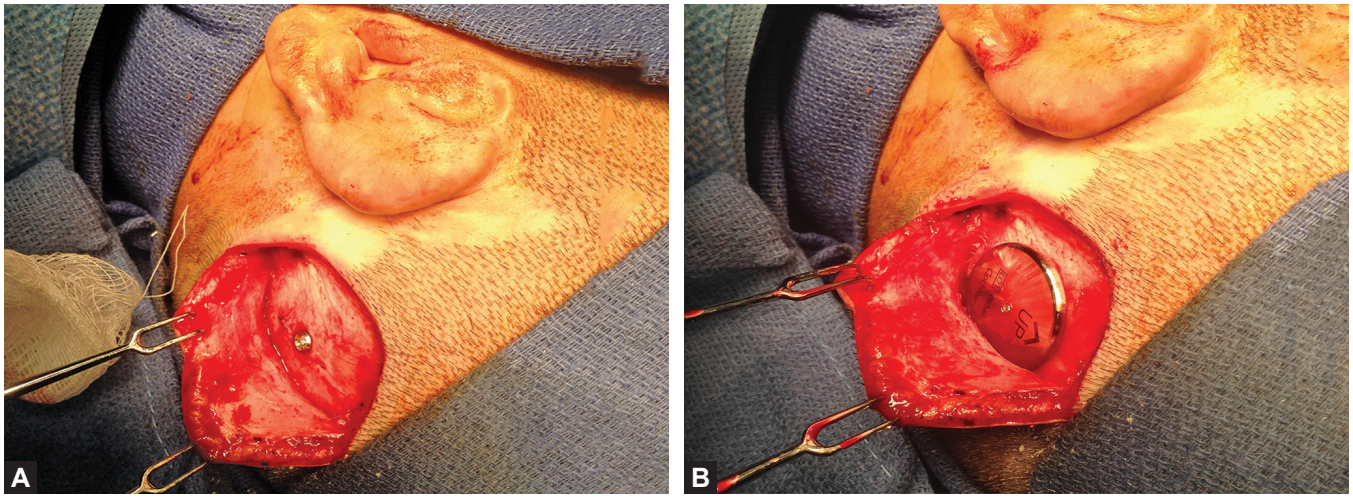
### Intraoral Bone Conduction Device

The SoundBite Hearing System developed in 2010 by Sonitus Medical is another device that amplifies sound via bone conduction, but this has the distinct advantage of not requiring surgical intervention for placement. A microphone is placed in the external auditory canal of the poorer hearing ear, while a removable in-the-mouth device provides direct coupling to the cranium via the teeth.[28]

A study in adults with single-sided deafness demonstrated that the SoundBite was at least as effective as an osseointegrated implant in improving ability to understand speech in noise, with an average improvement of 25% on HINT scores, with one third of the patients improving by over 30%.[28] Another study looking at adults who used the device for 6 months showed similar results with no complications.[28] The primary reason for decreased satisfaction was the comfort of the device in the mouth. With regards to the pediatric population, no literature has been published at this time, but it is conceivable that this device may be used in the older teenage population.[29] Use in the younger children is precluded by the intraoral component, as this could potentially be a choking hazard and would be difficult to fit with a child's mixed dentition.

## MIDDLE EAR IMPLANTS

Middle ear implants, also known as implantable hearing aids, were developed initially for the treatment of sensorineural hearing loss. They provide acoustic amplification and transmission of sound energy by coupling a vibratory element, the floating mass transducer (FMT), directly to the long process of the incus.[30] Because of the difficulty of fixation of the FMT to malformed ossicles in many patients with congenital aural atresia, in 2005, Colletti et al. described another alternative to the BAHA in patients



**Figs. 21.2A and B:** Transcutaneous BAHA surgical site with titanium screw in place (A); same site with magnet now in place (B).

with congenital aural atresia using the round window membrane as the site for the FMT of the MED-EL VSB implantable hearing device. The procedure consists of making a retroauricular incision in the region of hair-bearing skin and creating a large C-shaped flap to preserve the superficial temporal artery. A precisely shaped bony bed is drilled out at the level of the squama temporalis for the demodulator. A transmastoid approach with posterior tympanotomy is used. Reshaping of the fossula of the cochlear fenestra, which is caudal to the subiculum, is done by paring away the anterior and posterior margins of the bony lip of the round window until the edge of the round window membrane can be seen for fitting of the VSB transducer.[31] A study in 2011 which included 14 children, ranging from 2 months to 16 years, demonstrated improvement in air conduction thresholds from 66 ± 12.9 dB to 22 ± 9.1dB, pre- and postoperatively, respectively, in the older children. Free-field auditory brainstem responses in the 4 younger children showed mean preoperative and postoperative AC thresholds of 85.6 ± 14.2 dB and 24.4 ± 8.8 dB, respectively.[32]

## SUMMARY

- Multiple options exist to treat congenital and acquired hearing loss in the pediatric population, including percutaneous osseointegrated implants, transcutaneous implants, intraoral devices, and middle ear implants
- BAHA is the most commonly used device but has the disadvantage of skin complications owing to the percutaneous abutment
- Other devices are being utilized less frequently but many show promise in the pediatric population and are feasible options for audiologic rehabilitation.

# 22

# Pediatric Cochlear Implantation

***Aaron D Tward, Michael S Cohen, Daniel J Lee***

## INTRODUCTION

There are few treatments in medicine that have altered patients' lives as radically as the cochlear implant. The cochlear implant is the most successful of all neuroprosthetic devices and provides meaningful sound and speech perception to the majority of infants, children, and adults with prelingual and postlingual deafness. The development of the cochlear implant from an idea to a viable and widely used treatment for hearing loss represents a triumph that required the synthesis of information from the fields of neuroscience, electrical engineering, signal processing, manufacturing, and surgery. At the time of this writing, well over 200,000 cochlear implants have been placed in adults and children worldwide.

## ANATOMY/PHYSIOLOGY

In normal hearing, sound vibrations enter the external auditory canal and vibrate the tympanic membrane. The ossicular chain then conducts the vibrations to the inner ear via the oval window. The inner ear has two portions: the vestibular apparatus, which is responsible for detecting acceleration and balance function, and the cochlea, which is responsible for hearing. The cochlea is a linear tube hollowed out of the temporal bone, which is coiled into two and a half turns. Along the length of the cochlea, there are sheets of soft tissue that divide the space into three key compartments. Reissner's membrane separates the perilymph-filled scala vestibuli from the endolymph-filled scala media (Fig. 22.1). The basilar membrane separates the scala media from the perilymph-filled scala tympani.

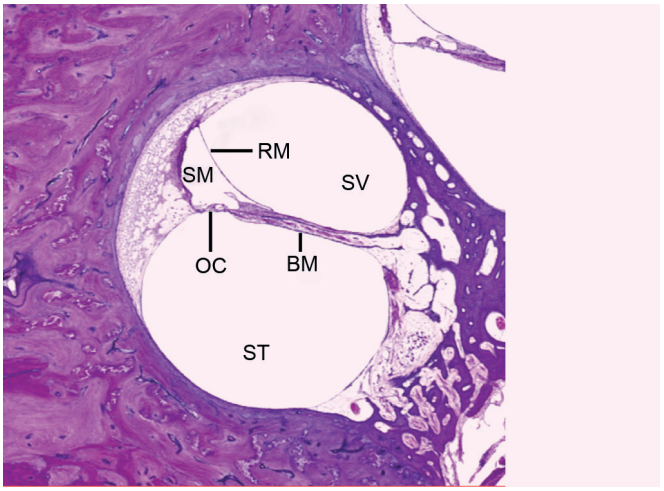

**Fig. 22.1:** Inner ear anatomy. Hematoxylin and eosin stained section of the cochlea. (SV: Scala vestibule; ST: Scala tympani; SM: Scala media; RM: Reissner's membrane; BM: Basilar membrane; OC: Organ of Corti).

Embedded in the basilar membrane, within the scala media, are hair cells, which convert mechanical energy from vibrations of the basilar membrane into electrical energy by depolarizing the hair cells. Once depolarized, hair cells release glutamate at their basolateral membranes that in turn activates spiral ganglion neurons. The spiral ganglion neurons are the first-order neurons of the auditory pathway and their axons travel via the cochlear nerve to the brainstem where they ultimately synapse on second-order neurons found in the cochlear nucleus. The cochlear nucleus is the target of all ascending information originating in the inner ear and these signals are ultimately

transmitted to the auditory cortex via the olivary complex of the auditory brainstem and inferior colliculus (midbrain). The vast majority of sensorineural hearing loss is caused by loss of hair cells. Cochlear implants function by electrically stimulating residual spiral ganglion cells with an electrode placed into the scala tympani, bypassing the absent or dysfunctional hair cells.

## HISTORY OF COCHLEAR IMPLANTATION

The first report that suggested a link between electricity and hearing came from Alessandro Volta in the late 1700s when he inserted two metal rods in his ears and drove a current through them. He observed "a boom within the head" and then described the sound of boiling soup. Subsequently, in 1930, Ernest Weaver and Charles Bray of Princeton University demonstrated that sound is converted to electricity by the peripheral auditory system.[1] They reported that when sound is presented to the ear of a cat, an electrode placed on the ipsilateral auditory nerve detects electrical signals that when amplified and played through a telephone receiver will produce intelligible sounds and speech similar to that presented to the ear. Although they believed the electric signal to have been produced by the auditory nerve, subsequent studies demonstrated this signal to have been generated by the cochlea itself (the cochlear microphonic). In 1957, André Djourno and Charles Eyriès implanted a patient with a device that directly stimulated the cochlear nerve and reported that he was capable of perceiving sound.[2] In 1961, William House and John Doyle implanted a few patients with single gold electrode devices. These patients were able to perceive sound, but the devices would fail as a consequence of tissue reaction to the electrodes.[3] The first multichannel implant in a human was reported in 1965 by Blair Simmons of Stanford and his colleagues at Bell Labs.[4] This implant had five steel electrodes that were implanted in the region of the modiolus. Stimulation of the different electrodes produced percepts of different pitches. In the late 1960s, William House and an engineer, Jack Urban, greatly improved hermetic sealing of the single-channel implant they had developed, thus paving the way for the approval of the single-channel 3M/House implant in 1984. Starting in the 1970s and continuing until roughly 1990, hundreds of children received the single-channel 3M/House implant.[5] With this implant, some children achieved open set speech recognition.

In the 1970s, multiple groups began working on multichannel cochlear implants, including those led by William House, Graeme Clark, Ingeborg Hochmair, Don Eddington, and Michael Merzenich. Ultimately, the first multichannel implant to be approved by the FDA for use in adults was the Cochlear Corporation's Nucleus Mini22 in 1985. Subsequently, the Cochlear Corporation obtained FDA approval for use in children as young as 2 years old. Later multichannel implants from both Advanced Bionics and Med-El were approved in the United States. Over time, the technology of cochlear implants and processing strategies has improved greatly, but the fundamental design of the components has remained similar for many years.

## DESCRIPTION OF MODERN COCHLEAR IMPLANTS

Cochlear implants are comprised of two main components: an external sound processor and an internally implanted receiver/stimulator (Figs. 22.2A and B). A battery powers both the speech processor (worn on the body or behind the ear) as well as the surgically implanted receiver/stimulator via induction. In a normally functioning cochlear implant, sound is first presented to the microphone on the sound processor. This acoustic information is converted to an electrical signal by the microphone and then presented to a digital processor. Using one of a variety of algorithms, the processor then extracts different features of the analog signal, encodes them, and transmits them to the internal receiver/stimulator via the transmitter coil. The induction coil of the internal receiver/stimulator ultimately transmits the signal to a linear array of 16–24 platinum electrodes,

**Figs. 22.2A and B:** Components of a modern cochlear implant. (A) External sound processor; (B) Internal receiver stimulator.

which can be independently activated. These electrodes stimulate fields of spiral ganglion neurons, which alter their pattern of firing in response to the stimulation. The signal encoded in this altered firing is ultimately transmitted to the auditory cortex via the brainstem and inferior colliculus where it is then interpreted as sound.

## CLINICAL CONSIDERATIONS

### Indications and Preoperative Evaluation

Cochlear implants are indicated in children with moderate to profound hearing loss in both ears and who derive minimal benefit from amplification. If there is residual hearing in one ear, the worse ear is generally implanted first and a hearing aid can be used in the better ear (bimodal hearing). These children must also have an inner ear with a cochlear nerve in continuity with the brainstem. The indications listed above guide the components of the preoperative evaluation. Although current devices are approved by the FDA for implantation into children 12 months and older, children as young as 3 months of age have been safely implanted with excellent hearing results.[6]

For children who are capable of conventional pure tone and speech audiometry, a standard audiogram is sufficient evidence of hearing loss. For children who are not capable of conventional pure tone and speech audiometry, auditory brainstem response testing can objectively measure pure tone and click thresholds. In children younger than 2 years of age, cochlear implants are indicated if audiometric testing indicates pure tone averages of 90 dB or greater. For children older than 2 years of age, pure tone averages of 70 dB or greater are sufficient to meet audiometric criteria for cochlear implantation. In addition, a 3–6 month trial of amplification should be attempted to see if any substantial benefit could be obtained. This trial of amplification may be deferred in children with severe to profound sensorineural hearing loss secondary to meningitis as rapid cochlear ossification may prevent the ability to place a cochlear implant if the procedure is delayed. Prelingually deafened children should be enrolled with Early Intervention or programs with similar services to aid in language and speech acquisition.

Noncontrast computed tomography (CT) scan of the temporal bones should be obtained during the preoperative workup in order to assess for cochlear or internal auditory canal anomalies. Particular attention should be paid to the possibility of cochlear ossification, the patency of the cochlear nerve canal, and the width of the internal auditory canal (Fig. 22.3). In addition, even among children with normal cochlear anatomy, CT imaging can aid in surgical planning. For example, identifying a large mastoid emissary vein or narrow facial recess may alter the surgical technique slightly in a way that makes the procedure safer and more efficient.

The addition of high-resolution magnetic resonance imaging (MRI) of the temporal bones with a far T2-weighted sequence such as a constructive interference in steady state (CISS)/fast imaging employing steady-state acquisition (FIESTA) is helpful in assessing the presence and caliber of the cochlear nerve (Fig. 22.4). In addition, the patency of the inner ear can be confirmed by the presence of fluid signal within the cochlea. If the cochlear nerve is absent, an auditory brainstem implant can be considered (*see* Chapter 23). At our institution, all infants with congenital profound hearing loss undergo an MRI scan of the temporal bones under anesthesia before cochlear implant surgery to ensure the presence of a fluid-filled cochlea and auditory nerve.

Active infection with acute or chronic otitis media is a contraindication to cochlear implantation. Infection should be treated with standard care (e.g. antibiotics, tympanostomy tubes, or surgery as needed), and once controlled, consideration can be given to proceeding with cochlear implantation. If the patient is medically unstable or cannot safely undergo general anesthesia, implantation should be postponed until anesthesia is safe. Patients with no cochlea cannot benefit from a cochlear implant, although some auditory benefit has been reported in

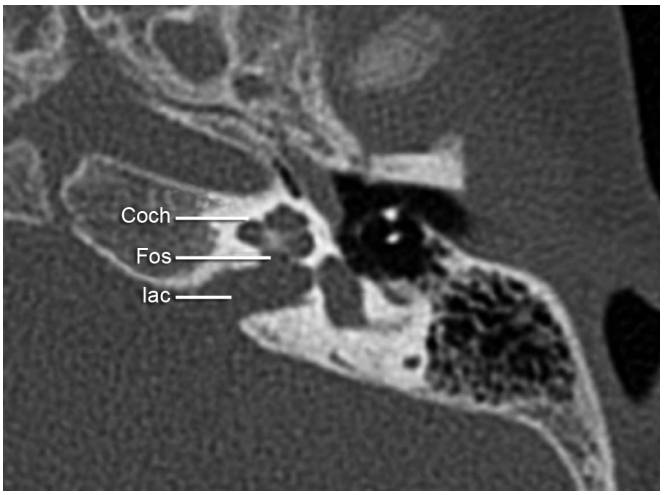

**Fig. 22.3:** Normal bony cochlear anatomy. Axial CT scan of the temporal bone showing two and a half turns of the cochlea, no ossification, and no partitioning defect, and a patent cochlear fossette and internal auditory canal. (Coch: Cochlea; Fos: Cochlear fossette; Iac: Internal auditory canal).

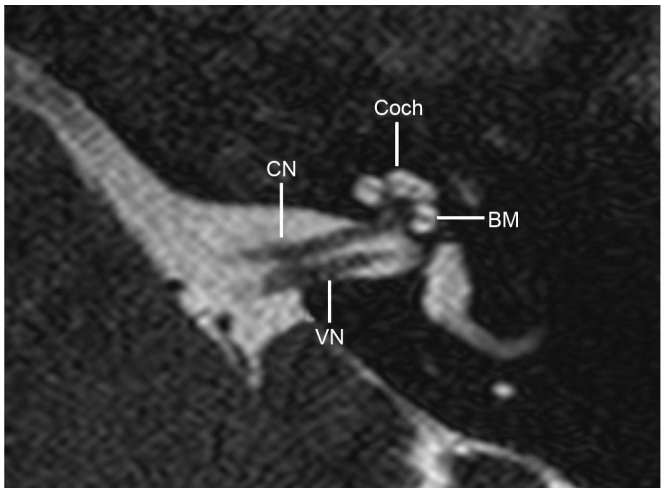

**Fig. 22.4:** Normal cochlear anatomy. Axial FIESTA weighted MRI scan demonstrating the normal appearance of the cochlear fluid spaces and internal auditory canal. (Coch: Cochlea; CN: Cochlear nerve; VN: Vestibular nerve; BM: Basilar membrane).

children with even severe inner ear malformations.[7] The patient's family must demonstrate both the desire and ability to participate in ongoing follow-up with audiologic, educational, and speech/language services in order to proceed with surgery.

In 2003, an increased incidence of meningitis in cochlear implant recipients was reported. This risk was substantially higher among those recipients with an implant and a positioner device.[8] The positioner was designed to be placed into a large cochleostomy after placement of the electrode in order to bring the electrode contacts in closer proximity to the modiolus and therefore the spiral ganglion cells. The positioner device was subsequently recalled with a corresponding decrease in the incidence of meningitis following implantation.[9] Other risk factors associated with meningitis following CI surgery include a history of meningitis, inner ear dysplasia, and an intraoperative cerebrospinal fluid (CSF) leak or gusher encountered following cochleostomy. As a consequence the Centers for Disease Control and Prevention recommends that prior to undergoing cochlear implantation, children who have not previously received vaccination for *Streptococcus pneumoniae* should receive the recommended course of the 13 valent pneumococcal conjugate vaccine (PCV13) (either two or three doses, depending on the age of the child), prior to having a cochlear implant. After the course of PCV13 is complete, children over the age of 2 years should receive a single dose of the 23-valent pneumococcal polysaccharide vaccine, although this need not delay implantation.

## Procedure

After the patient is placed under general anesthesia, facial nerve monitoring is set up on one or both sides (if bilateral simultaneous implantation will be performed). A template of the device may be used to plan the location of the internal receiver/stimulator. If simultaneous or the second side of sequential implantation is planned, then a template can be created with a piece of paper on the first side, and the position of the internal receiver/stimulator on the second side can be planned to match the position on the first side for improved cosmesis. The ear is then prepared using standard aseptic technique and draped. A 4–5 cm postauricular incision is planned approximately 1 cm posterior to the postauricular crease, with care being taken to ensure that the incision does not traverse the body of the internal receiver/stimulator (📻 22.1). The region of the incision is then infiltrated with 1:100,000 epinephrine with or without local anesthetic. The skin is incised sharply and skin flaps are elevated anteriorly and for a short distance posteriorly in the plane superficial to the periosteum of the mastoid cortex. A number 7 shaped incision in the periosteum is created, with the option of a superior releasing incision it the periosteum superiorly. Care should be taken to not place a limb of the incision directly over the device. Using a periosteal elevator, a tight pocket for the device is created, and the depth of the pocket confirmed with a silastic dummy. A well and tie-down holes may be drilled, if desired. A small piece of soft tissue is harvested for later use in sealing the cochleostomy. The periosteal flap overlying the mastoid cortex is elevated, and self-retaining retractors introduced. A simple canal-wall up mastoidectomy is then performed with identification of the short process of the incus, the horizontal canal, and the posterior wall of the bony external auditory canal. Thinning, but not violating, the bone of the posterior wall of the external auditory canal is critical to adequate visualization of the round window niche. A facial recess approach is completed with diamond burrs and copious irrigation to prevent thermal injury to the facial nerve. Once the round window niche is seen, the bony lip overlying the round window niche is carefully drilled away to examine the round window in its entirety. The receiver/stimulator is then inserted into its periosteal pocket and secured. If a round window insertion is desired, a small amount of hyaluronic acid gel can be placed over the round window membrane. The round window is then incised with either a fine tip needle or a sharp Rosen needle. The electrode array is then inserted through the round

window by specifications of the individual manufacturer. No significant resistance should be encountered during insertion. If a cochleostomy is planned, the cochleostomy should be created either 1 mm directly inferior or anteroinferior to the round window membrane in order to ensure scala tympani insertion. The cochleostomy may incorporate the round window itself, or may be separate. The cochlea may be filled with hyaluronic acid if desired. Once the cochleostomy is created, the electrode array is inserted by the specifications of the individual manufacturer. If a ground electrode is present, it is inserted into a periosteal pocket overlying the zygoma. Redundant electrode is then placed in the mastoid cavity, and the periosteal flaps are closed with interrupted absorbable suture. The skin and underlying soft tissue is then closed in a multilayered fashion. If bilateral simultaneous implants are planned, then the head is turned and the procedure above is repeated on the opposite side. Once the operation is complete, a dressing is then placed.

## Special Intraoperative Circumstances

A number of issues may necessitate deviation from the standard, straightforward procedure detailed above, many of which can be anticipated from information gathered in the preoperative workup. In the case of partial ossification of the cochlea, either a narrow electrode array may be selected, or the basal turn can be widened with a drill and the full-length electrode array placed. In the case of complete ossification of the cochlea, multiple cochleostomies may be created and channels drilled for a split electrode. In cases of complete ossification, outcomes do tend to be worse than in those cases without ossification.[10,11]

In cases of cochlear malformations, implantation may be attempted with either a modiolar conforming or straight electrode if at least the basal turn is present, or a straight electrode in cases of severe partitioning defects. One issue that may arise in the context of a cochlear malformation is the presence of an intraoperative CSF leak following cochleostomy or opening the round window. Should this occur, the implant may still be placed and the cochleostomy or round window plugged with soft tissue. The head of the bed may be elevated slightly and the implant placed after the CSF has been given an opportunity to drain, or the implant can be placed through actively flowing fluid. Additionally, a lumbar drain may be placed at the end of the procedure, but the procedure can be safely completed without one. If, however, a postoperative CSF leak persists, a lumbar drain should be placed and the patient placed on bed rest for 3 days in order to resolve the leak. The presence of intraoperative CSF leak does not correlate with worse postoperative outcome.[12]

In cases of the need for replacement of a cochlear implant due to device failure, the old electrode should be left in place in the cochlea until the final moments before the new electrode is placed through the same cochleostomy. Because of the robust soft tissue response to cochlear implants,[13] if the old electrode is removed at an earlier point in the procedure then there is a risk of soft tissue sheath collapse and encountering substantial difficulty in replacing the electrode. If the receiver/stimulator needs to be removed as a consequence of infection or exposure, it is prudent to cut the electrode within the mastoid, leave the electrode in place in the cochlea, and remove the remainder of the device and close the wound. Once a sufficient amount of time to treat the infection and permit healing has elapsed (at least weeks), then in a second stage the old electrode can be removed and a new receiver/stimulator package and electrode placed. Outcomes following revision cochlear implant surgery in children are on average at least as good as those following initial placement.[14]

If during electrode placement resistance is encountered, particularly with a styletted electrode, then insertion should be stopped. The electrode may be pulled back a few millimeters, and an attempt at gentle advancement may be made. Should resistance be encountered again, it is best to accept a partial insertion of the device, rather than forcing the electrode through the cochlea and running the risk of either breaching the basilar membrane or dissecting the soft tissues of the lateral wall.[15]

## Postoperative Care

A mastoid dressing is placed over the surgical site, but may be removed after 48 hours. Particularly with younger children, it may be beneficial to leave a loose dressing on for a longer period of time in order to prevent inadvertent manipulation of the wound or device. Postoperative antibiotics, particularly those which cover gram-positive organisms, may be given for a week after the operation, although there is little evidence to support their routine use. Pain control should be age appropriate with either acetaminophen or opiates as necessary. Children over the age of 2 years may be discharged on the same day as surgery, and children under 2 years of age should be observed overnight for any sequelae of anesthesia.

## Outcomes

Although some variability exists, the majority of children who receive cochlear implants achieve excellent results. Over the long term, most children who receive cochlear implants develop open set speech recognition, use the telephone, are in mainstream schools, and use exclusively oral communication.[16,17] In a recent cost-utility analysis, cochlear implantation was estimated to cause a gain of approximately 10 quality-adjusted life years (QALYs) per implanted prelingually deafened child.[18] The estimated lifetime cost of cochlear implantation was $160,000 per child. As a consequence, the estimated cost per QALY was on the order of $16,000, consistent with a very cost-effective intervention. Further, when indirect costs of nonmainstream schools or additional school services are considered, cochlear implantation in prelingually deafened children is estimated to be *cost-saving*.

Among children who are prelingually deafened, implantation over the age of five substantially limits but does not eliminate the maximal benefit of cochlear implantation (Fig. 22.5).[19] Further, among prelingually deafened children, earlier implantation is correlated with earlier receptive and spoken language improvements and more rapid improvement over time (Figs. 22.6 and 22.7).[20] Children undergoing bilateral cochlear implantation appear to have improved receptive and spoken language development than those who undergo unilateral implantation. The longer the duration between the first and second implants, the worse their language performance.[21] Improved sound localization can be achieved with bilateral as opposed to unilateral cochlear implantation in children.[22,23] Hearing in noise is a particular challenge for children with cochlear implants, just as it is for children with hearing loss who use hearing aids.[24]

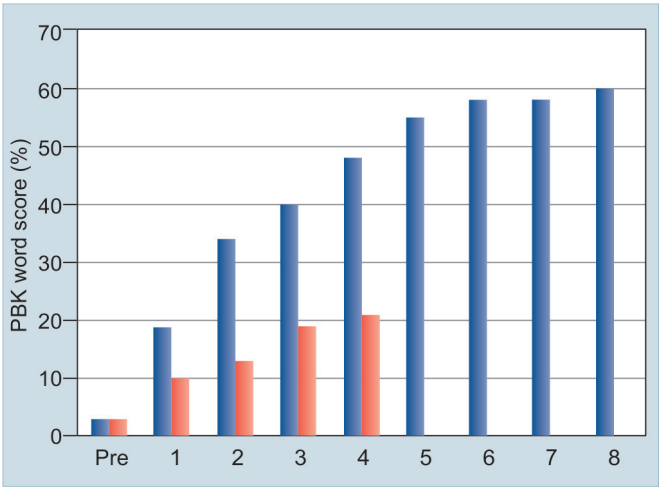

**Fig. 22.5:** Open set speech improvement by age at implantation of prelingually deafened children. Average phonetically balanced kindergarten (PBK) word scores grouped by age of implantation are plotted by number of years after implantation. Blue bars represent the mean scores of children implanted between ages 2-5 (N = 59); red bars represent the mean scores of children implanted between ages 8-13 (N = 18). Pre represents preimplantation scores. Adapted from Harrison et al.[19]

Children with cochleovestibular anomalies show wider variation in hearing outcomes than children without those anomalies.[7,25] Among these children, the best hearing outcomes are obtained in children with either incomplete partition defects or enlarged vestibular aqueduct. Variable outcomes are seen in children with hypoplastic cochleas, and worse outcomes are obtained in children with more severe deformities such as common cavity malformation. Children with developmental delay also tend to have somewhat worse audiologic outcomes than those children without developmental delay; they nonetheless derive substantial audiologic benefit in addition to improvements in intelligence and adaptive behaviors relative to those children with severe to profound hearing loss who are not implanted.[26] Children with auditory neuropathy may also derive substantial benefit from cochlear implantation, but also with more variable audiological outcomes that children with purely cochlear hearing loss.[27]

## Complications

Infection or soft tissue complications following cochlear implantation are uncommon in children with rates reported below 5%.[28] Should a superficial infection occur, antibiotic treatment is typically sufficient to resolve the issue. In cases where the device extrudes and is grossly contaminated, it should be explanted, the infection treated, and the device reimplanted once the wound bed is well healed. Device migration is rare, regardless of the technique of device fixation used.[29] In cases where either no benefit is achieved or when there is initial benefit that is subsequently lost, the device should be interrogated by the patient's audiologist. When the device is found to be malfunctioning this is referred to as a "hard failure". When auditory benefit is lost despite a functioning device, this is referred to as "soft failure".

Additional complications include aberrant nonauditory side effects of stimulation. These can include off-target facial nerve stimulation or vestibular stimulation

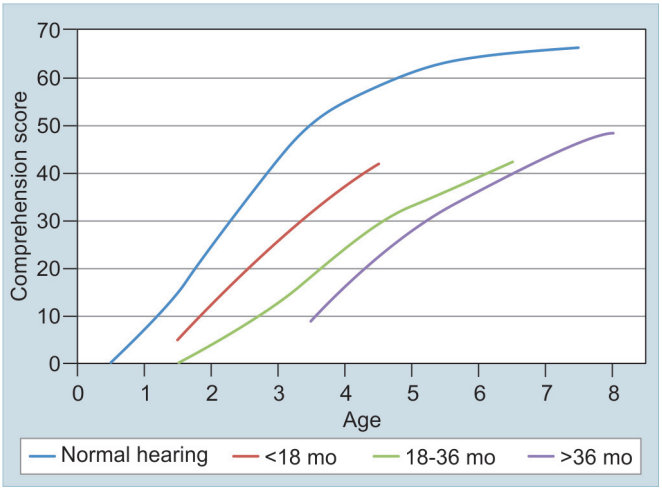

**Fig. 22.6:** Comprehension scores of prelingually deafened children following cochlear implantation before the age of 5. Depicted are nonparametric fits of Reynell Developmental Language Scales Raw scores of language comprehension stratified by age at implantation. Adapted from Niparko et al.[20]

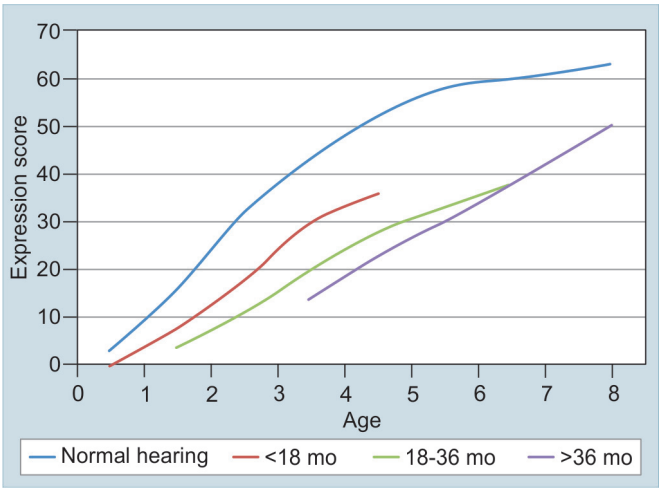

**Fig. 22.7:** Expression scores of prelingually deafened children following cochlear implantation before the age of 5. Depicted are nonparametric fits of Reynell Developmental Language Scales Raw scores of language expression stratified by age at implantation. Adapted from Niparko et al.[20]

and can often be resolved with altering the programming of the device. There may also be failure of the external device to maintain magnetic coupling with the implanted receiver-stimulator. This may require a stronger magnet on the external device, thinning of the skin and soft tissue flap or, least commonly, replacement of a demagnetized internal magnet.

## CONCLUSIONS

In summary, cochlear implants have revolutionized hearing rehabilitation for children with severe to profound hearing loss. Despite the incredible success of these prostheses, there remains a great deal that is unknown regarding the underlying pathology of hearing loss as well as the determinants of outcome following cochlear implantation. With a better understanding of the pathophysiology of hearing and improvements in technology and surgical technique, the coming years are sure to bring substantial progress in hearing rehabilitation for children.

CHAPTER

# 23

# Pediatric Auditory Brainstem Implantation

***Aaron D Tward, Daniel J Lee***

## INTRODUCTION

Cochlear implantation has revolutionized the hearing rehabilitation options of children with severe to profoundly hearing loss. Results from commercially available single-channel cochlear implant technology in the 1970s[1] and multichannel cochlear implant technology in the 1980s[2] demonstrated that direct electrical stimulation of the neural components of the auditory system can provide meaningful perception of sound and speech among children and adults with severe to profoundly hearing loss. The primary pathology in the majority of children with severe to profound sensorineural hearing loss lies in the soft tissue components of the inner ear (Organ of Corti), rather than gross malformations of the cochlea or lack of development of an auditory nerve. Therefore, the majority of children with severe to profound sensorineural hearing loss have anatomy that is favorable for placement of a cochlear implant and cochlear implantation is the treatment of choice for these children and their families who desire hearing habilitation/rehabilitation. However, there exists a rare but distinct subset of children with severe to profound sensorineural hearing loss who are unable to benefit from cochlear implantation, either as a consequence of unfavorable cochlear anatomy or lack of a functional cochlear nerve. If hearing rehabilitation with an auditory prosthesis in this subset of patients is desired, then stimulation must necessarily be directed beyond the level of the primary lesion in the auditory pathway to higher centers of auditory processing, such as the cochlear nucleus. The auditory brainstem implant (ABI) bypasses an abnormal, absent, or damaged inner ear and auditory nerve to directly stimulate the second order auditory neurons found in the cochlear nucleus. This device was originally developed by the House Ear Institute for those patients deafened by neurofibromatosis type 2 (NF2), a genetic syndrome resulting in the development of multiple brain and spinal cord tumors, including bilateral vestibular schwannomas. The growth and or removal of these tumors often result in bilateral profound hearing loss that in most cases cannot be helped with the cochlear implant. The ABI was approved by the FDA in the US in 2000 for patients age 12 and over with NF2 and overall outcomes have been modest compared with cochlear implant performance.

A breakthrough came in 2001, when Professor Vittorio Colletti performed the first two non-NF2 infant ABI surgeries in Verona, Italy.[3] Since then, investigators have begun to use ABIs in this population of children for hearing rehabilitation and as of 2013, over 150 infants and children who are deaf from causes not related to NF2 have been implanted. With this novel indication for the ABI, children have the possibility of achieving sound awareness, and in some cases, meaningful speech recognition.

## ANATOMY/PHYSIOLOGY

In normal hearing, sound vibrations enter the external auditory canal, and vibrate the tympanic membrane. These vibrations are then transmitted to the fluid-filled space of the inner ear via the malleus, incus, and stapes and ultimately the oval window. In turn, the basilar membrane of the cochlea vibrates, with the apex of the cochlea being most sensitive to low-frequency sounds and the base of the cochlea being most sensitive to high-frequency sounds.

This property of different frequencies being represented in different positions in space is referred to as tonotopic organization (Fig. 23.1). The inner hair cells sit atop the basilar membrane and convert these vibrations into the rapid release of neurotransmitters at the first neural relay in the auditory system, the ribbon synapse. The ribbon synapse connects the basolateral membrane of the hair cell to the afferent type I spiral ganglion neuron. The axons of the spiral ganglion neurons pass through the modiolus of the cochlea where they coalesce into the cochlear nerve, a branch of the eighth cranial nerve. The cochlear nerve then enters the brainstem near the pontomedullary junction lateral to the entry point of the facial nerve. The axons of the spiral ganglion cells then synapse in either the dorsal or ventral cochlear nucleus. From the ventral cochlear nucleus, neurons project to either the ipsilateral or contralateral superior olivary complex (sometimes by way of the trapezoid body). The neurons of the dorsal cochlear nucleus project either to the ipsilateral or contralateral superior olivary complex or directly to the contralateral inferior colliculus in the midbrain. The inferior colliculus also receives inputs from the superior olivary complex. From the inferior colliculus, projections are then sent to the medial geniculate nucleus and from the medial geniculate nucleus, projections are sent to the auditory cortex. In a similar fashion to the cochlea, the dorsal and ventral cochlear nuclei harbor a tonotopic map (Fig. 23.1), where different nuclei are maximally activated by different frequencies of sound. It is the presence of this tonotopic map that is the driving rationale for use of a multichannel ABI.

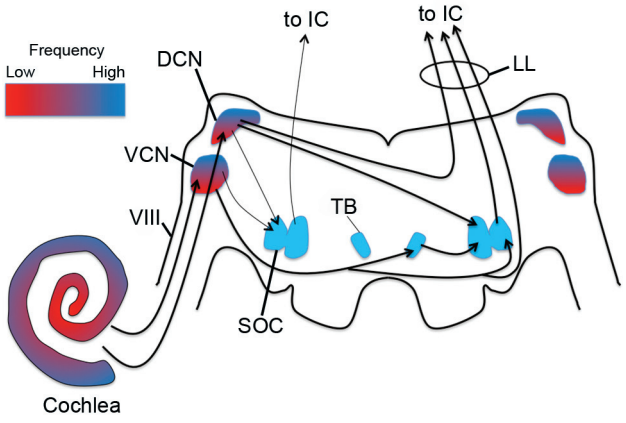

**Fig. 23.1:** Cochlear and brainstem auditory pathways. The cochlear is organized with cells maximally responsive to low-frequency sounds at the apex (red) and high-frequency sounds at the base (blue). This organization is referred to as a tonotopic map. The spiral ganglion neurons of the cochlea project to the cochlear nucleus via the cochlear nerve. The tonotopic map is preserved in the dorsal cochlear nucleus (DCN) and ventral cochlear nucleus (VCN). The neurons of the cochlear nucleus then project either directly or indirectly to the inferior colliculus (IC) via the lateral lemniscus (LL), and after additional relays ultimately to the auditory cortex. (VIII: Cochlear nerve; SOC: Superior olivary complex; TB: Trapezoid body).

## HISTORY OF ABIs

As mentioned in the introduction, the ABI was originally designed to meet the need for auditory rehabilitation in patients with NF2. William Hitselberger and William House performed the first ABI in 1979 on a woman with NF2 immediately after she had her second vestibular schwannoma removed via a translabyrinthine craniotomy.[4] This early generation ABI was a single-channel ball implant with a pair of electrodes placed on the surface of her dorsal cochlear nucleus. Once activated, this patient was able to hear sound and had significant improvement in lip reading. She continued to use the device for at least 20 years. Subsequent work by multiple groups resulted in progressive improvements in the design of ABIs, including the advent of multiple electrodes, transcutaneous stimulation via induction coil, and improved programming strategies.[5] In 2001, the result of the first two pediatric ABI placements in young children with congenital anomalies was reported by Vittorio Colletti and his colleagues in Verona. Both implanted children achieved speech detection and some speech discrimination.[3] In 2013, Colletti performed an ABI surgery in an 8-month-old infant, the youngest performed to date. The largest experience in the world continues to be at the University of Verona, with over 80 ABIs performed in infants and children. Professor Levent Sennaroglu's center in Ankara, Turkey has performed over 50 ABI surgeries in pediatric patients between 12 months and 5 years of age.

The ABI is not yet FDA approved for use in infants and children who are deaf and do not have NF2. With compelling outcome data from Europe, four centers in the United States have established pediatric ABI programs. As of December, 2013, four infants have undergone ABI surgery, in the United States, at New York University, University of North Carolina Chapel Hill, and Massachusetts Eye and Ear Infirmary/Massachusetts General Hospital, and Harvard Medical School. University of North Carolina, Harvard, and House Ear Clinic have approved FDA clinical trials to study outcomes following pediatric ABI surgery. The youngest pediatric ABI recipient in the United States, as of the writing of this chapter, was a 16-month-old male infant with cochlear and

auditory nerve hypoplasia. He underwent uneventful retrosigmoid craniotomy and ABI placement in October, 2013, at the Massachusetts General Hospital, and at 2 months following activation is demonstrating behavioral auditory responses with the ABI.

## DESCRIPTION OF ABIs

The ABI is a modified cochlear implant and consists of an internally implanted receiver/stimulator and an externally worn microphone and speech processor (Fig. 23.2A). Sound is detected by an external microphone, worn either on the body or behind the ear. The signal is then sent to an analog to digital processor that encodes the sound information by one of several processing algorithms. The processor sends the encoded signal to the internal receiver/stimulator via the transmitter coil. The internal receiver-stimulator is composed of an induction coil attached to a ground electrode and an array of 12 (MED-EL ABI, not FDA approved) or 21 disk-shaped platinum electrodes (Cochlear Corp, FDA approved) arranged on a paddle designed to be placed on the surface of the human dorsal cochlear nucleus (Fig. 23.2B). The signal is received by the internal induction coil, activating distinct electrodes (Fig. 23.2C), which are in proximity to or on the cochlear nucleus. Activation of the electrodes electrically stimulates groups of neurons within the cochlear nucleus, and the information is relayed to higher centers in the auditory system. Ultimately, this results in the perception of sound (and varying degrees of speech recognition in some patient cohorts) by the successful ABI user.

## INDICATIONS AND PREOPERATIVE EVALUATION

In general terms, children with severe to profound hearing loss who would otherwise be candidates for cochlear implantation, but for whom cochlear implantation is not

**Figs. 23.2A to C:** The auditory brainstem implant. (A) External processor of an auditory brainstem implant. The transmitter coil contains a magnet in the center that permits it to sit in opposition to the internal induction coil. (B) Internal receiver-stimulator of an auditory brainstem implant. (C) Close-up of electrode array. This array is placed directly on the cochlear nucleus. Each electrode or electrode pair stimulates fields of neurons within the cochlear nucleus.

an option due to unfavorable anatomy are candidates for ABIs. In addition, children with unfavorable anatomy who have had a prior cochlear implant and no significant benefit after 6 months of use with no possibility of revision or contralateral implant can be considered candidates for ABI. At the time of this writing, over 150 children have received ABIs worldwide (V. Colletti and L. Sennaroglu, personal communication).[6–9] As a consequence of increasing interest in the use of ABI in children, a conference on ABI in children and non-NF2 adults was convened in Turkey in 2009. A first consensus statement on the indications for ABI in children was drafted.[10] Two distinct groups of children were identified as candidates: (1) prelingually deafened children with inner ear malformations and/or cochlear nerve hypoplasia or aplasia and (2) postlingually deafened children with cochlear ossification, bilateral temporal bone fractures with cochlear nerve avulsion, or intractable facial nerve stimulation with cochlear implantation. A second consensus meeting on pediatric ABI surgery was held in Ankara, Turkey, in 2013 and the conclusions from this meeting will be published in 2014 following peer review.

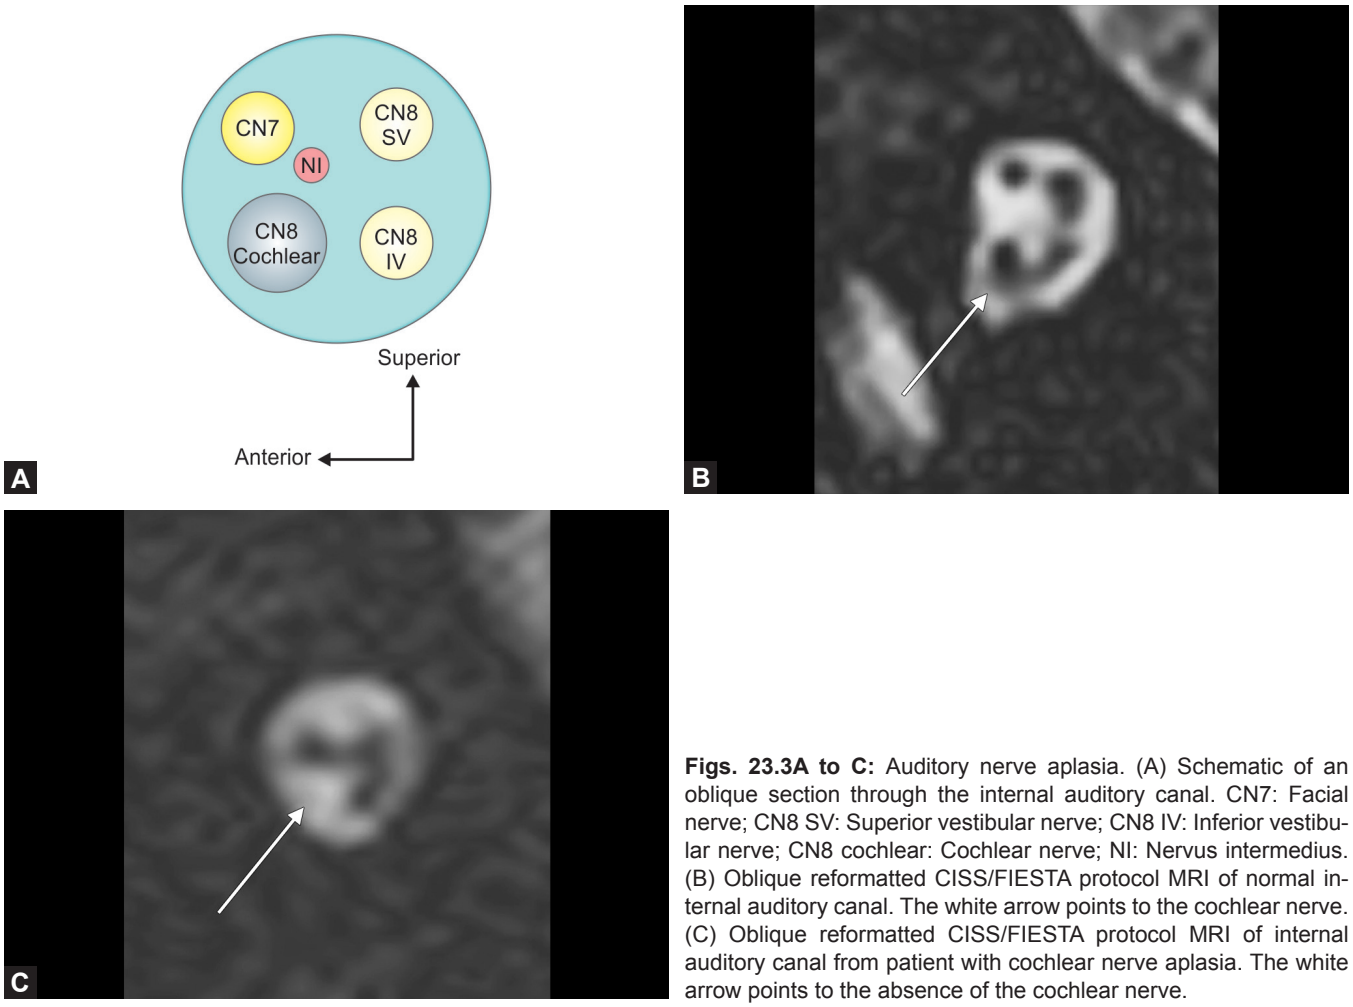
High-resolution imaging and interpretation by an experienced neuroradiologist are critical in the workup of potential pediatric ABI candidates. In particular, a noncontrast high-resolution computed tomography (CT) scan of the temporal bones as well as 3 T high-resolution magnetic resonance imaging (MRI) of the temporal bones including a T2-weighted FIESTA/CISS sequence should be obtained (with direct oblique or reformatted views of the internal auditory canal). A number of factors should be considered that influence surgical planning. First, the gross anatomy of the brainstem should be assessed to evaluate the likelihood that the cochlear nucleus is intact and present along with the vestibulocochlear nerve at the root entry zone. The cochlear nuclei themselves typically cannot be easily distinguished on MRI. The presence and patency of the lateral recess should be confirmed if possible, and attention paid to any structures that might obstruct the lateral recess, including blood vessels or scar tissue. The presence or absence of the nerves of the internal auditory canal may inform the interpretation of landmarks intraoperatively.

In children with complete labyrinthine aplasia, cochlear aplasia, cochlear nerve aplasia, or cochlear aperture aplasia (Figs. 23.3A to C), bilateral temporal bone fractures with cochlear nerve avulsion, or complete ossification of the cochlea with no T2 signal on MRI within the cochlear duct, it is reasonable to consider ABI without first considering cochlear implantation. In cases where there is cochlea, cochlear aperture, or cochlear nerve hypoplasia (< 50% of the diameter of the normal cochlear nerve), or cochlear ossification but with at least a partially patent cochlear duct, then cochlear implantation can be considered as an option, although ABI may still be preferable a priori depending on the particular circumstances of the patient. In cases where it is unclear if there is any functional connection between the cochlea and the brainstem, electrical auditory brainstem response (EABR) testing with cochlear promontory stimulation may be considered. If consistent EABR responses with promontory stimulation cannot be obtained, then cochlear implantation is less likely to provide benefit.[11]

Although data on the subject are limited, it is likely that there is a critical period from birth to age of 3 years after which the ability of the central auditory system to maximally utilize information from an ABI begins to decline. This critical period likely mirrors the critical period for cochlear implantation, or is perhaps even more stringent.[10] As a consequence, among prelingually deafened children, we recommended performing auditory brainstem implantation before the age of 3 years.

A complete medical history and physical is necessary to rule out any comorbidities that would be a contraindication to general anesthesia. In postlingually deaf children, evaluation by an experienced audiologist with audiometry and speech perception testing is necessary. In prelingually deaf children, the audiologic evaluation should include auditory brainstem response testing. A speech-language pathologist and neurodevelopmental evaluation are helpful in assessing the general and domain-specific cognitive abilities of the child. A social work evaluation should be undertaken to assess and reinforce the importance of family support.

Two main factors influence the choice of side for implantation: anatomy and functional evidence of hearing. If there is no evidence of any functional hearing on either side, then the side with the most accessible lateral recess and with any evidence of a cochlear nerve should be selected for implantation. If there is functional evidence of hearing on only one side, such as the presence of ABR at high thresholds, then that side should be selected for implantation as it has a greater likelihood of having a functional cochlear nucleus present.



**Figs. 23.3A to C:** Auditory nerve aplasia. (A) Schematic of an oblique section through the internal auditory canal. (C) Oblique reformatted CISS/FIESTA protocol MRI of internal auditory canal from patient with cochlear nerve aplasia. The white arrow points to the absence of the cochlear nerve.

## PROCEDURE

The ABI can be implanted via a retrosigmoid or translabyrinthine approach in older children. The retrosigmoid approach is the desired approach for infants and young children without NF2, and has the advantage of preserving vestibular anatomy and function that is present on that side. Due the small size of the temporal bone, the translabyrinthine approach does not provide adequate access to the lower cranial nerves and lateral recess needed to safely guide the electrode in small infants compared to a retrosigmoid craniotomy. After confirming the correct side to be implanted, the child is brought to the operating room and placed under general anesthesia, without the use of long acting paralytics. The patient's head and body are placed in a modified supine position or lateral decubitis position, rotated 45° away from the surgeon. After this, facial nerve monitoring is set up with three subdermal needle electrodes placed and secured in the frontalis, orbicularis oculi, and orbicularis oris muscles, as well as ground and stimulating electrodes placed in the chest. For EABR recording, subdermal needle electrodes are placed and secured in the midline at the vertex of the skull, in the neck over C7, and with a ground over the inion.[12] Monitoring of additional cranial nerves such V, IX, X, and XI may also be established at this point, if desired. An appropriate amount of hair is shaved and the patient is prepped and draped using sterile technique. A device template may be used to determine optimal position of the receiver/stimulator, and the position may be marked on the bone by placing methylene blue through the skin at the end of a needle. An approximately 5–7 cm curvilinear incision is created in the postauricular region (Fig. 23.4A) and a skin flap is elevated in the plane of the temporoparietal fascia, superficial to the periosteum of the mastoid and occipital bones and superficial to the

superficial layer of the temporalis fascia (Fig. 23.4C). An inferiorly based periosteal flap is subsequently elevated (Fig. 23.4D), and the suboccipital muscles are partially detached from the region of the planned craniotomy. A subperiosteal pocket for the device is created superior and posterior to the region of the planned craniotomy and the depth and width are determined by the template (Fig. 23.4B). A well for the device is drilled superior and posterior to the craniotomy site, although this approach is avoided in young infants. At this point, the template is left in the pocket until the ABI is placed.

A 3 × 3 cm craniotomy is created with the anterior limit at the sigmoid sinus, and the superior limit at the transverse sinus (Fig. 23.4D). The sigmoid is fully decompressed to allow for sufficient dural reflection anteriorly in order to minimize cerebellar retraction. Bone wax is placed into any exposed air cells to prevent cerebrospinal fluid (CSF) leak. An incision is created in the dura and the dural flaps are retracted. The cisterna magna is opened, and the cerebellum is decompressed by permitting CSF to drain until flow slows considerably. Using gentle retraction if necessary, the facial, vestibular,

cochlear (if present), glossopharyngeal, vagus, and spinal accessory nerves are identified (Fig. 23.5A). Identification of the seventh cranial nerve is confirmed with stimulation. Using microdissection, the lateral recess is identified (Fig. 23.5B). Key landmarks to identify the lateral recess include the entry points of the glossopharyngeal nerve, the cochlear nerve, and choroid plexus, which may be protruding through the lateral recess. In addition, the cerebellar flocculus may obscure the lateral recess and need to be retracted. Once opened with microdissection, the position of the lateral recess may be confirmed by observing the outflow of CSF. The cochlear nucleus may be appreciated as a bulge protruding into the floor of the lateral recess.

The device is then opened and inspected for any gross manufacturing defects. The magnet is only replaced with a nonmagnetic metallic spacer if routine MRI surveillance is indicated as would be the case in a patient with NF2. The device is placed and secured using a tight subperiosteal pocket technique or using nylon suture tie downs, anchored either to titanium screws or to grooves drilled into the bone. The grounding electrode is placed deep to the temporalis muscle anterior to the craniotomy site in line with the zygoma.

Under microscopic control, the electrode array is then placed on or near cochlear nucleus through the lateral recess. Given the relatively small size of the lateral recess in infants, the Dacron wings of the electrode array are often trimmed to facilitate insertion. An EABR is obtained using bipolar stimulation of electrode pairs across the electrode paddle to confirm proper placement (Fig. 23.6). In general, one to two positive peaks seen in the first 2–3 ms are associated with an auditory response postoperatively. Larger amplitude and long latency responses are generally nonauditory responses. If a consistent EABR cannot be obtained, the electrode array is repositioned until one can be obtained. Once this is confirmed, muscle and/or fat is placed to stabilize the electrode array within the lateral recess. The dura is closed in a watertight fashion with several layers of muscle and bovine collagen dural grafts, and the incision is closed in multilayered fashion with deep layers of absorbable suture and a superficial layer of running, locking, slowly resorbable (Monocryl), or nonresorbable (nylon) suture. A mastoid pressure dressing is then placed.

## POSTOPERATIVE CARE

Patients are monitored in a pediatric intensive care unit with frequent neurological checks for at least one day. A postoperative CT scan is often obtained 6–8 hours after the completion of the procedure to confirm electrode placement and to rule out hemorrhage or hydrocephalus (Fig. 23.7). Postoperative steroids are given and tapered over the course of 4 days. Pain control is achieved with acetaminophen and opiates if necessary. The patients can typically leave the hospital after 3–4 days. The pressure dressings are changed at least once during the hospital stay and parents are encouraged to keep the dressings on for at least 1 week to help reduce the risk of a CSF leak. Wound sutures, if not dissolving, are removed in follow-up 2 weeks after the procedure. As long as there

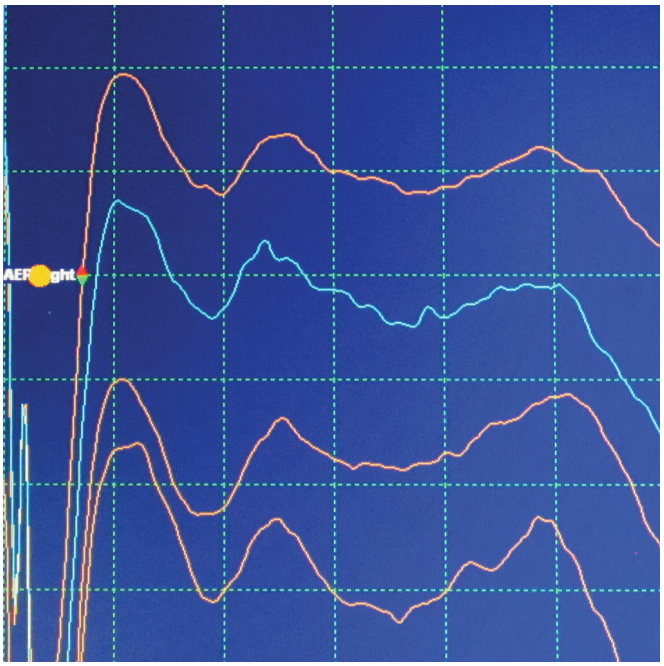

**Fig. 23.6:** Intraoperative auditory brainstem response (ABR). Upon bipolar stimulation of two electrodes, a biphasic response with latency characteristic of brainstem auditory processing was elicited.

**Fig. 23.7:** Postoperative CT scan after auditory brainstem implantation. An axial noncontrast CT scan was obtained 6 hours following the completion of the operation. The white arrow indicates the electrode paddle in position on the brainstem.

are no wound-related issues, the device can be activated 6–8 weeks after the procedure. We perform the initial activation for infants under dexmedetomidine (alpha 2 agonist/Precedex) intravenous sedation in order to set initial ABI stimulation levels and monitor ABRs and to determine the thresholds required to generate nonauditory side effects such as bradycardia and gag reflex. The ABI can then be more safely activated and mapped in an awake child, with a medical team present, on the following day.

## OUTCOMES

Because we are still in the early days of pediatric auditory brainstem implantation, only a small number of papers have been published by various international groups describing their experience (Table 23.1). In 2007, Colletti reported on the outcomes of 18 children who underwent ABI surgery in Verona, Italy. All of the children used their devices for >75% of their waking hours. On the category of auditory performance scale, the range of scores for these 18 children was from 1 (sound awareness) to 7 (able to speak on a telephone), with an average score of 4 (can discriminate between two sounds).[6] Eisenberg reported the comprehensive evaluation of a child with Goldenhar's syndrome and bilateral cochlear nerve agenesis who had been implanted in Verona at age 3 years, 3 months, and evaluated 6 months and 12 months after ABI activation.[7] At 12 months after activation, this child had Infant-Toddler Meaningful Auditory Integration Scale (IT-MAIS) and Early Speech Perception (ESP) category scores near the median for cochlear implant users at the same point in time following activation. Goffi-Gomez[8] reported on the results of four children implanted with ABI in Brazil. All four children gained sound awareness, and three of the four had significant improvements of IT-MAIS and Meaningful Use of Speech Scale (MUSS) scores. Choi[9] reported on eight children implanted in South Korea. All eight achieved sound awareness, and seven out of the eight children had some sound recognition. Sennaroglu has reported on the outcome of 29 children implanted in Turkey (L. Sennaroglu, personal communication). All 29 achieved sound awareness, and 12 of the children achieved some open-set speech recognition. Some of the diversity of reported outcomes is likely to be a consequence of the different ages of children implanted in these initial efforts, with significantly better results obtained with younger children. In sum , although there exists a range of performance with ABIs in children, almost all children do achieve sound awareness, and a substantial portion achieve a level of performance that is likely to significantly improve

**Table 23.1:** Outcomes after pediatric auditory brainstem implantation

| *Study* | *Sound awareness* | *Daily use* | *Sound recognition* | *Open-set speech* |

their cognitive development. Going forward, prospective studies are necessary to better understand the predictors of good performance and optimize outcomes for those children with ABIs.

## COMPLICATIONS

Colletti and colleagues have reported on complications in children following ABI surgery.[13] Among 29 children, major complications were observed in 2/29 children and minor complications in 5/29 children. The major complications were cerebellar contusion, and meningitis, which was treated with antibiotics and resolved. The minor complications included wound seroma/CSF leak, minor infections, balance problems, temporary dysphonia, and non-auditory side effects of stimulation. Sennaroglu has also observed two children with transient facial palsy and five children with CSF leak out of 39 children implanted with ABI. Taken together, these data indicated that auditory brainstem implantation is a relatively safe procedure in children, and has a risk profile that is low, but still somewhat higher than cochlear implantation.

## CONCLUSION

Auditory brainstem implantation in children has opened an exciting avenue of hearing rehabilitation for a group of children with a challenging set of pathologies. Despite the fact that relatively few children have been implanted and prospective studies have not yet sharpened our focus on ways to optimize patient selection and performance, there have been some encouraging success stories among implanted children. Continued and careful research will clarify the safety and success of ABI surgery in this selected cohort of deaf children who are not candidates for the cochlear implant.

# Balance Disorders in Children

***Michael S Cohen, Richard Lewis, Daniel J Lee***

## INTRODUCTION

Dizziness is a common symptom in children that can be challenging to manage. While dizziness may represent a vestibular disorder, it can also have central neurologic and non-neurologic causes. The term "dizziness" generally refers to an alteration of orientation to the surrounding environment, and it can be difficult for children to describe. Vertigo is defined as the perception of movement, typically spinning or turning, in the absence of actual movement. Children are especially good at compensating for loss of vestibular function and are able to rely on vision, hearing, and proprioception to maintain balance in many cases. A comprehensive approach to management of balance disorders in children will be presented in this chapter.

## PHYSIOLOGY

Vestibular hair cells can be stimulated by rotation, translation, or change in orientation with respect to gravity. This stimulation causes a change in the firing rate of the eighth nerve fiber innervating that particular hair cell, altering the input to the vestibular nucleus. These inputs are integrated in the vestibular nuclei along with visual, auditory, and somatic signals, resulting in compensatory eye movements, truncal control, and spatial orientation.

The vestibulo-ocular reflex (VOR) is a manifestation of the vestibular pathway that keeps the eyes fixed on a target while the head is moving by producing a proportional stimulus to the extraocular muscles in response to vestibular stimulation. The VOR is readily measurable using electro- or videonystagmography, and disturbances of the VOR are apparent in many vestibular disorders.

When an acute loss of peripheral vestibular function occurs unilaterally, there is a loss of resting neural discharge activity in that vestibular nerve and the ipsilateral nucleus. This loss of symmetry between the two nuclei is interpreted by the brain as a rapid head movement toward the healthy labyrinth. "Corrective" eye movements are produced toward the opposite side, resulting in nystagmus, with the slow component moving toward the abnormal side and the fast component moving toward the healthy labyrinth.

## OFFICE EVALUATION

It is important to elicit a chief complaint from the patient in his/her own words. Allowing the child to use his/her own vocabulary can be particularly instructive with regard to his/her subjective experience. History of present illness should include onset, duration, and frequency of episodes, association with other activities, and associated symptoms such as headache, nausea, or vomiting. A history of otologic symptoms such as hearing loss, tinnitus, aural fullness, otorrhea, and otalgia; and neurologic symptoms such as mental status changes, weakness, numbness, dysphagia, dysgeusia, facial weakness, and visual disturbances should be sought. Past medical and surgical history should include gestational age, birth trauma, complications, and history of central nervous system infections. Family history should include presence of migraine headaches, epilepsy, hearing loss, and syndromic illness. A questionnaire sent to the patient before the initial assessment can be useful to organize thoughts about the child's dizziness before the assessment. Children being evaluated for dizziness should have a complete audiologic evaluation, either with age

appropriate behavioral audiometry or with auditory brainstem response testing for children who cannot provide adequate responses with behavioral audiometry.

## Physical Examination

Physical examination should begin with observation of the patient and assessment of his/her general appearance, level of distress, and maintenance of posture. Orthostatic blood pressure measurements should be obtained. Ear examination should include pneumatic otoscopy. The nose, oral cavity, oropharynx, and neck should also be evaluated as part of a complete head and neck examination. Neurologic evaluation with special attention to cranial nerve function should be performed, including visual field testing and fundoscopic examination.

Observation of the child when walking can reveal abnormalities of coordination. Dysmetria may be demonstrated by the finger-to-nose and heel-to-shin tests. Additional abnormalities associated with cerebellar lesions can be assessed by evaluating the patient for dysdiadochokinesia, hypotonia, and decreased deep tendon reflexes.

### *Evaluation of Nystagmus*

Evaluation of nystagmus can best be performed in the office through observation. Frenzel goggles are high-magnification lenses with internal illumination that both reduce visual fixation and magnify the eyes for the observer. These can significantly aid the office evaluation of nystagmus. Alternatively, an infrared video system may be used.

*Spontaneous and gaze-evoked nystagmus*: Spontaneous nystagmus is an involuntary, rhythmic movement of the eyes not induced by any external stimulation. Nystagmus is named by the direction of the fast component. Spontaneous nystagmus is tested by having the patient look straight ahead with and without fixation. Gaze-evoked nystagmus is assessed by having the patient deviate the eyes laterally (no > 30°) with fixation. Nystagmus observed at the extreme limits of gaze, i.e. greater than 30°, is usually physiologic. Nystagmus is often reduced when looking in the direction of the slow component and increased when looking in the direction of the fast component.

*Positional nystagmus*: Positional nystagmus is assessed by examining the patient in each of the following six positions: sitting, supine, supine with the head turned to the right, supine with the head turned to the left, and right and left lateral positions. Persistent positional nystagmus presents without latency and persists as long as the patient remains in the provoking position. Paroxysmal nystagmus has a brief latency, fatigues on repeat provocations, and is usually associated with vertigo. It is often provoked by the Dix–Hallpike maneuver, in which the patient is moved rapidly from the sitting position to a right or a left head-hanging position.

### *Perilymph Fistula Test*

Perilymph fistula testing can be performed by applying pressure to the tympanic membrane either by repeatedly pressing the tragus or by applying positive and negative pressure in the external auditory canal with the use of a Politzer bag or a tympanometer. The patient's eyes are observed using Frenzel goggles. The fistula test is considered positive if nystagmus and vertigo are generated.

### *Head Thrust Test*

The head thrust test is performed by having the patient fix his/her gaze straight ahead. This can be accomplished with an interesting toy in younger children. The examiner then rapidly turns the head to the right or left. In a normal test, the eyes will stay fixed on the object of interest. In cases of vestibular hypofunction, the eyes will remain stationary within the orbit, turning away with the head, and then one or two saccadic movements will bring the gaze back to the object of interest.

### *Motor Function Testing*

The Peabody Development Motor Scale (PDMS), the Bruininks-Oseretsky Test of Motor Proficiency (BOTMP), and the sensory organization test of computerized dynamic posturography (CDP) are valid tools for the evaluation of balance in children.

The PDMS assesses motor development, and is designed for children up to 7 years of age, whereas the BOTMP is appropriate for children from 4.5 years to 14.5 years of age. The BOTMP is generally the tool used after children become able to complete the PDMS gross motor items. The BOTMP takes less time, space, and equipment than the PDMS.

### *Vestibular Testing*

Vestibular laboratory testing is recommended in any child with a history of dizziness in whom a thorough history and physical examination has not established a diagnosis, to differentiate between a peripheral or central vestibular

lesion, and to identify side of lesion in a peripheral abnormality.[1] Because children with severe sensorineural hearing loss (SNHL) may have vestibular abnormalities, vestibular laboratory testing is recommended.[2] This is especially important in infants and young children with delayed motor development.[3] Vestibular laboratory testing assesses both the VOR and vestibulospinal reflexes.

Videonystagmography, having generally replaced electronystagmography, uses infrared goggles to record eye movements in a number of clinical conditions. Spontaneous and positional nystagmus, ocular motor testing, caloric testing, and rotational testing are generally included in the test battery. Only caloric testing gives definitive information about the condition of each labyrinth individually.

Binaural bithermal caloric testing stimulates each ear at 30°C and 44°C using direct irrigation of the ear canal or a closed loop balloon system in patients with a nonintact eardrum. When the irrigation is performed at 44°C the nystagmus (fast component) is toward the irrigated ear, and when using 30°C irrigation the nystagmus is away from the irrigated ear. Several formulas exist to quantify the degree of vestibular response for each side.

Rotational testing is a physiologic test to assess the VOR, as rotation is the natural stimulus to the semicircular canals. Both labyrinths are stimulated simultaneously. Rotational testing uses a specially designed chair to generate physiologic stimuli while eye movements are recorded. Major advantages in children include decreased nausea compared with caloric testing and the ability to seat the child in a parent's lap during testing. Three parameters are derived from the rotational testing; gain measures magnitude of the response (eye velocity) in relation to stimulus, phase measures timing between the response and the stimulus, and asymmetry measures difference in response between sides.

Computerized dynamic platform posturography is a physiologic test of the vestibulospinal and motor systems and assesses balance and posture by modifying visual, proprioceptive, and vestibular inputs under six sensory conditions referred to as the sensory organization test. In conditions I through III, the patient stands on a pressure platform that senses changes in center of gravity. In condition I the visual surround is static, in condition II the patient is blindfolded, and in condition III the background moves in synchrony with the patient's center of gravity, creating the illusion of no visual movement. Conditions IV through VI repeat the visual conditions of conditions I through III; however, the pressure platform is mobile, attenuating proprioceptive inputs. Sway amplitude and speed of sway can be measure in each axial direction or as a composite score. Conditions V and VI, the "vestibular conditions", most reliably isolate the vestibular inputs, and patients with a vestibular loss are likely to lose their balance and fall in these conditions.

Vestibular-evoked myogenic potentials (VEMPs) refer to electrical activity recorded from neck or eye muscles in response to intense auditory clicks or vibrations.[4,5] VEMPs reflect stimulation of the saccule, and may give unilateral information in some cases. VEMPs have been performed successfully in children as young as age 3.[6] Normative data for children may differ from that of the adult population.[7] Elevated amplitudes of VEMPs can be seen in some normal children and should be interpreted with caution.[8]

### *Laboratory Testing*

Laboratory testing may be helpful especially in cases where nonvestibular causes of dizziness are suspected. Complete blood count, serum glucose, and thyroid function tests can reveal common causes of lightheadedness or orthostasis. Additional testing for evidence of rheumatological, metabolic, and autoimmune conditions may be fruitful in select cases.

## Imaging

Imaging studies include computed tomography (CT) with or without contrast enhancement for the evaluation of bony structures of the temporal bone and middle ear. CT is performed to rule out congenital malformations or abnormalities such as infectious processes, cholesteatoma, or temporal bone fractures. Magnetic resonance imaging (MRI) with gadolinium enhancement is the best available imaging modality for clearly demonstrating central lesions and the contents of the internal auditory canal.

# ETIOLOGY

## Prevalence

While estimates of the prevalence of vertigo in children range from 7% to 8%,[9,10] vertigo is the chief complaint of only 0.7% of children presenting to an otolaryngology clinic.[11] These studies suggest that vertigo is not uncommon in children, but is often not brought to the attention of the otolaryngologist. This discordance may be exacerbated by the often vague and ephemeral nature of symptoms. When carefully evaluated, however, balance disorders can be diagnosed in children.

## Central Causes of Dizziness in Children

The majority of children who present with vertigo have a neurologic basis for their symptoms, and in this sense they differ from the adult population. By far, the most common central cause of vertigo in children is a migraine variant, while other central etiologies are relatively infrequent.[10a] Although all children presenting with vertigo do not require imaging of the brain, it is useful to organize the underlying central etiologies of vertigo in two categories, based on the absence or presence of a structural brain abnormality.

### *Central Dizziness without a Structural Brain Abnormality*

Vestibular migraine (VM), previously called benign recurrent vertigo of childhood, is the most common cause of vestibular symptoms in the pediatric population. One large study found that about 40% of all children presenting with vertigo were ultimately diagnosed as having a migraine variant as the cause of their symptoms.[11] VM is a well-recognized but poorly understood disorder. The mechanisms that relate migraine to vestibular symptomatology are unclear, but probably are due to the close juxtaposition and many interconnections between the regions in the brainstem that are thought to generate migraines (e.g. dorsal raphe nucleus) and the vestibular nuclei.[12] Although there have been occasional reports to the contrary,[13] VM is considered a central disorder and in general should not be associated with symptoms, signs, or test findings that clearly localize the pathology to one inner ear.

The diagnosis of VM, which generally follows the criteria first explicated by Neuhauser et al.,[14] has both inclusionary and exclusionary elements. The former generally requires a history of headaches that meet the international headache association (IHS) criteria for migraine,[15] but in children a clear headache history is often absent. Instead, factors that suggest VM include a family history of migraine and a personal history of motion intolerance. If there is a migraine history, then a temporal association between migraine (or related symptoms, such as noise or light sensitivity) and vestibular symptoms is needed to meet the "definite" Neuhauser criteria; if headaches and vertigo episodes are temporally independent, then the diagnosis based on the Neuhauser criteria would be "probable" VM.[14]

The specific characteristics of the vertigo episodes, such as their duration or provoking features, are usually not helpful in making the diagnosis of VM,[15] although vertigo episodes caused by VM are often provoked or exacerbated by changing head position relative to gravity (e.g. turning while in bed). Correlations of vertigo with other known migraine triggers such as foods (e.g. chocolate), sleep deprivation, or hormonal cycles (ovulation or menses) can also be suggestive. As noted above, VM is usually not considered when patients describe symptoms that clearly localize to one ear. The neurologic examination in VM is usually normal and does not display peripheral vestibular or auditory findings. In contrast, central vestibular or eye movement abnormalities are sometimes noted between episodes, although this is more common in adults with VM.[16] Similarly, audiograms and tests of peripheral vestibular function (caloric, rotation, VEMP) are generally normal, although several studies have related increased VEMP thresholds to VM in adult subjects.[17] If imaging is obtained, it is invariably normal. Unfortunately, a specific diagnostic test for VM is not currently available, although recent research suggests that quantitative measures of motion perception may eventually provide a more definitive way to diagnose VM.[18,19]

When a child is diagnosed with definite or probable VM, there are two treatment options to consider. Usually one begins by minimizing migraine triggers, which require lifestyle changes including adequate sleep, regular meals, stress reduction, dietary changes, and aerobic exercise. If this approach is not adequate, then it is reasonable to consider the use of prophylactic migraine medications.[20] It is important to emphasize that abortive migraine drugs such as sumatriptan have not been shown to affect vestibular symptoms,[21] and this approach to therapy is not recommended. However, the decision to use daily preventative medication is difficult in children, and depends on the extent that the vertigo episodes are affecting the quality of life and how the patient and his/her family feel about taking daily medication. The drugs used are not specific for VM, but rather are the typical migraine prophylactic medications, which include Periactin, beta-blockers, calcium channel blockers, tricyclic antidepressants, or antiepilpetic drugs. Treatment is empiric, with the medication chosen based on potential side-effect profiles and on other medical issues in the specific patient. The starting dose is low to minimize side effects, and is raised every 2–3 weeks. It is important to emphasize that a minimum of 2 weeks is needed on a given dose to determine if it is efficacious. Generally, as the dose is raised, the vestibular symptoms will improve, side effects will develop, or a substantial dose will be reached without affecting the vestibular symptoms. In the latter two cases the drug should

be stopped and an alternate drug should be tried. If the patient fails to respond to two or three medications that are tried in this manner, then the underlying diagnosis must be reconsidered. If the patient does respond well, then one could consider tapering and stopping the medication after 6–12 months to determine if it remains necessary. Many children with VM outgrow the vestibular symptoms but they generally develop typical migraine headaches.[22]

Other central causes of vertigo in children who have structurally normal brains are uncommon. Episodic ataxia type 2 is an autosomal dominant calcium channelopathy that presents with recurrent episodes of vertigo and ataxia, which are superimposed on a slowly progressive ataxia.[23] History is notable for a strong family history of similar symptoms and absence of other otologic or neurologic symptoms. Physical examination usually demonstrates central abnormalities such as vertical (e.g. downbeat) nystagmus and abnormal eye movements, and imaging may show atrophy of the cerebellum. The gene responsible for this disorder has been mapped to the CACNA1A gene and this can be tested in clinical laboratories. It is critical not to miss this disorder since the vertigo episodes (but not the progressive ataxia) usually respond very well to medical therapy. For several decades this disorder was treated with acetazolamide, but it is clear that the potassium channel blocker 4-aminopyridine is a more effective form of therapy and is usually well tolerated.[24]

Vestibular epilepsy is quite rare and is thought to reflect abnormal activity in the vestibular region of the cerebral cortex in the temporal or parietal lobes.[25] For this reason, other elements of temporal lobe (e.g. complex partial) seizures, such as reduced level of consciousness, automatisms, or a post-ictal state, may be associated with the vestibular symptoms. EEG may support this diagnosis if it demonstrates epileptiform activity in the temporal lobe, although a normal EEG does not exclude it. EEG monitoring, either inpatient or outpatient using an ambulatory device, increases the probability of capturing epileptiform activity in cases of vestibular epilepsy, but normal results remain nondefinitive, even if episodes occurred during the period of monitoring. Vestibular epilepsy is treated like other temporal lobe seizures with standard antiepileptic drugs.

Psychologic causes of vertigo are relatively common in children, accounting for 6% of all patients in one large study.[11] This can take two forms, either a conscious form that is similar to malingering, where a clear secondary gain (such as school avoidance) can be identified. More commonly, psychogenic dizziness is not conscious but is a form of an anxiety reaction. This diagnosis is considered when the characteristics of the dizziness seem nonphysiologic (e.g. vertigo is present continuously for months), the evaluation is normal, and stressors or a depressive/anxiety disorder is suspected.[26] In this scenario, referral to a psychologist or psychiatrist is warranted, as this problem generally responds well to appropriate behavioral and/or medical therapy.

### *Central Dizziness with a Structural Brain Abnormality*

Two types of structural abnormalities can present with vertigo, either congenital abnormalities or tumors. By far the most common congenital abnormality that presents with episodic vertigo is a Chiari 1 malformation (Fig. 24.1). In this disorder, the caudal brainstem and cerebellar tonsils are located below the foramen magnum, and vertigo and other symptoms are caused by direct mechanical pressure exerted by the bone on these brain structures.[27] Vertigo caused by Chiari malformations is often brief and provoked by Valsalva maneuvers such as coughing or sneezing. In this sense, it can be mistaken for the symptoms of a perilymph fistula or superior semicircular canal (SSC) dehiscence. Other lower cranial nerve symptoms, such as problems swallowing or articulating words, are often associated. Physical examination usually demonstrates downbeat nystagmus, which can be provoked or magnified with a Valsalva maneuver or neck extension, and associated eye movement abnormalities such as gaze

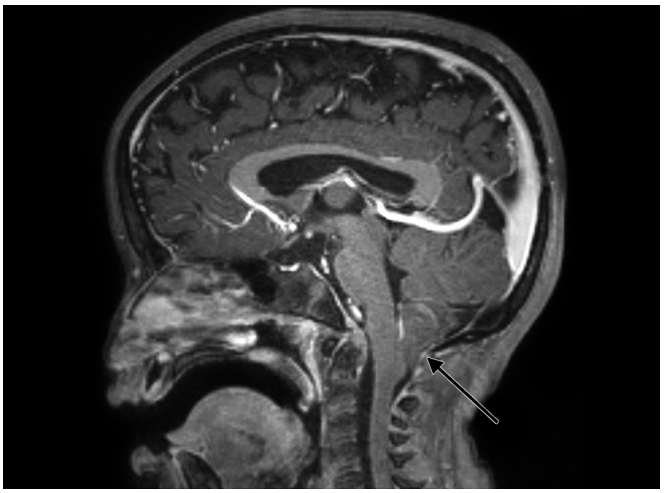

**Fig. 24.1:** Post-contrast sagittal magnetic resonance imaging (MRI) in a 6-year-old patient with dizziness, ataxia, and Chiari malformation. Arrow demonstrates cerebellar tonsils and caudal brainstem present below the foramen magnum.

holding nystagmus and impaired pursuit.[28] MRI displays not only a downward displacement of the caudal brain but also a evidence of "crowding" or pressure of bone on the displaced neural structures. If the symptoms warrant a surgical approach, decompression of the caudal brain by removing surrounding bone can improve or at least stabilize symptoms. One common issue regarding Chiari malformations is that many asymptomatic people have some degree of downward displacement of the cerebellar tonsils, and this becomes a diagnostic issue if people with this anatomic variant develop vestibular symptoms. As a general rule, in the absence of "crowding" on MRI or physical signs of caudal brainstem or cerebellar dysfunction, such as those outlined above, downward displacement of the tonsils is very unlikely to be responsible for vestibular symptoms.

Tumors that present with vertigo are invariably located in the posterior fossa, and can directly affect the brainstem or the cerebellum. Astrocytomas, medulloblastomas, and ependymomas are examples of tumors that can present initially with vertigo.[29] As expected, patients with these tumors rapidly develop other symptoms and signs of brain stem dysfunction, leading to diagnosis with MRI. The one exception is ependymomas, which are located in the ventricle and typically grow very slowly. For these reasons, ependymomas may produce vestibular symptoms for a longer period than other posterior fossa tumors before they are diagnosed with brain imaging.[30]

## Peripheral Causes of Dizziness in Children

### *Head Trauma*

Head trauma can cause an acute episode of vertigo by abruptly affecting the vestibular end organ directly, i.e. a labyrinthine concussion. Although several theories have been proposed, the mechanism of injury in labyrinthine concussion is poorly understood. Pressure waves transmitted directly to the labyrinth through the skull or intracranially via the cochlear aqueduct may cause rupture of the membranous labyrinth or damage to hair cells, hair bundles, or specialized structures in the ampulla or macula. The child usually recovers completely within a short period of time, but, on rare occasions, benign paroxysmal positional vertigo or delayed endolymphatic hydrops may develop. Benign paroxysmal positional vertigo is characterized by nystagmus and associated vertigo elicited by rapid changes in head position from upright to head hanging. It is thought to be caused by canalithiasis and can be treated with particle repositioning.[31] Other mechanisms of vertigo after head trauma include parenchymal injury of the CNS, temporal bone fracture, and perilymphatic fistula.

### *Perilymphatic Fistula*

Perilymphatic fistula is an anomalous connection between the inner ear and middle ear spaces and has been well documented in children.[32] Although perilymphatic fistula is usually associated with hearing loss, it can be associated with vertigo alone.[33] A perilymphatic fistula can be acquired or congenital. The congenital fistulas are associated with abnormalities in the temporal bone, particularly in the area of the stapes, but also in the vicinity of the round window. Acquired perilymphatic fistulae are generally caused by trauma, which may include iatrogenic trauma, barotrauma, penetrating trauma, or other head trauma.

The diagnosis and treatment of perilymphatic fistula consist of exploration of the middle ear and repair of the fistula by packing with temporalis fascia or muscle. At the time of surgery, fluid from the middle ear should be collected and sent for beta-2 transferrin testing, which is considered to be an objective test for the diagnosis of a perilymphatic fistula.[28]

### *Visual Problems*

Visual problems such as refraction abnormalities (myopia, hypermetropia, or astigmatism) or anomalies in ocular convergence (convergence insufficiency or latent strabismus with binocular vision) are a common cause of vertigo in children. The symptoms usually occur in children 6 years or older and are often associated with fatigue and excessive exposure to television, computer, and handheld device display screens. Episodes are usually recurrent and of short duration. The vertiginous symptoms typically consist of a sensation of rotation or displacement of the environment of mild-to-moderate intensity. Headaches occur in nearly 50% of children, particularly when a family history of migraine is present. Neurologic and vestibular evaluations are normal. A complete ophthalmologic examination is indicated. Treatment includes correction of refraction anomalies and comprehensive orthoptic therapy. The sensation of imbalance and dizziness may be due to failure in binocular vision or convergence causing inadequate gaze stabilization during movement and double or blurry vision during fixation. Extensive screen time may unmask a latent ophthalmologic condition.

### *Vestibular Neuritis*

Vestibular neuritis is rarely seen in children younger than 10 years old. It should be considered when a viral syndrome is followed by symptoms suggestive of an acute unilateral peripheral vestibular loss, which is more common in children than in adults.[34] It presents with acute severe vertigo, nystagmus, nausea, and vomiting. The vertigo is worsened by head movements, and patients often prefer to lie down, usually with the affected ear up. There is no hearing loss or tinnitus. Vestibular laboratory testing indicates a unilateral reduced vestibular response to bithermal caloric testing. The symptoms resolve in children within a few days. Management is supportive and symptomatic with early ambulation. A short course of vestibular suppressants such as meclizine may be given, but should be limited as it may delay central nervous system compensation. Corticosteroids, such as prednisone, may shorten the duration of the illness, but no studies of their efficacy in children have been performed.

### *Labyrinthitis*

Acute labyrinthitis is an inflammatory condition that affects the labyrinth and generally leads to both vestibular and auditory symptoms and signs. The etiology of serous (toxic) labyrinthitis is unknown, but bacterial toxins or other biochemical substances in middle-ear fluid are thought to be absorbed into the inner ear through the round and oval windows. Bacterial or suppurative labyrinthitis occurs when bacteria directly infect the labyrinth via the middle ear or from a central route as a sequela of bacterial meningitis. Suppurative labyrinthitis may leave the patient with permanent deficits in vestibular and auditory function. When diagnosed, treatment should be initiated immediately with IV antibiotics and surgical management if appropriate.

### *Meniere's Disease*

Meniere's disease is characterized by a complex of symptoms including dizziness, unilateral hearing loss, tinnitus, and aural fullness. While some patients may have only hearing loss and tinnitus, others may have only vestibular symptoms. The duration of the vertiginous episodes may vary from 30 minutes to several hours, and episodes are frequently accompanied by autonomic symptoms such as pallor, perspiration, nausea, and vomiting. Between these acute episodes, adults and rarely children may have vague symptoms of disequilibrium. Children are more likely to recover auditory function than adults. With time, a reduction in the responsiveness of the involved peripheral vestibular system occurs. Management of endolymphatic hydrops in children includes reassurance and explanations of the condition to the parents in addition to salt restriction and a diuretic.[35] The need for surgical treatment is rare in children.

### *Vestibular Dysfunction in Sensorineural Hearing Loss*

Numerous studies in children with hearing loss have found that the incidence of vestibular hypofunction ranges from 49% to 95% of those tested. Horak et al. compared 30 hearing impaired children and 15 learning-disabled children to a group of 54 normal controls using both vestibular and motor testing. Two-thirds of hearing impaired children had abnormal VOR compared with one-fifth of learning disabled children and 7% of normal controls.[2] Further studies suggest that a component of learning disabilities in the context of hearing loss may be due to deficiencies in reading acuity associated with vestibular dysfunction.[36]

An interesting subpopulation of children with SNHL is those who have undergone cochlear implantation (CI). While numerous studies have evaluated vestibular function following unilateral CI in adults,[37-40] fewer studies have examined the impact of unilateral CI on vestibular function in children. Jacot et al. examined 224 children with profound SNHL prior to unilateral CI and found 50% to have abnormal bilateral vestibular function. Of the patients with existing vestibular function prior to CI, 70% experienced a post-CI worsening of vestibular function. Ten percent of patients developed complete ipsilateral vestibular areflexia.[41] Licameli et al. investigated the prevalence and severity of vestibular impairment in two groups of children with CI and found that 52% had abnormal VOR, 39% had abnormal CDP, and 80% had reduced or absent VEMP in the ipsilateral ear after CI.[42] Cushing et al. performed vestibular testing in a group of 40 children with unilateral CI and found abnormal caloric responses in 50% of patients.[43]

Based on their findings, the above investigators advocate for vestibular testing, when feasible, in any pediatric CI candidate prior to surgery. While no consensus has been reached on the ideal timing and extent of such testing, Jacot et al. suggest a clinical vestibular examination including the head thrust test, bithermal caloric testing, and VEMP.

### *Vestibular Dysfunction in Conductive Hearing Loss (CHL)*

Otitis media is one of the most common diseases in infants and children.[44] Acute otitis media (AOM) occurs at least once in up to 71% of children under 3 years of age and an episode of AOM is followed by persistent middle ear fluid (otitis media with effusion, OME) for at least 4 weeks in 60% of cases.[45] The principal effect of OME on hearing consists of a mild-to-moderate CHL with an average threshold of 27 dB.[46] This degree of hearing loss may delay speech development and be associated with learning disabilities. In addition, Eustachian tube dysfunction with and without middle ear effusion is considered one of the most common cause of vestibular disturbances in children.[47,48] Anecdotal evidence from parents suggests that children with OME often exhibit a high degree of movement disorganization and propensity for falls especially compared with their peers without middle ear disease. Parents further report that their children often begin to walk or become less clumsy after tympanostomy tube insertion. More recently, studies in children have produced evidence supporting both the notion that vestibular, balance, and motor function may deteriorate in the setting of middle ear effusion and that this deterioration is reversed with resolution of OME.

Placement of tympanostomy tubes in children with otitis media has been shown to improve balance. Casselbrant et al. tested 41 children with OME using moving platform posturography before and after insertion of tympanostomy tubes and found a higher speed of sway was in children with OME than in normal children.[49] Golz et al. tested 136 children, 4–9 years of age, using electronystagmography and the BOTMP before and after tube ventilation of the middle ear. Pathologic findings on either study were found in 58% of the children with chronic middle ear effusion, as compared with only 4% of healthy controls. Balance disturbances resolved in 96% of subjects after tympanostomy tube insertion.[50] Casselbrant et al. found that children aged 3–9 years with OME had increased postural sway in response to moving visual scenes compared with age- and gender-matched controls, with statistically significant differences noted at both tested frequencies of surround movement.[51] The above studies indicate that balance-related symptoms in young children may result from OME and that these symptoms often resolve after middle ear aeration returns to normal.

## REHABILITATION OF BALANCE AND MOTOR SKILLS IN THE HEARING IMPAIRED CHILD

As described above, children with peripheral vestibular hypofunction in the setting of a normal central nervous system are likely to compensate well in most environments. Nevertheless, early identification of specific functional deficits can guide rehabilitative efforts. Even when such children have excellent motor skills, strength, and speed, they may be labeled clumsy when they fall or lose balance in conditions with poor or unreliable visual and proprioceptive inputs.[2]

Rine et al. demonstrated a statistically significant improvement in motor development in children with SNHL and vestibular dysfunction treated with exercise intervention. Control patients were subsequently treated with exercise intervention, and demonstrated a comparable improvement.[52] In a preliminary study involving two subjects with SNHL and bilateral vestibular hypofunction, an exercise program using head movements in the setting of complex backgrounds was employed. Both subjects showed improvement in critical print size nearing clinical significance. One subject had an improved dynamic visual acuity score.[53]

With the exception of the above studies, the literature is relatively deficient on the potential for various interventions to improve balance and motor development in SNHL patients with vestibular loss and impaired motor development.

## PEDIATRIC SUPERIOR SEMICIRCULAR CANAL DEHISCENCE

### Introduction

Superior canal dehiscence syndrome (SCDS) was first recognized in adult patients by Minor et al. in 1998,[54] and the first pediatric cases were reported in 2005.[55,56] It can present with a myriad of auditory and/or vestibular symptoms that are associated with a bony defect of the superior canal. High-resolution CT demonstrates a dehiscent area of bone in the region of the arcuate eminence (in contact with temporal lobe dura) or the medial (nonampullated) limb associated with the superior petrosal sinus (SPS-SCD).[57] The etiology of SCD remains unknown, but several hypotheses have been presented. Nadgir et al. suggest that SCD is an acquired condition with an increased prevalence in

older populations.[58] However, others theorize that some patients are born with thin or absent bone overlying the SSC,[56,59-61] and that a "second event" (e.g. skull base trauma, a Valsalva maneuver, or intense acoustic exposure) causes a sudden disruption of the canal defect. The presence of a bony defect in the superior canal at birth is supported by a number of pediatric SCD cases reported in the literature.[57,62-64]

## Embryonic Development

The semicircular canals arise with the budding of the membranous labyrinth from the otocyst. The superior canal develops first, followed by the posterior canal and then the horizontal (or lateral) canal. As the membranous labyrinth approaches adult size, ossification begins at the basal turn of the cochlea and progresses to the semicircular canals (first the superior canal, then posterior, and lastly the horizontal).[65,66] In infants the SSC is initially covered by a thin inner periosteal layer (endosteum). As the child develops, the inner and outer periosteal layers, along with the middle endochondral layer, mature into the trilaminar structure of the otic capsule and continue to thicken to adult thickness by 3 years of age.[59]

Chen et al. suggest that the presence of SCD in the pediatric population may be the result of abnormal development.[63] If SCD is a developmental abnormality, it is possible that superior canal dehiscence is caused by an arrest in the ossification process. However, one would expect the posterior and horizontal canals to be affected more than the superior, as they ossify later.[63] It is also conceivable that the middle endochondral layer and outer periosteal layer may fail to develop and thicken over a section of the canal. If dehiscent, or near-dehiscent, bone is subsequently traumatized, the inner ear may become sensitive to transmitted changes in fluid dynamics and intracranial pressures (resulting in vestibular symptoms).[59] SCD has also been found in patients with other craniofacial or developmental abnormalities (e.g. enlarged vestibular duct),[62,64,67] but there is no evidence to support that these additional anomalies directly cause SCD. An alternative theory is that some patients with SCD are born with relatively low-lying tegmen in relation to the arcuate eminence. Consequently, the superior canal becomes vulnerable to dural pulsations and subsequent thinning of the overlying bone. In patients with SPS-related SCD (a subset of the SCD population in adults and children), the superior canal may not be able to fully ossify during development because the SPS has already developed and may impinge on the canal and block complete ossification.

## Clinical Features

Pediatric SCDS patients can present with similar signs and symptoms as their adult counterparts. They may experience auditory symptoms, vestibular symptoms, or both. Auditory symptoms include hearing loss, autophony, conductive hyperacusis, aural fullness, or tinnitus (may or may not be pulsatile). Vestibular symptoms include disequilibrium, sound- or pressure-induced vertigo (Tullio phenomenon and Hennebert sign, respectively), or chronic dizziness.[57] It is important to note that it may be very difficult for children to accurately identify and verbalize their symptoms. Vestibular symptoms may be even harder for the child to recognize if those symptoms have persisted for the majority of their life. Parents, too, may experience difficulty in distinguishing vestibular symptoms from normal development. Auditory complaints (especially hearing loss) are commonly the presenting symptom as parents tend to notice a lack or delay in verbal development; audiometric testing makes these complaints more objective and easier to track long term.[64] However, children who have a bony defect involving the superior canal and the SPS may have atypical signs and symptoms (*see* Case 2 below).[57] The following are two pediatric SCDS cases from our institution, one with defects of the arcuate eminence (Case 1) and the other with a unilateral defect of the medial superior canal associated with the SPS (Case 2).

### *Case 1*

An otherwise healthy 7-year-old male presented with severe hyperacusis, and dizziness and vertigo provoked by loud noises, coughing, and sneezing. He also reported autophony, tinnitus, and otalgia with loud noise exposure. He denied hearing loss. At the time of presentation, his mother noted that he had extreme sensitivity to loud sounds even as a toddler. The patient was avoiding noisy situations, like the school cafeteria, and had already missed a significant amount of school as a result. His neurotological examination was normal with the exception of the Weber test that lateralized to the right. No spontaneous nystagmus was observed, and he had normal rotary chair and posturography tests. Audiometric testing showed supranormal bone conduction bilaterally and circular VEMPs (cVEMPs) revealed bilateral low thresholds (55 dB

nHL at 500 Hz). CT of the temporal bone revealed bilateral "blue-lined" superior canal defects (very thin bone covering the canal) (Fig. 24.2).

Due to the disabling nature of his symptoms, the patient and his family decided to undergo bilateral transmastoid "resurfacing" (in two stages, right then left ear) with calvarial bone graft and hydroxyapatite bone cement with round and oval window plugging at an outside institution. He initially reported symptom improvement, especially vertigo. His hearing remained stable postoperatively with audiometric testing showing supranormal bone conduction bilaterally (Fig. 24.3). A few months after his second surgery, the patient was hit in the right ear while playing and immediately had re-emergence of his preoperative noise-induced vertigo.

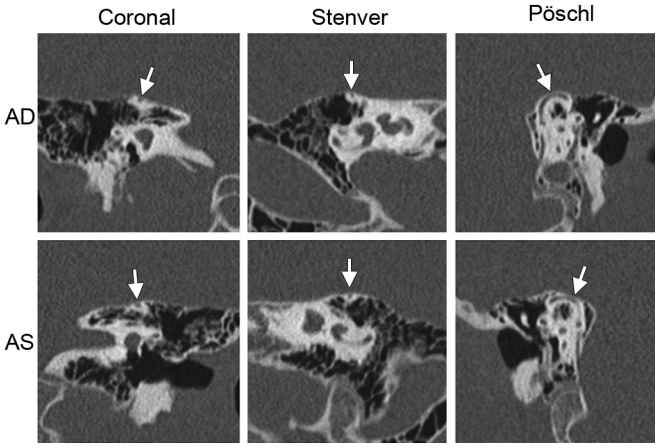

**Fig. 24.2:** Case 1. High-resolution computed tomography (CT). AD, right ear; AS, left ear. All views (coronal, Stenver, and Pöschl) show thinning of the arcuate eminence (peak) of the superior canals bilaterally (arrows), but no clear dehiscence. The tegmen is intact without evidence of dural herniation on either side, and mastoids are well aerated bilaterally.

## *Case 2*

A healthy 15-year-old female presented with vertigo and dizziness and associated nausea that began while playing field hockey.[57] She denied vertigo and dizziness induced by heavy lifting, straining, or loud noise, and did not report any hearing loss, aural fullness, tinnitus, or autophony. There was no prior head trauma. Symptoms subsided after a few days but intermittently re-emerged, especially after exercising. Neurotological examination was unremarkable. The patient exhibited no spontaneous nystagmus or nystagmus elicited with provocative maneuvers behind Frenzel lenses. Her preoperative audiogram revealed low-frequency supranormal bone conduction with an air–bone gap (ABG) in her right ear (Fig. 24.4A), and low cVEMP thresholds (60 dB at 250 Hz, 60 dB at 500 Hz, 65 dB at 750 Hz, and 70 dB at 1000 Hz). Temporal bone CT scan revealed a right-sided superior canal defect involving the posteromedial limb (nonampullated end) contacting the adjacent SPS (Figs. 24.5A and B).

The patient was initially managed conservatively with no surgical intervention, but persistent, exercise-induced vertigo began to severely affect her quality of life. At this point, surgical options were considered, and she and her family decided to undergo a right-sided transmastoid SCD repair. After identifying both limbs of the SSC and the SPS, individual labyrinthotomies were made in the ampullated and nonampullated ends of the superior canal (to isolate

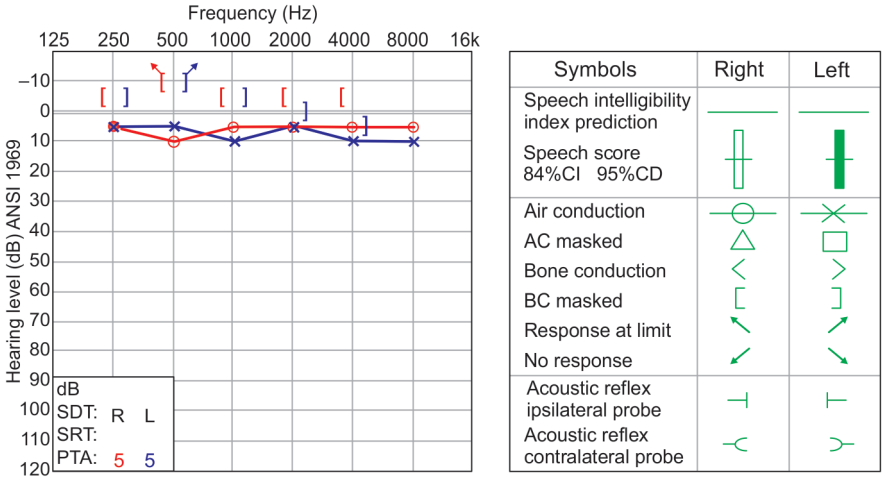

**Fig. 24.3:** Case 1. Audiometric testing, postoperatively. Hearing is within normal limits bilaterally, but there are supranormal bone conduction thresholds at 250, 500, 1000 Hz on the left and at 250, 500, 1000, 2000, and 4000 Hz on the right. These findings were seen before surgery as well. An air–bone gap of 20 dB at 500 Hz is present on the right.

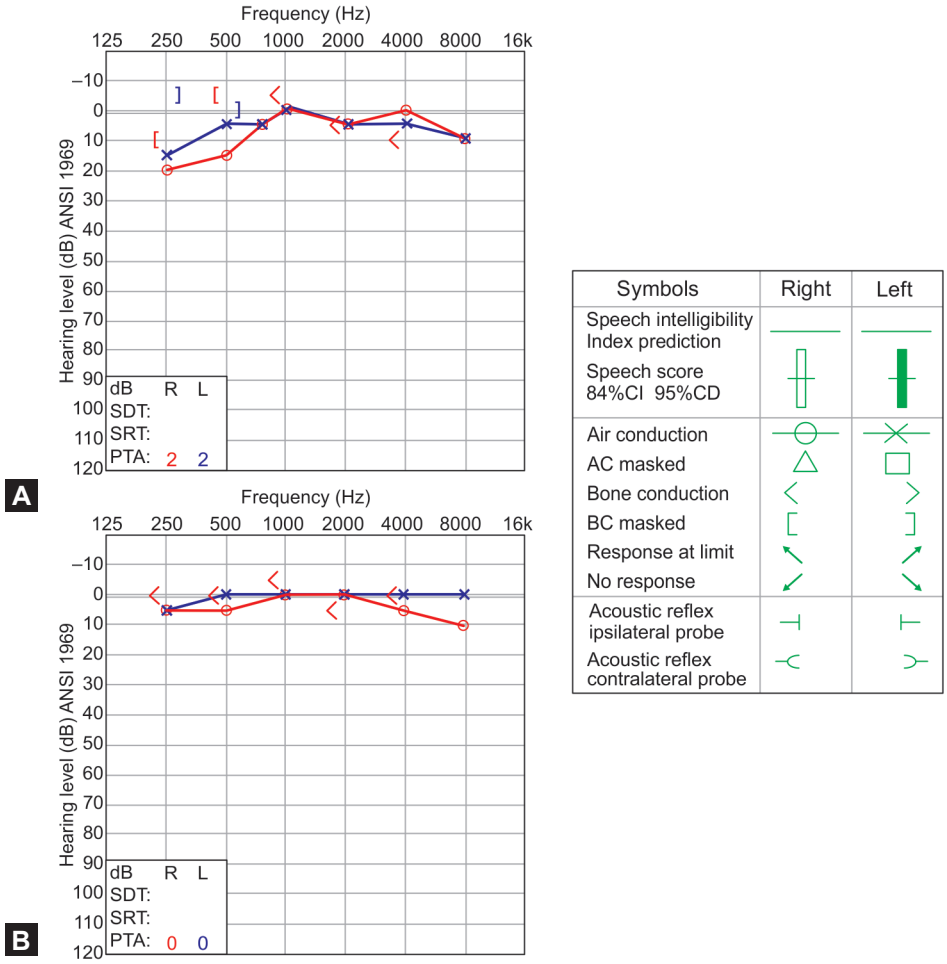


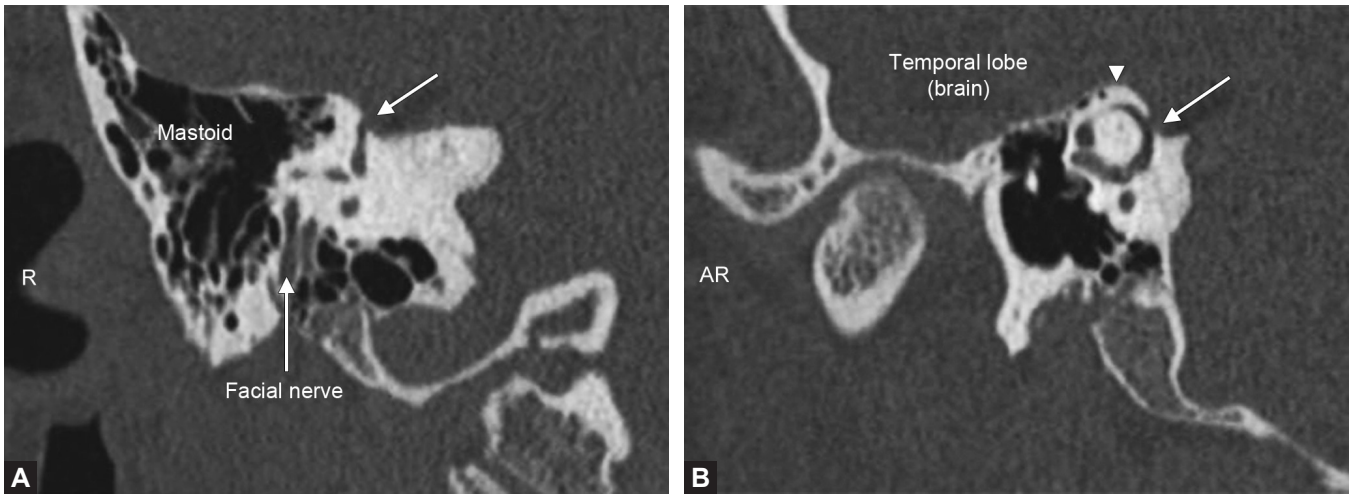
**Figs. 24.4A and B:** Case 2. Audiometric testing. (A) The preoperative audiogram shows supranormal bone thresholds at 500 and 1000 Hz in the right ear with a low-frequency air–bone gap (20 dB at 500 Hz); (B) The postoperative audiogram shows resolution of the supranormal bone threshold at 500 Hz and closure of the air–bone gap. Hearing was normal in the left ear (no superior canal dehiscence in left ear).

the bony defect associated with the SPS). These holes were then occluded with bone wax (Figs. 24.6A to F). The patient experienced mild transient disequilibrium during the first several postoperative days, but subsequently had complete resolution of all pre- and postoperative symptoms.[57] Supranormal bone-conduction thresholds (Fig. 24.4B) and low cVEMP thresholds on preoperative testing also normalized following her surgery.

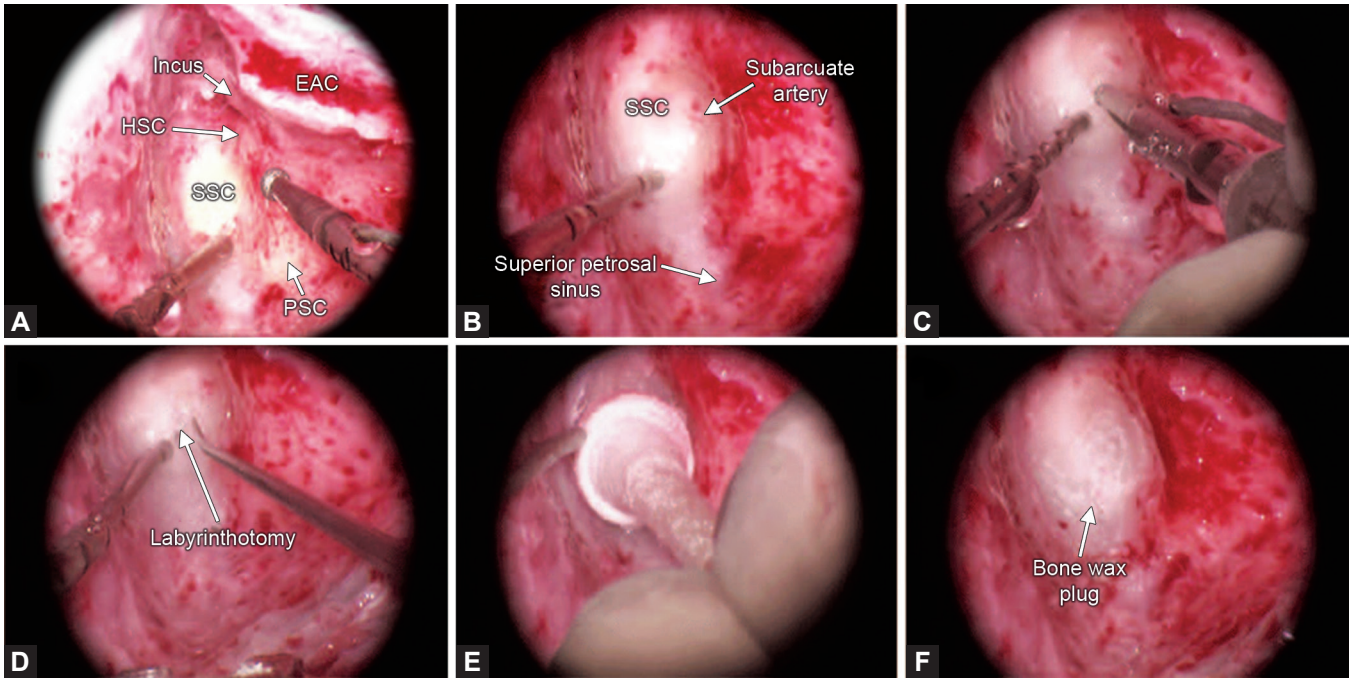
## Diagnostic Testing

High-resolution CT is essential in the diagnosis of anatomic SCD.[67] Furthermore, it is important to have multiple views of the temporal bone to better assess the defect. It can be difficult to visualize the extent of the dehiscence on coronal views, so Stenver (perpendicular to the plane of the SSC) and Pöschl (parallel to the SSC and 45° oblique to the coronal) reconstructions are routinely performed at our institution. In addition, SCD detected radiographically in children < 3 years of age should be considered a normal developmental finding, as the bone overlying the SSC does not reach the average adult thickness until approximately 36 months of age.[57]

Pure tone audiometry is an essential component of the workup and should include bone conduction testing at –5 and –10 dB to exclude the possibility of supranormal bone conduction. Minor et al. reasoned that the dissipation of acoustic energy through the dehiscence can create an ABG and an apparent CHL.[57a] Tympanometry and acoustic reflexes should also be evaluated to exclude middle ear disease or ossicular fixation as a cause of the ABG.[57] These measurements are by no means diagnostic, but hearing should be periodically evaluated to detect any significant change over time.



**Figs. 24.5A and B:** Case 2. High-resolution computed tomography (CT) scan. Right ear of same patient. (A) Coronal view demonstrating a right superior canal dehiscence in the region of the superior petrosal sinus (white arrow) of the right middle fossa. Note that the tegmen is NOT low-lying and otherwise intact; (B) Pöschl view demonstrating right superior canal dehiscence in the region of the superior petrosal sinus (white arrow). Note that the top of the SCC is intact (arcuate eminence) (arrowhead).



**Figs. 24.6A to F:** Case 2. Intraoperative images. Right ear, transmastoid approach. (A) Right mastoidectomy, canal wall up with the superior semicircular canal (SSC) exposed. HSC: Horizontal semicircular canal; PSC: Posterior semicircular canal; EAC: External auditory canal; (B) High magnification view showing the right SSC and the bluish hue defining the prominent superior petrosal sinus in the middle fossa; (C) Careful drilling using a low speed setting and a diamond burr to gently perform a labyrinthotomy, or hole, of the right SCC behind the dehiscence. A second labyrinthotomy is also performed (not shown) in front of the dehiscence; (D) The exposed membranous labyrinth is exposed following labyrinthotomy of the right SCC; (E and F) Plugging of the labyrinthotomy created in the SSC.

A measurement that has been consistently useful in the evaluation of symptomatic SCD is cVEMP testing. cVEMPs may show abnormally low thresholds and elevated amplitudes for patients with SCDS.[68] cVEMPs measure a vestibulospinal reflex mediated through the saccule and the inferior vestibular nerve in which a loud auditory stimulus induces an ipsilateral inhibition to the tonic neck muscle activity recorded on an electromyogram. There is evidence that the threshold to elicit a VEMP response is abnormally low due to an enhancement of endolymph

flow in the labyrinth with a dehiscence.[62] Not all patients (pediatric or adult) have abnormally low cVEMP thresholds; however, Niesten et al. found that patients with a smaller bony defect located further away from the ampulla may not present with lowered cVEMP thresholds (Niesten et al. 2013, in press). Consequently, SCD should not be ruled out solely on the basis of normal cVEMP testing.

### Treatment

Once a diagnosis of SCDS is made, treatment can be conservative or surgical. Conservative management includes observation with interval audiometric testing (hearing aids if appropriate), neurotologic examination, and ensuring that the child meets all developmental balance milestones.[57] This method is preferred due to the age of the patient population.[57,64] Surgical intervention should be saved for those patients with persistent and disabling vestibular and/or auditory symptoms.[64] There are two established surgical approaches to access the superior canal[57]—middle fossa craniotomy and transmastoid—and a number of methods that have been described to repair the bony defect. Both approaches have been used to safely and successfully manage SCD.[57,64] Finally, round window plugging via transcanal tympanostomy is a less invasive option, but has been sparsely described in the literature and has varying outcomes in studies involving small numbers of patients.[69,70] Prospective studies with larger cohorts are needed to determine the ideal surgical approach and repair method in both pediatric and adult patients with SCDS.

## CONCLUSION

Dizziness and vertigo are common symptoms among children. Attention to detail in history taking, thorough physical examination, and appropriate use of ancillary testing will enable the practitioner to navigate the complex differential diagnosis of dizziness and help this important patient population.

CHAPTER

# 25 Evidence-Based Medicine in Pediatric Otology

***Judith EC Lieu***

## INTRODUCTION

"Evidence-based medicine" (EBM) was coined in 1992 and defined as "the conscientious, explicit, and judicious use of current best evidence in making decision about the care of individual patients".[1,2] Although criticized as "cookbook medicine" that only incorporated randomized clinical trials (RCTs), it was intended to involve "tracking down the best external evidence with which to answer our clinical questions".[2] This has led to the establishment of "levels of evidence" (Table 25.1) and "grades of recommendation" (Table 25.2) to help practitioners evaluate the strength of the evidence in an individual article, clinical guideline, and other recommendations in an exercise called "critical appraisal of the literature".[3]

Importantly, appraising the medical literature requires an understanding of the types of clinical questions asked and the types of studies that offer evidence to answer these questions. As Table 25.1 shows, RCTs provide Level 1 evidence only for studies of therapy or prevention, etiology or harm; in the absence of Level 1 evidence, other comparative methods (i.e. cohort, case-control, and cross-sectional studies) provide as much evidence as the literature contains for these types of studies. The main concerns with non-RCT study designs are that (1) causality is more difficult to attribute to the intervention or exposure being studied, and (2) observational studies are more susceptible to various forms of bias than RCTs, which are intended to be truly experimental in design. However, due to practical concerns about the ethics of randomization, feasibility of performing randomized studies, and selection bias among participants that leads to limited external generalizability, RCTs do not always provide perfect evidence for clinical questions. Indeed, rigorous observational studies with validation provide Level 1 evidence for all of the other study types shown in Table 25.1 (i.e. prognosis, diagnosis, differential diagnosis/symptom prevalence, and economic and decision analyses). Systematic reviews of multiple controlled studies, regardless of study type, remain the best way of synthesizing good quality studies to evaluate the current medical science for the benefit of patients. When systematic reviews incorporate high-quality primary studies and are able to quantitatively combine results into a meta-analysis, they provide the most reliable evidence from the available medical literature. Unfortunately, if the systematic reviews have only poor-quality studies to evaluate and analyze, the product of those reviews is often a call for better future research.

Several sources are well known for their contribution to EBM and are referenced here as for further information and practice. First is the Cochrane Library (http://www.thecochranelibrary.com), named for Archie Cochrane, a British epidemiologist who published *Effectiveness and Efficiency: Random reflections on health services* in 1972, which pointed out the lack of collective knowledge about the effects of health-care. The Cochrane Library contains several databases, of which the most widely used is the Cochrane Database of Systematic Reviews, the leading source for systematic reviews in medicine. The main limitation with this database is that these systematic reviews include only RCTs. The second is the Centre for Evidence-Based Medicine in Toronto, Canada (http://ktclearinghouse.ca/cebm), which publishes the book *Evidence-Based Medicine: How to Practice and Teach EBM*.[4] This softbound book is recommended to all who benefit from a hard-copy

RCTs, randomized clinical trials.

*By homogeneity we mean a systematic review that is free of worrisome variations (heterogeneity) in the directions and degrees of results between individual studies. Not all systematic reviews with statistically significant heterogeneity need be worrisome, and not all worrisome heterogeneity need be statistically significant. As noted above, studies displaying worrisome heterogeneity should be tagged with a "-" at the end of their designated level.

†Clinical decision rule. (These are algorithms or scoring systems that lead to a prognostic estimation or a diagnostic category.)

‡See note above for advice on how to understand, rate and use trials or other studies with wide confidence intervals.

§Met when all patients died before the Rx became available, but some now survive on it; or when some patients died before the Rx became available, but none now die on it.

§§By poor-quality cohort study we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both exposed and nonexposed individuals and/or failed to identify or appropriately control known confounders and/or failed to carry out a sufficiently long and complete follow-up of patients. By poor-quality case-control study, we mean one that failed to clearly define comparison groups and/or failed to measure exposures and outcomes in the same (preferably blinded), objective way in both cases and controls and/or failed to identify or appropriately control known confounders.

§§§Split-sample validation is achieved by collecting all the information in a single tranche, then artificially dividing this into "derivation" and "validation" samples.

††An "Absolute SpPin" is a diagnostic finding whose specificity is so high that a positive result rules-in the diagnosis. An "Absolute SnNout" is a diagnostic finding whose sensitivity is so high that a negative result rules-out the diagnosis.

‡‡Good, better, bad, and worse refer to the comparisons between treatments in terms of their clinical risks and benefits.

†††Good reference standards are independent of the test, and applied blindly or objectively to applied to all patients. Poor reference standards are haphazardly applied, but still independent of the test. Use of a nonindependent reference standard (where the "test" is included in the "reference," or where the "testing" affects the "reference") implies a Level 4 study.

††††Better-value treatments are clearly as good but cheaper, or better at the same or reduced cost. Worse-value treatments are as good and more expensive, or worse and the equally or more expensive.

**Validating studies test the quality of a specific diagnostic test, based on prior evidence. An exploratory study collects information and trawls the data (e.g. using a regression analysis) to find which factors are "significant."

***By poor-quality prognostic cohort study we mean one in which sampling was biased in favor of patients who already had the target outcome, or the measurement of outcomes was accomplished in < 80% of study patients, or outcomes were determined in an unblinded, nonobjective way, or there was no correction for confounding factors.

****Good follow-up in a differential diagnosis study is > 80%, with adequate time for alternative diagnoses to emerge (e.g. 1–6 months acute and 1–5 years chronic).

**Table 25.2:** Grades of recommendation, based on 2009 Oxford Centre for Evidence-Based Medicine levels of evidence[3]

| *Grade* | *Criteria* |
|---|---|
| A | Consistent Level 1 studies |
| B | Consistent Level 2 or 3 studies or extrapolations from Level 1 studies |
| C | Level 4 studies or extrapolations from Level 2 or 3 studies |
| D | Level 5 evidence or troublingly inconsistent or inconclusive studies of any level |

reference and flashcards, and includes a CD-ROM with additional materials. The website includes information about how to practice and teach EBM, syllabi for practicing EBM, and other resources. Finally, the Centre for Evidence-Based Medicine at the University of Oxford (http://www.cebm.net/) provides additional workshops, conferences and training, as well as online tools and resources that can be used to practice or teach EBM. They publish and update the Levels of Evidence and Grades of Recommendation in Tables 25.1 and 25.2.

Practicing EBM is an iterative process at multiple levels. First, every clinician should evaluate results of new studies for applicability to individual practices and patients as they are published. However, critical appraisal of the literature takes training and practice, and should be incorporated as an element of resident training and continuing medical education. Second, incorporating recent studies into updated systematic reviews usually falls to those who are familiar with the methodology of

systematic reviews. The questions asked in systematic reviews may range from efficacy ("Does the intervention work at all?") to effectiveness ("Does the intervention work in the real world?") and to comparative effectiveness ("How well do interventions work compared to each other?"). Third, professional societies and specialty groups produce or update clinical guidelines to provide their membership with recommendations for the pragmatic application of synthesized studies, especially when wide variations in practice exist.[5] Clinical guidelines from different societies may vary and conflict, however, when those guidelines value one type of outcome over another, or represent standard of care rather than best evidence. Finally, the clinician must again assess the applicability of the guidelines and systematic review results to individual practices and patients. Based on practice and patient characteristics, recommendations from systematic reviews and guidelines may be adopted for many or some patients, but rejected for others due to limitations of the studies included in the systematic reviews, especially generalizability.

The goal of this chapter is to review topics in pediatric otology where there are large controlled studies, or systematic reviews of controlled or high quality studies. It will provide commentary on the applicability of these studies and reviews for clinical practice, and propose topics where pediatric otology could improve the evidence base from which clinicians practice. This review cannot be either exhaustive or completely up-to-date because new studies are presented and published continuously. Nevertheless, this compilation can establish a baseline from which future iterations of EBM in pediatric otology can proceed.

## OTITIS MEDIA

In pediatric otology, the best example of EBM has been in the management of acute otitis media (AOM) and otitis media with effusion (OME), where the sheer prevalence of this disorder has allowed the performance of many RCTs for preventative and therapeutic interventions, resulting in many reviews and generating multiple clinical guidelines. Table 25.3 shows a listing of Cochrane reviews within the past 5 years regarding specific questions in the management of AOM and OME, and the number of RCTs that contributed to the synthesized conclusions.

**Table 25.3:** Cochrane systematic reviews regarding otitis media or otitis media with effusion in children, since 2008

| *Year* | *Title* | *# RCT included (# participants)* | *Results/conclusions* |
|---|---|---|---|
| 2008 | Grommets (ventilation tubes) for recurrent acute otitis media in children[6] | 2 (148 children < 3 years old) | Mean reduction of 1.5 episodes of AOM in first 6 months after treatment; 20–25% incidence of no AOM in first 6 months after tubes vs. 2–10% in no tubes group |
| 2009 | Interventions for ear discharge associated with grommets (ventilation tubes)[7] | 4 (397 children) | Oral amoxicillin clavulanate compared to placebo decreased the odds of discharge persisting 8 days (OR 0.19, 95% CI 0.07–0.49); no benefit of steroids added to topical antibiotic drops |
| 2013 | Autoinflation for hearing loss associated with otitis media with effusion[8] | 6 (404 children, 198 adults) | Autoinflation approximately doubled the rate of improving a composite measure of tympanogram or audiometry at > 1 month. Reasonable to consider autoinflation while awaiting natural resolution of OME |
| 2009 | Pneumococcal conjugate vaccines for preventing otitis media[9] | 7 (46,885 children) | The 7-valent pneumococcal conjugate vaccine has marginal benefit to preventing AOM in infants, but 6–7% reduction may be substantial from public health perspective. Noninfant children with a history of AOM do not benefit when immunized at an older age |
| 2010 | Short-course antibiotics for acute otitis media[10] | 49 (12,045 participants) | Higher risk of treatment failure with short course (< 7 days) antibiotics, OR 1.34 (95% CI 1.15–1.55), absolute difference 3% at one month |
| 2010 | Grommets (ventilation tubes) for hearing loss associated with otitis media with effusion in children[11] | 10 (1728 children) | Grommets were mainly beneficial in the first 6 months after placement. By 12–18 months of follow-up, there was no difference in mean hearing levels. No effects were found on speech-language development, behavior, cognitive, or quality-of-life outcomes. Tympanosclerosis developed in about one-third |

*Contd...*

*Contd...*

| *Year* | *Title* | *# RCT included (# participants)* | *Results/conclusions* |
|---|---|---|---|
| 2010 | Adenoidectomy for otitis media in children[12] | 14 (2712 children) | For the primary outcome of time with OME, adenoidectomy w/tube increases the resolution of OME by 22% and 29% at 6 and 12 months, respectively, over tube alone. For the secondary outcome of AOM, studies were too heterogeneous to pool results |
| 2011 | Antihistamines and/or decongestants for OME in children[13] | 16 (1880 children) | No statistical or clinical benefit. Treated study subjects experienced 11% more side effects (NNT = 9) |
| 2011 | Oral or topical nasal steroids for hearing loss associated with otitis media with effusion in children[14] | 12 (945 children) | No hearing benefit from steroids; higher OME resolution at < 1 month (RR 4.48; 95% CI 1.52–13.23) with oral steroids, but not at > 1 month follow-up. No benefit from steroids in terms of symptoms |
| 2011 | Xylitol for preventing acute otitis media in children up to 12 years of age[15] | 4 (3103 children) | Among healthy children attending day care, reduced risk of AOM in the xylitol group (RR 0.75; 95% CI 0.65–0.88). Among children in day care with respiratory infection, there was no reduction in AOM. Xylitol chewing gum was superior to syrup in preventing AOM among healthy children (RR 0.59; 95% CI 0.39–0.89) but not during respiratory infection, with no difference between xylitol lozenges and syrups |
| 2012 | Zinc supplements for preventing otitis media[16] | 12 (6820 participants) | Among healthy children < 5 years old in low-income communities, there is mixed evidence of for zinc supplementation reducing the incidence of OM |
| 2012 | Antibiotics for otitis media with effusion in children[17] | 23 (3027 children) | Increased complete resolution of OME at 2–3 months ranged from 1% to 45%, whereas complete resolution at > 6 months increased 13% (95% CI 6–19%). No evidence of substantial improvement in hearing or effect on rate of ventilation tube insertion. Adverse events with antibiotics was increased by 3–33% |
| 2013 | Antibiotics for acute otitis media in children[18] | 11 (antibiotics vs. placebo, 3317 children) 5 (immediate antibiotics vs. expectant observation, 1149 children) | Antibiotics reduced pain at day 2–3 and 4–7 days (NNT 20), TM perforations (NNT 33) and contralateral AOM episodes (NNT 11); they did not decrease the rate of abnormal tympanogram at 4–6 weeks or 3 months, or AOM recurrences. Adverse events with antibiotics was increased, NNH 14. No difference in pain, TM perforations, or AOM recurrence for expectant observation |

(RCT: Randomized clinical trial; RR: Risk ratio; CI: Confidence interval; NNT: Number needed to treat; NNH: Number needed to harm; AOM: Acute otitis media; OME: Otitis media with effusion; TM: Tympanic membrane; OR: Odds ratio; OM: Otitis media).

These systematic reviews suggest the following practices, with editorial remarks added in italics:

## Prevention of AOM

- The 7-valent pneumococcal conjugate vaccines prevent AOM in infants on a population level, but may not have a noticeable effect on an individual child[9]
- Among healthy children attending day care, xylitol gum or syrup 5 times/day reduces the incidence of AOM.[15] *Any intervention that requires administration 5 times/day, however, is burdensome to parents and caregivers*
- Among healthy children < 5 years old living in low-income communities, zinc supplementation has a mixed effect on the incidence of AOM.[16]

## Antibiotics for AOM or OME

- There is a higher risk of treatment failure with < 7 day course of antibiotics, with a difference of 3% at one month.[10] *The risk of treatment failure needs to be balanced with the risk of adverse effects, such as diarrhea*
- Antibiotics for AOM reduced pain at 2–3 and 4–7 days, incidence of TM perforations, and contralateral AOM episodes compared to placebo[18]

- Compared to expectant observation, there was no difference from giving antibiotics immediately for outcomes of pain, TM perforations or AOM recurrence[18]
- Antibiotics for OME increases the rate of complete resolution at 2–3 months, ranging from 1% to 45%, but there is no substantial improvement of hearing outcomes or rate of ventilation tube insertion. Antibiotic usage increased the adverse event rate by 3–33%.[17] *In the current age of increasing antibiotic resistance, this practice requires careful consideration of patient factors, such as immunodeficient states, to recommend it.*

## Adjuvant Therapies for AOM or OME

- Autoinflation improved the rate of improving tympanogram/audiogram composite outcome at >1 month for OME[8]
- There was no benefit to using decongestants or antihistamines in children with OME, but a higher rate of side effects.[13] *Use of decongestants and/or antihistamines solely for the treatment of OME ought to be actively discouraged*
- Topical nasal steroids do not improve hearing loss associated with OME; oral steroids have a short-term (<1 month) effect but not a longer-term effect.[14]

## Ventilation Tubes for AOM or OME

- Tubes reduced the number of AOM episodes in the first 6 months after placement, and increased the number of patients with no AOM episodes[6]
- Tubes improved the hearing loss associated with OME in the first 6 months after placement. There is no statistical effect on speech-language development, behavior, cognitive, or quality-of-life outcomes[11]
- Topical quinolone antibiotics were better at clearing the otorrhea associated with tubes than systemic (oral) antibiotics. There was no additional benefit of topical steroids to topical antibiotic drops.[7] *The acute otorrhea in these studies did not include that which was associated with granulation tissue and tubes.*

Table 25.4 lists other notable large studies published in the past 5 years of children with AOM or OME that were not included in the Cochrane reviews. These studies support the practices outlined above, as well as the suggestions below:

- The influenza vaccines, both live attenuated and inactivated, significantly reduce the rate of AOM.[19,24,25] *In the absence of contraindications, receipt of the influenza vaccine ought to be strongly encouraged as a way to prevent AOM*

**Table 25.4:** Non-Cochrane systematic reviews, RCTs, and large clinical studies regarding otitis media or otitis media with effusion that were not included in the Cochrane reviews

| *Year* | *Title* | *Study design* | *# Participants (age of participants)* | *Results/conclusions* |
|---|---|---|---|---|
| 2008 | Effects of influenza plus pneumococcal conjugate vaccination vs. influenza vaccination alone in preventing respiratory tract infections in children: a randomized, double-blind, placebo-controlled trial[19] | RCT, double-blind, placebo-controlled | 579 children (18–72 months) | During influenza seasons, AOM episodes reduced by 57% in those receiving influenza vaccine and 71% in those receiving influenza + Pneumovax vaccines compared to controls |
| 2008 | Tube associated otorrhea in children with recurrent acute otitis media; results of a prospective randomized study on bacteriology and topical treatment with or without systemic antibiotics[20] | RCT, unblinded | 50 children (9–36 months) | Ototopical gtt (hydrocortisone, oxytetracycline, polymyxin B) vs. amox or amox/clav were not different in duration of otorrhea (88% resolved by 7 days). In 33%, oral antibiotics were added to ototopical gtt due to fever or pain |
| 2009 | Recurrence up to 3.5 years after antibiotic treatment of acute otitis media in very young Dutch children: survey of trial participants[21] | Prospective cohort study after RCT | 168 children (6–24 months) | 3 years after randomization, 20% more recurrence of AOM in children receiving amox vs. placebo (aOR 2.5; 95% CI 1.2–5.0). No difference in rate of eventual ENT surgery |

*Contd...*

*Contd...*

| *Year* | *Title* | *Study design* | *# Participants (age of participants)* | *Results/conclusions* |
|---|---|---|---|---|
| 2009 | Effect of antibiotics for otitis media on mastoiditis in children: a retrospective cohort study using the United Kingdom general practice research database[22] | Population-based retrospective cohort study | 2,622,348 children (3 months to 15 years) | Risk of mastoiditis was 1.8/10,000 episodes if treated with antibiotics, compared to 3.8/10,000 episodes that were not treated with antibiotics. Number need to treat = 4831 to prevent one episode of mastoiditis |
| 2010 | Comparison between myringotomy and tympanostomy tubes in combination with adenoidectomy in 3–7-year-old children with otitis media with effusion[23] | RCT with 12 month follow-up | 78 children (42–86 months) | No difference in rate of AOM or otorrhea episodes between adenoidectomy + myringotomy vs. adenoidectomy + tympanostomy tube placement |
| 2011 | Pneumococcal vaccination in children at risk of developing recurrent acute otitis media—a randomized study[24] | Randomized, observer-blinded study, high-risk children | 96 children (< 2 years) | Incidence of AOM was reduced 26% in those with PCV7 vaccine, from 4.3 to 3.2 mean episodes, and 50% reduction ventilation tube placement |
| 2011 | The efficacy of live attenuated influenza vaccine against influenza-associated acute otitis media in children[25] | SR of RCTs | 24,046 children (6–83 months) | Live-attenuated flu vaccine (LAIV) reduced any AOM by 38% (10.3 vs. 16.8% placebo). Similar result to trivalent inactivated (TIV) flu vaccine. Influenza-related AOM was reduced by 85% vs. placebo, and 54% vs. TIV |
| 2011 | Ventilation tube treatment: a systematic review of the literature[26] | SR of RCT, controlled trials, and cohort studies | | Grade I evidence for VT improving hearing in SOM for at least 9 months, QoL improved up to 9 months (grade 2). Insufficient evidence for VT decreasing rAOM episodes |
| 2012 | Adjuvant adenoidectomy in persistent bilateral otitis media with effusion: hearing and revision surgery outcomes through 2 years in the TARGET randomized trial[27] | Randomized 3-armed trial | 376 children (> 3.5 years) | Adenoidectomy provided hearing benefit over tubes along at 12–24 months, but not 3–6 months, and reduced by half the number of children meeting 25 dB bilateral hearing loss cutoff for repeat tubes |
| 2012 | Tympanostomy with and without adenoidectomy for the prevention of recurrences of acute otitis media[28] | Randomized 3-armed trial | 300 children (10 months to 2 years) | Primary outcome was intervention failure (2 AOM in 2 months, 3 in 6 months or OME for 2 months), with 13% absolute reduction with tubes alone and 18% absolute reduction with tubes with adenoidectomy. AOM incidence was 1.15 for tubes, 0.91 for tubes with adenoidectomy, and 1.70 for control |

(RCT: Randomized clinical trial; AOM: Acute otitis media; QoL: Quality-of-life; CI: Confidence interval; OR: Odds ratio; PCV: Pneumococcal conjugate vaccine; VT: Ventilation tube; SOM: Serous otitis media; aOR: Adjusted odds ratio; rAOM: Recurrent acute otitis media; SR: systematic review).

- Use of antibiotics in children with OM decreases the incidence of mastoiditis, but with a number needed to treat of over 4800 to prevent one case of mastoiditis[22]
- Adenoidectomy in children older than 3.5 years provides additional hearing benefit in the longer term (12–24 months) over that of tympanostomy tubes alone.[27]

The American Academy of Otolaryngology-Head and Neck Surgery Foundation published the *Clinical Practice Guideline: Tympanostomy Tubes in Children* to provide evidence-based recommendations regarding the appropriate use of tympanostomy tubes in children with AOM and OME, summarized in 12 action statements.[29]

These statements incorporated the evidence summarized in Tables 25.3 and 25.4 pertaining to tympanostomy tubes and summarized other literature synthesized for the purposes of recommending best practices. While the guideline carries the weight of recommendation from the largest otolaryngology specialty organization in the United States, importantly they include the disclaimer that it "is not intended to replace clinical judgment or establish a protocol for all individuals with this condition and may not provide the only appropriate approach to diagnosing and managing this program of care (p. S31)".

The other major publication that deserves notice is the Comparative Effectiveness Review for OME, published by the Agency for Healthcare Research and Quality in 2013.[30] This systematic review addressed Key Questions regarding treatment options for OME that affect the following:

- Clinical outcomes, health utilization, or functional and health-related quality-of-life
- Harms and tolerability among the different treatment options
- Benefits and harms of treatment options in subgroups of children with OME
- Factors affecting health-care delivery or receipt of pneumococcal vaccination.

For these questions of comparative effectiveness, the systematic review of the literature from that publication[30] revealed the following results that were not already mentioned in the Cochrane reviews:

- Longer term tympanostomy tubes were retained for longer duration than other tubes. No other conclusions about the tube design or approaches to insertion could be made. Rates of otorrhea differed by tympanostomy tube type, with a higher probability of otorrhea with longer term tubes. Otorrhea and tympanosclerosis occurred more frequently in ears with tympanostomy tubes than watchful waiting or myringotomy
- There were no differences between tympanostomy tube placement and watchful waiting on language, cognitive development, academic achievement or quality-of-life outcomes during preschool and elementary school
- There is insufficient evidence to support improved quality-of-life outcomes in children who received tympanostomy tubes with adenoidectomy compared to myringotomy plus adenoidectomy
- Adenoidectomy alone was better than no treatment for resolution of OME at 6 and 12 months. There is no additional harm from adenoidectomy except for the rare chance of postoperative bleeding
- There were insufficient studies to compare effectiveness of interventions for subgroups of patients or by health-care factors.

Although tens of thousands of patients are represented by these studies, there are notable limitations to the answers they provide. Foremost, while the outcomes assessed are important to clinicians, they often missed quality-of-life and other patient-based outcomes that are likely very important to children and their parents, and may modify the balance of benefit versus cost/harms. These studies were performed in typically developing children, so that results are not generalizable to children who are considered at risk for speech-language delays and hearing loss, such as those with cleft palate, Down syndrome or neurodevelopmental delays.[30,26]

## HEARING SCREENING

Screening programs are considered feasible and worthwhile from a public health standpoint when all of the criteria below are met:[31]

- The impairment or disease is not immediately or obviously apparent
- The screening test used to identify the impairment or disease is not harmful
- The screening test is inexpensive, yet accurate with high sensitivity and specificity
- There are effective treatments for the impairment or disease
- Early identification of the impairment or disease leads to better outcomes.

Hearing screening appears to meet all of these criteria, and programs for newborn hearing screening (NHS) have been established in most developed and many developing countries. Hearing screening in preschool and school-age children is performed to a varying degree in many states of the United States and other countries, but has not received the same degree of attention as in newborns.

NHS has been legislated in 43 states of the United States, mostly in the late 1990s and 2000s, with the intent of identifying infants with moderate-to-severe bilateral permanent congenital hearing loss. The underlying assumption was that screening would lead to early identification and early treatment/habilitation of hearing loss, which would in turn result in improved speech, language, and educational outcomes. Summaries of the evidence regarding NHS have confirmed the improvement in the early identification of infants with hearing loss and subsequent treatment, thus establishing the *efficacy* of NHS.[32,33] Others have continued to document the challenges of

fitting hearing aids within the recommended time frame (i.e. by 6 months of age) and loss to follow-up after hearing loss was diagnosed.[34] A 2008 systematic review showed that while a good-quality cohort study showed improvements in receptive and expressive language in children identified through NHS compared with those identified later, other observational studies were significantly flawed methodologically by multiple factors, including lack of information on attrition and follow-up.[32] These challenges dilute the overall *effectiveness* of NHS in real-world application.

Preschool and school hearing screening have less evidence to support its routine use in healthy asymptomatic children, despite recommendations from professional organizations[35,36] and awareness that many children with congenital hearing loss are identified after the newborn period.[37,38] A systematic review from 2007 shows that there have been no RCTs of hearing screening in children older than infants and that an observational study of preschool children was inconclusive as to the effectiveness of screening.[39] Intuitively, screening programs ought to identify young children at early stages of hearing loss as they appear. However, there has been insufficient evidence to demonstrate improved identification and outcomes through the implementation of screening programs. Thus, the justification for the cost and effort of hearing screening programs in schools has not yet been established. Because screening programs require considerable time, effort, and expense, further study is needed to establish the effectiveness in preventing or ameliorating poor outcomes due to hearing loss.

## HEARING LOSS

Hearing loss in children is associated with many negative effects, including delayed speech-language development, decreased rates of literacy and high school graduation. Early amplification and rehabilitation of hearing, as soon as the hearing loss is identified, is the standard goal, but the best interventions, protocol, and timeline to maximize benefit and minimize harms have yet to be determined as technology brings new advances to hearing rehabilitation. The Institute of Medicine included the evaluation of comparative effectiveness of different treatments for hearing loss in children and adults among the top 25 in priority in their 2009 recommendations.[40] A search of Medline using the terms "hearing loss, children" or "congenital hearing loss" and "systematic review" over the past 10 years identified 12 articles pertinent to the clinical and economic evaluation of interventions for hearing loss, evaluation of function and health-related quality of life. These articles are listed with results summarized in Table 25.5.

Eight of the 12 systematic reviews pertained to cochlear implantation (CI); one article each addressed boneanchored hearing aids, therapy for cytomegalovirus, auditory neuropathy spectrum disorder, and functional skills and quality-of-life. Overall, unilateral CI in children was found to produce improved outcomes in speech and language, with advantage if occurring prior to 18 months of age over later implantation; there was insufficient data to determine whether CI prior to 12 months of age has an outcome advantage.[42,44,47] Unilateral CI was considered cost-effective, but bilateral CI (simultaneous or sequential) may not be cost-effective, depending on the threshold per quality-adjusted life year.[42,46,48] There were mixed reports on improvements in quality of life among children who received CI.[41] The sole systematic review evaluating boneanchored hearing aids in those with bilateral hearing loss showed mixed results when compared to use of airconduction hearing aids, although there appeared to be audiologic benefits over bone-conduction hearing aids.[49] For congenital cytomegalovirus infection, intravenous ganciclovir protected hearing in symptomatic infants, with trends toward protection when using oral valganciclovir. CI in children with congenital cytomegalovirus infection could improve their language skills, but degrees of improvement were mixed.[50] Similarly, children with auditory neuropathy spectrum disorder could benefit from acoustic amplification and CI but degrees of improvement were mixed.[51] Finally, hearing loss in children is associated with suboptimal level of postural control and motor skills, but overall quantitative degree could not be analyzed.[52]

Several major methodological problems plagued many of the systematic reviews on this topic. First, many of the studies did not specify a research question but instead sought to review the literature for evidence of effectiveness of a particular intervention. Second, the quality of the primary articles was often poor, consisting of uncontrolled case series or retrospective cohort studies, which increased the problem of bias. Unfortunately, poor-quality primary studies leads to poor-quality synthesized evidence. Third, heterogeneity of outcomes precluded synthesis of outcomes so that no quantitative meta-analyses were possible, and only qualitative conclusions of overall effect could be made. To correct these methodological problems does not require that an RCT be conducted for each research question (which might be considered unethical for some

**Table 25.5:** Systematic reviews of studies regarding hearing loss in children

| *Year* | *Title* | *Studies included* | *# Participants (age of participants)* | *Results/conclusions* |
|---|---|---|---|---|
| 2006 | Measuring health-related quality-of-life after pediatric cochlear implantation: a systematic review[41] | 10 cross-sectional studies of children with hearing loss only | 476 (children and adolescents) | Heterogeneity prevented quantitative meta-analysis. Studies that used validated QoL measures showed parent-reported improvements in health utility after CI; lower self-reported QoL in children with HL but not significantly different QoL in adolescents with HL |
| 2009 | Effectiveness of multichannel unilateral cochlear implants for profoundly deaf children: a systematic review[42] | 15 studies, including pre-/post-, cross-sectional, and non-randomized clinical trial designs | 1058 deaf children | Heterogeneity precluded quantitative meta-analysis. All studies reported improved scores on all outcome measures. Five economic evaluations found unilateral CI to be cost-effective |
| 2009 | The effectiveness and cost-effectiveness of cochlear implants for severe to profound deafness in children and adults: a systematic review and economic model[43] | Same as above | Same as above | For prelingually deaf children, the cost-effectiveness ratio for unilateral CI was £13,413 per quality-adjusted life-year, but £40,410 for simultaneous bilateral CI and £54,098 for sequential bilateral CI |
| 2010 | Cochlear implantation under the first year of age—the outcomes. A critical systematic review and meta-analysis[44] | 5 controlled observational studies | 125 children with CI before age 1 year | No quantitative meta-analysis. Only 17 with follow-up of at least 2 years. More rapid development of language skills with earlier implantation, although with wide variation. Robust and reliable outcome measures are lacking |
| 2010 | The effectiveness of bilateral cochlear implants for severe-to-profound deafness in children: a systematic review[45] | 13 controlled observational studies | Children | Heterogeneity precluded quantitative meta-analysis. Middle to high risk of bias. "No robust conclusions could be drawn about the clinical effectiveness of bilateral CIs from the present body of evidence" |
| 2011 | What is the effect of time between sequential cochlear implantations on hearing in adults and children? A systematic review of the literature[46] | 11 case series (6 pediatric) | 122 adults and 223 children | Heterogeneity prevented quantitative meta-analysis. Quality of studies was low. Current evidence suggests a second CI may be beneficial, but effect of time could not be satisfactorily answered |
| 2011 | Systematic review of the literature on the clinical effectiveness of the cochlear implant procedure in pediatric patients[47] | 49 studies (22 related to age at CI, 20 related to bilateral vs. unilateral CI, 7 related to disabilities) | n/a | Not possible to perform meta-analysis due to heterogeneity. CI prior to 18 months has confirmed advantage compared to after 18 months; there may be advantage to CI prior to 12 months. Compared to unilateral CI, bilateral CI has advantages with hearing in noise and quiet, sound localization. CI is also beneficial for children with disabilities |
| 2011 | Systematic review of the scientific literature on the economic evaluation of cochlear implants in pediatric patients[48] | 9 studies (3 prospective, 3 retrospective, 3 cross-sectional) | n/a | Heterogeneity did not allow meta-analysis of cost-effectiveness. Direct cost ranged from €39,507 to €68,235 (2011 values). Cost per quality adjusted life year ranged from $2154 to $16,546 |

*Contd...*

*Contd...*

| *Year* | *Title* | *Studies included* | *# Participants (age of participants)* | *Results/conclusions* |
|---|---|---|---|---|
| 2011 | Bone-anchored hearing aids (BAHAs) for people who are bilaterally deaf: a systematic review and economic evaluation[49] | 12 studies (7 pre-/poststudies, 5 cross-sectional) | Children and adults | Meta-analysis not possible due to differences in outcome measures and patient populations. Some audiologic benefits of BAHA over bone conduction hearing aids; mixed results compared to air-conduction hearing aids; mixed results with bilateral BAHA compared to unilateral. The greater the benefit from aided hearing and > 8 h of usage per day, the more likely BAHAs are a cost-effective option |
| 2011 | Medical and surgical interventions for hearing loss associated with congenital cytomegalovirus: a systematic review[50] | 19 studies (2 RCT, 3 prospective cohort, 8 retrospective case series, 5 case report) | 446 children, 365 with complete audiologic results | No quantitative meta-analysis due to heterogeneity. Intravenous ganciclovir appears to protect hearing in infants with symptomatic CMV; oral valganciclovir trends toward protecting hearing; neutropenia is common. With CI, children improved their language skills beyond their preimplanted state, but degree of improvement was mixed |
| 2011 | Audiologic management of auditory neuropathy spectrum disorder in children: a systematic review of the literature[51] | 18 case reports or case series | 115 participants | No quantitative meta-analysis could be performed. Children with ANSD can benefit from acoustic amplification and CI. "The findings from this review do not resolve the controversies surrounding the audiologic treatment of ANSD in children" |
| 2012 | Postural control, motor skills, and health-related quality-of-life in children with hearing impairment: a systematic review[52] | 17 studies (4 cross-sectional, 1 correlational, 12 no design stated) | Age 5–11 years | Heterogeneity prevented methodological quality assessment and meta-analysis. Children with hearing impairment exhibit suboptimal levels of function in postural control, motor skill performance, and health-related quality-of-life |

(QoL: Quality-of-life; CI: Confidence interval; HL: Hearing loss; ANSD: Auditory neuropathy spectrum disorder; CMV: Cytomegalovirus).

questions, such as the efficacy of CI for profound bilateral hearing loss). Instead, prospective planning of studies to document and account for biases, systematic recording of predetermined outcomes, and increased collaboration among researchers to identify outcomes of interest would improve the quality and level of the evidence we have in this area.

## TYMPANOPLASTY

Tympanoplasty and myringoplasty are common procedures for children with a history of chronic middle ear disease or cholesteatoma, with a wide variety of surgical approaches to the repair of tympanic membrane perforations and conductive hearing loss. A Medline search using the terms "tympanoplasty children" and "comparative study" revealed one randomized study and 11 controlled studies. Two studies of the same study population were excluded. There were no identified systematic reviews pertaining to tympanoplasty for the repair of tympanic membrane perforations. One systematic review evaluated cartilage tympanoplasty or ventilation tubes for the treatment of tympanic membrane retraction pockets using hearing as the outcome; unfortunately, no definitive conclusions could be made regarding efficacy of either of these treatments.[53]

Six of the identified studies compared cartilage grafts with temporalis fascia grafts; results were mixed, with some investigators reporting better perforation closure rates with cartilage and other with temporalis fascia.[54-58]

Four used alternative graft material, including pressed scar tissue, Alloderm, and areolar connective tissue. All studies reported similar success with closure of perforations. One study reported closure rates and hearing improvement in children (age 8–14 years) compared to adults who underwent tympanoplasty, finding no statistically significant difference.[59] Finally, a study of patients (age 2–55 years) with a history of repaired cleft palate compared to age- and procedure-matched controls without cleft palate showed similar closure rates, hearing results, and need for postoperative tympanostomy tube placement.[60] While these comparative studies are helpful to review, a systematic review with a more complete search of the worldwide literature and synthesis of the results would be invaluable to determine whether results were mixed due to the problem of small numbers in studies, differences in technique, or patient factors.

## EDITORIAL COMMENTS

EBM in pediatric otology has gained much scientific basis that aids clinicians to deliver the most benefit and avoid the most harm to children. These four topics—otitis media, hearing screening, hearing loss, and tympanoplasty—were ultimately chosen out of a host of others (e.g. management of aural atresia, assessment of vertigo and balance in children, etiologic workup for hearing loss) that deserve attention and scrutiny. Yet we ought not to be content with the state of EBM in this field and should continue to endeavor to improve the quality of the studies performed, broaden the applicability of studies beyond the typically developing child, and continue to critically review current clinical practices in order to benefit our patients. Future versions of this chapter and other authors will be required to document the progress we make in diagnosis, prognosis, intervention, prevention, and effectiveness studies. Rather than publish more uncontrolled series of cases, we should endeavor to compare results of new and established modes of care. When feasible and ethical, randomized controlled trials should be performed to provide the highest level of evidence by reducing the amount of bias in studies. In order to provide better care for the at-risk or developmentally delayed child, we should collaborate across institutions on larger studies of children who do not fit the criterion of "otherwise healthy". Systematic reviews should be methodologically rigorous, following widely accepted criteria, rather than being an upgraded review of the literature.[4,61] When the opportunity arises to change our understanding of pathophysiology, abandon treatments or procedures that relied on the placebo effect, or advocate for treatments that truly work, we ought to embrace the evidence that produces these changes.

# Pediatric Sinonasal Anatomy and Embryology

***Graham M Strub, Sanjay R Parikh***

The embryologic development of the nose and paranasal sinuses is a complex and dynamic process, beginning at the third to fourth week of gestation and continuing until the age of 18 years.[1] Clinicians who treat diseases of the nose and paranasal sinuses must have an intimate knowledge of the normal anatomy and physiology of these regions, and should therefore have a thorough understanding of both the normal and abnormal embryologic development of these structures. This chapter discusses the embryology of the developing nose and paranasal sinuses and highlights the aberrations of this process that manifest in clinically treatable pathology.

## DEVELOPMENT OF THE PRIMITIVE MIDFACE

The first event in the eventual formation of the paranasal sinuses occurs in the initial yolk sac vesicle, specifically the rotation of the cephalic end of the embryonic disk to form the embryonic head. In this early embryo, the anterior foregut develops with an ectodermally lined membrane, termed the buccopharyngeal membrane, at its anterior limit. At this stage the pericardial cavity lies caudal to this membrane, while the primitive forebrain lies rostrally. The foregut elongates, with its most anterior part becoming the stomodeum. The pericardial sac then rotates around the axis of the buccopharyngeal membrane and brings the cardiogenic region, the eventual transverse septum, and the cranial mesoderm into a ventral position. During this time the ectodermal and endodermal layers of the embryonic disk are separated by a layer of mesoderm that differentiates into the somites, or the "paraxial structures", from which the pharyngeal arches are derived.

It is at this point during the third week of gestation that three primordial facial projections appear: the frontonasal process, the maxillary process, and the mandibular process (Fig. 26.1). The frontonasal process is an ectodermally derived structure within which the nasal olfactory placodes develop. The olfactory placodes form the medial and lateral nasal prominences, and between these prominences proliferating mesoderm creates deepening nasal pits that will eventually become the nares. Between the pits, the medial nasal folds fuse to form the upper lip, premaxilla, and nasal septum. The deepening nasal pits eventually become the nasal sacs, and their posterior walls, or "bucconasal membranes", eventually dissolve and give rise to the posterior choanae.

At this stage, the maxillary process of the first branchial arch grows medially across the inferior border of the nasal pits and fuses with the medial nasal folds of the frontonasal process, effectively closing the inferior aspect of the nasal pits and thus forming the nasal cavities. The outer aspect of the maxillary process also fuses with the lateral nasal processes, forming a solid rod at the nasolacrimal ridge. This rod eventually canalizes to form the nasolacrimal duct, connecting the conjunctiva to the primitive nasal cavity, and assumes an oblique angle as the developing eye migrates medially toward the developing nose. The fusion of the maxillary process with the caudal aspect of the frontonasal process begins the formation of the anterior palate. As the nasal cavities deepen, a ridge along the caudal aspect of the frontonasal process develops and becomes continuous with the partition between the primitive nasal cavities, thus forming the septum. The free edges of the lateral maxillary mesoderm, termed the palatal processes, begin to grow toward each other and

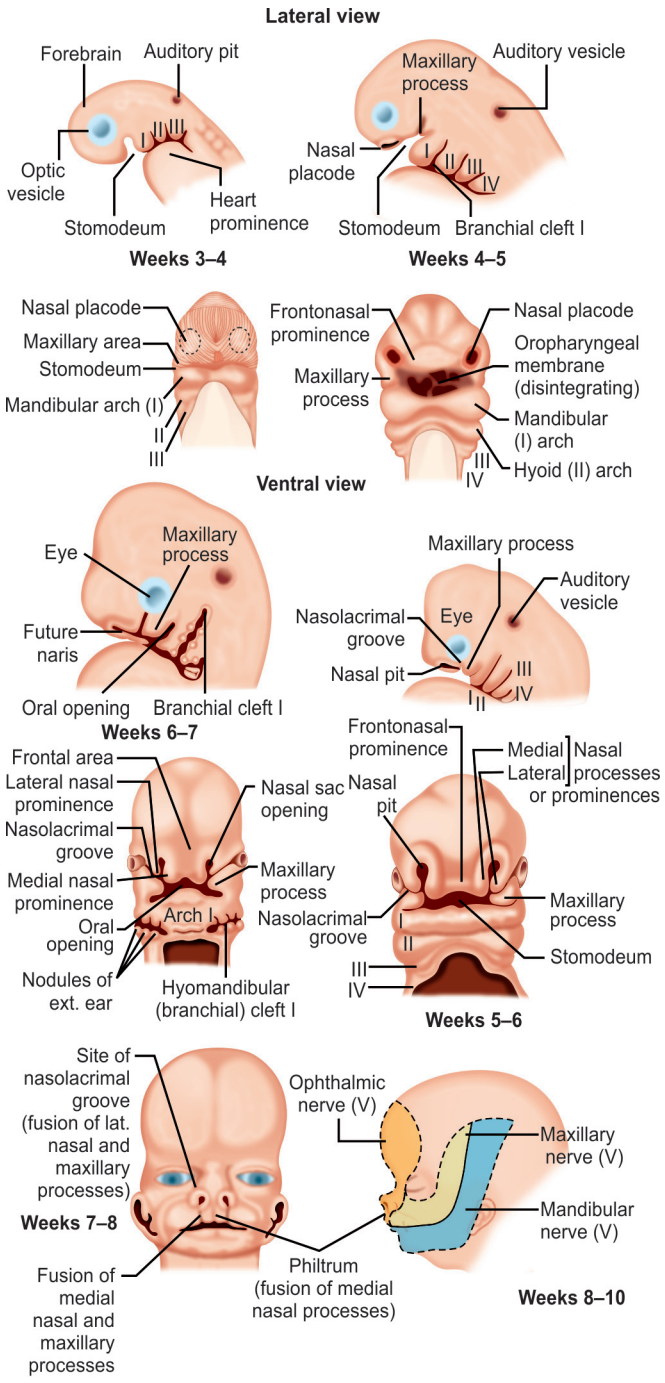

**Fig. 26.1:** Development of the midface structures. At weeks 3–4, the heart prominence, stomodeum, and pharyngeal arches are visible. Development of the nasal placodes and frontonasal process can be seen during week 4. The nasal processes and pits as well as the nasolacrimal grooves are visible at weeks 5–6. By weeks 7–8, the maxillary and frontonasal processes have fused. Adapted from Pansky.[2]

the developing septum, initially growing vertically but then turning to extend horizontally and eventually fusing. This fusion occurs in an anteroposterior direction, eventually forming the soft palate and uvula, and effectively separating the nasopharynx from the oral cavity.

## TURBINATE FORMATION

During weeks 7–8 of development, the lateral nasal walls increase their surface areas and the turbinates and their meatuses begin to form a series of mesenchymal ridges. The first to form is the inferior turbinate and develops at week 7 from the inferior ridge termed the maxilloturbinal. During the eighth week, a series of five to six additional ridges form superior to this, eventually fusing to form three to five ethmoturbinals. The agger nasi cells and the uncinate process are formed from the first ethmoturbinal, while the second and third ethmoturbinals give rise to the middle and superior turbinates, respectively. The fourth and fifth ethmoturbinals regress, although persistence of these structures can occur and results in the formation of the supreme turbinate.

## PARANASAL SINUS DEVELOPMENT

It is at this time, during the third fetal month, that the paranasal sinuses begin to develop. The maxillary, frontal, and ethmoid sinuses develop from evaginations of the lateral nasal wall, while the sphenoid sinus develops from an evagination of the nasal capsule. Only the maxillary and ethmoid sinuses are present at birth (Fig. 26.2).

### Maxillary Sinus

The maxillary sinus is the first sinus to appear and begins as an outgrowth in the lateral nasal wall of the nasal capsule, immediately posterior to the uncinate in the uncibullous groove.[3] It begins as a fluid filled cavity and remains so at birth. The maxillary sinus grows rapidly after birth for the first 3 years, then slows, then rapidly enlarges again between the 7th and 12th year of life. The rapid rate of growth is estimated to be 2 mm vertically and 3 mm anteroposteriorly each year.[4] Pneumatization of the maxillary sinus extends laterally to the lateral orbital wall and inferiorly to the floor of the nasal cavity, bringing the maxillary sinus in close proximity to the maxillary dentition. The adult maxillary sinus is a pyramidal

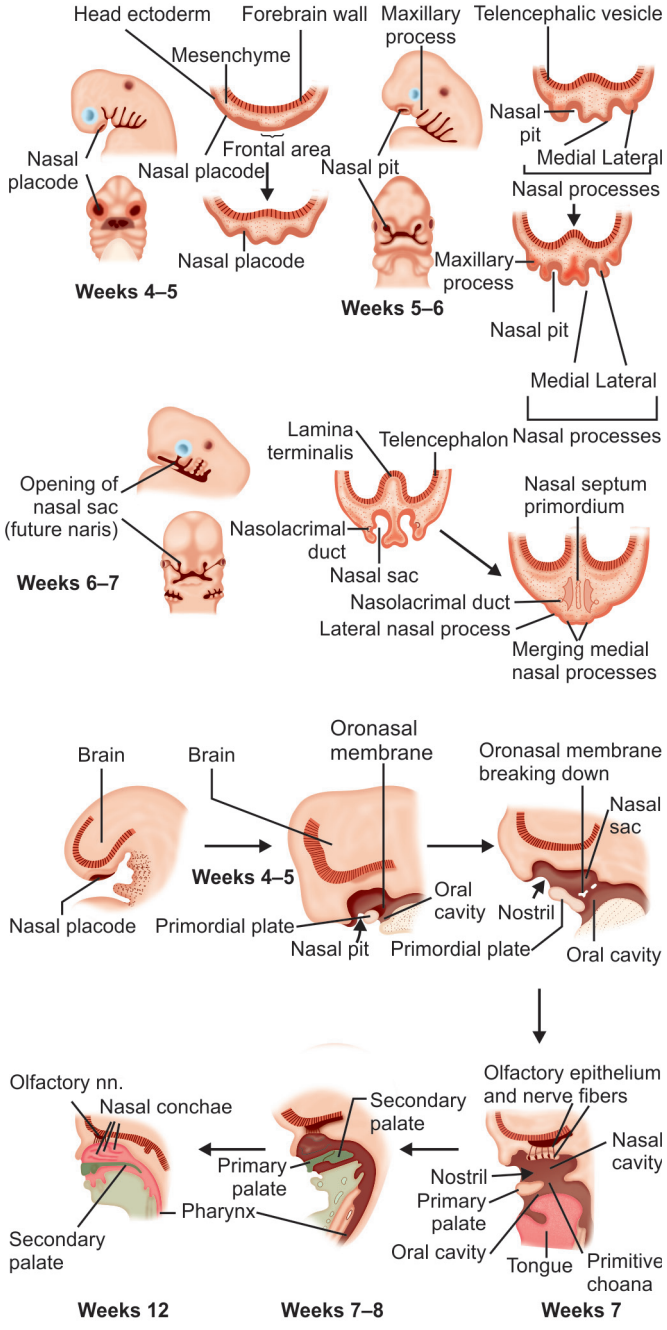

**Fig. 26.2:** Development of sinonasal structures. During weeks 4–5 the nasal placodes and nasal pits are forming, and by week 5 the lateral and medial nasal processes are visible. The nasal sac deepens and the bucconasal membrane breaks down, and by week 7 the nostril, primitive choana, and the primitive primary palate are visible. Development of the palate structures continues through week 8 and the nasal and oral cavities become separated. By week 12, the secondary palate and the nasal conchae have developed. Adapted from Pansky.[2]

structure with dimensions approximately 34 mm antero-posteriorly, 33 mm vertically, and 25 mm horizontally.[4] The boundaries of the maxillary sinus cavity are the orbital floor superiorly, the ascending process of the palatine bone laterally, the maxillary bone anteriorly, and the pterygomaxillary space (containing the internal maxillary artery, sphenopalatine ganglion, foramen rotundum, vidian canal, and greater palatine nerve) posteriorly.[5] Near the anteromedial roof of the maxillary sinus lies the maxillary ostium, an elliptical shaped communication at the merging point of mucociliary flow and draining into the ethmoid infundibulum. Variations in the anatomy of the maxillary sinus occur, including incomplete septi (50%), sinus duplication (2.5%), accessory ostia (25%), and hypoplasia (6%)/aplasia (< 1%).[4] The maxillary sinus receives its arterial blood supply from branches of the internal maxillary artery, including the infraorbital, lateral nasal branch of sphenopalatine, descending palatine, and posterior and anterior superior alveolar arteries. It is innervated by V2 branches including greater palatine, as well as the superior alveolar branch of the infraorbital nerve, and the posterolateral nasal branches.

## Ethmoid Sinus

During the third fetal month, lateral evaginations from the middle meatus begin the formation of the anterior ethmoidal cells, and later evaginations from the superior meatus begin the formation of the posterior ethmoidal cells.[3] The development of the anterior ethmoidal cells occurs anterior to the second ethmoturbinal, while the posterior cells develop posterior to this structure. This accounts for the different drainage pathways from these sinuses; the anterior ethmoids drain through the middle meatus and anterior to the basal lamella of the middle turbinate, while the posterior ethmoids drain posterior to the basal lamella through the superior meatus. The ethmoid sinuses are the most variable sinus structure, and are also fluid filled at birth. They are initially spherical in shape, eventually flattening out and reaching their approximate adult size by 12 years of age. The borders of the ethmoid sinuses include the lamina papyracea laterally, the middle and superior turbinates medially, the face of the sphenoid sinus posteriorly, and the intracranial cavity and cribriform plate superiorly. As the ethmoid sinus cells pneumatize, they can invade adjacent bone, and are subsequently named after the bone invaded. Examples of this concept

include an anterior ethmoidal cell that invades the frontal bone to become part of the frontal sinus, or invading the lacrimal bone to become the agger nasi. Individual ethmoid cells can also be found within the confines of the maxillary sinus or sphenoid sinus. This variability of the ethmoids and their proximity to critical structures such as the orbit and brain make preoperative evaluation with CT scans crucial for safe endoscopic sinus surgery.

Despite this variability, a series of five ethmoid lamellae with their attachments to the lateral nasal wall can serve as a guide during endoscopic sinus surgery. The first encountered (most anterior) is the uncinate process, a sagittally orientated crescent-shaped structure forming the anterior and medial borders of the ethmoid infundibulum. It attaches to the maxilla and lacrimal bone and inferior turbinate at its anterior and inferior borders, respectively. Superiorly the attachment varies, with the most common configuration (70%) attaching to the lamina papyracea laterally and directing frontal sinus outflow medial to the uncinate. The other two attachment configurations, to the ethmoid roof superiorly (19%) or to the middle turbinate laterally (11%), direct frontal sinus outflow through the ethmoid infundibulum.[6,7] The second lamella is the ethmoid bulla, which is the largest of the ethmoid cells and is the most reliable landmark during ethmoidectomy due to its visibility within the middle meatus. Posterior to this the surgeon encounters the third lamella, the basal (or ground) lamella, which serves as the anterior border of the posterior ethmoid cells and is the attachment of the middle turbinate to the lateral nasal wall. The fourth lamella encountered is the basal lamella of the superior turbinate, and the rarely encountered basal lamella of the supreme turbinate lies posterior to this when the supreme turbinate is present (15% of population).[8] The ethmoid sinus receives its arterial blood supply from the ophthalmic artery to the anterior and posterior ethmoidal arteries, as well as the sphenopalatine to nasal branches. They are innervated by V1 to the nasociliary nerve to the anterior and posterior ethmoidal nerves, as well as V2 to the posterolateral branches.

## Frontal Sinus

During the third fetal month, an evagination from the anterosuperior part of the middle meatus forms. This is the frontal recess, which deepens into a small diverticulum that is present at birth. The frontal sinus then forms by either direct expansion of the frontal recess, by pneumatization of an ethmoid cell within the frontal recess, or by pneumatization of an ethmoidal cell from within the ethmoid infundibulum.[9] The mechanism by which the frontal sinus forms will determine the shape and pathway of the drainage tract. The slow process of upward pneumatization then occurs through the frontal bone from the fifth year of life into late adolescence. This pneumatization occurs independently for each side of the frontal bone, so asymmetry between the frontal sinuses is common. The frontal sinus receives its arterial blood supply from the ophthalmic to supraorbital and supratrochlear arteries. It is innervated by V1 to the frontal nerve to the supraorbital and supratrochlear nerves.

## Sphenoid Sinus

During the fourth fetal month the sphenoid sinus begins as an evagination of the posterior nasal capsule. This evagination remains small until approximately 3 years of age when pneumatization into the sphenoid bone begins, extending to the level of the sella turcica by age 7, making it the first paranasal sinus to reach full development. There are three patterns of sphenoid pneumatization: sellar (90%), with pneumatization extending beyond tuberculum sellae; presellar (8%), with pneumatization only up to the tuberculum sellae; and conchal (2–3%), with pneumatization arrest at the initial infantile stage.[9] Dehiscent bone over the optic nerve (5%) or carotid arteries (25%)[10] has been observed and should give the surgeon caution when approaching the sphenoid sinus. The sphenoid sinus receives its arterial blood supply from the posterior ethmoid artery and branches of the sphenopalatine artery. It is innervated by V1 to the nasociliary nerve, as well as the sphenopalatine branches of V2.

# DEVELOPMENT OF SINONASAL MUCOSA

Paralleling the development of the bony and cartilaginous structures of the midface and paranasal sinuses, the mucosal lining that functions in olfaction, air transport, humidification, and purification of air also develops. During the formation of the lateral nasal wall, the sinonasal mucosa exists as a single layer of undifferentiated epithelial cells overlaying the nasal wall mesenchyme. Between 8 and 9 weeks, when the nasal septum and turbinates are developing cartilage, olfactory epithelium appears in the superior nasal cavity and ciliated pseudostratified

columnar epithelium along the nasal septum.[11] By 14 weeks the lateral nasal wall is covered with ciliated respiratory epithelium, and by 16–18 weeks, the maxillary and ethmoid sinuses have ciliated epithelium containing goblet cells. Throughout this time the mucosal lining throughout the paranasal sinuses becomes thicker and more vascularized.[11]

## SINONASAL DEVELOPMENTAL ANOMALIES

The precise coordination of events during embryogenesis of the nose and paranasal sinuses leaves room for several anomalies to develop. These anomalies can occur in isolation or as part of broader syndromes and are of clinical importance to physicians. The most common is choanal atresia, which occurs when the bucconasal membrane fails to rupture during the sixth week of development. Choanal atresia can be unilateral or bilateral and can be either mucosal or bony. Bilateral choanal atresia presents with immediate postnatal respiratory distress due to the fact that newborns are obligate nasal breathers. These newborns typically undergo tracheotomy followed by surgical repair. Choanal atresia occurs in conjunction with several other anomalies in the CHARGE association (coloboma of eye, heart anomalies, choanal atresia, retardation, genital, and eye anomalies) and is due to a microdeletion at chromosome 22q11. Other more rare defects include failure of nasal placode formation leading to absence of a nose. If only one nasal placode forms patients can present with the presence of only one nostril. Facial clefts can occur when the frontonasal prominence fails to merge with the maxillary prominence. Failure of migration of neurons from the nasal placode to the hypothalamus due to a mutation in the *KAL* cell adhesion protein-encoding gene produces Kallmann's syndrome, characterized by anosmia, hypogonadic hypogonadism, micropenis, and unilateral renal agenesis. In addition, there are several congenital masses that can be present within the midface and paranasal sinuses such as dermoids, meningoceles, and encephaloceles. Finally are the anomalies of cleft lip and cleft palate, which are discussed in detail elsewhere in this text.

## CONCLUSION

The development of the paranasal sinuses begins after the formation of the primitive midface structures at month 3 of development and follows a generalized pattern of enlargement and pneumatization. Despite this pattern, there is a great deal of variation between patients and even within the same patient, and therefore, the surgeon must have a sound understanding of the normal embryology and anatomy of these structures, as well as the variations that result in treatable pathology.

CHAPTER

# 27

# Role of Human Evolution in Rhinosinusitis

***Charles D Bluestone, Jeffrey T Laitman***

## INTRODUCTION

We have recently proposed that both otitis media and rhinosinusitis are unique diseases of humans and consequences of human evolution.[1,2] In this chapter, we show how evolution has been instrumental in making rhinosinusitis a disease of humans, which, if present in animals in the wild, would have been incompatible with survival due to predation. We also posit that an understanding of evolution's role in rhinosinusitis has implications for possible innovative management, albeit somewhat unorthodox, that may have a future role for this commonly encountered malady, especially when chronic, irreversible disease is present.

The impact of evolution on otitis media, which has a similar scenario, is covered in another chapter in this textbook (*see* Chapter 3).

## EVOLUTION'S ROLE IN THE ANATOMY OF THE HUMAN HEAD AND NECK

The three most significant evolutionary changes from our immediate ancestors and other primates are that humans are habitually bipedal, have adapted unique speech, and have a craniofacial skeleton that is substantially different.

## BIPEDALISM, BIG BRAIN, AND "BORN TOO SOON"

The first relevant report published by one of us (CDB) was on evolution's role in the ears, nose, and throat, following a trip to East Africa.[3] During that adventure, it became evident that some animals in the wild, such as elephants, could walk at birth as they had to join a constantly moving herd; any who could not would soon become prey for hungry predators. By contrast, we humans walk at approximately 1 year of age. The conclusion was that humans are born too early or "born too soon." The question is why? Anthropologists have termed human birth to be "secondarily altricial"; some higher mammals are mature ("precocious") at birth, whereas others, such as dogs and cats, are "altricial," i.e. relatively helpless at birth. Humans should be precocious when born but are not.

The reason is that approximately 4 million years ago our hominid ancestors began to walk upright on two legs, i.e. bipedal (Fig. 27.1), after which the female pelvic outlet became smaller. Later, as the human brain enlarged in newborns, we are born about 12 months earlier than ideal—humans should have a 21-month gestational period and not 9 months (Fig. 27.2).[4] Infants triple their birth weight during the first year of life and together with a 23% increase in head circumference, parturition at that age would be impossible. Even at 9 months gestation humans have a difficult delivery through the tight birth canal; we are the only species that requires assistance during birth. Today, with the survival of preterm babies, the impact of evolution on premature birth is that they are "born way too soon," which has even greater problems of birth that is too early. A more detailed discussion of the adaptation of humans to bipedalism and its consequences related to parturition on the ear, nose, and throat are described elsewhere.[3]

In addition to the effect of bipedalism on gestational age, our upright posture had an impact on craniofacial anatomy, e.g. anterior foramen magnum and cranial-base angulation, as described later.

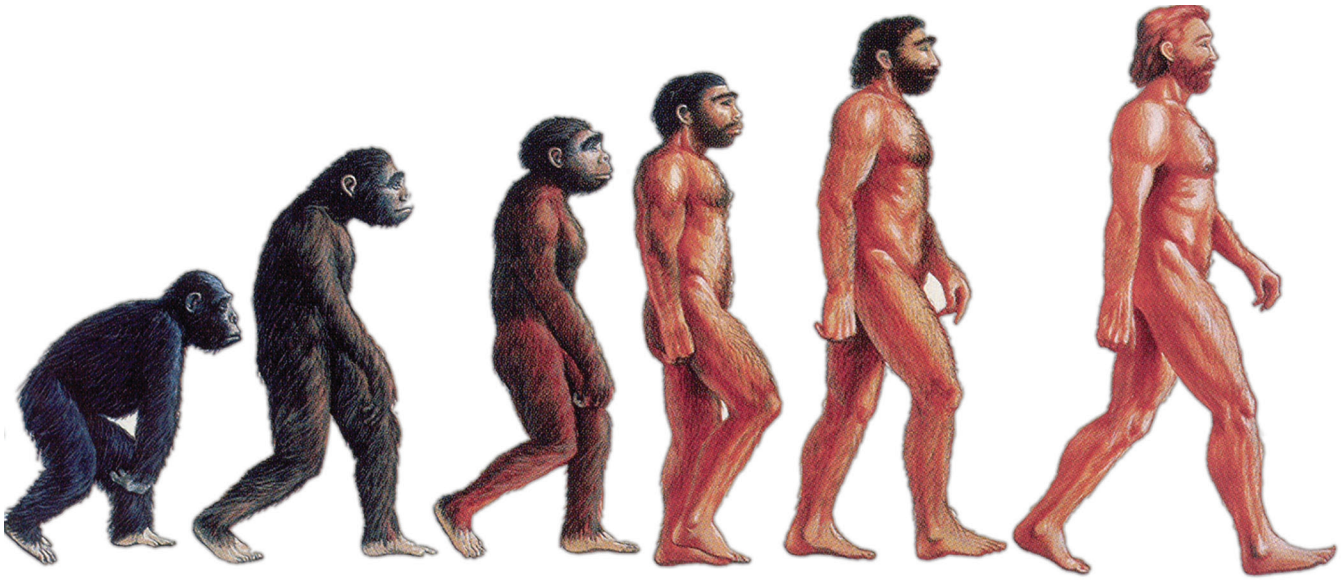

**Fig. 27.1:** Evolutionary changes in locomotor behavior from knuckle-walking chimpanzee-like ancestors to habitual bipedalism in modern humans.

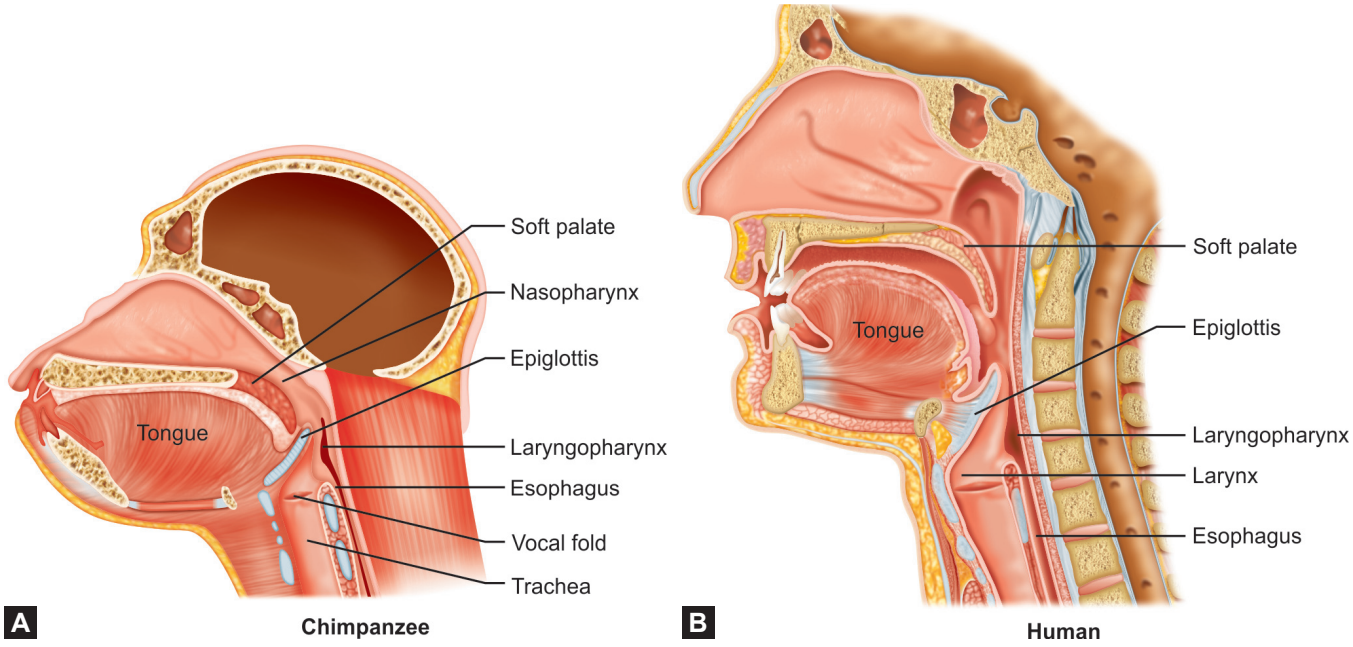
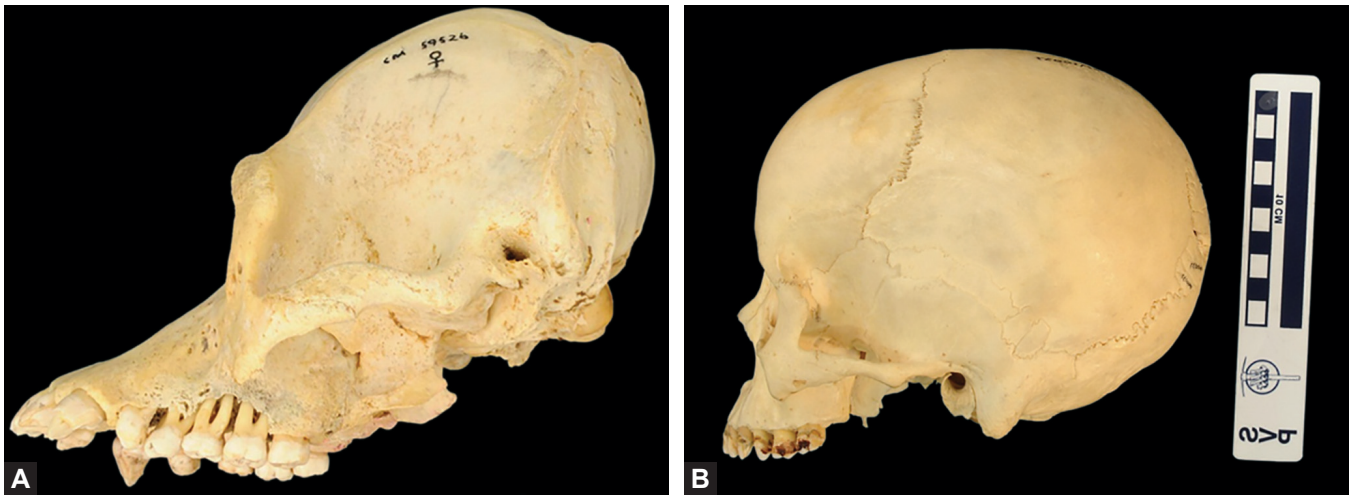
## ADAPTATION FOR SPEECH

No other species in the animal kingdom is capable of speech, which, in addition to habitual bipedalism and our relatively large brain, is one of our most unique attributes. What anatomic changes occurred during evolution that enabled us to develop speech? An important and significant difference between humans, after the neonatal age, and most other mammals is that the nonhuman laryngeal epiglottis is in contact with the soft palate, which facilitates swallowing while breathing through nose, enabling animals to eat for prolonged periods of time. This is termed the "epiglottic-soft palate lock-up." Human neonates also have a high-riding larynx and "lock-up" that enables them to suck and swallow during nasal breathing; neonates are essentially obligate nasal breathers. After about 2–3 months of age, the larynx in the human begins its structural descent and becomes permanently lower than in the nonhuman primate and reaches the level of the adult larynx after 3–5 years of age (Figs. 27.3A and B). The descent of the larynx elongated the throat and formed our unique two-tube configuration of our narrowed supralaryngeal vocal tract, facilitating speech.[5] As described below, in addition to our lower larynx, humans have lost the prognathism (facial flattening) so prominent in nonhuman primates, and, along with other anatomic differences, is a major factor in the development of human speech.



**Figs. 27.3A and B:** Line drawing in the midsagittal plane comparing the chimpanzee and human showing the shorter palate, oropharyngeal tongue, narrower pharynx, and descended larynx (loss of "epiglottic—soft palate lock-up") in the human when compared with the chimpanzee.



**Figs. 27.4A and B:** Comparison of skulls between the orangutan (Pongo) with its prominent prognathic jaws (A) and human (B), which shows the dramatic facial flattening in the human.
*Source*: From Bluestone et al.[2]

## EVOLUTION'S IMPACT ON CRANIOFACIAL ANATOMY

When one compares the facial profile of the great apes (i.e. gorilla, chimpanzee, and orangutan) with that of humans, the most impressive difference is the ape's prognathic jaw (Figs. 27.4A and B); humans have a relatively flat face. During evolution, humans lost the prognathic jaw (facial flattening) along with a smaller oral cavity, smaller and crowded teeth, and a shorter maxilla, mandible, and palate; impacted third molars are only present in man. The reason humans, and to varying extent our hominid ancestors (i.e. extinct precursors of man), lost the prominent prognathic jaw of the apes, is controversial. Some

have postulated that it is related to selective pressure for speech, whereas others posit it was most likely the result of a change in diet. As proposed by Wrangham,[6] cooking probably started with *Homo erectus* about 1.8 million years ago, which significantly contributed to our being human. With cooking, humans could eat fibrous fruits and tubers and raw meat, which became more rapidly edible and provided much-needed energy for our fast-growing brain. Another hypothesis is that with this change in our diet, a large oral cavity with big teeth suited for prolonged chewing of uncooked food was unnecessary and resulted in facial flattening. One can compare this evolutionary change to the adaptation of the beaks of the 13 different species of Darwin's finches on the Galapagos Islands; their beaks adapted to the specific ecological niche for eating on the different islands. Also, the unique endemic Galapagos marine iguana of these islands developed a flat face, when compared with the land iguana, which adapted to eating algae from the underwater lava rocks.[7]

Other anatomic changes that facilitated speech are an anterior migration of the foramen magnum, acute angulation of the cranial base, a shortened ethmoid bone, and an oropharyngeal tongue. Figures 27.3A and B show that the tongue in the chimpanzee does not encroach on the pharynx, whereas in the human it does, significantly compressing the oropharynx, which has an impact on the upper airway and is related to the pathogenesis of obstructive sleep apnea.

## RHINOSINUSITIS IN OTHER SPECIES IN THE WILD; IMPLICATIONS FOR OTITIS MEDIA

Rhinosinusitis—like otitis media—is also incompatible with survival in animals in their natural environment (*see* Chapter 3). Olfaction, as with hearing and vestibular function, is another special sense that is severely and adversely affected when rhinosinusitis occurs.[8] The sense of smell is critical in most terrestrial animals for recognition, avoidance, and defense against predators.[9] Indeed, if animals in the wild had routinely developed sinusitis, they most likely would have been selected out during evolution. Odor sources from predators have been identified by Apfelbach et al. as coming from the whole animal or from its feces, urine, anal gland secretions, and bedding.[10] Olfaction also aids animals in selecting food that is safe[11] and helps animal mothers in identifying their young. Except for humans (after the neonatal age), most mammals, including our primate relatives, are highly habitual—obligatory in many cases—nasal breathers, and if rhinosinusitis, with its associated nasal obstruction, would have been present they would not only have had poor olfactory function, but they would not have been able to suckle, eat, and swallow while breathing through the nose. Most mammals that are "macrosomatic" (i.e. largely dependent on olfaction for communication with their environment) must keep their nasal airways and olfactory system open to detect the scent of predators. Humans—in contrast to most other mammals, including other primates—are "microsomatic," i.e. less dependent on olfaction.

Thus, rhinosinusitis in most other mammals in a natural setting is probably "rare" in contrast to its frequent occurrence in humans.[12] Although proof is lacking, we hypothesize that if a viral upper respiratory tract infection (URI) regularly occurred in animals, they most likely would not have survived and thus not garnered the evolutionary robustness that would have accompanied acquired immunity.

Indeed, the presumed absence of URI in wild animals could shed light on the etiology and pathogenesis of acute otitis media in humans. In addition to more favorable anatomy of the paratubal muscles (e.g. tensor veli palatini) of the Eustachian tube and its function as present in the Rhesus monkey when compared to humans, lack of viral URI has probably contributed to the probable absence of acute otitis media in animals in the wild; we have never observed spontaneous acute otitis media in the hundreds of monkeys in our laboratory in 30 years. Humans, on the other hand, have relatively poor tubal function and are susceptible to URIs, which has resulted in our high incidence of acute middle-ear infections, especially in infants in day-care environments (*see* Chapter 3).

Chronic middle-ear effusion, also not evident in the monkey, is common in humans, but not necessarily associated with URI. Occurrence of chronic otitis media with effusion has been linked to dysfunction of the Eustachian tube characterized by paradoxical "constriction" during attempts to open (dilate) the tube during swallowing, such as in the infant with an unrepaired cleft, which is thought to be secondary to a functional abnormality of the levator palatini veli muscle.[13] Not only is tubal dysfunction related to the pathogenesis of otitis media but also there is a genetic predisposition.[14] Some populations, such as certain Native Americans (e.g. Inuits, Apaches, and Navajos) and Australian Aborigines, have an extraordinary incidence of otitis media, which undoubtedly is hereditary (*see* Chapter 3).

**Table 27.1:** Presence or absence of paranasal sinuses in Old and New World monkeys

| *Taxa* | *Paranasal sinus* | | | |
|---|---|---|---|---|
| | *Maxillary* | *Ethmoid* | *Frontal* | *Sphenoid* |
| *Cercopithecoidea (Old World monkeys)* | | | | |
| Most taxa<br>e.g. *Papio* (baboon), *Mandrillus* (Mandrill) | No | No | No | No |
| *Macaca* (Rhesus macaque) | Yes | No | No | No |
| *Platyrrhini (New World monkeys)* | | | | |
| Most taxa<br>e.g. *Alouatta* (howler monkey), *Ateles* (spider monkey) | Yes | Yes (in some) | No* | No* |
| *Cacajao* (Uakari) and *Saimiri* (squirrel monkey) | No | No | No | No |

*Recesses that may be homologs of sinuses are variably present.

## COMPARATIVE ANATOMY OF PARANASAL SINUSES

The anatomy of the paranasal sinuses, or lack thereof, is dramatically different in nonhuman primates when compared with humans. Table 27.1 shows the super family Cercopithecoidea (Old World monkeys) have no sinuses except for one genus, the *Macaca* (Rhesus macaque), in which only the maxillary sinus is present.[15] Platyrrhine primates (New World monkeys) exhibit variations in their sinus anatomy with most reported having maxillary sinuses, some having ethmoids, but only homologs of the human having sphenoid and frontal sinuses; two genera, *Saimiri* and *Cacajao*, have no paranasal sinuses. As shown in Table 27.2, the great apes, the gorilla and orangutan, have the largest maxillary sinuses, but their ethmoids are essentially rudimentary (Fig. 27.5); ethmoids in humans have the largest volume in comparison with the great apes[16] (Fig. 27.6).

It has been proposed the ethmoid sinuses are not a true paranasal sinus and probably only has an olfactory function, whereas the other sinuses do not.[12] Also, as concluded by Marquez et al., the ethmoids are "phylogenetically, embryologically, anatomically, and functionally completely different from all other paranasal sinuses, and only in humans has it taken a key position between all the other paranasal sinuses, controlling their ventilation and drainage."[12] Thus, the ethmoid sinus has key role in the pathogenesis of rhinosinusitis in humans. Also, ethmoid sinusitis is a major factor in impairment of olfaction, whereas the other paranasal sinuses are not.

Animal species that lack or have rudimentary ethmoid sinuses, including the great apes, are unlikely to have olfactory impairment, and when present, are not adjacent to the cribriform plate, the outlet of the olfactory system into the nasal cavity. By contrast, the cribriform plate is in intimate contact with the ethmoid sinuses in humans. In most other mammals, the ethmoid bone is more posterior, and the cribriform plate lies in front for optimum olfactory function, whereas only in humans does the ethmoid bone become pneumatized and exhibit a sinus (probably related to bipedalism, facial flattening, and loss of prognathism); along with anterior migration of the orbits results in deepening of the face. As stated by

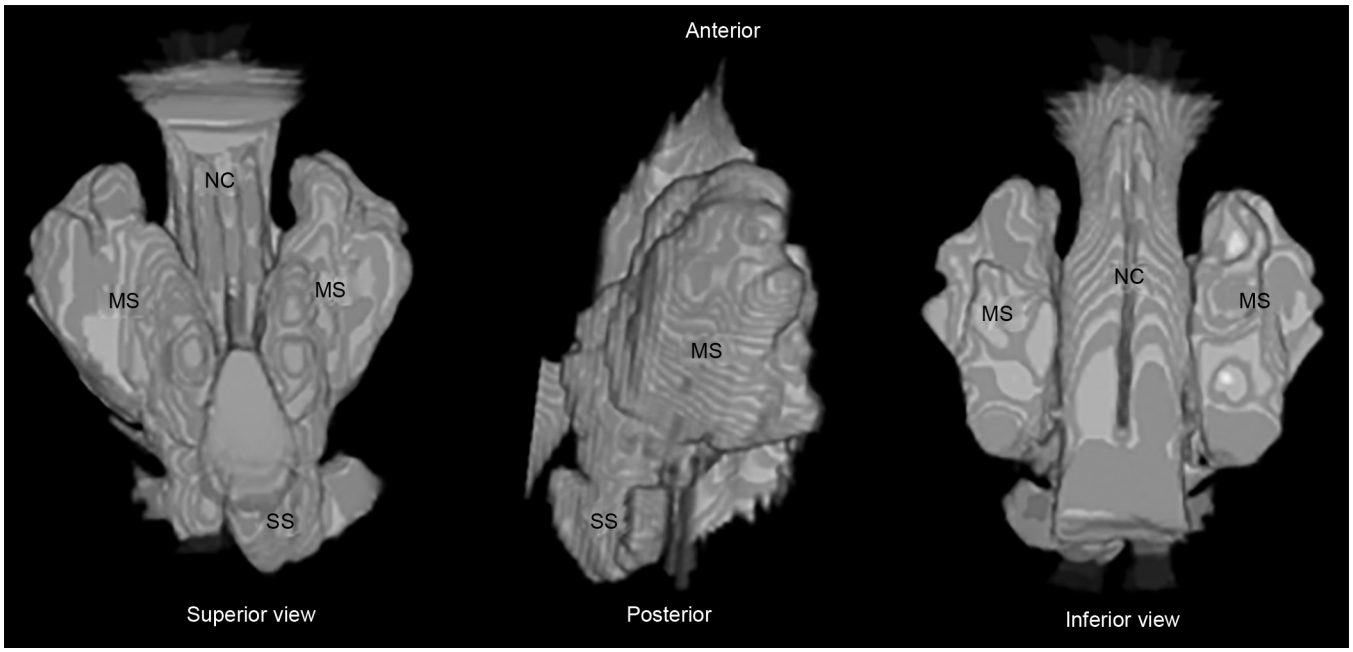

**Fig. 27.5:** Three-dimensional reconstruction of the nasal cavities and paranasal sinuses of an orangutan (Pongo) showing lack of ethmoids in the nasal cavities and large maxillary sinuses. (MS: Maxillary sinus; NC: Nasal cavities; SS: Sphenoid sinus.
*Source*: From Bluestone et al. 2012.[2]

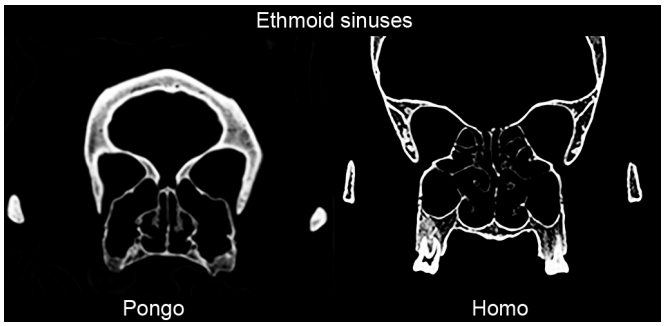

**Fig. 27.6:** Computed tomographic scan, coronal view, of skulls of Pongo (orangutan), left frame, and Homo (human), right frame, showing a lack of ethmoid sinuses in the orangutan compared with prominent ethmoid sinuses (arrow) in the human.
*Source*: From Bluestone et al.[2]

Marquez et al.[12] in "humans the anterior migration of the ethmoid sinus displaced the frontal sinus superiorly that disconnected the frontal sinus from the maxillary sinus and the ethmoids migrated along with the descent of the larynx that contributed to the unique human speech apparatus."

Thus, similar to the effect of evolution on the anatomy of the palate and paratubal muscles of the Eustachian tube, adaptations to bipedalism and speech and loss of prognathism have had a major effect on the anatomy of the paranasal sinuses, especially the ethmoids, which most likely predisposes humans to developing rhinosinusitis when exposed to airborne irritants.

## EVOLUTION'S ROLE IN PARANASAL SINUS AND MIDDLE-EAR DRAINAGE

When humans adapted to habitual bipedalism, there was a significant effect on drainage of the maxillary and sphenoid sinuses, as well as the middle ear. The bipedal posture resulted in the maxillary ostia being high in the medial wall in which drainage into the nasal cavity is by gravity, whereas in quadrupeds, drainage is aided by gravity as a result of the relative anterior tilt characterizing their head position.[17] Although not tested for drainage by gravity, similar anatomy exists in the sphenoid sinus as the ostia are high on the anterior wall. There is a similar impact of upright posture on drainage of the middle ear as it is less likely to drain by gravity into the nasopharynx, because the osseous portion of the Eustachian tube in the middle-ear is high at the level of the neck of the malleus, not in the most advantageous position in the inferior portion of the hypotympanum. In humans, the maxillary and sphenoid sinuses, as well as the middle ear, drainage is dependent on mucociliary transport, which in the middle ear is impaired by negative pressure and inflammation.

## DO THE HUMAN PARANASAL SINUSES HAVE A SIGNIFICANT FUNCTION?

Marquez,[18] in a review of 86 publications in the world literature, reported there were 19 hypothesized functions of the paranasal sinuses in humans over the past 2,000 years, but none reached consensus among researchers. However, production of nitrous oxide (NO) within the paranasal sinuses was the most interesting. As proposed by Lundberg et al.,[19] NO in the upper respiratory tract is produced in the paranasal sinuses and has a role in respiratory physiology, since it enhances pulmonary oxygen uptake due to local vasodilation. High production of NO is unique in humans and most other primates, but much lower in other mammals, such as dogs, rabbits, mice, and rats. In support of this hypothesis, Lewandowski et al.[20] reported that baboons that have no paranasal sinuses were found to have markedly lower concentrations of exhaled concentrations of NO than mammals with paranasal sinuses.

But why have Old World monkeys, except *Macaca*, that have no paranasal sinuses (*see* Table 27.1), survived without sinus NO and why do other mammals that have been identified as having NO require its production from the paranasal sinuses? In addition, nonprimate mammals that have paranasal sinuses (e.g. dogs and rabbits) produce low concentrations of NO and have survived. If some mammals (e.g. almost all Old World monkeys and some New World monkeys) can live without paranasal sinuses, the sinuses probably have no major physiologic function related to the production of NO.

Another possible function for paranasal sinuses is that they provide a biomechanical advantage, but Rae and Koppe[21] reported the hypothesis that sinuses arose in response to biomechanical requirements of skull architecture through dissipating masticatory stress forces related to dietary activities can be rejected. Among the other proposed functions are that they lighten the skull, aid in resonance to the voice, assist in regulating intranasal pressures, warm and humidify air, and are part of normal skull pneumatization. The human ethmoid sinuses, with their relatively small intranasal position (they are not truly a paranasal sinus since they are intranasal), most likely do not play any role in making the skull lighter, but one could argue their position in the nasal airway may be involved in vocal resonance, in addition to the proposed olfactory function and production of NO. The other sinuses also probably don't lighten the skull in the bipedal position of humans. Still another hypothesis is that yawning may activate a ventilator system in the paranasal sinuses for selective brain cooling.[22] Since is there is no consensus on function at this time, most likely the paranasal sinuses in humans exist as primitive retentions, i.e. "evolutionary remains of useless air spaces."[18,23,24]

## DOES HUMAN EVOLUTION HAVE IMPLICATIONS FOR MANAGEMENT?

A reasonable question related to rhinosinusitis, as well as otitis media is since both are probably limited to humans, how does that assumption help otolaryngologists manage patients with these diseases? From our understanding of the consequences of evolution related to otitis media, we learned that there are differences in the anatomy and function of the muscles of the Eustachian tube between the Rhesus monkey and the human that might improve tubal function following repair of the palate in patients with palatal clefts, i.e. levator veli palatini muscle.[25] Are there any implications for management of rhinosinusitis related to evolution?

### Caldwell-Luc Redux?

Given the unfavorable position of the human maxillary ostia due to bipedalism, is there ever a role for the Caldwell-Luc procedure? This old standby was the most common surgical procedure for treatment of chronic maxillary sinus disease for more than a century, but has more recently been replaced by less invasive endoscopic sinus surgery. Since there may be a presumed advantage of gravity drainage of the sinus by surgically making an antrostomy in the inferior meatus of the nasal cavity, there may still be an indication, albeit rarely, for a Caldwell-Luc operation, or modifications of it, when endoscopic sinus surgery of the osteomeatal complex fails to provide a permanent middle meatus antrostomy.[26] Most recently, functional endoscopic balloon dilation of sinus ostia for chronic rhinosinusitis has been become popular, but the efficacy of this new innovation has not had convincing evidence for supporting its use compared with conventional surgical procedures.[27,28]

### Exenteration and Obliteration of Sinuses?

In humans, when a nonvital organ has chronic disease that is irreversible, the organ is deemed useless and removed.

There are a many examples of organs, such as the tonsils and salivary glands, in which other healthy organs continue to function (for tonsils, other lymphoid tissue of Waldeyer's ring; following surgical excision of a diseased parotid or submaxillary gland, the other healthy major and minor salivary glands). Since there is no consensus on the physiologic role of the paranasal sinuses, except for possible production of NO, can a sinus, such as the maxillary, that has end-stage disease, be exenterated and obliterated?

There seems to be a real reluctance to obliterate the maxillary sinus. To date, there are no safe and effective procedures proposed. Yet, there is an example of an obliteration procedure in sinus disease, as when the frontal sinus communication into the nasal cavity cannot be restored following fracture of the frontal bone and its sinuses; in these cases, a fat graft is used for obliteration.[29] Also, there is an operative procedure for placing bone grafts in the maxillary sinus. Maxillary sinus floor augmentation procedure (i.e. sinus-lift) has been a very successful operation to permit tooth implants when there is not enough maxillary alveolar bone for implantation.[30] Can bone grafting techniques used for sinus lift surgery be used to obliterate a maxillary sinus that has failed surgery and has irreversible disease? Another example of an obliteration procedure is for chronic tympanomastoiditis, especially when that ear has no serviceable hearing. The Rambo procedure, using a temporalis muscle flap for obliteration of the tympanomastoid cavity, has been successful in most patients in preventing chronic otorrhea for the more than 50 years since Thomas Rambo first introduced it.[31,32]

If there is any sinus that would have important physiologic functions, it would be the ethmoids, since they are directly in the nasal airway and might be involved in vocal resonance as well as possible production of NO and olfaction. Yet, currently, ethmoidectomy is one of the most common surgical procedures for chronic rhinosinusitis in both children and adults. Thus, obliteration of an offending maxillary sinus is no more detrimental than ethmoidectomy. Candidate patients for obliteration of the maxillary sinuses could be individuals with cystic fibrosis or primary ciliary dyskinesia who have end-stage sinusitis (i.e. irreversible disease), especially since NO concentration is extremely low, or almost nonexistent, in these patients; even in patients without these relatively rare diseases, who have other more common etiologies of chronic sinusitis, NO concentrations have been found to be low.[18] Individuals with cystic fibrosis in whom maxillary sinuses are deemed to have chronic intractable disease, especially prior to lung transplantation, could have the offending sinuses obliterated. Topical daily nasal medical treatment could then be used without the need for repeated treatment of the offending sinuses.

## SUMMARY AND CONCLUSION

Rhinosinusitis, similar to otitis media, is most likely a human disease, secondary to consequences of evolution (i.e. adaptations to bipedalism and speech, and loss of prognathism), which resulted in anatomic differences compared to other mammals, mainly in the ethmoid sinuses and ventilation and drainage of the maxillary and frontal sinuses. In otitis media, the associated special sense of hearing, and more rarely vestibular function, would have been diminished, making survival of animals in the wild unlikely. Similarly, if rhinosinusitis occurred, animals would not have survived during evolution due to the loss of olfaction, another special sense. Although proof is lacking, if animals had developed viral URI during evolution, they would also have been selected out for the same reason and probably developed immunity. Humans have no doubt survived despite development of otitis media, URI, and sinusitis due to our excellent eyesight (another sense organ) and big brain along with protection from predators afforded by our family and social structure.

Because human paranasal sinuses apparently have no agreed upon physiologic function, except for possible production of NO, individuals with irreversible sinus disease might be candidates for exenteration and obliteration of the offending sinus cavity (e.g. maxillary) without loss of any known major physiologic function, as the mucosal lining of the sinus would no longer be capable of any possible function. Although this suggestion is currently unorthodox, indications for an exenteration and obliteration procedure of a sinus, as well as the ideal approach and implant material, should be a subject for future research and clinical goals.

In conclusion, rhinosinusitis is most likely unique to humans and extremely common, especially in infants and young children, and is a consequence of human evolution, as well as immunologic and environmental factors.

CHAPTER

# 28 Evaluation of the Child with Rhinologic Disease

*Derek J Lam, Carol J MacArthur*

## INTRODUCTION

Expertise in the evaluation of the child with rhinologic disease is a necessary part of the armamentarium for the otolaryngologist treating children. Pediatric rhinologic disease is common; pediatric sinusitis is estimated to complicate the common cold in approximately 5–10% of cases, and children have on average six to eight respiratory infections every year.[1] Most young children will allow very little instrumentation of the nasal cavity or sinuses in the office setting, so the challenge is how to best make a meaningful assessment and come to an accurate diagnosis of the catarrhal child.

## HISTORY

### Nasal Obstruction

Nasal obstruction is perhaps the most common rhinologic complaint in children. A detailed history of the age at onset, duration, chronicity, laterality, and associated symptoms can help to determine the likely etiology of the nasal obstruction and direct further workup or treatment. The differential diagnosis includes infectious etiologies such as viral upper respiratory infections (URIs) and bacterial rhinosinusitis, common inflammatory conditions such as allergic and nonallergic rhinitis,[2–4] allergic fungal sinusitis,[5] asthma,[6,7] cystic fibrosis (CF),[7,8] and gastroesophageal reflux disease (GERD).[9,10] Congenital or acquired tumors and cysts of the sinonasal tract also commonly present with nasal obstruction. These include nasolacrimal duct cysts (NLDC),[11,12] encephaloceles or gliomas, nasal dermoids,[13] vascular malformations,[14,15] antrochoanal polyps,[16] and rare malignant tumors such as teratomas, rhabdomyosarcomas, or esthesioneuroblastomas.[17,18] Nasal polyposis is rare in children except in children with CF; therefore, a history or observation of nasal polyps should prompt a workup for CF if it has not already been done.[7,19–21] A fixed nasal obstruction may be caused by a nasal foreign body, septal deviation, inferior turbinate hypertrophy, choanal atresia/stenosis, pyriform aperture stenosis, and maxillary or midface hypoplasia due to an associated syndrome.[22] This broad differential diagnosis can be categorized based on the age of symptom onset (Table 28.1).

### Rhinorrhea

Rhinorrhea is a nonspecific symptom that is associated with allergic rhinitis and asthma, viral rhinitis, and bacterial rhinosinusitis. Differentiating between allergic and viral rhinitis can often be difficult. Allergic rhinitis is rare in children younger than 2 years old.[23,24] This is because atopic responses to environmental allergies typically develop after two or more seasons of pollen exposure; therefore, a detailed allergy history should be elicited in any child older than age 2 with symptoms of chronic nasal obstruction and rhinorrhea.[4,25] Risk factors for the development of atopy include a significant family history of allergies, especially among first-degree relatives, cigarette smoke exposure, higher socioeconomic class, and being a first-born or only child.[26] Food allergies, most commonly to milk or egg, and atopic dermatitis in infancy are both associated with later development of inhalant allergies, allergic rhinitis, and asthma.[23,27,28]

**Table 28.1:** Age of onset and differential diagnosis for nasal obstruction

| *Age* | *Differential diagnosis for nasal obstruction* |
|---|---|
| Neonate (0–3 months) | Neonatal rhinitis<br>Choanal atresia/stenosis<br>Congenital pyriform aperture stenosis<br>Nasal encephalocele, glioma, or dermoid<br>Nasal hemangioma<br>Nasolacrimal duct cyst<br>Midface hypoplasia |
| Infant (3–12 months) | Adenoid hypertrophy<br>Recurrent viral URI<br>Nasal hemangioma<br>Nasolacrimal duct cyst |
| Toddler (12–24 months) | Adenoid hypertrophy<br>Recurrent viral URI<br>Nasal foreign body |
| Preschool (2–4 years) | Adenoid hypertrophy<br>Recurrent viral URI<br>Recurrent acute rhinosinusitis<br>Chronic rhinosinusitis<br>Allergic fungal sinusitis<br>Allergic rhinitis<br>Nasal foreign body<br>Nasal polyposis (cystic fibrosis)<br>Immunodeficiency |
| Early school age (5–12 years) | Recurrent acute rhinosinusitis<br>Chronic rhinosinusitis<br>Allergic fungal sinusitis<br>Allergic vs. nonallergic rhinitis<br>Adenoid hypertrophy<br>Septal deviation<br>Inferior turbinate hypertrophy<br>Septal hematoma<br>Antrochoanal polyp<br>Nasal polyposis (Cystic fibrosis)<br>Immunodeficiency |
| Teenager (13–18 years) | Recurrent acute rhinosinusitis<br>Chronic rhinosinusitis<br>Allergic fungal sinusitis<br>Allergic vs. nonallergic rhinitis<br>Adenoid hypertrophy<br>Septal deviation<br>Inferior turbinate hypertrophy<br>Septal hematoma<br>Antrochoanal polyp<br>Nasal polyposis (cystic fibrosis)<br>Immunodeficiency<br>Juvenile nasopharyngeal angiofibroma |

## Epistaxis

A report of epistaxis should prompt questions about the frequency, duration, severity, and laterality of the bleeding episodes. The majority of pediatric epistaxis can be attributed to prominent vessels in Kiesselbach's plexus of the anterior septum with thin overlying mucosa that is susceptible to breakdown with either digital trauma or persistently dry air. An association of bleeding with dryer climates is consistent with this etiology. Recurrent epistaxis of significant volume, duration or frequency, especially if associated with syncope, hypotension, or need for blood transfusion, should prompt a more detailed workup for bleeding disorders, vascular anomalies, or vascular tumors. Recurrent epistaxis can be the presenting symptom of an underlying bleeding dyscrasia; therefore, the patient should be asked about easy bruising, frequent or prolonged bleeding episodes in addition to epistaxis, and a family history of hematologic disorders. Symptoms of fixed nasal obstruction or facial pain are suggestive of a nasal mass or tumor such as a juvenile nasopharyngeal angiofibroma.

**Table 28.2:** Chandler classification of orbital complications of sinusitis

| *Chandler class* | *Diagnosis* | *Clinical signs* |
|---|---|---|
| I | Preseptal cellulitis | Eyelid edema and erythema<br>Normal extraocular movements<br>Normal visual acuity |
| II | Orbital cellulitis | Diffuse edema of orbital contents<br>No discrete abscess formation |
| III | Subperiosteal abscess | Subperiosteal purulence of lamina papyracea<br>Lateral and downward globe displacement |
| IV | Orbital abscess | Purulent fluid collection within orbit<br>Proptosis, chemosis, ophthalmoplegia<br>Decreased visual acuity |
| V | Cavernous sinus thrombosis | Bilateral ocular findings<br>Prostration<br>Meningismus |

## Orbital Symptoms

Periorbital cellulitis and abscess are well-known complications of bacterial rhinosinusitis. A history of periorbital edema, erythema, increasing retro-orbital pain, visual acuity changes, or diplopia in the setting of an acute episode of rhinosinusitis should prompt a careful evaluation for possible periorbital abscess. Orbital complications of rhinosinusitis are most commonly described in terms of the Chandler classification scheme (Table 28.2).[29]

However, a more recent classification of orbital complications of acute rhinosinusitis based on a systematic review of the available evidence has been proposed.[30]

## Nasal Pain

Pain is an uncommon rhinologic complaint in children. Report of chronic or worsening nasal pain is suggestive of a severe infection such as complicated bacterial rhinosinusitis or an enlarging or invasive sinonasal tumor. Consideration should be given to nasal endoscopy and computed tomography (CT) or magnetic resonance imaging (MRI) to further evaluate this possibility.

## Assessing Pediatric Sinonasal Quality of Life

The SN-5 is a 5-item questionnaire for assessing health-related quality of life in children aged 2–12 years with persistent sinonasal symptoms. It demonstrated good test-retest reliability, validity, and responsiveness to change when compared with several external constructs.[31] This instrument has been used to demonstrate significant improvement in sinonasal-related quality of life after adenoidectomy or endoscopic sinus surgery.[32] A related instrument is the Pediatric Rhinoconjunctivitis Quality of Life Questionnaire that was developed to measure the quality of life in children ages 6–12 years old with seasonal allergic rhinoconjunctivitis. It has shown good reliability and responsiveness to change.[33]

## Bacterial Rhinosinusitis

Diagnosis of bacterial rhinosinusitis in children relies primarily on a detailed history. It is important to differentiate uncomplicated viral URIs from bacterial rhinosinusitis. Both can be characterized by nasal congestion, rhinorrhea, postnasal drip, hyposmia, cough, fever, and halitosis. Facial pain or headache, while common complaints in adult sinusitis, is less common in children. Acute bacterial rhinosinusitis has been purported to complicate approximately 6–8% of viral URIs, though the exact incidence remains unknown.[34] Viral URIs typically last 5–7 days and have at least begun to improve if not resolve completely after 10 days. There are three general patterns of symptom presentation that are suggestive of a viral URI that has progressed to acute bacterial rhinosinusitis[35,36]:

1. URI with nasal discharge, daytime cough worse at night with symptoms lasting > 10 days
2. URI that is more severe than usual characterized by high fevers for at least 3–4 days with concurrent copious purulent discharge or periorbital edema and pain
3. URI that was improving but suddenly worsens (double sickening)

The duration and specific pattern of symptom presentation has been used to define different categories of rhinosinusitis in children (Table 28.3).[37,38] In addition to these classifications, recurrent acute rhinosinusitis is defined as 3 acute episodes of acute bacterial rhinosinusitis in 6 months or ≥ 4 episodes of bacterial rhinosinusitis in 1 year, each lasting < 4 weeks, separated by intervals of at least 10 days without symptoms.

Thus, a detailed history should include the timing, duration, and severity of symptoms signaling a sinus infection, history of previous sinus infections, antibiotic use, nasal treatments such as steroid or saline sprays, and any previous hospitalizations for sinusitis-related complications. This includes periorbital cellulitis or abscess, Pott's puffy tumor, and meningitis.

Predisposing factors and possible etiologies should be explored. These include frequency of viral URI, daycare attendance or older school-age sibling in the household, allergy history including environmental and food allergies, asthma or eczema, and history of GERD, CF, ciliary dyskinesia, and immunodeficiency,[36,39] Approximately 50% of children with sinusitis also have environmental allergies, and there are known associations between allergies, asthma, and chronic sinusitis.

**Table 28.3:** Classification of bacterial rhinosinusitis

| | *Acute* | *Subacute* | *Chronic* |
|---|---|---|---|
| Symptoms | Purulent nasal discharge or postnasal drip for ≥ 3–4 days<br>High fevers (> 39°C)<br>Cough (worse at night) | Nasal discharge or postnasal drip (any quality)<br>Daytime cough<br>Periodic low grade fever | Nasal discharge or postnasal drip (any quality)<br>Daytime cough<br>Periodic low grade fever |
| Chronicity | Complete symptom resolution during this period | Complete symptom resolution during this period | Persistent symptoms with acute exacerbations and only partial response to antimicrobials |
| Duration | 10 days to 4 weeks | 4–12 weeks | > 12 weeks |

## CLINICAL EXAMINATION

### Head and Neck Examination

A thorough head and neck examination will include an assessment of the overall appearance of the child. The clinical evaluation and examination should be done in a nonthreatening manner for young children, perhaps with the child seated on the caregiver's lap to provide reassurance and for assistance in restraint if necessary. Allowing the child to see and touch the instruments to be used may also help. The facial appearance will often provide clues to the underlying pathology. An open-mouth posture, for example, will indicate that there is nasal or nasopharyngeal obstruction to breathing. Allergic shiners (dark circles under the eyes) will provide a clue that there may be allergic or infectious pathology in the nasal and sinus cavities. The allergic crease (a horizontal crease in the nasal supratip area), or evidence of the "allergic salute" performed in the office, will provide clues to possible allergic rhinitis. Foul odor emanating from the nasal cavity may indicate bacterial sinusitis, and if the odor is putrid and unilateral, indicates a nasal foreign body. Throat clearing or repetitive cough observed in the office may indicate the presence of postnasal drip from allergic rhinitis or sinusitis. A hyponasal voice will also indicate nasopharyngeal of nasal obstruction significant enough to cause alteration in the vocal resonance.

### Neonates and Infants (0–12 Months)

Neonates will more likely have congenital lesions, such as choanal atresia, pyriform aperture stenosis, nasal hemangiomas, NLDC, delivery-related septal deviation, dermoid cysts, gliomas, and encephaloceles (Table 28.1). Unilateral choanal atresia presents with unilateral constant mucoid drainage from one side of the nose. Once this is removed with suction, nasoendoscopy will reveal the atretic plate at the posterior choana (Fig. 28.1). An endoscopic view of the choanal atresia is a nice complementary study to the CT scan in terms of timing of the repair, level of the skull base, septal position and extent of inflammatory changes in the nasal cavity. A 70° telescope can also be used to see the choanal atresia from the nasopharyngeal view (Fig. 28.2). In the neonate, the diagnosis of choanal atresia can be made rapidly and with confidence with the flexible fiberoptic endoscope, even prior to any imaging. Because babies are obligate nasal breathers, bilateral choanal atresia is associated with respiratory distress immediately after birth, with cyclical cyanosis every time the baby stops crying. With a bedside fiberoptic examination, appropriate measures can be taken to stabilize the airway until repair can be scheduled. Pyriform aperture stenosis will present with nasal congestion and difficulty feeding as the narrowed nasal aperture prevents easy nasal airflow during feeds. Anterior rhinoscopy will reveal narrowed nasal vestibules bilaterally and the flexible scope may be difficult to pass, even with nasal decongestion. A single central incisor has been observed in up to 60% of children with pyriform aperture stenosis and is suggestive of possible holoprosencephaly.[40] In such cases one should consider MRI and endocrine evaluation to assess the hypothalamic-pituitary-thyroid axis.[41] Septal deviation can cause nasal obstruction and

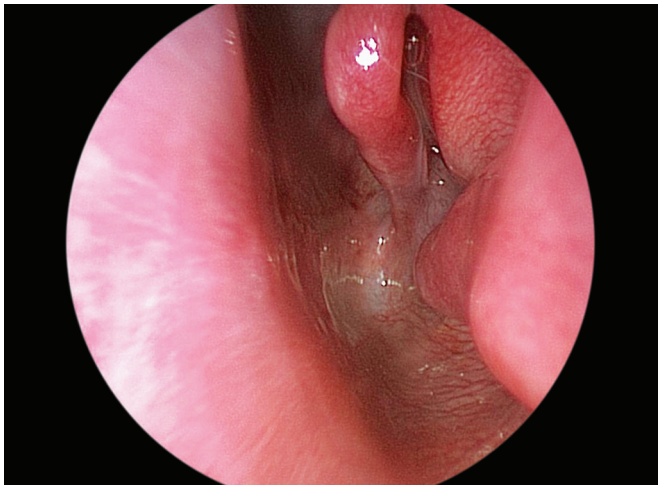

**Fig. 28.1:** Unilateral choanal atresia seen by nasal endoscopy after suctioning secretions to reveal the atresia plate.

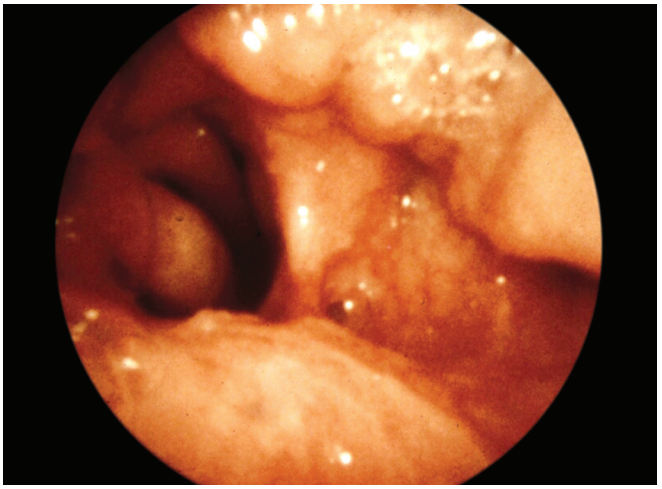

**Fig. 28.2:** Unilateral choanal atresia seen by endoscopy with 70° telescope (nasopharyngeal view).

feeding difficulties (Fig. 28.3). Reduction of the dislocated septum can alleviate the deviation if done acutely in the newborn period shortly after birth. NLDC will present as the triad of epiphora, nasal obstruction, and a cystic lesion inferior to the inferior turbinate (Fig. 28.4). As with choanal atresia or pyriform aperture stenosis, bilateral NLDC can cause significant nasal obstruction, especially with feeding. Congenital nasal masses, such as dermoid cysts, gliomas (Fig. 28.5), teratomas (Fig. 28.6) and encephaloceles will present with unilateral nasal obstruction and a solid or cystic complex mass within the nasal cavity. A midline pit is a clue to the dermoid sinus/cyst (Fig. 28.7). Nasal decongestion and endoscopic examination of the nasal cavity and nasopharynx in infants with nasal obstruction is essential to avoid missing the correct diagnosis in these cases.

Nasal hemangiomas located in the vestibule (Fig. 28.8A) or extending from the alar skin into the vestibule (Fig. 28.8B) can cause significant airway obstruction in an infant and may require treatment. Although hemangiomas are often easily recognizable by their appearance and time course of onset of symptoms, a biopsy sent for Glut-1 immunohistochemical staining will confirm the diagnosis. Ultrasound with color Doppler flow is also helpful to make the diagnosis of infantile hemangioma prior to or instead of MRI imaging.

**Fig. 28.3:** Septal deviation in a newborn causing respiratory obstruction and feeding difficulties.

**Fig. 28.4:** Nasolacrimal duct cyst as seen inferior-to-inferior turbinate in the left nasal cavity.

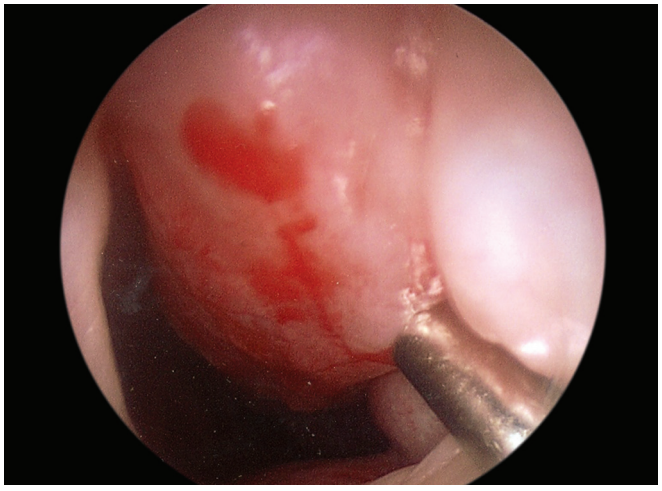

**Fig. 28.5:** Left nasal glioma filling most of left nasal cavity. Presented with unilateral nasal obstruction and feeding difficulty in an infant.

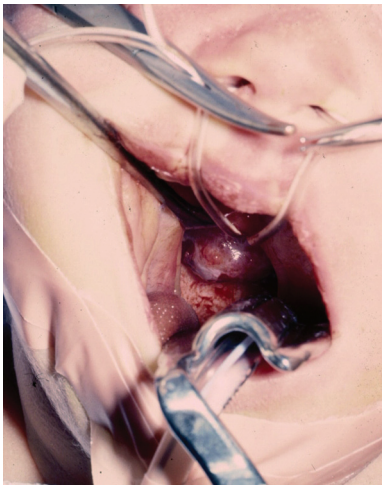

**Fig. 28.6:** Nasopharyngeal teratoma extending into the oropharynx causing complete nasal obstruction and need for urgent management in infancy to re-establish the nasal airway.

In the absence of an intranasal or nasopharyngeal mass, stertor in infants is usually secondary to GERD, until proven otherwise. Nasal endoscopy is often normal in appearance, although the presence of feeds within the nasal cavity can be a clue to GERD causing stertor in the infant.

## Toddlers and Preschool (12–48 Months)

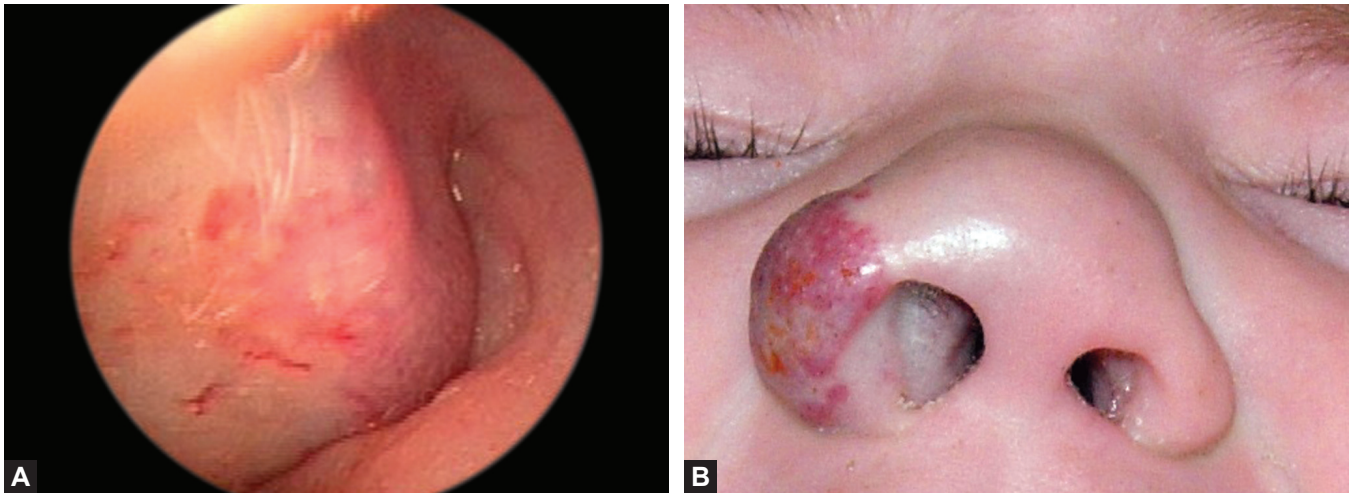
Toddlers and young children will have primarily infectious and inflammatory entities precipitating their visit to the otolaryngologist: enlarged adenoids, viral URI, rhinosinusitis, foreign bodies, polyps, turbinate hypertrophy from allergic rhinitis or smoke exposure, and excoriated anterior nasal septum from epistaxis and nasal digital trauma.

**Fig. 28.7:** Nasal dermoid sinus and cyst with midline nasal dorsal skin pit.

## School Aged Children and Older (> 5 Years)

Pre-teens and teens will also frequently present with infectious and inflammatory conditions as mentioned above. In addition, an intranasal mass associated with epistaxis, especially in males, must be biopsied with a high index of suspicious for juvenile nasopharyngeal angiofibroma. Other nasal and nasopharyngeal tumors can present in this age group as progressive nasal obstruction and discharge. Neoplasms presenting in this anatomic location require a high index of suspicion (Fig. 28.9). Nasal endoscopy and imaging must be obtained to delineate extent of involvement. Trauma can cause nasoseptal deformity, resulting in chronic nasal obstruction as well. This can often be observed with anterior rhinoscopy or nasal endoscopy.

Anterior rhinoscopy can be done on almost any age child with a hand-held otoscope to examine the septum, vestibule, turbinates, and anterior nasal cavity to evaluate for nasal purulence, inflammation, polyps, masses, or deformity. Alternatively, a headlight and nasal speculum can be used, although this can be more difficult than the otoscope in a young, anxious child. Anterior rhinoscopy can be quite informative about the state of the nasal cavity, especially if the otoscope is used to examine the nasal cavity, inferior and middle turbinates and even middle meatus. Examination of the anterior septum and Little's



**Figs. 28.8A and B:** (A) Nasal vestibular hemangioma causing complete unilateral nasal obstruction in infant and feeding difficulties; (B) Nasal alar and vestibular hemangioma causing unilateral nasal obstruction and breathing problems.

**Fig. 28.9:** Nasopharyngeal rhabdomyosarcoma presenting as unremitting nasal obstruction and discharge.

**Fig. 28.10:** The mucosal atomization device (MAD Nasal) can be used to deliver topical anesthetic to the nasal mucosa in any aged child.

area (Kiesselbach's plexus) will reveal a possible source of epistaxis, with prominent vessels, mucosal erosion, and crusting. Identification of prominent vessels in Little's area may target candidate vessels for cauterization, if indicated.

Nasoendoscopy (fiberoptic or rigid telescope) is the next step in the evaluation of the child with rhinologic disease. Examination of the nasal cavity before and after topical decongestion is important to evaluate the condition of the nasal airway before and after is it decongested. Topical anesthesia, such as 4% lidocaine with phenylephrine, applied via atomizer or intranasal mucosal atomization device (MAD Nasal) (Fig. 28.10) is gently sprayed into the nasal cavities. Since the local anesthetic will create anesthesia to the nasal cavity as well as the oropharynx, it may be wise to avoid lidocaine in small infants and patients unable to protect their upper airway from aspiration of secretions.

After topical anesthesia is achieved (usually within minutes), the flexible fiberoptic scope is passed into both nasal cavities, to allow a thorough examination of the nasoseptal mucosa, the turbinates, the nasopharynx, and adenoids. While the flexible fiberoptic scope is versatile and perhaps less uncomfortable for the patient, the rigid rod lens telescope will give the clinician better optics and allow simultaneous instrumentation of the nasal airway, e.g. in suctioning secretions, removing foreign bodies, nasal packing, stents, crusting, examination of postoperative sinus antrostomies, etc. Anatomic abnormalities will be identified that may predispose to infection[42] such as a concha bullosa (will appear as a widened middle turbinate on endoscopy), paradoxical middle turbinate, septal deviation, boggy edematous inferior turbinates (allergic changes), and others; however, the relationship of anatomic abnormalities to pediatric sinusitis is debated.[43]

## Microbiologic Assessment (Cultures)

If the rhinologic examination is being performed for infectious disease of the sinus cavities, middle meatal cultures may be the most accurate for choosing antibiotic therapy, although the reliability in children is debated as well as the most appropriate method.[44–46] A middle meatal culture can be accomplished with a rigid scope and small culture swab (rayon-tipped applicator swab) or endoscopically directed middle meatal aspiration into a culture trap. Nasal cavity cultures may not be as accurate, but can be used to diagnose the etiology of infectious rhinitis in the absence of being able to obtain middle meatal or direct sinus cultures as one could do under anesthesia in the operating room. While the reliability of nasopharyngeal cultures for the diagnosis of acute rhinosinusitis is debated,[46] a recent study shows a high concordance with middle meatal samples in adults.[47] In an immunocompromised child, it is imperative to obtain an accurate sample for culture. Therefore, cultures may have to be obtained from the sinus or middle meatus in the operating room under anesthesia at the time of a sinus endoscopy or other surgical intervention. Cultures should

be sent for bacterial and fungal analysis. If invasive fungal sinusitis is suspected, viable tissue must be sent for frozen section looking for angiogenic spread into the tissues.

## IMAGING

The most common modalities for imaging of pediatric rhinologic disorders are CT and MRI. While plain films have historically been used to evaluate the paranasal sinuses, they have largely been supplanted by CT, which offers far greater detail and precision in evaluating bony anatomy and erosion and soft tissue edema or obstruction. CT scanning with contrast can help to identify abscess collections, while MRI offers superior differentiation of soft tissue masses, inflammatory tissue, and intracranial extension. Depending on the age and temperament of the patient, both may require sedation in order to avoid motion artifact; however, sedation is most frequently needed with MRI scanning due to the small enclosed space and duration and noise of scanning. The primary disadvantage of CT scanning is the exposure to ionizing radiation. This is thought to be a particular concern in children because (1) a child's developing tissues are particularly radiosensitive, (2) the overall radiation risk is cumulative over the child's lifetime, and (3) children have a longer lifetime and life expectancy in which to express the increased risk posed by this radiation exposure.[48] A recent study of the effect of cumulative radiation exposure from CT scanning found significant associations with leukemia and brain tumors in a dose-dependent fashion. Patients who received a cumulative dose of at least 30 mGy had a relative risk of leukemia of 3.2, while in those receiving > 50 mGy the relative risk of developing a brain tumor was 2.8.[49]

### Nasal Obstruction

For imaging studies of congenital causes of nasal obstruction, bony abnormalities such as choanal atresia or pyriform aperture stenosis are best evaluated with a maxillofacial noncontrast CT. In choanal atresia, there is typically narrowing of the posterior nasal cavity with medialization of the lateral nasal wall and thickening of the vomer (Fig. 28.11). The choanal airspace usually measures < 34 mm. In the case of congenital nasal pyriform aperture stenosis, a width of < 11 mm at the narrowest point of the pyriform aperture is diagnostic (Fig. 28.12).[50] Neonatal soft tissue masses such as an encephalocele, dermoid, or glioma are best evaluated with MRI that can help elucidate any intracranial extension. In extensive nasal polyposis, as seen in CF, the CT appearance is typical for demineralization of the medial wall of the maxillary sinuses and ethmoid septations and widening of the nasal cavities (Fig. 28.13).

### Bacterial Rhinosinusitis

Imaging studies including plain films, CT, and MRI are generally not recommended in children for routine evaluation of sinusitis due to their lack of specificity. More than 50% of children with a viral URI demonstrated evidence of maxillary sinus inflammation on plain radiographs, and

**Fig. 28.11:** Axial CT scan demonstrating bilateral choanal atresia.

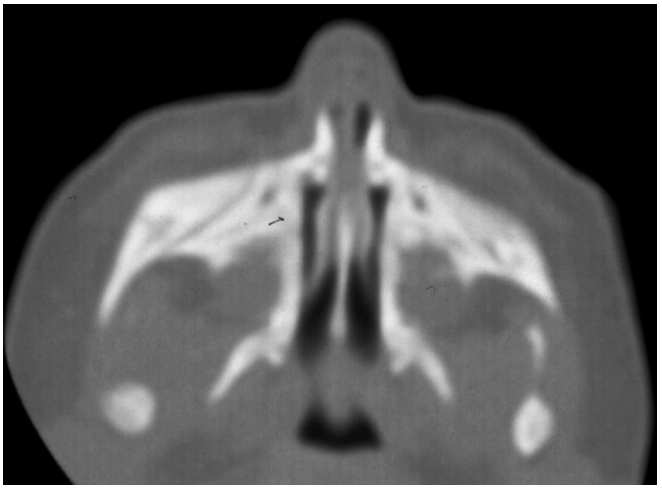


**Fig. 28.12:** Axial CT scan demonstrating pyriform aperture stenosis.

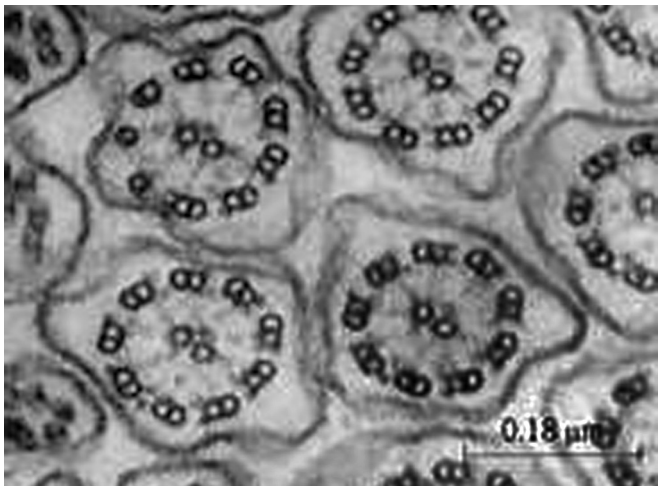

**Fig. 28.13:** The proper ciliary architecture ("nine plus two" central and outer microtubules) shown here on electron microscopic ciliary cross-section.

sinus CTs and MRIs are often abnormal even in healthy children or those with uncomplicated viral URIs.[51–55] Plain radiographs in particular are inadequate for evaluating pediatric sinuses, showing poor correlation with coronal CT scans.[56,57] In 2012, a panel of sinus experts produced a consensus statement on the appropriate use of CT scanning for paranasal sinus disease. This included the recommendation that CT imaging is indicated only when medical management has failed to control the symptoms of sinusitis, for suspected tumor, complications of sinusitis, and prior to sinus surgery. They also stated that pediatric CT imaging is limited by radiation safety concerns and possible need for sedation.[37,58] MRI was the recommended imaging modality for the assessment of immunocompromised patients with suspected invasive fungal sinusitis. CT imaging with contrast has been recommended for evaluating patients likely to have orbital complications of acute rhinosinusitis such as those with proptosis, retro-orbital pain with eye movement, or gaze restriction. MRI is considered the modality of choice for evaluating for intracranial extension of infection.[30]

## MEDICAL ANCILLARY WORKUP

### Immune Workup

Immunodeficiencies can predispose children to an increased risk for rhinosinusitis. While there is conflicting evidence for this in the literature,[59] an immunologic workup should be considered in a child with poor response to aggressive medical therapy or surgical management of their sinus disease. Studies to consider include (a) complete blood cell count (CBC with differential), (b) total immunoglobulin A, G, M, E levels and IgG I-4 subclass levels, and (c) antibody levels to rubella, conjugate *Haemophilus influenzae* type b and pneumococcal polysaccharide antigens. Primary immunodeficiencies diagnosed among patients with chronic/recurrent rhinosinusitis[60] include common variable immunodeficiency,[61] IgA deficiency and IgG subclasses deficiencies (IgG1, 2, 3, 4) and impaired polysaccharide responsiveness (partial antibody deficiency). In patients with humoral immunodeficiencies, sinusitis can be identified in as many as 60%.[62] Immunosuppressed children undergoing chemotherapy will be at greater risk for invasive fungal sinusitis and must be aggressively managed with a high level of suspicion and early biopsy for fungal organisms.[63] Children with absolute neutrophils count < 600 are especially at high risk for invasive fungal sinusitis.[63] Urgent tissue biopsy is indicated in these children and if positive for invasive fungal disease, debridement must be performed emergently under anesthesia, with plans for frequent surveillance and debridement until the disease is controlled.

### Allergy Workup

It can be approached by either measurement of serum levels of total and specific IgE for inhalant allergens, molds and food allergens or by skin testing. Testing very young children with skin prick testing, especially for food allergies, may be less accurate than in adults and older children.[64]

Hyper IgE syndrome (Job's syndrome) is also associated with recurrent sinopulmonary infections, so testing for total IgE levels should be performed when this is suspected, looking for marked elevations in serum IgE of > 2,000 IU/mL.[65] The role of GERD in sinusitis continues to be investigated and debated.[66–69] However, the child with chronic sinusitis who is refractory to medical or surgical management should be considered for a thorough investigation of GERD and a trial of anti-GERD management. An empiric trial of a proton-pump inhibitor may be advised. While each center may approach the child with suspected GERD and sinusitis differently, interventions such as esophagogastroduodenal endoscopy with biopsies for inflammation and eosinophilic infiltrate, 24 h pH monitoring, and esophageal manometry should be considered.

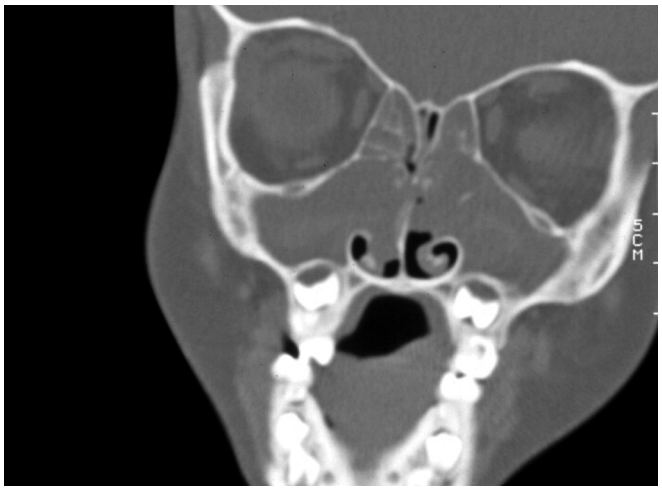

**Fig. 28.14:** Coronal CT in cystic fibrosis patient with classic findings of extensive nasal polyposis.

Ciliary biopsies are a part of the workup of a child with unremitting sinus, ear, and pulmonary disease to evaluate for primary ciliary dyskinesia or Kartagener's syndrome. A nasal ciliary biopsy can be performed in the clinic setting under local anesthesia, but is often difficult to obtain a suitable ciliated epithelial sample in the nasal passage of a child with chronic rhinosinusitis with the associated loss of ciliated epithelium. Obtaining a sample from high in the nasal cavity would be the most likely to yield a good sample. More often, a good, uncrushed sample of ciliated epithelium can be obtained from the bronchus with a bronchial brush biopsy at the time of rigid or flexible bronchoscopy, avoiding the crush artifact from biopsy forceps and obtaining a sample from lower in the respiratory tract where the cells may remain ciliated. The brush is then placed whole into 3% glutaraldehyde (electron microscopy fixative) for fixation and examination by electron microscopy (Fig. 28.14). Diagnosis will be made if the expected 9 + 2 microtubule architecture is altered.

Sweat chloride testing should be obtained in a child with chronic rhinosinusitis, especially with polypoid disease and/or failure to thrive. With a carrier rate of up to 1 in 25 among people with northern European ancestry,[70] CF in its classic form and atypical CF from rare mutations will present to the otolaryngologists' clinic. CF arises from mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. While most children are now diagnosed early in life, some CF genetic mutations produce an atypical CF picture and therefore are not discovered early in life, especially if the mutation primarily causes sinus disease and less fulminant pulmonary and digestive disorders. Sweat chloride testing is considered normal if ≤ 39 mmol/L, intermediate if 40–59 mmol/L, and abnormal ≥ 60 mmol/L, regardless of age. When a borderline sweat chloride test is present, full genetic testing can be obtained for the numerous mutations now recognized in CF.[71] Individuals with sweat chloride values in the intermediate range (30–59 mmol/L for infants under age 6 months; 40–59 mmol/L for older individuals) should undergo extensive CFTR mutation analysis (i.e. expanded panel of CFTR mutations, evaluation for deletions, or gene sequencing). In the presence of 2 CF-causing mutations, a diagnosis of CF can be made. Individuals with no or 1 CF-causing mutation and clinical findings suggestive of CFTR dysfunction (i.e. male infertility, bronchiectasis, or chronic pancreatitis) may be diagnosed with a CFTR-related disorder, depending on their clinical picture or family history, and are at risk for CF. Borderline abnormal sweat chloride testing results should be repeated in infants by age 2–6 months and immediately in older individuals. If sweat chloride values remain in the intermediate range on repeat testing, then further assessment should be performed at a CF care center that can provide basic and ancillary testing to clarify the diagnosis. In atypical CF, the relationship between genotype and phenotype (i.e. sinus, pancreatic, and pulmonary disease) is weak, so close follow-up is important. In the operating room at the time of sinus surgery, identification of significant nasal polyps and the pathognomonic characteristic purulence in the sinus cavities or lower airways seen with CF (extremely mucoid and pasty green/yellow), should alert the surgeon to consider the diagnosis of atypical CF in an older child by sweat chloride and/or genetic mutation testing. Any cultures collected in a CF or suspected CF child should be sent to the microbiology laboratory for special CF bacterial cultures and sensitivities.

CHAPTER

# 29

# Pathophysiology of Pediatric Rhinosinusitis

***Scott C Manning***

## DEFINITIONS

Young children can suffer six to eight episodes of viral upper respiratory infection per year and up to 5% of these episodes are estimated to become superinfected with bacteria leading to acute rhinosinusitis or contributing to chronic rhinosinusitis (CRS) (*see* Table 29.1 for a list of abbreviations used in this chapter). Pediatric CRS is usually defined as symptoms persisting >12 weeks including some type of congestion and/or rhinorrhea and with endoscopic and/or radiographic evidence of sinus inflammation.[1] Unfortunately, that definition is vague and overlaps with common predisposing conditions such as recurrent viral infection and allergy. Also, chronic unremitting congestion in children implies some type of fixed upper airway anatomic obstruction such as adenoidal or inferior turbinate hypertrophy that may or may not be associated with sinus inflammation. Also, chronic headache, an increasingly common symptom in older children, may be attributed clinically to sinusitis, but more often is a sign of developing migraine or other primary headache diagnosis. From a practical standpoint, a better definition of pediatric CRS is probably recurring symptoms which may include congestion, rhinorrhea, cough and low energy with radiographic or endoscopic evidence of sinus inflammation occurring more than four times in 1 year and lasting more than the expected 10-day course of a viral illness alone.

In an attempt to better understand and treat CRS in adults, researchers are increasingly attempting to categorize patients into "phenotypes"—observed properties resulting from the interaction of genotype with environmental factors and "endo types"—discrete pathogenic pathways often characterized by distinct inflammatory cellular and chemical profiles.[2] The strongest subtyping in adults is between CRS with and without nasal polyps

**Table 29.1:** Abbreviations

| | |
|---|---|
| CRS | Chronic rhinosinusitis |
| CRSwNP | Chronic rhinosinusitis with nasal polyps |
| CRSsNP | Chronic rhinosinusitis without nasal polyps |
| Th 1 | T helper cell 1 |
| Th 2 | T helper cell 2 |
| Th0 | T helper naive |
| CF | Cystic fibrosis |
| CFTR | Cystic fibrosis transmembrane conductance regulator gene |
| AERD | Aspirin-exacerbated respiratory disease |
| AR | Allergic rhinitis |
| AFS | Allergic fungal sinusitis |
| RNA | Ribonucleic acid |
| IL | Interleukin |
| SVCs | Small colony variants |
| STAT3 | Signal transducer and activator of transcription 3 |
| NO | Nitric oxide |
| PCD | Primary ciliary dyskinesia |
| MUC5ac | gene encoding protein mucin 5ac. |
| MHC 1 | Major histocompatibility complex 1 |
| FOX P3 | Forkhead box P3 |
| TGF | Transforming growth factor |
| T-bet | T-box transcription factor |

(CRSwNPs and CRSsNPs), with the former demonstrating a pronounced Th2 skewing (at least in Western patients). Nasal polyps are relatively unusual in the pediatric population and should prompt an immediate evaluation for cystic fibrosis (CF). Interestingly, CF is a complex of diseases in which the causes are known deletions involving the CF transmembrane conductance regulator gene (CFTR). The endo type usually involves primarily an intense chronic Th1 inflammatory response but the CRS phenotypes are highly variable ranging from debilitating recurrent polyposis to few upper respiratory symptoms. The variability of sinonasal symptoms in CF patients illustrates the complex relationship between host and environmental factors with CRS.

Arguably the most relevant subtyping in pediatrics would be CRS with tissue eosinophilia (Th2) versus without (Th1). The former is more often associated with reactive airways disease or asthma and CRS is more clinically important when it triggers or aggravates underlying pulmonary disease. Subcategories in the Th2 category can include allergic rhinitis (AR), asthma-associated CRS, and aspirin-exacerbated respiratory disease (AERD). Examples of Th1 skewing could be CF, and physiologic (immune maturation) or primary immunodeficiency. Better characterization of CRS subtypes will presumably lead to more effective individual treatment regimens.

## THE HYGIENE HYPOTHESIS

The critical period of immune system development is infancy (and prenatal). Antigens interact with antigen processing cells including epithelial dendritic cells and macrophages that in turn release cytokines and other factors that influence Th0 cells (T helper naïve) to differentiate to Th1, Th2, or Th13. Also, pathogens are potent stimulants of the innate immune system's toll-like receptor system (TLR) that recognizes their highly conserved surface pathogen-associated molecular patterns (PAMPs). One basis of the hygiene hypothesis is the idea that TLRs need to be stimulated by certain PAMPs early in life in order to skew Th0 populations away from their in-utero Th2 bias toward Th1 in the adaptive immune system.

Epigenetics refers to the influence of environmental factors on gene expression usually via functional modifications such as DNA methylation and histone modification. These environmentally determined modifications may be permanent for the life of the individual and may even cross over into subsequent generations. Even dietary factors and the gut biome (folic acid, Vitamin B12) can influence epigenetic modifications. The hygiene hypothesis supports the notion that modern living is making the world's current and subsequent generations more "allergic" (Th2 skewed).

While CRS is hard to define, many researchers feel that the incidence is increasing at least in the developed world. The hygiene hypothesis suggests that the pattern of early childhood pathogen exposure could skew the individual to a more inflammatory response and a higher incidence of allergy-type diseases. DP Strachan in Great Britain in 1989 noted that AR and eczema were inversely related to the number of older siblings in the household.[3] He hypothesized that lack of early exposure to certain pathogens could skew the child's immune responses toward Th2 during the early critical period of immunologic maturation. Other researchers have demonstrated increased incidence of AR with smaller family size, especially in boys, and a decreased incidence of asthma associated with a greater number of younger siblings. Additional studies have demonstrated a decreased incidence of AR in children growing up on farms, possibly due to the role of lipopolysaccharides from gram-negative bacteria exposure on immune system development. Also in Great Britain, studies have shown that early exposure to antibiotics, especially cephalosporins and macrolides, can increase the odds of developing asthma, possibly due in parts to alterations in the gut biome and resultant immunoregulatory effects.

The strongest link between an individual pathogen and subsequent Th2 skewing comes from studies demonstrating significantly less allergy in hepatitis A seropositive patients. *Helicobacter pylori* gut colonization has also been linked to decreased incidence of asthma although studies are mixed. Other aspects of a "western" lifestyle with a possible link to Th2 skewing include early introduction of food antigens, high fat diets and vitamin D deficiency (vitamin D inhibits T cell proliferation and induces T regulatory cell hyporesponsiveness).[4]

"Atopic march" refers to the common clinical observation of onset of dermatitis before age 2, then reactive airways disease/asthma shortly thereafter, then AR diagnosed by the early 20s (and increasingly, gastrointestinal inflammation such as gastroesophageal reflux or eosinophilic esophagitis). These patients are increasingly viewed as the result of environmental factors early in life in a genetically predisposed individual causing permanent epigenetic upregulation of the Th2 arm of adaptive immunity.[5]

## UNIFIED AIRWAYS

Asthma has long been associated with CRS both in pediatric patients with and without AR (although allergy testing may be insensitive in young children) and those patients should be considered to be potentially inflamed along the entire respiratory tract.[6] Children with documented AR are likely to demonstrate increased bronchial responsiveness to antigen or irritant stimulation. In one recent prospective pediatric study, chronic and recurrent rhinosinusitis was more prevalent in older children and more likely to be associated with AR, atopy, and asthma versus children with acute rhinosinusitis.[7] Both asthma and bronchiectasis have been found to be associated with higher Lund-Mackay computed tomography sinus scores in adult patients with CRS.[8] And in a recent retrospective study of over 4000 children with a diagnosis of CRS followed in a tertiary center allergy practice, 18% had a diagnosis of asthma.[9]

## ALLERGY

While allergy in detail is the subject of another chapter, the topic has obvious relevance to any discussion of CRS. For one thing, the standard definitions of CRS as symptoms including congestion and rhinorrhea lasting at least 6 months could be entirely caused by AR. In fact, many patients presenting with a diagnosis of CRS have clear sinuses on imaging and not surprisingly derive no benefit from systemic antimicrobial therapy. Studies are mixed regarding causative links between AR and CRS, but there is definitely an association especially in pediatric patients with asthma. One study found that 27% of pediatric patients average age 8 with CRS had AR with skin testing.[9] In another pediatric study, pediatric CRS as opposed to acute rhinosinusitis associated with more AR and adenoidal hypertrophy.[10] And prospective randomized studies of children with CRS have found significant benefits with corticosteroid therapy versus antibiotics alone, but corticosteroids have a generalized immunoregulatory effect on atopic and nonatopic inflammation alike.[11]

From a pathophysiology standpoint, AR could contribute to defects in epithelial barrier defense allowing for more antigen presentation and potentially for easier development of microbial biofilm. AR also has systemic immunoregulatory effects. In adult studies, sensitivity to aeroallergens in general, dust mite allergy in particular and elevated total IgE are all independently associated with CRS, particularly in patients with nasal polyps.[12]

### Localized Allergy

The true prevalence of AR in children with CRS may be significantly underestimated in the current literature due to the relative lack of sensitivity of standard testing in younger patients. Recently the concept of localized mucosal allergy has been introduced, defined as evidence of IgE mediated inflammatory response secondary to nasal antigen challenge.[13] The gold standard in defining this entity is mucosal biopsy after antigen challenge, but pre- and post-challenge rhinometry may be a suitable surrogate for routine clinical studies. Using that technique, a significant percentage of asthmatic CRS patients with negative skin testing are "allergic" defined as reacting to nasal challenge.[14]

### Allergic Fungal Sinusitis

Allergic fungal sinusitis (AFS) is worth mentioning as an extreme example of tissue Th2 response with heavy eosinophilic recruitment to surface epithelium, mucosal sloughing (loss of barrier defense), and buildup of central sinus concretions of eosinophils, Charcot-Leyden crystals (major basic protein) and scattered branching fungal forms all similar to asthmatic plugs (Fig. 29.1). The etiology of the classic form is believed to involve allergic reaction to antigenic fungi usually in the class of dematiaceous (Bipolaris, Alternaria, Exserohilum) or *Aspergillus* species.

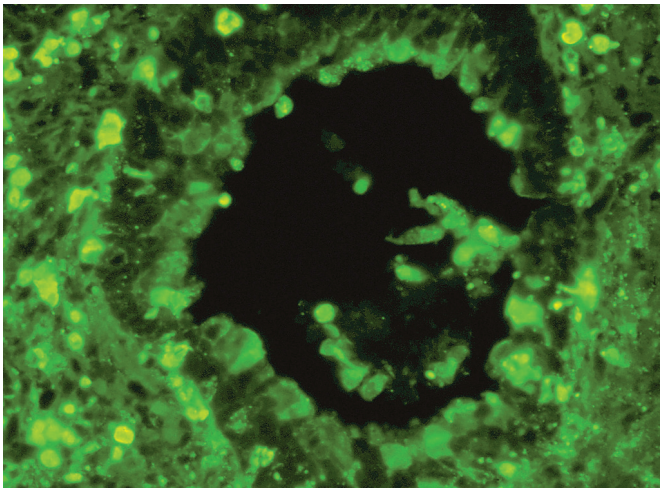

**Fig. 29.1:** Immunohistochemical stain for major basic protein in a mucosal sample from a 12-year-old patient with allergic fungal sinusitis (bipolaris culture). Eosinophils are seen recruited to the mucosal and even sloughing into the mucosal lumen. This illustrates the barrier hypothesis with loss of epithelial integrity potentially leading to a self-perpetuating cycle of further antigen contact, Th2 skewing and upregulated inflammation. (Original photo).

That form of AFS is most commonly located along the 30th parallel of latitude where those types of fungal spores are more commonly present in inspired air. Some authors believe that a phenotypically milder form may be common in all latitudes but prospective studies have not found benefit for treatment for CRS symptoms with systemic or topically antifungal medication.

## Biome

Most CRS researchers no longer believe that microbial infection is the primary cause of CRS and treatment studies generally show no benefit for systemic antibiotics. However, evidence is mounting that patterns of host microbial colonization do indeed have significant effects on host local and systemic immune defense and hyperinflammatory states. Recent advances such as microchip sequencing of 16S ribosomal RNA has led to the realization that all body surfaces are colonized with bacteria that exist in a state of equilibrium via mutual interference secondary to competition for nutrients, blockage of adherence sites, release of antagonistic substances, and many more mechanisms.

As mentioned above, changes in the gut biome (easily modified by antibiotic use and diet) can contribute to Th2 skewing and an increased systemic inflammatory state. Thus, indiscriminate use of antibiotics in early childhood and the practice of routinely using antibiotics in animal feeds may contribute to the perceived increase in CRS in developed societies.

The nasal biome in healthy children usually consists of *Staphylococcus aureus*, *Staphylococcus epidermidis*, alpha and nonalpha hemolytic streptococci, aerobic diphtheroids and anaerobes. Potential pathogens not usually found in healthy individuals include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Some studies in children have shown more diversity and more bacterial interference in healthy controls, and less diversity and more colonization with bacterial pathogens in sinusitis patients.[15] In another recent pediatric study, adenoid tissue was found to have its own biome including the usual pathogens associated with otitis media (the "pathogen reservoir hypothesis") with evidence of ecologic equilibrium via bacterial interference.[16]

In recent studies of the adult sinus biome, healthy patients showed increased Actinobacteria (*Propionibacterium* species and *Corynebacterium* species) and less staphylococcal species, while CRS patients showed more *S. aureus* and less *S. epidermidis*.[17] While studies of the sinonasal biome are new and results vary probably in part due to differing molecular biological techniques, some interesting conclusions have come to the surface. Healthy sinuses are not sterile, systemic antibiotics (and potentially vaccines) alter the natural ecology and potentially reduce bacterial interference allowing for growth of pathogens and *S. epidermidis* appears to be a competitive antagonist to *S. aureus*. Interestingly, *S. pneumoniae* is felt to be a significant competitive inhibitor of *S. aureus* and the use of polyvalent streptococcal vaccines may have contributed to a possible rise in carrier state frequency of pathogenic staphylococcal species (another hygiene hypothesis example).

Unfortunately, the sinonasal biome story is not as simple as good commensals versus bad pathogens. One recent adult study showed fairly similar bacterial profiles in CRS patients and controls but CRS patients demonstrated increased IL-4, IL-5, IL-8, IL-13, tissue eosinophils and basophils and increased peripheral leukocyte antigen response. Thus CRS patients appear to have a hyperinflammatory response to normal commensals as well as to pathogens. The authors conclude that the microbiome can be thought of as a spectrum referred to as "mutualism" of commensals with beneficial host-bacterial interactions (symbionts) interacting with pathogens with the potential for harming the host. The underlying host level of immune response helps keep the balance but too strong a response (Th2 skewing for example) can lead to inappropriate inflammation and host damage (barrier defense).[18]

## Biofilms

Bacteria in nature usually exist as structured colonies in polymeric matrices fixed to the underlying surface. Epithelial damage and reduced innate immunity presumably can promote biofilm formation and studies have shown a 30–70% incidence of microbial sinus biofilm in patients with CRS. Bacteria in biofilm colonies can evade cellular and complement-mediated cytotoxicity and they have a reduced rate of metabolic activity conferring relative resistance to antibiotics. Biofilm presumably can result in states of constant reinfection as hibernating bacteria re-emerge in a planktonic form and shed. Also, biofilms contribute to the cycle of chronic inflammation partly via the phenomenon of "frustrated phagocytosis" where neutrophils degranulate outside the biofilm structure leading to further surrounding epithelial damage.[12] Microbes that have been demonstrated to cause biofilm in CRS patients include *S. aureus*, *Pseudomonas aeruginosa*,

*H. influenzae* and Alternaria. Biofilm no doubt explains some of the failure of antibiotic therapy for CRS and also the chronicity of the condition.

## MICROCOLONY STAPHYLOCOCCUS/ INTRACELLULAR—INTRAMUCOSAL INFECTION

Bacteria, like all organisms, respond to environmental pressure and one response to antimicrobial therapy pressure can be to undergo transition to a more facultative state with subsequent intramucosal or even intracellular transition (seeking oxidative metabolism). These are presumably the in vivo equivalents of the small colony variants (SCVs) culture from patients undergoing intense antibiotic pressure including those with CF, osteomyelitis, or surgical implant infection. Staphylococcal organisms are the most commonly implicated and studies in adult CRS patients have shown evidence for intramucosal staphylococcal species derived from surface bacteria.[19] Intramucosal *Staphylococcus* has been associated with surface biofilm and may be one more mechanism explaining chronicity and resistance to therapy with CRS[20] (Fig. 29.2).

### Superantigens and *Staphylococcus*

Superantigens are proteins that bypass normal antigen processing and bind directly to the beta-chain of T-cell receptors leading to nonspecific activation of large numbers of T-cells with an immediate release of inflammatory cytokines. The superantigen role for CRS was first proposed for the antigenic fungi (dematiaceous) in AFS, but many bacteria, especially *S. aureus*, are capable of acting as superantigens. The dermatologists implicated staphylococcal species superantigens in the pathogenesis of eczema long ago and otolaryngologists have adapted the strategy of topical antistaphylococcal therapy (mupirocin) for the treatment of CRS.

IgE antibodies to staphylococcal enterotoxins have been identified in up to 28% of nasal polyp adult patients overall and up to 54% of CRS patients with polyps and asthma. Presumably a vicious cycle of more cytokine release, more epithelial barrier degradation, more antigen contact, and more Th2 skewing plays an important role in many patients with CRS. Staphylococcal species colonize up to 30% of patients with noneosinophilic rhinosinusitis, 70% of patients with nasal polyps, and 90% of patients with AERD. The presence of staphylococcal organisms predicts worse outcomes for patients with CRS.[12,21]

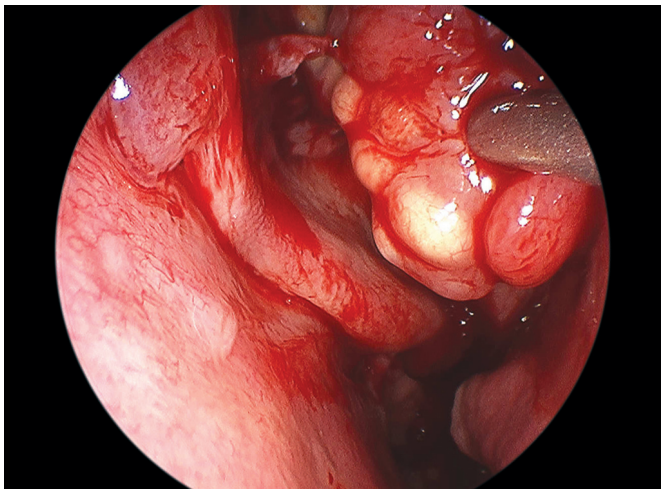

**Fig. 29.2:** A 16-year-old male with pronounced but focal unilateral ethmoid polyposis. After initially poly debridement, intramucosal abscesses became apparent within the left ethmoid. Culture of an abscess open after excision yielded a sensitive *Staphylococcus aureus*.

## BARRIER DEFENSE

The immune barrier hypothesis maintains that epithelial compromise from whatever cause leads to a cycle of microbiological colonization, further epithelial degradation and a self-amplifying cycle of dysfunction immunological response. Epithelial defects can lead to dysfunction of the membrane bound pattern recognition receptors including the toll-like receptors that in turn can cause problems with production of the S100 antimicrobial proteins including STAT3 (signal transducer and activator of transcription 3) a transcription mediator for the IL-6 family of cytokines important in host defense. Establishment of staphylococcal colonization, biofilm, and intramucosal infection can lead to further immune dysfunction as previously mentioned.[22] Eosinophilic inflammation in particular with release of major basic and eosinophilic cationic protein can promote epithelial sloughing. Indoor and outdoor air pollution, cigarette smoke exposure and chemical exposure can also contribute to break down of epithelial integrity.

## PRIMARY IMMUNODEFICIENCY

CRS is probably the most common symptom of primary immunodeficiency in any age group. Immunodeficiency should be suspected when confronted with unusual organisms, context, persistence, or recurrence of disease.

When in doubt, a full immunologic evaluation is appropriate, ideally with the help of an immunologist. For B-cell problems, advances in administration of gamma globulin are broadening the scope of effective therapeutic options especially for CRS.

All children experience a "physiologic" immunodeficiency of childhood in that the immune system develops and does not reach adult levels of function until around age 12. Especially under the age of 7, children are prone to contract viral upper respiratory illness, as much as six to eight times per year, a primary trigger or aggravator of acute or CRS. And children with clinical Th2 skewing such as asthmatics appear often to be slower to develop normal immunoresponse to bacterial pathogens (vaccine nonresponder state). This fact may explain the clinical observation that some asthmatic children seem to rapidly develop purulent rhinorrhea, cough, and asthma exacerbation at the first hint of a viral upper respiratory infection. Fortunately, the majority of even asthmatic children experience normal, though possibly delayed, immune maturation. The current terminology for vaccine underresponse is "specific antibody deficiency to unconjugated pneumococcal vaccine or SAD" and it is usually transient when diagnosed in childhood.[23]

Specific antibody production deficiency cannot reliably be diagnosed under age 2 and the most common age for diagnosing common variable immunodeficiency is age 25. But most of those patients with have a history of unusually persistent and severe respiratory tract infection as children so presumably the condition is underdiagnosed in the pediatric age group. Interestingly, common variable immunodeficiency is often associated with an increased likelihood of allergic disease.

IgA deficiency is common in young childhood but usually transient. X-linked Bruton's agammaglobulinemia presents as refractory bacterial respiratory infections in infancy and young childhood. T-cell problems including severe combined immunodeficiency can present as *Pneumocystis carinii* infection. Neisseria infection should prompt consideration for complement deficiency. Chronic granulomatous infection can present as chronic lung disease, invasive fungal infection, and/or colitis and can be diagnosed via the oxidative burst test.

Although beyond the scope of this chapter, acquired immunodeficiency can contribute to CRS. In a pediatric tertiary care center, children immunosuppressed for transplant or for treatment of lymphoreticular malignancies are at risk for bacterial CRS with the usual organisms or for invasive fungal CRS (Fig. 29.3).

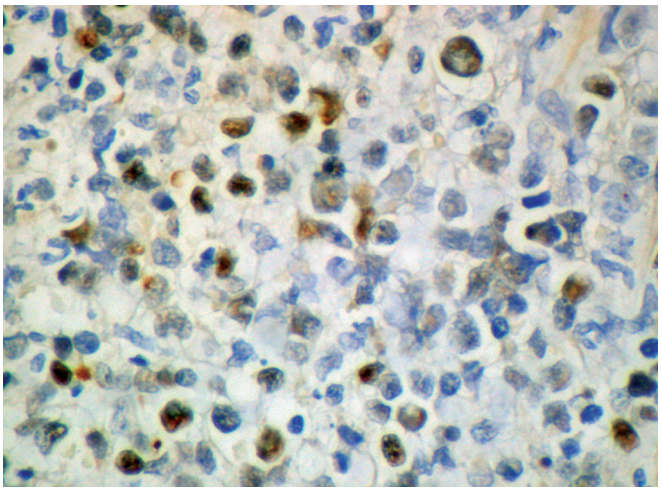

**Fig. 29.3:** A 8-year-old boy on chronic chemotherapy for hemophagocytic lymphohistiocytosis with debilitating sinopulmonary infections refractory to medical therapy. A sinus mucosal sample shows strong intracellular staining for EBER (Epstein–Barr virus RNA transcript). Presumably, viral illness in an immunocompromised host can significantly compromise epithelial immune defense.

## NITRIC OXIDE AND PRIMARY CILIARY DYSKINESIA

Nitric oxide (NO) is involved in many aspects of inflammation and contributes to immune defense, ciliary function, and overall airway ventilation-perfusion matching. A principal source of NO for the upper airways is the sinus epithelium and reduced levels of NO have been recorded in patients with rhinosinusitis, polyposis, CF, and asthma.[24] Reduced levels of NO are often associated in general with eosinophilic inflammation.

Primary ciliary dyskinesia (PCD) is associated with particularly low levels of NO and in fact, very low NO levels combined with chronic lung disease, chronic middle ear effusion, and sinusitis appears to be very specific for PCD, useful when situs inversus (Kartagener's syndrome) is not present (Alsaadi MM, Habib SS). Also, many children with an ultimate diagnosis of PCD have a history of neonatal respiratory distress, sometimes requiring intubation at or shortly after birth. Definitive diagnosis is made via ciliary biopsy with electron microscopy of ciliary ultrastructure. Most disease associated mutations involve the dynein axonemal heavy chain 5 or intermediate chain 1 and clinical molecular testing is becoming more available.[25] PCD is an example of a severe innate barrier immune defense problem that can possibly alter adaptive immunity by increasing antigen presentation early in life.

## Histology

The effects of chronic inflammation over time in CRS lead in general to histologic changes including goblet cell and mucous glandular hypertrophy, chronic inflammatory cell infiltrates, epithelial sloughing and bony osteitis. Studies comparing routine CRS surgical specimens in children versus adults tend to show a high density of submucosal lymphocytes but less percentage of eosinophils, and less basement membrane and submucosal gland hypertrophy.[26] A recent study of pediatric patients with polyps (including allergic fungal sinusitis) versus controls showed an increased mucosal dendritic cell infiltrate in the polyp patients which was associated with vitamin D3 deficiency (T regulatory cell effects).[27] The differences between pediatric and adult CRS histology may reflect differing inflammatory mechanisms or may represent the results of similar inflammatory pathways over greater periods of time. CF patients are characterized by very prominent mucosal goblet cell and submucosal gland hyperplasia with increased glandular MUC5AC (mucin—5a) expression.[28]

## GENES AND GENE EXPRESSION

The classic genetic link to pediatric CRS would have to be the CFTR deletions causing CF. But the literature is expanding rapidly with new information about links between CRS patients and genes involved in pathways of inflammation and immune regulation. The technology for doing genome wide studies is advancing rapidly while the cost, especially using pooled samples from case and control populations, is dropping. Adult CRS pooled sample studies have shown a genetic basis for low circulation CD8 lymphocytes leading to speculation about a possible syndrome-like condition involving major histocompatibility complex 1 (MHC1) deficiency.[29] Other genetic studies of adult CRSwNP patients have shown less FOX P3 (Forkhead Box P3) mRNA and TGF-beta 1 protein (a suppressive cytokine) but higher expression of T-bet (T-Box transcription factor) and IL-5, and IL-13 mRNA compared with controls.[30] Studies of adults with noneosinophilic CRS have found other gene expression patterns with upregulation of innate inflammatory genes for IL-6 and IL-8.[31]

## COMORBID STATES

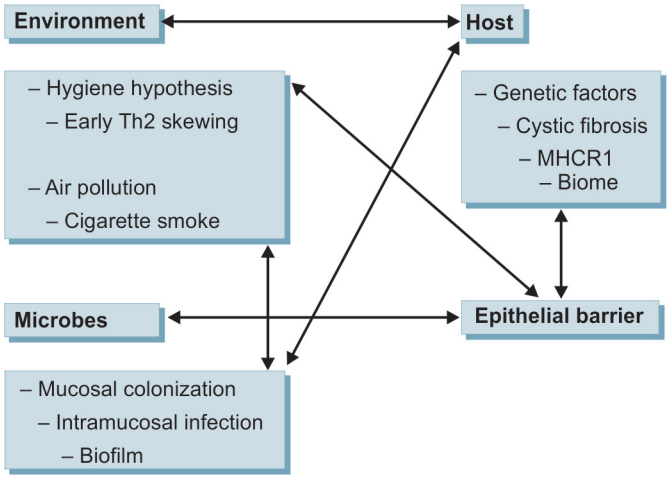
Pediatric CRS is commonly associated with many other conditions, but to date, few causal links have been determined in the associations. The most common comorbidities for younger CRS patients are viral illness, eczema, reactive airways disease, adenoiditis, otitis, and gastroesophageal reflux. For older CRS children, common comorbidities include allergic rhinitis, asthma, eosinophilic esophagitis, and migraine headache. Adenoiditis presumably has some causality based upon studies showing outcome improvement with adenoidectomy and some recent studies suggest a causal link between AR and CRS in adults. In one retrospective pediatric study, gastroesophageal reflux was associated with CRS, asthma, laryngitis, and bronchiectasis, but overall, outcome studies on reflux treatment and CRS have not shown consistent benefit to date (Nation J). A common denominator for many of the above comorbid states is Th2 skewing with tissue eosinophilia (CRS, asthma, eczema, esophagitis, AR).

## CONCLUSION

Long gone are the days when CRS was assumed to be the result of specific microbial infection. Microbes appear to play an important role but mainly by inciting chronic inflammation via colonization of an individual with an inflammatory diathesis as a result of complex genome-environmental interaction potentially starting in utero. CRS is a complicated mixture of conditions with differing symptom expression (phenotype) and mucosal and systemic inflammatory-immune system dysregulation (endo type). The effects of modern living seem to be creating an increasing number of Th2 skewed individuals more prone to be over-reactive to pathogens and allergens (hygiene hypothesis). Staphylococcal bacteria established as mucosal colonies, biofilm, and/or intramucosal infection can incite a more rapid, severe and persistent inflammatory response (super antigen theory) especially when epithelial barrier defenses are compromised. Chronic inflammatory response to established microbial colonization leads to a cycle of further epithelia damage and further microbial establishment (Flowchart 29.1 and Fig. 29.4).

From a therapy standpoint, better understanding of the pathogenesis of CRS has already led to abandonment of the strategy of prolonged systemic antibiotic use (potentially contributing to CRS via negative gut and mucosal biome effects). Topical antibiotics against *S. aureus* (mupirocin) and Th2 modulating therapies (topical steroids, leukotriene antagonists) have become mainstays of CRS treatment as our understanding of the pathogenesis has improved. New treatment horizons include biofilm

**Flowchart 29.1:** Pathophysiology of pediatric CRS (multiple interacting pathways)



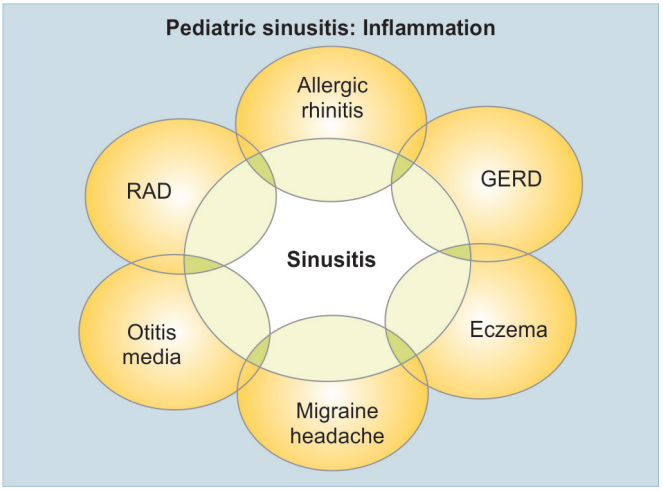


**Fig. 29.4:** Comorbid states of inflammation with pediatric chronic rhinosinusitis. Some associations may be in part causal such as adenoiditis but for others, such as reflux, evidence for causation is lacking.

disruptors, bacterial interference therapy, and more specific (nonsteroidal) blockers of inflammatory pathways. The new era of genetic research is rapidly expanding our understanding of this fascinating condition.

# Pediatric Rhinosinusitis: Diagnosis and Management

*Marianella Paz-Silva, Fuad M Baroody*

## INTRODUCTION

Rhinosinusitis, a complex inflammatory process of the paranasal sinuses, is generally considered a multifactorial problem which, in children, can be precipitated/exacerbated by viral, bacterial or fungal infections, as well as immunodeficiency, cystic fibrosis, allergen exposure, anatomical defects, or mucociliary dysfunction. It is considered a significant health problem around the world.[1,2]

## CLASSIFICATION

Classification of the disease is usually based upon symptoms and their duration and includes both acute and chronic rhinosinusitis (CRS).

### Acute Rhinosinusitis

In children, acute bacterial rhinosinusitis (ABRS) often follows a viral upper respiratory tract infection. The upper airway symptoms generated by these two entities are very similar and include nasal congestion, nasal discharge, and cough. In uncomplicated upper respiratory infections (URIs), fever and other constitutional symptoms (headaches, myalgia) disappear within the first 24–48 h and the nasal symptoms linger for as long as 7–10 days before resolving. It is, therefore, the persistence of these symptoms without improvement beyond 7–10 days that suggests a diagnosis of ABRS.[3] Another clinical presentation in the context of a viral URI that might suggest ABRS is what is often referred to as "double sickening". In this presentation, children experience substantial and acute worsening of respiratory symptoms (nasal discharge, nasal congestion, cough) or a new fever often on the sixth or seventh day of illness, after initial signs of recovery from a URI. Finally, a third clinical scenario that denotes severe ABRS is characterized by the onset of high fever and purulent nasal drainage for the first 3–4 days of a URI. Thus, the duration of symptoms that denote ABRS are usually of < 12 weeks in duration.[1]

### Chronic Rhinosinusitis

In children, CRS is also characterized by the presence of two or more symptoms, one of which should be either nasal blockage/obstruction/congestion or nasal discharge (anterior or posterior), with or without cough and/or facial pain or pressure as well as objective signs of disease documented by either nasal endoscopy or computed tomography (CT) scan. The duration of these symptoms is for at least 12 weeks.[1,2]

## PREVALENCE

The exact prevalence of rhinosinusitis in children is difficult to determine and the clinical diagnosis remains very challenging, given the condition's frequent symptomatic overlap with common colds and upper respiratory tract infections that are otherwise widespread among children. Most of the common symptoms consistent with the diagnosis of rhinosinusitis, including cough and purulent rhinorrhea, may affect as much as 40% of the pediatric population at some point during childhood.[1,4]

In a longitudinal study of 112 children aged 6–35 months, 623 URIs were observed over a 3-year period, and episodes of acute rhinosinusitis as defined above were documented by the investigators.[5] Eight percent of the URIs were

complicated by rhinosinusitis, with 29% of the episodes diagnosed because of an increase in the severity of symptoms before 10 days of illness and the remaining diagnosed on the basis of persistent symptoms beyond 10 days. The occurrence of rhinosinusitis in the context of URIs was 7% in the 6–11 month age group and in children over 24 months, and 10% in children who were 12–23 months old. On average, a child younger than 5 years of age has 2–7 episodes of URI per year,[6,7] and a child attending day care may have up to 14 episodes per year.[8] With the incidence rates reported above, the number of acute rhinosinusitis episodes in children every year is sizeable.

To date, several studies have investigated the prevalence of CRS in groups of children with chronic upper respiratory complaints. In 1989, Van der Veken et al. obtained CT scan images of 196 children between 3 and 14 years old, presenting with chronic rhinorrhea, nasal congestion, and cough.[9] They found that within the youngest age cohort there was a predominant maxillary involvement (63%), followed by ethmoid disease (58%) and sphenoid changes (29%). In contrast, in the older age group (13 to 14 years old), the ethmoids were involved in only 10% of the subjects, the sphenoids in none, and the maxillary sinuses in 65% of the study patients.

Another study done by Nguyen et al. in 1993 included 91 new patients between 2 and 18 years of age, presenting with symptoms following at least 3 months of upper respiratory tract infection.[10] CT scans were recorded and reviewed to determine specific sinus abnormalities. The data showed that 36% had no sinus disease, while 63% of the group had chronic sinusitis with clinical signs and positive CT findings. The study likewise found that when symptoms of rhinorrhea, cough, and the absence of sneezing were all present, there was a greater association with CT scan abnormalities. Interestingly, age was the single most important risk factor associated with CRS; CT abnormalities were observed less frequently among the group of 10+ years of age, with only 38% of this group of children having CT abnormalities. Meanwhile, in the group between 2–6 years and 6–10 years, 73% and 74% had CT abnormalities, respectively. When evaluating a series of CT scans in children, the most commonly occurring sinus disease location was the maxillary sinus (99%) followed by the ethmoids (91%).[11]

## QUALITY OF LIFE

Cunningham et al. used parental and childhood generic quality of life questionnaires and administered them in children with recurrent or chronic sinusitis about to undergo sinus surgery.[12] They found that these children had lower quality of life, both by child filled and parental questionnaire compared to a normative, nondiseased population and had even lower quality of life when compared to children with other chronic diseases such as asthma, attention deficit hyperactivity disorder, juvenile rheumatoid arthritis, among others. More recently, the SN-5, a 5 domains survey, has been validated as a measure of sinonasal symptom change over time.[13] The survey addresses sinus infection, nasal obstruction, allergy symptoms, use of medication, emotional distress, and activity limitations; and is filled out by parents to reflect the child's symptomatic distress over the previous 4 weeks. In a prospective study of 32 patients with CRS aged between 2 and 12 years, Terrell et al. showed a correlation between SN-5 scores and disease severity as measured by Lund MacKay CT scan scores.[14] These results suggest that the survey can be used for clinical follow-up, in place of repeated CT scans. Likewise, there is some limited data that show improvements in quality of life as measured by the SN-5 questionnaire for patients with CRS after undergoing procedures such as adenoidectomy or endoscopic sinus surgery.[15]

## DIAGNOSTIC WORKUP AND EVALUATION OF COMORBID CONDITIONS

### History

A careful and detailed history is essential. The lack of ability among young children to adequately communicate their symptoms warrants a reliance on information provided by the parents. The most common clinical symptoms consistent with the diagnosis of rhinosinusitis—as suggested by several studies—are, rhinorrhea, nasal congestion, cough, and postnasal drip.[1,4,16] Sniffling and halitosis have also been reported.[4,11] Children with acute sinusitis might present with additional problems such as fever, purulent rhinorrhea or prolonged upper respiratory infection.[4] On the other hand, in some cases, symptoms of CRS can prove more subtle including malaise, difficulty concentrating, headaches, anorexia, and general fatigue.[2,17]

As mentioned previously, part of the diagnostic challenge might involve differentiating this condition from other symptomatically similar conditions such as allergic rhinitis and upper respiratory tract infections. Thus, the timing ofthe symptoms in relation to the onset of an URI is essential as that is critical for the diagnosis of ABRS.

## Physical Examination

General physical examination should include a complete ear, nose and throat evaluation, including anterior rhinoscopy with or without application of a topical decongestant so as to decrease edema and improve visualization. This can usually be done using the otoscope with the largest speculum. If possible, and tolerated, nasal endoscopy should be performed to evaluate structures such as the adenoids and nasopharynx and to check for signs of mucosal inflammation, polyps, and drainage in the ostiomeatal units. An oral cavity examination may reveal purulent drainage, cobblestoning of the posterior pharyngeal wall, or tonsillar hypertrophy. The finding of nasal polyps in children is unusual and, if seen on exam, should raise the suspicion for cystic fibrosis or allergic fungal sinusitis.

In patients unresponsive to conventional medical therapy, obtaining cultures may be useful in directing further treatment. In adults, cultures obtained from the middle meatus seem to correlate relatively well with cultures obtained from punctures or aspirates of the maxillary sinuses. In children, however, data regarding the usefulness of this approach is limited. In 2010, Hsin et al. obtained 29 paired endoscopically directed middle meatal cultures and 30 paired samples obtained via endoscopically directed middle meatal suction aspiration, and compared them with cultures of maxillary sinus taps obtained under general anesthesia from children (1–17 years) suffering from rhinosinusitis unresponsive to medical treatment.[18] These showed that endoscopic sampling by swab provided a sensitivity of 52%, a specificity of 100%, and a correlation of 66% compared to maxillary sinus taps. Meanwhile, the group where samples had been obtained by suction aspiration provided a sensitivity of 86% and a specificity of 100% and a correlation of 87%, leading the authors to conclude that the aspiration technique might further improve the reliability of endoscopic cultures in children.

Despite this data, most otolaryngologists prefer to reserve this technique for older children more likely to tolerate rigid endoscopy in the office setting. Once general anesthesia has been applied there is no further reason not to rely on the gold standard: obtaining a culture from the maxillary sinus itself via antral puncture.

# COMORBIDITIES

## Allergic Rhinitis

Allergic rhinitis is a common coexistent complaint in patients with rhinosinusitis. The extent of correlation between allergic rhinitis and rhinosinusitis is variable depending on the studies one looks at in the literature. It is certainly useful to evaluate for family history of atopy as well as symptoms of allergic rhinitis and the occurrence of the symptoms during known allergy seasons in one's practice area. If the history is suggestive of the diagnosis, skin or serologic testing might be useful and appropriate therapy recommended.

## Asthma

Asthma is often present in patients with rhinosinusitis and exacerbations of sinus disease are commonly associated with worsening of asthma. Unfortunately, this correlation is not well described in the literature as most studies lack appropriate controls and randomization.[19,20]

## Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) has also been associated with CRS in several studies.[21-23] In some of these studies, the number of cases with a concomitant diagnosis of sinusitis was significantly higher in the children with GERD (4.19%) compared to the control group (1.35%).[22] In other studies, GERD was documented in a significant proportion of children with CRS and treatment resulted in improvement of CRS and avoidance of surgery.[21,23] Although some evidence supports an association between GERD and CRS, more controlled studies are required to strengthen this association and validate it, and routine antireflux treatment of children with CRS is not warranted.

## Immune Deficiency

Recurrent acute episodes or CRS should raise concerns and can require further investigation as to the potential underlying causes including common variable immunodeficiency (CVID), IgG subclass deficiency, and selective antibody IgA deficiency. Several studies have shown sinus disease in children to be a common manifestation of other underlying immune deficiencies.[4] In 2008, Urschel et al. studied 32 children (between 1 and 17 years of age) presenting with CVID. Their results showed that 78% of participants presented with sinus disease before the CVID was made.[24] Similarly, in a study done with patients referred by primary care doctors and pediatricians due to recurrent rhinosinusitis, Shapiro et al. showed that 56% of them also possessed concomitant immune deficiency, with depressed IgG3 levels and poor response to pneumococcal antigen 7 being most common.[25] It seems prudent

to evaluate immune function in the child with chronic/recurrent rhinosinusitis with an immunoglobulin quantitation and titers to tetanus and diphtheria as well as pneumococcal titers. If responses are abnormal, a repeat set of titers post pneumococcal vaccination is appropriate.

## Cystic Fibrosis

Cystic fibrosis is a genetic disease with autosomal recessive inheritance that affects approximately 1 in 3500 newborns. It is caused by a mutation in the CFTR gene on chromosome 7 that leads to disruption in cAMP-mediated chloride secretion in epithelial cells and exocrine glands. This leads to increased viscosity of secretions resulting in bronchiectasis, pancreatic insufficiency, CRS, and nasal polyposis. The prevalence of chronic sinusitis is very high and nasal polyps occur in between 7% and 50% of affected patients.[26,27] In fact, this is one of the few causes of nasal polyposis in children.

## Ciliary Dyskinesia

The normal movement of mucus by mucociliary transport toward the natural ostia of the sinuses and eventually to the nasopharynx can be disrupted by any ciliary dysfunction or mucosal inflammation. The most common cause of ciliary dysfunction is primary ciliary dyskinesia (PCD), an autosomal recessive disorder involving dysfunction of cilia and present in 1 of 15,000 of the population.[28] Half the children with PCD also have situs inversus, bronchiectasis, and CRS and are known as Kartagener's syndrome. The diagnosis should be suspected in a child with atypical asthma, bronchiectasis, chronic wet cough and mucus production, rhinosinusitis, chronic and severe otitis media (especially with chronic drainage in children with ear tubes). Screening tests for PCD include nasal nitric oxide (lower levels than controls) and in vivo tests such as the saccharin test that documents slower mucociliary transit time. Specific diagnosis requires examination of cilia by light and electron microscopy that is usually available in specialized centers. The most commonly described structural abnormality involves lack of outer dynein arms, or a combined lack of both inner and outer dynein arms.[29] Because chronic nasal inflammation could interfere with the integrity of the cilia, a biopsy from a distant, uninflamed, site such as the carina is preferred to a biopsy of the nasal mucosa or the adenoids.

## Allergic Fungal Rhinosinusitis

Fungi have been implicated in some children with CRS. Allergic fungal rhinosinusitis (AFRS) is thought to be an allergic inflammatory reaction to environmental fungi in immunocompetent patients. This causes a significantly severe form of rhinosinusitis with significant opacification of one or more paranasal sinuses and pressure on surrounding organs leading to findings such as proptosis. The radiologic picture is quite unique[30] and the pathology of the inflamed tissue is characterized by a strong eosinophilic infiltrate of the sinus mucosa. In fact, this is one of the few causes of nasal polyposis in the pediatric age group. The fungi responsible for AFRS are uniform in adult and pediatric populations and include *Bipolaris* species followed by *Curvularia*.[31,32] The exact incidence of AFRS in the pediatric population is not well known, but it tends to occur in older children. The treatment of choice for this entity is endoscopic sinus surgery with debridement of the fungal load and all inflammatory disease followed by anti-inflammatory therapy with intranasal and sometimes systemic steroids.

A multidisciplinary team consisting of allergy, immunology, infectious disease, pulmonary and genetic specialists should be available in order to best evaluate some pediatric patients with medically refractory sinus disease.

# IMAGING

Computed tomography scans have become the standard of choice for supporting the diagnosis of rhinosinusitis. The diagnosis of ABRS is primarily a clinical diagnosis based on symptoms and signs and their duration and imaging is reserved in case complications are suspected such as orbital or central nervous system involvement.[3] In these cases, contrast is used to facilitate visualization of rim enhancement of abscess walls. In uncomplicated CRS, scanning is reserved to evaluate for residual disease and anatomic abnormalities after maximal medical therapy. Abnormalities in the CT scan are assessed in the context of their severity and correlation with the clinical picture and guide the plan for further management that might include surgical intervention. In children with the clinical diagnosis of rhinosinusitis, the most commonly involved sinus is the maxillary sinus (99%) followed by the ethmoid sinus (91%).[11] CT use and applicability has increased as new scanners have become faster and their images have

achieved greater resolution without requiring the use of contrast. These advantages have facilitated the acquisition of these scans in most children without sedation that is still occasionally required in the younger child to minimize motion artifact. CT scans can also provide anatomical guidance for surgical treatments and intraoperative tracking and are useful for identifying potential areas of bony erosion or attenuation. Unique radiologic characteristics can make us suspect other entities such as allergic fungal sinusitis and cystic fibrosis. Magnetic resonance (MR) imaging of the sinuses, orbits, and brain should be performed whenever complications of rhinosinusitis are suspected.

## MEDICAL TREATMENT OF RHINOSINUSITIS IN CHILDREN

The main goal of medical therapy in rhinosinusitis is to reduce the inflammatory process, thus improving sinus drainage and eradicating pathogenic bacteria. An approach that typically combines several agents such as antibiotics, topical or systemic steroids, and irrigations are recommended.

### Antibiotics

Antibiotics are the most frequent treatment administered to children with acute or CRS. Nevertheless, there continues to be a fair amount of controversy as to how to best treat the disease. Acute rhinosinusitis is believed to be largely self-limited, and most practitioners will treat with a 10–14 day course of antibiotics if a child satisfies the clinical criteria for ABRS discussed above. Falagas et al. performed a meta-analysis of randomized controlled trials in order to evaluate antibiotic treatments for acute rhinosinusitis.[33] Three of their studies were done in pediatric patients and their review suggested that antibiotics were associated with faster and better improvements and resolutions of symptoms when compared to placebo. A more recent randomized, placebo-controlled trial not included in the meta-analysis evaluated the efficacy of amoxicillin (90 mg/kg) with potassium clavulanate (6.4 mg/kg) or placebo in children 1–10 years of age with a clinical presentation compatible with ABRS (persistent symptoms, acutely worsening symptoms or severe symptoms).[34] Symptom scores were obtained at multiple time points and the children were evaluated at day 14 from onset of treatment and their condition rated as cured, improved, or failed. Twenty-eight patients in each group completed the study and their average age was around 5 years. Children receiving the antibiotic were more likely to be cured (50% vs. 14%, $p = 0.01$) and less likely to experience treatment failure (14% vs. 68%, $p < 0.001$) than children receiving placebo. Similar to other studies, there were more side effects in the antibiotic treated group compared to the placebo treatment (44% vs. 14% of children, $p = 0.014$). Some studies, however, are not as conclusive. In another study, children with clinical diagnosis of acute rhinosinusitis and upper respiratory complaints lasting between 10 and 28 days were randomized into three groups: one receiving amoxicillin, the second amoxicillin clavulanate, and the third a placebo for 14 days.[35] All three groups improved compared with baseline, and there were no significant differences among the group results, indicating that in uncomplicated cases of acute rhinosinusitis patients are likely to improve regardless of the use of antibiotics.

The most recent clinical practice guidelines based on an evaluation of existing data recommend antibiotic therapy for severe or worsening ABRS because of the benefits observed in randomized controlled trials.[3] In children with persistent ABRS, the recommendation is for either antibiotic therapy or an additional period of observation because some children might improve on their own irrespective of administered treatments. Obviously, the benefits of antibiotic therapy should be weighed in the context of local bacterial resistance trends and other considerations such as drug allergies and negative effects on quality of life of the affected child.

Early studies using maxillary sinus aspiration[36,37] recovered three main pathogens in acute rhinosinusitis, namely, *Streptococcus pneumonia*, nontypable *Haemophilus influenza*, and *Moraxella catarrhalis*. As no recent sinus tap studies have been performed, estimates of the microbiology of ABRS have been based primarily on that of acute otitis media that historically has had a very similar set of organisms causing disease. Taking into account the recent observed changes in the prevalence of causative organisms after the routine administration of the pneumococcal conjugate vaccine, it is currently estimated that *S. pneumonia* and *H. influenza* are currently each responsible for approximately 30% of cases of ABRS in children, with *M. catarrhalis* accounting for 10% and the rest of the cases probably yielding no identifiable organisms.[3] Based on these assumptions and the recent trends of antimicrobial resistance among these organisms, amoxicillin remains the agent of choice for first-line

treatment of uncomplicated ABRS in which antimicrobial resistance is not strongly suspected (resistance is usually suspected in children younger than 2 years, those who attend daycare, and those who have received antibiotics within the previous 30 days).[38,39] Amoxicillin at a standard dose of 45 mg/kg/day in two divided doses is appropriate for children without risks for pneumococcal resistance, while a higher dose of 80–90 mg/kg/day in two divided doses is more appropriate for the children considered at high risk or who live in communities with a high prevalence of nonsusceptible *S. pneumonia*. Amoxicillin clavulanate (using either 45 mg/kg/day or 80–90 mg/kg/day of the amoxicillin component) can also be used in high-risk patients and improves the chances of coverage against *H. influenza* and *M. catarrhalis*. Ceftriaxone at 50 mg/kg/day as a single dose can be useful to initiate therapy for children who have a hard time with PO medications. When patients have a nontype 1 (late or delayed > 72 h) hypersensitivity reaction to amoxicillin, they can be safely treated with cefdinir, cefuroxime or cefpodoxime. Patients with a true type-1 reaction to amoxicillin can also be treated with the above-mentioned cephalosporins, as recent publications have indicated that the risk of a serious allergic reaction to second and third generation cephalosporins in patients with penicillin allergy appears minimal.[40-42] Other options include clindamycin and linezolid (good activity against *S. pneumonia* but lacks activity against *H. influenza* and *M. catarrhalis*). Recent resistance surveillance data suggest resistance of pneumococcus and *H. influenza* to trimethoprim-sulfamethoxazole and azithromycin, to a degree that precludes recommending these agents for the treatment of ABRS in patients with penicillin hypersensitivity.[3] The duration of antimicrobial therapy for ABRS has not been investigated but most recommendations suggest a 10-day course of therapy or treatment for 7 days after resolution of symptoms that, in most cases, would lead to a 10–14 day course of therapy.

Despite the lack of good evidence to support the use of antibiotics for any length of time in children with CRS, in practice, these children are often treated with the same antibiotics listed in the section on acute rhinosinusitis but typically for longer periods of time that vary between 3 and 6 weeks. Because of the lack of data to support this practice, its usefulness must be weighed against the increasing risks of inducing antimicrobial resistance. It is also difficult to ascertain whether what is actually being treated is CRS or acute exacerbations on top of preexisting chronic disease. The exact type of antibiotics used is usually dependent on local resistance patterns that might be different in different countries. Further, it is advisable to always treat with as narrow a spectrum of antibiotics as will likely cover the bacteria that are prevalent in a specific geographic locale.

Intravenous antibiotic therapy for CRS resistant to maximal medical treatment has been studied as a potential alternative to endoscopic sinus surgery. Don et al. retrospectively reviewed 70 children between 10 months and 15 years of age with CRS who were treated with a combination of adenoidectomy, sinus irrigation, and intravenous antibiotics.[43] They report that 89% of the children had complete resolution of symptoms after maxillary sinus irrigation and selective adenoidectomy followed by 1–4 weeks of culture-directed intravenous antibiotics. The most frequently used antibiotics were cefuroxime, followed by ampicillin-sulbactam, ticarcillin clavulanate, and vancomycin. Adverse side effects were also reported including superficial thrombophlebitis (9%), necessity of venotomy (1%), as well as other types of antibiotic side effects such as serum sickness, pseudomembranous colitis, and drug-induced fevers. At least one other study of similar design showed favorable results.[44] The retrospective design, lack of randomization, and lack of placebo arms of these trials limit their value. Furthermore, it is hard to assign benefit to intravenous antibiotic therapy when other interventions were utilized such as irrigation/aspiration of the sinus and adenoidectomy. Therefore, available data does not justify the use of intravenous antibiotics alone for the treatment of CRS in children.

## Intranasal and Systemic Steroids

Studies in adults with acute rhinosinusitis suggest that administering intranasal steroids can result in an additive benefit to antibiotic therapy when compared to placebo.[45,46] Barlan et al. conducted a double-blinded placebo-controlled trial in 89 children with acute rhinosinusitis treated with oral antibiotics.[47] Intranasal budesonide was given to 43 of these patients, while the remaining 46 received placebo saline spray. Their results showed that the budesonide group had greater improvement in cough and nasal discharge symptoms at week 2, although both groups had similar improvements by the end of the study at week 4.

There are no randomized controlled trials evaluating the effect of intranasal steroids in children with CRS. However, the combination of proven efficacy of intranasal corticosteroids in CRS with and without nasal polyps in adults and proven efficacy and safety of intranasal

corticosteroids in allergic rhinitis in children makes intranasal corticosteroids the first line of treatment in CRS.[48-50]

As far as systemic steroids, there is no data to support their use in the context of ABRS in children. In CRS, and since inflammation is a prominent component, the administration of short courses of systemic steroids are commonly used clinically. Significant side effects have precluded the use of prolonged courses. A placebo controlled, randomized, double-blind trial has provided some support for this practice.[51] The trial was conducted in children showing signs and symptoms as well as CT evidence of CRS (a total Lund Mackay CT score suggestive of mild-moderate disease). All the participants were treated with amoxicillin/clavulanate for 30 days, and randomized to receive either oral methylprednisolone or placebo during the first 15 days of treatment. The study showed significant improvements in all parameters (symptoms and CT scores) in both groups when compared to baseline. However, there were significant additional beneficial effects in the steroid group versus placebo related to cough, CT scan scores, nasal obstruction and drainage, and total symptom scores.

## Adjunctive Treatments

Adjunctive treatments are generally used to promote the drainage of secretions and decrease mucosal edema, the most frequently used being nasal irrigations and decongestants. Both have been shown to help in reducing the frequency of rhinosinusitis episodes. Michel et al. in 2005 performed a randomized, prospective, double-blind, controlled study evaluating outcomes, given the degree of mucosal inflammation and nasal patency.[52] They observed the effect of a 14-day treatment (1–2 sprays) with either isotonic saline solution or nasal decongestant in children 2–6 years of age with symptoms of acute rhinosinusitis. Their results showed that both groups experienced improvement in outcomes with no significant differences between the groups. There were no side effects observed with the saline spray, although the decongestant group did use 120% more drug than had been prescribed, demonstrating a worrying potential for these medications to be overused. While no cases of rhinitis medicamentosa were reported in this study, rebound effects are always a risk with these drugs.

A systematic review of the literature was undertaken to evaluate the efficacy of decongestants (oral or intranasal), antihistamines, and nasal irrigation in children with clinically diagnosed acute sinusitis.[53] Of 402 articles reviewed, 44 references were retrieved and were all excluded because they did not satisfy the set criteria. The authors conclude that there is no evidence to determine whether the use of the above-mentioned agents is efficacious in children with acute rhinosinusitis. Nevertheless, it is common clinical practice to recommend a limited (2–4 days) course of intranasal decongestants in cases of severe ABRS to facilitate drainage.

In a more recent publication, erdosteine, a mucolytic agent, was investigated in a randomized, placebo-controlled trial in children with acute rhinosinusitis.[54] Eighty-one patients completed the study and their average age was 8.5 years. Both treatment groups had an improvement in symptoms on day 14, but there were not statistically significant differences between the active and placebo groups. Therefore, there is really no good evidence to support the use of ancillary therapies in the treatment of ARS in children.

As for saline nasal irrigations, a Cochrane review evaluated 8 studies, with 3 of them having been conducted in children. Saline (delivered by several techniques and in different tonicity levels) was evaluated in comparison with either no treatment, placebo, use in conjunction with other treatments, or against other therapies.[55] Results showed that saline, if used as a unique treatment was beneficial in the treatment of the symptoms of CRS. Wei et al. conducted a prospective, randomized, double-blind study comparing daily saline to saline with gentamicin irrigations in children who presented with symptoms compatible with CRS and a positive CT scan to a pediatric otolaryngology office.[56] Forty children were randomized to receive either saline alone or saline with gentamicin irrigations (40 ml to each nostril administered via squeeze bottle) for 6 weeks. The children had a CT scan at baseline and another performed after 6 weeks of therapy and SN-5 quality of life scores at baseline and at weeks 3 and 6 of therapy. Over 90% of the children used the irrigations appropriately and consistently. There were significant improvements in quality of life of the children at 3 and 6 weeks of therapy compared to baseline with no difference between the treatment groups. Furthermore, the total Lund Mackay score at baseline was in the range of 10–12 on a total scale of 24 and this decreased significantly after 6 weeks of therapy to a range between 3.5 and 6 with no significant differences between the groups. These data suggest a benefit of saline irrigation in children with CRS and do not support the addition of an antibiotic.

Clinicians have also tried other treatments for CRS including antihistamines and leukotriene modifiers, especially given their effectiveness in treating allergic rhinitis, but the efficacy of such treatments for chronic sinusitis is not yet well established.

## SURGICAL TREATMENT OF RHINOSINUSITIS IN CHILDREN

Surgical intervention for rhinosinusitis is usually considered for patients with CRS who have otherwise failed maximal medical therapy (including a course of antibiotics, intranasal and/or systemic steroids, and saline irrigations). Children with cystic fibrosis and obstructive nasal polyps, antrochoanal polyps, or allergic fungal sinusitis with obstructive polyps and extensive sinus disease will usually undergo surgery as the initial favored option. In these instances, surgical therapy is targeted at diminishing disease load and improving nasal obstruction and facilitating the administration of topical therapies to the more accessible post surgical cavity. Less commonly, but as importantly, surgery is also used in the context of ABRS with complications such as orbital cellulitis/abscess or brain abscess.[4] The rest of this section will deal with the appropriate surgical approaches that are available to children with CRS who have failed medical therapy.

### Adenoidectomy with/without Sinus Irrigation and Balloon Dilation

The removal of the adenoids in patients with CRS relies on the belief that the adenoids are a bacterial reservoir in the nasopharynx and have been shown to be more likely to harbor bacterial biofilms in children with CRS. Further, in some instances, hypertrophy and/or inflammation/infection of the adenoids themselves (adenoiditis) might be the cause of the presenting symptoms and are hard to distinguish from CRS proper. The benefit of adenoidectomy alone in the treatment of children with CRS has been evaluated by a meta-analysis of nine studies.[57] All of these studies showed that sinusitis symptoms and outcomes improved in 50% or more of the patients after adenoidectomy. Meanwhile, eight of those nine studies were similar enough to undergo meta-analysis, with the results estimating that 69.3% of patients significantly improved after adenoidectomy. Ramadan and Tiu reviewed adenoidectomy failures over a 10-year period and found that children were more likely to fail adenoidectomy if they were younger than 7 years of age or had asthma.[58] Given that adenoidectomy is frequently performed along with maxillary antral irrigation, Ramadan et al. studied 60 children who underwent adenoidectomy for CRS.[59] In this study, postoperative antibiotic therapy was given for 2 weeks and 32 of the children also had a maxillary sinus wash and culture via the middle meatus. The children were followed for 1 year postoperatively and the success rate was 88% for patients who underwent adenoidectomy with a sinus wash compared to 61% for the group undergoing adenoidectomy alone. Interestingly, they also reported that children with a high Lund-McKay CT score and asthma benefited more from adenoidectomy with a wash that from adenoidectomy alone.

Balloon sinuplasty is a common procedure used in adults with CRS and has been shown to be safe in children.[60] In a feasibility study, the cannulation success rate was as high as 91%, and failure was most commonly caused by the presence of a hypoplastic sinus. The majority of cannulated sinuses in children are maxillary. Currently, most surgeons will confirm cannulation of the sinus by using an illuminated catheter. In a nonrandomized, prospective evaluation of children with CRS failing maximal medical therapy, balloon catheter sinuplasty and adenoidectomy were compared.[61] Outcomes were assessed at 1 year after surgery and were based on SN-5 scores and the need for revision surgery. Twenty-four out of 30 patients (80%) who underwent balloon sinuplasty showed improvement in their symptoms compared to 10/19 (52.6%) of the patients who underwent adenoidectomy ($p < 0.05$). As some of the balloon patients also underwent irrigation, it is hard to discern the effect of dilation vs. irrigation from this study. In a more recent study, children with persistent symptoms after adenoidectomy, despite medical treatment, as documented by SN-5 scores and the Lund-Mackay CT score were evaluated.[62] Twenty-six children underwent balloon sinuplasty and it is not clear from the article whether irrigation of the sinuses was performed with sinuplasty. Furthermore, a few children had concomitant anterior ethmoidectomies or revision adenoidectomy. Nevertheless, as a group, surgical success, measured by a predetermined decrease on the postoperative SN-5 score, was achieved in 81% of the children. The reduction in SN-5 scores postoperatively was still significant when the children with hybrid procedures were excluded. Therefore, despite methodological limitations, as mentioned above, this study suggests that use of balloon sinuplasty after failed adenoidectomy might be beneficial.

In sum, most of the available surgical data support adenoidectomy with sinus irrigation as a first step in the surgical management of the child with CRS refractory to maximal medical management. Whether or not balloon maxillary sinuplasty imparts additional benefit to irrigation alone, in combination with adenoidectomy, cannot be established with available data to date.

## Functional Endoscopic Sinus Surgery

Functional endoscopic sinus surgery (FESS) in children is usually more limited than the similar procedure in adults and consists of anterior ethmoidectomy and maxillary antrostomies in most cases with posterior ethmoidectomies and sphenoid and frontal sinus work reserved usually for older patients who show evidence of disease in these sinuses on preoperative CT scans. Early concern over the possible adverse effects of FESS on facial growth were addressed by Bothwell et al. who showed no impact of FESS on qualitative and quantitative parameters of childhood facial growth up to 10 years after surgery.[63] The only meta-analysis reviewing FESS in children was performed in 1998 and showed that using FESS as a surgical approach can be effective in reducing symptoms with an 88% success rate and a tolerably low complication rate.[64] Another study by Change et al. showed that, even using a limited approach to FESS where the surgeon only removed the most obvious obstructions within the child's sinuses, the result was a significant improvement in symptoms such as nasal obstruction, rhinorrhea, postnasal drip, headaches, hyposmia, and chronic cough in more than 90% of patients.[65]

Second look procedures, once common after FESS, are currently avoided given available use of absorbable packing. Ramadan et al. found that the use of corticosteroids during initial FESS might avoid necessitating a second look procedure.[66] Walner et al. after finding comparable rates of revision sinus surgery in children both with and without a second look procedure has likewise suggested that these may not be necessary.[67] The most common findings associated with failure of FESS in children are adhesions, maxillary sinus ostium stenosis, and missed maxillary sinus ostium.[68]

In conclusion, both acute rhinosinusitis and CRS are very common diseases in the pediatric age group and have a significant healthcare burden to both the child and family. The mainstay of management is medical with surgery reserved for treatment failures and complications. The initial surgical approach to the child with CRS should consist of an adenoidectomy with a maxillary sinus wash (with or without balloon dilation) followed by FESS in case of recurring symptoms. It is important to note, however, that most of the data supporting this recommendation stem from observational, not always methodologically optimal, studies.

CHAPTER

# 31

# Cystic Fibrosis-Related Rhinosinusitis

***Megha Parekh, Kristina W Rosbe***

## INTRODUCTION

Cystic fibrosis (CF) is caused by a mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) gene on chromosome 7, affecting 1 in 3500 newborns. The most common mutation is F508, but at least 1500 different mutations have been identified. This mutation leads to the production of highly viscous secretions and impaired mucociliary transport that can contribute to sinonasal disease, bronchiectasis, pancreatic insufficiency, and focal biliary cirrhosis. Chronic inflammation of the sinuses and nasal mucosa has been reported in 74–100% of CF patients with the incidence of nasal polyposis reported as high as 44% of patients.[1] Multiple factors including genetic, inflammatory, and bacteriologic contribute to the development of chronic rhinosinusitis (CRS) in CF patients.[2]

## PATHOGENESIS

Paranasal sinuses rely on mucociliary transport for effective clearance of secretions, especially in dependent areas that may not spontaneously drain through the natural ostia. Sinonasal mucosa consists of mucus, motile cilia, and respiratory epithelial cells linked by adhesion complexes that include apical tight junctions. Nasal secretions are created by submucosal glands, goblet cells, epithelial cell proteins, lacrimal secretion and vascular transudate. Mucociliary transport promotes clearance of foreign material and bacteria out of the sinuses toward the nasopharynx.

The CFTR gene regulates the CFTR protein. This is a cAMP-activated ATP-gated anion channel that is found across the membrane of cells that produce mucus. The channel transports chloride ions and subsequently the movement of water with direct effects on mucus viscosity. This milieu of tenacious secretions, attenuated mucociliary transport, and upregulated proinflammatory mediators can lead to CRS in CF patients. The pathway to generate hypothiocyanite, an important antimicrobial that selectively kills microorganisms and spares host cells is ineffective in CF, leading to increased proinflammatory cytokines and additional oxidative stress.[3]

## HISTOLOGY

Differences between CF sinonasal mucosa and non-CF patients have been demonstrated at the histopathologic level. Studies have shown dilated glandular ducts and a predominance of mucous glands with a significantly elevated number of plasma cells and mast cells compared to non-CF patients.[4] Ultrastructural changes such as wide mucous cells, cystic dilatation, thicker layers of respiratory epithelium, and a high proportion of goblet cells compared to non-CF samples have also been reported.[5]

## MICROBIOLOGY

The most common organisms found in CF patients with CRS are *Pseudomonas aeruginosa* and *Staphylococcus aureus*.[6] These bacteria commonly colonize the airways of CF patients and create biofilms that are more resistant to traditional antibacterial treatment. Culture samples taken from bronchoalveolar lavages and paranasal cavities during endoscopic sinus surgery show a statistically

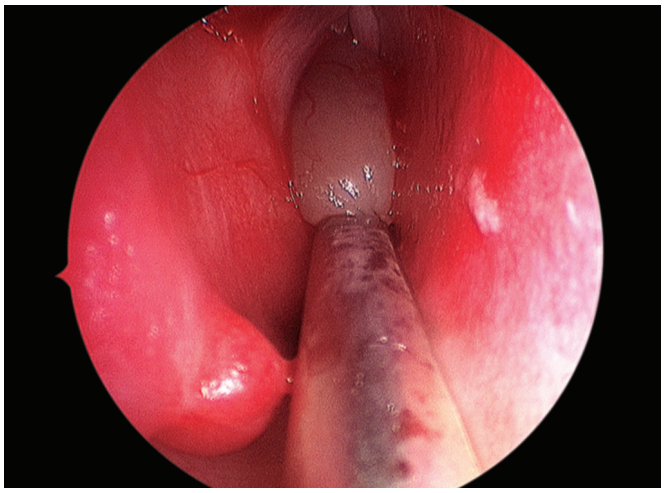

**Fig. 31.1:** Polyp in right nasal cavity.

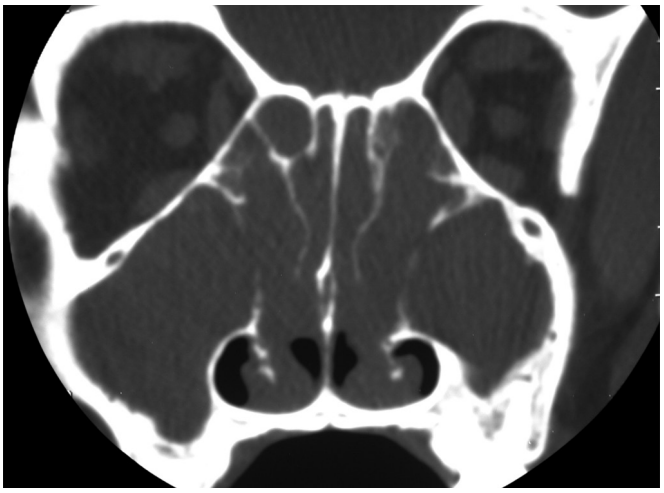

**Fig. 31.2:** Coronal CT scan demonstrating panopacification of the maxillary and ethmoid sinuses.

significant association between paranasal cavity cultures and lower airway cultures for *P. aeruginosa* and *S. aureus* in CF patients. Management of these chronic infections remains challenging due to emerging development of resistance to standard antimicrobial regimens.

## CLINICAL FINDINGS

Symptoms of CRS in CF patients are similar to non-CF patients including nasal obstruction, rhinorrhea, cough, and facial pain or pressure. Some CF patients may also present with reduction of pulmonary function.[7] Young CF patients, who have polyposis, may present with a widened nasal bridge.

A thorough physical examination should include anterior rhinoscopy as well as nasal endoscopy, although this can be challenging in younger patients. Polyps should be identifiable on nasal endoscopy as well as mucopurulent secretions in the area of the middle meatus (Fig. 31.1). There is evidence to suggest that patients who are homozygous for the CFTR-mutation may have a higher incidence of nasal polyposis.[8]

## IMAGING FINDINGS

Historically, the imaging study of choice for CF patients with CRS has been a noncontrast sinus computed tomography (CT) scan. With the increased awareness of cumulative radiation exposure and links to development of malignancy, many centers are developing low-dose radiation protocols, especially for pediatric patients.[9] Some centers are using "cone beam CT", also called digital volume tomography, which can lead to up to an 80% reduction in radiation without loss of resolution compared to standard CT protocols.[10] Other centers have started using magnetic resonance imaging (MRI), although this is traditionally felt to be not as helpful for bony anatomy, takes longer, and therefore may require sedation or general anesthesia for young children. Intraoperative image guidance, especially for revision sinus surgery, is commonly utilized. At our institution, as a tertiary referral center for these patients, our patients often come with imaging that was already ordered by their local physicians. We make every attempt *not* to repeat imaging if at all possible. Almost all CF patients will have abnormal sinus imaging; therefore, a scan should only be ordered for patients who are refractory to medical therapy and in whom, surgical intervention is being considered. Using imaging to monitor CRS or to confirm response to medical therapy is *not* recommended. Symptoms and endoscopic examination should be used to guide treatment.

Characteristic findings on sinus CT include medial displacement of the lateral nasal walls, uncinate process demineralization, and panopacification of the sinuses (Fig. 31.2). There can also be aplasia or hypoplasia of the frontal and sphenoid sinuses.

## MEDICAL TREATMENT

Medical treatment for acute or CRS in CF patients generally includes antibiotics, nasal steroids, and saline irrigations although there are limited outcomes studies on the

efficacy of topical steroids and saline irrigation for CRS in CF patients. A Cochrane review concluded that saline irrigations in non-CF patients improve symptoms and disease-specific quality of life (QoL) scores.[11] Hypertonic saline has been proposed to increase mucociliary clearance, pulmonary function, and decrease inflammation through reduction in proinflammatory cytokines such as interleukin-8 (IL-8), but these effects have not been demonstrated as well in CRS.[12] Culture directed antibiotic treatment is preferable but cultures of the middle meatus, the preferred location, may not be tolerated in younger patients. There is no consensus on duration of antibiotic therapy but longer durations of at least 3 weeks are usually prescribed.[13] Older patients may also be prescribed a course of oral steroids to treat inflammation of sinonasal mucosa. Controlled studies of optimal medical therapy in CF patients are lacking. For those patients with obvious sinonasal polyposis, medical therapy alone may not be adequate.

Nasally inhaled dornase alfa (Pulmozyme, Genentech) is a human deoxyribonuclease that selectively cleaves DNA. This has been proven to reduce the viscosity of pulmonary secretions. Several studies have also examined the use of nasally inhaled dornase alfa and demonstrated an improvement in nasal-related symptoms and nasal endoscopic appearance. There are ongoing investigations of the use of nebulized topical antibiotics and other substances, such as mannitol to rehydrate mucus membranes, for CF patients with CRS.

## SURGICAL TREATMENT

It remains unclear why some CF patients develop symptomatic CRS and/or sinonasal polyposis and others do not. As mentioned previously, extent of radiographic disease may not correlate with symptomatology and should not be used as the sole determinant for surgical intervention. Severity and progression of sinonasal symptoms as well as deteriorating pulmonary function are the most common reasons for surgical intervention. At some centers, CF patients being considered for lung transplantation may be referred for sinus surgery to reduce airway bacterial colonization, although this indication remains controversial. Sometimes, sinus surgery is coordinated at the end of a scheduled admission for a pulmonary "cleanout"—usually a 7–10 day admission for IV antibiotics and aggressive pulmonary toilet to try to optimize pulmonary function.

Goals of sinus surgery in CF patients are generally to remove obstructing polypoid disease, open sinus ostia to promote more efficient clearance, and remove mucopurulent secretions to decrease bacterial colonization (Fig. 31.3).[14] Development and refinement of endoscopic sinus instrumentation has made sinus surgery, even in young patients, possible and safe. Tools such as the straight and angled microdebrider blades allow for relatively fast removal of bulky polypoid disease in the sinuses with less operative time and bleeding compared to prior more traditional methods (📹 31.1). Powerful irrigating systems such as the hydrodebrider can help irrigate out thick secretions and reduce bacterial colonization (📹 31.2 and 31.3). Intraoperative image guidance is also used during endoscopic sinus surgery in CF patients, especially for patients undergoing multiple revision surgeries to confirm anatomic landmarks. Adjuvant medical therapies during sinus surgery such as irrigating with topical antibiotics and/or steroids are being investigated.

Concerns have been raised about alterations in sinus and facial growth of sinus surgery in pediatric patients, but multiple studies have not been able to demonstrate any long-term effects on facial growth.[15,16] Most pediatric sinus surgeons remain conservative, however, in removal of tissue to minimize this potential risk. Hemostatic agents and/or other bioabsorbable products are sometimes placed at the end of sinus surgery to minimize postoperative bleeding and prevent synechiae. Scheduled second look procedures to examine and debride under general anesthesia in children who would not tolerate this type of examination in the office have fallen out of favor.

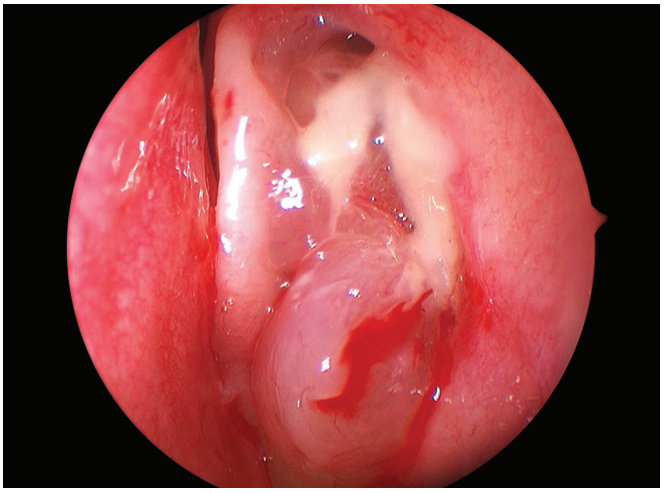

**Fig. 31.3:** Polyp and mucopurulence emanating from left maxillary sinus.

Although there are some studies suggesting that endoscopic sinus surgery is linked to improvement in QoL in CF patients, effects on pulmonary function, hospitalization, and overall medical therapy are less clear and further studies are needed to more fully elucidate the long-term outcomes.[17]

Recent United States Food and Drug Administration (FDA) approval and successful trials of ivacaftor, a CFTR modulator and the first therapy targeting the underlying defect in CF, are promising and may have the potential for significant impact on the future medical care and QoL of patients with CF.[18]

# Congenital Nasal Malformations

***Steven M Andreoli, Ken Kazahaya***

## INTRODUCTION

Congenital anomalies of the nasal cavity and nasopharynx include a diverse collection of presentations and pathologies. Although many lesions may be indolent or incidental, clinically relevant lesions routinely present with external findings with cosmetic implications, nasal obstruction, or intracranial communication. Because of obligate nasal breathing during the neonatal period, congenital nasal malformations causing nasal obstruction often result in acute respiratory compromise. The three most common pathologies in this group include choanal atresia (CA), congenital pyriform aperture stenosis (CPAS), and midline nasal masses. Congenital midline nasal masses include dermoid cysts and sinuses, gliomas, and encephaloceles.

## CHOANAL ATRESIA

### Epidemiology and Pathophysiology

CA is a rare anomaly present in <1 per 10,000 births.[1] The majority of CA cases (71%) are mixed bony and membranous atresias, while the remaining 29% are solely bony.[2] There is a nearly equal distribution between unilateral and bilateral cases. Associated abnormalities are identified in 70% of cases, and CHARGE syndrome must be considered.[3]

### Presentation

Secondary to obligate nasal breathing, neonates with bilateral CA routinely present with airway obstruction and respiratory failure. Infants with bilateral CA exhibit paradoxical cyanosis in which respiratory distress is relieved by crying. An oral airway and prone positioning may temporize nasal obstruction. Ultimately, oral intubation is often required prior to surgical intervention.

Unlike bilateral atresia, an indolent presentation is characteristic of unilateral CA. Unilateral chronic obstruction and rhinorrhea are the most common findings in unilateral CA. Because of mucous stasis within the nasal cavity purulent and odorous drainage may ensue raising concern for possible nasal foreign body. As a result of nonspecific symptoms, diagnosis of unilateral CA is made between 2 and 5 years of age.

### Workup

Bilateral CA presents with neonatal respiratory distress. Paradoxical cyanosis raises suspicion for a fixed nasal obstruction. Inability to pass a nasal suction catheter past 3.5 cm is the first finding specific to CA. A mirror placed at the nares will not fog during exhalation. Gold standard diagnosis of CA is made via flexible nasal endoscopy. Following diagnosis, a CT of the midface allows characterization of the atretic plate[4] as seen in Figure 32A.1. The thickness of the bony atretic place, vertical height of the skull base, and medial position of the pterygoid plates are of particular concern for surgical planning.

Unilateral CA is routinely an office based diagnosis. Children with chronic unilateral nasal obstruction and rhinorrhea undergo flexible endoscopy in the outpatient setting. After endoscopic identification of unilateral CA, again CT is recommended to investigate the nature of the atretic plate.

**Fig. 32A.1:** CT demonstrating bright bony and membranous choanal atresia.

## Management

The surgical management of CA continues to evolve. Early surgical management consisted of blind bougienage of the atretic plate with curettage of the vomer and pterygoid plates. This technique placed both the skull base and carotid arteries at risk. Subsequent to blind techniques, the transpalatal approach was applied. This technique offers excellent exposure, but results in palatal arch growth concerns.

Endoscopic techniques have largely supplanted the transpalatal approach. Many technique modifications are reported employing either a 0° transnasal or a 120° transoral approach. Following puncture of the atretic plate, the choanae are widened in all directions using both hand and powered instrumentation.[5] The authors prefer drilling laterally along the pterygoid plate to maximize choanal dimensions. Because of the circular nature of the neochoanae, cicatricial scarring is common. Performing posterior septectomy with resection of the posterior portion of the vomer using a back biting endonasal instruments results in a three dimensional aperture less likely to stenose. In our experience, an anteriorly based mucosal flap is raised on one side and draped across the septal defect to improve mucosalization and decreased granulation tissue.

Postoperative management for bilateral CA remains controversial. Questions remain regarding duration of orotracheal intubation, use of nasal stents, application of topical medications, and revision surgery. Similar to airway surgery, allowing air passage through the reconstructed choanae improves patency. As such, short-term intubation of 1 or 2 days is advocated. In review of nasal stents, there is little evidence to support improved patency with time.[6] In revision cases or cases with narrow choanal dimensions, stents may decrease revision rate. Several topical medications have been utilized attempting to reduce scar formation. Topical mitomycin C prevents fibroblast growth; however, the evidence reports conflicting results about efficacy. Topical nasal steroids may serve to reduce swelling and granulation following surgery; however, significant systemic uptake of nasal steroids can cause adrenal insufficiency.[7] Thus, we advocate a short-term postoperative nasal steroid course followed by saline alone. Revision after bilateral CA repair is unfortunately common. Known predictors of revision surgery include bilateral CA, repair at age < 6 days, prematurity, and associated congenital anomalies.[8]

Surgical management of unilateral CA is met with higher success rates. A similar approach is required, but the ability to use the contralateral side as a landmark facilitates protection of the skull base. Following puncture of the atretic plate similar techniques are performed to drill along the pterygoid plates and a posterior septectomy is performed. As in bilateral cases, an anteriorly based ipsilateral septal mucosa flap is again draped to the opposite side. A lateral flap either superiorly or anteriorly based can also be raised and draped over the exposed pterygoid plate to improve mucosalization. Neither postoperative stenting nor intubation is routinely required.

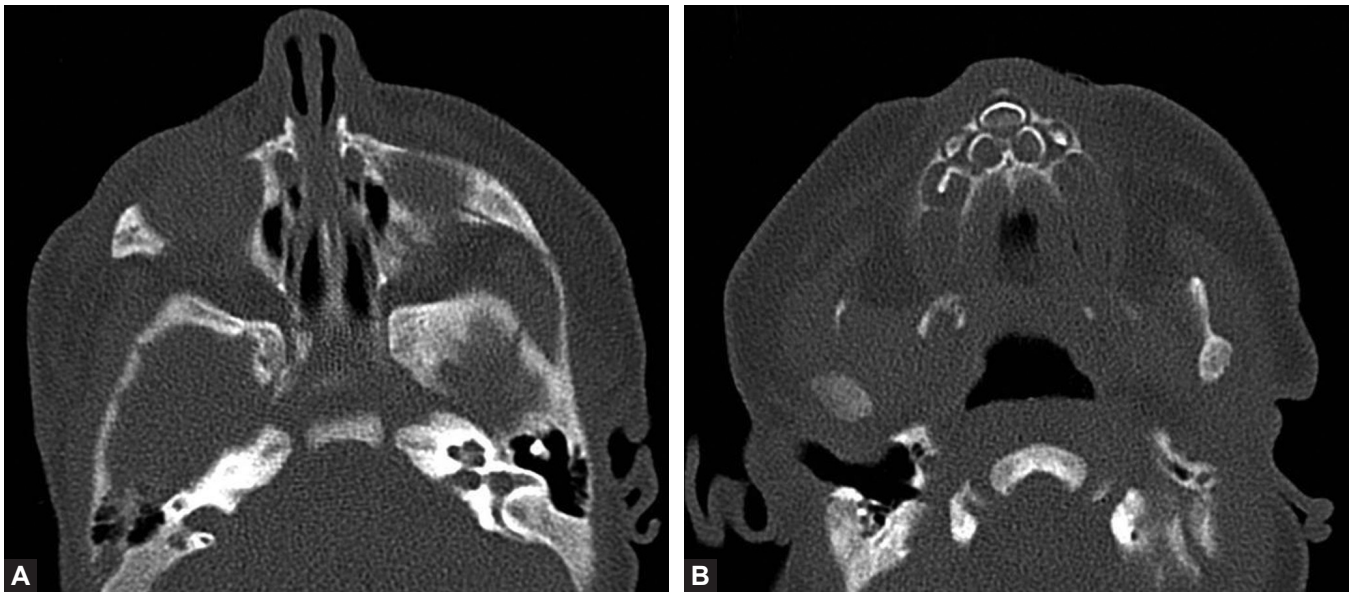
# CONGENITAL PYRIFORM APERTURE STENOSIS

## Epidemiology and Pathophysiology

CPAS results from premature fusion of the medial nasal prominence. Children with CPAS often exhibit complete nasal stenosis. The true incidence of CPAS is unknown. Although not seen in all cases, the associated single median maxillary central incisor is estimated to occur in 1:50,000 births.[9]

## Presentation

CPAS presents with neonatal respiratory distress. Similar to bilateral CA, paradoxical cyanosis is common as crying with oral respiration bypasses the nasal airway obstruction.



**Figs. 32A.2A and B:** (A) CT showing pyriform aperture stenosis, note the associated narrow nasal dimension in the middle nasal vault; (B) Associated solitary median maxillary central incisor.

Conservative airway management is accomplished with oral airway placement. Unlike neonates with bilateral CA, some infants with CPAS are able to maintain a natural airway for an extended period of time. Infants with severe CPAS often require intubation prior to surgical intervention.

## Workup

Anterior rhinoscopy in an infant with CPAS demonstrates narrow nasal vestibules. The lower lateral cartilage is often effaced to the septum. Nasal suction catheters cannot be introduced into the nasal cavity. Inability to pass a flexible endoscope is a common finding with CPAS. CT imaging of the pyriform aperture quantifies the severity of CPAS (Figs. 32A.2A and B). Total diameter < 11 mm is diagnostic of CPAS.[10] In addition to measurement of the pyriform aperture, examination of the mid-nasal and posterior-nasal dimensions is useful in predicting surgical success.[11] CT imaging also detects the presence of an associated midline megaincisor and holoprosencephaly. In patients identified to have holoprosencephaly also require an MRI of the brain.

## Management

Initial management for CPAS revolves around establishing a stable airway. Because of incomplete obstruction, some infants may not require immediate intubation. Enteral feeding is often required in this setting because of poor coordination with feeding in the absence of nasal breathing. For infants with respiratory distress, oral intubation provides a secure airway until surgical management is performed.

The traditional technique for surgical management of CPAS begins with a sublabial approach carried down to the face of the maxilla.[12] Subperiosteal dissection is then performed superiorly into the nose. Because of the extremely narrow dimensions the surgeon must be attentive to remaining midline at all times. A pitfall for surgery is dissection lateral to the pyriform aperture placing the infraorbital nerve at risk. A 0.5 and 1 mm diamond drill are then used in conjunction with either loupe magnification or microscopy to drill laterally against the pyriform aperture. Posterior dissection is carried to the coronal plane of the inferior turbinate head. The medial surface of the burr must be kept off the septum to prevent perforation. In patients with more posterior nasal stenosis, out-fracture of the turbinates can be performed to improve posterior nasal dimensions. Short-term stenting may be useful in preventing stenosis.

More recently, reports have discussed using balloon dilation and stenting as an alternative to the sublabial approach.[13] In select cases at our institution, we have used urethral sounds with nasal stenting. Sequential stenting of the pyriform for several weeks may be sufficient to carry an infant through the obligate nasal breathing period, allow for oral feeding, and obviate the need for alternative alimentation.

## MIDLINE NASAL MASSES

### Epidemiology and Pathophysiology

Three types of midline nasal masses result from faulty closure of the anterior neuropore. The classic differential for a midline nasal mass includes dermoid cysts and sinuses, gliomas, and encephaloceles. The incidence of midline nasal masses ranges from 1:20,000 to 1:40,000.[14] The pathophysiology of the herniated or excluded contents dictates the diagnosis.

During early development, a dural diverticulum extends into the prenasal space.[15] The frontal and nasal bones are segregated by the fonticulus frontalis. With the progression of embryogenesis, the dural projection recedes and the foramen cecum is formed. Incomplete closure of the anterior neuropore results in the spectrum of defects seen with midline nasal masses from the frontal bone and across the anterior cranial base.

Nasal dermoid cysts are theorized to represent failed regression of the dural diverticulum. A stalk projection from the anterior neuropore results in a dermoid sinus tract, which may extend intracranially. Residual attachment to the nasofrontal epithelium results in the pathopneumonic midline nasal dimple and hair tuft. A glioma is neural tissue excluded from the intracranial vault following closure at the foramen cecum. Incomplete closure of the foramen cecum with herniation of neural tissue into the prenasal space or nasal cavity is characteristic of an encephalocele. To avoid complications, differentiation of the midline nasal masses is paramount prior to surgical management.

### Presentation

Dermoids, gliomas, and encephaloceles can range from subtle anomalies to large lesions causing respiratory symptoms. A midline nasal dimple and/or hair tuft are characteristic of a nasal dermoid. Dermoid sinus tracts are lined with epithelium, and keratinous drainage may occur. Dermoid sinus tracts with intracranial extension may result in meningitis or intracranial abscess formation. Encephaloceles, because of the intracranial association, are subject to changes in intracranial pressure. The Furstenberg test, or compression of the internal jugular vein, results in enlargement of the encephalocele as intracranial pressure increases. A glioma presents with a midline prenasal or intranasal mass that may associate with the lateral nasal wall. Unlike an encephalocele, because of complete foramen cecum closure, the Furstenberg test is negative.

### Workup

Physical examination findings with midline nasal masses often narrow the differential. The hair tuft and dimple are characteristic of nasal dermoids. A positive Furstenberg test is diagnostic of an encephalocele. Gliomas and dermoids within the prenasal space have similar examination findings. Radiographic findings characteristic of midline nasal masses were identified in the 1982 by Sessions. In his landmark article, a bifid crista galli was identified as a predictor of intracranial extension.[14] Plain film radiography was used at the time, and may still be used. CT imaging will allow assessment of the bony cranial base. Meanwhile, imaging with MRI offers greater soft tissue characterization and visualization of intracranial involvement and is the imaging of choice for the authors (Figs. 32A.3 and 32A.4).

### Management

Surgical planning for excision of the midline nasal mass hinges on the presence of intracranial involvement. Preoperative imaging allows for anticipation of a CSF leak during excision. Lesions with exclusively extracranial involvement of the prenasal space may be excised via direct midline incision or external rhinoplasty approach.[16] Masses with intranasal extension can be excised with external and endoscopic combined approaches. Lesions with intracranial involvement require coordinated surgery between otolaryngology and neurosurgery. Endoscopic assisted approaches continue to expand our minimally invasive access to the anterior skull base. For lesions with endonasally approachable intracranial extension we have been able to manage without a craniotomy; however external craniotomy continues to be needed for lesions with larger intracranial components.

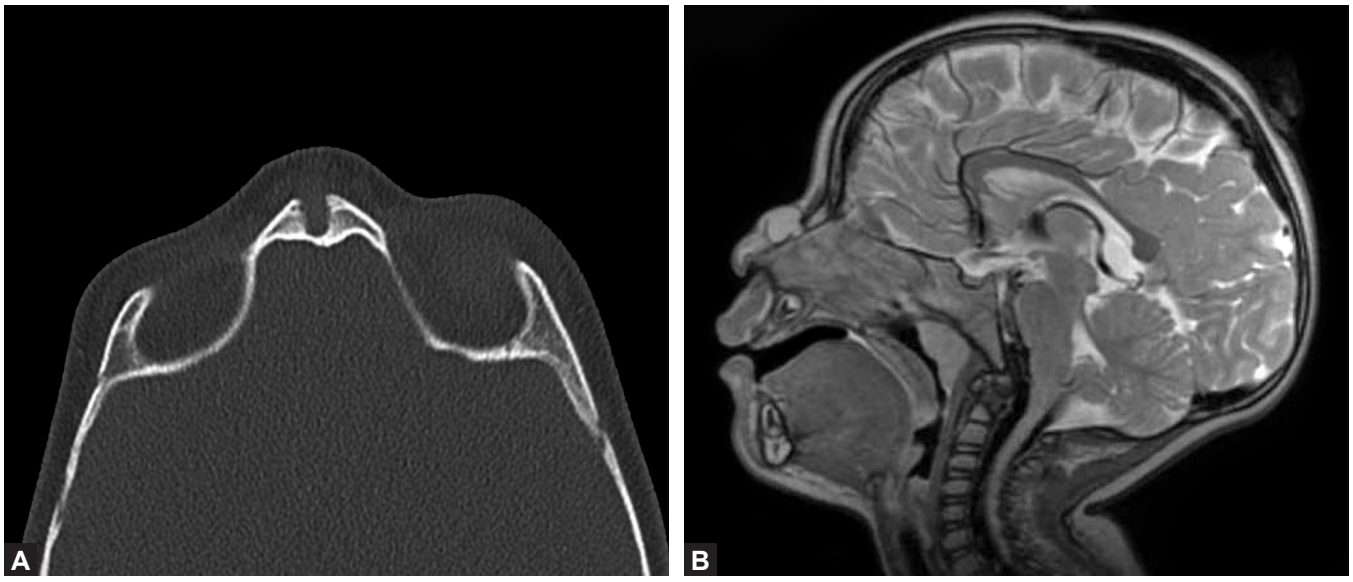
## PROBOSCIS LATERALIS

### Epidemiology and Pathophysiology

Proboscis lateralis (PL) is a rare nasal anomaly affecting 1:100,000 births.[17] There is no known genetic link. PL develops from a failure of fusion or the absence of a medial and lateral nasal process. The embryonic fusion plane between the frontonasal process and anterior maxillary process dictates the position of the proboscis.

### Presentation

PL manifests with a tubular nasal structure originating from near the medial canthus. This structure is analogous



**Figs. 32A.3A and B:** (A) CT showing dermoid cyst extending into the frontal bone; (B) Sagittal MRI with dermoid cyst in the prenasal space with extension through nasal bone.

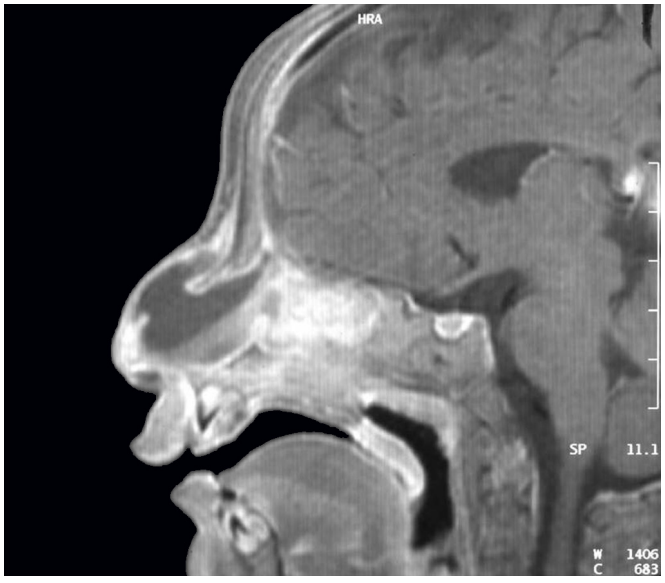


**Fig. 32A.4:** MRI showing large prenasal and intranasal encephalocele.

in appearance and composition to the proboscis of insects. The lining within a proboscis is squamous epithelium.

PL has been classified into four groups based on the associated nasal, ocular, and philtrum findings. The classification system is summarized in Table 32A.1.[18]

**Table 32A.1:** Boo-Chai classification for proboscis lateralis[18]

| *Group* | *Defect* |
|---|---|
| I | Normal nose with supernumerary PL |
| II | PL with ipsilateral nasal defect |
| III | PL with ipsilateral nasal and ocular defects |
| IV | PL with cleft lip and/or palate |

(PL: Proboscis lateralis).

## Workup

PL is evident at birth, and may be diagnosed prenatally on ultrasound in some cases. The contralateral nasal cavity is routinely patent, and airway symptoms are uncommon. Imaging with CT or MRI is prudent to investigate for any intracranial involvement (Fig. 32A.5).

## Management

PL is managed in accordance with the group typing. In patients with group 1 PL and an otherwise normal nose the proboscis can be excised. In patients with ipsilateral nasal defects, the proboscis is used as tissue for reconstruction of the nose.

# ARRHINIA

## Epidemiology

Arrhinia is very rare, with scattered case reports in the literature.[14] There is no known genetic or embryologic cause for arrhinia.

**Fig. 32A.5:** CT of skull base in patient with group II right-sided proboscis lateralis resulting in rudimentary right nasal cavity and paranasal sinuses.

## Presentation

Children with arrhinia have neonatal respiratory distress secondary to obligate nasal breathing. Paradoxical cyanosis would be expected. Management of arrhinia is infancy depends on establishing a secure airway. Because of a complex staged nasal reconstruction, neonatal tracheostomy is expected.

## Workup

Arrhinia is evident at birth. CT imaging of the maxilla and midface are important in understanding the anatomy of the midline face.

## Management

Arrhinia requires a complicated reconstructive course. During this time, a tracheostomy is often required. Management of arrhinia involves establishing a nasal cavity space and creating an external nose. The neocavity is drilled and lined with skin grafts. The external nose is constructed from calvarial bone, cartilage, and regional tissue flaps.

CHAPTER

32B

# Pediatric Nasal Tumors

***Steven M Andreoli, Ken Kazahaya***

## NASAL TUMORS

Pediatric nasal tumors are comprised of a diverse collection of histologic and clinical presentations. The differential diagnosis includes both benign and malignant neoplasms. Differential diagnoses are outlined in Tables 32B.1 and 32B.2.[1] Attentive workup and diagnosis is integral in appropriate management. Coordinated efforts using a multidisciplinary tumor board is required for children with nasal malignancies.

**Table 32B.1:** Benign neoplasms of the nasal cavity and paranasal sinuses

## BENIGN NASAL MASSES

### Juvenile Nasopharyngeal Angiofibroma

#### *Epidemiology and Pathophysiology*

Juvenile nasopharyngeal angiofibroma (JNA) is a rare benign vascular neoplasm of the pterygopalatine fossa and nasopharynx with an incidence of 1:5,000 to 1:60,000.[2] JNAs are found almost exclusively in adolescent males and comprise 0.05% of all head and neck tumors.

These tumors are theorized to originate from the superior aspect of the sphenopalatine foramen; however, the definitive etiology of JNAs is not known. Because of the age and gender predilection, a hormonal pathogenesis has been proposed. Paraganglionic cells within the terminal

**Table 32B.2:** Malignant neoplasms of the nasal cavity and paranasal sinuses

| Rhabdomyosarcoma |
| Squamous cell carcinoma |

branches of the maxillary artery have also been implicated with deletions identified on chromosome 17 involving both *p53* and *Her-2/Neu*.[3]

The growth of JNAs tends to be bilobed. The intranasal component of the tumor extends medially toward the nasopharynx. Large tumors displace the septum, or may erode into the sphenoid or cavernous sinus. The lateral portion of the tumor spreads toward the pterygopalatine fossa and eventually the infratemporal fossa. Orbital involvement may occur with extension through the inferior orbital fissure. Intracranial extension may occur via erosion through the greater wing of the sphenoid.

### *Presentation*

The most common manifestations of a JNA are unilateral nasal obstruction and recurrent unilateral epistaxis in a teenage male. Growth within the nasopharynx results in Eustachian tube dysfunction and unilateral otitis media with effusion. Although benign, local invasion is common. Tumors with extension into the pterygomaxillary and infratemporal fossa may also exhibit proptosis, diplopia, cranial neuropathies, facial asymmetry, and chronic headaches.

### *Workup*

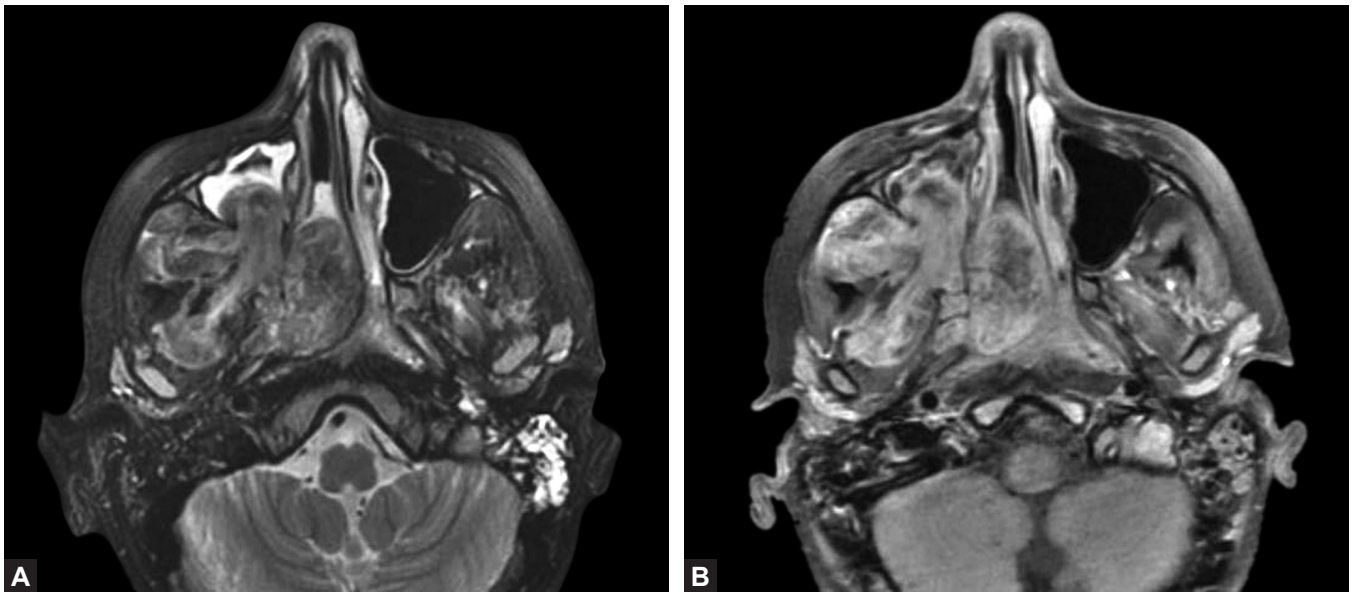
Diagnosis of a JNA begins with careful history and physical examination including flexible or rigid nasal endoscopy. Thorough examination of the nasal cavities and nasopharynx surrounding the sphenopalatine foramen is required. Because of their vascular nature, office biopsy is contraindicated.

Both contrast CT and MRI can define the lateral extent of tumor growth; however, MRI offers improved soft tissue resolution and can provide detailed vascular information (Figs. 32B.1A and B). CT may be required for surgical planning and intraoperative stereotactic navigation. Conventional angiography is useful to identify the feeding blood supply. In a review of cases, bilateral vascular supply was evident in 69% of cases and unilateral vasculature in the remaining 31%.[4] Preoperative angiography also affords the opportunity for embolization that can reduce intraoperative blood loss.

Multiple classification systems have been proposed for JNA, first by Sessions in 1981 and later modified by Radkowski (Table 32B.3).[5,6] Alternative staging is proposed by Fisch separating pterygomaxillary from infratemporal fossa spread. More recently, Snyderman has proposed a new staging system for JNAs that is based on the endoscopic endonasal techniques now utilized.[7]

### *Management*

JNAs are managed with either surgical resection or radiotherapy. Numerous surgical approaches including endonasal endoscopic, lateral rhinotomy, transpalatal, midface degloving, facial translocation, or Fisch infratemporal



**Figs. 32B.1A and B:** (A) T1 precontrast imaging of large right-sided juvenile nasopharyngeal angiofibroma involving the pterygopalatine and infratemporal fossas; (B) Postcontrast imaging of tumor.

**Table 32B.3:** Radkowski modification of the Sessions classification for JNA[6]

| *Stage* | *Description* |
|---|---|
| I | Tumor limited to the nose or sinus |
| II | Pterygomaxillary or infratemporal fossa tumor extension |
| IIIa | Intracranial but extradural tumor extension |
| IIIb | Intradural intracranial tumor extension |

(JNA: Juvenile nasopharyngeal angiofibroma).

fossa have been utilized. In stage I and II tumors, endoscopic surgery is associated with decreased blood loss, operative time, and hospital stay when compared to craniofacial approaches.[8] The authors prefer to ablate the tumor endoscopically using coblation. This technique allows excellent visualization, decreased intraoperative bleeding, and reduced operative time.[9]

Surgical cure rates are comparable despite approach. In a review of 42 consecutive JNAs, recurrence was identified in no endoscopic cases and 17% of craniofacial resection cases. However in this series more stage III tumors were treated with open resection.[10]

Radiation therapy is a surgical alternative in the management of JNA. In a series of 66 JNA patients receiving 30 cGy of external beam, tumor control was achieved in 80% of patient. Recalcitrant disease was successfully managed with additional radiation.[11] A second review of 22 children with JNA demonstrated tumor control in 91% of patients with 30–36.6 cGy of external beam radiation.[12] Residual disease in two children was managed with salvage surgery. Radiation treatment side effects included cataracts, central nervous system syndrome, and secondary basal cell carcinoma.

## Inverted Papilloma

### *Epidemiology and Pathophysiology*

Inverted papilloma (IP) is an uncommon entity in the adult population, and rarely reported in the pediatric literature.[13,14] IPs represent 0.5–4% of all nasal tumors.[15] The ingrowth of epithelium into the subepithelial stroma is characteristic of IP. The etiology for IP is unknown; however, multiple factors have been implicated including allergy, chronic rhinosinusitis with nasal polyposis, and human papilloma virus serotypes 6, 11, 16, and 18.[16] Malignant transformation to squamous cell carcinoma is reported with variable rates.

### *Presentation*

IP presents with a unilateral nasal mass causing obstruction, rhinorrhea, or epistaxis. Less commonly, IP can present with hyposmia or headaches.[17] In large IPs, symptoms may include proptosis, epiphora, and hypesthesia in the distribution of $V_2$.[18] Intranasal examination demonstrates a polypoid mass. The middle meatus is the most common site with attachment to the lateral nasal wall. Septal IP has also been reported in the pediatric literature.[13]

IP has a strong propensity for recurrence with rates reported from 0% to 78% depending on the method of excision, and as such a recalcitrant nasal mass after excision should raise concern for IP. Pediatric recurrence has been reported, but the rate of recurrence is unknown secondary to small case series. In a meta-analysis examining modern endoscopic excision via modified endoscopic medial maxillectomy, recurrence rates were 12% in patients undergoing endoscopic surgery compared to 20% with craniofacial resection.[19]

### *Workup*

Intranasal examination using anterior rhinoscopy demonstrates a mulberry polypoid mass routinely emanating from the middle meatus. Relative to an inflammatory nasal polyp, IPs may demonstrate increased vascularity and be more firm on palpation with nasal instrumentation. Purulent surrounding secretions are common. The extent of the mass should be further investigated using nasal endoscopy. Imaging allows qualification of bony erosion and invasion. Although bony erosion may be better elucidated by CT, MRI is superior for assessing tumor versus inspissated mucus.[20] Preoperative planning and stereotactic navigation may require CT.

Confirmation of pathology is completed with intranasal biopsy. When the origin of the mass is unclear, imaging prior to biopsy is prudent to rule out encephalocele. Depending on the age of the child, office biopsy may be possible. Characteristic pathologic findings include a thick epithelial covering comprised of squamous, respiratory, or transitional epithelium with extensive stroma invasion by hyperplastic epithelium. In cases with malignant transformation, anaplasia with cellular atypia, increased nuclear-to-cytoplasmic ratio, and a loss of structural polarity are noted.

Multiple staging guidelines exist for IP.[21,22] Previous staging systems were not well adopted for comparison of open and endoscopic techniques. As endoscopic

**Table 32B.4:** Cannady classification for IP[22]

| *Group* | *Description* |
|---|---|
| A | IP confined to the nasal cavity, ethmoid sinuses, or medial maxillary wall |
| B | IP with involvement of any maxillary wall (other than medial wall), frontal sinus, or sphenoid sinus |
| C | IP with extension beyond the paranasal sinuses |

(IP: Inverted papilloma).

techniques have evolved and shown similar recurrence rates, a revised staging is proposed and geared toward endoscopic resection (Table 32B.4).[23] In the event of squamous cell carcinoma, tumors are staged based on the American Joint Committee on Cancer guidelines.

### *Management*

IP is primarily managed with surgical approaches. Historically, IP has been managed with open medial maxillectomy via a lateral rhinotomy or midface degloving approach. More recently, endoscopic modified medial maxillectomy has been applied for the treatment of nonmalignant lesions with recurrence rates comparable to craniofacial resection. Intraoperatively, removal of the tumor attachment and drilling the adjacent bone is necessary to reduce the risk of recurrence.

Following surgery routine endoscopic and radiographic surveillance are required for recurrent disease. In patients unable to undergo surgery, successful tumor control can be achieved with radiotherapy.[24] Similarly, patients with identified squamous cell carcinoma may benefit from postoperative adjuvant radiotherapy.

## Nasopharyngeal Teratoma

### *Epidemiology and Pathophysiology*

Teratomas are congenital germ-cell tumors with variable composition of ectodermal, mesodermal, and endodermal components. The most common sites for head and neck teratomas are the neck and nasopharynx.[25] Epignathus refers to a nasopharyngeal teratoma with contributions from all three germ cell layers. The incidence of epignathus is estimated 1:35,000 to 1:200,000 births.[26]

Nasopharyngeal teratomas evolve as endoderm and mesoderm are entrapped with the rostral migration of ectoderm during formation of Rathke's pouch.[27] This process results in a nasopharyngeal collection of all three germ layers.

### *Presentation*

Most cases of nasopharyngeal teratoma are identified prenatally with polyhydramnios secondary to gastrointestinal obstruction. Associated findings may include a nasopharyngeal mass or cleft palate identified on ultrasound. Fetal MRI demonstrates a heterogeneous mass within the nasopharynx projecting into the nasal cavity and/or the oral cavity.

After birth, the growth of a nasopharyngeal teratoma may be dramatic. Fetal respiratory distress is imminent, and prenatal airway preparation is required. Delivery via ex utero intrapartum treatment (EXIT procedure) may allow for intubation or tracheostomy to be performed while the neonate remains on maternal circulation.

### *Workup*

Prenatal workup for polyhydramnios is integral in preventing neonatal respiratory distress. Following delivery, elevated serum alpha-fetoprotein is characteristic of teratomas.

### *Management*

The treatment for nasopharyngeal teratomas is surgical excision. Combined endoscopic and transoral approaches are utilized based on tumor location and extent. Serial AFP measurements may be used for surveillance. Although metastases are not reported, case reports of dramatic recurrence after excision infers malignant behavior in some tumors.[28]

# MALIGNANT TUMORS

## Rhabdomyosarcoma

### *Epidemiology and Pathophysiology*

Rhabdomyosarcoma (RMS) is the most common soft tissue malignancy involving the head and neck in children. RMS is a small blue-cell malignancy that is thought to arise from muscle progenitor cells. The annual estimated incidence of RMS is 6-8 cases per 1,000,000 with a slight predilection for males. There is a bimodal distribution for RMS routinely presenting from 2–6 years and 10–18 years.[29] Head and neck RMS is more common in the younger cohort. Orbital RMS is the most common site for head and neck RMS. However, parameningeal RMS may involve one of several subsites including nasal cavities, paranasal sinuses, infratemporal fossa, pterygopalatine fossa, middle ear, and mastoid.

**Table 32B.5:** Pretreatment staging for Intergroup RMS Study IV—Head and Neck[31]

| *Stage* | *Site* | *T (Invasiveness)* | *T (Size)* | *N* | *M* |
|---|---|---|---|---|---|
| I | Head and neck, excluding parameningeal | T1 or T2 | a or b | N0, N1, or Nx | M0 |
| II | Parameningeal | T1 or T2 | A | N0 or Nx | M0 |
| III | Parameningeal | T1 or T2 | B | N0, N1, or Nx | M0 |
| IV | All sites | T1 or T2 | a or b | N0 or N1 | M1 |
| *T Stage* | | | | | |
| T1: Confined to anatomic site of origin<br>T2: Extension<br>Ta: ≤ 5 cm in diameter<br>Tb: > 5 cm in diameter | | | | | |
| *N Stage* | | | | | |
| N0: Not clinically involved<br>N1: Clinically involved<br>Nx: Clinical status unknown | | | | | |
| *M Stage* | | | | | |
| M0: No distant metastasis<br>M1: Distant metastasis present | | | | | |

(RMS: Rhabdomyosarcoma).

### *Presentation*

RMS typically presents with a painless and enlarging mass. Symptoms are associated with location of the primary tumor. Within the nasal cavities and paranasal sinuses RMS presents with nasal obstruction, serous otitis media, epistaxis, and proptosis. Pain may be associated with orbital or anterior cranial fossa erosion. Central nervous extension may result in meningeal symptoms or cranial neuropathies.[30]

### *Workup*

Following identification of an intranasal mass, imaging with CT and/or MRI is warranted to examine tumor extent. Endoscopic biopsy is necessary for histological confirmation and tumor typing. Histologically, RMS is composed of cells resembling rhabdomyoblasts. Cytologically, cells stain for proteins associated with muscle fibers including desmin, vimentin, actin, and myoglobin. The three histologic subtypes of RMS are embryonal (75% of head and neck cases), alveolar (20% of head and neck cases), and pleomorphic (> 5% of pediatric head and neck cases).

Metastatic disease most commonly involves the lungs, bones, and CNS in parameningeal disease. As such, metastatic workup includes CT chest, bone scan, and lumbar puncture.

The Intergroup Rhabdomyosarcoma Study first reported staging for RMS in 1972. The current staging from Study IV is outlined in Table 32B.5.[31]

### *Management*

Locally isolated and resectable disease is treated primarily with surgical excision. Adjunct chemotherapy is necessary because of assumed micrometastatic disease at presentation. For locally advanced tumors with significant morbidity associated with resection, combination chemoradiotherapy is indicated. Persistent or recurrent disease may be salvaged with surgery. Through the efforts of the IRS protocols, 5-year mortality for parameningeal disease is 69%.

## Esthesioneuroblastoma

### *Epidemiology and Pathophysiology*

Esthesioneuroblastoma (ENB), also referred to as olfactory neuroblastoma, is a rare malignancy of the olfactory neuroepithelium. The incidence of pediatric ENB is 1 per 1,000,000 children.[32] A bimodal distribution exists during the second and fifth generations of life. There is no identified predilection for gender.

### *Presentation*

Symptoms associated with ENB are related to the size and location of the primary tumor. Nasal obstruction is the most common symptom followed by epistaxis and nasal discharge and anosmia. Tumor invasion into surrounding structures may cause neurologic and ophthalmological symptoms. Intracranial involvement is associated with

headaches and nausea. Orbital involvement is associated with proptosis, ophthalmoplegia, and blindness.

### Workup

Intranasal examination demonstrates a red or gray mass emanating from the olfactory cleft medial to the middle turbinate. Because of the possibility of encephalocele from the same location, imaging prior to biopsy is warranted. CT and MRI can be used to delineate bony and intracranial extension, respectively. MRI findings characteristic of ENB include hypointensity on T1 with contrast enhancement and T2 hyperintensity. Intracranial involvement is associated with cyst formation at the tumor–brain interface.[33]

Histological confirmation is required with endoscopic biopsy. ENB is a vascular tumor with propensity for bleeding with biopsy. ENB are small blue-cell tumors that stain positive for S-100 and neuron-specific enolase. Electron microscopy demonstrates true rosettes (Flexner–Wintersteiner rosettes) or pseudorosettes (Homer-Wright rosettes).

Staging for ENB was first reported by Kadish in 1976. Kadish A tumors are localized to the nasal cavity. Kadish B tumors extend to the paranasal sinuses. Kadish C tumors have extension beyond the nasal cavity and paranasal sinuses. Although a TNM staging does exist, Kadish staging remains the common reference in the literature.

### Management

Because of the limited case series management algorithms for pediatric ENB are variable. Endoscopic or endoscopic-assisted craniofacial resection with or without radiation is recommended for tumors with isolated disease.[34] Locally extensive and metastatic disease may benefit from adjuvant chemotherapy, but survival rates from the largest case series have failed to show a clear survival advantage.

## Nasopharyngeal Carcinoma

### Epidemiology and Pathophysiology

Nasopharyngeal carcinoma (NPC) is the most common nasopharyngeal malignancy, representing 33–50% of cases. There is a wide distribution of age at diagnosis; however, pediatric cases are most common during adolescence.

Undifferentiated NPC is endemic to southern China, Southeast Asia, and Alaska. In these cases, there is a strong association with Epstein–Barr virus (EBV). Genetic susceptibility has also been associated with *HLA-A2*, and *HLA-B-Sin2* loci.[35]

### Presentation

Unlike other nasal and sinus tumors, the most common presentation of NPC is a painless neck mass. Associated symptoms include nasal obstruction and discharge, epistaxis, and serous otitis media. Intracranial extension is associated with neuropathies of cranial nerves III, IV, V, and VI.

High index of suspicion in Asian and African American children with a level V neck mass warrants fiberoptic nasopharyngoscopy. Endoscopic examination may vary from a discrete mass to a large mucosalized bulging mass within the nasopharynx.

### Workup

Identification of a nasopharyngeal mass warrants both imaging and endoscopic biopsy. CT and MRI are both useful in workup to identify skeletal and soft tissue involvement. Metastatic workup may include chest and abdomen CT, bone marrow biopsy, and lumbar puncture to evaluate CNS involvement. EBV titers may be prognostic for recurrence surveillance.

NPC is histologically divided into three categories based on the World Health Organization classification. Type I NPC is a keratin producing squamous cell carcinoma. Type II NPC demonstrates a nonkeratinizing carcinoma. Most common in children, type III NPC is an undifferentiated carcinoma with undifferentiated round cells with prominent nucleoli.

### Management

Because of surgical morbidity associated with nasopharyngectomy, the mainstay treatment in the pediatric population is radiotherapy or combined chemoradiotherapy in advanced disease. Surgical salvage may be utilized for locoregional control after treatment failure. Because of a propensity for advanced disease in pediatric cases, 5-year survival rates are reported from 20% to 60%.[36]

## Sinonasal Lymphoma

### Epidemiology and Pathophysiology

Primary lymphoma involving the nasal cavity and paranasal sinuses is rare. Most pediatric sinonasal lymphomas are B-cell non-Hodgkin's lymphomas (NHL). In a review of 208 patients with NHL, 8 (3.8%) children were identified to have maxillary sinus primary disease.[37] Pediatric natural killer (NK)-/T-cell neoplasms, formerly referred to as midline lethal granuloma, are rarer and

represent 1.5% of all lymphomas. There is an increased incidence among Asian and Latin American ethnicities. Case reports of metastases from nonhead and neck T-cell lymphomas have also been reported in the maxillary sinus.[38]

### *Presentation*

Nasal obstruction is the most common symptom in sinonasal lymphoma. Constitutional symptoms including fevers, night sweats, and weight loss are identified in 62% of patients with sinonasal and Waldeyer's ring lymphomas.[39] Intranasal examination reveals a regular and mucosalized mass in B-cell lymphomas, whereas NK-cell lymphoma may manifest with a necrotic and eroding mass.

### *Workup*

Endoscopic biopsy and subtyping is needed in all cases. Imaging with CT of the primary site, chest, abdomen, and pelvis for metastatic workup is warranted. Furthermore, systemic workup including bone marrow aspirate, lumbar puncture, and peripheral blood work is needed for complete staging. The most common staging tool for NHL is the St. Jude or Murphy system that accounts for nodal disease and CNS involvement.

### *Treatment*

Treatment regimens for sinonasal lymphoma are based on the histologic subtypes. Primary therapy for B-cell lymphoma is chemotherapy alone. In invasive NK-/T-cell lymphoma, there is a role for radiation therapy or surgery because of local tissue destruction.

CHAPTER

# 33

# Pediatric Sinonasal and Anterior Skull Base Surgery

***Dylan K Chan, Sanjay R Parikh***

## INTRODUCTION

Pediatric sinonasal and anterior skull base pathology represents a unique challenge for the otolaryngologist. As in adults, there has been a trend toward development of endoscopic and minimally invasive approaches to pediatric sinonasal disease, but given the anatomic limitations particular to pediatric and especially neonatal disease, knowledge of open approaches remains essential. In this chapter, we address surgical indications and techniques specific to pediatric sinonasal and anterior skull base disorders. These include congenital abnormalities, infectious and inflammatory conditions, and neoplasm.

## CONGENITAL NASAL CAVITY ANOMALIES

### Nasal Dorsal Mass

#### *Preoperative Workup*

A congenital nasal dorsal mass may represent a nasal dermoid, glioma, or encephalocele/meningocele.[1] Such lesions present either as an asymptomatic or infected nasal dorsal mass. Rarely, they present with intracranial infectious complications. Preoperative imaging with computed tomography (CT) and/or magnetic resonance imaging (MRI) is mandatory to evaluate for intracranial extension and can distinguish between a nasal dermoid, glioma, and encephalocele. Bony findings suggestive of intracranial extension include a patent foramen cecum, bifid crista galli, and widened cribriform plate, but any of these features can be present normally, especially in young infants. Soft-tissue characteristics include intrinsic signal characteristics of the mass itself, such as high intensity without gadolinium enhancement on T1-weighted MRI findings for dermoid, or T2 signal intensity for cerebrospinal fluid (CSF)-containing structures, a discrete soft-tissue tract from the mass connecting to the dura, or a frank intracranial mass. Complete absence of any of these concerning findings permits an operative plan limited to resection of the mass itself; any concern for intracranial extension requires preoperative consultation with neurosurgery and preparation of the patient for the possibility of frontal craniotomy for intracranial clearance.

#### *Operative Technique*

The extracranial component may be excised via a direct approach through an incision in the vertical midline or horizontal glabellar skin crease, or through an external rhinoplasty approach. Decision making regarding choice of technique will vary based on pathology and surgeon preference. In general, hidden incisions via intranasal or external rhinoplasty techniques are preferable for benign lesions of the nasal dorsum that may be readily accessible. Malignant or recurrent nasal dorsal lesions may be better suited with a direct incision for maximal exposure. It is unclear if one incision is better than the other to reduce postoperative comorbidities such as recurrence. Cosmetic results will be enhanced with open rhinoplasty techniques for benign pathology such as with a nasal dermoid cyst as long as any associated pit is removed.

The direct approach has the advantage of speed, convenience if a skin pit associated with the dermoid cyst needs to be excised as well, and good visualization; the disadvantage is a visible scar. The external rhinoplasty approach takes longer and may result in irregularities in

redraping of the skin envelope, but overall is cosmetically superior owing to the more-hidden columellar and intranasal incisions. Both techniques permit adequate exposure of the underlying nasal dorsal bone, which must be explored to rule out the presence of a medially directed tract.

If a very limited tract extends through the nasal dorsal bone into the nasal cavity, this may be excised and osteotomies performed via any of the external approaches. Transnasal endoscopic approaches through intercartilaginous and membranous incisions and division of the upper lateral cartilages from the septum have also been described for complete excision of nasal dermoid and subsequent exploration of a dural stalk.[2] Ultimately, biopsy and frozen section of the dural attachment is necessary to determine the necessity for intracranial exploration. Frank intracranial extension subsequently requires a coronal approach and frontal craniotomy. Finally, complete excision of combined intracranial and extracranial dermoid components has been described using a completely endoscopic anterior skull base technique, with reconstruction using autogenous fascia and pedicled nasoseptal flap. If extensive bony work and reconstruction is performed, an external nasal splint can be applied for 1-week postoperatively. Intranasal splints are not required, even if a nasoseptal flap reconstruction is performed.

### *Postoperative Follow-up*

If no intracranial component is seen or suspected upon preoperative imaging and intraoperative exploration of the nasal dorsal bone, clinical observation alone for recurrence of the subcutaneous cyst may be employed. Otherwise, an interval screening MRI at 3–6 months is advisable to evaluate for recurrent disease.

## Nasolacrimal Duct Cyst

Nasolacrimal duct cysts, which may be unilateral or bilateral, occur as a result of membranous obstruction and cystic dilation at the valve of Hasner at the inferior end of the nasolacrimal duct in the inferior meatus. These cysts can lead to significant nasal airway obstruction and respiratory distress in neonates.

### *Preoperative Workup*

Nasolacrimal duct cysts are readily identified on clinical examination, and do not require additional imaging unless there is clinical suspicion for a synchronous lesion. In addition to anterior rhinoscopy, nasopharyngolaryngoscopy should be performed to rule out synchronous lesions, especially choanal atresia. If concomitant ophthalmologic abnormalities other than mild epiphora are noted, an ophthalmology consult should be obtained. In cases of routine nasolacrimal duct cysts, however, such consultation is typically not necessary.

### *Operative Technique*

Treatment of nasolacrimal duct cyst focuses on its decompression and marsupialization; complete excision is not typically required. In the healthy neonate without respiratory distress (usually unilateral), or in those intubated in the intensive care unit (ICU) (often bilateral), this may be done at the bedside. After application of topical anesthetic, the cyst is visualized directly or endoscopically, grasped with a cup or through-cut forceps, and marsupialized and decompressed simultaneously. In situations where greater airway control is desired, or if the cyst recurs after bedside management, the procedure may be done in the operating room under general anesthesia using hand instruments, powered microdebrider, or laser for definitive decompression and marsupialization. Because nasolacrimal duct cysts are typically isolated anomalies at the valve of Hasner at the inferior end of the nasolacrimal duct, the rest of the lacrimal drainage system is typically normal, and marsupialization alone is successful. Lacrimal duct probing is not necessary for primary cases. Should the cyst recur, or should there be continued epiphora even after successful marsupialization, ophthalmology evaluation and treatment should be sought.

### *Postoperative Follow-up*

Babies typically have immediate relief of nasal congestion after cyst marsupialization. Routine clinical follow-up for observation of recurrence can be performed; no imaging is necessary.

## Piriform Aperture Stenosis

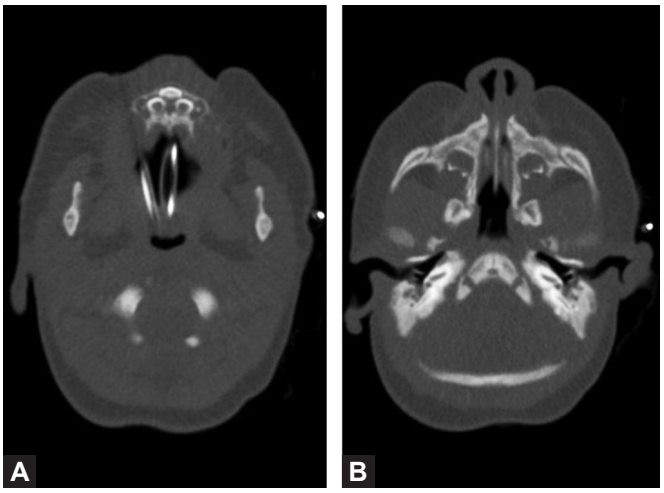
Piriform aperture stenosis is a rare cause of neonatal respiratory failure related to nasal airway obstruction. It refers to bony narrowing at the anteriormost bony margin of the nasal cavity just anterior to the inferior turbinates. Congenital piriform aperture stenosis can occur in isolation, but a significant fraction is seen as part of a spectrum of midline craniofacial developmental defects. This can be as mild as a single central mega-incisor, or as significant as holoprosencephaly.

### *Preoperative Workup*

There are no clear size criteria for operative repair for piriform aperture stenosis. Initial management should be with conservative measures to decrease mucosal edema, including a brief trial of topical decongestant such as oxymetazoline or phenylephrine (no longer than 3 days), topical steroid such as dexamethasone or prednisolone drops (no longer than 1–2 weeks), and nasal saline. Use of a McGovern nipple (a large nipple with the end cutoff) can encourage mouth breathing. These techniques can provide time to allow for growth of the facial skeleton and nasal airway, so as to avoid surgical intervention. However, should the child have persistent symptomatic nasal obstruction causing respiratory distress, failure to thrive, or significant feeding difficulties despite maximal medical management, surgical repair is indicated. Preoperative CT scan is necessary to assess the width of the piriform aperture, single central mega-incisor, and holoprosencephaly (Figs. 33.1A and B). Careful attention should be paid to concurrent dysmorphic features, and genetic analysis considered. The presence of comorbidities does not necessarily change the approach to management, except that children with more significant development abnormalities may have poorer prognosis even after successful management of the piriform aperture stenosis. All parents should be counseled as to the risk of re-stenosis, necessity for stent placement or revision surgery, and nasolacrimal duct injury.

### *Operative Technique*

The piriform aperture is exposed through a sublabial approach. Soft tissue is elevated in a subperiosteal plane to expose the face of the maxilla and inferior half of the piriform aperture without violating the mucosa of the nasal floor. The lateral nasal walls are exposed posteriorly up to and including the nasolacrimal ducts. The lateral piriform aperture and lateral nasal wall bone is drilled to widen the opening; this may be carried out as far as to expose the soft tissue of the nasolacrimal duct without violating it. The nasal spine and anterior maxillary crest may also be narrowed. Controversy exists as to whether intranasal stents are effective in preventing restenosis. Bilateral stenting carries the risk of anterior septal and columellar necrosis. Unilateral stenting is an option to maintain at least a unilateral airway, with the option for delayed treatment of any resulting septal deviation or nasal asymmetry later in life. Stents, when placed, can be fashioned with an uncuffed endotracheal tube with the milled end in the nasopharynx. No smaller than a 3.0 tube should be used, as smaller tubes are very difficult to keep patent. The stent should be secured with a stitch through the membranous septum, ensuring a downward pull on the stent toward the nasal floor so as to avoid the tendency of the stent to ride superiorly and cause pressure necrosis of the alar rim and soft tissue triangle of the nostril. Stents can be maintained for 4–6 weeks with assiduous irrigation and suctioning to ensure its patency. Our preference is for stentless repair, which has the advantage of simplicity of care, avoidance of pressure necrosis, and maintenance of nasal symmetry.



**Figs. 33.1A and B:** Piriform aperture stenosis. Axial noncontrast CT scans at the level of the anterior maxilla (A) and nasal cavity (B) demonstrate a case-specific associated single central mega-incisor (A) and stenosis of the piriform aperture (B).

### *Postoperative Follow-up*

Patients can usually be extubated immediately after this procedure, or shortly thereafter in the ICU. Systemic and topical corticosteroids can reduce edema and promote airway patency. If a stent is used, ample nasal saline irrigation and suctioning of the stent, but not beyond, is necessary. Revision surgery may be necessary should restenosis occur.

## Choanal Atresia

Failure of the bucconasal membrane to canalize in utero leads to either unilateral or bilateral membranous or bony-membranous atresia of the choanal openings.

### *Preoperative Workup*

Bilateral choanal atresia is typically suggested by respiratory failure and cyanosis relieved by crying, whereas unilateral atresia may manifest as mild respiratory distress

in infancy or persistent unilateral nasal congestion and rhinorrhea as an older child. Diagnosis is suggested by a failure to pass catheters through the affected nasal cavity and confirmed by flexible bedside endoscopy and non-contrast CT scan (Fig. 33.2). Given the association of the choanal atresia with other congenital anomalies, particularly cardiac and renal defects in CHARGE, a full preoperative workup for these conditions, including echocardiogram and renal ultrasound, should be performed prior to surgery. Attempts can be made to manage neonates with bilateral choanal atresia with an oral airway or McGovern nipple, but these babies typically require surgery within the first week of life to avoid prolonged intubation. Children with unilateral atresia can be repaired electively at an older age as symptoms dictate.

CHARGE syndrome is a particular challenge; such children often continue to have significant airway obstruction even after successful repair of the choanal atresia and eventually require tracheotomy. Many children with CHARGE have a particularly low roof of the nasopharynx; these children, as well as those without CHARGE that have this anatomic configuration, are at higher risk for restenosis and operative failure. In cases where the anatomy is particularly unfavorable, or other synchronous airway lesions are present that would likely necessitate tracheotomy, one can consider early tracheotomy and delayed repair of the choanal atresia.

### *Operative Technique*

We recommend performing a direct laryngoscopy and bronchoscopy at the time of choanal atresia repair to fully assess the airway. This permits the identification of synchronous airway lesions, which are often associated with CHARGE syndrome, and also provides valuable information should the child have persistent respiratory distress after choanal atresia repair. Children with multiple levels of upper-airway obstruction, gastroesophageal reflux disease, or unfavorable anatomy, particular a small, shallow nasopharynx, are at higher risk for surgical failure.

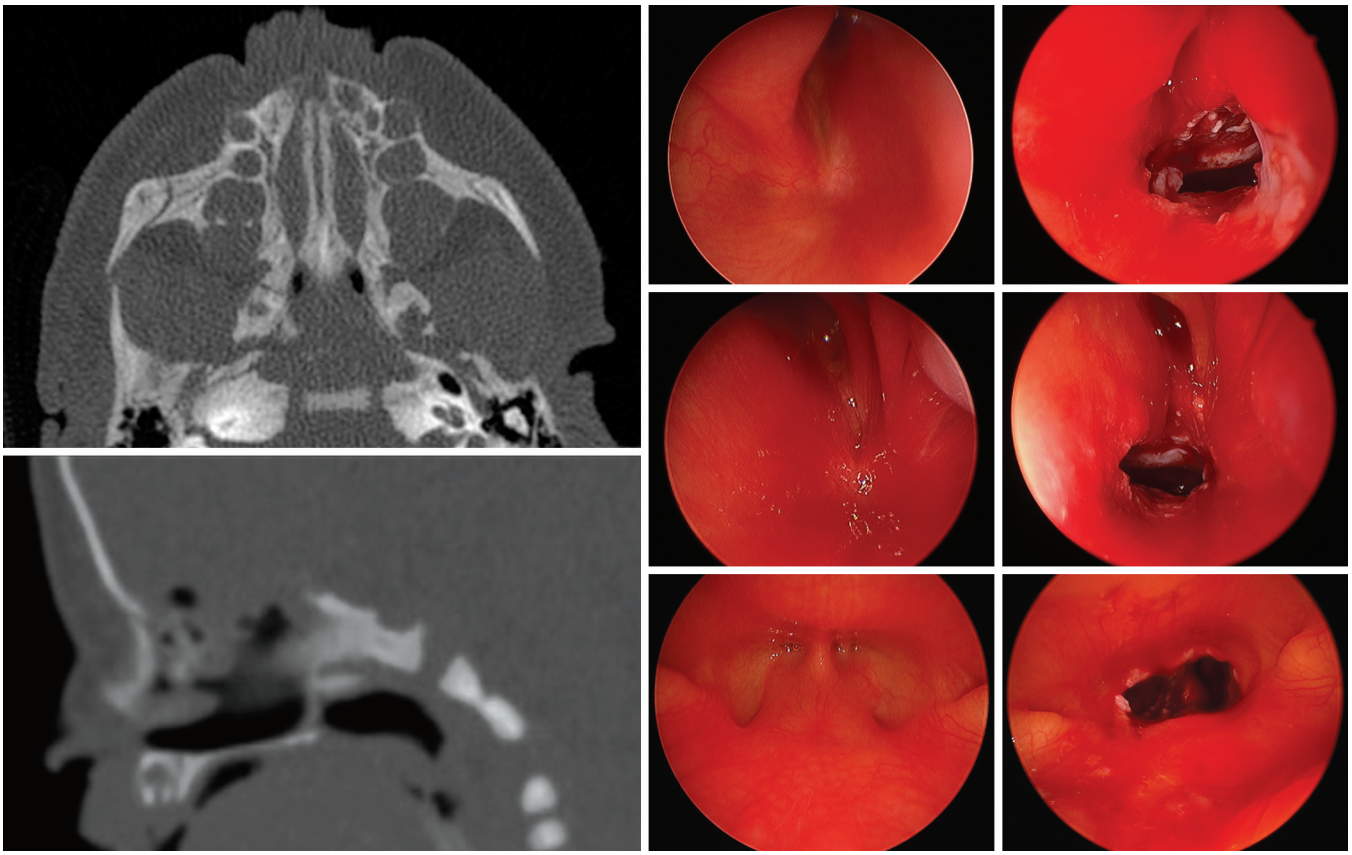


**Fig. 33.2:** Choanal atresia. Axial (top left) and sagittal (bottom left) CT images demonstrating bilateral choanal atresia. Pre- (middle column) and post- (right column) operative endoscopic images of the right (top) and left (middle) choanae from the nasal cavity, and 120° endoscopic views from the oropharynx showing the nasopharyngeal view of the posterior choanae (bottom) are shown.

Transpalatal, sublabial-transnasal, transantral, and trans-septal approaches have been described for choanal atresia repair, but are mostly of historical interest. With the advent of endoscopic instrumentation, endoscopic transnasal approaches have become standard[3] (Fig. 33.2). Image guidance can be considered, but is usually difficult to register with sufficient precision in neonates, and visual landmarks are reliable, so we do not routinely use it. Surgery consists of three phases—visualization of the defect; initial opening of the choana; and widening of the choanal aperture. Visualization is accomplished with a transnasal 2.7-mm 0° endoscope, which is typically an appropriate size for a neonatal nose. A 120° endoscope can also be used through the mouth with appropriate tongue and mouth retraction using a mouth gag to visualize the nasopharynx and posterior aspect of the choanae. The initial opening can be performed under direct visualization with the endoscope using a 7-French suction directed inferior and medial toward the atretic plate, or under visualization from behind with the 120° endoscope and ureteral sounds in the nasal cavity. Once the initial opening is made, it is widened with either standard manual or powered endoscopic rhinologic instruments. The narrowest portion of the choana may be widened by performing a posterior septectomy to achieve a confluent choanal opening, and by using an endoscopic drill to lateralize the medial pterygoid component of the choanae. As with piriform aperture stenosis, intranasal stent placement is controversial, with expert opinions ranging from completely stentless repair to unilateral or bilateral stent placement for many weeks.

### *Postoperative Follow-up*

Postoperative management is similar to that for piriform aperture stenosis, though the presence of intranasal circumferential incisions makes the risk for restenosis and subsequent need for revision surgery higher. Intranasal topical antibiotics, steroids, and saline are important, though caution must be taken with topical steroid drops in neonates, as systemic absorption is significant and can lead to steroid toxicity.

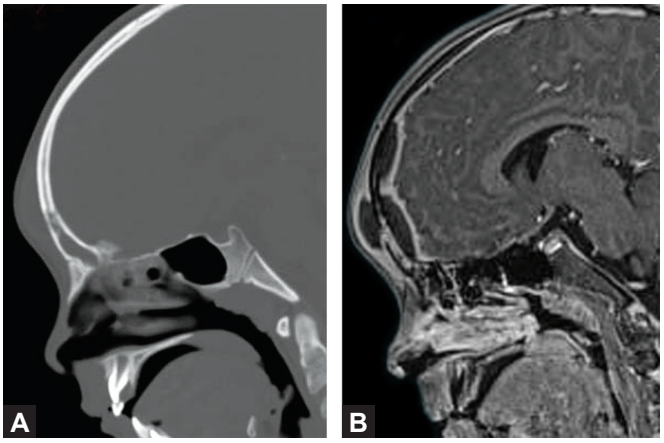
## PEDIATRIC RHINOSINUSITIS

### Acute Rhinosinusitis

Recurrent acute rhinosinusitis is very common in the pediatric population, and rarely requires surgery. However, extension of acute sinusitis into surrounding structures often necessitates surgical intervention. The most common pathways of extension are orbital, frontal subperiosteal, and intracranial. The first two of these are thought to occur primarily as a result of direct extension through bone and are usually found directly adjacent to areas of sinus opacification. Intracranial extension, on the other hand, is thought to occur via diploic veins in the frontal sinus, such that the focus of intracranial involvement may not be directly adjacent to the frontal sinus, but is still likely to be related to frontal sinusitis.

### *Preoperative Workup*

Definitive identification of the involved extra-sinonasal structures is provided by contrast-enhanced CT (for orbital and frontal subperiosteal disease) and MRI (for intracranial involvement) (Figs. 33.3A and B). Ophthalmologic consultation should be obtained for orbital involvement, to assess visual acuity, intraocular pressure, and extraocular movements. Neurosurgical involvement is necessary for extradural and intracranial disease. Discussion can be had with the consulting service regarding the option of initial medical management with intravenous antibiotics, systemic corticosteroids, topical nasal decongestion, and saline irrigation, which can be considered in cases of mild extra-sinonasal involvement, especially if the child is antibiotic-naïve. If any visual or mental status changes are present, however, or if no improvement is noted after 24–48 hours of conservative management, operative intervention is indicated.



**Figs. 33.3A and B:** Acute frontal rhinosinusitis with intracranial epidural abscess. Noncontrast CT (A) and gadolinium-enhanced T1 MRI (B) sagittal images are shown. The intracranial and frontal subperiosteal abscesses were drained directly via frontal burr hole and brow incision, respectively. Endoscopic frontal sinusotomy was performed concurrently.

### *Operative Technique*

The goals of operative intervention are twofold: (1) to irrigate and re-establish drainage pathways within the sinonasal cavity, particularly within the sinuses directly adjacent to the site of extrasinonasal involvement and (2) to directly drain the extra-sinonasal abscess, if present. Computer-guided navigation is a useful aid. The first goal is achieved through routine sinonasal endoscopic techniques for total ethmoidectomy (for orbital involvement) and frontal sinusotomy (for frontal subperiosteal and intracranial involvement). Acute inflammation can make definitive identification of the frontal recess difficult; in such cases, a mini-trephination can be performed and irrigation inferiorly through the frontal recess used to aid in its identification from below. Drainage of an orbital subperiosteal abscess can be achieved endoscopically[4] by removing the lamina papyracea after total ethmoidectomy, or through an external incision, either through the lid for a superior abscess or through a Lynch incision for a medial abscess; in neither case should the periorbita be violated. In general, small (< 6–10 mm), medial subperiosteal abscesses in younger children (< 9 years of age) with minimal proptosis (< 2 mm) and gaze restriction do well with endoscopic drainage alone. Any of these approaches is acceptable for entry through the periorbita and drainage of an orbital abscess unless there is evidence for extension lateral to the vertical plane of the optic nerve; in such cases, direct access to the orbit, such as achieved through a transconjunctival or lateral orbitotomy approach, may be required. A frontal subperiosteal abscess may be simply needle aspirated or drained directly through a small brow incision with placement of a Penrose drain. Intracranial abscesses may be drained concurrently by neurosurgery.

In general, the younger the child, the more difficult it can be to achieve safe endoscopic access due to restricted working area in light of the acute inflammation. Regardless of age, however, we first attempt endoscopic drainage, which restores natural intranasal drainage pathways and treats the source of the infection, and only resort to open approaches should the endoscopic approach fail.

### *Postoperative Follow-up*

The patient should be maintained on intravenous antibiotics and nasal saline irrigations. Use of postoperative systemic corticosteroids and topical steroids and antibiotics may be considered. Duration of intravenous antibiotic therapy depends on the severity and location of the initial infection, with intracranial abscess often requiring consultation with infectious disease and prolonged intravenous therapy with periodic MRI to follow the intracranial component. Typically, so long as continued clinical improvement is noted, the patient may be transitioned to oral antibiotics and discharged home with close otolaryngologic follow-up. Imaging is only obtained as indicated by worsening clinical signs or symptoms.

## Chronic Rhinosinusitis

### *Preoperative Workup*

True chronic rhinosinusitis, especially with polyposis, in a child is relatively unusual; in such cases, one should consider a workup for systemic disorders such as allergy, gastroesophageal reflux disease, primary immunodeficiency, cystic fibrosis (CF), and primary ciliary dyskinesia. Initial medical management with topical nasal steroid, systemic allergy treatment and antireflux management can be attempted. As the most common cause for nasal obstruction and chronic rhinorrhea in children is adenoidal hypertrophy, evaluation and surgical treatment of this should be performed prior to any consideration of more extensive sinus surgery. Only with persistence of symptoms despite maximal medical management and initial conservative adenoidectomy, and radiographic evidence of chronic mucosal inflammation and sinus opacification, should sinus surgery be considered in a child.[5] Conditions such as allergic fungal sinusitis, invasive fungal sinusitis, mucocele, antrochoanal polyp, and Samter's triad do present in children, and should be managed as they are in adults.

### *Operative Technique*

Functional endoscopic sinus surgery for chronic rhinosinusitis in children is largely similar to that performed in adults. Depending on the age of the child, the frontal and sphenoid sinuses may be not developed or underdeveloped, but otherwise the principles of mucosal preservation, restoration, or expansion of natural drainage pathways are consistent with those described in adults. Initial concerns regarding interference with midface growth by sinus surgery, suggested by animal studies, have since been repudiated by prospective studies in children.

### *Postoperative Follow-up*

Straightforward functional endoscopic sinus surgery can be performed on an outpatient basis. Postoperative antibiotics, systemic corticosteroids, and topical nasal saline,

steroid, and antibiotic drops are typically prescribed. Nasal saline irrigations are helpful, but infrequently tolerated by children. Furthermore, most children will not tolerate extensive endoscopy or even minimal debridement in the clinic. Routine "second look" endoscopy under anesthesia for these purposes has been the standard in the past, but is no longer considered to be necessary. Prospective studies have demonstrated a lack of value for "second look" endoscopy.

## Cystic Fibrosis

Children with CF almost universally have evidence of sinusitis on CT or endoscopy, but only a fraction of them have symptoms associated with it that affect their quality of life.[6] Some postulate that sinus bacterial colonization can be detrimental to pulmonary disease both in the context of active pulmonary disease and potential for reseeding after lung transplant, but these associations have not been definitively established. Primary ciliary dyskinesia is also associated with poor mucociliary clearance, and is typically managed similarly to CF with respect to sinonasal disease.

### *Preoperative Workup*

Indications for surgery are controversial, but center on symptom improvement and decreasing overall burden of bacterial disease.[7] Anesthetic complications after sinus surgery are no higher for the CF population compared to non-CF controls, and surgery can be performed on an outpatient basis, though some pulmonologists advocate preoperative pulmonary optimization and postoperative hospital admission. Orbital and intracranial complications of acute sinusitis are rare, though mucocele associated with chronic sinusitis is fairly common.

### *Operative Technique*

Children with symptomatic chronic sinusitis associated with CF will often ultimately require multiple procedures. Disease is typically characterized by profuse polyposis and relatively poorly developed sinus cavities owing to lifelong poor aeration and multiple surgeries. Surgery is directed toward debriding affected tissue and creating large confluent cavities that will be able to drain appropriately despite the impaired mucociliary clearance intrinsic to the disease, as well as to improve irrigation potential. Image navigation is a particularly helpful adjunct given the variable anatomy, especially in revision cases. Limited endoscopic medial maxillectomy (mega-antrostomy, with takedown of the midportion of the inferior turbinate to facilitate gravity-driven drainage of the maxillary sinus)[8] has been described as an effective technique to treat refractory cases. Additionally, some practitioners advocate placement of irrigation catheters in the maxillary sinus at the time of surgery and secured outside the nose, allowing for antibiotic irrigation for a few days following surgery.

### *Postoperative Follow-up*

Follow-up is as for routine chronic sinusitis, except for the high rate of recidivism and requirement for revision surgery as dictated by return of symptoms.

# PEDIATRIC SINONASAL NEOPLASM

With the exception of juvenile nasopharyngeal angiofibroma (JNA), sinonasal neoplasms are exceedingly rare in the pediatric population. For the most part, when they occur they are managed similarly as in the adult. Particular conditions and considerations specific to the pediatric population are delineated here.

## Juvenile Nasopharyngeal Angiofibroma

### *Preoperative Workup*

Diagnosis of JNA is typically made from imaging alone without definitive preoperative biopsy (Fig. 33.4). Given the highly vascular nature of the tumor, type and crossmatch for packed red blood cells is necessary even for small tumors. High-stage tumors, particularly those with involvement of the internal carotid system, should have postoperative ICU monitoring for bleeding and neurologic monitoring. Preoperative embolization by interventional radiology decreases intraoperative blood loss, and should be performed no more than 48 hours prior to surgery, lest collateral vasculature develops. Typically, only contributions from the external carotid system (most typically supply through the internal maxillary artery) can be embolized, whereas internal carotid feeders (usually through the vidian artery) are much more difficult to safely embolize. Residual blood supply after embolization is an important predictor of intraoperative blood loss and postoperative complications. Grading systems by Chandler, Fisch, Sessions, and Radkowski have historically been used to describe extent of disease, but a more recently developed system takes into account both tumor extension and postembolization residual vascularity, and has excellent predictive value for perioperative outcomes for endoscopic resection[9] (Table 33.1).

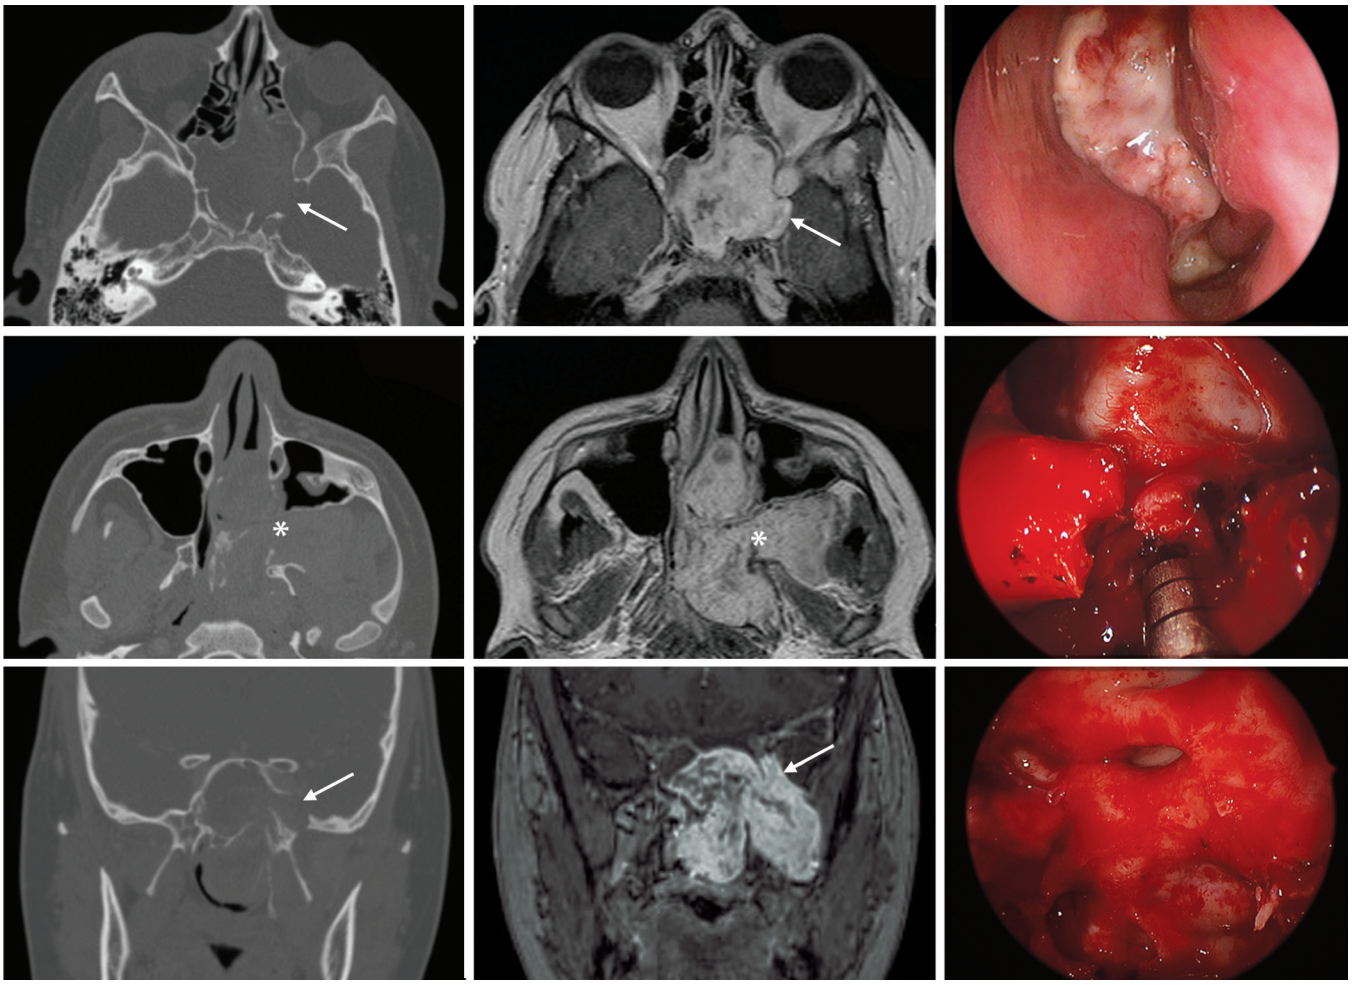


**Fig. 33.4:** Juvenile nasopharyngeal angiofibroma, stage III. Noncontrast CT (left column) and T1 gadolinium-enhanced MRI (right column) axial midorbit (top), axial midmaxillary sinus (middle), and coronal images demonstrate lateral sphenoid skull-base effacement at the medial temporal lobe (arrow), and widening of the pterygomaxillary fissure and sphenopalatine foramen (asterisks). Right column shows endoscopic intraoperative views of the tumor in the nasal cavity (top), lateral sphenoid defect (middle), and opticocarotid recess after tumor removal (bottom).

**Table 33.1:** Staging system for juvenile nasopharyngeal angiofibroma

| *Stage* | *Description* |
|---|---|
| I | Nasal cavity, medial pterygopalatine fossa |
| II | Paranasal sinuses, lateral pterygopalatine fossa; no residual vascularity |
| III | Skull base erosion, orbit, infratemporal fossa; no residual vascularity |
| IV | Skull base erosion, orbit, infratemporal fossa; residual vascularity |
| V | Intracranial extension, residual vascularity; (M: Medial extension; L: Lateral extension) |

Adapted from Snyderman et al.[9]
This staging system provides improved prediction of intraoperative blood loss, need for reoperation, and tumor recurrence, taking into account in particular primarily endoscopic endonasal approaches for resection.

## *Operative Technique*

Historically, JNA was resected using a variety of open approaches tailored to the extent of disease as determined by preoperative imaging. These included lateral rhinotomy, midfacial degloving, transpalatal, transmaxillary, Le Fort I, infratemporal, orbitocraniozygomatic, and subtemporal craniotomy approaches. With the development of improved endoscopic instrumentation and CT and MRI-based intraoperative navigation systems, there has been a trend toward endoscopic-assisted and completely endoscopic approaches[10] (Fig. 33.4). Comparable surgical outcomes in terms of intraoperative blood loss, perioperative complications, and tumor recurrence have been described with endoscopic approaches, with significantly improved length of hospital stay and postoperative

morbidity. General principles of endoscopic sinonasal and skull base surgery and the limits of endoscopic excision are described elsewhere, and apply equally to JNA. Two-surgeon, four-handed technique is recommended for all but the smallest tumors.

Particular surgical considerations are the highly vascular nature of the tumor and its characteristic blood supply pattern. Because of the tumor vascularity, centripetal dissection is recommended, with wide exposure initially and dissection and ligation of major arterial contributions prior to debulking of the mass. If initial debulking may be necessary for exposure, and can be performed with suction electrocautery, bipolar radiofrequency, or powered microdebrider. There are two major vascular pedicles. The first enters laterally from the internal maxillary artery and external carotid through the pterygopalatine fossa and sphenopalatine foramen. This contribution is often embolized preoperatively, but should also be directly ligated intraoperatively. Additionally, infiltration with local anesthetic containing epinephrine through the greater palatine foramen can provide additional hemostasis within the pterygopalatine fossa. For small, stage I tumors without significant lateral extension into the pterygopalatine fossa, the sphenopalatine artery may be exposed at its exit through the sphenopalatine foramen, which is located by incising the mucosa of the lateral nasal wall approximately 1 cm anterior to the basal lamellar insertion of the middle turbinate, elevating mucosa posteriorly, and identifying the crista ethmoidalis. The sphenopalatine foramen will lie just posterior to the crista ethmoidalis. Once the sphenopalatine artery and foramen are identified, a Kerrison rongeur can be used to remove bone of the posterior maxillary sinus wall starting at the foramen and moving laterally. As much of the posterior wall can be removed to identify the lateral extension of the tumor and artery, such that the artery is ligated lateral to the tumor. Alternatively, for larger tumors that clearly extend laterally beyond the sphenopalatine foramen an endoscopic medial maxillectomy with wide exposure and subsequent takedown of the posterior maxillary sinus wall can be performed. Dissection through the fibrofatty tissue usually reveals the artery, which can be ligated with multiple endoscopic clips at its lateralmost extent. Care must be taken to identify and preserve the maxillary nerve ($V_2$), which courses through the pterygopalatine fossa, usually superior and deep to the internal maxillary artery as it travels toward foramen rotundum.

The second major arterial contribution enters posteriorly near the face of the sphenoid through the vidian canal, which can be exposed with a posterior septectomy, contralateral wide sphenoidotomy, and ipsilateral posterior ethmoidectomy and partial resection of the middle and superior turbinates. It is typically not possible to directly ligate these contributions owing to obstruction by the tumor mass, but centripetal tumor removal toward the face of the sphenoid permits controlled dissection and hemostasis as this vascular pedicle is approached within the vidian canal. The endoscopic drill can be used to follow the vidian canal posteriorly to ensure complete tumor removal at this site, which is to most typical for persistent disease. Bleeding in this region is common, and can be controlled with hemostatic foams, packing, and judicious electrocautery.

Additional access may be required for lateral and superior extension toward the infratemporal fossa and superior orbital fissure, respectively. This may be achieved via a sublabial Caldwell-Luc approach, or an anterior septal window, which provides an improved angle of access and instrumentation laterally.

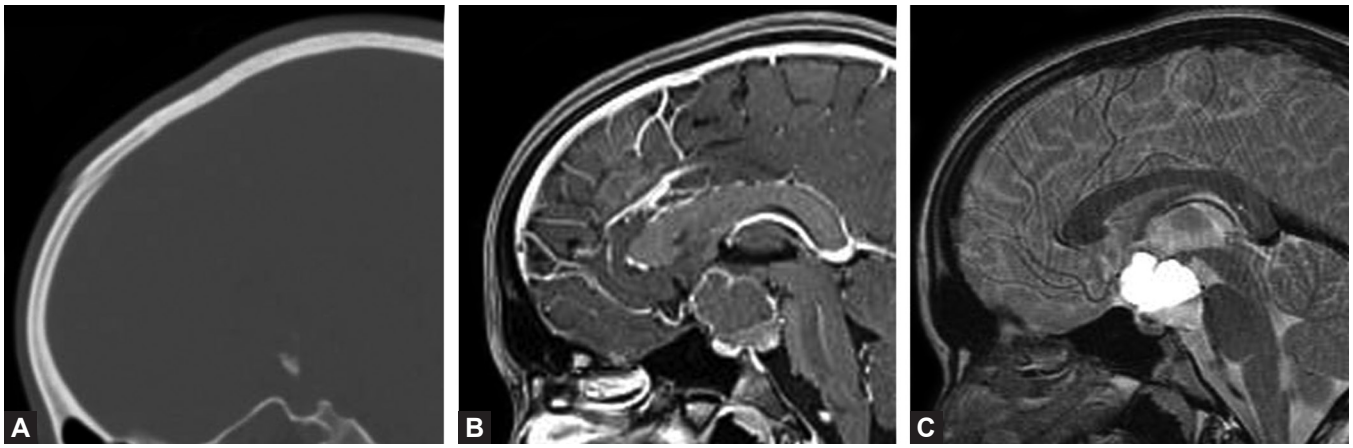
Need for reconstruction of a skull base defect can be predicted somewhat based on preoperative imaging; if it is thought to be necessary, an ipsilateral or contralateral nasoseptal flap should be elevated and placed in the nasopharynx for use or replacement at the end of the case as necessary. Packing of the operative site is determined on a case-by-case basis depending on the concern for postoperative hemorrhage. For stage III and IV tumors, multiple rounds of surgery and embolization may be required.

### *Postoperative Follow-up*

Because of the typically extensive exposure and dissection required for tumor extirpation, saline irrigation and clinic debridement is advocated to maintain sinonasal hygiene and promote remucosalization. Tumor surveillance is typically performed by nasal endoscopy and MRI at 3–6 months after surgery and thereafter as suspicion warrants.

## Other Skull Base Lesions

Skull base pathology is rare in children, and can be classified as neoplastic/cystic (craniopharyngioma (Figs. 33.5A to C), Rathke cleft cysts, chordoma, or pituitary adenoma) or structural (CSF leak, encephalocele or meningocele), and are approached surgically as they are in adults. A major concern with traditional open approaches to the skull base in children is disruption of growth centers and subsequent altered craniofacial development. Thus, pediatric skull base surgery has followed the trend of increasing use of endoscopic endonasal techniques for extirpation



**Figs. 33.5A to C:** Craniopharyngioma. Noncontrast CT (A), T1 gadolinium-enhanced MRI (B), and T2 MRI (C) sagittal images are shown. Drainage of the associated cyst was performed via an endoscopic trans-sphenoidal approach, with immediate relief of optic nerve compression.

and reconstruction, which theoretically can lead to less disruption of craniofacial growth centers compared to open approaches. Endoscopic skull base surgery has particular challenges in children, owing primarily to the small size of the operative field and relative under-pneumatization of the paranasal sinuses; however, the majority of pathology occurs in adolescents, whose sinonasal anatomy approaches that of adults.

Early case series have demonstrated the efficacy and safety of endoscopic skull base surgery in children, with oncologic outcomes, symptom resolution, and complication rates comparable to those achieved with open approaches.[11] In particular, rates of complications such as intracranial infection, CSF leak, major vascular injury, and cranial neuropathy are similar between adult and pediatric endoscopic skull-base surgery, and between open and endoscopic skull base approaches; diabetes insipidus and other endocrinopathies have been suggested to be more frequent with endoscopic compared to open resection of craniopharyngioma, and sinusitis may be more prevalent after endoscopic skull base surgery in children compared to adults. However, given the rarity of these cases, definitive comparisons are impossible to make at this time.

## *Craniopharyngioma*

Craniopharyngiomas are rare benign brain tumors of childhood that arise from Rathke's pouch (the embryologic precursor of the anterior pituitary gland). Although not typically locally aggressive, they may grow indolently adjacent to the pituitary gland with destruction and compression of local neurovascular structures. Presenting symptoms include headache, visual field change (bitemporal hemianopsia), visual acuity change, and diplopia. Compression of the pituitary gland may lead to endocrinopathies. Diagnosis is suspected with imaging in the forms of MRI and/or CT scan and confirmed with biopsy.

The ideal treatment algorithm for a craniopharyngioma is controversial in children with some favoring radical excision with local neurovascular preservation while others favor biopsy followed by narrow field radiation. For either excision or biopsy, transnasal trans-sellar approaches are currently favored although trans-septal techniques are still equally efficacious.

Post-treatment short-term or long comorbidities include headache, CSF leak, visual impairment, and pituitary-related endocrinopathies such as syndrome of inappropriate antidiuretic hormone secretion.

## *Pituitary Neoplasia*

Pituitary neoplasias are rare in childhood and the vast majority are benign in nature consisting of a pituitary adenoma. Such adenomas are typically functional with hypersecretion of an associated hormone. Children often present with the sequelae of increased production of the hormones prolactin, cortisol (Cushing's syndrome), or growth hormone.

Diagnosis is confirmed by sellar exploration with biopsy and excision of adenoma. Approaches to the sella include the classic trans-septal approach and the currently more popular endonasal trans-sphenoidal approach. Sellar exploration and biopsy of the adenoma is often both diagnostic and therapeutic sometimes obviating the need for additional intervention. Patients may be monitored for recurrence by imaging and by regular endocrine evaluation.

### *Congenital Anterior Skull Base Defects*

Congenital defects of the anterior skull base may present in infancy or later in life. As infants are congenital nasal obligate breathers, meningoceles or meningo-encephaloceles may present early in life. Smaller or acquired lesions may present later when patients experience unilateral nasal obstruction, anosmia, or headaches. Rarely, there may be a spontaneous CSF leak related to skull base defect.

Treatment for congenital anterior skull base defects vary depending on the lesion, age of the child, and surgeon preference. Endonasal approaches are advancing for the transnasal removal of protruding nonfunctional dural/brain tissue along with concurrent skull base repair with either autologous or synthetic membranes. Vascular flaps such as the nasoseptal flap have also been demonstrated to be useful for such a repair. In smaller children, endonasal approaches may not be possible secondary to nasal space limitations so traditional subfrontal craniotomy approaches may be appropriate to identify and repair anterior skull base defects.

## CONCLUSION

Surgery in the sinonasal cavity and skull base in the pediatric population presents unique challenges. Nevertheless, a variety of open and endoscopic techniques exist to address the wide range of pathology and anatomy found in children.

CHAPTER

# 34

# Evidence-Based Medicine in Pediatric Rhinology

***Eleni M Benson, Emily F Boss***

## INTRODUCTION

Chronic rhinosinusitis (CRS) is common in children and frequently encountered in primary care and pediatric otolaryngology clinics alike. CRS can have a significant negative impact on child health and quality of life.[1,2] Management is initially medical, with surgical therapy reserved for cases that fail to respond to maximal medical therapy. Indications for surgery as well as outcomes of surgical intervention are poorly defined, with limited available evidence largely restricted to variable outcome measures and small, nonrandomized, single-institution studies.

## CRS IN CHILDREN: CONSIDERATIONS FOR SURGICAL THERAPY

When considering children as candidates for surgical management of CRS, diagnostic accuracy is a critical first step for the clinician to interpret and apply existing evidence-based treatment paradigms. CRS in children is defined as 12 weeks or more of ongoing symptoms including nasal obstruction or nasal discharge with either facial pressure or cough.[3] CRS should be differentiated from acute rhinosinusitis, acute bacterial rhinosinusitis, recurrent acute bacterial rhinosinusitis, and exacerbations of allergic rhinitis (discussed elsewhere in this text).[4]

There are unique considerations in the pediatric population that should be kept in mind. The impact of the disease on the patient's quality-of-life must be ascertained from the caregiver and patient, and expectations of medical and surgical outcomes frankly discussed. Decision making should be shared among the clinician, the caregiver, and the child when appropriate. When treating children with CRS, it is also important to remain cognizant of possible undiagnosed or untreated comorbid conditions, such as asthma, gastroesophageal reflux disease, allergic rhinitis, cystic fibrosis (CF), primary ciliary dyskinesia (PCD), or immune deficiencies.[3,5-7] The clinician should also ensure that the child's vaccinations are up to date.[3,8]

## INDICATIONS FOR SURGERY

There are no established clinical practice guidelines for surgical management of pediatric CRS, and current practice is based largely on expert opinion, small cohort studies, and individual surgeon preference and experience. Indications include a failure of "maximal medical therapy", which is not well defined but typically includes some medley of saline nasal lavage, prolonged antibiotics, topical and/or oral corticosteroids,[3] antihistamines, and leukotriene inhibitors.

## PATIENT SELECTION AND SURGICAL TREATMENT OPTIONS

Current surgical interventions for CRS primarily consist of adenoidectomy and endoscopic sinus surgery (ESS). Other procedures are largely of historical interest in the United States, including inferior antral windows and the Caldwell-Luc maxillary antrostomy via the supra-canine fossa window.

Following failure of medical management, adenoidectomy is generally employed as first-line surgical therapy, with ESS then performed for persistent symptoms. In 1995, Rosenfeld described a "stepped treatment approach" that proceeded to sinus CT scan and immunological workup only if symptoms persisted after adenoidectomy. If the CT revealed ostiomeatal complex disease, conservative ESS including maxillary antrostomy and anterior ethmoidectomy would then be performed.[9] A 2005 survey of 175 members of the American Society of Pediatric Otolaryngology confirmed that the majority of clinicians use some variation of this algorithm.[10] In some cases, simultaneous adenoidectomy and ESS or ESS alone may be indicated and beneficial rather than the stepwise approach.[11]

These principals apply to treatment of uncomplicated CRS without underlying systemic disease such as CF, PCD, or immune deficiency. In these scenarios, surgical therapy is considered an important adjunct to medical therapy and can be beneficial or even necessary, but is unlikely to result in permanent disease control as monotherapy.[5-7] Approach and outcomes vary in the setting of systemic disease, and are beyond the scope of this chapter.

## EXISTING CLINICAL PRACTICE GUIDELINES

There are several existing clinical practice guidelines that address pediatric CRS in various capacities with no specific recommendations for surgical intervention. The *American Academy of Pediatrics (AAP) 2001 Clinical Practice Guideline: Management of Sinusitis*[12] is geared toward primary care physicians and primarily emphasizes diagnostic criteria for the various categories of rhinosinusitis and appropriate use of antibiotics. There are recommendations to refer to a specialist for surgical management of suppurative complications, but no clear recommendations for surgical intervention for CRS. This guideline also includes indications for imaging in children, with an emphasis on the futility of plain films in the diagnosis of ARS or CRS in children (Table 34.1). The *American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) 2012 Clinical Consensus Statement: Appropriate use of Computed Tomography for Paranasal Sinuses Disease* pediatric sinusitis statements[13] also include recommendations for appropriate use of imaging studies in pediatric rhinosinusitis with no specific surgical guidelines.

Other related guidelines include the American Academy of Otolaryngology—Head and Neck Surgery (AAO-HNS) Clinical Practice Guideline 2007 for Adult Sinusitis[14] which excludes pediatric patients, and the European Position Paper on Rhinosinusitis and Nasal Polyps 2012[3] which provides medical treatment recommendations for children but does not comment on surgery in the pediatric population.

## MEASURING OUTCOMES IN TREATMENT OF PEDIATRIC CRS

Current outcomes measures for surgical management of CRS include quality-of-life (QoL) assessment tools, radiographic imaging, and nasal endoscopy (Table 34.2). Procedural efficacy is in part difficult to evaluate due to a paucity of standardized outcome measures, with inconsistent reporting of outcomes in the literature. In addition, none of the existing outcome measures account for comorbidities of CRS such as asthma, atopic disease, immunologic disorders, PCD, and CF.

**Table 34.1:** Existing imaging guidelines for pediatric rhinosinusitis

| *Guideline* | *Imaging indications* | *Imaging cautions* |
|---|---|---|
| AAP 2001[13] | Persistent/recurrent infections not responsive to medical therapy<br>Suspected complication of RS<br>Surgical planning | ≤ 6 years old: rarely necessary; symptoms correlate to radiographic studies 88% of time<br>High rate (near 100%) of false positives in children with recent URI |
| AAO-HNS 2012[14] | Failure of medical management and/or adenoidectomy<br>Suspected tumor<br>Suspected complication of RS<br>Surgical planning<br>MRI: immunocompromised patient, concern for invasive fungal disease | CT limited by radiation safety concerns, sedation<br>< 3 years old: not indicated for uncomplicated ARS without appropriate prior management<br>Not indicated for uncomplicated cold of < 10 days duration |

(AAP: American Academy of Pediatrics; RS: Rhinosinusitis; URI: Upper respiratory tract infection; AAO-HNS: American Academy of Otolaryngology—Head and Neck Surgery; ARS: Acute rhinosinusitis).

**Table 34.2:** Outcome measures for evaluating disease severity and surgical effectiveness in pediatric rhinosinusitis

| *Outcome measure* | *Strength* | *Limitation* |
|---|---|---|
| Symptoms | Obtained from caregiver | Nonspecific<br>Subjective<br>Difficult to assess in younger age groups<br>Overlap with other childhood conditions: allergic rhinitis, recurrent viral URIs, chronic adenoiditis, Eustachian tube dysfunction |
| CT | Sensitive and specific in predicting persistent rhinosinusitis in known disease[15] | Radiation exposure<br>Mucosal inflammation can be nonspecific<br>Cost<br>Possible need for anesthesia |
| Nasal endoscopy | Direct visualization<br>Anatomic abnormalities<br>Access for cultures, debridement<br>Avoid radiation | Poorly tolerated in children; pain, bleeding<br>Poor inter/intra rater reliability<br>Second look endoscopy unhelpful[16] |
| Quality of life | Minimal risk<br>Specific to intended outcome (i.e. improved QoL) | Subjective caregiver perceptions may be biased; evaluation by parent proxy<br>Paucity of validated instruments; most common disease-specific instrument in children is the SN-5[15,17] |

(CRS: Chronic rhinosinusitis; URI: Upper respiratory infection; QoL: Quality of life).

## Quality-of-life Instruments

QoL instruments are easily obtained and administered to the caregiver. As CRS is a disease that severely impacts health-related QoL in children, these instruments are useful in specifically addressing the pertinent sequelae of CRS. However, QoL instruments are subject to caregiver interpretation and bias, and there is a paucity of CRS-specific instruments validated for use in children.

The SN-5 is a commonly used CRS-specific instrument that has been validated for use in children. It is a caregiver-completed questionnaire assessing five domains of sinonasal disease on a Likert scale, including sinus infection, nasal obstruction, allergy symptoms, emotional distress, and activity limitations. The SN-5 is specific to pediatric CRS and may be useful in the development of evidence-based guidelines in the future.[2,17]

Other QoL instruments are available that are specific to CRS but not validated for use in children,[18-22] or specific to children and related to but not specifically addressing CRS,[23] such as the S-5 score for acute sinusitis.[24] Finally, many global QoL questionnaires are validated for use in children and may be broadly applied to CRS but lack specificity; one example is the Child Health Questionnaire.[1]

## CT Findings

Several measures of disease severity are based on CT findings alone. CT is useful in children for the assessment of disease recalcitrant to medical management, surgical planning, and to assess for complications of rhinosinusitis; however, its utility as a measure of assessing treatment efficacy is limited by safety concerns over radiation exposure and its high rate of false positives in children with recent symptoms of upper respiratory infection (*see* Table 34.1).[12] CT should be used judiciously in the pediatric population to help guide clinical decision making and surgical planning in properly selected patients.

The Lund–MacKay score, developed for adults, is a scale of 0–24 with 0–2 points for each sinus (0 = no opacification, 2 = complete opacification) and for ostiomeatal complex disease.[25] In children with known paranasal sinus disease, it was found to be 86% sensitive and 85% specific in predicting persistent rhinosinusitis using a cutoff score of ≥ 5 for CRS.[15] However, it fails to account for adenoid disease that is an important component of CRS in children.[9] The Pediatric Rhinosinusitis CT Scoring System was developed for children but has not been widely applied or substantiated. This system scores 0–3 for each side of the paranasal sinuses: 0 if no opacification, 1 if < 50% opacified, 2 if > 50% opacified, and 3 if completely opacified.[26]

## Nasal Endoscopy

Second-look nasal endoscopy has been used in the past to examine and debride the nasal cavity in the 2–4 weeks

following ESS.[27] While this provides direct visualization of the operative site, it is also invasive and may require additional general anesthesia in young children. It has not been shown to impact improvement or resolution of symptoms,[16] and the correlation of nasal endoscopy with symptomatology is unclear.[28,29]

## EVIDENCE-BASED MEDICINE: ADENOIDECTOMY FOR CRS

The adenoid pad contributes significantly to pediatric CRS, and adenoidectomy is generally considered first line surgical therapy for medically refractory disease (Table 34.3). The adenoid pad is often hypertrophied in children causing obstruction of the nasal airway. The adenoid pad has also been shown to serve as a bacterial reservoir,[33] so that adenoidectomy may provide symptom relief even if a small amount of tissue is removed.[9] In Rosenfeld's stepwise approach, a prospective cohort of 41 children with CRS was treated first with antibiotics, followed by adenoidectomy for patients in whom antibiotics failed, and finally ESS if these measures did not provide relief and/or the adenoids were scant. 67% of children in this study experienced improvement of all major symptoms after antibiotics, 75% after adenoidectomy, and 100% after ESS.[9]

A 2008 meta-analysis of adenoidectomy in children with medically refractory CRS found that 69% of patients significantly improved after adenoidectomy when measured by caregiver report of symptoms. The study concluded that adenoidectomy should be considered first-line therapy for pediatric CRS unrelieved by appropriate medical therapy.[30]

## EVIDENCE-BASED MEDICINE: ENDOSCOPIC SINUS SURGERY FOR CRS

ESS with enlargement of the natural drainage pathways of the maxillary and ethmoid sinuses is considered by many otolaryngologists to be definitive surgical intervention for CRS. ESS is more invasive than adenoidectomy with a risk of potentially significant complications (*see* Table 34.3). For these reasons, ESS is reserved by many specialists for disease that is unresponsive to medical therapy and adenoidectomy.

Most trials of ESS for CRS in children are retrospective and single institution, with variable outcome measures used to determine surgical efficacy. Existing studies report success rates of 82–100% with complications of 0.6–1.4% in children.[31,32] There is similarly limited evidence for ESS in adults, with a 2006 Cochrane review concluding that available studies do not definitively demonstrate superiority of ESS to medical treatment.[34]

Several trials compare ESS with adenoidectomy or with combination ESS and adenoidectomy (Table 34.4). Ramadan et al. in a prospective, nonrandomized trial found improvement in symptoms at 12 months in 87% of patients undergoing both ESS and adenoidectomy, compared with 75% and 52% of patients after ESS alone and adenoidectomy alone, respectively ($p < 0.0001$).[11] However, another prospective study using the SN-5 for outcome measurement found no difference in ESS with or without adenoidectomy versus adenoidectomy alone, although both groups experienced improved outcomes compared with patients receiving no surgical intervention.[17] Existing studies are of unclear significance in a nonrandomized and single institution setting.

**Table 34.3:** Advantages and limitations of adenoidectomy and ESS for pediatric CRS

| *Intervention* | *Advantage* | *Limitation* |
|---|---|---|
| Adenoidectomy | 50–80% improvement[30]<br>Simple<br>Low risk<br>Short recovery | Controversy: older children with small adenoid pad<br>May require additional surgery if symptoms persist |
| ESS | 82–100% success rate in selected patients[31,32]<br>Complication rate 0.6–1.4% in experienced hands[31,32] | Higher risk<br>Requires pediatric specialist<br>Multiple postoperative visits<br>Requires preoperative CT<br>No RCTs |

(ESS: Endoscopic sinus surgery; CRS: Chronic rhinosinusitis; RCT: Randomized controlled trial).

**Table 34.4:** Selected studies evaluating ESS outcomes for pediatric CRS

| *Reference* | *N* | *Study* | *Findings* |
|---|---|---|---|
| Rosenfeld[9] | 41 | Prospective, nonrandomized stepwise approach:<br>1. Antibiotics<br>2. Adenoidectomy<br>3. ESS | Improvement in major symptoms at 10–12 months: antibiotics group 67%; adenoidectomy group 75%; ESS 100% |
| Ramadan[11] | 183 | Prospective, nonrandomized ESS vs. ESS + adenoidectomy vs. adenoidectomy alone | Improvement in symptoms at 12 months: ESS + adenoidectomy 87%; ESS 75%; adenoidectomy 52% |
| Chang[35] | 101 | Retrospective | Improvement in symptoms at 23.6 months after ESS: 86% |
| Lusk[36] | 67 | Retrospective<br>Medical therapy vs. ESS | Improvement in pediatric rhinosinusitis CT score at 10 years: medical therapy 69%; ESS 97% |
| Rudnick[15] | 22 | Prospective<br>ESS +/– adenoidectomy vs. adenoidectomy alone | Improvement in SN-5 score at 6 and 24 months: equal for two cohorts |
| El Sharkawy[28] | 81 | Prospective<br>ESS for CRS with allergy, without allergy, and with polyposis | Improvement at mean 28 months in clinical, radiographic and endoscopic findings: predicted by adenoidectomy, second look operation, extent of preoperative disease on CT scan<br>Overall success rate 88% |

(ESS: Endoscopic sinus surgery; CRS: Chronic rhinosinusitis).

## NEW TECHNIQUES

Balloon catheter sinuplasty (BCS) is a new technique that is potentially less invasive than traditional ESS. A preliminary retrospective single institution study demonstrated nonsignificantly improved overall sinus symptoms for BCS compared with ESS, with significant decreases in antibiotic requirement, sinus congestion, and headaches in the BCS group.[37] The use of BCS has not been validated in children and further studies are needed to support its widespread utilization.

## CONCLUSION

CRS can significantly impact health, behavior, and QoL in children. There is limited evidence establishing efficacy of surgical intervention in pediatric CRS, and current practice is largely based on expert opinion and experience. Still, there are widespread reports of symptomatic and clinical improvement, as measured by a variety of outcome measures, following surgery for children who fail maximal medical management. A step-wise approach with initial medical therapy followed by adenoidectomy in refractory cases is most widely accepted. ESS is often used as an adjunct to adenoidectomy or in cases where adenoidectomy fails to relieve symptoms, with promising preliminary results. Further research including well-designed randomized controlled prospective trials and use of validated outcome measures is crucial in delineating the optimal algorithm for surgical management of pediatric CRS.

# Pediatric Aerodigestive Care

CHAPTER

# 35 Developmental Anatomy of the Unified Airway

*Jennifer M Lavin, James W Schroeder Jr*

## INTRODUCTION

Knowledge of the developmental anatomy of the upper and lower respiratory tracts (unified airway) is essential to understanding airway pathology. The signs and symptoms of these disease processes can be attributed to distortion of normal anatomic structures and physiological processes. In this chapter, the embryologic development of the upper and lower respiratory tracts will be described, and the comparative anatomy between the infant and adult airway will be discussed. After this discussion, pathology associated with deviations from this normal development will be highlighted.

## THE LARYNX

The larynx is located at the point where the combined aerodigestive tract separates into distinct airway and digestive systems. Thus, the larynx most importantly acts as a valve that protects the lower airway from aspiration. In addition to this role, the larynx is also involved in respiration and phonation. To effectively carry out these functions the larynx has developed into a complex organ under both voluntary and reflexive neurologic control.

## PRENATAL DEVELOPMENT

After conception, prenatal development is separated into the embryonic and fetal periods. The embryonic period is defined as the first 8 weeks of gestation and the fetal period is defined as the period from 8 weeks gestation until birth.[1] At the completion of the embryonic period, the precursors to all organs are formed. Development in the embryonic period is separated into 23 stages by the Carnegie staging system. In this system, each stage has at least one aspect that is not found in the previous stage. Laryngeal development begins in the fourth week and has eight phases. These phases occur between Carnegie stages 11 and 23 (Fig. 35.1). The mucosa of the larynx develops from endoderm, and the laryngeal muscles and cartilages are derived from the mesenchyme of the fourth and sixth branchial arches.[3]

In the first phase of laryngeal development (Carnegie stage 11), the respiratory primordium forms as a thickening of the epithelium of the ventral foregut. At this point, the lumen of the foregut is patent.

During phase II (Carnegie stage 12), the respiratory diverticulum arises as an outpouching of the patent lumen of the foregut. This portion of the foregut is the primitive pharyngeal floor that will develop into the glottis. The superior extent of the respiratory diverticulum becomes the infraglottic region.[4] Finally, in this stage, two bronchopulmonary buds form off the respiratory diverticulum. These buds later become the lower respiratory tract.

In phase III (Carnegie stages 13–14), the respiratory diverticulum and primitive pharynx migrate cranially and the bronchopulmonary buds migrate caudally.[5] This leads to the formation of the trachea and further separates the upper and lower respiratory tracts. At the same time, the esophagus is also lengthening posterior to the developing trachea.

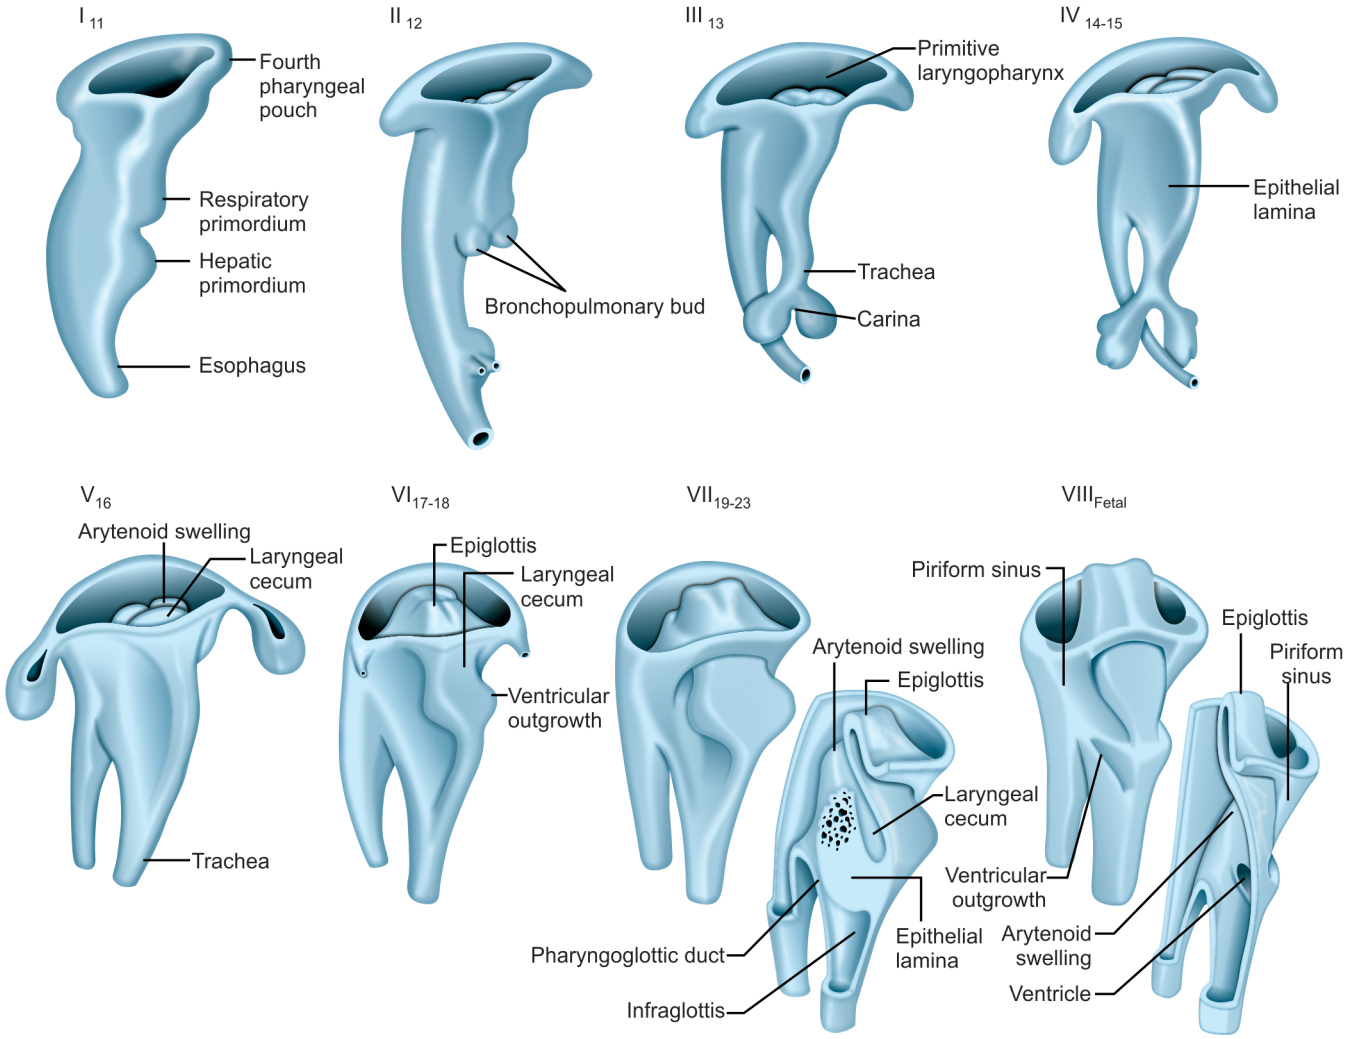

**Fig. 35.1:** The eight phases of laryngeal development within the corresponding Carnegie stages. Adapted from Kakodkar et al.[2]

In phase IV (Carnegie stage 15), the pharyngeal mesoderm, consisting of precursors of laryngeal cartilages, muscles, and arteries, compresses the developing airway cephalic to the respiratory diverticulum up to the level of the fourth pharyngeal pouch.[4] This begins to obliterate the lumen of the airway in this region and forms the epithelial lamina.

In phase V (Carnegie stage 16), obliteration of the primitive laryngopharynx continues from ventrally to dorsally due to the developing epithelial lamina, leaving only a narrow pharyngoglottic duct at the dorsal most extent. During this stage, the arytenoid swellings and epiglottis also become apparent and a depression between these structures called the laryngeal cecum forms. It should be noted that, as mentioned above, the glottis forms from the primitive pharyngeal floor as part of the tracheobronchial anlage. In contrast, the structures of the supraglottic larynx develop more superiorly as part of the buccopharyngeal anlage. This difference in anatomic origin accounts for the different lymphatic drainage patterns found in these two regions of the larynx.

In phase VI (Carnegie stages 17–18), the laryngeal cecum descends further caudally to the level of the glottic region. In phase VII (Carnegie stages 19–23), recanalization of the epithelial lamina begins. This occurs in a dorsocephalic to ventrocaudal direction with the ventral glottis being the last portion to recanalize. This process is due to reorganization and growth of cells as opposed to actual cell loss and is complete by the eighth postovulatory week.[6] During this phase, the recurrent laryngeal nerve is

innervating the transitional area between the laryngopharynx and esophagus, most of the laryngeal muscles are present and the muscular innervation is close to its mature form.[6,7]

In phase VIII (fetal period), the laryngeal ventricles, saccules, and vocal processes of the arytenoid cartilage form. The ventricles are formed by outpouchings of the laryngeal cecum. At this point, recanalization is complete and continuity between the supraglottic and subglottic airway is reestablished. For the remainder of gestation, the larynx continues to grow and its neurologic reflexes are formed. Differentiation of the myenteric plexuses and ganglion cells occurs by week 13, and by week 16, the fetus begins to swallow amniotic fluid. Elastic cartilage forms in the epiglottis and the corniculate cartilages form in the fifth and sixth month. At this point in gestation, fetal breathing and laryngeal movement is present. In a study by Kalache et al., it was determined that there was a linear relationship between gestational age and the diameter of the larynx, pharynx, and trachea on prenatal ultrasound.[8]

## POSTNATAL DEVELOPMENT

### The Adult Larynx

The skeleton of the larynx is made up of the thyroid and cricoid cartilages. The thyroid cartilage is composed of two alae that are fused in the midline and open on the posterior surface. The angle of fusion of the alae in women is more oblique than in men. The cricoid cartilage is the only complete ring in the airway.[9,10] The shape of the cricoid cartilage has been described as a signet ring with the anterior portion measuring 3–7 mm in height and the posterior portion measuring 20–30 mm in height.[1,11,12] Attached to the inside of the thyroid cartilage is the epiglottis. This structure is made of elastic cartilage and functions to prevent swallowed material from penetrating into the airway.

The paired arytenoid cartilages are pear-shaped and articulate on the posterior surface of the cricoid cartilage. At the apex of the arytenoid cartilage lies the corniculate cartilage. Lateral to the corniculate cartilage, within the aryepiglottic fold, lies the cuneiform cartilages.[13] While these structures do not articulate with the arytenoid cartilages, it is theorized that they may provide rigidity to the aryepiglottic fold.[14] In the adult, the inferior aspect of the cricoid cartilage is located at the level of C7.

Ossification of the laryngeal framework occurs throughout development. It should be noted that only hyaline cartilage ossifies so the epiglottis never undergoes this process.[15] The hyoid bone is completely ossified by 2 years of age. The thyroid cartilage ossifies at 20 years in males and later in females. This process starts on the posteroinferior aspect and then extends anteriorly and superiorly. Ossification of the cricoid cartilage occurs beginning on the inferior border and occurs later in life. Similarly, arytenoid cartilage ossification occurs after thyroid cartilage ossification begins.

The muscles of the larynx can be divided into intrinsic and extrinsic muscles. The intrinsic muscles all have insertions and attachments that are contained within the laryngeal framework. The intrinsic muscles of the larynx, which act to abduct and adduct the vocal cords, all attach to the arytenoid cartilages. The extrinsic muscles of the larynx work to elevate and depress the larynx.

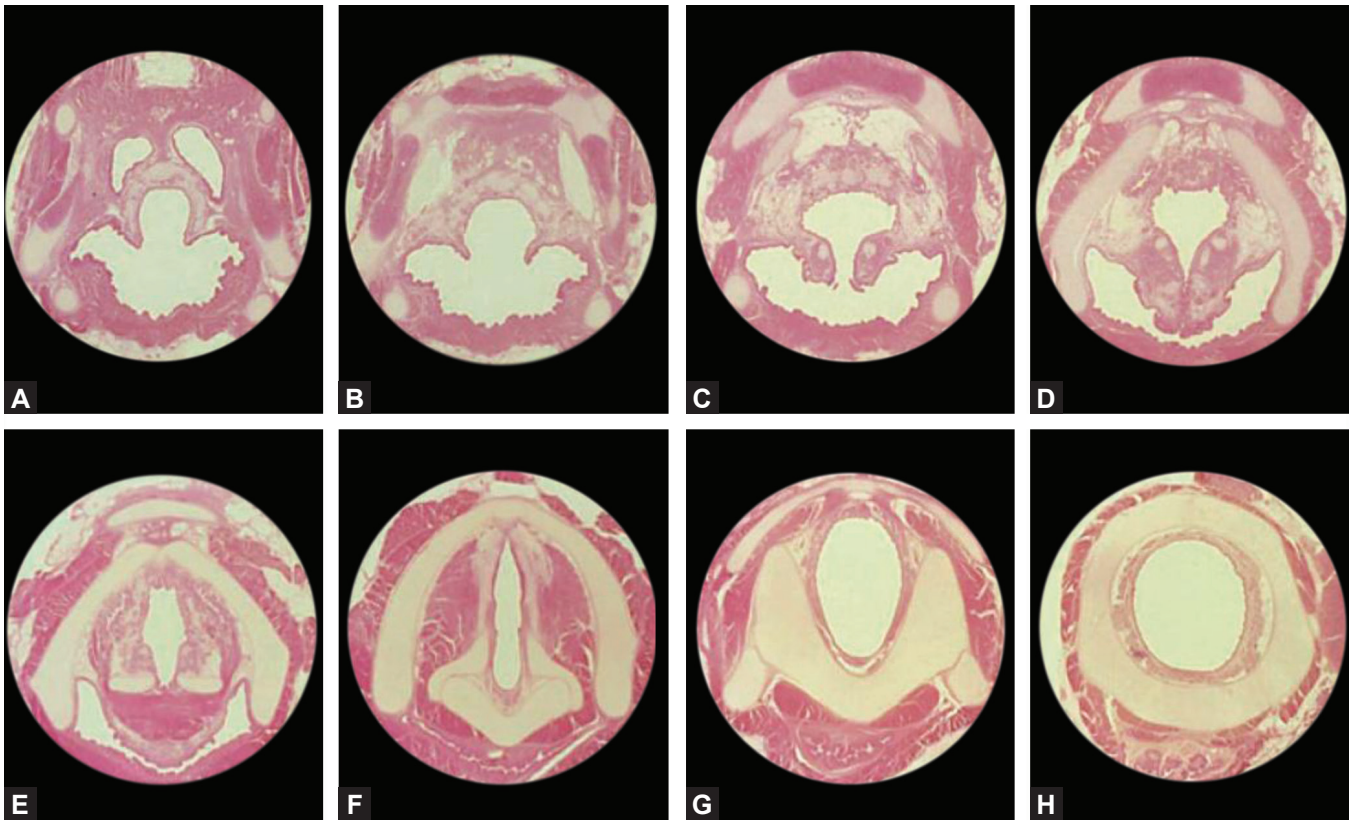
The overall structure of the larynx can be divided into the supraglottis, the glottis, and subglottis. The supraglottic larynx consists of all structures bounded by the epiglottis superiorly and the midpoint of the laryngeal ventricle (the space between the true and false vocal folds). The glottis extends from the midpoint of the laryngeal ventricle to 1 cm below the true vocal folds. Located anteriorly at the level of the laryngeal ventricle lies the saccule. Obstruction of this region results in saccular cysts and occasional airway obstruction. The subglottic airway begins at this point and extends to the lower border of the cricoid cartilage.

### The Infant Larynx

There are several features that vary between the infant and adult larynx (Figs. 35.2A to H). It is essential to understand these differences in anatomy as the presentation of common pathology and the management of the pediatric airway differ due to this varied anatomy.

The position of the infant larynx in the neck with respect to the cervical spine is different than in on adult. At birth, the infant epiglottis is located at the level of C1 and the inferior portion of the cricoid cartilage is at C4. This more superior positioning allows the epiglottis to make contact with the soft palate, facilitating more efficient respiration during feeding. This elevated laryngeal positioning causes the infant to be an obligate nasal breather.[16] As the child grows, the laryngeal framework travels inferiorly.

The infant larynx also varies from the adult larynx with respect to its size and shape. The larynx at birth is one third the size of the adult larynx. Also the proportional size of laryngeal subsites is different in infants and adults.



**Figs. 35.2A to H:** Axial sections through the larynx of an 18-month old from the superior aspect of the epiglottis to the inferior aspect of the cricoid cartilage. (A) At the level of the epiglottis. Note the omega-shape; (B) At the level of the thyroid cartilage. Note the position of this structure posterior to the hyoid bone; (C) The laryngeal saccule as it travels superiorly; (D) Additional depiction of the hyoid location anterior to the thyroid notch; (E) The laryngeal saccule at the level of the false vocal folds. Note the location medial to the thyroid cartilage; (F) The superior portion of the posterior cricoid cartilage; (G) Mid cricoid cartilage; (H) Inferior cricoid cartilage. From Kakodkar et al.[2]

In the infant, the vocal process of the arytenoids makes up about one-half of the glottis. In the adult larynx, this process occupies up to one fourth of the length of the glottis (Fig. 35.3).[18] The soft tissue of the posterior glottis, and the cuneiform cartilages also are proportionally larger in the infant.

The cartilage and submucosal soft tissue of the infant larynx is more pliable than in adults. The looseness of the submucosal soft tissues of the infant larynx can allow for increased edema and loss of airway diameter during states of increased inflammation.[19]

The infant epiglottis is more omega shaped than the adult epiglottis. The thyroid cartilage is flatter in the infant larynx and the superior portion of the thyroid cartilage is posterior to the arch of the hyoid (Fig. 35.4). The cricothyroid membrane is more slit like in infants. Therefore, endotracheal intubation or tracheotomy over a rigid bronchoscope instead of cricothyrotomy is the preferred course for the emergency management of the infant airway. The lumen of the airway at the level of the glottis is pentagonal during inspiration. At the level of the cricoid, the airway is more elliptical with the wider diameter in the anterioposterior direction.[2] The cricoid cartilage is the narrowest portion of the infant airway, whereas the glottis is the narrowest portion of the adult airway.[17] This accounts for the biphasic nature of stridor in infants and young children presenting with croup.

## ASSOCIATED PATHOLOGY

### Posterior Laryngeal Clefts

Posterior laryngeal clefts (PLC) arise secondary to failure of fusion of the posterior cricoid lamina and tracheoesophageal septum, causing an abnormal communication between the larynx and hypopharynx and the esophagus. The incidence of laryngeal clefts is believed to be 1 in 10,000–20,000; however, the incidence is increasing likely

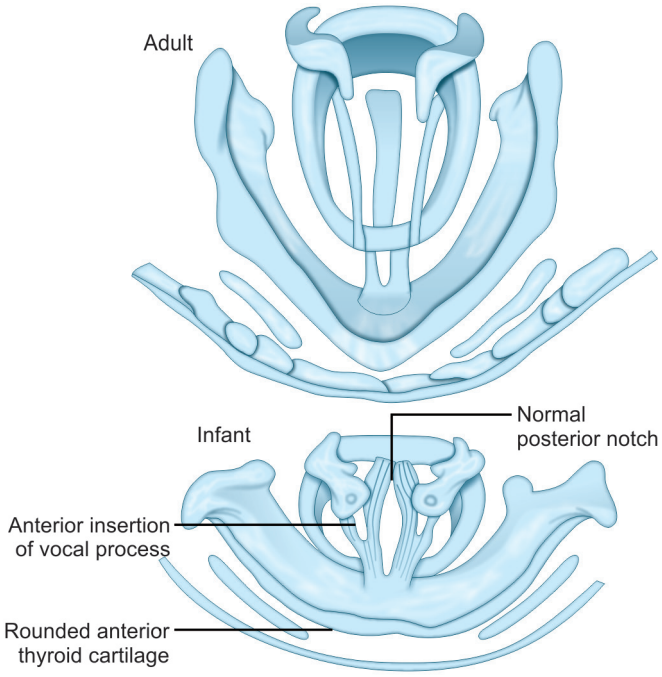


**Fig. 35.3:** Axial view of the adult and infant larynx. Note the relatively large arytenoids and the rounded nature of the thyroid cartilage in the infant larynx when compared to the adult larynx. Adapted from Cunningham.[17]

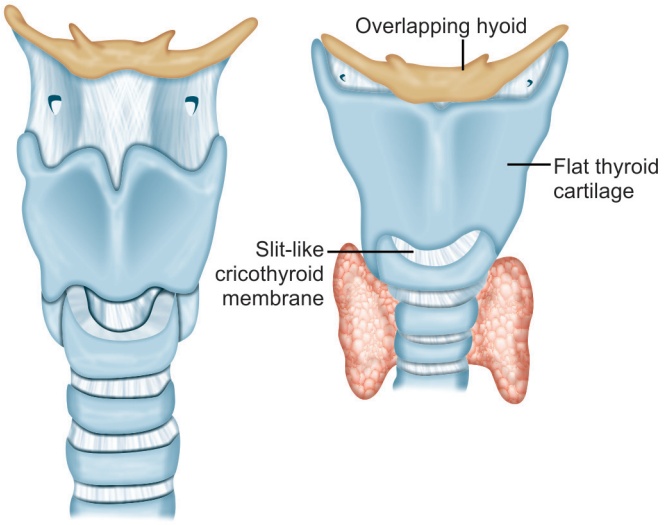

**Fig. 35.4:** Anterior view of the adult and infant larynx. The hyoid bone overlaps the superior portion of the thyroid cartilage and the cricothyroid membrane is slit like in the infant. Adapted from Cunningham.[17]

due to a higher index of suspicion by clinicians.[20,21] Syndromes such as Pallister-Hall and Opitz-Frias syndromes are associated with PLCs.[22]

Patients with PLCs may present with symptoms of choking resulting from aspiration with feeding. Many patients are referred to the pediatric otolaryngologist after a videofluoroscopic swallow study has demonstrated laryngeal penetration or aspiration. The gold standard for diagnosis of PLC is microlaryngoscopy with palpation of the posterior larynx.

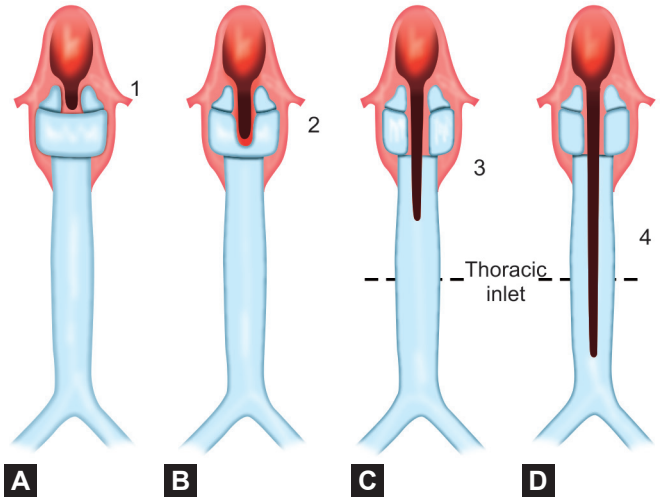
The most widely used grading system of PLC is that described by Benjamin and Inglis (Figs. 35.5A to D).[20] Type 1 clefts represent a defect in interarytenoid soft tissue that does not extend below the level of the true vocal cords. In type 2 clefts, the defect extends into the cricoid lamina below the level of the true vocal cords. Type 3 clefts are defined by extension though the entire cricoid lamina and possibly the cervical trachea. Type 4 clefts extend into the thoracic trachea.

The treatment of PLC is dependent on the severity as many small clefts are asymptomatic and do not require intervention. Most type 1 PLC can be managed medically by managing the dysphagia with thickened feeds but some need to be managed surgically via an endoscopic approach. Bakthavachalam et al. recommended endoscopic repair in patients with severe symptoms or symptoms after age two.[21] More severe clefts can be managed surgically via a transcervical approach.

## Laryngeal Atresias and Webs

Laryngeal atresias and webs occur secondary to failed or incomplete recanalization of the epithelial lamina during phase VI of laryngeal development. In laryngeal atresia, there is complete failure in recanalization of the epithelial lamina. Unless a tracheoesophageal fistula (TEF) is also present to allow for enough respiration to perform tracheotomy, the death rate at birth is high.

Laryngeal webs represent incomplete recanalization of the epithelial lamina and are located anteriorly due to the posterior to anterior direction of the recanalization process. Some webs are thin and may be lysed on intubation of the infant at time of respiratory distress. More commonly, anterior glottic webs are thick and with subglottic extension. Treatment of these thicker webs requires open reconstruction of the anterior commissure or keel placement. Congenital glottic webs have been associated with 22q11 syndrome.[23]



**Figs. 35.5A to D:** Posterior laryngeal clefts. (A) Type 1, with lack of extension into cricoid cartilage; (B) Type 2, with extension into the lamina of the cricoid cartilage; (C) Type 3, with extension through the entire cricoid cartilage; (D) Type 4, with extension into the thoracic trachea. Adapted from Benjamin and Inglis.[20]

## Congenital Subglottic Stenosis

Congenital subglottic stenosis is defined as stenosis of the airway that is present at birth. It is the third most common congenital laryngeal anomaly.[19] Subglottic stenosis can be grouped into two types: cartilaginous or soft tissue. Deformities of the cricoid cartilage and trapped first tracheal rings cause cartilaginous subglottic stenosis. The elliptical cricoid cartilage was first described by Tucker et al. and represents the most common cause of subglottic stenosis by an abnormally shaped structure.[24] When there is an elliptical cricoid cartilage, the transverse diameter of the subglottis is less than the anterioposterior diameter, resulting in a decreased cross-sectional area. The elliptical cricoid has also been known to be associated with a trapped first tracheal ring.[24]

Presentation of subglottic stenosis varies with the degree of airway narrowing. Patients with severe stenosis often present at birth with stridor and respiratory distress, whereas patients with mild stenosis may be asymptomatic or present later in life after recurrent episodes of croup. Diagnosis of subglottic stenosis is made by imaging, endoscopy, and sizing of the airway with endotracheal tubes. A full discussion of the treatment of subglottic stenosis is beyond the scope of this chapter, but in patients with stenosis causing 50% or greater narrowing of the airway surgical management may be required.[25]

## THE LOWER AIRWAY

The lower airway includes the trachea, bronchial tree, and lungs. Knowledge of the developmental anatomy of the lower airway is important because pathology of the tracheobronchial tree can directly affect the upper airway. For example, patients with acquired subglottic stenosis often have this condition secondary to a prolonged intubation due to prematurity and bronchopulmonary dysplasia.

## PRENATAL DEVELOPMENT

Development of the lower airway is separated into five periods: the embryonic, pseudoglandular, canalicular, terminal sac, and alveolar. The first four periods occur entirely prenatally whereas the last period starts prenatally and continues after birth. The initial events in the development of the tracheobronchial tree occur during the embryonic period and are the same as those in the development of the larynx. During Carnegie stage 12, the bronchopulmonary buds form off of the respiratory diverticulum. The location of this lung bud is directed by fibroblast growth factors. During Carnagie stage 13-14, the lung buds migrate caudally. Prior to this migration, there is communication between the lung buds and the foregut (Figs. 35.6A to C).[3] However, when the lung buds travel caudally, two tracheoesophageal ridges form creating a separation between the developing airway from the foregut. These two ridges fuse in the midline to form the tracheoesophageal septum, creating the trachea and lung buds anteriorly and the esophagus posteriorly.

At the time of separation of the airway from the foregut, two outpouchings form at the distal extent of the primitive trachea. These bronchial buds lengthen and become the right and left mainstem bronchi. On the right, three secondary bronchi form. On the left, two form. These secondary bronchi later become the right upper, middle, and lower lobes and the left upper and lower lobes.

The trachea and lung buds continue to migrate caudally until they enter the primitive thorax. Next, the visceral and parietal pleura are formed and the space between the two pleura becomes the pleural cavity.

During the pseudoglandular period, which occurs between gestational weeks 5–16, branching of the tracheobronchial tree continues. In a study performed on rats by Yoshimi et al., this branching is at least partially dictated by homeobox b3 and b4 genes.[26] During this period, the

primitive lung acts more like an endocrine gland and it has no potential for respiration. If a fetus is delivered at this time, it is thus not viable.

The canalicular period occurs between gestational weeks 16-26. During this period, the lumen of each bronchiole enlarges in size and branching of the tracheobronchial tree continues with seventeen subdivisions occurring by the end of the sixth month of gestation.[3] Respiratory bronchioles are formed by the 19th intrauterine week, which then branch to form alveolar ducts.[27] These divisions result in progressively smaller airways that have more intimate connection to an increasing number of blood vessels. This association between the airways and blood supply is what permits the respiratory function of the lung, which is possible near the end of this period.

During the terminal sac period, which occurs between 26 weeks and birth, the terminal sacs, or primitive alveoli, form and capillaries continue to maintain close contact with these airways. Surfactant is produced by the primitive alveoli during this period, which reduces surface tension in the alveoli. Surfactant initially begins to be secreted at 23–24 weeks and its production is sufficient by 28–32 weeks. In the fetal lung, glucocorticoid receptors are present throughout the tissue and stimulation of these receptors induces production of surfactant-associated proteins and may stimulate cell maturation and differentiation.[28]

## POSTNATAL DEVELOPMENT

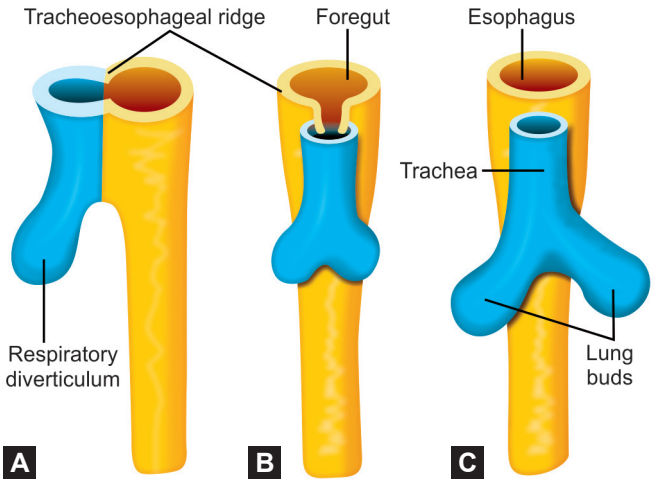
### The Adult Lower Airway

The trachea is the portion of the airway that lies between the inferior aspect of the cricoid cartilage and the carina. The adult trachea's length varies based on gender and height but ranges from 10–14 cm long and is comprised of 16–20 cartilaginous rings.[29] The diameter of the trachea ranges from 12–23 mm, but this diameter varies during breathing and coughing and in changes in head and neck position and intrathoracic pressure.[30] The cartilaginous rings of the trachea are incomplete and the posterior wall of the trachea is membranous. The membranous trachea is made of the trachealis muscle as well as fibroelastic tissue. In the normal trachea, the ratio of the cartilaginous to membranous trachea is 4.5:1.

At the carina, the trachea bifurcates and forms the right and left mainstem bronchus. The right main bronchus has a more vertical course, branching at 25°, whereas the left mainstem bronchus branches at 45°.[22] This accounts for the fact that aspirated foreign bodies are often found in the right mainstem bronchus. Like with the trachea, the mainstem bronchi have incomplete cartilaginous rings.

In normal anatomy, the mainstem bronchi separates into three lobar bronchi on the right and two lobar bronchi on the left. The right mainstem bronchus bifurcates into the right upper lobe bronchus and the bronchus intermedius that then bifurcates into the right middle and right lower lobe bronchi. On the left, the mainstem bronchus bifurcates into the left upper lobe and left lower lobe bronchus. Further branching forms segmental bronchi that are anatomically more variable than that of the lobar bronchi. On the right, the right upper lobe bronchus branches into anterior, posterior, and apical segments. The middle lobe bronchus becomes the medial and lateral segments. The lower lobe bronchus becomes the superior segment, and the medial, anterior, lateral, and posterior basal segments. On the left, the upper lobe bronchus splits into the upper and lingular divisions. The upper division has anterior and apicoposterior segments. The lingular division forms superior and inferior segments. The lower lobe bronchus splints into the superior segment and the anteromedial, lateral and posterior basal segments. Instead of having cartilaginous rings, the lobar, segmental, and more distal bronchi have cartilaginous plates.[31]

With further division, bronchioles and alveoli are formed. At the level of the bronchioles, the airways no longer contain cartilage. Gas exchange occurs at the level of the alveoli, which have intimate association with capillaries.



**Figs. 35.6A to C:** Formation of the tracheoesophageal septum. (A) Lateral view of the formation of the tracheoesophageal ridges; (B) Anteroposterior view of the formation of the tracheoesophageal ridges; (C) Fusion of the tracheoesophageal ridges in the midline to form the tracheoesophageal septum. Adapted from Sadler.[3]

## The Infant Lower Airway

In full-term newborns, the normal trachea is 4 cm long and 4–5 mm in diameter.[32] The trachea in neonates is more complaint than the adult form and it collapses more easily. At the carina, the tracheal bifurcation is less acute in infants than in adults. The alveolar sacs and alveoli are not in their mature form until after birth.[27] This maturation of the alveoli is called the alveolar period of lung development and starts at 8 months gestation and continues into childhood. During this time, intimate associations between alveolar epithelium and capillary endothelium continue to develop and alveolar septa mature. By 1.5 years of age, alveolar septa are in the adult form, where an isolated capillary network and connective tissue stabilize the interalveolar wall.[33]

# ASSOCIATED PATHOLOGY

## Complete Tracheal Rings

Complete tracheal rings are a congenital tracheal anomaly where complete rings replace the normally C-shaped cartilage of the trachea. This results in a narrowing of the normal tracheal diameter and is the most common cause of congenital tracheal stenosis. Complete tracheal rings can be found in only a few rings or it can extend throughout the entire trachea or even into the mainstem bronchi. Slide tracheoplasty has been described as a means of surgical management for this anomaly.[34]

## Tracheomalacia and Vascular or Cardiac Anomalies

Knowledge of the anatomy of the great vessels is important to the otolaryngologist because external compression of the tracheobronchial tree can be due to variations in normal anatomical structures. Tracheomalacia is defined as the narrowing of the tracheal walls and can be defined as primary or secondary. Primary tracheomalacia exists when the defect is due to the trachea itself. In this case, the ratio of the cartilage to membranous trachea may be reduced to 3 to 1 or 2 to 1, and the membranous trachea demonstrates dynamic collapse during respiration. In secondary tracheomalacia, the tracheal walls are narrowed secondary to extrinsic compression, often from vascular anomalies (Fig. 35.7). Similarly, bronchomalacia can be primary or secondary in nature with the secondary form often being secondary to vascular or cardiac anomalies. These anomalies are described below.

### *Aberrant Innominate Artery*

Compression of the trachea by an aberrant innominate artery can be seen on the right anteriolateral wall of the superior portion of the trachea. Compression in this region results in a triangular appearance of the tracheal lumen on endoscopy. If one lifts the tip of the bronchoscope against this area of narrowing, the right brachial pulse will become weaker.

Patients with an aberrant innominate artery may present with symptoms ranging from croup-like cough, expiratory stridor and wheezing, to apneic spells. If obstruction is severe, resulting in apparent life-threatening events, recurrent pneumonia secondary to impaired clearance of secretions, surgical management in the form of innominate arteriopexy may be required. In this procedure, the innominate artery and aorta are suspended from the sternum. In most patients, however, no surgical management is necessary because obstruction is not frequently severe.

### *Double Aortic Arch*

The double aortic arch is rare and is caused by the persistence of both fourth branchial arches and both

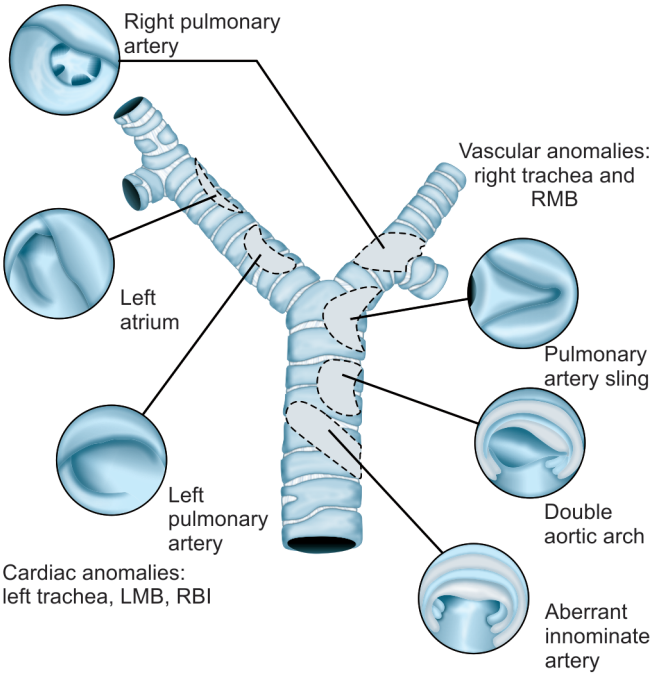


**Fig. 35.7:** Schematic representation of the tracheobronchial tree with the typical endoscopic appearance and location of extrinsic compression of the airways from vascular and cardiac anomalies. Adapted from Kakodkar et al.[2]

dorsal aortas. The result is a complete vascular ring that encircles both the trachea and the esophagus. Typically, the right arch is dominant and posterior to the trachea and esophagus, whereas the left arch is hypoplastic and anterior to these structures. The apex of the right arch is typically more superior to the left arch. The two arches join distally to form the descending aorta, which remains on the left.

Patients with a double aortic arch display symptoms, often at birth, that are secondary to tracheal or esophageal compression. This condition can be diagnosed by esophagram, echocardiography, CT scan, or MRI. It should be noted that both CT and MRI are better at establishing the relationship between the vessels, trachea, and esophagus and are preferred for preoperative planning. After surgery, patients' respiratory symptoms frequently resolve; however, it may take 1–2 years for symptomatic improvement in some patients.[19]

### *Pulmonary Artery Sling*

The pulmonary artery sling is a congenital anomaly where the normal left pulmonary artery is absent. Instead, the left pulmonary artery arises from the right pulmonary artery and travels between the trachea and the esophagus. This results in compression of the right mainstem bronchus and the right side of the lower trachea, which is visible on endoscopy as a slit-like lumen. As with double aortic arch, this results in symptoms of airway obstruction. Treatment of this anomaly involves division and reimplantation of the pulmonary artery and results in an improvement of symptoms.[35]

### *Congenital Cardiac Anomalies*

Compression of the airway can also be caused by congenital cardiac defects that lead to left-to-right shunts and result in pulmonary hypertension. This results in enlargement of the pulmonary arteries, which leads to compression of the left main bronchus. Cardiac defects associated with left-to-right shunts that lead to pulmonary artery hypertension and airway compression include ventral septal defects and patent ductus arteriosis.[35]

Patients with airway compression secondary to pulmonary artery hypertension present with varying symptoms depending on the degree of obstruction. These symptoms are similar to the obstructive symptoms found in the other vascular anomalies above. Treatment of the airway symptoms in these patients involves treating the underlying pulmonary hypertension.

## Tracheoesophageal Fistula and Esophageal Atresia

A congenital TEF is an anomaly, where there is an abnormal communication between the trachea and the esophagus. TEFs may or may not be associated with esophageal atresia, where the esophagus ends in a blind pouch either in its proximal extent, distal extent, or both. The incidence of TEF is estimated to be 1 in 3000–5000 live births. Five types of TEF have been described (Fig. 35.8), with type C being found in 80–86% of cases.[36,37] In type C TEF, proximal esophageal atresia with a distal TEF is found. Type E, or H-type fistulas, are more rare but occasionally go undiagnosed until later in life.[38,39] One proposed mechanism of TEF formation is vascular compromise as the trachea and esophagus are lengthening prenatally.

Patients with TEF and esophageal atresia typically present with feeding difficulties including aspiration, and respiratory difficulties. In the setting of proximal esophageal atresia, polyhydramnios may be found on prenatal ultrasound. Treatment of TEF and esophageal atresia is surgical. Postoperative complications include tracheomalacia, esophageal strictures, recurrent fistulas, and reflux.

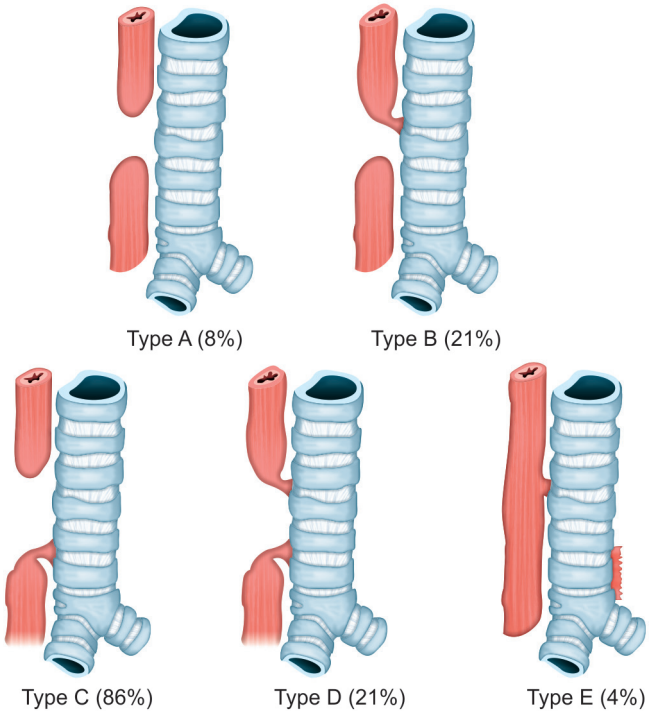

**Fig. 35.8:** The five types of tracheoesophageal fistula. Type C, with proximal esophageal atresia and a distal tracheoesophageal fistula is the most common. Type E, or the H-type fistula may be diagnosed later in life. Adapted from Kakodkar et al.[2]

## SUMMARY

- The unified airway undergoes developmental changes both prenatally and postnatally. Understanding the developmental anatomy of these structures leads to better understanding of the pathology that arises due to deviations from this normal development.
- Development of the larynx occurs in eight stages, seven of which occur during the embryonic period.
- At birth, the infant larynx has several structural differences when compared to the adult larynx. The infant epiglottis is omega shaped and the arytenoid process occupies a larger portion of the infant glottis. The cricothyroid membrane is less developed and the thyroid cartilage lies underneath the hyoid bone in infants.
- Deviations from normal laryngeal development lead to PLC, subglottic stenosis, and laryngeal atresias and webs.
- Development of the lower respiratory tract forms the tracheobronchial tree and promotes maturation of the lungs. Maturation of alveoli continues after birth.
- Congenital cardiovascular anomalies can lead to extrinsic compression of the trachea and mainstem bronchi, resulting in symptoms of airway obstruction.

CHAPTER

# 36

# Imaging of the Pediatric Airway

***Nikhila Raol, Christopher J Hartnick, Matthew R Naunheim***
***Robert Liu, Hugh D Curtin, Paul A Caruso***

## INTRODUCTION

While imaging in otolaryngology is invaluable in helping with diagnosis and with delineation of surgical anatomy, several considerations are needed when considering imaging in a child. Radiation risks and the need for sedation are among the most critical issues that differ between obtaining radiographic studies in children and adults. This chapter discusses some of the salient points about imaging in the pediatric population, as well as outlines how to decide which type of imaging is preferred based on clinical presentation. Lastly, it will describe how to interpret the studies and how to use them appropriately to help in making a diagnosis.

The initial portion will discuss the various types of imaging used and considerations specific to each type.

The clinical portion is arranged by clinical scenario in alphabetical order and includes:

- Dysphagia
- Infection
- Nasal obstruction
- Obstructive sleep apnea (OSA)
- Stridor
- Velopharyngeal insufficiency (VPI).

## PART I: IMAGING MODALITIES

The modalities most commonly used to image children with airway disorders are presented in alphabetical order for ease of reference. Special considerations for the different modalities are then reviewed.

### Computed Tomography

CT imaging is versatile and can be useful in a variety of scenarios, including defining the extent of infection, identifying a mass in or adjacent to the airway, delineating vascular anatomy, and clearly demonstrating bony anatomy. In the pediatric population, however, the benefit of CT must be weighed against the risk of radiation exposure.

Diagnostic CT increases the risk of malignancy in exposed children. Standard of care practice aims to reduce radiation dose in the workup of children.

#### *Terminology*

The quantity $CTDI_{vol}$ (Volume CT Dose Index) is currently used in CT dosimetry.[1] When a scan is prescribed, the scanner displays the $CTDI_{vol}$ in mGy on the console. The dose displayed, however, is not the dose for the specific patient under examination. Instead, the $CTDI_{vol}$ represents the average dose in the central section of a standardized phantom scanned with the selected protocol.[2] The head phantom is an acrylic cylinder with a diameter of 16 cm and a height of 15 cm.

The effective dose $E$ is used to assess the radiation detriment from partial-body irradiation (e.g. irradiation of only the head or only the abdomen). The effective dose is a weighted sum of the doses to all exposed tissues. $E = \Sigma(w_t \times H_t)$, where $H_t$ is the equivalent dose to a specific tissue and $w_t$ is the weight factor representing the relative radiosensitivity of that tissue. The unit of effective dose is sievert (Sv). The effective dose for a typical CT examination of the airway using the airway survey

protocol described above is about 1 mSv (i.e. 1/1000 Sv). In comparison, the average effective dose from cosmic rays, radioisotopes in the soil, radon, etc., is about 3.11 mSv per year in the United States. The effective dose can be estimated from the dose-length product (DLP = $CTDI_{vol}$ × scan length), which is also displayed on the CT scanner console. The effective dose for a head study in mSv is approximately 0.0021 × DLP (mGy cm) for an adult and approximately 0.0067 × DLP (mGy cm) for a 1-year-old patient.[1]

### *Factors Influencing Patient Dose*

The CT scanning protocols should be optimized such that the quality of images is sufficient for diagnosis and the patient dose is kept as low as reasonably achievable (ALARA). To get the best balance of the image quality and patient dose, it is important to understand the effects of imaging parameters on the dose and imaging quality.

Patient dose depends on three group factors: equipment related factors, patient related factors, and application related factors.

The factors in the first group include X-ray beam filtration, X-ray beam collimation, system geometry, and detector efficiency. Although users do not have control of most of these factors, it is important to understand that the z-axis dose efficiency is reduced when the total X-ray beam width becomes very small for multidetector CT due to the need to keep the beam penumbra out of any detector row.

The dose is strongly dependent on patient size. If the same technique is used to image the heads of an average adult and a newborn, the dose to the newborn is significantly higher.

Imaging parameters such as kVp, mAs (the product of the tube current and the time in seconds per rotation), and pitch (the table travel per rotation divided by the total X-ray beam width) are selected by the operator.

If all other parameters are fixed, the patient dose is proportional to the effective mAs which is defined as the mAs (mA × seconds per rotation) divided by the pitch.

The dependency of dose to kVp is more complicated. In general, the dose increases as a power function of kVp ($D \sim kVp^p$) if all other parameters are fixed. The value of p is in the order of 2–3 depending on the type of the scanner.

### *Image Quality*

Image quality is characterized by spatial resolution, contrast resolution, image noise, and other quantities. It is difficult to use a single variable to characterize completely the quality of an image. In practice, image noise has been widely used to judge the CT image quality since the detectability of low-contrast objects is strongly dependent on the contrast to noise ratio. The standard deviation of CT numbers of an ROI in the image is usually used to represent the noise. In CT, for a given reconstruction kernel, the noise is primarily due to the fluctuation of the X-ray photons reaching the detector. The noise is approximately inversely proportional to the square root of patient dose. To reduce the noise by a factor of 2, dose must be increased by a factor of 4. In general, image quality is better when the patient dose is increased.

### *Radiation Risks*

The biological effect of radiation is either deterministic or stochastic. The deterministic effect will not occur unless a threshold dose is exceeded. The stochastic effects, however, may occur at any dose level and the probability of occurrence increases with dose linearly according to the linear-nonthreshold dose–response model.[2] Stochastic effects include carcinogenesis and the induction of genetic mutations.

Children are inherently more sensitive to radiation because they have more dividing cells and radiation acts on dividing cells. Also, children have more time to express a cancer than do adults.[3]

The increased risk of malignancy associated with medical CT exposure has received considerable attention starting with analyses based largely on extrapolation from the Hiroshima data and culminating more recently in large scale population studies of children exposed to CT radiation.[3–7] The upshot of this research is the ethical imperative to reduce radiation dose including from diagnostic CT during the workup of children including for pediatric airway disorders.

Mathews et al. studied 10.9 million children between 1985 and 2005 of whom 681,211 underwent a diagnostic CT scan during the study period.[7] 3150 cancers were found in patients who had a CT scan at least one year prior to detection, that is, with a lag period of one year. At a mean follow-up period of 9.5 years, the cancer incidence in the CT exposed group was found to be 24% greater than the non-CT exposed group that yielded an incidence rate ratio (IRR) of 1.24 and an absolute excess incidence rate of 9.38 per 100,000 person years.[7] Incidence risk correlated inversely with age (the younger the patient at time of exposure, the greater the risk) and proportionally

with number of scans and with scans of the chest, abdomen, or pelvis. Lag periods of 5 years yielded IRR of 1.21 and 10 years yielded an IRR of 1.18.[7]

Pearce et al. performed a retrospective study on patients without previous cancer diagnosis who underwent CT in the United Kingdom between 1985 and 2002.[6] They then obtained data on cancer incidence and mortality from the National Health Service (NHS) Central Registry in the United Kingdom between January 1, 1985, and December 31, 2008, in these patients, looked at absorbed brain and red bone marrow doses per CT scan, and determined excess incidence of leukemia and brain tumors in this retrospective cohort. The study began follow-up for leukemia 2 years after the first CT and for brain tumors 5 years after the first CT to avoid the confounding factor of CTs performed related to the cancer detection. Data on 178,604 patients were included in the leukemia analyses and 176,587 patients in the brain tumor analyses. 283,919 CT scans were included in the analysis of leukemia risk (the most common of which, 64%, were head CTs) head and a similar distribution of scan types in the brain tumor analysis. Compared with doses of <5 mGy, the relative risk (RR) of leukemia for patients who received doses of at least 30 mGy was 3.18, and the RR of brain tumors for patients receiving 50–74 mGy was 2.82.[6] For CTs obtained after 2001, 5–10 head CTs in children younger than 15 years result in cumulative doses of 50 mGy to the red bone marrow dose and 2–3 head CTs resulted in cumulative brain doses of 60 mGy. In short cumulative CT doses of 50–60 mGy may triple the risk of leukemia and brain tumors in children.[6]

### *Strategy for Dose Reduction*

In light of the cumulating evidence that CT-associated radiation increases cancer risk, dose reduction strategies are now standard of care for pediatric imaging practices. This effort is often expressed as an ALARA (as low as reasonably achievable) principle.[4]

An important initial step is to consider alternative imaging modalities such as magnetic resonance imaging (MRI) or ultrasound and such consideration de facto is often most efficiently carried out by the ordering pediatric ENT. In the second portion of this chapter, imaging strategies are proposed that favor such alternative modalities whenever feasible.

A second step is to optimize the CT technique; the image quality required for the specific indication is assessed based on the radiologist's experience. The imaging parameters are then selected based on the patient size and organ type under examination such that the required image quality is achieved while the patient dose is kept as low as possible. Weight- and age-based pediatric protocols should be operative at the imaging centers to which the pediatric ENT refers and are considered now to be standard of care.

## Reformats and Reconstructions with MDCT

Multidetector CT provides shorter acquisition times, decrease in tube current load, and improved spatial resolution.[8] Low-image acquisition time (IAT) is useful in pediatric airway imaging in order to reduce motion artifact and in particular in children in the 2 month to 3 year age group who are imaged postprandially without pharmacologic sedation. Although the radiation dose with multidetector scanners in high-quality mode remains an issue compared with single detector scanners; the improved spatial resolution allows for high-quality reformats that essentially obviates the need for rescanning the patient in a second coronal plane.[8] Reformats may, moreover, be obtained in sagittal or oblique planes to improve the detection of pathology in specific clinical settings.

Surface reconstructions of the facial bones, mediastinal vessels, laryngeal cartilages, airway casts, and virtual CT endoscopy are CT reconstruction tools that may aid in diagnosis and surgical planning.

## Fluoroscopy of the Airway and Barium Swallow

Airway fluoroscopy, often in combination with single-contrast barium esophagography, continues to play an important role in the initial imaging workup of the child with difficulty breathing. Because this imaging modality is used to observe the child's breathing over a given period of time, it can help demonstrate dynamic obstruction or narrowing that may be difficult to identify on a static image. This is best done with the neck in hyperextension and arms/hands held above the head. In addition, a barium swallow is useful in assessing a vascular ring or sling which may be compressing the airway.

Fluoroscopy times and total exposure for combined airway fluoroscopy and single contrast barium swallow vary depending on patient age, cooperation, size, and pathology but generally range from 1 to 10 minutes and 10–60 mGy.

## Magnetic Resonance Imaging

MRI is the modality of choice for the initial nonemergent evaluation of head and neck masses, including branchial arch anomalies, hemangiomas, and lymphatic/vascular malformations, which may involve the airway. Although the confined space of the MRI milieu remains a challenge for children usually 2 months to 6 years of age, the superior contrast resolution, noncontrast angiographic techniques, and lack of ionizing radiation (in contrast to CT) present distinct advantages. MRI should also be considered in cases of infection when a patient has already received multiple CT scans within a short period of time, as the bony and vascular anatomy has already been delineated by previous CT.

In addition, it can be used in the form of dynamic imaging (cine MRI) to evaluate functional aspects of the airway. However, given the length of time needed to obtain a proper MRI, the need for sedation becomes a relevant topic in many scenarios. Coordination between otolaryngology, radiology, and anesthesiology is paramount in these situations. Lastly, MRI is useful in identifying brain abnormalities when neurologic abnormalities on head and neck examination are noted.

### *Comments and Caveats*

*Branchial arch anomalies*: A CISS/FIESTA/3D DRIVE sequence may be considered when there is high clinical suspicion for a sinus tract, e.g. pharyngeal cleft sinus tract or fistula; the cutaneous and subcutaneous course of the tract may be best depicted on this sequence that allows for thin section (0.8–1 mm) volumetric acquisitions. A cutaneous marker may be useful to mark the exit site of the tract the scan excursion is then carried axially back to the suspected site of connection usually the external auditory canal, palatine tonsillar fossa, or piriform sinus.

*Hemangiomas*: Laryngeal hemangiomas may be difficult to image and may require high resolution (e.g. 500 frequency × 400 phase matrix) motionless sequences such that targeting of the imaging on the site of obstruction becomes critical for diagnostic imaging. The authors have found three components of the protocol to be critical:

- Discuss the bronchoscopy prior to the MRI and coordinate the findings with the anesthesiologist. Prior to the MRI the site of the suspected obstruction or mass, e.g. subglottic, needs to be discussed with the ENT so that the imaging can be targeted appropriately on this segment of the airway and so that the anesthesia can be planned to avoid compression of the mass by the endotracheal tube in so far as a patent airway can be maintained during the MRI
- Consider pharmacologic paralysis during the MRI. High-resolution sequences are susceptible to motion artifact that may occur from respiration even in a sedated and intubated patient. The authors have found that boluses of paralytics such as vecuronium in intubated patients under the supervision of the anesthesiologist or intensivist managing the airway may provide an adequate temporal window for such high-resolution images
- Targeted imaging: High-resolution images are time costly. The level of the obstruction, e.g. with respect to the vocal folds or carina must be known in advance in order for diagnostic imaging to be obtained through the level of obstruction.

*Vascular malformations*: Characterization of vascular lesions as high or low flow may be helpful for diagnosis i.e. for distinguishing high flow arteriovenous malformations and some hemangiomas from lower flow venolymphatic malformations and for management considerations of embolization and for presurgical planning.[9] A 3D time of flight sequence is thus included into the imaging protocol.

*Fat saturation*: Fat saturation in pediatric head and neck imaging is generally avoided as in the authors' experience the air–bone soft tissue interfaces of the skull base produce artifact that limits the evaluation for perineural tumor and skull base foraminal encroachment and because fat saturation adds several minutes to each additional scan.

*Vocal fold paralysis*: The emphasis on central nervous system (CNS) and craniocervical junction imaging in the above protocol for vocal fold (VF) paresis in children reflects the differences between the results of etiologic studies in adults and children. Ko et al., e.g. studied 161 patients aged 15–85 years (110 patients with unilateral VF paresis) and found iatrogenic causes in 48%, tumor in 12%, neck trauma in 7%, and radiation effect in 6% of cases.[10] Rosin et al., by contrast, studied 51 children with bilateral (29) and unilateral (22) VF paresis. While the leading etiology in the unilateral group was found to be cardiac surgery, 15 of the 29 cases of bilateral VF paresis had neurologic causes.[11] Peripheral neuropathies, both axonal and demyelinating, may results in both unilateral and bilateral VF paresis, are important diagnostic considerations in children, and may, as has been reported in MFN2 mutations, present with CNS manifestations on MRI.[2,12–16]

## Radiography

For certain indications such as the evaluation of stridor in a stable child or the initial evaluation of a child with OSA, plain film radiography continues to play a role in the imaging of the pediatric airway.

## Ultrasound

Ultrasound presents several distinct advantages in the evaluation of pediatric neck lesion that may involve the airway. It is noninvasive, does not produce ionizing radiation, can often be used without sedation even in those age groups where CT and MRI may require anesthesia, and provides for evaluation of vascularity without IV contrast.

## Sedation: What the Ordering Pediatric ENT Needs to Know

Procedural sedation is common in pediatric ENT practice including for diagnostic imaging and the use of procedural sedation has been shown to have increased over the last decade.[17] Below we summarize what the pediatric ENT needs to know with regard to the use of sedation for pediatric imaging:

1. For developmentally normal patients, under 2–3 years of age for CT and under 6 years of age for MRI, you should run requests for imaging through the procedural sedation team (usually composed of appropriate anesthesiology and radiology personnel) for approval before the examination is scheduled, because many of these children will likely require child life assistance or anesthesia. Do not schedule these children routinely as you would other outpatient examinations, even if your electronic ordering system allows it. For developmentally delayed children, all requests for imaging should be reviewed by the procedural sedation team radiology-anesthesiology team
2. General anesthesia (GA) may cause developmental delay in children and examinations such as MRI or CT that require GA should thus be ordered judiciously[18–21]
3. Pediatric ENTs should therefore refer children to medical centers that provide procedural sedation teams.

### *Background*

In light of the growing demand for procedural sedation including imaging studies under GA such as MRI and CT, national consensus guidelines for procedural sedation were published in 1992 and then updated in 2002, 2006, and most recently affirmed in 2012 by the America Academy of Pediatrics, American Academy of Pediatric Dentistry, and American Society of Anesthesiology.[22–25] These guidelines serve as a national standard for procedural sedation.

### *What to Tell the Parents or Caretakers: The Common Questions*

Why does my child need sedation and if so why does it need to be a general anesthetic?

MRI and certain CT examinations require the child to remain still for a certain period of time; this time may range between several minutes, e.g. for CT examinations to an hour, e.g. for some MRIs. Most children, under 3 years of age for CT and under 6 years of age for MRI, experience too much anxiety to remain motionless for the periods of time required to obtain diagnostic imaging. In such settings, anesthesia may be required to ensure that the child does not move during the examination.

What will happen next?

Now that it has been decided that your child will need an imaging study, the procedural sedation team will contact you to discuss how to prepare your child for the examination and what to expect including fasting prior to the study.[25]

### *Effect of Anesthetics on the Developing Brain*

Procedural sedation carries with it a risk for injury to the developing brain: the effect of anesthetic agents including the ones used for procedural sedation such as ketamine, midazolam, propofol, and inhaled agents such as isoflurane have been shown to cause neuronal apoptosis in the dose ranges used for procedural sedation.[26–28] These animal models prompted more recent investigations of the effect of anesthetic agents on the developing human brain. DiMaggio et al., e.g. conducted a retrospective cohort study of 10,450 siblings who underwent surgery before 3 years of age that included an exposed group of 304 children without presurgical history of developmental or behavioral disorder and an unexposed group of 10,146 children. The incidence of subsequent diagnoses of developmental and behavioral disorders was found to be 128 per 1000 person-years in the exposed cohort and 56 per 1000 person-years for the unexposed cohort, and the estimated hazard ratio of developmental or behavioral disorders was 1.6; however, the extent to which the excess risk is causally attributable to anesthesia or mediated by factors such as surgery remained to be determined.[19]

In an attempt to determine the effects of anesthesia versus surgery, Bong et al. studied 100 full-term, apparently healthy children aged 12 years, exposed to general anesthesia for minor surgery before age 1 with an age-matched cohort of 106 nonexposed children. The odds of a diagnosis of learning disability in the exposed group were 4.5 times greater than the nonexposed cohort.[18]

## Procedural Sedation Teams, Child Life, and Alternatives to Sedation

The upshot of such studies for the pediatric ENT or pediatric head and neck imager is the recognition that the ordering of imaging studies under GA should be done judiciously, that (1) there is a clear indication to seek alternatives to GA when feasible, and (2) that referrals for imaging should be made to centers with establish procedural sedation teams.

### *Alternatives to Imaging Under GA Include*

- Alternative modalities such as ultrasound
- Child life specialists that are skilled personnel trained in managing anxious or developmentally delayed children in the imaging suite
- Rapid MRI techniques that may be of sufficient diagnostic yield to obviate the need for a sedated study,[29] and
- Video goggles that may allow certain children to tolerate the enclosed MR environment long enough to allow for diagnostic imaging and have been shown to decrease the need for MR imaging under GA.[30]

### *Procedural Sedation Teams*

The authors' current policy, that we believe to be consonant with national trends, is to require all procedural anesthesia to be managed by a procedural sedation team comprised of anesthesiologists, radiologists, nurses, and child life specialists, under the direction of the anesthesiology department.

The benefits of such procedural sedation teams have been shown to be substantial and referral to institutions supporting such a team is thus an important consideration for the ordering ENT: Ruess et al., e.g. showed that the sedation failure rate dropped from 15% in the 7 months prior to the establishment of a procedural sedation pathway was 15% (19/124) to 1.5% (6/388) ($P < 0.0001$) in the first 25 months after pathway initiation, failures were significantly reduced to. Three (50%) of the six failures after pathway initiation.[31] King et al., e.g., collected data from 5444 sedations, 2148 before, and 3296 after activation of a procedural sedation service activation. The rate of incomplete studies secondary to inadequate sedation decreased from 2.7% before to 0.8% after the procedural sedation-service period. Decreases in cancellations caused by patient illness dropped from 3.8% to 0.6% and rates of hypoxia during sedation dropped from 8.8% to 4.6%.[32]

# PART II: REFERRALS AND IMAGING STRATEGIES

This part of the chapter is organized according to the major clinical indications for which a child may be referred for airway imaging. The indications are listed in alphabetical order below. For each clinical indication, the following points are addressed:

- What is the pertinent clinical background?
- What is the first imaging modality of choice?
- What are the clinical questions that the imaging needs to address?
- What is your approach to the interpretation of the imaging?

## Dysphagia

### *Clinical Background*

Difficulty swallowing in children may manifest as choking/gagging with feeds, recurrent pneumonias, aversion to feeding or refusal of particular types/consistencies of food, and failure to thrive. Particular attention should be given to the consistency of food with which difficulty occurs. If consumption of thin liquids leads to choking or coughing, attention should be given to timing of the symptoms with relation to swallow. When symptoms occur upon initiation of swallow, an anatomic abnormality, such as a laryngeal cleft or a tracheoesophageal fistula, should be considered. If the symptoms are occurring after the swallow or after feeding and are accompanied by arching of the back and discomfort, abdominal pain, food impaction, and emesis, acid reflux or eosinophilic esophagitis may be more likely.[33] In children who present with recurrent pneumonias, silent aspiration may be present, and the parents may not report choking or coughing with feeds. When the history is highly suspicious for reflux, imaging is not immediately indicated. However, if there is question of aspiration or an anatomic abnormality, functional imaging that captures

the act of swallow, such as modified barium swallow, is indicated. Flexible laryngoscopy should be performed prior to imaging, however, to evaluate for VF immobility.

When children have difficulty with swallowing solid consistencies, inflammation from reflux may again be the culprit, but obstructive pathology may also need to be ruled out. These patients may also complain of pain, emesis, and experience weight loss. In these situations, a barium esophagram with small bowel follow through will evaluate the upper digestive tract for any causes of obstruction. Etiologies to consider include neoplasm, stricture, gastric volvulus, and cricopharyngeal spasm.

### *Imaging Modality of Choice*

Modified barium swallow or barium esophagram(s) with small bowel follow-through.

### *Clinical Questions*

1. Is there aspiration occurring, and if so, when is it occurring?
2. Is there evidence of reflux?
3. Is there any suggestion of obstruction?

### *Interpretation*

Single-contrast barium esophagram(s) address these clinical questions well.

The swallow is traditionally divided into oral, pharyngeal, and esophageal phases.

During the pharyngeal phase, as barium transits through the upper esophageal sphincter, attention is given to the laryngeal introitus. If contrast coats the laryngeal surface of the epiglottis but does not cross the vocal folds, this finding is termed penetration. If, however, the contrast passes beyond the vocal folds, this finding is termed aspiration.

If the penetration or aspiration occurs early, e.g. during the antegrade phase of the swallow, an anatomic abnormality such as a cleft or TE fistula should be considered. If the aspiration occurs later, then attention should be made to the esophagus and UES since reflux may result in return of contrast from the esophagus into the pharynx and larynx.

The contrast bolus is then followed through to the lower esophageal sphincter, gastric body, and duodenum to the ligament of Treitz. Failure of passage along this course should raise concern for obstruction including mass, stricture, and malrotation or functional disorder such as delayed gastric emptying.

## Infection

### *Clinical Background*

Pediatric patients with infections that affect the airway may present in a variety of ways. As discussed in the section on stridor, patients may present with acute onset of fever, drooling, inspiratory stridor, and preference for the "sniffing position". These findings suggest epiglottitis, and although rare, can have lethal consequences. In these patients, flexible fiberoptic laryngoscopy is deferred due to possible provocation of an airway crisis; therefore, plain radiography can be useful in these cases but is also often deferred to simple clinical judgment due to the severity of symptoms.

In patients with biphasic stridor, fever, and a barky cough, croup is the most likely diagnosis. These patients often have a prodrome with a gradual progression of symptoms over time. Once again, patients are often treated medically based on clinical symptoms.

When patients present with the history of 1–2 weeks of a viral infection with sudden onset deterioration over a period of hours and fever, stridor, and possible tracheal tenderness, bacterial tracheitis should be at the top of differential diagnosis. Some studies have shown that up to 50% of patients may have concomitant pneumonia, thus a chest X-ray may be helpful in both identifying a tracheal abnormality as well as a consolidation.[34,35]

Cellulitis and abscesses located in the spaces adjacent to the airway, such as the sublingual space, submental/submandibular space, parapharyngeal space, and retropharyngeal space, can have obvious effect on the airway due to narrowing. In sublingual cellulitis or abscess, also termed Ludwig's angina, children may have a history of a dental infection or trauma, and they present with floor of mouth edema and induration, with elevation of the tongue.[36] Imaging is certainly useful in the patients, but the airway must be secured first, followed by CT scan. With infections located in the parapharyngeal and retropharyngeal spaces, neck edema may be seen externally, as well as intraoral edema of the lateral or posterior pharyngeal wall. Limited range of motion of the neck may be noted. In these cases, CT scans are the most commonly used imaging modality, as they can distinguish between cellulitis and abscess, thereby guiding surgical management.[37–39] Lateral radiographs have limited utility in evaluation for retropharyngeal abscesses: a classic radiographic fake-out may occur when a lateral radiograph is obtained in flexion and can produce a radiographic false-positive for

retropharyngeal abscesses. If the radiographic finding seems incongruent with the clinical picture, a CT should be performed to clarify the findings.

### *Imaging Modality of Choice*

While imaging is not used in all of these cases, particularly where the patient is in imminent danger of losing his/her airway, it is useful in cases where the patient is stable:

- Croup, epiglottitis, bacterial tracheitis-plain film radiography
- Deep space neck infection or lymphadenitis-CT scan of neck
- NOTE: Keep in mind that if a patient has had multiple CT scans in a brief timeframe, MRI should be considered to track progression of the infection.

### *Clinical Questions*

1. For radiographs, what is the location of the infection?
2. For CT of the neck, Is there a drainable fluid collection?
3. Is there impending airway collapse not evidenced by the patient's physical state?

### *Interpretation*

Standard radiographic evaluation for airway infection includes lateral and AP radiographs.

The "thumb sign", indicating thickening of the epiglottis, can be seen on lateral neck films in epiglottitis.

Plain film radiographs demonstrating subgottic narrowing and blunting of the subglottic angle on the AP view is also known as the "steeple sign" and is consistent with the diagnosis of croup.

While radiography does not definitively make the diagnosis of bacterial tracheitis, demonstration of irregularity of the tracheal borders and clouding of the air column, sometimes called the "candle-dripping sign", may be seen.

For deep neck infections or suppurative lymphadenitis, a contrast-enhanced CT is performed. Rim enhancing findings that show central hypoattenuation raise concern for abscesses. Lymph nodes may enhance and show central low attenuation and although such findings suggest suppuration, in our experience such nodes may not yield pus upon attempted drainage; when the collection demonstrates irregular margins that extend beyond the expected border of the node, such findings usually indicate drainable collections (Fig. 36.1).

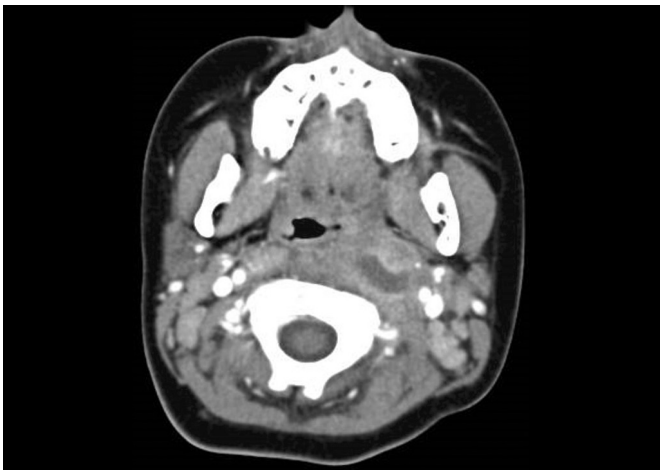

**Fig. 36.1:** Retropharyngeal abscess in a 7-year-old boy presenting with fever and difficulty breathing and swallowing. An axial contrast enhanced CT shows a rim enhancing central low attenuation lesion in the left retropharynx. The lesion lies in the expected local of the left node of Rouviere but the enhancing borders appear irregular and extend slightly outside the borders of the lymph node—findings suggest suppuration.

## Nasal Obstruction

### *Clinical Background*

Etiology of nasal obstruction varies with age at presentation. The pediatric otolaryngologist is often consulted for nasal congestion in the nursery or neonatal ICU. The patients may have difficulty feeding, cyclical cyanosis, nasal flaring, retractions, and desaturations. On physical examination, anterior rhinoscopy may reveal masses if located anteriorly, such as a dermoid, neuroglial heterotopion (so-called nasal glioma), cephalocele, nasolacrimal duct cyst, or neoplasms, such as teratoma, hamartoma, rhabdomyosarcoma, and hemangioma, among many others. In order to distinguish between true obstruction and edema, decongestant may be applied to decrease the swelling. In addition, a 6-french catheter should pass easily through bilateral nasal cavities. If difficulty is encountered anteriorly, pyriform aperture stenosis should be considered. If difficulty is encountered posteriorly (32–35 mm), choanal atresia or stenosis should be on the differential diagnosis. Flexible nasal endoscopy should be performed to evaluate for the site of obstruction more precisely.[40] If narrowing or mass is suspected, imaging is critical in evaluation, with CT being useful for bony anatomy and MRI allowing for improved characterization of a mass. It is important to keep in mind that nasal obstruction can be just one part of a syndrome, such as CHARGE syndrome, Apert syndrome, or Crouzon syndrome.

In the older pediatric population, patients will now be able to describe symptoms, including pain, pressure, and difficulty breathing. If symptoms have an acute onset and have accompanying signs of infection, with physical examination demonstrating pus, acute sinusitis is likely the cause of the obstruction. If physical examination demonstrates a mass, imaging again must be obtained to ensure that this mass has no connection to the brain and to help better characterize the lesion. In additional to those things mentioned above, neoplasms that are also seen in the adult population, such as esthesioneuroblastomas, or benign disease, such as sinonasal/antrochoanal polyps and inverting papillomas, can be seen. In the case of polyps, imaging is helpful in determining the extent of sinus disease and identifying abnormal anatomy for surgical planning.

If a history of trauma exists, a septal hematoma should be evaluated for on physical examination. Septal deviation or nasal bone fracture may also be present, and imaging is not typically necessary in any of these cases as physical examination is adequate for diagnosis.

### *Imaging Modality of Choice*

- For osseous narrowing or obstruction and for trauma or sinus disease, CT maxillofacial without contrast
- For soft tissue masses, MRI face and sinus.

### *Clinical Questions*

1. Is there a mass causing obstruction, and if so, is there connection to the brain?
2. Is there a bony narrowing or atresia?
3. Is there sinus disease?
4. Are there other findings on imaging that may suggest a syndrome?

### *Interpretation*

For CTs in neonates where the clinical findings suggest piriform aperture or choanal stenosis, thin section noncontrast axial images should be performed and reformatted in the coronal and sagittal planes. Piriform aperture stenosis is usually evidenced by an inversion of the normal convex curvature of the frontal process of the maxilla; in piriform aperture stenosis, the frontal process appears concave and curves toward the nasal cavity where it may contact the septum. For choanal stenosis, the distance between the periosteum of the palatine bone along the lateral wall of the choana and the vomer is measured. Traditionally, in normal neonates, the right or left choana measure at least 6 mm and lower measurements raise concern for stenosis. Usually as well the palatal process of the palatine bone appears dysplastic and the vomer appears abnormally thick (Figs. 36.2A to D).

For evaluation for sinusitis, the images are reviewed for abnormal opacity along the walls of the sinuses and nasal cavity. High attenuation opacities raise concern for allergic fungal rhinosinusitis (Fig. 36.3).

Septal hematomas may be subtle radiographically. Interpretation of the images in the context of recent trauma and congestion is important. Hematomas usually arise subperichondrial and thus lie along the anterior cartilaginous septum where they produce an asymmetric bulge that may exhibit hypoattenuation on CT.

For masses, high-resolution coronal T2-weighted images are favored that allow for evaluation for defects along the anterior skull base and communication of the brain with the sinonasal cavity. Contrast-enhanced MRI may help to distinguish cephaloceles that may demonstrate rim enhancement versus neoplasms that would be expected to enhance confluently (Figs. 36.4 to 36.6).

## Obstructive Sleep Apnea

### *Clinical Background*

Diagnosed in approximately 2–3% of all preschool aged children in the United States,[41] OSA has been become the most common diagnosis for which adenotonsillectomy is performed. Parents may report heavy snoring, pauses in breathing while sleeping, behavior problems, poor attention, memory and cognitive deficits, and poor school performance.[42] Physical examination may reveal enlarged tonsils in many patients. However, some patients may not demonstrate enlarged tonsils but have symptoms consistent with OSA. Because these patients are often younger in age, nasopharyngoscopy may be poorly tolerated and examination can be limited. In this situation, plain radiography can demonstrate adenoid enlargement and has been shown to correlate well with intraoperative findings of adenoid hypertrophy.[43]

In adult patients Riley et al. have described a staged approach to the treatment of OSA where stage I consists of uvulopalatopharyngoplasty, anterior maxillary osteotomy, and hyoid myotomy, and stage II surgery involves mandibular maxillary advancement.[44] In children, however, first-line treatment typically consists of adenotonsillectomy. In patients with persistent OSA following

**Figs. 36.2A to D:** Choanal atresia in a tracheostomy dependent 2-year-old girl. Noncontrast CT axial images obtained at the roof (A) and floor (B) of the nasal cavity demonstrate complete choanal atresia. No aerated passage is seen between the choanae (c) and the nasopharynx (C). The vomer (v) rises abnormally superiorly and is inseparate from the palatine bones (p). The pterygopalatine fossae have formed between the pterygoid bodies and the palatine bones. Sagittal 2D reformat shows the complete osseous plate that closes the posterior nasal cavity. A surface reconstruction air cast (D) shows the aerated nasal cavity back to the choana (c) but no demonstrable aeration between the nasal cavity and the nasopharynx.

adenotonsillectomy, the site of obstruction may be difficult to identify. Drug-induced sleep endo copy may be used help locate where the obstruction is occurring. In addition, the use of static and cine MRI has been shown to be useful in pinpointing areas where narrowing or collapse is occurring.[45–47] For children with suspected craniofacial dysmorphisms, CT may be of use as a guide to surgical management.[48]

**Fig. 36.3:** Sinusitis. Coronal CT reformat in a 12-year old girl who presented with left facial pain shows complete opacification of the left maxillary and ethmoid air cells consistent with sinusitis. Some of the opacity along the left middle turbinate appears more radiodense (higher in attenuation) that may represent more inspissated or proteinaceous secretions.

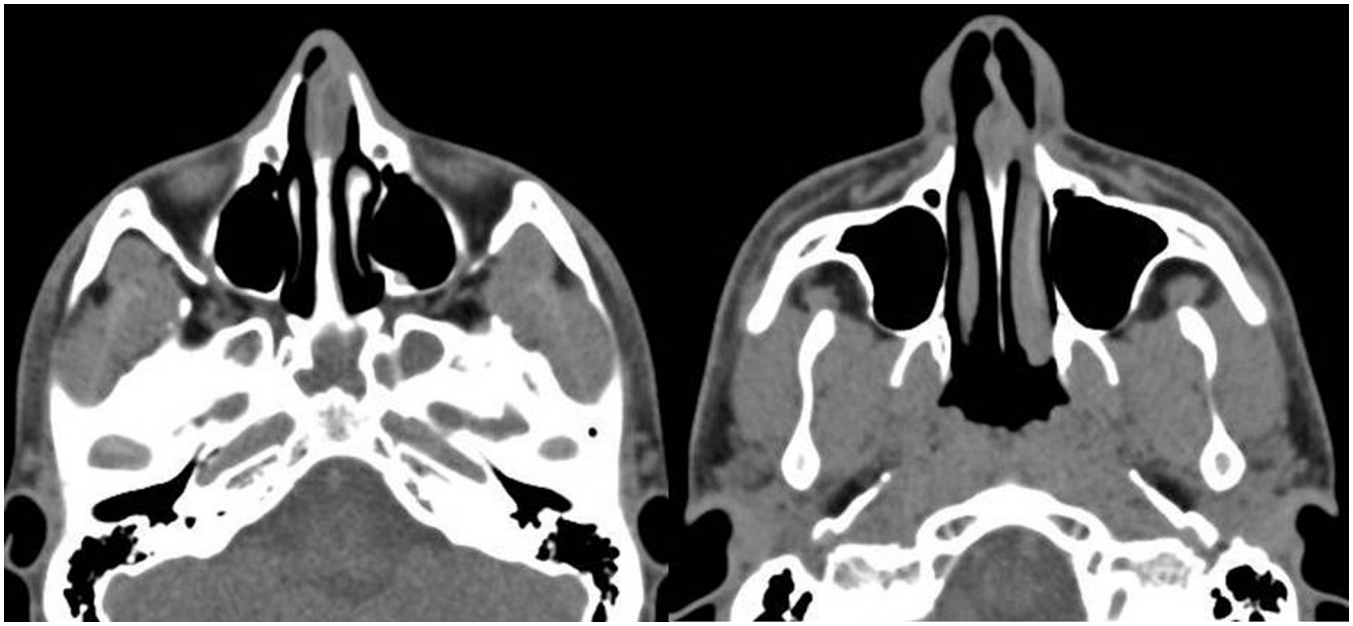

**Fig. 36.4:** Septal hematoma in 16-year-old boy who suffered trauma to the nose 5 days earlier. Two noncontrast axial CT images through the nasal cavity demonstrate abnormal focal expansion at the base of the columella in the cartilaginous nasal septum consistent with a septal hematoma.

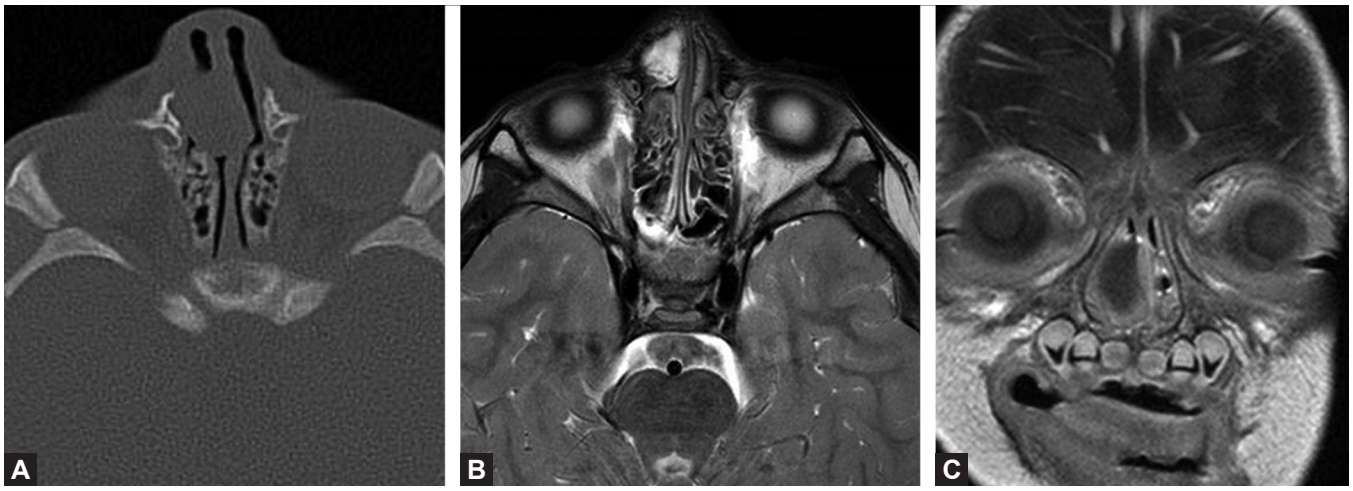
## *Imaging Modality of Choice*

- For suspected adenoid hypertrophy, plain film radiography of the nasopharynx
- For persistent sleep apnea following adenotonsillectomy, cine MRI
- For those patients where craniofacial reconstruction is a consideration, noncontrast low-dose CT of the airway.

## *Clinical Questions*

1. Is adenoid hypertrophy the etiology for obstruction?
2. Are there additional sites of obstruction, which are difficult to identify on physical examination?
3. Are there craniofacial dysmorphisms, e.g. long SI dimension of the airway (Abramson Kaban article) that may predispose to OSA and benefit from reconstruction?



**Figs. 36.5A to C:** Neuroglial heterotopion in a 2-month-old boy presenting with nasal obstruction. An axial noncontrast CT (A) shows a round opacity that obstructs the right nasal cavity at the piriform aperture. An axial T2-weighted image (B) and a coronal postcontrast T1-weighted imaged (C) show the lesion centered in the nasal cavity with no demonstrable intracranial connection to suggest a cephalocele.

**Fig. 36.6:** Juvenile angiofibroma in a 6-year-old boy presenting with nasal obstruction and epistaxis. Axial contrast enhanced CT in bone algorithm shows a mass centered in the right pterygopalatine fossa that obstructs the right choana medially, erodes the right sphenoid bone posteriorly, and laterally protrudes into the right masticator space.

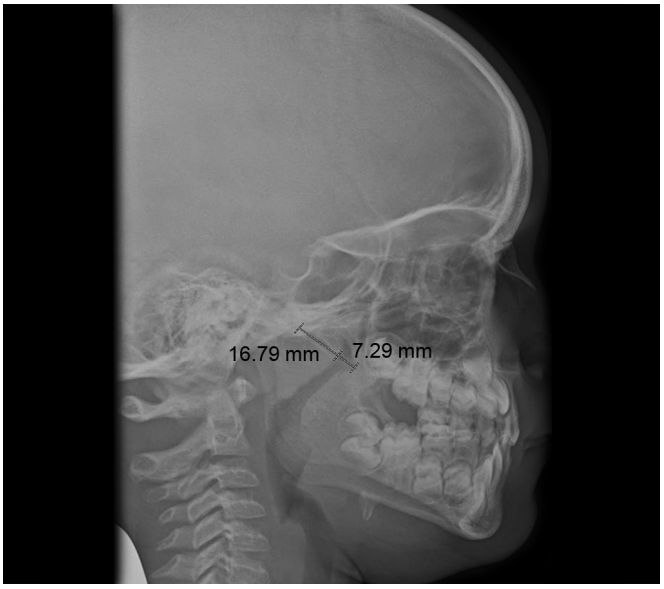


**Fig. 36.7:** Adenoid hypertrophy. Lateral radiograph in a 6-year-old girl with noisy breathing shows a prominent nasopharyngeal pad that measures 17-mm-thick and that narrows the airway to 7 mm AP. The lateral radiograph provides rapid assessment of the caliber of the nasopharyngeal lumen that may be more practical than nasopharyngeal endoscopy in and infant or child.

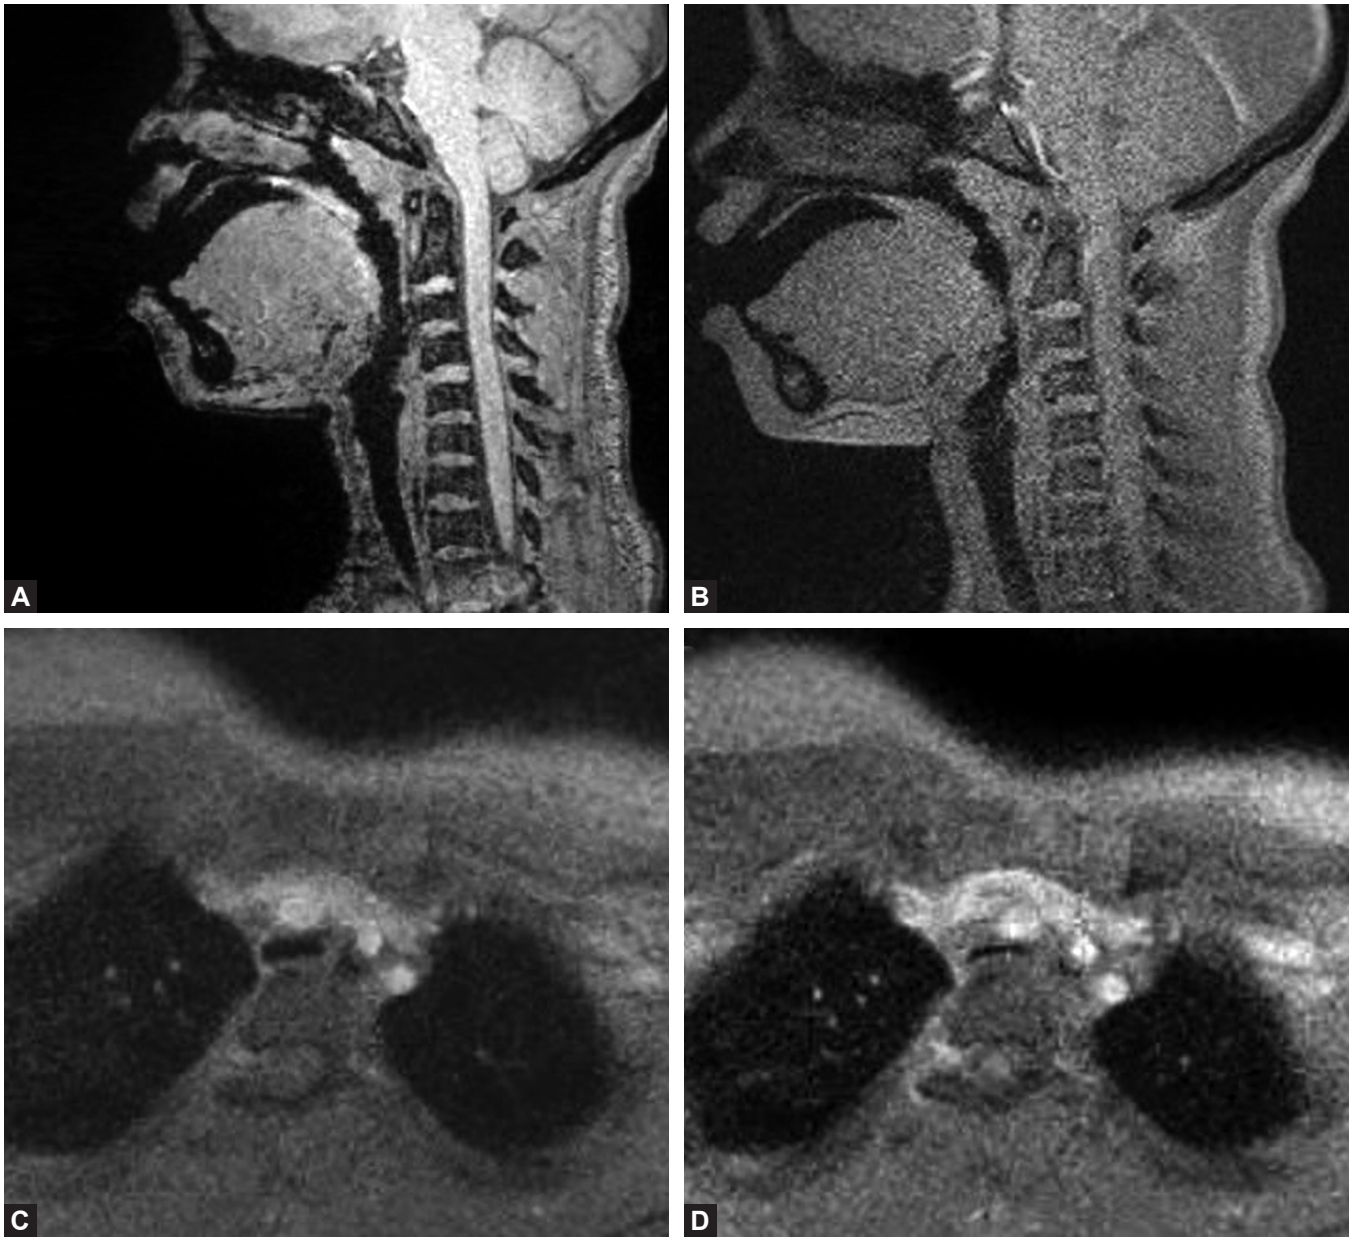
## *Interpretation*

For adenoid hypertrophy a single lateral radiograph is obtained and the adenoid pad and airway are measured along a line drawn from the posterior nasal spine to the anterior-most aspect of the adenoid pad, and from the anterior aspect of the adenoid pad to the nasopharyngeal base of the spheno-occipital synchondrosis. The adenoid pad is considered normal when it measures about 5–10 mm. At 10–20 mm, there is mild to moderate hypertrophy, and at >20 mm, severe hypertrophy is present, potentially causing nasal obstruction. This is evidenced by the concomitant decrease in the width of the air column as the adenoids enlarge (Fig. 36.7).

When cine MRI is done for persistent OSA, sedation is administered to mimic sleep. Both continuous and intermittent obstruction can be identified during the study. Following anatomic imaging, single sagittal, axial, and coronal slices through the airway can be targeted and reviewed at 1–2 second intervals for movement and collapse during the respiratory cycle. Airway narrowing is most commonly observed at the level of the nasopharynx from the adenoid pad, tongue base from glossoptosis or lingual tonsillar hypertrophy, and along the trachea from tracheomalacia or innominate impression (Figs. 36.8A to D).



**Figs. 36.8A to D:** Cine MRI of the airway in a 12-year-old girl with trisomy 21 and obstructive sleep apnea that persisted after adenoidectomy. (A) a sagittal SPGR at rest and (B) a single sagittal frame from a cinematographic T1-weighted FLASH MRI sequence provides a temporal snap shot of motion of the airway every 0.5 seconds that shows a dynamic collapse of the oropharynx from the tongue base. In (C) and (D), an axial FLASH image obtained through the distal trachea at the crossover point of the innominate artery, the cine MRI shows marked collapse of the tracheal lumen during the respiratory cycle from innominate artery compression. In this study sleep was induced with IV propafol and an oral airway tube that was removed during the cine sequences.

## Stridor and Respiratory Difficulty

### *Clinical Background*

Stridor may present as a manifestation of numerous pathologies, so clinical history is of paramount importance. As a neonate, a child may present with high-pitched inspiratory stridor that has been present since birth or shortly after birth which may be accompanied by failure to thrive, cyanotic or desaturation episodes, and/or difficulty feeding. This history would be consistent with laryngomalacia, and flexible fiberoptic laryngoscopy would be adequate to make the diagnosis. Imaging has been shown to have poor sensitivity for diagnosing laryngomalacia.[49] However, inspiratory stridor may also represent a glottic pathology, such as a VF paralysis. Although this diagnosis is also made with flexible fiberoptic laryngoscopy, imaging is useful in uncovering an etiology, such as an Arnold–Chiari malformation, which may cause bilateral VF paralysis.

As an infant, a child may present with inspiratory or biphasic stridor with a barky cough. The patient may be febrile and appear sick, which point to the infectious etiology of croup. Infants may also present with acute onset inspiratory stridor, fever, drooling, and dysphagia. These symptoms suggest an acute bacterial infectious process, such as epiglottitis. When biphasic stridor is present in conjunction with signs of infection, including high fever, bacterial tracheitis should be considered. Imaging can be helpful in these cases, but should be pursued as long as there is no impending airway collapse.

When an infant presents with stridor that is not associated with infection, other etiologies must be considered. In patients who are diagnosed with recurrent croup who may or may not have a history of previous intubation, subglottic stenosis should be assumed until proven otherwise. Subglottic cysts may also present in a very similar fashion, and may indeed be a precursor to subglottic stenosis. Often, these patients only become stridulous with an upper respiratory infection and have persistent stridor when other symptoms of infection resolve. Imaging plays a limited role here, as direct laryngoscopy serves as the gold standard. Subglottic hemangioma should also be considered, particularly if the patient has any evidence of a cutaneous hemangioma, found in 50% of patients with subglottic hemangioma. While direct laryngoscopy is again the gold standard for diagnosis, imaging may serve to provide additional useful information in providing clues. Lastly, a foreign body, whether airway or esophageal, may cause stridor due to narrowing from intraluminal obstruction or extraluminal compression. These can be seen on plain films and/or fluoroscopy.

Biphasic or expiratory stridor that is coarse in nature should point to a tracheal pathology, whether a fixed lesion, such as complete tracheal rings, or a dynamic lesion, such as tracheomalacia. Dynamic airway imaging, such as fluoroscopy, may be used as an adjunct, but the sensitivity is only in the range of 50–60% and it therefore cannot replace bronchoscopy.[49,50] In addition, a vascular ring may also cause biphasic or expiratory stridor, depending on the location of compression. Bronchoscopy is typically the first step in diagnosis, but imaging, particularly a CT angiogram, is very helpful in identifying the type of anomaly present and whether or not surgery is indicated.[51]

In pediatric patients of any age, stridor may represent a neoplasm in the airway, such as a chondroma, minor salivary gland tumor, laryngotracheobronchial papillomas, or rhabdomyosarcoma, or an autoimmune pathology, such as amyloidosis, Wegener's granulomatosis, or sarcoidosis. In the oral cavity and oropharynx, other masses that may present include thyroglossal duct cyst, lingual thyroid, vascular malformations, foregut duplication cysts, and ranula. Imaging is certainly useful when evaluating a neoplasm but is of limited utility in autoimmune diseases.

### *Imaging Modality of Choice*

- For evaluation of dynamic airway narrowing, airway fluoroscopy/barium swallow
- For possible foreign body aspiration, airway fluoroscopy or left lateral decubitus plain film radiography
- For evaluation of possible vascular compression of the airway, CT angiography of the neck and chest
- For evaluation of a possible mass in the airway, CT of MRI of the neck
- For congenital VF paralysis, MRI brain.

### *Clinical Questions*

1. Is there a mass in the airway?
2. Is there dynamic narrowing of the airway?
3. Is there vascular compression of the airway?
4. Is there a neurologic etiology which may explain VF paralysis?
5. Is there suggestion of an infectious etiology?

### Interpretation

On airway fluoroscopy, the pharynx, larynx, and trachea are studied to evaluate for abnormal collapse during the respiratory cycle, while the pharynx and larynx are often evaluated endoscopically in the office, evaluation of the trachea beyond the vocal folds depends more on the radiographic evaluation. Abnormal collapse of the posterior wall of the trachea during expiration raises concern for tracheomalacia.

On barium swallow, the contours of the esophagus are evaluated for abnormal impressions that may suggest a vascular ring or sling. Normally, along the posterior esophageal wall three impressions are seen: the aortic arch, the left main stem bronchus, and the left ventricle. In a pulmonary sling, where the left pulmonary artery arises anomalously from the right pulmonary artery, the left PA produces an abnormal impression along the anterior wall of the esophagus and the posterior wall of the trachea. In a vascular ring, abnormal impressions are seen along the anterior wall of the trachea and the posterior wall of the esophagus.

CT is useful to survey the entire airway in cases of suspected compression. Although vascular lesions such as hemangiomas may be difficult to detect by contrast-enhanced CT, the rapidity and ease of access of CT makes it the modality of choice for initial imaging of the airway. Vascular rings and slings, narrow segments of the airway, and neoplasms causing mass effect are usually detectable (Figs. 36.9 and 36.10).

MRI is useful for targeted evaluation of compressive airway lesions, in particular for subglottic hemangiomas. We have found MRI to be most useful when the initial bronchoscopic evaluation raises concern for a focal narrowing. MRI often requires sedation and control of respiratory motion by intubation and pharmacologic paralysis to image the airway sufficiently that present relative drawbacks compared to CT. MRI is, however, the modality of choice for suspected central causes of airway compromise such as VF paresis from a Chiari malformation or from suspected myelin disorders (Figs. 36.11 to 36.14).

## Velopharyngeal Insufficiency

### Clinical Background

Children with VPI most commonly present to the pediatric otolaryngologist as part of the multidisciplinary evaluation for treatment, along with the speech pathologist. These children present with hypernasality and have trouble with sounds that require velopharyngeal closure, such as "p", "b", "g", "t", and "d". While much of the diagnosis is made on physical examination with nasopharyngoscopy and with nasometry, imaging can be helpful in uncooperative patients and provide additional information regarding closure pattern. Multiview fluoroscopy allows for visualization of closure in three different planes, but it has been criticized for oversimplification of VPI in one plane, underestimation of the anteroposterior pharyngeal dimension, and the potential to overdiagnose VPI due to speed of radiography when compared to velopharyngeal closure.[52] In addition, due to the radiation exposure, its use has declined in favor of nasopharyngoscopy.[53]

Cine MRI with or without audio has also recently been found to be helpful in more precisely identifying the pattern of closure, specifically looking at motion, bulk, and orientation of the levator veli palatini; however, it is of limited use due to the expense.[53,54]

On clinical presentation, close attention should be given to the possible presence of a syndrome, particularly 22q11.2 deletion syndrome, also known as velocardiofacial syndrome. In these children, a medialized carotid artery may be present, and this may be seen on nasopharyngoscopy. Suggestion of this finding should prompt the physician to obtain vascular imaging to evaluate for this entity, as this may change the surgical plan (Figs. 36.15A and B).

### Imaging Modality of Choice

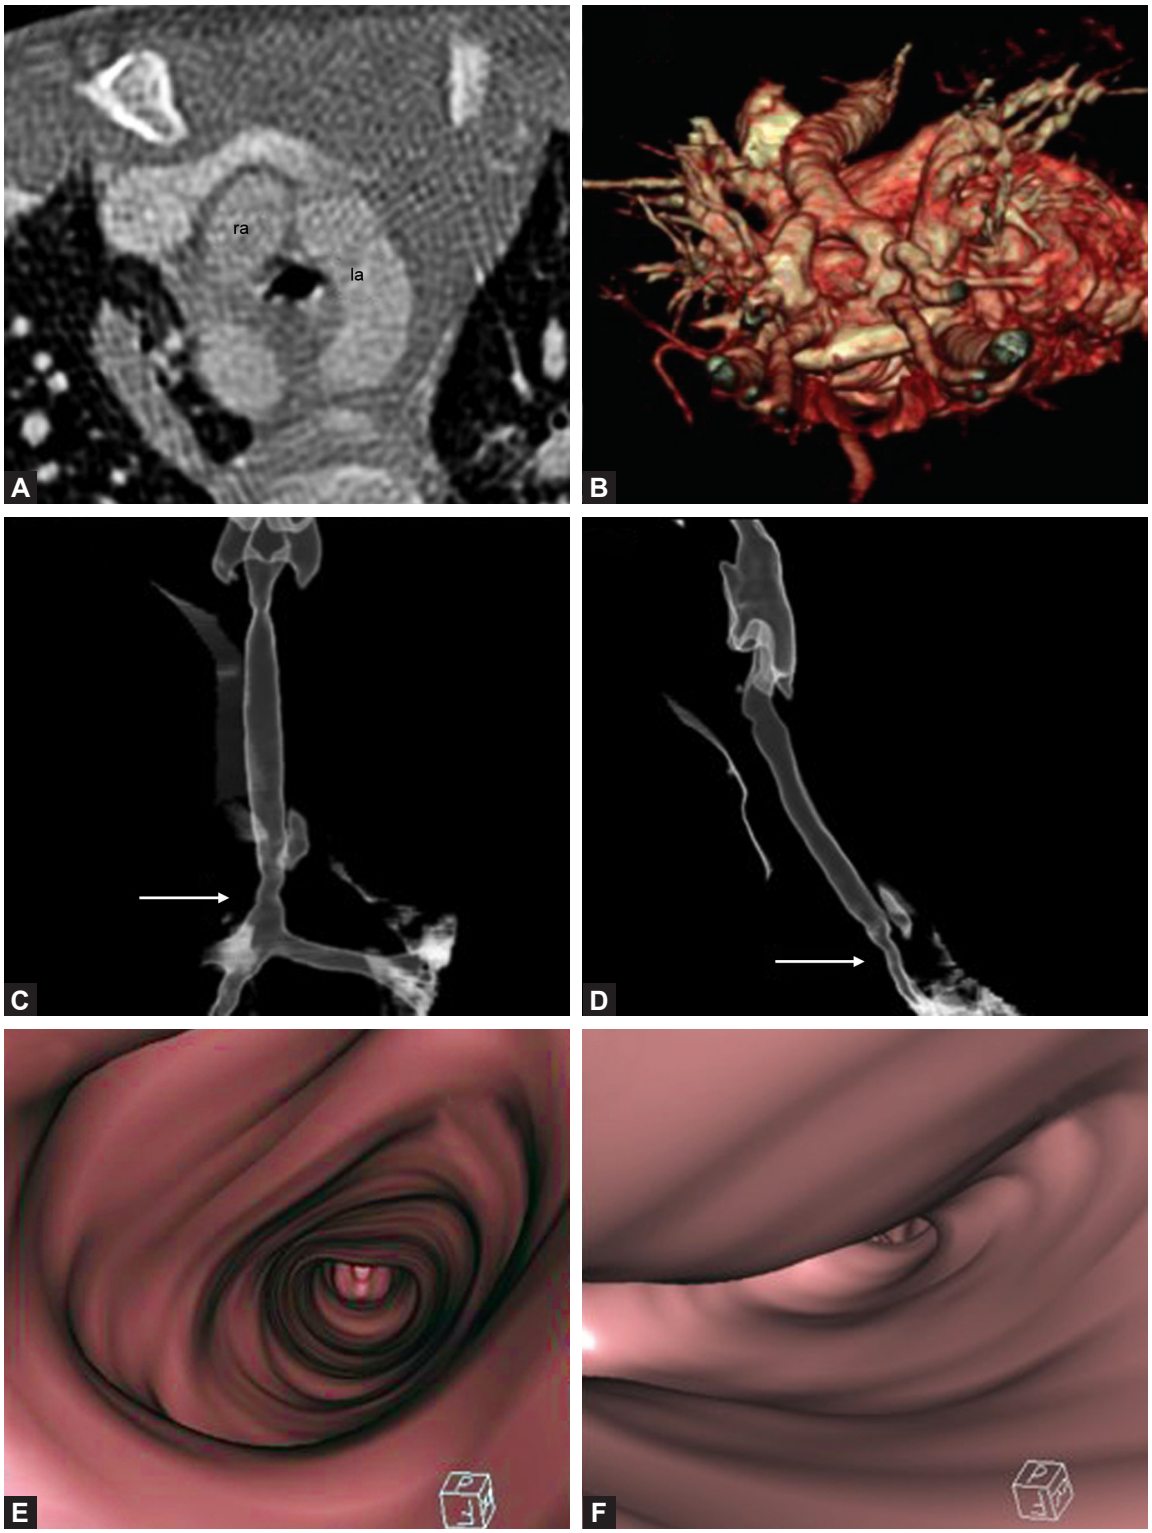
- For evaluation of closure pattern as an adjunct to endoscopy, cine MRI VPI studies
- For evaluation of abnormal vasculature, MRI and magnetic resonance angiography (MRA) of the neck.

### Clinical Questions

1. What is the pattern of closure noted?
2. Is there abnormal vasculature that may alter the planned surgical intervention?

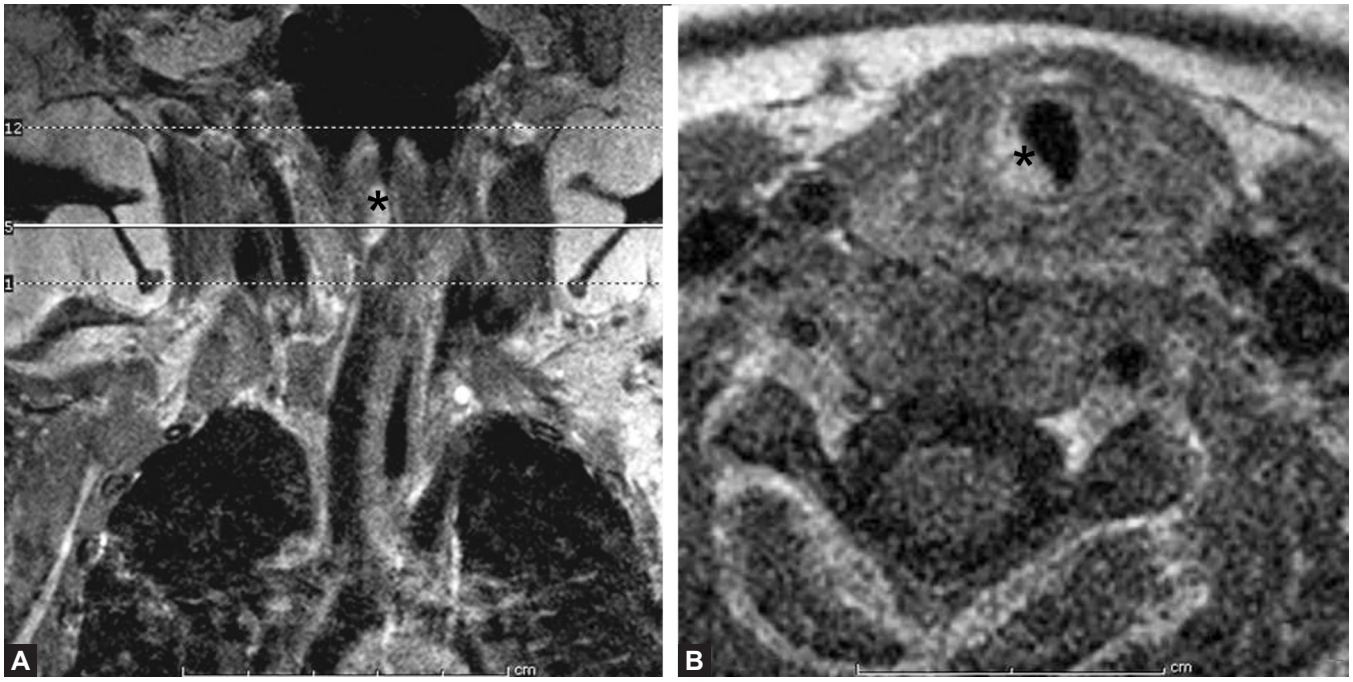
### Interpretation

The cine imaging is coordinated synchronously with voice recordings conducted by the speech pathologist. Silver et al. and Maturo et al. describe the voice recording apparatus constructed of readily available hospital supplies such as a plastic cup held by the patient at his or her mouth during



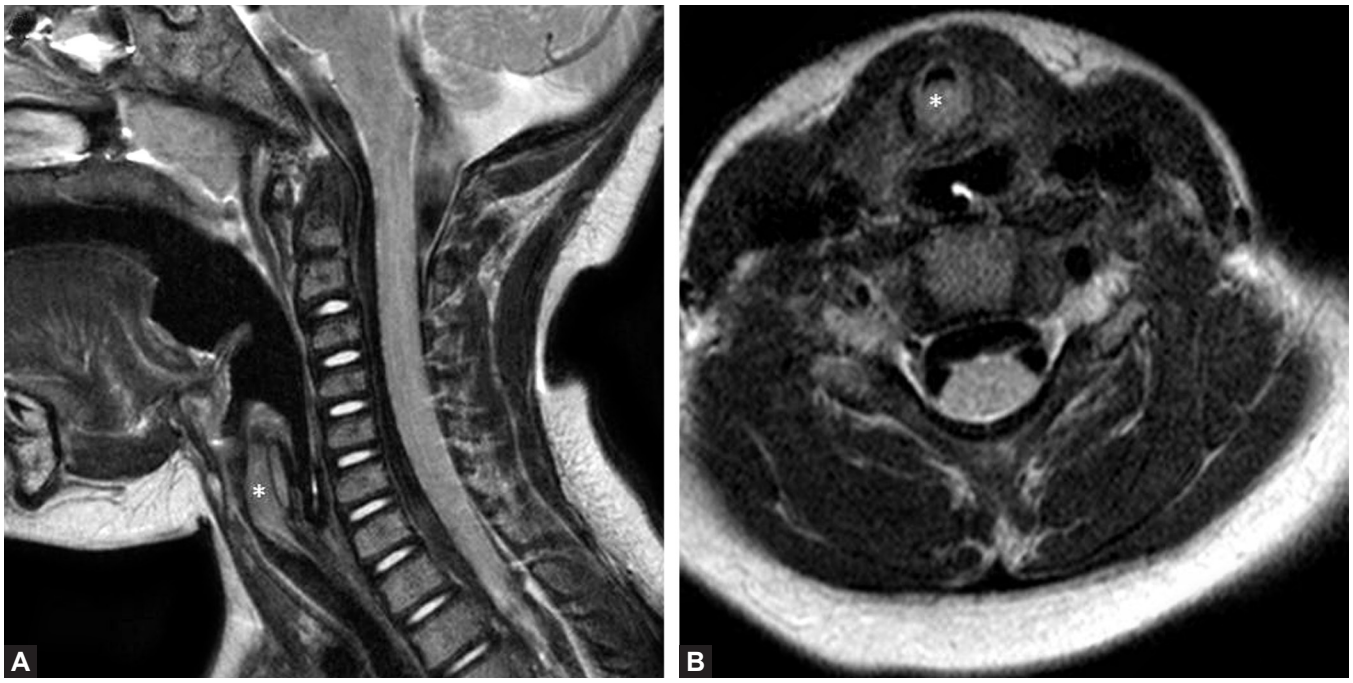
**Figs. 36.9A to F:** Double aortic arch in a 16-month-old boy presenting with difficulty breathing and stridor. (A) Axial contrast-enhanced CT shows the right aortic arch (ra) and left aortic arch (la) as they form a vascular ring and constrict the trachea. (B) A surface reconstruction shows in a rostrocaudal projection the two aortic arches as the form a circle in the superior mediastinum. (C) (An AP projection) and (D) (a lateral projection) 3D surface renderings of the airway show the abnormal constriction of the distal trachea, white arrows. (E and F) Virtual bronchoscopic fly through renderings of the airway show the tracheal lumen above and at the level of the vascular ring.

**Fig. 36.10:** Complete tracheal ring in a 1-year-old boy who presented with difficulty breathing. Sagittal reformat from a helical contrast enhanced CT acquisition of the airway shows an abrupt segmental constriction of the tracheal lumen at the T2 level. No extrinsic compressive lesion was seen such that the findings appeared to be most consistent with a luminal abnormality.

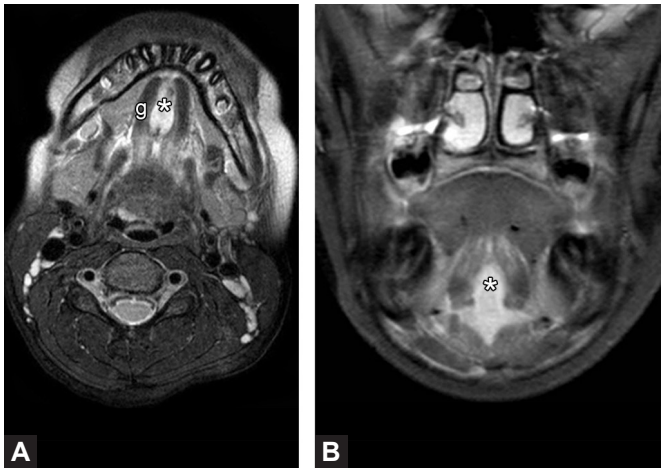


**Figs. 36.11A and B:** Suglottic hemangioma in a 16-month-old girl presenting with difficulty breathing. Coronal (A) and axial (B) post-gadolinium high-resolution T1-weighted images show a subglottic enhancing lesion that protrudes from the right posterolateral wall of the subglottis into the laryngeal lumen. Asterisk (*) indicates a subglottic enhancing lesion consistent with hemangioma.

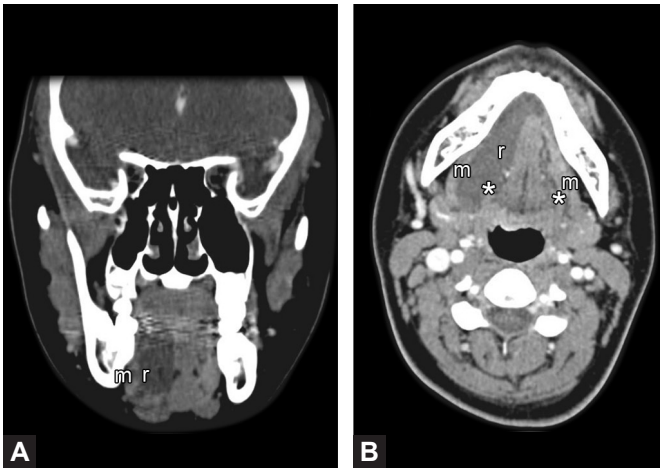
the cine MR imaging and connected via oxygen tubing using hospital tape that is fed through the wave guide, the hole in the wall between MR unit and the technician area, and amplified to a USB preamplified connected to a laptop computer with recording software. Target phrases selected by the speech pathologist similar to those used for videofluoroscopic velopharyngeal studies are used and corecorded with the cine MRI,[53,55] and abnormalities in closure of the velopharyngeal port are evaluated real time during phonation.



**Figs. 36.12A and B:** Subglottic ectopic thymus presenting in 19-month-old boy with difficulty breathing and subglottic mass on endoscopy. Sagittal T2 (A) and axial T2 (B) noncontrast MR images show a subglottic mass (*) that demonstrates intermediate signal on the T2-weighted images, that narrows the sublottis and proximal trachea, and that protrudes ventrally along the perichondrium of the cricoid cartilage.



**Figs. 36.13A and B:** Foregut duplication cyst in a 1-month-old boy with difficult breathing from glossoptosis. An axial (A) and a coronal (B) T2-weighted images show a well marginated high signal finding in the anterior floor of mouth that splays the geniohyoid muscle (g) and appears clearly separate in origin from the sublingual glands, which thus distinguishes it from a ranula. Asterisk (*) indicates a foregut duplication cyst.



**Figs. 36.14A and B:** Ranula presenting in a child with mouth swelling and pain. Coronal reformat (A) and axial image (B) from a contrast enhanced CT show a well-defined low attenuation lesion consistent with a ranula (r) that expands the right sublingual space between the styloglossus-hyoglossus muscles (*) and the mylohyoid muscle (m). The ranula fills the right sublingual space back to the right submandibular gland that lies along the posterior margin of the lesion.

**Figs. 36.15A and B:** Medial deviation of the internal carotid artery in a child with del22q phenotype most consistent with velocardiofacial syndrome who presented with velopharyngeal insufficiency and had pulsatile finding along the right lateral oropharyngeal wall. In (A) an axial source image from a 3D time of flight MR angiogram shows marked medial deviation of the right ICA that abuts the medial wall of the oropharynx. (B) A maximum intensity projection (MIP) reconstruction shows the medial buckle of the right ICA compared to the normal course of the left.

## CONCLUSION

For imaging of the airway in children, a range of techniques is still useful, including the traditional plain film radiograph of the airway, fluoroscopy, barium swallow, US, CT, and MRI. The determination of the modality of choice depends on the clinical indication for the imaging study and the clinical questions that need to be addressed, the age of the patient, and the growing concern for morbidities associated with radiation and sedation, all of which need to be weighed when deciding on the best approach to imaging.

CHAPTER

# 37 Preoperative Evaluation of the Child Needing Airway Surgery

*Mary Shannon Fracchia, Jyoti Ramakrishna*

Anesthesia for airway surgery is particularly challenging in the pediatric age group.[1] We know that these children are at an increased risk of compromised airways due to their underlying condition. Hence, the preanesthesia evaluation is crucial in guiding the anesthesiologist on the day of surgery.

A comprehensive visit, ideally in an aerodigestive clinic, or preanesthesia evaluation is necessary prior to airway surgery. The patient is seen by the ENT surgeon and also meets with other specialists (such as pediatric pulmonary or pediatric gastroenterology) who may be performing procedures on the child. At this time, a complete review of history and prior workup, as well as a thorough physical examination, are performed.[2]

For an elective surgery, it is preferable to perform the procedure when the child is not having intercurrent airway symptoms such as an upper respiratory tract infection or wheezing. However, if a patient has recurrent problems with upper respiratory infections, sinusitis, chronic cough, congestion, or croup caused by the underlying airway condition, then performing the procedure to rectify this may have to occur at a time when the airway symptoms are present. It may not be possible to find an optimal time, and risks versus benefits need to be evaluated and discussed with the family. Depending on the level of concern it may be appropriate to discuss with pediatric anesthesia staff ahead of time. Some cases that are determined to be high risk or complex will benefit from meeting the pediatric anesthesia staff for a preoperative visit prior to the day of the procedure.

## SPECIAL CONSIDERATIONS ON PREOPERATIVE HISTORY AND PHYSICAL EXAMINATION IN PEDIATRIC AIRWAY PATIENTS (also *see* Tables 38.1 and 38.2)

### Prematurity

Often, children with airway concerns were born prematurely. Some have been intubated at birth for varying periods. Subglottic stenosis, gastroesophageal reflux, and bronchopulmonary dysplasia are common comorbidities in this population. These children with bronchopulmonary dysplasia and chronic lung disease have decreased pulmonary reserves at baseline and are particularly prone to infection.[2,4] They require chronic respiratory therapies, including oxygen, nebulized steroids, diuretics, and frequent antibiotics.

### Perinatal History

Important points that may have a bearing on surgical outcomes include low Apgar scores or birth hypoxia; maternal diabetes, pre-eclampsia, or drug/alcohol use; perinatal trauma, seizures, prolonged mechanical ventilation, apnea and bradycardia; and sepsis.[2]

### Developmental

Children may have developmental delays as a result of intra- or perinatal events, or an underlying syndrome, and

may not function at their age level. It is important to note this so that the team working with the family on the day of surgery is able to adapt their care appropriately.[2,3]

## Compromised Airway

Laryngomalacia and/or tracheomalacia are other common issue in this population. For instance, surgery might be successful in repairing subglottic stenosis, but the child might not be able to be decannulated because of a floppy airway, known as tracheomalacia.[5] Gastroesophageal reflux can cause inflammation and airway irritability.[7]

In older children, pulmonary function tests are a valuable tool to investigate airway dynamics of a compromised airway. Flow volume loops can differentiate between upper, lower, and fixed airway obstructions and the degree of the compromise. Any child >6 years of age should get a pulmonary function test.

## Aspiration

Many patients with airway problems in early life present with symptoms of feeding difficulties or choking on feeds. Modified barium swallow testing performed with the help of a pediatric radiologist and a speech language pathologist helps preoperatively to assess for evidence of aspiration, especially with liquids. Fiberoptic endoscopic evaluation of swallowing is another test performed at many centers to assess anatomic deficits in the airway that may lead to feeding difficulties and risk for aspiration.[6] Bronchial lavage specimens are often sent for lipid-laden macrophages, the presence of which may indicate microaspiration, although this is known to be an imprecise marker.[7] Aspiration increases the risk of surgery; hence it may be necessary to advise against oral feedings and recommend placement of a gastrostomy tube while delaying airway surgery until such time as this issue is addressed.

## Oxygen Status

From a pulmonary standpoint, many children requiring airway surgery have decreased pulmonary reserves at baseline, especially those who are premature, aspirate, or have a compromised airway. Undergoing general anesthesia during airway surgery will compromise the pulmonary reserve even further. To optimize pulmonary reserve, we need to understand the pulmonary mechanics preoperatively. Before a laryngeal tracheal reconstruction, for instance, we often recommend an overnight oximetry or sleep study with a capped tracheostomy to assess the ventilation and oxygen needs of the child prior to the procedure.[8]

## Medications

A complete list of current medications and doses should be in the chart. Clarifications of which medications should be taken and which held the morning of the procedure are helpful in avoid unnecessary confusion. This also helps in alerting the anesthetist to potential interactions with anesthetic agents.[2]

In particular, a history of steroid use is important. Children with compromised airways and/or premature lungs are usually managed with steroids throughout pulmonary exacerbations. Nebulized steroids typically do not have profound systemic effects but oral steroids do. Children with compromised airways often suffer from episodes of croup treated with dexamethasone. If a child requires more than two courses of steroids in 6 months, the airway reconstruction needs to be deferred. Steroids interfere with healing of wounds and grafts that may be placed during reconstruction.[8]

## Gastroenterological

Gastroesophageal reflux is common in the first few months of life and considered physiological in otherwise normal infants. Gastroesophageal reflux disease or GERD is defined as symptoms or mucosal damage caused by acid reflux. It is often seen at a higher frequency in conjunction with other underlying issues mentioned above such as prematurity, asthma, tracheomalacia, developmental delays, and many genetic syndromes.[7,9] Airway symptoms such as cough and hoarseness may represent extraesophageal manifestations of GERD. Although often a clinical diagnosis, a thorough workup may be mandated including pH probe or impedance measurements and endoscopy. When poor gastric emptying is suspected as a contributory factor, a gastric emptying scan may be of benefit. If reflux is a concern then it should be adequately managed medically in collaboration with a pediatric gastroenterologist prior to surgery and up to 8 weeks postoperatively to aid in recovery.[10] Although concerns have been raised regarding aggressive medical therapy with proton pump inhibitors in the pediatric age group, patients with specific airway concerns often merit aggressive therapy; hence the

risks versus benefits need to be discussed with the family. Occasionally, fundoplication surgery may be necessary if medical therapy fails.[7]

Less commonly, a tracheoesophageal fistula may contribute to airway symptoms. These can be difficult to diagnose on a contrast upper gastrointestinal study, requiring a "tube study" where dye is injected into the esophagus with a nasogastric tube under some pressure; rarely an endoscopic methylene blue injection into the esophagus on the operating table while visualizing the trachea may be necessary.[7]

Eosinophilic esophagitis has recently been recognized to contribute to airway symptoms in children. This is a clinicopathologic diagnosis, which includes a triad of esophageal symptoms such as dysphagia, poor feeding, vomiting, and abdominal pain; lack of response to adequate acid suppressive therapy; and >15 eosinophils/high-power field on esophageal biopsies. It is related to underlying food allergies and often responds to dietary manipulation, rarely requiring treatment with steroids.[11] A team approach, including pediatric gastroenterologists, allergists, and a dietitian, is best for these patients.

## Infection

If the lower airways are chronically infected, this can impair recovery and overall outcomes. Bronchoscopic lavage is often performed to assess for infection. Of specific concerns are methicillin-resistant *Staphylococcus aureus* and *Pseudomonas aeruginosa*, which can be difficult to treat and interfere with wound healing.[12] Obtaining a specimen for culture is helpful to determine sensitivity of the bacteria and guide specific antibacterial therapy.

Human immunodeficiency virus, hepatitis B and C, or other chronic infections must be documented in the patients' chart so that appropriate precautions may be taken.

## Allergies

Drug and latex allergies must be determined and clearly marked on the chart. Asthma from seasonal allergens should be worked up and if possible the peak season avoided when setting a date for surgery.[2] The pulmonologist and allergist need to have the child on a regimen that has airway inflammation well under control. Food allergies and eosinophilic esophagitis (*see* above) are not uncommon, causing irritability of the airways; it is important to obtain a good history and work with a gastroenterologist as well as an allergist to get the inflammation under control prior to any major airway surgery.

## Nutrition

Airway patients often present with nutritional compromise. This could be multifactorial. Poor feeding can result from frequent respiratory illnesses, choking or gagging on feeds, or poor intake related to esophagitis caused by reflux or food allergies. Some children have increased caloric needs due to cardiac or pulmonary issues. Some have neurological impairment or other significant comorbidities that cause impairment of their ability to take oral feeds, often requiring gastrostomy tube feeds. Working with the feeding team, including a pediatric dietitian, and trying to optimize nutritional status preoperatively is important in ensuring the best possible outcome as far as recovery from anesthesia as well as healing from the surgery itself.[13]

## Metabolic

Underlying metabolic diseases can affect how a child may respond to anesthesia.[1] In tertiary care pediatric centers it is not uncommon to have a child with fatty acid oxidation or urea cycle defects, storage diseases, mitochondrial disorders, and other rare conditions presenting for airway surgery. It is necessary to work with the metabolic team to establish guidelines for specific fluid, electrolyte, and medication concerns ahead of time.

## Genetic

Children with genetic syndromes such as Trisomy 21 (Down's), Pierre Robin, and VATER syndrome (or VACTERL association, involving three or more of the following: vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities), to name a few, often require airway surgery. Poor muscle tone, association with congenital defects that affect the airway, and issues such as atlanto–axial joint mobility need to be taken into account. The individual needs of each patient must be kept in mind, with a specific focus on multisystem involvement.[3]

## Endocrine

Every so often, we will be in the situation of performing an airway procedure on a child with type 1 diabetes. Such

children are always scheduled as the first case in the morning. The endocrinologist is consulted ahead of time and a protocol for insulin and fluids is established for each individual patient. Blood sugars are monitored frequently until the time of discharge.[14]

## Hematology

Anemia can contribute to heightened surgical risk. Anemia can occur from a variety of etiologies, ranging from nutritional to a hemoglobinopathy to bone marrow suppression from chemotherapy or other medications. Coagulopathies or clotting disorders may be present and need to be documented, with a plan in place to address them. If transfusion of blood products may be required, this should be discussed with the family and with pediatric anesthesia staff ahead of time and necessary arrangements made.[2]

## Other Organ Involvement

Neurologic and cardiac issues are of special concerns. Muscle tone and seizures may change the anesthetists' approach. Seizure medications should be optimized. A cardiologist may need to clear the patient or give recommendations for antibiotic prophylaxis if a heart lesion is present. The possible need for other specialists, e.g. nephrologist and geneticist, to evaluate preoperatively depends on associated conditions. Many pediatric airway patients have complex multisystem involvement, and a team approach is critical in the success of the surgery.[1-3]

## Anxiety/Psychological

Coming to the operating room is stressful for children as well as for families. It is estimated that 50–75% of children experience significant anxiety before surgery.[15] Some centers offer tours and simulated experiences of what is to be expected so that the child is familiar with the setting when he or she comes in for surgery. Having Child Life specialists available on the day of the procedure has been found to be of great benefit in some centers. Some children have enhanced issues with anxiety due to previous experiences or underlying conditions. It is vital to work with families to help alleviate this. Conversely, many of these children may need to undergo anesthesia several times, so their experience at the first procedure will determine how they react in the future. Talking to the child and explaining the upcoming procedure at their level of understanding often helps things go more smoothly the day of the procedure.[3] However, parents know their children best, and if a parent feels it is best not to alarm the child ahead of time with too much information, one should respect their wishes.

## Autism and Attention-Deficit Hyperactivity Disorder

This growing population of patients is a challenging group to work with. It is important to understand each child's communication skills, level of comprehension, sensory issues, and triggers that cause decompensation. These children may already be on medications to modulate their behavior and mood. A team approach, which includes the primary caregivers, will yield the best results.[3,15]

## Anesthesia Reactions

Although many of these patients are very young, they may have been exposed to anesthesia previously due to comorbidities requiring various procedures. It is important to ask about reactions to anesthetic agents in the past and try and identify which agents were used.[2] History of malignant hyperthermia in the child or a family member would alert the anesthetist to avoid certain volatile anesthetic agents.[16] Also, some children have difficulty when waking up from anesthesia, either due to being disoriented and crying, even screaming inconsolably, or due to nausea and vomiting. If such reactions are known then the anesthetist may be able to modify the protocol to try and avert them.

## Past Surgical History

Patients may have undergone surgery at other institutions for anything from hernia repair to heart surgery. These records should be obtained and reviewed prior to airway surgery.

## Laboratory

Routine lab testing is not indicated as such. However, pulmonary function testing, airway, and chest X-rays, modified barium swallow studies, and allergy testing are often performed, and the results need to be reviewed and documented. Occasionally, a child may be on an anticoagulant where laboratory testing is required and specific guidelines need to be known. Overnight, pulse oximetry and/or a sleep study might also be warranted if the child is on oxygen.

## Consent

Due to the heightened risk of airway surgery when compared with other surgery in this age group, it is even more crucial to meet with the family in a clinic setting to explain the procedure(s) being planned and review risks and benefits before getting signed consent. Families are often anxious and their questions and concerns can be addressed ahead of time in a less stressful environment. Expectations for postoperative care, such as complications and need for admission, can be discussed. There may be circumstances where child custody and legal guardianship issues need to be sorted out so that consent can be obtained from the person who has legal custody of the child. This is best done in advance, since having a fasting child in the preoperative area and not being able to find the person who needs to give permission is an undesirable position to be in.

## Instructions

Written instructions for where and when to arrive and when they can eat and drink prior to the procedure are helpful in assuring a timely procedure and minimizing the need to delay or cancel. A telephone number to contact the team if any questions or issues should arise in the interim is also useful.

# Pediatric Anesthesia for Airway Surgery

***Corey Collins***

## INTRODUCTION

There is an interdependence of the pediatric airway surgeon and anesthesiologist that may be unique to medicine. Beyond the typical reliance between the two specialties, it may be argued that the dynamic and foundational trust needed to ensure smooth, efficient, safe, and effective care is consistently required and tested in the care of the pediatric airway patient. As outlined in this chapter, the clinical approach to pediatric anesthesia for airway surgery builds upon this relationship to encompass risks assessment, clinical judgment, crisis management, communication, and myriad other skills. While no text can delineate such diverse and emotive subjects, this chapter offers an overview of the interplay of our interdependent specialties.

## RISK

Pediatric airway surgery entails risks that must be considered by surgeon and anesthesiologist. Shared knowledge of such risks can improve patient care and outcome through mutual respect for decision-making, predictable clinical challenges, or other concerns.

Though no available datasets accurately quantify specific risks, numerous studies provide insight into the risks associated with a number of pediatric airway surgeries.

For over three decades, Pediatric ENT surgery is disproportionately identified as a risk for perioperative complications, including medical liability closed claims, perioperative cardiac arrests, adverse airway events or unplanned hospitalizations. Such data may indeed reflect a higher risk of complications associated with pediatric ENT surgery and anesthesia, attributable to the inherent pathophysiology of the child with head and neck diseases, the role of airway manipulation and surgery, and the associated challenges of individual clinicians' competencies and expertise when faced with adverse events.

The Pediatric Perioperative Cardiac Arrest registry has collected voluntary data from US centers since 1994 and consistently documents higher cardiac arrest rates (but not deaths) among ENT patients.[1] The interplay of obstructive sleep disordered breathing, young age, and the unpredictable pharmacology related to opioids creates a high-risk scenario for the anesthesiologist caring for these routine cases. The American Society of Anesthesiologists (ASA) database of settled cases from US insurance groups documents that airway events accounts for most claims, and laryngospasm specifically was noted in nearly one-quarter of pediatric cases. Misinterpreted monitoring data, pulmonary aspiration, and unintentional tracheal extubation were quoted as avoidable complications in a number of cases. Over four-fifths of cases involved healthy (ASA PS 1-2) children.[1,2] When complications occur that are attributable to anesthesia care following adenotonsillectomy, liability awards are consistently higher then those attributable to surgical or other causes. Most often these events involve anoxic injuries related to airway management and opioid dosing.[3]

Unplanned intensive care admissions, delayed ambulatory discharge, low parental satisfaction, operating room efficiency, perioperative maladaptive behavior, long-term neurocognitive injury, and other risks may coincide with these more severe clinical events. Postoperative nausea and vomiting increases the likelihood of unplanned admission and significantly delays discharge. Young children may manifest behavioral disturbances for up to 14 days following tonsillectomy. All team members should be aware of these shared risks.

## CENTRAL NERVOUS SYSTEM EFFECTS OF ANESTHESIA

Anesthetic agents are known to induce neurodegenerative changes in neonatal nonprimate mammalian brains via increased apoptotic cell death and additional evidence documents that certain anesthetic agents induce developmental and neurocognitive deficits in primates.[4] Available data in humans, however, are inconclusive and correlation from animal trials to humans is not possible at this time.

Pediatric specialists must balance the risks and benefits of proposed surgery with possible risks of injury related to anesthesia. In pediatric airway surgery, the immediate need for airway protection will likely override possible long-term neurocognitive risks. For example, the child with recurrent papillomatosis cannot be managed with "watchful waiting" regardless of the child's age.

It is important to note that pain and stress produce long-term negative effects on neonatal development and behavior in humans.[5,6] Until significant advances occur, children should continue to receive balanced and effective anesthesia care for necessary surgeries. As recommended by a multidisciplinary clinical panel and the US Food and Drug Administration, clinicians should: "Discuss with parents and other caretakers the risks and benefits of procedures requiring anesthetics or sedatives, as well as the known health risks of not treating certain conditions; Stay informed of new developments in this area; Recognize that current anesthetics and sedatives are necessary for infants and children who require surgery or other painful and stressful procedures".[7]

## CRISIS MANAGEMENT

Crisis management and simulation have been applied to pediatric anesthesiology and otolaryngology.[8,9] Shared training in these areas is encouraging but scientific inquiry into the durable effects of these efforts is early and data supporting the value of such expensive training programs are scant. Nevertheless, simulation has become an element of the maintenance of certification process for anesthesiologists and an increasingly employed method of technical training in US surgical programs.

The shared knowledge of crisis management language, team training, and simulation can positively impact the area of pediatric airway surgery through enhanced communication, trust, resource management, and human factors comprehension. Such an effect has been recommended in the operating room.[10]

High fidelity medical simulation improves team performance in many critical situations including pediatric emergency airway management.[11] While it is likely that the focused team training provided in such simulation may explain some of the benefit, the simulated crisis experience can provide a durable improvement on team member performance. While many surgical teams inherently practice good team behaviors, it is likely that a consistent simulated crisis-training curriculum will further improve performance during rare airway events.

## PREPARATION AND TRAINING FOR PEDIATRIC AIRWAY SURGERY

There is no specific training available to prepare an anesthesiologist for pediatric airway surgery. Current Accreditation Council for Graduate Medical Education (ACGME) requirements for anesthesiology and pediatric anesthesiology do not establish any specific competency component for pediatric airway surgery. Therefore, individual anesthesiologists will have diverse expertise for the management of such cases. Similarly, referral centers will naturally develop institutional expertise with specific techniques and clinical strategies to manage the pediatric airway patient. Teams, therefore, should consider such variables in developing a supporting training environment for new staff and provide appropriate opportunity for orientation to ensure safe patient care and minimize patient and provider risk.

For a variety of reasons, anesthesia for high acuity pediatric airway surgery requires advanced expertise in pediatric anesthesiology. Great Britain, e.g., requires advanced training in pediatric anesthesiology and an annual volume of 200+ pediatric cases to qualify a physician to provide anesthesia for most pediatric cases. Each center will need to consider their local resources and proceed with planning airway surgery in children appropriately.

## PREOPERATIVE PLANNING

Pediatric airway surgery encompasses a wide variety of clinical pathophysiological states, acuity, and complexity. A system to enable efficient case planning, preoperative consultation, equipment readiness, and other time-sensitive issues must be developed locally.

Preoperative medical clearance is often required although few empiric guidelines exist. Consultation with the pediatric anesthesia service in advance of the planned procedure is mandatory for children with structural heart disease, significant dysmorphic syndromes, severe metabolic diseases, and other conditions outlined in Table 38.1. The critical nature of some airway diseases will preclude timely consultation beyond the surgical team; perioperative risks may be significantly increased and consent conversations should document accordingly. Conflict exists in the available literature regarding the importance of preoperative clearance from consultants; e.g., some experts suggest mandatory cardiac echocardiography for children with severe obstructive sleep apnea[12] yet other authors note the lack of clinically relevant findings with such examinations.[13] On balance, clinical judgment, surgical urgency, and individual clinician experience and comfort with each specific child will likely dictate the necessity for referrals and testing.

Current standards in anesthesiology require a preoperative evaluation by the anesthesiologist caring for the child. This mandates a review of records, patient/parent interview, and a physical examination.[14] In high acuity airway cases, specific attention to birth history, previous intubations, critical events, and other important history items is mandatory (Table 38.2).

Examination of the child will focus on the airway, especially quality of respirations, airway anatomy, chest and auscultation, palpation of distal pulses, and visual

**Table 38.1:** Elements of patient history that may impact planned anesthetic

| *Area of interest* | *Significant elements* | *Possible impact on planned anesthetic* |
|---|---|---|
| Birth history | Prematurity | Increased risks of concomitant disease; increased risk of respiratory events; increased incidence of significant medical and surgical history; prolonged endotracheal intubation; possible subglottic stenosis |
| | Low Apgar scores | History of developmental delay; encephalopathy; intrauterine injury |
| | Birth trauma | Neurologic injury; head and neck trauma |
| Pregnancy history | Toxic exposure | Opioid dependence; dysmorphism |
| | Polyhydramnios | Intrauterine renal dysfunction; esophageal obstruction |
| | Oligohydramnios | Fetal hyperglycemia; macrosomia |
| Neonatal history | Apnea/bradycardia syndrome | Anemia; postoperative risk of sudden death |
| | Prolonged endotracheal intubation | Bronchopulmonary dysplasia; subglottic stenosis |
| | Cardiac surgery | Persistent lesions; repaired physiology; shunt |
| Family history | Inheritable disease | Chromosomal abnormalities; dysmorphisms |
| | Anesthetic complications | Malignant hyperthermia; hemoglobinopathies; coagulopathies |
| | Tobacco exposure | Reactive airway |
| Medications | Past and current medications | Compliance with medical therapy; awareness of prior diagnoses; insight into stage of chronic illness |
| | Medications | Interaction with planned anesthetics |
| Surgical history | List of surgical procedures | Complications of surgery; reasons for surgery; impact on chronic health |
| Anesthetic history | Types of anesthesia | Complications with anesthesia; address patient/parent concerns regarding anesthesia |
| Hospitalizations | Reasons for admissions | May reveal undisclosed events or diagnoses; more thorough discussion of chronic illness |
| | Frequent admissions for minor problems | Missed diagnosis; poor access to care; social factors |

**Table 38.2:** Interrelated specialties and possible anesthetic implications

| *Specialty* | *Pertinence* | *Possible impact on planned anesthetic* |
|---|---|---|
| Neurology | Seizure history | Avoid epileptogenic drugs |
| | Communication/development | Appropriate sensitivity to parents and child's abilities; adjust doses of centrally acting opioids |
| | Motor disease/myopathy | Assess risk of MH, hyperkalemia; possibly withhold paralytics |
| Pain management | Current modalities of pain management (e.g. baclofen, methadone, and fentanyl patch) | Accurately prepare for effective analgesic requirements while avoiding harmful drug interactions. Consider tolerance and role on dosing analgesics |
| | History of postoperative pain management challenges | Avoid inefficient and ineffective pain management; improve patient and family satisfaction |
| Metabolic/nutrition | Metabolic disease | Avoid incompatible drugs and hydration solutions |
| | Document nutritional state | Poor nutrition increases risk of adverse drug reaction, inability to tolerate surgical stress |
| | Documents growth and development | Accurate body mass data; better estimation of total body water |
| Nephrology | Renal function | Avoid or reduce doses of renally excreted or nephrotoxic drugs; assess potential hyperkalemia; secondary hypertension |
| Neonatology | Prematurity | Postconceptual age; stigmata of prematurity; life-threatening events |
| Respiratory therapy | Respiratory status | Mode of ventilation; bronchorrhea; oxygen requirement; pulmonary toilet |
| Social work | Family status | Improve communication; prepare for consent discussions; avoid conflict |
| | Guardianship | Identify legal consenting party |
| | Social status of patient and family | Improve family comprehension of health, consent, risk discussion |

examination of the chest and abdomen for evidence of airway obstruction. Other key elements of the physical examination are listed in Table 38.3.

Review of the surgical plan with the surgical team well before induction in the operating room is recommended, even in the most urgent circumstances. The ubiquitous surgical "time out" pauses currently conducted in the United States provides an excellent opportunity for the team to quickly identify and discuss key concerns.

## Current Upper Respiratory Tract Infection

School-aged children will experience between 5 and 10 upper respiratory tract infections (URIs) per year with approximately 4–6 weeks after resolution of symptoms before the risks for perioperative adverse airway events returns to baseline.[15,16] Considerable attention is warranted for the child with a URI scheduled for airway surgery. Despite the considerable literature on the topic, it remains the responsibility of the anesthesiologist and surgeon to decide if the risks of an adverse airway event are balanced by the surgical benefit.[17-20] Associated complications may include laryngospasm, bronchospasm, significant coughing, and arterial desaturation. Respiratory complications are also associated with level of experience of the anesthesiologist.[21]

Certain clinical decisions may decrease risk. For example, avoiding tracheal intubation, extubation of the trachea while deeply anesthetized but with adequate respirations,[18] and avoiding excessive pressure on the tracheal cuff[22] may decrease airway irritation and postoperative bronchospasm, laryngospasm, or arterial desaturation. The supraglottic airway (SGA) may cause less adverse respiratory events.[23]

Children with any of the seven specific risk factors identified by Tait et al. warrant particular consideration: copious secretions, endotracheal intubation in children under 5 years of age, former prematurity, nasal congestion, paternal smoking, history of reactive airway disease, and planned airway surgery.[24] Should an airway procedure proceed in the setting of a recent URI, additional risks

**Table 38.3:** Summary of physical examination findings and possible impact on planned anesthetic

| *Area of examination* | *Specific findings of interest* | *Possible impact on planned anesthetic* |
|---|---|---|
| Airway | Retrognathia; micrognathia; macroglossia; cleft palate | Small oral volume versus large tongue predicts difficult laryngoscopy |
| | Prominent incisors | Possible difficult visualization of larynx |
| | Ankylosed mandible | Limited mouth opening |
| HEENT | Wide-set eyes; malformed ears; cleft lip | Association with cardiac anomalies |
| | Microtia | Associated with difficult intubation |
| | Stridor | Laryngotracheomalacia; vocal fold paralysis; gastrointestinal reflux |
| Cervical mobility | Limited extension; unstable cervical spine | Limited ability to align visual axis with larynx |
| Heart | Murmurs | New murmurs may be innocent or pathologic and often require evaluation |
| | Heave | Right heart overload accompanies pulmonary hypertension; left ventricular outflow obstruction must be evaluated |
| | Thrills | Harsh thrills often accompany serious lesions |
| Lungs | Wheeze | Reactive airway; foreign body; poor compliance with medical management |
| | Rhonchi | Acute lower respiratory infection; poor ventilatory capacity; physical deconditioning |
| Skin | Rash | Viral exanthems; chronic dermatologic disease; preoperative drug eruptions |
| | Cyanosis | Pulmonary/respiratory insufficiency |
| | Lymphatic malformations | May displace airway |
| | Turgor | Dehydration |
| Abdomen | Scars; stoma; feeding tubes | Surgical history; nutritional status; decompress stomach preprocedure |
| Extremities | Clubbing | Chronic hypoxia |
| | Pseudohypertrophy of muscles | Muscular dystrophy |
| | Subcutaneous adiposity | Difficult intravenous access |
| Nervous system | Activity | Assess level of function; focused defects; avoid confusion with postoperative examination findings |
| | Communication | Improve patient recovery; predict ability to assess emergence from anesthetic; predict ability to assess for pain |
| | Motor | Avoid iatrogenic respiratory depression; optimize respiratory mechanics for emergence and postprocedure airway management |

(HEENT: Head, Eyes, Ears, Nose and Throat).

should be explained to the parent and the team should be prepared for a higher likelihood for laryngospasm, bronchospasm, and arterial oxygen desaturation.

## Preoperative Admission

Preprocedure admission for elective airway surgery is most often determined by clinical severity of respiratory distress. There are a number of disease states that may require admission based on medical risks.

### *Insulin-Dependent Diabetes Mellitus*

The diabetic child requires careful assessment of metabolic control before elective surgery. Preferably, consultation is advised well before surgery though if airway surgery is more urgent, admission and consultation with pediatric endocrinology is recommended. Careful adherence to published management guidelines such as the Boston Children's Hospital guidelines is highly recommended.[25]

### *Sickle Cell Disease*

Perioperative complications associated with sickle cell disease include acute chest syndrome, painful crisis, neurologic event, or death. Such complications are typically associated with hypoxia, hypoperfusion, or acidosis. Children having airway surgery may be at higher risk for such events. Strategies to decrease risks preoperatively typically include intravenous hydration and blood transfusion to decrease the hemoglobin S level to < 30%. The impact of such interventions, however, has been poorly documented. A multicenter trial in 1995 documented no benefit to aggressive transfusion and a cohort that included approximately 25% children.[26] While significant practice variability remains, consensus suggests consultation, admission, and management with close communication with hematologic experts, especially in high acuity cases.[27]

### *Complex Congenital Heart Diseases*

Patients with structural heart disease should be referred for preoperative evaluation and possibly extensive testing before airway procedures. Consultant input is mandatory in cases of cyanotic lesions as acute respiratory embarrassment may cause significant perturbations in pulmonary blood flow. Certain lesions or repairs may require standby of invasive cardiopulmonary support.

### *Poorly Controlled Systemic Disease*

Many pediatric diseases add significant perioperative risk if inadequately managed at the time of surgery. Myopathies, seizure disorders, glycogen storage diseases, renal disease, and pervasive dermatologic disease (e.g. epidermolysis bullosa) are but a few examples of conditions that must be evaluated carefully before determination if preoperative admission is necessary. Early and detailed discussions should occur as early as possible for all children with any significant systemic disease.

## Preoperative Testing

Preoperative testing before pediatric airway surgery is only necessary for a small subset of children with significant systemic disease. Very few published reports provide strong evidence for most tests. Testing should be reserved for children with known metabolic derangements, recent clinical exacerbations, or unstable diseases known to add risks.

## Preoperative Preparation

In addition to a standard room preparation dictated by current standards in anesthesiology, specific equipment may be necessary. Medical liability associated with airway mismanagement has taught most anesthesiologists to approach the airway patient with numerous options for airway management available. These include direct laryngoscopy (DL), indirect videolaryngology, SGA devices, fiberoptic bronchoscopy, high-pressure "jet" ventilation, and spontaneous ventilation techniques. All techniques require expertise, training, competency, and preparation.

Pharmacological management of each child will be individualized. Specific goals may include sympatholysis, anesthesia, analgesia, hypnosis, immobility, antisialorrhea, or cardiac support. The armamentarium of available medications changes often. The surgical team may consider review of specific agents to be used to improve awareness of possible complications and the planned pharmacologic state of the patient during the procedure.

Emergency equipment must be available and is described elsewhere in this section. Specifically, options for emergent surgical airway must be immediately available. These will include cricothyrotomy kits, tracheostomy kits, rigid bronchoscopes, or retrograde intubation kits. At a time of crisis, it is important to quickly determine the best option for surgical airway based on the expertise of the physicians and the available resources. Preoperative discussions regarding the "cannot ventilate/cannot intubate" scenario will improve team response and possibly patient outcomes. In many pediatric critical events involving difficult airway management, surgical airways were either delayed or not attempted resulting in poor outcome. Successful surgical airway access requires practice, training. Emergency surgical airway rates are low (< 0.01–2/10,000).[28] Training and practice help, although there is evidence that adherence to published protocols remains unimproved after simulation training.[29]

## Airway Management

Advances in technology have made important changes in the airway management. As costs of fiberoptic fibers and liquid crystal displays have decreased, new devices have come onto the market that permit indirect visualization of the glottis. These proprietary devices use a variety of designs to introduce a camera or fiber optic bundle into the hypopharynx and obtain a visual display of the airway without requiring typical forces involved with DL.

There are three device types routinely used in the United States: devices that are similar in design and use to standard Macintosh and Miller laryngoscope blades; devices that are anatomically curved to match various sized patients that do not permit direct visualization of the glottis or the introduction of the tracheal tube (TT); and anatomical devices with a guide to introduce the TT directly into the visualized glottis. Comparisons with DL are available but no consensus has emerged.

Generally, indirect videolaryngoscopes provide an excellent glottic view, but multiple studies demonstrate time to passage of a TT is longer compared to DL. First attempt success rates are typically higher for these devices. Expert laryngoscopists' success rates are less improved compared to novices and the added time to intubation may increase the rate of oxygen desaturation in patients with low oxygen reserves such as children.[30] The success of these devices in difficult airways or emergencies has increased their use in emergency departments and intensive care units. Holm-Knudsen reviewed the use of the four available devices in pediatric patients and the unique attributes and limitations of each.[31] While success has been reported for each in various settings, most authors continue to recommend awake flexible fiberoptic intubation as the gold standard in the management of the pediatric difficult airway.

### Access Information: IO, Central Lines, Urinary Catheters

In the United States, a majority of pediatric anesthetics are induced by inhalation of anesthetics agents versus perioperative indwelling intravenous lines. While often a safe and reliable option, this method adds important risks should an adverse event occur during or soon after induction. In addition, surgery can only follow the subsequent successful placement of an IV line in all but the most minor of procedures. Occasionally, such access will be quite difficult and mandate alternative access to be considered.

When standard sites for peripheral venous access are unsuccessful, other sites may be considered including the scalp, external jugular, or less commonly, the azygos, gonadal, or inferior epigastric veins. Complications specific to each site should be considered and may be serious.

The advent of an easy to use intraosseous device (Arrow EZ IO; Vidacare, Shavano Park, TX) has made safe, rapid central access readily available for children > 3 kg in weight. While important safety information must be reviewed and considered before its use, this device can provide rapid and definitive access for perioperative or emergency care. Such devices, however, must be replaced within 24 h.

Central venous access may be indicated for long-term access in children having airway surgery. Many children require prolonged sedation after airway reconstruction, for example. Typical sites for central access are the femoral and subclavian veins.

Urinary catheters are rarely indicated following airway surgery unless coexisting diseases mandate careful measurement of urine production and fluid balance. Children are at risk for nosocomial urinary bladder infections following catheterization.

## CASE MANAGEMENT

A brief overview of the major pediatric airway cases follows with a focused discussion of the typical approach to anesthesia management options.

### DL/Bronch/EGD/FOB

Diagnostic endoscopic procedures are often necessary for children exhibiting signs of clinical airway disease. Such signs may include stridor, hoarseness, dysphagia, or chronic cough. While many of these children will have relatively mild disease, there is a consistent risk of more severe occult underlying pathology such as airway tumors, foreign bodies, vascular compressions, or cardiac abnormalities.

Spontaneous ventilation may minimize the risk of a lost airway. An inhalational induction, followed by careful titration of intravenous medications such as opiates or intravenous anesthetics, will provide an adequate depth of anesthesia and permit rigid bronchoscopy without coughing, laryngospasm, or injury to the airway. Brief procedures such as DL may be performed under inhalational anesthesia. The use of suspension microlaryngoscopy will necessitate more profound sympathetic blockade and possibly anti-cholinergic therapy to mitigate a vagotonic decrease in heart rate. If it is clear that there is no significant dynamic or space-occupying lesion threatening the airway, the use of paralytics may be warranted. In such cases, intermittent intubation may simplify the procedure and maintain ventilation and a more routine fashion. The use of SGAs may permit access to the glottis for fibrotic bronchoscopy while allowing positive pressure ventilation as needed. However, such devices do not protect against laryngospasm or aspiration.

## Tracheostomy

Tracheostomies are often necessary to establish definitive airway access in a variety of surgical patients. Anesthetic management will require careful discussion with the surgical team to ensure safe induction of anesthesia, especially in children with known difficult airways. Children who arrived to the operating room intubated must be carefully managed to ensure adequate sedation prior to the onset of anesthesia to avoid dislodgment of the endotracheal tube. Paralytics may be warranted. High-inspired oxygen concentration should be avoided during electrosurgical entry into the airway to reduce the risk for airway fires. Intravenous or inhaled anesthesia may be selected based on concomitant medical concerns. Once the tracheostomy is matured, careful attention must be paid to avoid excessive coughing or breath holding and the child resulting in hypoxemia. There is a risk for immediate subcutaneous emphysema and possible pneumomediastinum or pneumopericardium. In addition, sudden hypoxemia concurrent with tracheostomy will create a challenging diagnostic scenario and is best avoided.

Typically, low-dose opiates are administered (1 mcg per kilogram fentanyl) for sympathetic blockade and antitussive effect. If paralytics are used, they may be administered at any time during the anesthetic; muscle relaxation should be ensured immediately prior to entering the airway.

The newly tracheotomized child will often recover in the pediatric intensive care unit. Transfer to the unit may be facilitated with the assistance of respiratory therapy, especially in children with underlying pulmonary disease or challenging ventilatory requirements.

## Airway Reconstruction

Reconstruction of the pediatric airway is an effective option for a number of indications including subglottic stenosis, tracheal stenosis, or other anomalies as described in Chapter 13. Local anesthetic management techniques have been published,[32,33] although rigorous literature comparing specific techniques, morbidity, or outcomes are lacking.

A careful plan should emphasize the transitions during the induction of anesthesia, airway management, and critical surgical steps. While techniques vary, often a DL will precede oral ETT placement. Ventilatory pressures should be monitored if a costal cartilage graft is obtained to avoid barotrauma and possible pneumothorax. Many children will have a history of chronic pulmonary disease related to prematurity, and peak inspiratory pressures may be elevated. Reduced inspired oxygen concentrations are indicated during electrocautery of the airway to avoid airway fire; any plan to relocate the ETT should be discussed with sufficient time to permit reoxygenation before an ETT is moved to minimize hypoxemia. Some children will be quite sensitive to perturbations in respiratory mechanics and promptly decompensate with the loss of positive end expiratory pressure. Full attention of the team will be required to exclude other causes for acute hypoxemia such as pneumothorax, pneumomediastinum, impaired cardiac preload, or other acute events.

Significant morbidity is difficult to assess and intraoperative events can occur anytime. Although some patients have benign medical histories, many children will have severe systemic disease such as prematurity, velocardiofacial syndrome, or cardiac diseases.

## Juvenile Onset Recurrent Respiratory Papillomatosis

Juvenile onset recurrent respiratory papillomatosis is a rare cause of pediatric airway obstruction and disease. Diagnosis may occur at any age, though 75% of cases are diagnosed by age 5 years and is heralded by hoarseness, stridor, or abnormal cry. Lesions rarely threaten the airway initially though aggressive disease can cause near-complete occlusion of the larynx, spread to the bronchial or pulmonary airways, and undergo malignant transformation to squamous cell carcinoma.[34]

Frequent anesthetics are often needed for debulking procedures. Assessment will focus on the level of airway compromise, though clinical signs of obstruction may be thoroughly masked by a compensating, calm child. Inhalational induction may be considered with preparations in place in case for the urgent lost airway including rigid bronchoscopy and a surgical airway. Avoidance of laryngospasm and frank airway obstruction is important. The use of continuous positive airway pressure (CPAP) hand delivered via the anesthesia circuit is often employed to maintain ventilation despite mild airway obstruction during the induction of anesthesia.

Anesthesia and airway management for respiratory papillomatosis patients has been described using jet ventilation[35,36], intermittent apnea/intubation, or tubeless

spontaneous ventilation[37]. No technique has been clearly demonstrated as superior and benefits to each can be argued. Teams will need to review the plan for airway management including discussion about planned interventions for adverse events. When surveyed, approximately two-thirds of surgeons prefer spontaneous ventilation techniques in the United States and United Kindom.[38,39]

Specific technical papers are available for the different techniques and the complications and benefits of each.[35,36,40] Jet ventilation permits paralysis and a quiet surgical field. Most children will tolerate this technique with stable $pCO_2$ levels and adequate oxygenation. Risks include barotrauma or direct tracheal injury related to the high-pressure (50 psig) oxygen source. Total intravenous anesthesia techniques are required. A number of technical systems have been described including high-pressure/low-pressure cannula techniques, supraglottic catheter placement, or tracheal catheter placement. Intermittent intubation with standard endotracheal tubes also allows the use of paralytics and is generally well tolerated by patients.[41] This technique has been associated with lower laryngospasm and apnea rates with no significant difference in operating time recovery time or post of voice quality. Spontaneous ventilation without an endotracheal tube, while preferred by a majority of US surgeons, may have higher adverse airway events including desaturation and apnea. The technique may be more challenging to learn than those that permit paralysis. Benefits include complete surgical access to the larynx and below, expedient transition from anesthesia onset to surgical start, and reduced trauma to the subglottis and trachea related to catheter placement or endotracheal tube. These techniques may be employed in other tenuous airway cases.

## Foreign Bodies in the Airway

Aspiration of foreign bodies into the pediatric airway is a regular challenge to many pediatric surgical centers. Careful management begins with optimizing the behavioral response of the child to mitigate agitation and possible migration of the foreign body. The child, once assessed, should be brought to the operating room where a calm and controlled inhalation induction should be pursued. Spontaneous ventilation is maintained and respiratory mechanics are supported with the use of CPAP while intravenous access is obtained. Transition to a total intravenous anesthesia (TIVA) technique may be employed to establish a stable plane of anesthesia. Careful assessment of anesthetic depth must be maintained continuously to avoid coughing or dislodgment of the foreign body. Extraction of the foreign body may require considerable time and surgical skill. Often the airway is irritated and prone to reactivity further complicating the anesthetic. Excellent medication among team members will play an important role in surgical success.

## Trauma

Pediatric airway trauma presents exceptionally high risks and warrants considerable preparation, training, experience, and teamwork. While beyond the scope of this overview, management of such patients follows many of similar principles previously offered: definitive communication, a shared plan for airway management with clear roles and alternative strategies to secure the airway, and resource management.[42]

## Burns

Management of the burn child is an area of specific skill and expertise. Airway management is often extremely challenging and subject to significant change during the course of initial resuscitation and subsequent healing. Often the airway is initially managed with intubation followed by tracheostomy and possibly airway reconstruction once the acute phase of injury has resolved. The nature of the burns around the airway will predispose some children to difficult intubation and may mandate awake fiberoptic intubation.

# CONCLUSION

The management of the pediatric airway places many demands on a surgical team. With appropriate training and experience, the full spectrum of pediatric airway patients will receive safe and effective care. The risk for sudden adverse events mandates vigilance and communication to promptly protect the child in distress from catastrophic complications related to airway compromise. A shared commitment to effective and safe patient care provides an excellent framework for the interplay of surgical and anesthesia related issues and can lead to enhanced teamwork and improved care for pediatric airway patients.

CHAPTER

# Perioperative Intensive Care Management in Airway Surgery

39

*Brian M Cummings, Ernesto Quinones, Natan Noviski*

## INTRODUCTION

The postoperative management of pediatric patients following airway surgery requires a comprehensive understanding of the surgery itself and extensive experience on the part of the surgeon, anesthesiologist, pediatric intensive care physician, respiratory therapist, and the nursing staff for a successful outcome. In the following chapter, we discuss some of the more common issues encountered in postoperative care for pediatric airway procedures from the pediatric intensivist perspective, focusing on operations involving tonsillectomy and adenoidectomy, supraglottic surgeries including supraglottoplasty and laryngeal cleft repair, and intratracheal surgeries including fresh tracheostomy and laryngotracheal reconstruction (LTR). Challenges during the perioperative period are discussed, with the goal to minimize morbidity and lead to successful outcome, and we detail our approach in the pediatric intensive care unit (PICU). More research is needed to determine best practice for pediatric care for many of these operative recoveries.

## TONSILLECTOMY AND ADENOIDECTOMY

The most common airway procedure in children is the tonsillectomy and adenoidectomy for obstructive sleep apnea. Most patients come to attention with classic symptoms of airway obstruction, as well as more subtle signs of behavioral changes and impaired school performance. The majority of procedures are performed with minimal complications. However, severity of upper airway obstruction varies and controversy exists over whether preoperative sleep studies are indicated and whether the use of noninvasive respiratory support measures are indicated prior to surgery. More severe cases with underlying genetic or congenital abnormalities, a severe apnea/hypopnea sleep index (AHI) on a formal sleep study, or the need for noninvasive ventilation prior to surgery are deemed to be at a higher risk for perioperative complications.

Most tonsillectomies and adenoidectomies are performed as outpatient surgeries or with < 24 h postoperative observation.[1] Less is known as to which patients should be admitted to the hospital, either to the general care ward or the PICU. Consensus recommendations state that children < 3 years of age, children with severe obstructive sleep apnea, or children with comorbid conditions such as obesity, sickle cell disease, coagulopathies, congenital heart disease, arrhythmias, and craniofacial abnormalities may require more protracted inpatient care and/or ICU observation.[2] In many centers, the preoperative requirement of noninvasive ventilation requires specialized caregiver skill that requires postoperative PICU monitoring and care. Additionally, we have found age < 2 years, an AHI >24 (whereas AHI > 10 is typically regarded as severe), intraoperative laryngospasm requiring treatment, oxygen saturations < 90% on room air in post anesthesia care unit (PACU) and prolonged PACU stay > 100 min each independently predicted postoperative complications leading to need for PICU care.[3] Overall, determining PICU observation versus ward observation for individuals remains unclear for patients, and should be adapted based on the skill sets of staff in recognizing expected airway complications and the underlying condition of the patient. Better patient selection criteria can potentially lead to more cost-effective care in this population.

Postoperative care is focused on pain control, hydration, and observation for respiratory complications. The use of dexamethasone in the perioperative period is standard of care allowing for pain control, decreased airway swelling, and earlier resumption of diet. One dose between 0.15 and 1 mg/kg is likely sufficient, with no difference in outcome found in varying dosage.[4,5] Additionally, there does not appear to be an association between steroids and postoperative hemorrhage, even in regards to higher dosage.[6,7] Our current practice is to administer one dose of 0.5 mg/kg (max 20 mg) in the perioperative period. Pain is universal after surgery, although the mechanism and best method to treat is unknown. Traditionally, treatment was provided with acetaminophen and codeine. However, codeine should be avoided as a pain medication in children due to varying metabolism and effectiveness in the population, and severe side effects including death following tonsillectomy.[8] Acetaminophen alone may be sufficient. Additionally, consensus recommendations now advocate for nonsteroidal medications, as there is no known increased bleeding risk with these medications.[9] Effective hydration with intravenous fluids (IVF) and prevention of dehydration are also associated with decreased pain.

Respiratory complications can occur intraoperatively, in the post anesthesia recovery unit (PACU) or during postoperative observation.[10] Patients may be sensitive to opiate analgesia and may have prolonged apnea following administration during surgery, requiring noninvasive or invasive respiratory support. For that reason, many advocate for reducing opiate dosages in children with obstructive sleep apnea. Laryngospasm requiring immediate intervention in the OR has been reported, and may require prolonged mechanical ventilation to recover. Additionally, postobstructive pulmonary edema has been reported both immediately in the OR and later in the postoperative period, demonstrated by respiratory distress, frothy sputum production and a chest X-ray (CXR) with diffuse pulmonary edema pattern. Patients require respiratory support with either supplemental oxygen or positive pressure ventilation, which may be noninvasive ventilation such as continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) in older children but younger children may require intubation. High expiratory pressures may be necessary to open the lung and oxygenate. Additionally, diuretics are effective to reduce ventilatory needs. Mechanical ventilation is continued until pulmonary edema resolves and the patient can tolerate decreasing support.

Bleeding is another common complication and although minor bleeding is most common, major bleeding complications can occur.[11] Typically two peaks of bleeding potential occur, in the immediate period and then following eschar formation in 5–7 days postoperatively. Patients with coagulopathies have anticipated bleeding complications and should have presurgical plans with pediatric hematology to prevent complications, such as the use of desmopressin (DDAVP) in patients with von Willebrand's disease. Hemorrhages presenting as outpatients often present to the emergency department (ED) without continued evidence of bleeding and may be observed as inpatients. Those with active bleeding or evidence of clot may require immediate surgical treatment. Young children with active bleeding will require general anesthesia, and securing the airway early with rapid sequence intubation and cricoid pressure to prevent blood aspiration may be beneficial.[12] Fluid resuscitation should occur, and blood products may be necessary depending on extent of bleeding. Major arterial bleeding is possible, and requires endovascular control and possible major vessel ligation.[13] Patients should be managed with a secure airway until bleeding is terminated, and stomach evacuated of blood products.

In our practice, patients requiring preoperative ventilatory support are all managed in the PICU postoperatively. Patients who have intraoperative or PACU-related complications are also transferred to the PICU for management. Consistent with consensus recommendations above, patients deemed high risk for complications are scheduled electively to be admitted postoperatively to the PICU for observation for 24 h. Many patients do not require intervention, so improved patient selection could contribute to improved cost-effective care strategies in the future.

## SUPRAGLOTTOPLASTY

Laryngomalacia is the most common laryngeal abnormality and the most common cause of stridor in infants. The spectrum of disease is diverse, from noisy breathing to life-threatening airway obstruction, for which supraglottoplasty is often performed. Postoperative observation is important to monitor for significant residual stridor or respiratory distress due to failure to remove enough tissue, as well as possible postoperative airway edema secondary to swelling. Comorbid conditions may play a significant role in postoperative complications that usually occur < 10% of the time.[14]

Best practice regarding appropriate patient location for postoperative management remains unknown and institutional practice varies. Some centers bring all patients to the PICU intubated overnight,[15] whereas others monitor all patients in the PICU regardless of intubated or not.[16] One center has shown it is safe to observe the majority of patients on the general care ward despite the presence of major comorbidities without any complications,[17] in contrast to another that demonstrated a 33% reintubation rate.[18] One possible distinguishing characteristic is the surgical technique, with the former study using cold steel versus the latter $CO_2$ laser, creating perhaps more postoperative swelling and risk of complications. The ideal practice thus remains unknown, but it is encouraging that morbidity is low for this procedure and hospital stays can be minimal.

Our practice following this procedure is observation without an endotracheal tube (ETT) in the PICU overnight given potential need for intervention with heliox or positive pressure ventilation if swelling occurs. Heliox is an helium–oxygen gas mixture that provides a lower density gas than room air. In obstructed proximal airways that result in turbulent airflow pattern and poor oxygen delivery, heliox can be beneficial due to its lower density in establishing laminar flow and in allowing oxygen delivery to distal airways. To be effective, however, heliox must be administered at 80:20 or 70:30 helium:oxygen concentrations. Thus, it cannot support children who have large oxygen requirements in addition to airway obstruction. Need for heliox is rare following this procedure but expertise should be available. All patients are administered dexamethasone at a dose of 0.5 mg/kg every 8 h for 3 doses. A proton pump inhibitor or antihistamine is administered for reflux prophylaxis. Patients are typically discharged to home the next day if in no respiratory distress and tolerating oral intake. If there are any residual concerns, patients are transferred to the ward for further monitoring or for advancement of oral feeding.

## LARYNGEAL CLEFT REPAIR

Laryngeal cleft is a rare congenital abnormality in which the posterior elements of the larynx fail to fuse. Diagnosis can be challenging and is based on clinical suspicion as presenting symptoms may be nonspecific including feeding difficulties, cough with drinking thin liquids, wheeze, chronic cough, and recurrent respiratory tract infections. Diagnosis is confirmed through direct endoscopy, with the diagnosis of type 1 clefts increasing. When conservative management fails, endoscopic repair through either suturing or laser techniques may be necessary. Typically postrepair observation occurs in the PICU setting for 24 h, and then patients are transferred to the general care ward for an additional 24 h observation.[19] Postoperatively, patients may have additional swelling with potential risk of airway obstruction. Continuous oximetry and telemetry are necessary and providers skilled in airway management are a must. Availability of heliox at 80:20 or 70:30 helium:oxygen concentrations may be helpful if stenosis is a concern. Dexamethasone is administered to reduce edema in similar dosing of 0.5 mg/kg every 8 h for 3 doses. Ampicillin-sulbactam is administered IV for 24–48 h and then converted to an oral regimen for 10 days. A proton pump inhibitor or anti-histamine is also started and continued for 3–6 months at the discretion of the surgeon.

In our center, we typically utilize a suture repair technique. Disruption of sutures may occur from vigorous crying or coughing, requiring reoperation. For this reason, we attempt to minimize patients' agitation and crying for the first postoperative night and administer an infusion of dexmedetomidine as it preserves normal respiratory drive, yet allows patients to be calm and comfortable.[20] Additional analgesia is provided with acetaminophen, narcotics and benzodiazepines as needed. The following day, the infusion is discontinued, the patient is awakened and allowed to advance their diet and dexamethasone is stopped. One more day of observation for airway obstruction or aspiration occurs on the regular ward, with a swallow study performed for any persistent aspiration concerns either immediately if oral feeds are not tolerated, or routinely a few months postoperatively.

## TRACHEOSTOMY

The major indications for tracheostomy placement in a child are anticipated long-term respiratory compromise from chronic respiratory insufficiency or a fixed upper airway obstruction that is not anticipated to resolve quickly.[21] Whereas in the past fixed obstruction was the most common indication in children, the former indications are increasing reasons for tracheostomy given improved intensive care and survival of patients with chronic neuromuscular and respiratory problems. Risks of the procedure vary based on indication and underlying patient comorbidities. Given the risk of loss of airway control and death, adequate informed consent with families is paramount.

Perioperative care includes preprocedural planning and observation in the postoperative period. A multidisciplinary standard approach to tracheostomy care in adults has potential to decrease morbidity and mortality after this procedure and application of standardization in children is desirable.[22] Overall, areas of consensus in tracheostomy care are emerging and will help defining future research and standardization in children.[23]

Preprocedure planning for the appropriate tube size is critical, with the size of the airway and clinical indication helping guide the decision. Diameter size that is too large can compromise the mucosal wall of the trachea, leading to ulceration and potential fibrosis. The tube should be small enough to allow the child to speak, if possible, but not so small as to lead to hypoventilation, respiratory distress or inability to clear secretions. Use of a cuffed tube will vary by indication, and overinflation of the cuff may lead to vascular compromise of the mucosal wall as well. A cuffed tube will often be necessary in the pediatric patient requiring chronic mechanical ventilation so appropriate sizing is necessary. Unlike adults, children will require progressive larger tracheostomy tubes as they grow, and annual reassessment of size is required. Formulas exist for calculating expected inner and outer diameters based on age.[24] Length is also important to consider, especially in neonates and small infants. Too long a tube may be at the carina or a bronchus, and compromise ventilation. A tube too short may lead to frequent decannulation. Therefore, direct visualization at time of placement may be helpful, and custom lengths may need to be determined if standard lengths are insufficient.

Early postoperative complications include pneumothorax, obstruction, and decannulation. It is critically important to know whether the child can be intubated from the airway above in case of an obstructed or dislodged tracheostomy. If the tracheostomy tube cannot be quickly replaced or is obstructed, oral endotracheal intubation is the best option. Pneumothorax may complicate the initial procedure, especially in neonates and young infants given the proximity of lungs and neck. A CXR is traditionally done after the procedure to evaluate the tracheostomy position and to determine presence of pneumothorax. Recent authors have questioned the utility to the CXR and suggest it may not need to be performed routinely.[25] Subcutaneous emphysema may also be present, but can typically be avoided through loose wound closure techniques and placement of a drain to allow air to track externally. Obstruction of tracheostomy can be best prevented by attention to suctioning needs, providing humidification, and staff awareness of the potential issue, especially in tracheostomy tubes with smaller inner diameters. Accidental decannulation can be a life threatening early complication in children. There may be inability to recannulate, with risks of false tracking the tracheostomy tube through friable tissue or creating alternative tissue planes leading to a life-threatening respiratory emergency. This is best avoided with well-placed stay sutures on either side of the tracheal incision, with sufficient length to be easily located on the chest in an emergency. In the event of decannulation, the stay sutures can be pulled up and out to open the incision clearly and allow safe placement of the tracheostomy tube. If the tracheostomy tube cannot be replaced, an ETT can be placed through the stoma or through the oral native airway to establish airway control. Accidental decannulation can also be prevented through removal of unnecessary tubing or equipment (including the ventilator if no longer required), pain and comfort control as required by age, and staff training to be attentive to a fresh tracheostomy. The use of a tracheostomy tie with an elastic component and hook and loop fasteners through the ends of the tracheostomy tube can also be helpful to ensure appropriate position of the tracheostomy and also help decrease skin erosion.

Hemorrhagic, infectious, and granuloma complications may occur, most often as late complications but additionally early in the perioperative period.[26] Hemorrhage is a life-threatening complication that can occur immediately on tracheostomy cannulation due to injury of the innominate, aorta or carotid artery depending on variability in anatomy. Pressure must be held to decrease bleeding and vascular repair as soon as possible with potential need for assistance from cardiothoracic or vascular surgery. In the ICU, bleeding can occur from pressure from the tracheostomy tube causing erosion into the anterior wall and a tracheo-innominate fistula. In the case of life-threatening bleeding, if the tube is cuffed it can be attempted to be inflated to create tamponade. A cuffed ETT can be inserted through stoma, or a finger can be inserted into the stoma to push anterior to attempt to tamponade bleeding. Immediate surgical intervention is crucial to survival, with overall survival < 25%. Patients with native tracheostomy presenting as outpatients with hemoptysis should prompt an immediate evaluation for potential life-threatening bleeding. This can be performed with a fiberoptic examination and a CT angiogram to evaluate for bleeding sources and potential for tracheoinnominate

fistula. In addition, a granuloma may be a source of irritation and bleeding from either suctioning or tracheostomy tube tip mucosal irritation. Large granulomas can develop and additionally cause life-threatening obstruction. Fiberoptic evaluation can identify and treatment may be with topical steroids or laser/surgical excision. Lastly, infection can also cause hemorrhagic secretions. Chronic intubated patients requiring tracheostomy may have a variety of colonizing flora that can cause tracheitis both acutely and later on as outpatients. Antibiotic prophylaxis during the perioperative period is controversial, although antibiotics are indicated if there is evidence of infection such as with fever, increased or thicker secretions, or irritated tracheal mucosal.

The first tracheostomy tube change is performed by the surgeon to confirm the safety and adequate healing of the stoma. The stay sutures can be removed and future changes performed by dedicated medical personnel or the family once adequately trained. The timing of the first tracheostomy tube change is dependent on the surgeon and the indication for the tracheostomy. In many cases, 3 days is enough time for adequate healing,[27] but practice varies from 4 to 7 days.[28] Our practice is to have all new tracheostomies recover in the PICU with stay sutures. Two replacement tracheostomies are available at the bedside, of the same and smaller size, and an emergent tracheostomy surgical kit is available in unit at all times. Typically at day 5, the surgical team will perform the first tracheostomy change, and remove the stay sutures at that time. Family training for tracheostomy changes then occurs and the patients are transferred to the general care ward until competency in tracheostomy change and cardiopulmonary resuscitation is demonstrated by home care providers and adequate airway supplies are obtained for the patient.

## LARYNGOTRACHEAL RECONSTRUCTION

Laryngotracheal reconstruction (LTR) involves surgical correction of a stenotic airway. Surgical techniques were primary introduced by Fearon and Cotton in 1972 with the aim of expanding stenotic airway segments in children with congenital and acquired laryngotracheal stenosis.[29] Typically this involves cartilage interpositional grafting, with or without a stent, followed either by placement of a tracheostomy (two stage) or placement of an ETT with postoperative sedation and mechanical ventilation for an extended period of time (single stage). Other surgical variations include end-to-end anastomosis and sliding tracheoplasty. Single-stage repair with prolonged intubation creates several perioperative challenges, and patient optimization is critical for successful graft outcome and minimization of morbidities. Our group has previously reviewed management strategies, and here we present a summary approach to typical perioperative issues for the intensivist and surgeon.[30]

### Airway and Respiratory Management

The choice of how to secure the airway postsurgery can vary. Some centers may avoid endotracheal intubation and positive pressure ventilation in older children after end-to-end anastomosis or sliding tracheoplasty. Given the extent of resection, limitation of neck movement may be necessary to avoid tension on the repair with a suture of the chin to the chest. Providers must be prepared to release the stitch for emergency airway management if the airway cannot be secured or visualized, and expert personnel should be available for airway manipulation. A postoperative drain may be utilized to allow any potential air leaks to escape through the skin and prevent pneumomediastinum, pneumothorax, or subcutaneous emphysema.

Although the oral route is generally chosen for endotracheal intubation in the PICU population, some studies have suggested that there may be advantages of using the nasal route.[31] The nasal route postoperatively may provide more secure control of the airway with a decreased risk of inadvertent extubation in the PICU, easier mouth care to prevent aspiration and hospital acquired pneumonia, and decreased sedation requirements from less gagging and oral discomfort, leading to faster recovery and shorter length of stay. Yellen and colleagues have recommended the nasal route, with 21 patients who underwent single-stage LTR nasotracheally intubated for a mean of 8.4 days (range 6–14 days) and a success rate of 95%.[32] Despite reported success and possible advantages, there remain some caveats. The ETT should be one size smaller than typical for patient's age, due to potential nares damage and epistaxis during tube placement. As nasotracheal intubation may be time-consuming, practitioners may choose to initially provide orotracheal intubation and then switch to the nasotracheal route when leaving the operating room (OR). Regardless of nasal or oral ETT, consideration should be given to the use of low profile, low pressure cuffed ETTs,

as uncuffed ETTs may lead to excessive leaks and interfere with effective positive pressure mechanical ventilation in the PICU, and a cuffed ETT may decrease need to replace the ETT in a surgically repaired airway with its inherent dangers.[33] The cuff should be inflated with minimal amount of air necessary to seal the airway, with frequent pressure checks to ensure that pressures are kept ≤ 20 cm $H_2O$ to avoid compromising tracheal perfusion pressure and potentially limiting postoperative subglottic damage. Overall, there are no prospective, randomized trials in either the adult or pediatric population to demonstrate the clinical advantages of the nasal versus the oral route for endotracheal intubation in the ICU setting so use will be dictated by clinical preference.

Airway and respiratory issues often affecting the postoperative course include atelectasis, tracheal secretions, nosocomial pneumonia, air leak syndromes, leakage at the tracheal graft site, and postextubation airway obstruction. Arrival to the PICU should include a CXR to determine ETT position and ensure correct location after travel from the OR, as well as to determine presence of atelectasis and air leaks. Atelectasis should be treated aggressively with positive end expiratory pressure (PEEP) and lung recruitment to minimize pulmonary complications during PICU stay, as its presence my lead to infection, need for high ventilator settings and subsequent longer ventilation, sedation and hospital length of stay until pulmonary status is optimized for extubation. Air leaks may be present on admission from graft harvest site if rib grafts are used, and may require serial observation or immediate drainage with a chest tube. In our institution, we typically utilize a pigtail catheter to drain air if present on arrival to minimize pulmonary compromise. Additional subcutaneous air my be present in the neck and mediastinum and can often be minimized with OR placement of a rubber band drain in the neck incision to allow easy egress of air. A CXR is utilized daily and as needed for clinical changes to confirm no movement of ETT and to assist with optimization of daily ventilation parameters.

Pulmonary secretion management and prevention of atelectasis with chest physiotherapy and endotracheal suctioning are traditional management approaches for prolonged mechanical ventilation. However, their routine use is not supported by evidence-based medicine, and may be detrimental.[34] Rather, our clinical experience suggests that respiratory issues can be decreased by adopting a ventilator strategy that provides for recruitment of atelectatic lung regions, especially early on. The use of lower tidal volumes to prevent the theoretical risks of barotrauma in mechanically ventilated patients has become commonplace and, combined with the use of sedation and neuromuscular blockade, may contribute to progressive atelectasis. In the relatively normal lung after this typically elective procedure, we advocate the use of tidal volumes of 8–10 mL/kg, provided the mean airway and plateau pressures are kept within acceptable ranges, the application of 5–8 cm $H_2O$ of PEEP, and the use of longer inspiratory times of 1–1.5 s, depending on age. Additionally, if so desired, intermittent recruitment breaths can be delivered manually intermittently by disconnecting the patient from the ventilator and providing manual breaths with a resuscitation bag that is attached to a manometer to limit excessive pressures.

Suctioning has many potential adverse effects reported in the literature. These include hypoxemia, bacteremia, lobar atelectasis, mucosal trauma, hemorrhage, bronchoconstriction, lobar atelectasis, decreased cerebral oxygenation, pneumothorax, cardiac arrhythmias, cardiac arrest and even death. Commonly used suctioning methods are open-ETT suctioning and closed system suctioning (CSS). CSS allows suctioning during mechanical ventilation with an in-line multiuse suction catheter system encased in a plastic sleeve. Use of CSS may prevent suctioning-induced hypoxia, atelectasis, and spread of infection between patients and from patients to staff by limiting the spread of aerosolized infectious mucus particles. However, there is a lack of evidence on the optimal suctioning method in the pediatric critical care population.[35] Additional techniques to reduce suctioning complications include reduction of suction pressure, limitation of the depth of insertion of the suction catheter, appropriate preoxygenation, adequate sedation and analgesia and muscle paralysis. We practice suctioning with the CSS and only when clinically indicated, such as with worsening pulmonary compliance due to excessive secretions and/or prior to extubation.

An evaluation of both the upper airway and respiratory function may be helpful in ensuring the appropriate timing of extubation following airway repair. There is no perfect measure to determine extubation readiness in children, and various techniques including leak, negative inspiratory force, and types of spontaneous breathing trials have been examined with varying effectiveness.[36] Overall extubation should proceed when surgical repair allows and typical intensive care extubation criteria are met. The presence of air leak around the ETT may provide a reasonable estimate of extubation success. Gustafson and

colleagues demonstrated that patients without an air leak at 20 cm $H_2O$ or less were twice as likely to fail their initial attempts at tracheal extubation.[31] A pressure support, CPAP or a T-piece trial prior to tracheal extubation may provide additional information regarding readiness for tracheal extubation, although conclusive data in children to support a particular approach is not available.

Upon extubation, immediate concerns are recurrence of airway obstruction, so stridor and work of breathing are monitored closely. Use of periextubation dexamethasone can be helpful to reduce edema caused by ETT, started the day before and continued for 24–48 hours. Respiratory distress after extubation may be categorized as reversible (presence of granulation tissue, mucosal edema, excessive secretions, sedative withdrawal, neuromuscular weakness) or irreversible (prolapsed grafts and/or restenosis of the airway site).[37] A limited trial of noninvasive ventilation may be sufficient to bridge the transition to extubation, especially if sedation, deconditioning and poor muscle tone are contributing to extubation distress. If there is no improvement, surgical evaluation from bronchoscopy is often warranted to determine etiology. In our approach after single-stage repair, the surgical repair is examined under direct visualization by the surgeon with OR bronchoscopy prior to extubation. If repair is deemed adequate, the ETT is downsized by half a size, and the patient is brought back to the PICU with a secure airway. The patient's sedation is then weaned, dexamethasone administered every 8 h for 24 h, and airway assessed for a leak. Extubation occurs in the PICU, with availability of surgeon and pediatric anesthesia as needed. CPAP or BiPAP is utilized to support to the airway, especially if residual tracheomalacia is present from the repair. A bronchoscopy is repeated in one week, or earlier if there are clinical concerns regarding the airway. Most respiratory support can be discontinued within the next 24 h, dependent upon sedation and deconditioning.

## Sedation

The use of continuous sedation following single-stage LTR in young and uncooperative children has been advocated to avoid movement and trauma from the ETT against the fresh graft site and the potentially life-threatening complication of inadvertent tracheal extubation.[38] Neuromuscular blockade may also be necessary to ensure immobility and decrease the risk of graft failure. Unfortunately, sedative use may result in adverse respiratory effects including depressed cough reflex, ineffective clearing of secretions, diminished sigh volumes, and decreased functional residual capacity. Additionally, tolerance and physical dependence may develop, depending on length of infusions, with discontinuation resulting in a withdrawal syndrome complicating the process of extubation. Therefore, optimizing sedation and muscle relaxation protocols are critical to minimizing perioperative issues.

Pediatric sedation and analgesia practice is best titrated to objective scoring measures to minimize oversedation. Pain scores can be obtained through various methods based on a patient's age, using the Face scale or FLACC score for young infants, or numeric scores for older, awake patients. Sedatives can be titrated through a number of scoring methods, depending on unit practice. The COMFORT score combines the scoring of a patient's response or movement in addition to various physiologic parameters, including measurement of alertness, respiration, blood pressure, muscle tone, agitation, movement, heart rate, and facial tension,[39] and can also detail specific ranges of over- or under-sedation with less reliance on physiologic measurements alone.[40] Other sedation scoring systems exist, including the sedation-agitation scale and the Ramsey scale.[41,42] The Ramsey score is limited by the need to disturb the patient, which may paradoxically increase sedation needs. Additionally, none of the sedation scales are valid when utilizing muscle relaxation, and adequate sedation must be inferred from vital sign parameters or during muscle relaxation holidays. Some have advocated use of the bispectral index (BIS monitor) in this situation, but its interpretation and utility in young patients remains investigational.[43] We utilize the COMFORT score for our intubated nonmuscle-relaxed patients, and titrate sedation infusions based on scoring trends to minimize future opiate and sedation dependence.

While sedation in intubated children traditionally requires continuous infusions of sedation, there is increasing interest in intermittent dosing or drug holidays to minimize adverse side effects. In adults, daily interruptions of sedative infusions decrease the duration of mechanical ventilation and the length of stay in the intensive care unit.[44] However, after tracheal repair, the practitioner must balance the safety of the repair and maintaining the endotracheal airway with the side effects of sedatives in children. For this reason, we often sedate young children until it is safe to be awake and potentially extubate. In older children who are cooperative and not likely to remove the ETT, we will utilize intermittent sedation, and potentially allow the child to be awake, maintaining the ETT nasally as

a stent and breathing spontaneously, and therefore minimizing prolonged sedative effects.[45] Clearing the ETT of secretions and ensuring adequate humidification, either through an HME attached at end of ETT or humidified blow by oxygen, are important to minimize obstruction. Spontaneous breathing off the ventilator can also facilitate walking and prevention of deconditioning and oral feeding can also be considered if cleared through a speech swallow evaluation that there is no aspiration with the ETT in place.

To facilitate successful tracheal extubation, avoiding sedative agents that may impair upper airway control and respiratory function is ideal. To accomplish this, switching to shorter acting agents may be beneficial to better control wakefulness at time of extubation. Therefore, it may be beneficial to utilize medications such as propofol, remifentanil or dexmedetomidine for 8–12 h prior to an anticipated extubation attempt. Propofol is short acting and can lead to early awakening on discontinuation, giving more control during this time period. However, the use in children is potentially dangerous given reports of propofol infusion syndrome.[46] Given that the majority of cases occur with high dosing and prolonged infusions, a short-term infusion 8–12 h may be acceptable with appropriate monitoring of acid base and cardiovascular status. Alternatively, the short-acting synthetic opioid, remifentanil, may be used to provide a deep level of sedation with a rapid offset once the infusion is discontinued, with the disadvantage of its cost and the rapid development of tolerance, requiring dose escalation. Our practice is to utilize propofol in children the evening prior to extubation and decrease other sedatives by 50%. In patients in whom propofol is contraindicated we utilize a dexmedetomidine infusion, which is increasingly becoming our preferred option. Dexmedetomidine is a $\alpha_2$-adrenergic receptor agonist that possesses sedative, analgesic, and anxiolytic properties with limited effects on respiratory drive. The short half life of dexmedetomidine allows for easy, quicker recovery, and fewer prolonged sedation-related adverse effects.[47] Adult data have shown dexmedetomidine to be a successful bridge to extubation, and reduce total cumulative sedative use with minimal adverse effects.[48] Following LTR, dexmedetomidine has been utilized successfully as part of the sedative regimen in children.[49]

Additional adjunctive sedatives have been utilized following LTR in attempts to limit tolerance and withdrawal. Diphenhydramine, clonidine, phenothiazines, nonsteroidal anti-inflammatory agents, acetaminophen, and chloral hydrate have all been used in this regard.[50] Given limited effects on respiratory function, they may provide significant benefit particularly when used in rotation with opioids and benzodiazepines. Additionally, the use of nonpharmacologic measures such as reduced stimulation, comforting, and regulation of day–night sleep cycle may reduce the amount of sedative medications.[45]

Given that sedation is often required for a week or longer, the development of tolerance, physical dependency, and withdrawal is expected.[51] The timing of withdrawal may vary according to the medication utilized for sedation and its half life. One strategy suggested for patients receiving long-term continuous sedation is replacing synthetic opioids such as fentanyl with nonsynthetic opioids such as morphine, as the synthetic opioids have increased affinity for the opioid receptor and may lead to a higher incidence of withdrawal.[52] Rotating sedation regimens has also been suggested. Wheeler and colleagues presented preliminary data on a rotating sedation strategy for two patients who required sedation following LTR, rotating a midazolam, fentanyl and dexmedetomidine infusion for a day each until extubation was achieved on day 6. No withdrawal was noted in the rotating regimen versus all patients exhibited withdrawal in the traditional approach, with withdrawal patients requiring longer PICU stay and longer length of time till oral fluids tolerated.

We utilize a time based and standard medication conversion treatment protocol for withdrawal in our patients.[51] If infusions are required for <7 days, the patients have their medications stopped and they are observed for withdrawal, with scoring systems available to objectively quantify the burden of symptoms.[53] Patients requiring infusions for 7–14 days are started on prophylactic replacement therapy on the day of discontinuation, usually with methadone for opiates and lorazepam for benzodiazepines. Therapy is gradually weaned off in 5–7 days, and switched to oral as soon as tolerated.[54] In infusions for rare patients requiring mechanical ventilation and sedation for > 14 days, the weaning occurs over a 10-day period, either in the hospital given need for repeat bronchoscopies, or as an outpatient if appropriate.

## Neuromuscular Blockade

Neuromuscular blockade may be necessary in the immediate postoperative period to minimize movement of the indwelling ETT and disruption of suture lines. Prolonged infusions should be avoided if possible, given the risks of

prolonged weakness and their negative impact on pulmonary clearance. Potential techniques to avoid complications from neuromuscular blockade include monitoring with a nerve stimulator daily to guide the appropriate dosing (allowing two twitches so there is not complete blockade), and discontinuation of the infusion on a daily basis ('vecuronium holiday') to allow for the return of neuromuscular function by allowing the patient to move and only resume blockade if ETT is threatened.[38] Daily evaluation of neuromuscular blockade infusion should occur, with consideration of intermittent boluses instead. Even with appropriate monitoring and drug minimization, patients may have prolonged weakness after discontinuation of blockade. Simultaneous use of corticosteroids for airway edema can also affect weakness and pulmonary toilet. We therefore recommend limiting the use of continuous infusion of blockade to the first 24 h after the surgery with transition to intermittent boluses as needed after this period if ETT safety will allow. Neuromuscular blockade is stopped 24 h prior to extubation attempt to ensure adequate muscle strength. Additionally, limiting the doses of corticosteroids to 24–48 h in the periextubation period can be effective in reducing airway edema as well as preventing worsening of neuromuscular weakness associated with more prolonged administration of corticosteroids.

## Nutrition

Nutrition should be optimized to prevent deconditioning and neuromuscular weakness and facilitate the process of tracheal extubation. Enteral nutrition is the preferred route as it is more physiologic and is associated with decreased infectious complications and decreased length of hospital stay when compared with parenteral nutrition.[55] Enteral nutrition should be started as early as possible in the postoperative period, to improve caloric intake and decrease development of ileus and constipation from prolonged opiate therapy. With gastroesophageal reflux and concerns over damaging the graft site, we typically utilize a proton pump inhibitor throughout the PICU stay. Placement of a nasogastric tube (NGT) may cause concerns over pressure to the graft area if a posterior graft is utilized in the surgical repair. For this reason, the NGT is preferably placed in the OR during the surgical repair so that future placement is not necessary with possible graft disruption. If unable to be placed, our practice is to wait 48 h in the PICU before the NGT is placed, under direct airway visualization while advanced to ensure it enters the esophagus. A nasojejunal tube may facilitate earlier tolerance of feeds, but placement is based on local institutional practice.[56] Regardless of the site of enteral feedings, tube placement should be documented radiographically before initiating feeds. Parental nutrition may be used to supplement or replace enteral nutrition, although the ideal timing to initiate parental nutrition in the PICU remains unknown. Use of parental nutrition requires secure access and may require a central venous line with its attendant infectious risks.

## Infection Prevention

Although there is no evidence-based data for the utility of prophylactic antibiotics in this select patient population, most centers advocate this practice until tracheal extubation is achieved. We typically utilize ampicillin-sulbactam intravenously, while in the PICU to cover for mouth and airway flora. Additionally, these patients carry a high risk of nosocomial infections, particularly if a Foley catheter and possibly a central venous line are utilized. A high index of suspicion should be maintained for infection and ventilator associated pneumonia, with sampling of tracheal secretions for a Gram stain and culture if temperature instability, worsening chest radiography, deterioration in respiratory function, or change in white blood cell count. Maintaining the head of the bed at 30° and oral care may help prevent ventilator associated pneumonia. Blood and urine cultures should be sent for fevers and antibiotic coverage expanded for clinical deterioration. Foley and central venous lines should be removed when no longer clinically indicated. Avoidance of excessive sedation, neuromuscular blockade, excessive laboratory evaluations, and early enteral feeding may facilitate this process. In older patients, we attempt to avoid both a Foley and a central venous line. In younger patients, we attempt to utilize peripheral inserted central catheters to minimize infection risk, and remove Foleys as soon as possible. Laboratory investigations are typically obtained daily for blood gas analysis, and otherwise only obtained for clinical indications to minimize excessive accessing of indwelling catheters and increasing infectious risk.

# CONCLUSION

There are many perioperative challenges after airway surgery based on the type of operation and age of the patient. Many patients have significant comorbidities that require

multidisciplinary care. The ideal type of pediatric unit in which to recover remains undetermined and depends on the surgery and the support required. The perioperative care around single-stage LTR is critical to ensuring a successful surgery with minimal morbidity and requires PICU care. Communication between the surgical and ICU staff can facilitate a smooth recovery and extubation period with minimal morbidity. Further investigation is needed to determine best practice in management and many areas are ideal for standardization, such as antibiotic prophylaxis, feeding regimens, sedation, and withdrawal treatment.

CHAPTER

40

# Congenital Nasal Masses

***Nikhila Raol, Christopher J Hartnick***

Congenital nasal masses occur at the rate of about 1 in 20,000 to 1 in 40,000 live births.[1] Children often present with either nasal obstruction, an intranasal mass, which does not cause obstruction, or an externally visible cosmetic deformity. In this section, the most common congenital nasal masses will be discussed, including pathogenesis, diagnosis, and management.

## NASOLACRIMAL DUCT CYST

Embryologically, the nasolacrimal duct arises from surface ectoderm located between the maxillary and frontonasal recesses. Beginning in the third fetal month, canalization of the system begins and continues through the sixth fetal month.[2] Also known as a congenital dacryocystocele, a nasolacrimal duct cyst is thought to occur due to a distal obstruction at the valve of Hasner, located at the junction of nasolacrimal duct and the nasal mucosa, and an obstruction proximally at the valve of Rosenmuller, which is the site of entry of the common canaliculus into the lacrimal sac.[3] As a result, distension of the nasolacrimal sac occurs when fluid accumulates in the drainage system. This is opposed to congenital nasolacrimal duct obstruction, where obstruction is only at the valve of Hasner, allowing for tears to flow freely onto the eye due to backpressure. The valve of Hasner is the most frequent site of incomplete canalization, and the incidence of imperforate nasolacrimal ducts in term fetuses ranges from 35% to 73%.[3] However, only about 1.75–5% of these children have persistent obstruction requiring surgical intervention.[4] The typical presentation of nasolacrimal duct obstruction includes epiphora and/or recurrent infections such as conjunctivitis.

Congenital dacryocystocele is a rare variant of congenital nasolacrimal duct obstruction, accounting for only 0.1% of these cases, with 80–90% being unilateral.[5] A significant female preponderance for congenital dacryocystoceles is seen, with an incidence as high as 55–75% reported in girls.[5,6] In addition, the possibility of a genetic bases has been raised by a few reported cases in the literature.[7-9]

Because of the dual site of obstruction, the uninfected dacryocystocele most commonly presents as a blue mass in the medial canthal region. However, in some patients, an intranasal mass causing nasal obstruction may be the only presentation.[10] Other possible presentations include epiphora, eyelash mattering, and conjunctival inflammation. Infection from stasis of lacrimal flow may lead to acute dacryocystitis, periorbital cellulitis, and orbital cellulitis.[4] This secondary infection is at least partially due to the absence of a well-defined fascial layer isolating the lacrimal sac from the orbit in very young children. Nasal obstruction may be secondary to a mass on one side coupled with cyclic vascular congestion on the contralateral side, or rarely, it may be due to bilateral dacryocystoceles.[10]

Endoscopic examination is necessary for patients with suspected dacryocystocele, which may demonstrate a cystic mass protruding from the inferior meatus or simply redundant mucosa at this level (Fig. 40.1).

Computed tomography (CT) scan can be used for confirmation of the diagnosis, although this is not routinely indicated. Expected findings on CT include a medial canthal cystic mass, a dilated nasolacrimal duct, and an intranasal cystic mass. Magnetic resonance imaging (MRI) can also be used if other etiologies need to be excluded, as improved soft tissue detail can be provided (Figs. 40.2A and B).

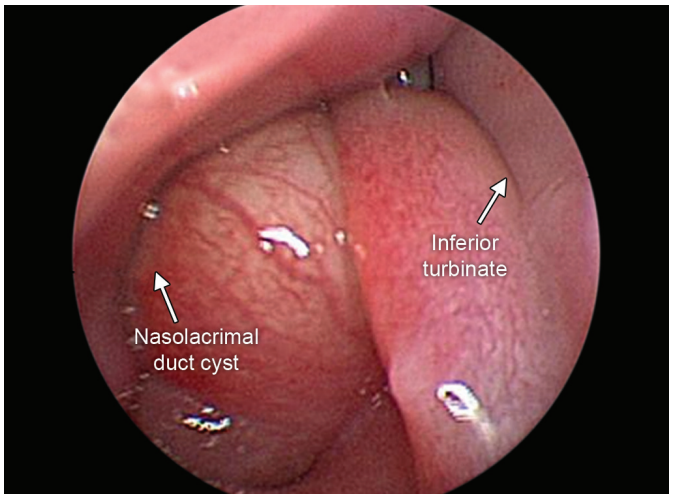

**Fig. 40.1:** Endoscopic intranasal view of large nasolacrimal duct cyst causing nasal obstruction.

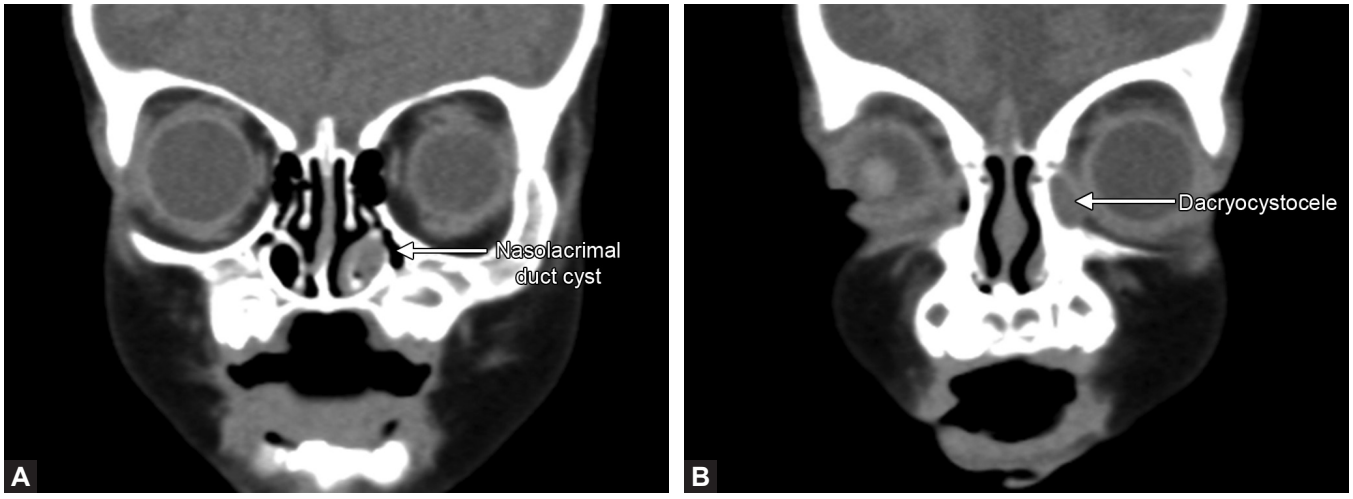
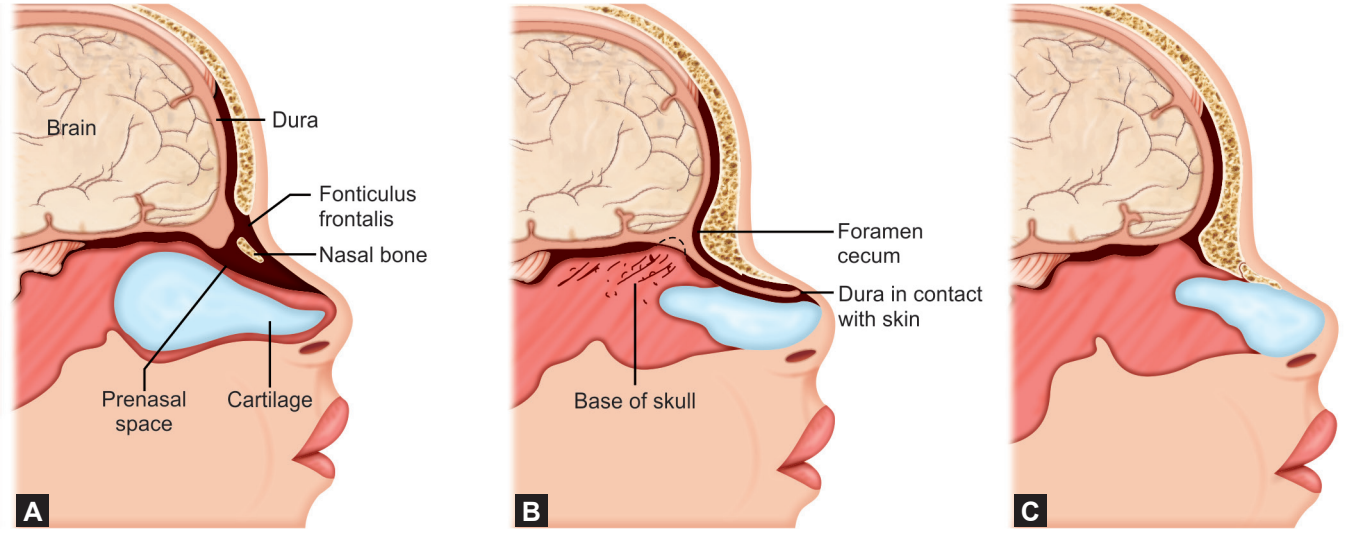


**Figs. 40.2A and B:** CT scan, coronal view, soft tissue window demonstrating obstruction along the course of the nasolacrimal duct. (A) Congenital nasolacrimal duct cyst with a mass seen in the left nasal cavity; (B) Congenital dacryocystocele with a mass seen along the medial wall of the orbit.

Both medical and surgical options exist for treatment. Spontaneous resolution has been shown to occur,[5] and medial canthal massage, warm compresses and antibiotics may hasten this process. With the intranasal component, a warm cloth may be applied over the nasal vestibule, or topical vasoconstrictor nose drops may be applied.[10] Surgical options include cyst decompression via needle aspiration, nasolacrimal probing and irrigation, nasolacrimal dilation using a balloon, and endoscopic dacryocystorhinostomy.[11,12] When only a cystic expansion in the inferior meatus is present, transnasal endoscopic treatment is the senior author's (Dr Christopher Hartnick) preference. In the case of a dacryocystocele that has not previously been treated, a combined approach with endoscopic marsupialization of the intranasal component and simultaneous verification nasolacrimal duct patency by probing and cannulating the duct with intranasal visualization of the probe is performed.[6] A microdebrider may also be used to remove the mass.[10] For revision cases, cannulation of the duct with short-term stenting with a Jones or Crawford tube can be considered.

## NASAL DERMOID

First described in 1817 by Cruvelier when he identified a hair-bearing sinus tract of the nasal dorsum in a child, the nasal dermoid is the most common midline congenital nasal lesion.[13] These masses are created by invagination of surface ectoderm with the formation of an epithelial-lined cyst. However, unlike the epidermoid cyst, this cyst



**Figs. 40.3A to C:** Pathogenesis of dermoid. Note dura contacting skin through foramen cecum with subsequent regression. Adapted from Barkovich AJ, Vandermarck P, Edwards MS, Cogen PH. Congenital nasal masses: CT and MR imaging features in 16 cases. Am J Neuroradiol. 1991;12(1):105-16.

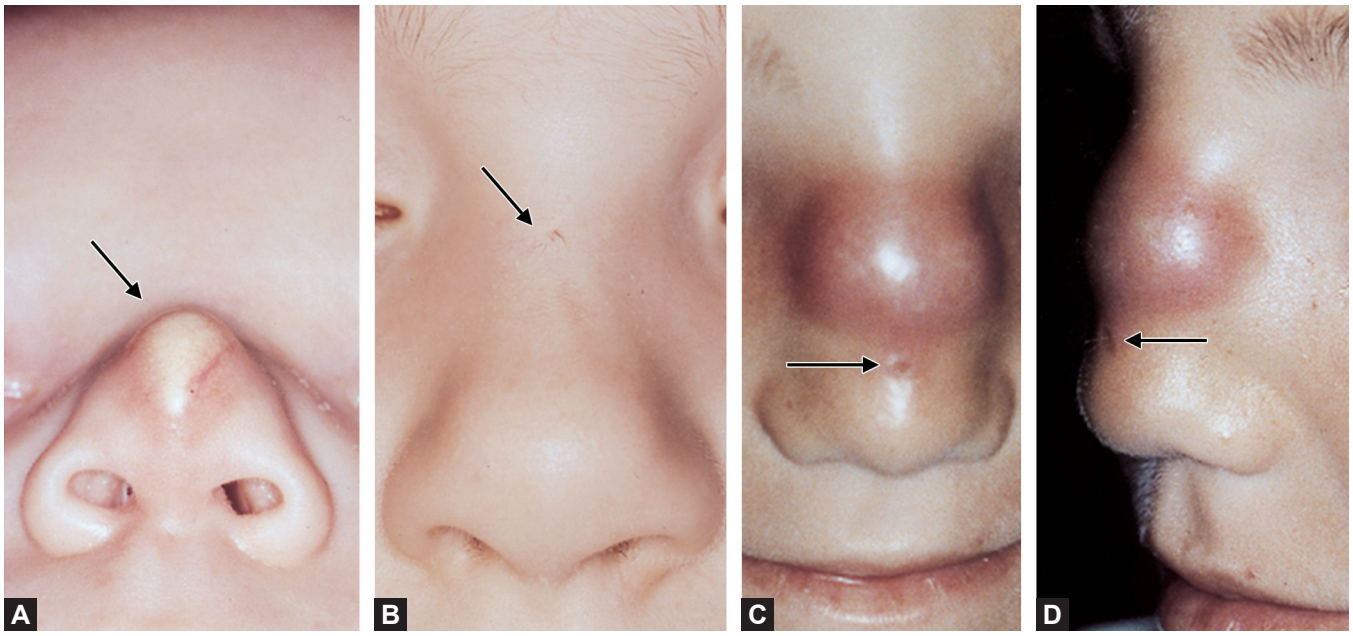
wall also contains hair follicles and supporting adnexa. Between 4 and 8 weeks of gestation, embryogenesis of the midface occurs. The nose has a trilaminar structure, with a superficial layer of ectoderm, a middle layer of mesoderm, and a deep layer of cartilaginous capsule. This cartilaginous capsule originates from the chondrocranium and forms deep to the nasal and frontal bones, which result from ossification of the mesoderm. Each layer is separated by a named space: the fonticulus frontalis temporarily separates the nasal and frontal bones, whereas the prenasal space separates the nasal bone from the deeper cartilaginous nasal capsule.

An extension of dura mater projects through the foramen cecum and temporarily occupies the prenasal space, fleetingly contacting the nasal tip skin. During normal embryologic development, the diverticulum involutes rapidly and the fonticulus frontalis is eliminated with creation of the nasofrontal suture. The prenasal space obliterates and the foramen cecum eventually fuses with the fonticulus frontalis to form the cribriform plate.[14] Abnormal regression of the neuroectodermal tract results in skin elements becoming trapped in the prenasal space and formation of a dermoid cyst or sinus tract, anywhere from the columella to the anterior cranial fossa. In about 5–45% of cases, connection to the dura is found,[15-17] and cases of brain parenchymal involvement has been described.[15] This most often occurs through the foramen cecum or cribriform plate (Figs. 40.3A to C).

Nasal dermoids account for 1–3% of all dermoid cysts and about 4–12% of head and neck dermoid tumors.[18,19] Mean age of presentation ranges from 14 to 34 months, and there is a slight male predominance.[15,17] Association with the Gorlin-Goltz syndrome, or nevoid basal cell carcinoma syndrome, has been reported.[20] In addition, other craniofacial anomalies, such as craniosynostosis, hemifacial microsomia, nasolacrimal duct cysts, cleft lip and palate, external ear deformities, hydrocephalus, and hypertelorism, have been linked with nasal dermoid cysts.[16]

A nasal dermoid cyst generally presents as a noncompressible midline nasal mass which may occur anywhere along a tract from the nasoglabellar region to the columella.[15] Often, a sinus opening with expressible or intermittently draining sebaceous material is also present; hair projecting through a punctum over the nasal dorsum is pathognomonic.[16] Upon examination, the mass does not transilluminate, and there is no enlargement with compression of the jugular veins (i.e. negative Furstenberg's sign)[14] (Figs. 40.4A to D).

Both CT and MRI are important and complementary imaging studies when diagnosing nasal dermoids and determining presence or absence and extent of intracranial involvement. Although CT can clearly show bony anatomy, MRI provides excellent soft tissue detail. CT imaging should be done with cuts no thicker than 3 mm, and findings suggestive of intracranial extension include widening of the foramen cecum, bony defect in the crista



**Figs. 40.4A to D:** (A) Nasal dermoid at tip, black arrow demonstrating mass; (B) Nasal pit, as demonstrated by black arrow; (C and D) Infected nasal dermoid with pit, black arrow demonstrating nasal pit. Reprinted with permission from Rahbar et al.[15]

galli, and a bifid or dystrophic crista galli.[21] On MRI, a high-intensity signal on T1-weighted postgadolinium contrast images in the area of the crista galli in newborns is indicative of a dermoid cyst with intracranial involvement.[21]

The average width of the foramen cecum is about 4 mm but can be as much as 10 mm. Its contents demonstrate soft tissue density on CT and low to intermediate intensity on MRI. The crista galli is on average 3 mm in width, and it has a similar appearance on CT and MRI to bone marrow. As children grow older, the crista galli is replaced by fat, usually by age of 5 but as late as age 14.[21]

Involvement of the neurosurgery team is appropriate when imaging demonstrates an enlarged foramen cecum and a bifid crista galli, indicating intracranial involvement; a combined approach to complete excision can then be accomplished in a single operation.[19,22,23] Imaging done with contrast can help differentiate skull base defects from enhancing lesions, as well as dermoid cysts (nonenhancing) from nasal mucosa (enhancing).[14]

Normal variable anatomy should always be kept in mind when interpreting imaging in cases of suspected dermoid cysts. Neonates and infants may display a midline gap between nasal bones or nonossification of the cribriform plate, which may be mistaken for a sinus tract or connection between the anterior cranial fossa and nasal cavity, respectively.[21] In addition, the fatty changes that develop in the crista galli may be misread as a dermoid cyst.[23,24]

Although timing of intervention remains controversial, surgery is certainly considered the mainstay of treatment for nasal dermoid cysts. Some advocate for removal expediently, but one must consider difficulty of access and decreased tolerance for blood loss in newborns and infants. The senior author does not typically excise these lesions until the age of 1.

Surgical approach must be adequate to allow for the following: (1) access to all midline lesions with medial and lateral osteotomies, (2) repair of skull base defects or cerebrospinal fluid leak, (3) reconstruction of any nasal deformity, and (4) a cosmetically acceptable scar.[23] A number of incisions have been described for removal of a nasal dermoid cyst, including midline vertical incision, which is the most commonly used for a simple cyst, transverse incision, inverted U incision, lateral rhinotomy, and midbrow incisions.[14,15,23,24] The open rhinoplasty is an excellent approach to allow for skull base exposure when a combined single-stage intracranial–extracranial procedure is needed.[13] Successful transnasal endoscopic excision with a small external incision for punctum removal has also been reported. This technique necessitates frozen section

**Fig. 40.5:** T1-weighted postcontrast sagittal image of nasal glioma.

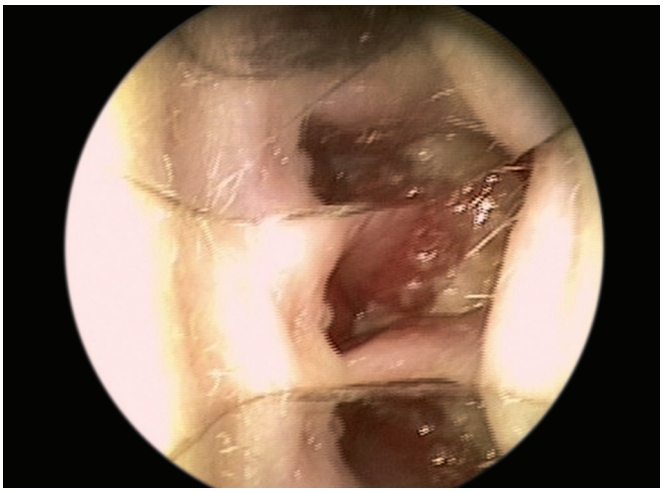


**Fig. 40.6:** Intranasal image of glioma seen on magnetic resonance image.

at the foramen cecum to confirm complete excision.[24] Regardless of technique utilized, complete excision is imperative, as recurrence rates have been shown to be as high as 50–100% when dermal elements are left behind.[14]

## NASAL GLIOMA

Although Schmidt coined the term glioma and gave a complete description in 1900, the initial account was actually given by Reid in 1852. Also described as nasal cerebral/glial heterotopia or encephaloma,[25,26] a nasal glioma is thought to develop due to initial herniation of intracranial tissues into the dural projection through the foramen cecum or fonticulus frontalis with subsequent separation from the brain and degeneration of the stalk, eliminating any cerebral connection.[27] Although it is slightly more common in males, there is no genetic basis nor is there any malignant potential.

Because encephaloceles and gliomas share many characteristics, including pathogenesis and often histopathology, correlation between imaging, surgical findings, and microscopic examination is needed to confirm diagnosis. Although both lesions contain glial tissue, presence of ependymal tissue can identify an encephalocele and rule out a glioma. However, lack of ependymal tissue does not help differentiate one from the other. An absolute lack of cerebral connection combined with the finding of glial tissue on pathology confirms the diagnosis.[27]

About 60% of nasal gliomas appear as an extranasal mass, 30% present with only an intranasal component, and 10% present with a combined lesion.[28,29] Those that present extranasally appear as a firm, smooth, noncompressible mass anywhere along the dorsum of the nose. When there is an intranasal component, the patient presents with nasal obstruction, and examination demonstrates a pale mass in the nasal cavity, at times protruding from the nostril.[27] Like a nasal dermoid, the Furstenberg's test is also negative with a glioma. Most commonly, the lesion originates from the lateral nasal wall near the middle turbinate, or less commonly, from the nasal septum.[30] Again, similar to the nasal dermoid, both high-resolution CT and high-resolution MRI with contrast provide complementary information regarding bony and soft tissue detail.[27] Biopsy of these lesions should be avoided (Figs. 40.5 and 40.6).

Surgical excision is the treatment of choice for these lesions. Because 10–25% of nasal gliomas may have a fibrous stalk extending toward the base of the skull with an associated bony defect (but no connection to the brain itself), neurosurgical consultation may be needed if the imaging dictates as such.[31] Extranasal gliomas require an external incision; ultimately, the approach must provide excellent exposure, allow for exploration of the stalk, and provide a good cosmetic outcome, regardless of the incision. An osteotomy may be needed if the lesion extends deep to the nasal bones to follow the entire stalk. The Boston Children's Hospital experience suggests that an external rhinoplasty incision allows for the best access in these cases. In addition, they suggest that if the mass is too large or in the nasoglabellar area where the external rhinoplasty approach does not provide adequate exposure, the midline nasal or bicoronal incision may be useful.[27]

Intranasal gliomas may be removed endoscopically under image guidance safely; in addition, repair of any

skull base defect can also be done at the same time without need for additional incisions or neurosurgical intervention.[32-34] However, a neurosurgical team should always be aware and available for any of these cases in case complete excision requires frontal craniotomy. Recurrence rates have been shown to be about 4–10%.[35]

## ENCEPHALOCELE

While an encephalocele is a rare entity, it occurs a rate of 1 in 4000 to 1 in 5000 live births. Encephaloceles are classified on the basis of two things: location and contents. The encephalocele is found in the occipital location about 75% of the time and in the frontal location about 25% of the time.[36] Posterior skull base or occipital encephaloceles are more common in females and in North America, whereas frontal encephaloceles are more common in males and in Southeast Asia. The overall rate of occurrence, however, is equal between males and females (Tables 40.1 and 40.2).

Presentation can vary from nasal obstruction to epistaxis to recurrent meningitis. However, in a congenital setting, nasal obstruction or a mass is typically what is encountered. On physical examination, a widened nasal root and increased intraocular distance may be noted.[37] A sincipital encephalocele appears as an external nasal mass, which may present anywhere along the outside of the nose, whereas a basal encephalocele presents as an internal mass with location dependent of site of herniation.[27] Unlike other nasal masses, however, the Furstenberg's test is positive (pulsation and expansion of mass with crying/straining/jugular vein compression) due to intracranial connection. Nasal endoscopy is vital for adequate characterization of the mass (Fig. 40.7).

Preoperatively, neuroradiological and neurosurgical consultations are mandatory. As with nasal gliomas and dermoids, both CT and MRI with contrast are useful and provide complementary information. Of note, contrast is useful to help delineate between and skull base defect and an incompletely ossified skull base, with is often present with young infants.[27] If only one imaging modality can be chosen, however, CT scan allows for better delineation of bony anatomy, making it the modality of choice for preoperative planning[38] (Fig. 40.8).

Surgical excision is once again the mainstay of treatment. This should be done expeditiously to reduce the chance of infectious and cosmetic complications. The procedure always involves a frontal craniotomy for excision of the intracranial component and repair of skull base defect. If an extranasal component is present, the bicoronal incision may be extended down to the bony–cartilaginous junction of the nasal dorsum to allow for excellent exposure. Both orbital osteotomies and hemiorbital advancement have been described to correct hypertelorism for improved functional and cosmetic outcome.[38] For those encephaloceles with an intranasal component, endoscopic excision under image guidance has been shown to have excellent outcomes in experienced hands and avoid external facial incisions. If needed, however, a lateral rhinotomy may be used for exposure.[27] Cerebrospinal fluid leak rates have varied from 17–22% without significant rates of recurrence.[27,38]

**Table 40.1:** Classification based on contents

| *Classification* | *Contents* |
|---|---|
| Meningocele | Meninges only |
| Meningoencephalocele | Meninges, neural tissue |
| Meningoencephalocystocele | Meninges, neural tissue, ventricular system tissue |

## CRANIOPHARYNGIOMA

Craniopharyngioma is a nonglial benign intracranial tumor of the sellar/parasellar region that occurs at a

**Table 40.2:** Classification of frontal encephaloceles based on location

| *Classification* | *Location of herniation* | *Location of mass* |
|---|---|---|
| Sincipital: nasofrontal | Fonticulusnasofrontalis | Forehead or nasal bridge |
| Sincipital: nasoethmoidal | Foramen cecum | Nasal bridge |
| Sincipital: naso-orbital | Medial orbital wall | Orbit |
| Basal: transethmoidal | Cribriform plate | Intranasal |
| Basal: sphenoethmoidal | Between ethmoid and sphenoid | Nasopharynx |
| Basal: trans-sphenoidal | Craniopharyngeal canal | Nasopharynx |
| Basal: sphenomaxillary | Superior and inferior orbital fissure | Pterygopalatine fossa |

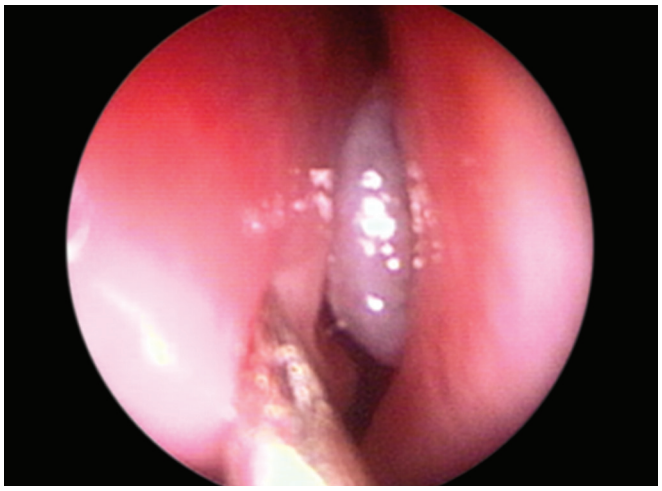

**Fig. 40.7:** Endoscopic view of encephalocele.

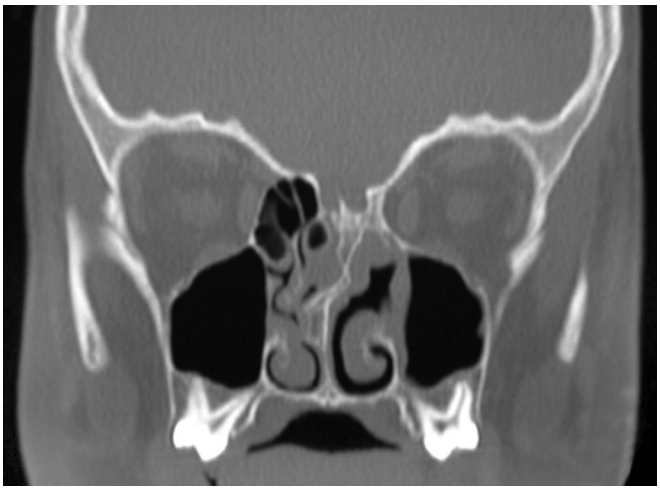

**Fig. 40.8:** Coronal computed tomography demonstrating encephalocele with bony defect at cribriform plate.

rate of about 0.5–2 cases per million persons per year.[39] It represents about 1.2–4% of all intracranial tumors of childhood, and approximately 30–50% of all cases are found during childhood/adolescence.[40] Two major schools of thought exist regarding the embryonal origin: some think that the tumor arises from the ectodermal remnants of Rathke's cleft, whereas others believe that the residual embryonal epithelium of the anterior pituitary gland and anterior infundibulum is the area of origin. Childhood craniopharyngioma typically is of the adamantinomatous histological type, which shows cyst formation and calcifications on imaging, aiding in diagnosis. Although there is a second peak of craniopharyngioma incidence in adulthood (between 50 and 75 years of age), it is of a papillary histological type. In addition, >70% of craniopharyngiomas of the adamantinomatous type express a β-catenin gene mutation, not seen in the papillary type.[41] This suggests that the two types are both histologically and genetically distinct.

Symptoms typically arise from mass effect, including increased intracranial pressure and optic nerve compression, and endocrine derangement, including hypothyroidism, growth hormone deficiency, and hypothalamic dysfunction. Although the symptom complex of headache, visual impairment, pathologic low growth rate, weight gain, and polydipsia/polyuria should point to the possibility of craniopharyngioma in the differential diagnosis, many patients present with one or more of these symptoms years before the diagnosis is made.[42] While growth retardation can manifest very early in the disease process, weight gain, which may lead to extreme obesity due to hypothalamic involvement, usually presents as a late manifestation. Delayed or early puberty may also be seen. Papilledema can be seen in 25–40% of patients due to elevated intracranial pressure. Rarely, ataxia and/or seizures may also be present.[43] No specific findings on an otolaryngologic examination provide additional clues in making this diagnosis.

The most common location of craniopharyngioma is suprasellar with an intrasellar component. Both CT and MRI with contrast are needed to accurately make the diagnosis of craniopharyngioma. While MRI is the gold standard for imaging, the cystic components can have variable signal based on the amount of protein content of the cyst fluid. CT can be used to detect calcifications and therefore confirm diagnosis.[44]

Surgical extirpation in some capacity is part of the treatment of these lesions. For tumors with large cystic components, some have advocated for a two-stage procedure. Initially, an intracystic catheter can be placed for relief of pressure and possibly for instillation of intracystic sclerosing agents. This can be followed by resection.[45] For tumors in surgically favorable locations, complete resection without perturbation of visual, hypothalamic, or pituitary function is preferred. Endoscopic transsphenoidal approaches are becoming increasing popular due to ability to leave the hypothalamus undisturbed.[40] For tumors that are in unfavorable locations, differing opinions exist regarding how much of a role surgical excision should play. While some believe in attempting complete resection, others advocate for planned limited resection, whether biopsy or partial/subtotal resection.

Critics of extensive surgery cite iatrogenic deficits, such as hypothalamic dysfunction, and the high rate of recurrence despite what appeared to a complete resection. While rate of progression of residual tumor after incomplete resection is as high as 71–90%, when radiation is administered after surgery, this rate decreases to about 21%.[46] External beam radiation, proton beam radiation, and intracavitary β-radiation have all been shown to be effective. Due to reasons relating to radiation biology, single-dose stereotactic radiation has been of limited use in the treatment of childhood craniopharyngioma.[42]

## OTHER CONGENITAL NASAL MASSES

Because hemangioma is the most common tumor of childhood, it should always remain in the differential for an intranasal or extranasal mass. In addition, a congenital teratoma may rarely present in the nasal cavity or nasopharynx. This differs from a dermoid tumor in that it contains ectoderm, mesoderm, and endoderm as opposed to only ectoderm and mesoderm.

## SUMMARY

Although congenital nasal masses are quite uncommon, ability to devise a differential and narrow the diagnostic possibilities is important. CT and MRI are both important modalities in characterizing these lesions. Prompt intervention should be undertaken, particularly with an encephalocele, to prevent intracranial complications. Although most of these lesions require complete surgical treatment, additional treatment may be needed to prevent recurrence and/or progression.

CHAPTER

# 41

# Congenital Lesions in the Oral Cavity and Oropharynx

***Mark Boston, Joseph W Rohrer***

## INTRODUCTION

The oral cavity and oropharynx are complex anatomic regions that begin the aerodigestive tract. Components in these areas arise from all three germ layers that undergo significant migrations to result in a functional oral cavity and oropharynx. The developmental relationships between embryonic cell lines make possible a variety of congenital malformations and anomalies. Variations in embryonic development lead to a wide range of oral cavity and oropharyngeal abnormalities; from minor cosmetic deformities requiring little to no treatment to potentially lethal anomalies. Congenital lesions of the oral cavity and oropharynx may be specific to a particular subsite or may span the entire region and beyond. In addition, other congenital syndromes often manifest with findings in the oral cavity and/or oropharynx.

Congenital lesions of the oral cavity and oropharynx result from failures of migration, trapped ectopic tissues, abnormal proliferation of tissues, embryologic fusion anomalies, and benign or malignant neoplasms. Ectopic tissue, heterotopic tissue, and choristomas are histologically normal tissues present in abnormal locations, whereas hamartomas result from an abnormal proliferation of tissues appropriate to the anatomic site. Embryologic duplications or failures in separation or migration can also lead to congenital abnormalities with impairment or loss of normal function. This chapter presents congenital lesions of the oral cavity and oropharynx by subsites progressing from the oral commissure to the oropharynx with generalized pathologies discussed at the end (Table 41.1).

## EMBRYOLOGY

At approximately 3 weeks' gestation, paired pharyngeal arches begin to develop alongside the pharyngeal foregut (Fig. 41.1). The arches have corresponding pharyngeal clefts lined by ectoderm and pharyngeal pouches lined by

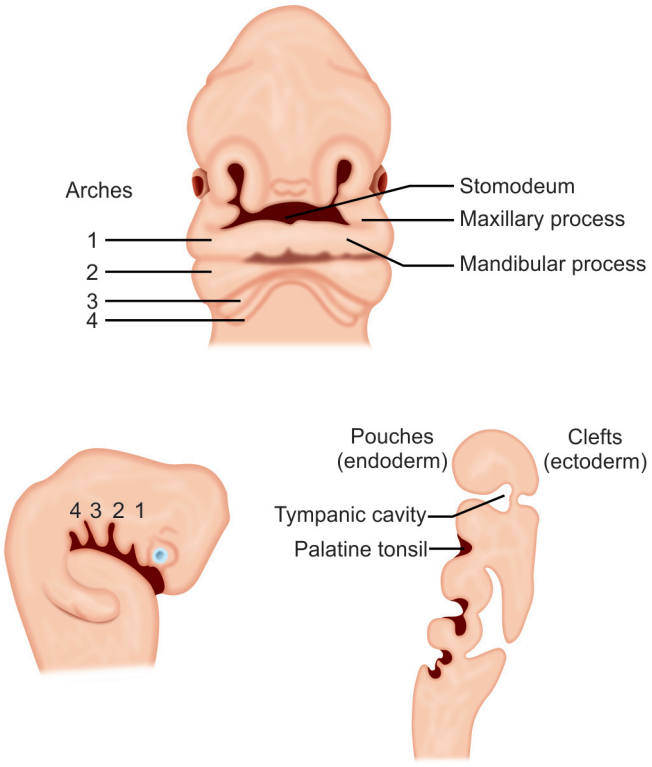

**Fig. 41.1:** Paired pharyngeal arches and their derivatives.

endoderm. The first pharyngeal arch forms the maxillary and mandibular processes. Extensions off of the nasal placodes form the primary palate with the secondary palate extending from the maxillary swellings. Fusion of the secondary palate takes place at around 10 weeks' gestation.

The first arch muscle derivatives, including the mylohyoid, tensor veli palatini, and muscles of mastication, are innervated by the trigeminal nerve. The facial nerve innervates the second arch derivatives to include the muscles of facial expression. The fourth arch gives rise to the levator veli palatini muscle, which is innervated by the superior laryngeal nerve.

Normal facial skeletal development depends on the accurate fusion of the five facial prominences; the frontonasal process, the paired maxillary swellings, and the paired mandibular swellings.[1] Cleft lip, cleft palate and other, rare facial clefts all occur as the result of improper fusion of the five facial prominences.

The buccopharyngeal membrane, composed of ectoderm and endoderm, separates the primitive mouth (stomodeum) from the primitive foregut. This membrane ruptures around day 24 of gestation, creating an opening that begins the oral cavity. The tongue forms during the 4th week and arises from endoderm covered swellings on the floor of the pharynx (Fig. 41.2). The anterior two thirds of the tongue form from the first pharyngeal arch while the posterior third arises from the second, third, and fourth pharyngeal arches. A median tongue bud (tuberculum impar) develops from the first arch and is overgrown by the lateral tongue buds. These three pharyngeal floor swellings compose the anterior two thirds of the tongue.

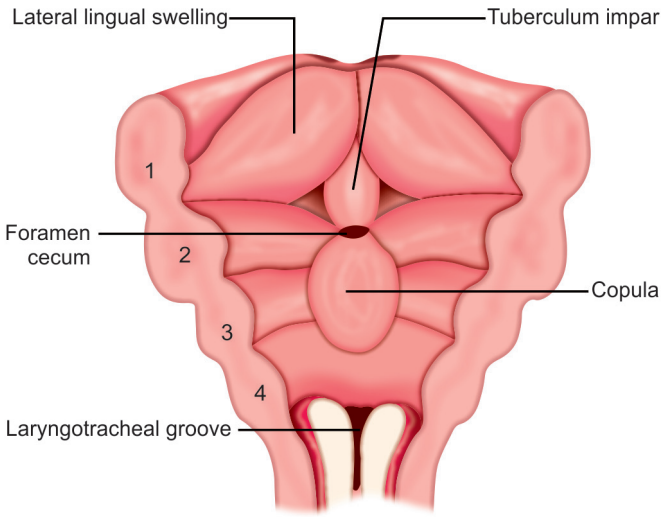

**Fig. 41.2:** Embryology of the tongue and pharyngeal floor.

The second and third arches develop a midline swelling (copula), which is overgrown by swellings from the third and fourth pharyngeal arches (hypopharyngeal eminence) forming the posterior third of the tongue. The occipital somites form the intrinsic musculature of the tongue. All the muscles of the tongue, except for the palatoglossus muscle, are innervated by the hypoglossal nerve. The palatoglossus muscle is innervated by the pharyngeal plexus and the vagus nerve. Separate innervations for taste and sensation versus motor function are explained by these complex tissue migrations.[2]

The thyroid develops in the foramen cecum at the base of the tongue at 4 weeks' gestation and descends along the thyroglossal duct to its final location in the neck by the 7th week.[3] The palatine tonsils develop from the endoderm of the second pharyngeal pouch, and the salivary glands develop from ectoderm invaginating between the maxillary and mandibular swellings (parotid glands), floor of the mouth (submandibular glands), and paralingual gutters (sublingual glands).

## ORAL APERTURE AND LIPS

### Microstomia/Macrostomia

Microstomia is a developmental anomaly resulting in a smaller than normal oral aperture. The most severe form is astomia, a complete failure of the upper and lower lips to divide and can be associated with holoprosencephaly. Other syndromes associated with microstomia are oropalatal dysplasia, Hallermann–Streiff's syndrome, Fine–Lubinsky's syndrome, hemifacial microsomia, trisomy 18, and Freeman–Sheldon's syndrome.[4] Clinical manifestations of microstomia can be barely perceptible to severe. Feeding difficulties are the main concern and both nonsurgical and surgical treatments exist ranging from oral commissure stretching to free tissue transfer.[5]

Macrostomia is an overly large oral aperture. Syndromes associated with macrostomia include Angelman's syndrome, Morquio's syndrome, Noonan's syndrome, Beckwith–Wiedemann's syndrome, Treacher–Collins' syndrome, and Williams' syndrome. Transverse facial clefts, also referred to as Tessier 7 clefts, create an enlarged oral stoma. Lateral facial clefts are rare, reported at 1:5000 births.[6] Surgical repair of lateral facial clefts has been the traditional treatment with combinations of z-plasties, commissure plasties, and local rotational flaps. The goal of surgical treatment is to create a functional oral sphincter with acceptable cosmetic outcomes.

### Lip Pits

Congenital lip pits are perhaps most associated with Van der Woude's syndrome; however, lip pits can also be found in other syndromes such as basal cell nevus syndrome (Gorlin), branchio-oto-renal syndrome, popliteal pterygium syndrome, Kabuki's syndrome, and orofacial digital syndrome.[4] Congenital lip pits typically occur bilaterally on the lower lip in a paramedian position and often contain minor salivary glands. Van der Woude's syndrome has a prevalence of 1:40,000 to 1:100,000 live births with an autosomal dominant pattern with high penetrance and variable expressivity. Cardinal features of the syndrome include lower lip pits, cleft lip with or without cleft palate and isolated cleft palate. Treatment is based on the severity of phenotype and isolated lip pits often require no treatment. Alternatively, the pits may be completely excised if they chronically drain, cause pain, or are cosmetically disfiguring.[7]

### Maxillary and Mandibular Labial Frenula

The maxillary and mandibular frenula attach to the infantile gingiva. After primary dentition erupts the frenula, if attached to far lingually on the gingiva, can cause incisor diastasis and pull at the gingiva leading to gum recession (Fig. 41.3). The absence of the mandibular labial frenula and lingual frenula may indicate a patient with Ehlers–Danlos' syndrome.[8] Patients can be observed until dentition erupts and symptoms develop. Surgical ligation or debulking of the frenulum is curative with orthodontic care as needed to correct dental diastasis.

**Fig. 41.3:** Attached upper labial frenulum with diastema of the upper central incisors and an upper lip hemangioma.

## TONGUE

### Ankyloglossia

Ankyloglossia results when the lingual frenulum is short, thick, or is attached too far anteriorly on the tongue. It is reported in 1.7–4.8% of newborns with a male predominance.[9-11] Ankyloglossia may result in feeding difficulties from poor latch, infant fatigue, and maternal nipple pain. Division of the frenulum can take place at the bedside in newborns, but occasionally may require formal frenuloplasty for a broad frenulum or in older children. For children without feeding difficulties, ankyloglossia may cause speech articulation difficulties or cause oral hygiene difficulties from periodontal food collections. Ankyloglossia is more likely to be problematic if the tongue is unable to reach the hard palate or protrude past the mandibular incisors. It may be preferable to delay frenotomy or frenuloplasty in the child without feeding difficulties as spontaneous lengthening can occur over time.

### Macroglossia

Macroglossia is a disproportionally large tongue that may be either a true enlargement or a relative enlargement due to retrognathism or other facial or oral cavity problems. The spectrum of macroglossia can be mild without sequelae to severe with airway obstruction or feeding difficulties.[12] Vascular malformations, tumors, lymphangiomas, or muscular hypertrophy (Beckwith–Wiedemann's syndrome) can all cause macroglossia.[13] Multiple syndromes have enlargement of the tongue as a feature including Down's syndrome, mucopolysaccharidoses, neurofibromatosis, and Beckwith–Wiedemann's syndrome. Beckwith–Wiedemann's syndrome has an incidence of 1:17,000 births and is associated with macroglossia, anterior abdominal wall defects, visceromegaly, gigantism, and neonatal hypoglycemia.[14] Surgical treatment for symptomatic macroglossia is a partial glossectomy (Figs. 41.4A to C). There are a variety of partial glossectomy techniques all with the goal of reducing bulk while maintaining normal motor function, taste, and sensation. Patients with macroglossia should also be evaluated for the presence of obstructive sleep apnea.

### Glossoptosis

Glossoptosis is defined as posterior displacement of the tongue into the pharynx. Pierre Robin malformation sequence, or Robin sequence, consists of micrognathia, upper airway obstruction, and glossoptosis. An associated syndrome is found in 27% to 82% of children with Robin sequence and include Stickler's syndrome, velocardiofacial syndrome, hemifacial microsomia, Treacher–Collins' syndrome, fetal alcohol syndrome, and other chromosomal abnormalities.[15] Glossoptosis may also be seen in Down's syndrome and other conditions with hypotonia. Surgical treatment of glossoptosis causing upper airway obstruction typically involved glossopexy or tracheotomy; however, mandibular distraction has emerged as an important alternative treatment and is discussed below in the section on micrognathia.

### Geographic Tongue/Fissured Tongue

Geographic tongue, also known as benign migratory glossitis, and fissured tongue (lingua plicata) affect 1.8% and 0.9% of the US population, respectively.[16,17] Both conditions are benign and do not require treatment other than adequate oral hygiene. Deep tongue fissures are associated with Down's syndrome and Melkersson–Rosenthal's syndrome (MRS). MRS is a rare condition marked by fissured tongue, recurrent facial swelling, and facial paralysis.[18] There is no known cause and treatments, including antibiotics, systemic and intralesional steroids, and

**Figs. 41.4A to C:** Macroglossia in a patient with Beckwith–Wiedemann's syndrome. Central tongue reduction sparing the tip and lateral borders. Immediate postoperative appearance.

methotrexate, have been used with varying degrees of success. Those found to have MRS should be screened for Crohn's disease and hairy cell leukemia as associations with these conditions have been made.[4]

## Median Rhomboid Glossitis

Median rhomboid glossitis is a benign condition affecting < 1% of the population. The lesion appears as a smooth, red, depapillated area in the midline of the tongue just anterior to the circumvallate papillae. This area corresponds to the tuberculum impar lending support to a congenital origin of this condition. However, the lesion can also be found off the midline prompting suspicion for noncongenital causes. Candida species have been implicated as a cause of median rhomboid glossitis.[19] Median rhomboid glossitis is usually asymptomatic, but patients may experience pain, burning, or pruritus. Treatment consists of oral hygiene, antifungal troches, and biopsy for any changing or atypical lesions. Surgical resection is rarely indicated.

## Ectopic Thyroid

Failure of normal thyroid migration during gestation results in ectopic thyroid tissue anywhere along the thyroglossal duct tract from the base of the tongue down to the inferior neck. A lingual thyroid is the most common location accounting for 90% of all ectopic thyroid tissue (Fig. 41.5).[20] The incidence of lingual thyroid is 1:100,000 births and females are affected four to eight times more often than males.[3] No additional thyroid tissue is present in up to 80% of cases of lingual thyroid. Lingual thyroids often do not become symptomatic until puberty and symptoms may include hemoptysis, dysphagia, dysphonia, dyspnea, globus, and obstructive sleep apnea. Patients may be euthyroid or hypothyroid. Treatment is unnecessary for

**Fig. 41.5:** Lingual thyroid.

asymptomatic patients. Nonsurgical treatment options include hormone suppression therapy and radioactive iodine ablation. If surgical excision is required, evaluation for additional thyroid tissue in the neck should take place prior to surgery. Scintigraphy with Tc-99, I-131, or I-123 can locate functioning thyroid tissue. Computed tomography, magnetic resonance imaging, and ultrasound can also asses for orthotopic thyroid.[21] Malignancy is rare and, if present, has characteristics similar to thyroid cancer found in the neck.[20] Surgical excision of a lingual thyroid may be performed either transorally or through a suprahyoid neck approach based on visualization. After resection, the patient should be monitored for the need for thyroid hormone replacement.

### Vascular Malformations and Cysts

The tongue is a frequent location of these common lesions. These lesions will be discussed in greater detail later in this chapter. Specific tongue lesions, in order of prevalence, are vascular/lymphatic, mucus extravasation phenomenon, and hamartomatous lesions.[22]

## MANDIBLE/MAXILLA/GINGIVA

### Facial Clefting

Cleft lip and cleft palate are the most common of the facial clefts. Van Der Meulen created an embryologic classification system of facial clefts, whereas Tessier created the most commonly used classification system based on cleft location.[23] The incidence of facial clefting is 0.17% and isolated clefts occur in 66% of these patients.[6] Risk factors for facial clefts include maternal smoking and alcohol consumption, folic acid deficiency, and corticosteroid use. Clefts also have racial variances with rates of 1 in 400 births among Asians and Native Americans to 1 in 2000 births among African Americans. Lateral facial clefts (Tessier 7) occur in 1:3500–5000 births with other Tessier clefts being extremely rare.[24] Clefts are thought to result from a failure of migration and contact of nasal, maxillary, and/or mandibular processes during gestation. Alternative theories include, vascular ischemia leading to developmental arrest, and tethered tissues (amniotic bands) preventing migration. Advances in feto-maternal imaging have made it possible to diagnose facial clefts and airway obstructing masses in utero with near 100% sensitivity.[25] Surgical treatment is based on the type of cleft and associated defects. Maintaining adequate nutrition in children with cleft lip, cleft palate, and lateral facial clefts can be a challenge secondary to incompetence of the oral commissures or oral cavity.

### Micrognathia

Micrognathia occurs as the result of mandibular hypoplasia with the mandibular alveolus positioned posterior to the maxillary alveolus. Stickler's syndrome, hemifacial microsomia, Treacher–Collins' syndrome, Nager's syndrome, and Robin sequence all have micrognathia in their phenotypes. Minor cases may be managed with conservative approaches such as repositioning, prone positioning, and the use of nasopharyngeal airways.[26] Children with micrognathia who require intubation within the first 24 hours of life, who have neurologic deficits, or who experienced intrauterine growth restriction have significantly increased odds of requiring definitive airway surgery.[27] Tracheostomy bypasses the obstruction until the mandible can grow or "catch up". Tracheostomy had been the standard of care until recently when significant advancements in mandibular distraction osteogenesis (MDO) were made. MDO, either intraoral or external, allows for lengthening of the mandibular deficiency and can help avoid tracheostomy or assist with decannulation in many children as anterior advancement of the mandible pulls the tongue forward, improving the airway. Distraction takes place until resolution of the obstruction and is often 15 mm in neonates and further in older children.[28]

### Nasopalatine Duct Cyst

Nasopalatine duct cysts (incisive canal cysts) are the most common nonodontogenic cyst of the maxilla, affecting

1:100 people. The cysts are unilocular and extend between the roots of the central incisors. The cysts arise from epithelial remnants of the nasopalatine duct and extend between the roots of the central incisors. Nasopalatine duct cysts are unlikely to be diagnosed before eruption of dentition. Although most cysts are asymptomatic, some lesions may become painful, drain, become infected, or cause orthodontic misalignment. Symptomatic lesions may require surgical excision and recurrence is rare with complete surgical removal.[29]

## Midpalatal Cysts (Epstein's Pearls)

Midpalatal cysts are epithelial inclusions trapped between fusion planes at the junction of the hard and soft palate and are found in up to 78% of newborns.[30] These small, keratin filled cysts may be present at birth or appear within the first few months of life. They can be found anywhere on the hard palate but rarely occur on the distal soft palate. No treatment is necessary as the cysts spontaneously rupture or regress. They do not cause feeding or respiratory issues.

## Alveolar Cysts (Bohn's Nodules)

Alveolar cysts are epithelial inclusions similar to palatal cysts. Almost 60% of children may present with alveolar cysts at birth. Infants with milia are more likely to present with alveolar cysts than are infants without milia.[30] Most (90%) alveolar cysts present on the maxillary alveolus, and they are more common on the anterior alveolus than on the posterior alveolus.[31] No treatment is necessary as the cysts spontaneously resolve within 4 to 5 weeks.

## Natal/Neonatal Tooth

A natal tooth is a tooth, which is present at birth. Primary dentition does not typically erupt until around 1 year of age. If a tooth erupts within the first 4 weeks of life, it is termed a neonatal tooth and occurs with a prevalence of 1:1000 to 1:3500. Mandibular incisors account for 85% of natal teeth.[32] Natal teeth can cause pain to the mother during breast feeding, or an ulcer in the infant's mouth where the tooth makes contact (Riga–Fede's disease). Natal teeth are the result of displaced tooth germs and are not supernumerary teeth. They are associated with many syndromes to include chondroectodermal dysplasia, Noonan's syndrome, pachyonychia congenita, oculomandibulodyscephaly, and Turner's syndrome. If stable, the tooth can be left in place and filed to remove sharp edges. Natal teeth may be hypermobile but eventually the roots develop and stabilize the tooth. Significantly hypermobile teeth may become an aspiration risk and extraction is recommended.[4]

## Cherubism

Cherubism is a rare, benign, skeletal dysplasia of the maxilla, and/or mandible. The lesions are symmetric, fibro-osseous, multilocular, expansile, and radiolucent, which first become noticeable between 2 to 7 years of age. Diagnosis is made on the basis of the clinical and radiographic findings. Cherubism occurs in three stages: aggressive, nonaggressive, and quiescent. The aggressive phase is seen in young children with rapidly growing lesions that cause tooth root displacement and cortical bone thinning. The nonaggressive phase is typically seen in teenagers and is characterized by slowed growth or stabilization of the lesions. The quiescent phase occurs after puberty when the lesions ossify and begin to remodel with improvement in facial contours. Cherubism has been linked to mutations of the SH3BP2 gene on chromosome 4p16.3.[33] The disease process is self-limiting and resolves spontaneously over time, and observation is the most common treatment. Large, rapidly growing lesions may cause airway obstruction or severe cosmetic deformity and can be treated with surgical curettage and contouring of the involved bone.[33]

## Granular Cell Tumor (Epulis)

Congenital epulis is a rare gingival neoplasm of unknown etiology found in newborns. Based on histological characteristics, it is also known as congenital granular cell tumor. It has an 8:1 female to male ratio and is most commonly found on the anterior maxillary alveolar ridge.[34] The lesions are pink, smooth, and often pedunculated and can be multilobular. Multiple tumors occur in 10% of cases. The lesions, when large, can often be identified on prenatal ultrasound. Large epuli may cause airway obstruction and feeding difficulties. Complete surgical resection is curative though very small, asymptomatic lesions may be observed as they may spontaneously regress.[35] Large tumors obstructing the airway may necessitate the need for an ex utero intrapartum treatment procedure to secure the airway upon delivery. Granular cell tumors can be found in other locations of the oral cavity to include the tongue and floor of mouth, but these are often not congenital lesions and have different immunohistochemical profiles.[36]

## Eruption Cysts

Eruption cysts develop within the mucosa overlying an erupting tooth. Eruption cysts are seen at a mean age of 4.7 years.[37] Eruption cysts present with a 2:1 male to female ratio. Half of all cases occur with secondary dentition, 40% primary dentition, and 10% neonatal teeth. They appear as blue-hued, gingival masses on the alveolar ridge. Eruption cysts may be observed or treated with marsupialization.[38]

## Odontogenic Tumors

Odontogenic tumors are a rare group of neoplasms arising from embryonic tooth structures. They are slightly more common in the mandible (54%) than in the maxilla. The most common of these is an odontoma, which comprises 39% of all odontogenic tumors.[39] Odontomas consist of both epithelial and mesenchymal cells and display tooth tissue differentiation. They have components of dentin, cementum, and pulp. The tumor arises during the normal tooth development and often goes unnoticed until tooth eruption or is found on routine dental imaging. Treatment is complete excision.[40] Ameloblastomas are slow growing but locally invasive bony tumors. They most often occur in the posterior mandible and 15% of cases develop before the age of 16.[40] Ameloblastomas account for up to 12% of pediatric odontogenic tumors.[39] Calcifying, cystic, odontogenic tumors (Gorlin cyst) are painless swellings that can cause displacement of tooth roots. Histologically, they are epithelial lined cysts with a collection of ghost cells.[40]

# ORAL CAVITY/OROPHARYNX

## Congenital Synechiae

Synechiae or adhesions may form in the oral cavity during development. Synechiae may be interalveolar (syngnathia) or from the tonsillar fossa (persistent buccopharyngeal membrane). Syngnathia can occur in connection with cleft palate, although it is seen in isolation as well. Interalveolar adhesions have been linked with multiple syndromes including Van der Woude's syndrome, popliteal pterygium syndrome, orofacial digital syndrome, and cleft palate lateral synechiae syndrome.[41] Surgical division of the adhesions is curative, although postlysis physical therapy may be needed to address temporomandibular joint ankylosis. A persistent buccopharyngeal membrane is the embryonic ectoderm separating the stomodeum from the foregut. When the buccopharyngeal membrane persists after birth, it creates a web spanning from the circumvallate papillae of the tongue to the soft palate and anterior tonsillar pillar. Respiratory distress is unlikely unless choanal atresia is also present. Surgical resection is performed to alleviate feeding difficulties and may need to be done in a staged approach or with radial excisions as circumferential resection may lead to stenosis.[42,43]

## Fordyce Granules

Fordyce granules are ectopic sebaceous glands in the oral cavity. They are similar to adnexal structures typically seen in the dermis and present as white or yellow papules 1–3 mm in diameter. They may be solitary or multiple. A line of Fordyce granules along the boundary between the white lip and vermilion border is classified as Fox-Fordyce's disease. Treatment is reserved for cosmetic concerns, and intraoral lesions do not need to be addressed.

## Oral Lymphoepithelial Cysts

Unlike lymphoepithelial cysts found in the parotid gland of HIV positive patients, oral lymphoepithelial cysts are most often found in the floor of the mouth. They are mobile with a white hue just below the mucosa. Histologically, they present as complete cysts lined with stratified squamous epithelium. It is unknown whether the cysts develop from trapped epithelium or lymphoid crypt obstruction. Surgical excision of these superficial lesions is curative.[44]

## Focal Epithelial Hyperplasia (Heck's Disease)

Focal epithelial hyperplasia is a benign mucosal disease most often seen in Native Alaskan and Native American populations. It has also been seen more prevalently in low socioeconomic groups. It is composed of multiple small painless plaques of the oral mucosa. It has been associated with human papillomavirus types 13 and 32 with virus detected in 80% of lesions. Geographic clustering and interfamilial expression has led many to believe there is a genetic predisposition to the disease. Exophytic lesions may require surgical excision if inhibiting normal occlusion or for cosmetic concerns. Surgery, $CO_2$ laser ablation, cryotherapy, and interferon have been trialed with varying results.[45]

## Mucocele/Ranula

Mucoceles are common lesions seen in the oral cavity. They do not have a true cyst lining and are therefore considered pseudocysts. They result from the collection

of extravasated mucous from minor salivary glands in the oral mucosa. Mucoceles can be marsupialized or surgically excised with the goal of removing the offending minor salivary gland. They are more commonly found in the lower lip and have been associated with trauma.[46] Mucoceles may be seen at birth but are more common in older children.

When the mucocele is located in the floor of the mouth, it is termed a ranula or "little frog". This colloquial name refers to the appearance of the throat of a frog. Ranulas often become larger than other oral cavity mucoceles and often have a blue hue. Ranulas form from the extravasation of mucous from the sublingual gland as opposed to minor salivary glands. Surgical excision of the sublingual gland at the time of resection decreases the rate of recurrence.

A plunging ranula is mucous filled pseudocyst that extends below the mylohyoid muscle. A plunging ranula usually presents as a neck mass and may also have an intraoral component. They are closely associated with the sublingual gland as are ranulas isolated to the floor of mouth. It is thought that plunging ranulas extend from the sublingual gland via a dehiscence in the mylohyoid or that they arise from ectopic salivary tissue elsewhere in the floor of mouth. Plunging ranulas often require a transcervical approach for complete resection and, as with other ranulas, excision of the sublingual gland is performed to reduce the risk of recurrence.[47]

## OROPHARYNX

### Hairy Polyp

Hairy polyp is a very rare ectodermal and mesodermal developmental malformation of the oropharynx and nasopharynx (Figs. 41.6A and B). It most commonly presents with intermittent respiratory distress or feeding difficulties in a neonate. Further examination reveals a pedunculated mass often arising from the tonsillar pillar, soft palate, or nasopharynx. Theories exist that these polyps represent first or second branchial cleft anomalies or very low grade, well-organized teratomas. There is a female predominance. Treatment is surgical excision.[48]

### Second Branchial Cleft Cyst

Second branchial cleft cysts arise from the incomplete obliteration of the embryonic cleft. These can manifest as cysts, sinuses, or fistulas and are the most common or the branchial cleft anomalies. Most often, they present as a neck mass. The tract of a second branchial cleft anomaly, if present, will course between the external and internal carotid arteries, lateral and superior to the glossopharyngeal and hypoglossal nerves, and exit into the tonsillar fossa.[49] Treatment is complete surgical excision.

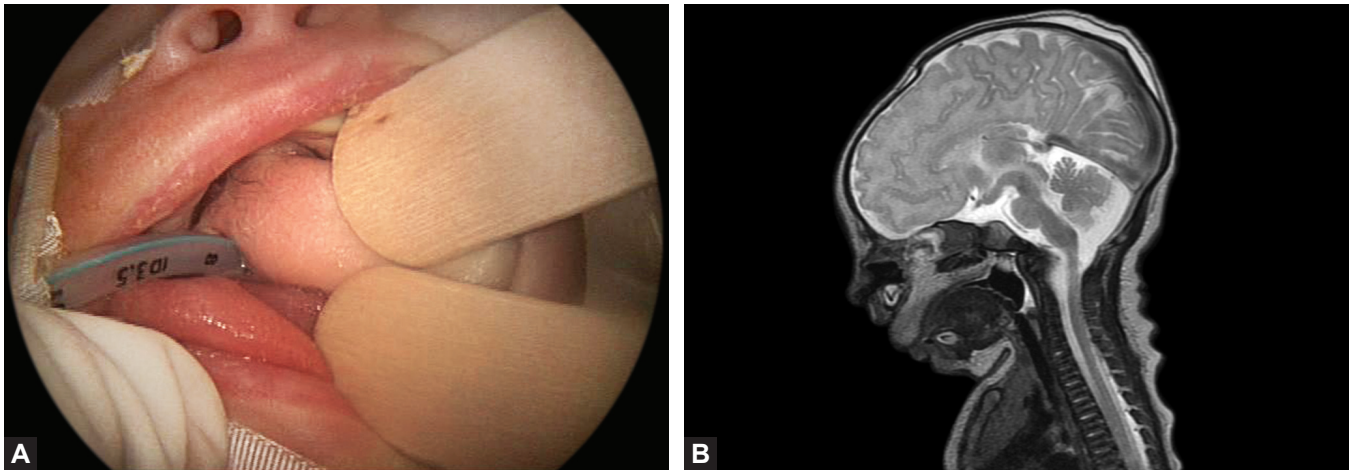
## GENERALIZED LESIONS

### Ephelis (Melanosis)

An ephelis is a well-circumscribed, uniform, pigmented lesion. It can occur in the oral cavity, lip, or tongue and is the equivalence of a freckle on the skin. No treatment is required for this benign lesion.[50]

### Infantile Hemangioma

Infantile hemangiomas are the most common soft tissue tumors in children.[51] The lips, tongue, and buccal



**Figs. 41.6A and B:** (A) Oral hairy polyp in a neonate; (B) T2 sagittal magnetic resonance imaging of neonate with oral hairy polyp. Note attachment of the mass to the skull base and nasopharynx.

mucosa are the most common head and neck sites for hemangiomas (Fig. 41.3). The incidence of head and neck hemangiomas is 4.5% in term newborns and rises to 10% in premature infants weighing <1000 g.[52] Hemangiomas are composed of thin-walled vessels surrounded by endothelial cells that undergo an initial growth phase followed by gradual involution. Observation is the treatment of choice with nearly 50% of lesions resolved by 5 years and 70% by 7 years. Large lesions causing feeding or airway complications, ulcerations, heart failure, or platelet trapping may necessitate aggressive early intervention.

Hemangiomas have been classified as superficial, deep, and mixed and, more recently, as localized or segmental. GLUT-1 is a cellular marker found in infantile hemangiomas, which help distinguish them from other vascular anomalies.[51] The presence of a hemangioma in the "beard" distribution of the lower lip and chin is associated with an airway hemangioma.[53] Rapidly involuting hemangiomas and noninvoluting hemangiomas are often present at birth, whereas infantile hemangiomas may not be noticed during the first few weeks of life.

Traditional hemangioma treatments have centered on intralesional and systemic corticosteroids and interferon injections. Beta-blocker therapy is currently advocated as the treatment of choice with excellent response rates.[51,53] Caution should be used when instituting beta-blocker therapy in children with heart conditions, bradycardia or asthma. In addition, there is a concern for hypoglycemia with beta-blocker therapy as young children have poor glycogen stores.[54] Topical timolol has also been used on small superficial hemangiomas.[55] Laser ablation has been used for superficial lesions, and surgical excision is also performed for nonresponsive lesions or those with life-threatening complications. Early resection following the involution phase can be carried out to improve cosmetic results in areas around the orbits and lips.[51]

## Vascular Malformations

Vascular malformations have a history of significant variability in classification and terminology. Currently, the International Society for the Study of Vascular Anomalies separates tumors (hemangiomas) from malformations. The Hamburg's classification was developed to improve consistency in terminology and is based on the predominant tissue origin of the malformation; arterial, venous, arteriovenous, lymphatic, and capillary.[55] Slow or fast blood flow through the malformation is important in distinguishing among the different lesions as well. Doppler ultrasound is the most cost-effective tool for distinguishing fast from slow flow, whereas magnetic resonance imaging with gadolinium is more effective in evaluating signal characteristics and associations with surrounding structures.

Vascular malformations develop from abnormally formed channels and have an endothelial lining. Unlike hemangiomas, vascular malformations do not regress but rather will expand over time.

Capillary malformations are often called port-wine stains or nevus flammeus. These superficial lesions are often asymptomatic but can be cosmetically problematic when large and located on the face. The pulsed dye laser has been shown to be effective in treating superficial capillary malformations.[56]

## Lymphatic Malformation

Lymphatic malformations (cystic hygromas) may be microcystic or macrocystic. Lymphatic malformations are the most common cause of macroglossia. Macrocystic lesions can be treated with sclerotherapy, whereas microcystic lesions typically require surgical excision or laser ablation. Sclerotherapy agents include OK-432, 100% ethanol, 3% sodium tetradecyl sulfate, bleomycin, and tetracycline. Treatment may not be permanent and recurrence or expansion is common.

## Dysontogenetic Cysts

Dysontogenetic cysts arise from abnormal embryonic development. Epidermoid cysts consist of a stratified squamous epithelium. Dermoids have additional adnexal structures such as hair follicles, sweat glands, or sebaceous glands. Teratomas have the aforementioned but also include mesodermal components. Up to 6.5% of dysontogenetic cysts develop in the floor of the mouth.[57] Teratomas are rare neoplasms in the oral cavity with an incidence of 1:20,000–40,000 live births.[58] Germ cell tumors are frequently grouped with teratomas and are extremely rare in the head and neck.[59]

## Heterotopic Tissue

Choristomas, heterotopias, and hamartomas all represent atypical proliferations of a normal tissue type. Hamartomas represent an overgrowth of tissue found in the anatomical area, whereas heterotopias are normal tissues in an abnormal location. Choristomas are a subset of heterotopias where the lesion is not native to the head and neck. Neuroglial tissues have been found in the tongue and

buccal mucosa and can cause airway obstruction.[60,61] Gastric tissue, as well as respiratory epithelium, have also been described.[62] The two most common locations for oral cavity choristomas are the floor of mouth and the anterior two thirds of the tongue. Surgical resection is curative, and recurrence is rare with complete excision.[63]

# Infections of the Larynx and Trachea

***Jamie N Andrews, Stephen Maturo***

Acute infections of the respiratory tract are endemic in the pediatric population. Acute respiratory disease is the leading cause of hospitalization in children < 4 years of age.[1] The severity of upper respiratory tract infection may range from mild, self-limited disease to impending airway compromise requiring immediate intervention. Acute infections of the respiratory tract often manifest as stridor, signaling narrowing of the laryngeal inlet, and subglottis. Stridor is the sound caused by abnormal air passage during breathing. It often has a musical, high-pitched quality produced by rapid, turbulent flow of air through a narrowed segment of the upper respiratory tract. A stethoscope placed on the presumed area of obstruction is often helpful in identifying the specific region of narrowing (supraglottis, glottis, subglottis, or proximal trachea). Stridor indicates airway obstruction and is a physical examination finding from which an underlying cause should be sought; it is not a diagnosis. This phenomenon is explained with an understanding of basic fluid dynamics. Airflow typically approximates laminar flow under normal circumstances. Inflammation of the airway results in narrowing of its lumen. As the lumen narrows, the rate of flow increases as explained by the Venturi effect. Bernoulli's principle states that as the speed of a moving fluid (liquid or gas) increases, the pressure within the fluid decreases and vice versa.[2] According to Bernoulli's formula, $1/2\ pv^2 + pgh + p$ = constant (where $p$ = density of fluid, $v$ = velocity of the fluid, $g$ = gravitational acceleration, $h$ = elevation, and $p$ = pressure gradient across the conduit), as the flow velocity increases, there is a drop in the intraluminal pressure. Negative intraluminal pressure promotes airway collapse. This increase in turbulence and collapsibility of the airway is appreciated as stridor.[3]

Children are more susceptible to acute airway compromise due to intrinsic anatomic differences between the pediatric and adult airway. For example, the glottis is the narrowest segment of the adult airway, whereas the pediatric airway is narrowest at the subglottis. The subglottis has a fixed diameter as the cricoid cartilage forms a complete ring that encircles the airway. As the cross-sectional area of a cylinder is proportional to the square of its radius, $A = \pi r^2$ (where $A$ = area, $r$ = radius) even small differences can result in dramatic narrowing of the airway caliber leading to acute airway compromise.[4] Supraglottic swelling classically produces inspiratory stridor. Narrowing at the level of the subglottis typically produces biphasic stridor. Expiratory stridor is caused when narrowing occurs in the intrathoracic trachea or bronchioles.

Although diagnosis is often achieved purely on the basis of physical examination findings, radiographs, laboratory evaluation, and flexible endoscopy often assist in diagnosis. Given the broad spectrum of presentation, clinicians must be adept in diagnosis and management of this disease process. This chapter will discuss the clinical features, diagnosis, and management of croup (laryngotracheitis), supraglottitis, bacterial tracheitis, and retropharyngeal abscesses in the pediatric population.

## Laryngotracheobronchitis

Viral laryngotracheobronchitis (croup) is the most common infectious cause of stridor, accounting for as much as 90% of infectious airways in children.[5] About 3 to 5% of children will experience viral croup at least once in their early development.[6] In patients who experience one episode of croup, 5% will have recurrent episodes.[7] This disease process primarily affects children between the ages of 6 months and 3 years. The peak incidence arises at 18 to 24 months of age, with boys more likely affected by at least a 2:1 ratio.[8] Although croup can occur at any time of the year, it typically occurs in the late autumn and winter months.

## Clinical Features

Patients with viral laryngotracheobronchitis typically present with an upper respiratory prodrome progressing to the characteristic barking cough, hoarseness, and high-pitched inspiratory stridor. The severity of viral croup ranges from mild airway impairment to severe, life-threatening airway obstruction, with the majority of children presenting on the mild spectrum of disease. Biphasic stridor, tachypnea, retractions, cyanosis, and oxygen desaturations are ominous signs, which signify impending airway compromise. Westley et al. proposed a scoring system grading the severity of symptoms, which is based on the level of consciousness, presence, and characteristics of stridor, air entry, and retractions.[9] Although such a classification system has utility in terms of research, the clinical scenario should always dictate management of the patient.

The most common etiologic organism is parainfluenza viruses type 1 and 2, although influenza A and B, respiratory syncytial virus, and *Mycoplasma pneumoniae* are other common infectious causes.[10] Croup transmission occurs mainly by direct contact with exposure to nasopharyngeal secretions.[11] This viral disease primarily involves the glottis and the subglottis, which results in dynamic subglottic narrowing more prominent on inspiration due to increased negative intraluminal pressure resulting in collapse of the subglottic tissues.

## Diagnosis

The diagnosis of croup is primarily obtained by history and physical examination alone. Radiographs are often utilized to confirm diagnosis. Frontal anteroposterior (AP) (high-kilovoltage) soft tissue neck films classically reveal a symmetric narrowing of the subglottic area, or "steeple sign".

## Treatment

The treatment of viral laryngotracheobronchitis depends on the severity of obstruction, with infrequent need for hospitalization (1.5% to 15%) or intubation (1% to 5%).[12] Management strategies for viral croup include humidified mist, racemic epinephrine, glucocorticoids, and heliox. In mild cases, with minimal stridor without increased work of breathing, patients may be managed in an outpatient setting. Historically, patients were treated with mist therapy. The presumed mechanism of action suggests reduced upper airway irritation by loosening thickened secretions, thus facilitating expectoration. Although the administration of humidified mist is often employed in the treatment of patients affected with viral croup, no scientific evidence exists that mist therapy has any effect on reducing subglottic edema or that patients have better outcomes.[13]

In children who demonstrate worsening stridor and increased work of breathing, racemic epinephrine should be administered. Racemic epinephrine is a nebulized solution with a 1:1 mixture of the levo (l) and dextro (d) isomers of epinephrine. Although the racemic mixture is the most common form administered, the l-isomer has been proven to be as effective as racemic epinephrine without increased side effects.[14] L-Epinephrine is administered as 5 mL of 1:1000, with racemic epinephrine administered in a 0.5-mL solution. The α-adrenergic effects of epinephrine work to cause mucosal vasoconstriction, leading to a reduction in subglottic edema. On the basis of a recent Cochrane review, both racemic and l-isomer epinephrine were associated with a clinically and statistically significant transient reduction of symptoms of croup 30 minutes post-treatment regardless of delivery method.[15]

Epinephrine's effect dissipates after 2 to 3 hours after administration, with rebound mucosal edema occurring in some patients. Historically, children treated with racemic epinephrine have been hospitalized for observation given the potential for rebound edema. Thus, if the symptoms of croup are severe enough to warrant the use of racemic epinephrine, then glucocorticoids should be administered to reduce any associated mucosal rebound edema 2 to 3 hours later. The administration of glucocorticosteroids reduces hospitalization.[16-19] Children should be observed closely after administering racemic epinephrine during this time period, and they are often discharged from the emergency department if symptoms resolve.

Nebulized budesonide (2 mg) or oral or intramuscular dexamethasone (dose range 0.15–0.6 mg/kg) is the most commonly used steroids. Oral dexamethasone is

often utilized due to its ease of administration, widespread availability, and lower cost.[20] Chub-Uppakarn et al. studied higher dose corticosteroids versus lower dose corticosteroids (dexamethasone 0.15 and 0.6 mg/kg) and found that both were equally effective in the treatment of moderate to severe croup, and both groups did not suffer adverse reaction from dexamethasone treatment in either group.[21]

The proposed mechanism of action for corticosteroids is that it works to decrease the permeability of capillary endothelium and stabilize lysosomal membranes.[1] This serves to reduce submucosal edema and decrease the inflammatory process. Regardless of its mechanism of action, the use of corticosteroids in the setting of croup has been well established. In a recent Cochrane review, use was associated with lower admission rates, and when hospital admission was indicated, the use of corticosteroids (dexamethasone and budesonide) demonstrated abbreviation of the length of hospital stay.[22]

Heliox, a helium–oxygen mixture, has been used in the setting of severe croup. It decreases the work of breathing by promoting laminar flow through the partially obstructed airway. Currently, no randomized clinical-control trial exists, which demonstrates any clinical reduction in symptoms or that patients have better outcomes. On the basis of a recent Cochrane review, there is a lack of evidence to establish the effect of heliox in the treatment of croup in children.[23]

In as much as 5% of hospitalized children, medical therapy fails and children will develop respiratory failure requiring airway intervention. For atypically presentations, formal endoscopy may be necessary to evaluate for bacterial tracheitis or foreign body. An endotracheal tube placed (nasotracheal or orotracheal) of at least a half size smaller than estimated based on the child's size or age should be used. Although mechanical ventilation can be life saving, it is associated with complications, such as ventilator-induced lung injury, nosocomial pneumonia, and subglottic stenosis.[24] The clinician must balance these risks against the risks of early extubation leading to reintubation. In a study conducted by Kurachek et al., extubation failure, as defined by reintubation within 24 hours of extubation, was independently associated with a fivefold increased risk of death in pediatric patients.[25] Thus, establishing objective criteria in determining the patient's readiness for extubation is critical in reducing complications. Successful extubation of mechanically ventilated patients depends on the patient's ability to sustain unassisted respirations while maintaining adequate gas exchange. This is dependent upon three factors: (1) the ability of the patient to maintain spontaneous, efficient respirations; (2) the effort exerted on the respiratory muscles; and (3) inspiratory drive. Parameters historically assessed to determine readiness for extubation include the air leak test, rapid shallow breathing index (RSBI), negative inspiratory force (NIF), fractional inspired oxygen content ($FiO_2$), volumetric capnography, and maintenance of spontaneous respiration, respiratory rate, and tidal volumes.[26]

The air leak test measures the pressure necessary to generate an audible air leak around the endotracheal tube. Although an air leak test has clinical utility in terms of assessing upper respiratory tract obstruction, it is a poor predictor of extubation success. A study conducted by Mhanna et al. demonstrated a low sensitivity when used as a screening test to predict postextubation stridor in young children (< 7 years old).[27] Another study demonstrated that an air leak pressure ≥ 30 cm $H_2O$ measured in the nonparalyzed patient before extubation was common and did not predict an increased risk for extubation failure.[28] The RSBI was first described by Yang and Tobin in 1991. It quantities rapid shallow breathing as the ratio of respiratory frequency to tidal volume ($f/VT$) and was found to have a sensitivity of 97% and a specificity of 64% in predicting successful extubation. The same study linked extubation failure with decreasing tidal volume to body weight ratio, increasing $FiO_2$, and decreasing mean inspiratory flow.[29] Respiratory muscle strength can be assessed by measuring the maximal inspiratory pressure or NIF. The NIF reflects the strength of the diaphragm and inspiratory muscles, and it is useful in predicting pediatric extubation success.[30] Volumetric capnography has also proven useful in determining a child's readiness for extubation.[31] However, evaluating a combination of variables may serve useful in predicting extubation success. A recent prospective analysis involving 227 mechanically ventilated children found that a spontaneous respiratory rate ≤ 45/min, spontaneous tidal volume ≥ 5.5 mL/kg, and an RSBI ≤ 8 breaths/min/mL/kg body weight were all accurate predictors of successful extubation.[32]

Protocol-based weaning has been proven to result in faster extubation with better outcomes in adults, but evidence of improved outcomes in the pediatric population is lacking. In a prospective trial conducted by Randolph et al., no advantage over clinical weaning was apparent.[33] Shorter weaning (by 12 hours) against historical controls with no increase in overall complication rates was reported in another study.[34]

## ACUTE SUPRAGLOTTITIS (EPIGLOTTITIS)

Acute supraglottitis in children represents an airway emergency. This disease process evolves rapidly and often results in a life-threatening emergency. As supraglottic edema increases, the epiglottis prolapses into the laryngeal inlet resulting in airway obstruction. Prior to the introduction of the *Haemophilus influenzae* type B (HIB) vaccine, children were predominately affected. Since the introduction of the monovalent vaccine for *H Influenzae* type B in 1985, and 2 years later the release of the conjugate vaccine, there has been a precipitous decline in the number of cases of supraglottitis.[35,36] Today, there is a relative decline in children affected with a rise in the proportion of adults affected.[1] The effectiveness of the HIB vaccine has led to an epidemiologic shift in the pathogens responsible for supraglottitis. The most common etiologic organism in the postvaccine era is Group A β-hemolytic streptococci, although *Staphylococcus*, *Klebsiella*, *Moraxella catarrhalis*, *Haemophilus parainfluenzae*, *Pneumococcus*, *Pseudomonas*, and *Candida* are other common infectious causes.[1]

### Clinical Features

Supraglottitis primarily affects children between the ages of 2 and 7 years. Although supraglottitis may occur at any time of the year, it typically occurs in the winter and spring months. The most common signs of supraglottitis are fever, severe throat pain, odynophagia, and respiratory distress. Children often appear toxic, with shallow respirations, retractions, inspiratory stridor, and inability to tolerate their own secretions. Characteristically, the child assumes the "tripod" position, leaning forward, chin up, and mouth open, with hands braced at their side, to maximize air exchange. The child with suspected supraglottitis should be kept under constant observation, preferably with oxygen saturation monitoring. The disease process evolves rapidly (within hours) from mild respiratory symptoms to respiratory distress. On physical examination, the child exhibits inspiratory stridor, increased work of breathing, and drooling. Activity is often limited as all efforts are exhausted in maximizing airflow. Stridor is a late finding that indicates near complete airway obstruction.

### Diagnosis

Although the diagnosis of supraglottitis is obtained by history and physical examination alone, laboratory evaluation, radiographs, and endoscopy can be used to verify the diagnosis. Patients will exhibit an acute leukocytosis on laboratory evaluation. Portable, lateral soft tissue neck radiographs are the single most useful study. Lateral films will reveal thickening and edema of the epiglottis ("the thumb sign") with obliteration of the vallecula. Endoscopy is utilized to confirm diagnosis. Endoscopic findings include diffuse erythema and edema of the supraglottis, epiglottis, arytenoids, and aryepiglottic folds. The normal architecture of the supraglottis is often obscured secondary to edema, and abscess formation over the epiglottis is a common finding.

### Treatment

If acute supraglottitis is suspected, the clinician should avoid over stimulating the child and potentially exacerbating the patient's airway distress. Thus, intravenous (IV) access, blood draws, imaging, and endoscopy should be avoided as this may trigger loss of the airway in an uncontrolled setting. All procedures should be avoided until a stable airway has been established. Establishing a stable airway is the highest priority. Once the diagnosis of supraglottitis is considered, plans for securing a definitive airway should be made as expeditiously as possible. Endotracheal intubation is the preferred method and may be accomplished by either nasal or oral routes. Tracheostomy is rarely necessary, but the surgeon must be prepared to perform a surgical airway if required. The patient is promptly brought to the operating room and using a nonparalytic, spontaneous ventilating, nonirritating, inhalational anesthetic, direct endoscopy is performed visualizing the supraglottic structures. Foreign body aspiration may mimic supraglottitis, thus the airway should be evaluated for the presence of a foreign body if clinical suspicion is raised.

Once endotracheal intubation is successfully attained, blood may be drawn for blood cultures and a complete blood count. Cultures should also be sent of the epiglottis to direct antibiotic therapy. Antibiotic therapy is initiated promptly after the establishment of IV access. Ceftriaxone, ampicillin–sulbactam, or clindamycin are appropriate antibiotic choices. Vancomycin is recommended in patients with a penicillin or cephalosporin allergy. Antibiotic therapy may be modified as blood cultures become available. Patients are then transferred to the intensive care unit for IV antibiotic therapy and ventilatory support. The edema of the supraglottic larynx usually subsides within 48 to 72 hours, allowing safe removal of the endotracheal tube.[1] Extubation can be considered when there is an air leak around the endotracheal tube at < 20 cm $H_2O$.

Extubation should be only performed in a controlled environment with appropriate airway equipment present, and consideration should be given to direct endoscopic evaluation of the airway prior to extubation.

## BACTERIAL TRACHEITIS (MEMBRANOUS TRACHEITIS)

Bacterial tracheitis, also called membranous tracheitis, bacterial croup, or bacterial laryngotracheobronchitis was first described by Jones et al. in 1979.[37] Bacterial tracheitis is thought to arise from a bacterial suprainfection of viral laryngotracheobronchitis. The clinical presentation of bacterial tracheitis is not as rapid as supraglottitis, although it is a potentially life-threatening condition. The most common presenting symptoms are stridor, cough, hoarseness, and fever. The secondary bacterial pathogen most commonly responsible is *Staphylococcus aureus* accounting for 36 to 75% of cases.[38] Cultures also frequently yield *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *H influenzae, Pseudomonas aeruginosa*, and *Streptococcus pyogenes*.[39] Membranous laryngotracheobronchitis affects a wide range of children from those several weeks old to children in their early teenage years with a mean age of 5.2 years.[38] Similar to viral croup, bacterial tracheitis typically occurs in the autumn and winter months when the incidence of viral upper respiratory tract infections are highest. In a recent retrospective analysis conducted by Hopkins et al., bacterial tracheitis was noted to be three times more likely to have caused respiratory failure than viral croup and epiglottitis combined.[40] Early recognition and expeditious intervention are critical to prevent complications arising from this infectious disease process.

### Clinical Features

Patients frequently present with a several day history of upper respiratory symptoms, fever, cough, and evolving stridor. Following a viral prodrome, patients demonstrate a sudden progression of respiratory symptoms, culminating with a harsh, inspiratory, or biphasic stridor with associated respiratory distress. A high fever is common, and patients often appear toxic. Bacterial tracheitis should be considered in any child who presents with acute upper airway obstruction. In contrast to other causes of pediatric upper airway obstruction, bacterial tracheitis does not respond to racemic epinephrine, and the epiglottis appears normal.[41] The only definitive way to diagnose bacterial tracheitis is by direct visualization of the trachea via bronchoscopy.

Patients commonly demonstrate an elevated white blood cell count on laboratory evaluation, although other inflammatory markers such as C-reactive protein may be unremarkable.[37] Blood cultures are frequently negative. Soft tissue AP and lateral plain film radiographs are frequently obtained, which confirm the diagnosis, but can potentially delay treatment and should be avoided in unstable patients. AP radiographs of the neck classically demonstrate the "steeple sign" as noted in viral laryngotracheobronchitis. Lateral radiographs of the neck characteristically demonstrate an irregular, hazy tracheal air column, which indicates soft tissue pseudomembranous detachment. This membranous-like debris is pathognomonic for bacterial tracheitis and is the source of the precipitous decline in the patient's respiratory status. Patients typically have a less severe clinical appearance in comparison with supraglottitis. In fact, a recent retrospective review of 94 patients treated for acute bacterial tracheitis reported a milder course than previously described.[42] Nonetheless, these patients require aggressive medical management and debridement.

### Diagnosis

According to a recent retrospective review, no clinical, radiologic, or laboratory feature was a reliable diagnostic predictor for bacterial tracheitis.[43] Only direct examination via bronchoscopy accurately distinguishes bacterial tracheitis from other forms of acute obstructive upper airway diseases. Bronchoscopy is both diagnostic and therapeutic. Rigid bronchoscopy with laryngotracheal debridement is the cornerstone of therapy. Direct laryngotracheobronchoscopy is performed to remove the adherent thick secretions obstructing the airway. Endoscopic findings are notable for a diffusely infectious process involving the subglottis, trachea, and main stem bronchi. Diffuse mucosal ulceration, copious purulent exudates, and sloughing of pseudomembranous tissue are characteristic findings on endoscopy. Blood cultures are typically negative, but tracheal cultures often yield the etiologic pathogen. Broad-spectrum antibiotic therapy is directed toward the most common pathogens and adjusted according to the tracheal culture results.

### Treatment

Patients often are intubated to assist with aggressive pulmonary toilet. In a multi-institute, retrospective review performed by Tebruegge et al., evaluating 34 patients with bacterial tracheitis, a total of 31 patients (91.2%) required

intubation. Twenty-seven out of the 31 patients (87.1%) were intubated within 24 hours after presentation to the hospital.[38] Recent research also suggests that patients may be effectively managed without intubation. A case series review performed by Shargorodsky et al. evaluated a total of six patients who were diagnosed with bacterial tracheitis who underwent urgent direct laryngoscopy and bronchoscopy with debridement of mucopurulent debris and tissue culture. The mean time to the operating room was 4.2 hours (range 2–7 hours). No patients in their series required urgent intubation, with only one patient requiring intubation postdebridement. All patients received broad-spectrum antibiotics and were kept on acute cardiopulmonary monitoring for at least 48 hours. Patients were then re-evaluated with direct laryngoscopy and bronchoscopy. All patients in their series achieved favorable results and were transitioned to a 10–14 day course of oral antibiotics after discharge.[39]

If intubated, meticulous airway care with frequent saline administration and suctioning of the trachea should be carried out to prevent accumulation of thickened secretions and mucosal debris that may obstruct the airway. Patients are frequently managed with serial examinations of the upper airway with subsequent debridements. In severe cases, repeat rigid bronchoscopy with debridement is required to maintain a patent airway. However, the majority of intubated patients require a relatively short period of assisted ventilation, with a mean duration of ventilation of 3.5 days (range 1–12 days), with 55% extubated within 72 hours.[38] The most common complication of bacterial tracheitis is pneumonia occurring in up to half of all children affected with this disease. Acute respiratory distress syndrome (ARDS) may also develop and is classically diagnosed based on chest X-ray noting bilateral ground-glass pulmonary infiltrates and the need for increased fraction of inspired oxygen ($FiO_2$) to maintain oxygen saturation. Other complications include septic shock, toxic shock syndrome, respiratory failure, and multiple organ dysfunction syndrome.

## RETROPHARYNGEAL CELLULITIS AND ABSCESSES

In the postantibiotic era, retropharyngeal abscesses are an uncommon consequence of upper respiratory tract infections. Suppuration of the retropharyngeal nodal basin, which serves to drain infections in the paranasal sinuses, nasopharynx, and oropharynx results in abscess formation. Other etiologies of infection include traumatic endoscopy or intubation, penetrating foreign bodies, vertebral body osteomyelitis, and dental procedures.[44] The retropharyngeal space is a potential space. It is invested in the deep layer of the deep cervical fascia and extends from the skull base to the mediastinum to the level of the sixth thoracic vertebrae. It is bounded anteriorly by the buccopharyngeal and pharyngobasilar fascia, which invests the superior, middle, and inferior constrictor muscles. Posteriorly, the retropharyngeal space is bounded by the prevertebral fascia. Its lateral limit is the carotid sheath. The retropharyngeal space communicates directly with the parapharyngeal space anterolaterally. This potential space is divided by a median raphe into a left and right compartment. Due to its communication with multiple potential spaces and unobstructed course to the mediastinum, a retropharyngeal abscess can be life threatening. Thus, early diagnosis and treatment are essential to prevent the development of complications.

### Clinical Features

Retropharyngeal abscesses are most common in early childhood with half of patients presenting < 3 years old. Seventy percent of patients who present with retropharyngeal abscesses are < 7 years of age. Infections frequently present with symptoms consistent with an upper respiratory tract infection. As suppuration of the retropharyngeal lymph nodes occur, the patient exhibits neck pain, limited neck range of motion, and frequently dysphagia so severe that the patient may be acutely unable to tolerate their own secretions. Patients commonly are febrile and toxic appearing.

### Diagnosis

Early diagnosis is essential to prevent the development of complications. A complete blood count with differential will characteristically demonstrate a leukocytosis with a leftward shift. If the clinician suspects the presence of a retropharyngeal abscess, a lateral soft tissue radiograph of the neck, in neck extension taken on expiration should be obtained. When the retropharyngeal space at the level of C2 is twice the diameter of the vertebral body, the diagnosis of retropharyngeal cellulitis or abscess is confirmed. If the lateral neck radiograph confirms the presence of soft tissue edema, computed tomography (CT) with IV contrast is useful in distinguishing abscess from phlegmon. CT imaging is also helpful in identifying the

extent of disease, spread to adjacent potential spaces, and mediastinal involvement. CT findings characteristically demonstrate a well-formed ring of contrast enhancement encircling a nonenhancing density.

Although CT imaging of the neck is useful in the diagnosis of deep space neck infections, it has its limitations. Smith et al. noted a 75% positive predictive value in accurately predicting the presence of a discreet collection of pus in patients who demonstrated radiographic evidence of abscess.[45] Based on this study, if a decision to take the patient to the operating room is based solely on the results of CT, a 25% negative exploration rate should be expected. Daya et al. evaluated 54 patients with deep space neck infections and noted a sensitivity of 81% in detecting an abscess by CT scan while CT scan was only 57% specific in identifying abscess.[46] Therefore, the entire clinical picture should be evaluated prior to making treatment decisions and CT findings alone should not determine the decision for surgical drainage.

## Treatment

Early IV antibiotic therapy is indicated when the diagnosis of a retropharyngeal abscess is confirmed. In stable patients, a trial of 24 to 48 hours of antibiotic therapy is appropriate. If the clinical course improves, then outpatient oral antibiotic therapy may be initiated. McCaly et al. evaluated the effectiveness of using IV antibiotics alone to treat clinically stable children with evidence of deep neck abscesses on CT scan. The presence of an abscess was defined as ring enhancement around a nonenhancing density, and a size greater than 1 cm in every dimension. In this series of 11 patients, only one patient did not respond to IV antibiotic therapy and went on to require surgical drainage.[47] These results suggest a 91% response rate to IV antibiotic therapy despite radiographic evidence of abscess on CT scan.

Another study conducted by Cheng and Elden examined 178 pediatric patients and sought to identify risk factors associated with an increased likelihood of medical therapy failure. Risk factors that were statistically and clinically significant in their study included younger patients (< 15 months) and those who had CT imaging findings of a rim-enhancing lesion consistent with abscess formation with size ≥ 2.2 cm. Both clinically findings increased the chances that patients would undergo surgical drainage. The same study noted a 66.3% response rate with IV antibiotics alone.[48] Antibiotic treatment should include coverage from gram-positive bacteria to include *Streptococcus*, *S aureus*, and Group A β-hemolytic streptococci. Abdel-Haq et al. noted a rising incidence in methicillin-resistant *Staphylococcus aureus* (MRSA) infections. In their study of 114 patients, MRSA positive retropharyngeal abscesses were most commonly found in younger patients (age < 3 years) and were associated with a higher complication rate. In fact, all patients in their series who developed mediastinitis were MRSA positive.[49] Clindamycin or ampicillin-sulbactam provides appropriate coverage for a majority of retropharyngeal abscesses. A third-generation cephalosporin such as ceftriaxone may be beneficial if gram-negative organisms are suspected. If the clinical course worsens or fails to improve significantly, surgical intervention should be strongly considered. Oral intubation should be performed, avoiding abscess rupture and subsequent aspiration. A transoral route is the most frequently used approach, allowing adequate exposure to drain the abscess. In cases where the abscess is lateral to the great vessels, or involves multiple spaces, a transcervical approach is frequently employed.[50] Trendelenburg positioning is also helpful in decreasing the potential for aspiration of purulent material. Repeat imaging is rarely necessary as it rarely changes management and exposes the patient to unnecessary radiation.

The retropharyngeal space is divided by a median raphe into a left and right compartment. This has clinical implications, as incision and drainage of a retropharyngeal abscess involves a posterior pharyngeal incision to the level of the prevertebral fascia in a vertically oriented, paramedian plane. The retropharyngeal space communicates directly with the parapharyngeal space anterolaterally. Abscess material often communicates between the two adjacent spaces and is apparent on CT scan. Because both spaces lie medial to the great vessels, both can be successfully managed with an intraoral approach. Additional complications that arise in children with retropharyngeal abscesses include ARDS, mediastinitis, sepsis, and airway obstruction.

# CONCLUSION

Acute infections of the larynx and trachea are common in the pediatric population. These disease processes occur over a broad spectrum of severity, from mild, self-limiting disease to life-threatening airway emergencies. Clinicians must be adept in timely recognition, diagnosis, and expeditious management to prevent complications due to delay in therapy.

CHAPTER

# 43 Inflammatory and Neoplastic Lesions of the Larynx and Trachea

***Dinchen A Jardine, Thomas Q Gallagher***

## INTRODUCTION

Neoplastic and inflammatory lesions of the pediatric larynx, trachea, and bronchi span a wide range of pathology from the very rare, for example, tracheal malignancies, to the very common, such as inflammatory disorders like laryngopharyngeal reflux (LPR). Symptoms of these lesions and their severity are related to their location and may include cough, voice changes, stridor, or airway obstruction. In this chapter, we highlight the neoplastic and inflammatory lesions found in the larynx and trachea with a focus on the pediatric airway. Table 43.1 offers an outline of the disorders reviewed in this chapter.

**Table 43.1:** Inflammatory and neoplastic processes reviewed in this chapter

| | |
|---|---|
| *Inflammatory disorders* | *Trachea* |
| Laryngopharyngeal reflux | Benign |
| Systemic lupus erythematosus | Granular cell tumor |
| Granulomatous diseases | Fibrous histiocytoma |
| Wegener's granulomatosis | Neurofibroma |
| Sarcoidosis | Hemangiopericytoma |
| Systemic sclerosis | Chondroma |
| Relapsing polychondritis | Malignant |
| Amyloidosis | Mucoepidermoid |
| Stevens–Johnson syndrome | Adenoid cystic carcinoma |
| Rheumatoid arthritis | Rhabdomyosarcoma |

| Rhabdomyosarcoma | |
| Squamous cell carcinoma | |
| Primitive neuroectodermal tumors | |
| Mucoepidermoid carcinoma | |

## INFLAMMATORY LESIONS

### Laryngopharyngeal Reflux and Gastroesophageal Reflux Disease

Gastroesophageal reflux (GER) is a normal phenomenon that about 44% of the population of the United States experience monthly.[1] It affects both adults and children, and may be associated with acute, chronic or intermittent laryngitis. In adults, symptoms typically follow large or especially fatty meals. GER disease (GERD) is a chronic condition where changes occur in the barrier between the stomach and the esophagus, including relaxation of the lower esophageal sphincter (LES). In children, GER is physiologic and self-limited and often responds to nonoperative treatment. GER has been reported in up to 60% of infants aged 6 months, the incidence declining to 5% by the end of the first year.[2] This early in life GERD predilection is believed to be due to anatomic immaturity of the LES and the predominantly liquid diet of neonates and infants.

GERD has been implicated in the etiology of many extraesophageal disorders including laryngitis.[3] The relationship between laryngitis and GERD is still evolving because of an ever-growing body of literature. LPR is the term given when retrograde flow of gastric contents comes in contact with the mucosa of the upper aerodigestive tract; alternative terms include extraesophageal reflux and supraesophageal GERD. LPR is used interchangeably with GER, but the former is more specific anatomically.

#### *Diagnosis*

Diagnosis begins with a thorough history and physical examination. The symptoms of GERD in both adults and children are described in Table 43.2. Certain medications and foods predispose patients to GERD by relaxing the LES. These items include caffeine, calcium channel blockers, and xanthines. Social behaviors like smoking, alcohol consumption, and poor dietary habits also predispose patients to GERD. Modification of these behaviors and elimination of certain foods from the diet may not only be diagnostic but also therapeutic in adults, older children, and adolescents. In young children, age and neurologic development must also be considered when evaluating a child with GERD. Certain disorders particularly predispose pediatric patients to chronic GERD, including significant neurologic impairment, genetic disorders such as the Cornelia de Lange's syndrome and Down's syndrome, congenital esophageal abnormalities such as repaired esophageal atresia or congenital diaphragmatic hernia, chronic lung disease, obesity, and family history of severe GERD.[4]

**Table 43.2:** Symptoms of gastroesophageal reflux in children and adults

| *Adults* | *Children* |
|---|---|
| Heartburn | Regurgitation and vomiting (70%) |
| Regurgitation | Chronic cough (50%)[87] |
| Chest pain | Epigastric pain and irritability (36%)[88] |
| Dysphagia | Feeding difficulties and feeding refusal (29%) |
| Nocturnal symptoms | Failure to thrive (28%) |
| | Acute/apparent life-threatening event (ALTE) |
| | Bronchospasm and asthma |
| | Sandifer's syndrome |

In infants, GERD and milk allergy may both manifest similar symptoms like regurgitation, vomiting, fussiness, and crying.[5] Both conditions may also coexist, further complicating the clinical picture. Elimination diet and evaluation by a pediatric gastroenterologist may be helpful in differentiating these two diseases.

Barium esophagram and an upper gastrointestinal (GI) series are radiographic studies that allow for identification of anatomic abnormalities of the esophagus, stomach, and duodenum, such as abnormal esophageal configurations, strictures, and hiatal hernia. Esophagogastroduodenoscopy (EGD) allows direct visualization of the upper GI tract to further identify strictures, infections, or inflammatory changes of the esophagus and stomach. Unfortunately, children with GERD infrequently manifest pathological features; therefore, a normal EGD cannot exclude GERD.[6]

Laryngeal findings in LPR and GERD may not always be present and are not very specific for disease. Most typically encountered is posterior laryngeal edema and erythema, particularly involving the arytenoid mucosa. In addition, edema of Reinke's space and diffuse edema of other laryngeal sites to the point of friable mucosa may be present. If there has been recent intubation or airway instrumentation in the context of GERD, granulomas (bilateral tongues of granulation tissue) may be present at the point of injury, most commonly at the vocal processes.

The current gold standard for the diagnosis of GERD is 24-hour pH probe monitoring, although its precision in making the diagnosis is probably not deserving of this description. A distal pH probe is placed 5 cm above the LES, and the proximal pH probe is usually placed 20 cm above the LES, just below the upper esophageal sphincter. A third

pH probe is placed in the pharynx to simultaneously record changes associated with acid escape into the pharynx. As an ambulatory procedure, it allows the patient to resume normal meals and activities. It allows for correlation of reflux events with reflux symptoms as well as measuring the total time that the pH of the esophagus is below 4.0. If this number is above 5% of the total time, it is considered positive. In infants, this number is increased to 9.7% due to expected physiologic reflux.[7] Esophageal impedance is one of the most commonly used tests to diagnose GERD in children today.[8] The test consists of a catheter with multiple electrodes that monitor distension of the esophagus during the passage of food as well as during reflux episodes. The probe also contains a pH probe so acidic and nonacidic events may be differentiated.

### *Treatment*

Whether one is treating GERD or LPR, lifestyle and behavior modifications are hallmarks for treatment of adults, adolescents, and older children. These include avoidance of provocative foods and modifications to eating habits such as eliminating meals just prior to bedtime. In infants, the introduction of thickened liquids like rice cereal and elevation of the crib or bed may be sufficient to treat most GERD. Evaluation of allergy to cow's milk in infants must be ruled out as well prior to moving on to other GERD therapies.

There are several medication choices for the management of reflux, the two most common being histamine-2 receptor antagonists and proton pump inhibitors (PPIs).

Histamine-2 receptor antagonists are the most commonly used acid-suppressive agents in children.[8] These medications are effective in reducing the gastric pH, relieving symptoms of GERD, and resolving esophagitis. Prolonged use, however, may cause tachyphylaxis or tolerance leading to ineffective treatment.[9] In addition, this class of medication is usually weight based and requires frequent dose adjustment as the child grows. Treatment with H-2 blockers fails in at least one third of patients with LPR.[10]

One of the most widely used medications for the treatment of GERD in adults and children are PPIs. PPIs are the most effective antireflux medicine available. Failure typically results from poor compliance, poor timing of medication dosing, or inadequate dose used. Duration of treatment should be approximately 6 months with symptoms of GERD and LPR resolving often in the first few months. Although the side effect profile of PPIs is excellent, otolaryngologists should be cautioned that chronic treatment could be associated with adverse effects such as an increased incidence of *Clostridium difficile* infections. Consultation with a gastroenterologist is recommended in children requiring chronic PPI therapy.[11]

Surgical intervention for GERD in children is indicated for those who do not respond to the above therapies, as well as for those children who manifest failure to thrive, experience acute life-threatening events (ALTEs), have associated severe pulmonary disease secondary to GERD, are neurologically impaired, or have significant complications from GERD such as Barrett's esophagitis.[8] The more common surgical interventions include Nissen fundoplication and percutaneous feeding tube placement.

## Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease that usually affects women in their second and third decades of life. However, 20% of SLE cases are diagnosed in the first two decades of life.[12] Pediatric SLE, which tends to be more severe, usually presents in the postpubescent female at the average age of 12 years. The incidence of SLE before the age of 19 years is between 6.0 and 18.9 cases per 100,000 in Caucasian females, but it is higher in African American (20–30/100,000) and Puerto Rican girls (16.0–36.7/100,000). A similar high incidence of SLE is reported in Hispanic, Native American, Pacific Islander, and Asian women.[12]

The SLE follows a relapsing and remitting course and is characterized by an autoantibody response to nuclear and cytoplasmic antigens. SLE can affect any organ system but mainly involves the skin, joints, kidneys, blood cells, and nervous system. Classically, the triad of fever, joint pain, and rash in a woman of childbearing age suggests the diagnosis. SLE may produce laryngeal inflammation in as many as one third of patients. The most common manifestations of SLE are arthritis, malar rash, and photosensitivity.[13] The symptoms of laryngeal involvement range from dysphonia to airway obstruction arising from edema, ulceration, and vocal fold paralysis. As with most other autoimmune diseases, treatment centers on systemic corticosteroid therapy.

## Granulomatous Diseases

Granulomatous diseases of the larynx and trachea had all but disappeared during the 20th century, and only recently, with the advent of organ transplantation, chemotherapy, and acquired immunodeficiency syndrome, have they

re-emerged, mainly in immunocompromised individuals. A granuloma is an imprecise term for any small, nodular, poorly demarcated aggregation of mononuclear inflammatory cells. Such a collection of modified macrophages may resemble epithelial cells and are usually surrounded by a rim of lymphocytes. Granulomas can be caseating with central necrosis or noncaseating. Granulomas arising in the larynx and trachea typically manifest as hoarseness, stridor, and airway obstruction. These granulomatous lesions have a wide breath of presentation on physical examination, ranging from smooth, diffuse swellings to distinct, well-defined nodules. There are numerous etiologies that exist for granulomatous diseases of the larynx and trachea, including bacterial, mycotic, and idiopathic. We review a couple of the most common idiopathic causes below. Infectious causes will be reviewed in separate chapters in this text.

## Wegener's Granulomatosis

Wegener's granulomatosis is characterized by necrotizing granulomatous inflammation and necrotizing vasculitis affecting small-to medium-sized vessels, with larger vessels rarely affected.[14] The disease has a predilection for the upper respiratory tract, lungs, and kidneys, but any organ can be involved. Although usually a systemic disease, rare isolated airway cases do occur, and airway involvement is reported in 15–55% of all cases.[15-17] A recent retrospective chart review of children with Wegener's found that 25% demonstrate airway lesions including vocal fold granuloma, subglottic stenosis, and multilevel stenosis.[18] The etiology of Wegener's granulomatosis remains unknown; the presence of antineutrophil cytoplasmic antibodies (ANCA) in most patients, and its response to immunosuppressive therapy, suggest an autoimmune pathophysiology.[19]

Tracheobronchial Wegener's granulomatosis occurs in <10% of cases.[17] Symptoms include hoarseness, cough, hemoptysis, dyspnea, stridor, and wheezing. Subglottic stenosis is the most common cause of stridor. Subglottic involvement is suspected when pulmonary function testing shows a fixed obstruction and can be confirmed by computerized tomography (CT) and direct laryngoscopy/tracheobronchoscopy. Clinical history and examination may reveal findings of other airway, lung, and kidney manifestations that further support the diagnosis. Laboratory testing for ANCA is confirmatory, keeping in mind that in cases of isolated airway disease, ANCA can be negative 20% of the time.[20] The management of Wegener's granulomatosis is complex and requires a multidisciplinary approach, including otolaryngology, pulmonology, and rheumatology. Medical management includes corticosteroids for systemic disease as well as immunomodulating medications like cyclophosphamide, methotrexate, and rituximab. Endoscopic techniques including balloon airway dilation and laser debulking, as well as the adjuvant use of intralesional steroids and mitomycin C, can help maintain airway patency. Open airway surgery (resection and reanastomosis) for isolated short-segment stenosis is a possibility if endoscopic treatment fails. Tracheostomy may be necessary in some cases.

## Sarcoidosis

Sarcoidosis is a multisystem inflammatory disease of unknown etiology that is manifested by noncaseating granulomas in the affected organ. It is a ubiquitous disease with an incidence that varies according to age, sex, race, and geographic origin.[21] Pulmonary and skin lesions are the most common manifestations of sarcoidosis. Incidence in the head and neck is estimated at 9%.[22] Laryngeal involvement in sarcoidosis occurs in 0.5–5% of cases; isolated laryngeal sarcoid is even more rare.[22,23] Laryngeal sarcoid is extremely rare in children with only three cases reported in the literature.[24-26]

Laryngeal sarcoid typically involves the supraglottis (80–85%) with symptoms that include hoarseness, dysphonia, dyspnea, stridor, dysphagia, globus sensation, and cough. Subglottic involvement also occurs in 20% of cases, whereas glottic involvement is very rare.[27] Direct laryngoscopy reveals a "turban-like" epiglottis, appearing pink with significant edema to the point of obscuring the true vocal folds (Fig. 43.1). Supportive but not pathognomonic findings on laboratory testing include elevated serum angiotensin-converting enzyme, elevated erythrocyte sedimentation rate, and evidence of abnormal calcium metabolism. The diagnosis is made on the basis of the combination of clinical and radiological presentation, evidence of noncaseating granulomas on biopsy, and exclusion of other granulomatous diseases.

The treatment of isolated laryngeal sarcoidosis revolves around maintaining airway patency. Tracheotomy is necessary in the setting of complete airway compromise, and laser resection and balloon dilation are useful endoscopic adjuncts. Oral or parenteral steroids have been used with success in the past for patients with symptomatic laryngeal sarcoidosis. Intralesional steroid injections may help treat localized disease and prevent progression to complete airway obstruction.

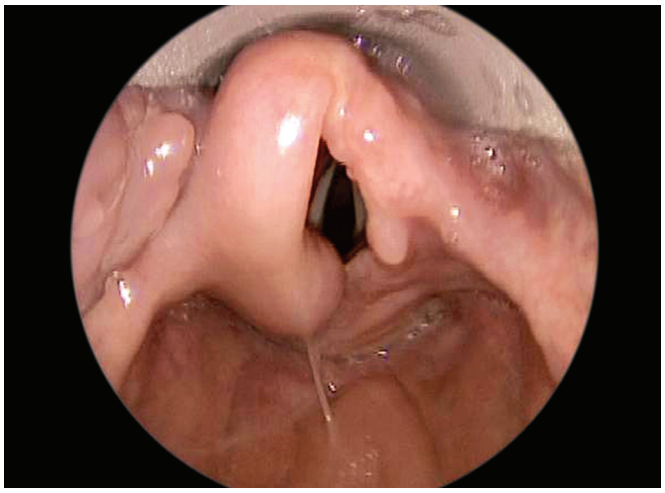

**Fig. 43.1:** Direct laryngoscopy evaluation of "turban-like" epiglottis seen in laryngeal sarcoidosis.

## Systemic Sclerosis (Scleroderma)

Scleroderma or systemic sclerosis, an uncommon disease of uncertain etiology that manifests with thickened, indurated skin with accompanying tissue fibrosis, and inflammation. However, it can occur in a localized form. It is a multisystem disease with relentless progression and can involve the visceral organs, vasculature, and immune system. The American College of Rheumatology's classification of scleroderma requires one major or two minor criteria to make the diagnosis.[28] Major criteria include systemic tightening and induration of the skin and fingers proximal to the metacarpophalangeal joints. These skin changes may not only extremities, but also the head, neck, and trunk. Minor criteria can be sclerodactyly, digital pits or scars, and bibasilar pulmonary fibrosis. Age of onset for this disease is usually in the middle ages, with women more affected than men. The prevalence is reported to be about 240 per million. This disease is exceedingly rare in children with most cases being the localized type. The juvenile-onset systemic sclerosis can overlap as a myositis and the disease tends to be self-limited.[29]

Head and neck manifestations include facial tightness, loss of facial rhytides, inability to open their mouth, sicca syndrome (often leading to poor dentition), hoarseness, and GERD caused by LES incompetence. Involvement in the cricoarytenoid joint has been described as well.[30] Similar to rheumatoid arthritis (RA) of cricoarytenoid joint, these patients have symptoms of pain with phonation, globus sensation, hoarseness, dysphagia, otalgia, and dyspnea. They can present with stridor and potentially respiratory distress. Laryngoscopy examination reveals restricted vocal fold mobility and edematous arytenoid cartilages. If left untreated, the disease process could progress to ankylosis of the joint.

Treatment is symptomatic, and rheumatologists have utilized use of immunosuppressive medications in management of these patients. Since most patients suffer from GERD secondary to the esophageal manifestations, treatment with proton-pump inhibitors is essential and may help cut down on the effects on the larynx. Calcium channel blockers can help with symptoms of the disease like Raynaud's phenomenon but may exacerbate GERD. Airway symptoms secondary to ankylosis may necessitate endoscopic management and potentially tracheotomy depending on severity.

## Relapsing Polychondritis

Relapsing polychondritis (RP) is a severe, episodic, and progressive inflammatory condition involving cartilaginous structures. The ears, nose, and laryngotracheobronchial tree are most commonly involved in the head and neck. Although the etiology is unknown, it is believed to be an autoimmune disease targeted against type II collagen. There is no gender predilection. RP is more common in Caucasians with onset usually in the fifth decade of life, although it can occur at any age. RP in childhood can be a life-threatening condition.[31] The disease can start as acute dyspnea, stridor, and polyarthritis. The diagnosis is made easier when auricular or septal chondritis occurs simultaneously. The frequency of chondritis and systemic manifestations of RP in children is similar to those observed in adults.

There is a known association of RP with other autoimmune disease including RA, Sjogren's syndrome and SLE. Bilateral auricular involvement is the most common otolaryngologic manifestation. Laryngeal disease can occur in about half of cases. When the larynx is involved in RP, inflammation, fibrosis, and destruction of laryngeal cartilage are all possible. In addition to nonspecific constitutional symptoms of fever, malaise and fatigue, symptoms of large airway disease include hoarseness, aphonia, wheezing, inspiratory stridor, cough, pain, and dyspnea.

No laboratory findings are specific for RP. Diagnosis is made clinically with several critical criteria required including biopsy. On laryngoscopy, glottic and subglottic edema and erythema are noted. Treatment varies depending on the severity of disease including the use of nonsteroidal anti-inflammatory drugs (NSAIDs), methotrexate, and systemic steroids. Tracheostomy is reserved for severe or recurrent airway obstruction.

## Amyloidosis

Amyloidosis is a clinical disorder caused by the extracellular and/or intracellular deposition of insoluble abnormal amyloid fibrils that alter the normal function of tissues. It can be systemic or localized. Laryngeal amyloidosis is associated with localized disease primarily affecting individuals (males greater than females by 3:1) between the ages of 40 and 60 years, with a peak incidence in the fifth decade.[32] It rarely presents during childhood, with only a few documented cases.[33] Laryngeal amyloidosis is usually a localized phenomenon that is rarely associated with systemic involvement.[32] Hoarseness is the most common presenting symptom. Clinical findings at laryngoscopy are variable and nonspecific, including diffuse mucosal thickening, submucosal nodules, and less commonly, polyps. The diagnosis is revealed by pathologic examination of tissue samples. Traditionally, treatment has included partial or total surgical excision to maintain a functional laryngeal airway and optimize voice. Life-long follow-up is important with this condition because of its chronic and recurrent nature.

## Stevens–Johnson Syndrome

Stevens–Johnson syndrome (SJS) is an immune complex-mediated hypersensitivity reaction that typically involves the skin and the mucous membranes. Also known as erythema multiforme major, SJS is debilitating and potentially life threatening. SJS is usually triggered by medications, such as sulfonamides, carbamazepine, and phenobarbital. Clinically, patients with SJS present soon after ingestion of the offending drug with symptoms of fever, malaise, conjunctivitis, rash, and severe oropharyngeal mucositis. Mucocutaneous lesions affect the mouth, eyes, skin, genitalia, and occasionally the esophagus. There is a variant of the disease that may involve the larynx. The skin lesions progress to bullae, desquamation, and necrosis, causing secondary skin infections and loss of electrolytes. Diagnosis is made by history, clinical examination, and tissue biopsy. Treatment is mainly supportive, although securement of the airway via endotracheal intubation or tracheostomy may prove necessary in some cases.

## Rheumatoid Arthritis

Rheumatoid arthritis is a chronic systemic inflammatory disease of unknown etiology. It is the most common autoimmune disease, affecting up to 3% of the adult population, with a reported prevalence of 15 to 35 per 100,000 in the pediatric population.[34] Although the hallmark feature is persistent, symmetric polyarthritis that affects the hands and feet, any joint lined by a synovial membrane may be involved, including the larynx in about 25% of cases.

Cricoarytenoid arthritis may present with hoarseness or airway obstruction via posterior laryngeal inflammation, tenderness, and decreased arytenoid mobility. As the disease progresses, it may cause ankylosis and nodules. These rheumatoid nodules may occur anywhere in the larynx or within the vocal folds themselves. Other symptoms are variable but may include globus sensation, stridor, and dysphagia. Cricoarytenoid arthritis should be considered in children with juvenile RA presenting with symptoms of upper airway obstruction. Laryngeal manifestations of RA may be the sole manifestation of active disease.[35] Systemic treatment includes corticosteroids, NSAIDs, or other immunosuppressive agents. Because of their smaller airway dimensions, children with acute onset cricoarytenoid arthritis may require intubation pending the beneficial effect or not of systemic steroid therapy. Surgical rehabilitation of arytenoid function is rarely possible; arytenoidectomy is the treatment of choice for symptomatic ankylosis of the cricoarytenoid joint. Surgical excision is performed for symptomatic rheumatoid nodules as well.

## Epidermolysis Bullosa and Cicatricial Pemphigoid

Epidermolysis bullosa (EB) encompasses a group of inherited disorders characterized by excessive susceptibility of the skin and mucosa to separate from underlying tissues after mechanical trauma. There are three broad categories of EB depending on the anatomic level of separation: EB simplex, junctional EB (JEB), and dystrophic EB.[36] Within each broad category are several subtypes with varying severity. The laryngotracheal manifestations of EB include laryngeal stenosis and stricture; these are most commonly seen within the JEB category (up to 40% by age 6 in one subtype of JEB).[37] Laryngeal compromise can occur as early as the first 12 months of life, requiring the need for careful monitoring for early clinical signs of airway obstruction, even during early infancy. The cumulative risk of laryngeal stenosis or stricture plateaus for both major JEB subtypes by mid-childhood. As a result, the need for continued close surveillance lessens after approximately ages 6 to 9 years. Symptoms include dysphonia (weak or hoarse cry),

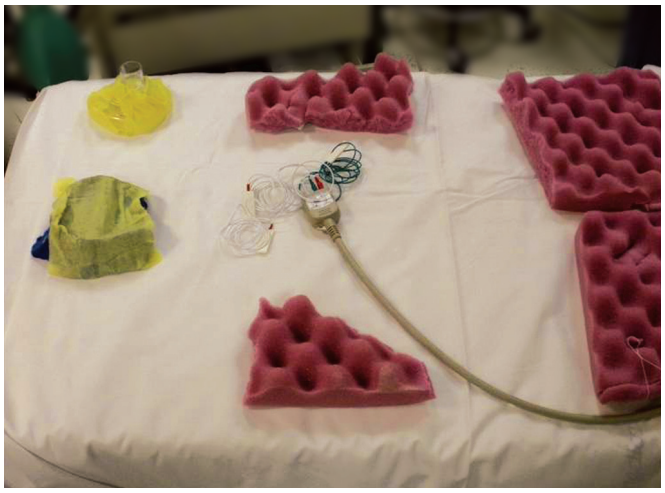

**Fig. 43.2:** Anesthesia considerations and operating room patient positioning in children with epidermolysis bullosa.

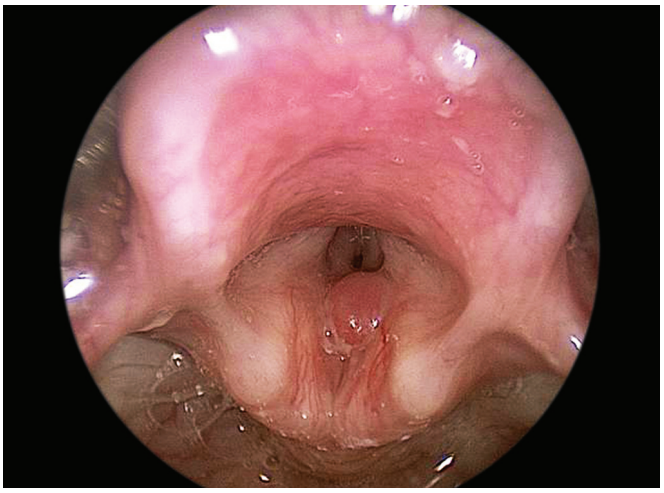

**Fig. 43.3:** Obstructive granuloma present on larynx of child with epidermolysis bullosa.

stridor, and potential significant airway obstruction. Laryngeal involvement is assessed by direct laryngoscopy. The diagnosis of EB is made by skin or mucosal biopsy.

Both the otolaryngologist and the anesthesia team need to take many things into consideration when taking a patient with EB to the operating room (Fig. 43.2). Simple concepts like masking a patient and placement of electrocardiogram (ECG) leads become more complex due to the risk of producing shearing forces leading to bullae formation. Therefore, steps are taken to use excessive amounts of lubricant around and on the contact surfaces of the mask, including the use of petroleum-impregnated gauze. ECG leads are needle electrodes instead of adhesive pads. All pressure points are padded with egg crate padding.

The mainstays of treatment for laryngeal EB include excision of scar and granulation tissue (Fig. 43.3) and concurrent intralesional and systemic steroids. Tracheostomy is reserved for life-threatening airway obstruction, as this procedure brings additional morbidity secondary to the shearing trauma it causes to the mucosa of the trachea and skin of the neck.

### Cicatricial Pemphigoid

Cicatricial pemphigoid (CP) refers to a group of rare chronic autoimmune blistering diseases that predominately affect the mucous membranes and occasionally the skin. Cicatricial scar formation can occur at any site of involvement, including the upper airway, larynx, and esophagus. Unlike EB, CP is rare in children and adolescents, characteristically affecting women over the age of 50 years. Laryngeal involvement occurs about 9% of the time with the symptom of odynophagia being most common.[38] Diagnosis is made by biopsy. Treatment consists of systemic steroid therapy and possible immunosuppressive therapy.

### Laryngeal Tumors

#### *Subglottic Hemangioma*

Subglottic hemangiomas are a manifestation of infantile hemangioma, also called infantile capillary hemangioma or hemangiomata. They seldom appear in the airway and comprise only 1.5% of all congenital anomalies of the larynx.[39] These lesions, when large, can result in airway obstruction. There is a female predominance of 1.4:1 to 2.4:1.[40,41] Risk factors for the development of infantile hemangioma include fair skin, white non-Hispanic ethnicity, prematurity, and low birth weight.[41,42] Other possible risk factors include advanced maternal age, multiple gestation, and pre-eclampsia, although all three are potential confounders with prematurity.[41] Chorionic villus sampling has been implicated in infantile hemangiomas as well.[43] There may be a genetic link for a small proportion of these lesions, although this has not been fully elucidated.[41]

In general, infantile hemangioma is the most common tumor of infancy, occurring in 4–12% of infants.[42,44-46] They are true neoplasms in that they have increased mitotic activity and endothelial cell proliferation.[45] They possess characteristic histochemical endothelial vascular markers

that differentiate these lesions from other vascular birthmarks. These markers, which include GLUT-1, merosin, Lewis Y antigen, and FcyRII, are all also present on placental blood vessels.[46] Current theories on pathogenesis expand on these links. One hypothesis is that the lesions are a result of "embolized" placental cells. It is further suggested that a single endothelial progenitor line of cells is stimulated by hypoxia to proliferate in an attempt to normalize relative hypoxemia in tissues. This theory is appealing in that it is supported by much of what we know about the growth phases, location preference, and risk factors for the development of infantile hemangioma.[46]

Infantile hemangiomas demonstrate a characteristic growth pattern. Typically, they are absent or imperceptible at birth and then undergo a rapid growth phase, called proliferation, in which the appearance changes from a pale or mildly pigmented lesion into a larger, often bright red lesion over the course of the first 5 months of life. A prospective study found that 80% of the eventual hemangioma size is reached at a mean age of 3 months though deep hemangioma seemed to follow a growth trend that begins later and continues longer than superficial hemangioma.[46-48] Following the proliferation phase is a second phase, termed the plateau stage, which lasts several months and is characterized by very slow growth. However, recent literature[47] suggests this phase is not one of no or slowed growth but rather a dynamic balance between the proliferation and involution phases. During this phase, the proliferative factors that drove the growth of the neoplasm begin to be outpaced by the factors that drive apoptosis. After usually 1 year of age, the apoptotic factors drive the involution phase, which takes place over the next several years.[47]

Hemangioma may be located throughout the body though 60% occur in the head and neck.[49] Extremities, visceral organs especially the liver and less likely the lungs and intestine, the trunk, and genitals are all other sites though notably the deep skeletal muscle seems to be spared.[49] Cutaneous lesions are classified as focal or segmental, superficial or deep, and single or diffuse.[48] Focal lesions typically occur at embryologic fusion lines between the growth centers of mesenchyme[49,50] and tend to be less aggressive lesions. Segmental lesions, on the other hand, follow dermatomal patterns or developmental segments and have been associated with higher incidence of complications including ulceration and morbidity from other associated sequelae.[47,50]

When present in the airway, particularly in the subglottis owing to it being the narrowest point in the airway in a child, the hemangioma typically becomes symptomatic when it enters the proliferative phase leading to airway obstruction. This complication is seen in 1.4–1.8% of all patients with a diagnosed infantile hemangioma.[51]

*Diagnosis*: The clinical history and a thorough head and neck physical examination, including an in-office flexible fiberoptic nasal laryngoscopy, should be performed in all such patients presenting with airway obstruction. Definitive diagnosis of a subglottic or airway hemangioma is made in the operating room with direct laryngoscopy and bronchoscopy visualizing the lesion and documenting its position, size, and character. Lesions are classically noted to have a bluish hue and are most commonly found on the left.[52] Biopsy is not required for diagnosis, which is usually made on history and endoscopic examination findings. Biopsy has been considered controversial for the theoretical bleeding risk.[53] Shikhani et al. reviewed approximately 10 cases of which one third were biopsied with no bleeding complication.[54] Magnetic resonance imaging (MRI) is preferred over other imaging modalities, if needed to guide therapy; however, its longer acquisition time requires sedation and likely intubation for these infants, and this can potentially increase both the relative complexity of the procedure as well as potential to make a tenuous airway critical secondary to trauma from the endotracheal tube.[50,53] Some authors recommend CT with contrast to better define bony remodeling, critical structure, and presence of invasion. CT has a relatively rapid acquisition time that may allow for evaluation of the unsedated, spontaneously breathing infant.[55] Ultrasound with Doppler imaging has been shown to be useful for superficial lesions to determine extent and vascularity; however, its use in the evaluation of airway hemangioma has been limited. Rossler et al. looked at a small series of infants presenting with stridor using ultrasound to evaluate the lesions then compared those results with later endoscopic findings. They found good correlation in lateral versus midline lesions, although they acknowledge a practical difficulty in performing an airway ultrasound on an infant with symptoms of respiratory distress.[56] Plain films have not been shown to provide value.[53]

Patients with cutaneous hemangioma in the "beard" or trigeminal nerve (V3) distribution are at increased risk of having airway hemangioma and should be carefully evaluated for possible airway complications. Lesions in

this area, which include the chin, anterior neck, lower lip, and preauricular/parotid region were found in approximately 8.5% of patients with head and neck hemangioma in a series reported by Orlow et al. Of these, 63% had some airway involvement and 40% required tracheostomy for airway management.[57] More recently, in a series of 1226 patients by O et al., 29% of those with segmental hemangioma in the V3 distribution were found to have airway involvement.[50] Hemangioma, particularly segmental, in this area should raise suspicion of and evaluation for a potential airway lesion.

*PHACE Syndrome*: One associated syndrome that deserves specific discussion is PHACE [posterior fossa malformations (P), hemangioma (H), arterial anomalies (A), coarctation of the aorta and cardiac defects (C), and eye abnormalities (E)]. This syndrome was first described by Frieden et al. in 1996 in a series of 41 patients.[58] PHACE is important in the discussion of subglottic hemangioma because 52% of patients with PHACE syndrome have airway involvement.[44] While the definition of PHACE continues to evolve, a recent consensus statement released in 2009[59] outlines the current criteria for PHACE and possible PHACE syndrome. Diagnosis of PHACE requires a facial hemangioma > 5 cm plus either one major criteria or two minor criteria. These criteria include anomalies of all the major systems impacted by the syndrome; cerebrovascular, such as anomalies of the major cerebral arteries, abnormalities in brain structure especially the posterior fossa, cardiovascular anomalies, including aortic arch abnormalities, posterior segment ocular abnormalities, and midline defects, such as sternal clefts.[59] Evaluation of patients with suspected PHACE should include additional cardiac, ophthalmologic, and neurologic evaluation.[48] Specific recommendations are for structural brain imaging via MRI with and without gadolinium as well as intracranial and cervical angiography with contrasts enhanced magnetic resonance angiography (MRA) as the preferred method.[59]

*Treatment*: Prior to 2008, the options for treatment of subglottic hemangioma included $CO_2$ laser, tracheotomy, interlesional injection, open surgical excision, and Nd:YAG laser.[40] Then in 2008 there was a serendipitous discovery of propranolol's ability to cause regression of hemangioma in children being treated for severe disfiguring infantile capillary hemangioma.[60] These patients were placed on propranolol due to the concern for right heart failure secondary to shunting of blood into these large hemangiomas. This paradigm shift in treatment ushered in a revolution in the ability to medically manage many cases previously only amenable to surgical management.

Although not currently Food and Drug Administration approved for this indication, it has become first-line therapy for most infantile hemangioma treatment. In 2011, a consensus conference was convened to establish best practices for initiation and use of propranolol for the treatment of hemangioma.[61] Their results were published in January 2013 and include both recommendations for monitoring as well as target dosing strategies based on risk assessment of the specific patient. Relative contraindications to propranolol therapy include sinus bradycardia, greater than first-degree heart block, bronchial asthma, heart failure, cardiogenic shock, and hypersensitivity to propranolol hydrochloride.

Current consensus guidelines recommend a pretreatment ECG and history for relative contraindications.[61] Target dose is 1 to 3 mg/kg/day divided three times a day. Children with comorbidities and those < 8 weeks corrected gestational age are not recommended for outpatient initiation of propranolol. When outpatient initiation is appropriate, patients should be monitored with heart rate and blood pressure at baseline then again at 1 and 2 hours on initial therapy. Parents should be counseled on the need for regular feeds and to discontinue propranolol dosing when the child has restricted oral intake such as with feeds to prevent hypoglycemia.[61]

Special consideration is given to patients with PHACE syndrome when considering propranolol as a treatment as they are at a theoretical higher risk for possible stroke by the lowering of blood pressure as a result of the therapy. While PHACE has a wide variety of arterial anomalies, those thought to be of highest risk are those patients with severe long segment narrowing or nonvisualization of major cerebral or cervical arteries especially when the patients have coarctation of the aorta or other cardiac anomalies.[61] Current recommendations for such patients include a full MRI/MRA evaluation of the head and neck and cardiac imaging with particularly attention to the aortic arch prior to consideration of propranolol therapy. Neurology consultation and follow-up for a careful risk-benefit assessment for the use of propranolol is recommended for those patients whose stroke risk is elevated. If deemed appropriate, then recommendation is for the lowest possible dose with a close titration upward, inpatient initiation, and three times a day dosing to minimize blood pressure changes.[61]

In the literature, there are reports of both late-responders and nonresponders to propranolol treatment. In addition, there are those who are unable to safely tolerate the medication. For these children, the more traditional therapies remain viable options. These include the following systemic steroids—usually oral prednisolone, intralesional steroids like triamcinolone and betamethasone, surgical excision, vincristine, and interferon.[48,62] Oral steroids, once one of the mainstays of treatment, remain a viable option; however, their variable efficacy and significant side effect profile warrant careful consideration. Interferon has been shown effective however with a poor side effect profile including spastic diplegia that does not resolve with treatment cessation. As such, it is only used in a life-threatening situation when it is the only alternative. Vincristine is considered safer than interferon and is generally used for patients with large hemangioma who have developed Kasabach–Merritt syndrome or are nonresponsive to other therapies.[48]

Surgical management may be used in conjunction with any of the medical therapies listed above or as an adjunct to medical therapy if the patient demonstrates only a partial response. Surgical management includes both endoscopic and open procedures, including endoscopic laser, transcervical open excision, and tracheostomy.[62] Tracheostomy was historically used during the proliferative phase of growth and remains an option for acute management of patients with poor or delayed response to medical therapy. Laser excision, particularly with $CO_2$ laser has long been described for airway hemangioma particularly for the ability to obtain microhemastasis. Serial laser sessions are usually performed during the lesion's proliferative phase; however, care must be taken to avoid aggressive laser therapy. In up to 20% of patients undergoing endoscopic laser therapy, subglottic stenosis is the primary complication.[63] Open excision may be performed as a single-stage procedure or as a double-stage procedure in a child with a pre-existing tracheostomy. The open technique uses a midline neck excision at the level of the cricoid cartilage. The laryngotracheal framework is exposed, and a temporary interoperative tracheotomy is placed. The surgeon enters the airway through a vertical incision in the cricoid cartilage. The hemangioma is then excised after a submucosal flap is raised over the hemangioma. For hemangioma that extends into the vocal fold, some tumor is purposely left behind to avoid damage to the vocal cord. Patients then undergo nasotracheal intubation and are left intubated for 3 days to allow healing prior to extubation. In 2002, a paper reporting a series of eight patients with airway hemangioma undergoing open excision found that five of the eight patients needed a cartilage graft as well due to subglottic stenosis identified at the time of the procedure.[64]

### *Neurogenic Tumors*

Tumors of peripheral nerves are seen throughout the body. Rarely, these neurogenic tumors can arise in the larynx and present as a submucosal mass. Neurogenic tumors include neurofibroma, schwannoma, malignant peripheral nerve sheath tumors,[65] and granular cell tumors.[66]

Neurofibromas of the larynx, while very rare, are most commonly associated with neurofibromatosis type 1 though they may occur in isolation. Laryngeal neurofibroma are only very rarely associated with neurofibromatosis type 2. The most common sites of involvement in the larynx include the aryepiglottic folds and the arytenoids.[65,67] This is thought to be a result of the point of origination occurring at the superior laryngeal nerve or the anastomosis between the superior and recurrent laryngeal nerve, also known as the Galen's anastomosis.[68] The tumor arises from the perineural fibrocytes.[69] On histologic analysis, they may be classified as plexiform, diffuse, or both. Plexiform growth pattern is diagnostic of NF1 and is described as a poorly localized pattern along existing nerves. This is contrasted with the diffuse pattern in which the growth occurs slowly as a nodule and symptoms vary in severity based on location and size.[65] Neurofibromas, in contrast with schwannoma, are not encapsulated.[68] Primary symptoms of neurofibroma in children include stridor, dyspnea, and voice changes.[67,68] However, in children under 1 year of age, stridor seems to be the presenting symptom as demonstrated in a series of five patients in the first year of life with neurofibroma of the larynx.[65] Malignant transformation may occur in 10% of neurofibromas, resulting in the malignant peripheral nerve sheath tumors.[70] Treatment consists of complete excision, including possible partial laryngectomy if needed, with close follow-up for possible recurrence as well as care for the other associated NF1 symptoms.[70-72] Preoperative angiography and embolization has been shown to decrease intraoperative blood loss.[72]

Similar to neurofibroma, schwannomas are rare accounting for only 0.1% of all laryngeal neoplasms in all ages. They are most commonly found in women in the fourth to fifth decade of life, but case reports of occurrence

in children also exist in the literature.[70] In contrast to the neurofibromas above, they are only rarely associated with neurofibromatosis, are encapsulated, and grow away from the trunk of the nerve from which it originates.[70] They originate from the Schwann cells, and on pathologic evaluation show the two classically described cellular regions: the Antoni A region of hypercellular palisading nuclei and the Antoni B region of loosely arranged cells in a myxoid matrix.[69] Complete excision with separation from the original nerve is theoretically possible in Schwannoma. Excision is the treatment of choice while incomplete resection can result in rapid regrowth. Malignant degeneration is much less common than in neurofibromas.[69]

Granular cell tumors are similarly rare and their origination from Schwann cells was initially much debated in the literature, although now seems to be widely accepted.[66,73] These tumors seem to be more common in females and predominance in African Americans has been described.[66] Although rare, granular cell tumors do occur most commonly in the head and neck region (>50% of the cases)[73] with approximately 10% of those in the larynx.[74] Approximately, half are located on the true vocal cords.[74] Case reports in the pediatric literature number a couple of dozen.[74] Histologic examination is required to establish the diagnosis with S-100 and vimentin positive staining and polyhedric cells with granular cytoplasm.[66,74] Excision of the lesion is the treatment of choice, but the literature reports a recurrent rate of 8–12% in these patients.[74] Close follow-up is advocated; however, the literature is not clear on the utility of repeated endoscopic examinations in the asymptomatic child.[66] In 2006, Pernas et al. reported on the role of laryngeal tracheal reconstruction (LTR) to allow for wide local excision in one patient with a historical review of the literature. Their patient had undergone two previous endoscopic excisions and returned with symptoms. She underwent a wide local excision via laryngofissure and single-stage LTR. They concluded that LTR was an option for patients with large lesions or those who recur after endoscopic removal.[74]

## *Malignant Laryngeal Neoplasms*

Malignant laryngeal neoplasms are fortunately a very rare entity in the pediatric population, with small numbers of cases reported in the literature. Primary rhabdomyosarcoma, squamous cell carcinoma, primitive neuroectodermal tumors, and mucoepidermoid carcinoma have all been described in small series and case reports.[75-78]

Rhabdomyosarcoma is most commonly of the embryonal type, which develops from the embryonal mesenchyme from which striated muscle arises. As such, it can present anywhere in the body where striated muscle is located. This malignancy accounts for approximately 5% of all malignant tumors in children up to 15 years old. Although approximately 50% of these tumors are located in the head and neck region, they are found in the larynx only about 1% of the time.[78] A case series described five pediatric patients treated with chemotherapy. Adjuvant radiotherapy was used in four of those patients with a follow-up period from 13 to 17 years with disease free survival reported for all patients.[78] Radiation in the prepubescent larynx carries both the risk of secondary irradiation-induced tumor development as well as fibrosis and stunted laryngeal development. Treatment with total laryngectomy has been described.[77,79] Ohlms et al. described one pediatric patient treated with laryngectomy in 1994 with survival at 18 years of follow-up.[77]

Squamous cell carcinoma of the larynx is reported in <1% of all childhood tumors.[80] A review of the literature in 2001 reported 58 known cases.[81] A more recent review in 2010 highlighted at (15:19) translocation in two poorly differentiated squamous cell carcinomas of the airway with a rapidly progressive course.[76] In addition, it has been associated in the past with malignant transformation of recurrent respiratory papillomatosis, especially when radiation had been used for treatment of the lesions.[80] Treatment includes both primary chemoradiation and surgical excision with adjuvant chemoradiation with no clear evidence to recommend either therapy though the psychosocial benefits of laryngeal preservation where possible are highlighted.[77,81]

Primary salivary gland malignancies occur in the pediatric population rarely; however, they account for 10% of all head and neck tumors in children. Of the malignant salivary gland tumors, mucoepidermoid carcinoma comprises approximately one third of all salivary gland tumors. Minor salivary glands exist throughout the upper airway and 0.1% to 1% of all laryngeal tumors are the result of malignant salivary gland tumors in the larynx.[75] Only a very small number of these cases occur in the pediatric population. On physical examination, salivary gland malignancy tends to spread in submucosal fashion without significant mucosal changes; therefore, symptoms may not present until significant tumor growth has occurred. Surgery followed by postoperative radiation therapy with long-term follow-up is recommended. Recurrence > 10 years after primary treatment has been reported.[75]

## Tracheal Tumors

Primary tracheal tumors are infrequent in the pediatric population. In one review of 198 primary tracheal tumors over a 26-year period, only four were in patients under 10 years of age and eight occurred between the ages of 10 and 18.[82] These included granular cell tumor, fibrous histiocytoma, neurofibroma, mucoepidermoid tumor, carcinoid (most common), adenoid cystic carcinoma, and rhabdomyosarcoma. Other tracheal tumors noted in childhood were fibrosarcoma, hemangiopericytoma, and chondroma. This seems to concur with a more recent single institution review of endotracheal and endobronchial tumors in 2011 finding 14 cases between 4 and 18 years old, the most common being carcinoid or mucoepidermoid carcinomas.[83] A 30-year review of the literature for pediatric tracheal neoplasms found only 36 cases reported between 1965 and 1995.[84] In this paper, the authors report 23 of the 36 as benign; the most common was hemangioma (5/23). Of the 13 (36%) malignant tumors, only 1 was carcinoid, instead the most common malignant tumor was malignant fibrous histiocytoma (4/13). In adults, the overwhelming majority of the primary tracheal tumors are squamous cell carcinoma and adenoid cystic carcinoma.[82]

Presentation of a tracheal tumor is based on clinical suspicion in an infant or child presenting with respiratory distress. Tracheal lesions most often present with wheezing or expiratory stridor. Stridor resulting from fixed intrinsic lesions of the airway does not change with position. Unlike a foreign body aspiration that presents with acute onset, tracheal neoplasms likely will present insidiously, perhaps initially being mistaken for reactive airway disease or an upper respiratory illness that does not resolve in due time. Cyanosis, apnea or apparent life-threatening events (ALTE) may initiate the diagnostic work-up after hospitalization. In rare circumstances, difficulty with intubation during unrelated surgery can prompt diagnosis.

Diagnostic evaluation should include a thorough and methodical physical examination. Flexible fiberoptic laryngoscopy will help rule out supraglottic and glottic masses but is limited in assessment of tracheal neoplasms. Radiography including modified barium esophagoscopy, airway fluoroscopy, and, more definitively, CT of the chest can delineate intrinsic versus extrinsic lesions. MRI is also helpful having advantages of good soft tissue evaluation and lack of radiation but likely requiring sedation in a child with an airway lesion. Clinical discretion to anesthetize such a patient is necessary. Definitive diagnosis is made on laryngoscopy and bronchoscopy in the operating room to determine the extent, characteristics, and stenosis of the airway. Pathological specimen of the lesion should be acquired at this time as well to ensure proper diagnosis.

Treatment of tracheal neoplasms is determined by pathological diagnosis. In some circumstances such as hemangioma, the lesion may be medically treated. In others, particularly benign lesions, simple excision (either endoscopic or open) may be all that is necessary. Complex open airway surgery including tracheal resection and reanastomosis may be required for certain larger lesions. In malignant lesions, adjuvant radiation and chemotherapy may be necessary in addition to surgical excision.

## Bronchial Tumors

Primary neoplasms of the bronchus and trachea most commonly present with recurrent pneumonia, cough, and wheezing or asthma unresponsive to treatment. Although tumors in these locations are rare, they have been shown in the literature to be approximately two-third malignant. Sixty-four percent have been found to be malignant on biopsy with pulmonary carcinoid being the most commonly described of the malignant lesions.[83] This rate was similar to a literature review on the subject in 1983.[83,85] In that paper, the same tumor was called a bronchial adenoma. In adults, metastasis is found in 10–30% of pulmonary carcinoid. Slightly fewer pediatric patients were found with metastasis at presentation.[85] Wheezing is thought to be a presenting symptom in part as a result of serotonin released into the airway.[83] Surgical excision is the treatment of choice in these lesions. Mucoepidermoid carcinoma was the second most common malignant lesion. Treatment is surgical excision with prolonged follow-up as when it is found in other areas of the airway. Other bronchial lesions include leiomyoma, adenocystic carcinoma, and bronchogenic carcinoma. In children most bronchogenic tumors are undifferentiated carcinoma or adenocarcinomas.

Of the benign lesions, the two most common are inflammatory pseudotumors, also known as inflammatory myofibroblastic tumors, and hamartomas. Inflammatory pseudotumors are classified by the World Health Organization as intermediate in terms of malignancy.[83] The histologic examination demonstrates a proliferation of reticuloendothelial cells.[85] Hamartomas are commonly found in the adult population but more rarely in the pediatric population. Of note, the triad of pulmonary chondroid hematoma, GI stromal tumors, and extra-adrenal paraganglioma is found in Carney's syndrome, which has been described in female patients.[83,86]

CHAPTER

# 44 Caustic Ingestions and Foreign Bodies of the Aerodigestive Tract

*Benjamin B Cable, Douglas Ruhl*

## BACKGROUND

Despite a progressive series of regulatory legislation and safety efforts over the last century, potentially hazardous chemical exposure remains to be a serious and relatively common occurrence among the pediatric population. One key contributing factor to this difficult problem is the sheer number of chemicals now available to the average home in the United States. The Household Products Database of the National Library of Medicine currently lists >2,000 widely available products in nine separate categories ranging from cleaning and automotive products to home improvement and pet care products. From this nearly unlimited access to chemical products, the potential for misuse and exposure logically follows. Accidental and purposeful ingestions make up approximately 80% of these cases, whereas dermal, inhalational, nasal, and ocular exposure routes make up the remaining 20%.

In its most recently published data set, the American Association of Poison Control Centers reports >2.3 million poison "exposures" in 2011, 48% of which regarded as children <6 years of age. This overall "exposure" rate is more double than that seen prior to 1987 and has been essentially stable for the last decade. The categories most frequently reported to the National Poison Data System (NPDS), in order of descending frequency, include cosmetic/personal care products, analgesics, cleaning substances, foreign bodies, topical preparations, vitamins, antihistamines, and pesticides. Despite representing a highly disproportionate amount of total exposures, fatalities in children are thankfully rare. Of the total number of reported case fatalities in 2011, <2% of patients were <5 years of age.[1]

When looking specifically at patients <19 years of age, 80% of exposure cases are reported in children <5 years of age. The remainder of cases are nearly equally divided between those from 6 to 12 and those between 13 and 19 years of age. Unintentional ingestions make up the vast majority of cases of those <5 years of age, but intentional ingestion becomes more common in older children. Intentional ingestions outnumber accidental in cases of patients between 13 and 19.[1]

Potentially "caustic" ingestions make up one portion of the overall number of these cases and are defined by exposure to chemicals, which have the ability to interact with and damage organic tissue. Specific data regarding the actual prevalence of pediatric caustic ingestions remain surprisingly rare. Reports by the American Association of Poison Control Centers, via the NPDS, do not delineate caustic agents from noncaustic agents, and the majority of recent literature citations regarding frequency can be directly traced or extrapolated from a single report published >40 years ago.[2] A singular report in 2012, using database queries of International Classification of Diseases, Ninth Revision (ICD9) codes, reported an estimated prevalence of 807 cases in the United States in 2009. The authors point out that this prevalence rate almost surely underestimates the true total number of cases as it deals only with hospitalized patients and requires both accurate coding and accurate reporting to capture cases.[3]

Simplistically, caustic substances are often divided into alkalis and acids. Alkali agents, or "bases", are those chemical substances with the ability to accept a free $H^+$ ion. Historically, the term Lye was used to denote any strong alkali used as a cleaning agent. Today, alkalis can be found in many products, which include drain and oven cleaners

as well as soaps and dishwashing agents. Recent interest in "environmentally friendly" nonphosphate detergents has resulted in the addition of alternate chemical mixtures, which add to the overall pH of available detergents.[4] Practically, alkalis are ingested far more frequently than acids, because they are relatively tasteless and are often more prevalent in the home. Alkalis cause direct damage to the lipoprotein lining of the aerodigestive tract via a liquefactive necrosis. This necrosis occurs as a result of "saponification", which is a term used to describe the direct hydrolysis of triglycerides in cellular tissue. This process is not self-limited and may progress through mucosal, submucosal, and muscular layers of the esophagus and stomach. Intense adjacent inflammation results in small vessel thrombosis and, ultimately, necrotic sloughing between 4 and 7 days after injury.[5]

Acid agents are those chemical substances that have the ability to donate a free $H^+$ ion. As they have a strong and often bitter taste, acid ingestions are reported to make up < 15% of total caustic ingestions.[6] Common acid agents found in the home include pool chemicals, some toilet-bowl cleaners, and battery fluids. As opposed to alkaline agents, acidic agents cause a coagulation necrosis, which results in the formation of an eschar. This eschar may limit overall depth of the resulting chemical reaction. Although this is often thought to be protective within the esophagus, acidic agents are known to have the potential too overwhelm the acidic environment of the stomach and cause severe gastric injury as well as systemic toxicity.

Although "critical pH" levels are often discussed for both acids and bases, the clinical utility of these measurements is questionable. For acids, a substance with a pH < 3 is often cited as having the potential for caustic injury. For bases, a substance with a pH > 12 is cited as having a similar potential for injury.[7] In reality, many factors are likely to be involved in the overall "caustic" nature of an ingested substance. Other factors include strength or concentration of the substance, viscosity, additional adjuvant chemicals present, and time of exposure to the tissue in question. These factors illustrate the critical importance of seeking out the specific identity of the potentially ingested substance and gaining poison control center advice regarding the substances known properties and potential for injury.

## CAUSTIC INGESTION

### Initial Presentation and Evaluation

The three most common presenting signs for children who have ingested a caustic substance are drooling, vomiting,

**Fig. 44.1:** Young child with history of caustic ingestion presenting with moderate lip edema and vermilion erosion.

and refusal of further oral intake. Less common signs include lip swelling, tongue erythema, leukoplakia, and oral ulcerations (Fig. 44.1).[8] Although numerous studies have attempted to correlate these presenting signs with the likelihood of deeper esophageal or gastric injury, most show no clear association. In particular, a review of the available literature makes it clear that normal oral and pharyngeal examinations do not rule out a significant distal injury.[9-12]

As always, initial evaluation begins with a detailed history. If at all possible, specific identification of the potentially ingested substance should be made and poison control center contact sought. Details surrounding the actual ingestion event should be clarified if at all possible. Intentional ingestions raise specific concern as the volume of ingested substance is typically larger and the subsequent sequelae possibly more significant.

Physical examination must begin with a broad-multisystem approach. Hemodynamic and airway instability are both unusual but must be evaluated and, if present, aggressively managed in light of exposure to each specific chemical agent. In severe cases, arterial pH disturbances (pH < 7.22 or base excess <–12) have been correlated with life-threatening esophageal injury.[13]

Plain film X-ray examinations of the chest and abdomen are used to rule out free air in the mediastinum and peritoneum.

Patients who present without acute hemodynamic or airway concerns should subsequently undergo thorough physical examinations. In most cases, flexible nasal endoscopy can be completed without difficulty and allows for careful assessment of the nasopharynx, hypopharynx, glottic structures, and esophageal inlet.

## Management

Evidence-based pathways for the management of caustic ingestion have yet to be defined. Historically, initial treatment options for caustic ingestion attempted to modulate the presence of the caustic substance itself and included the induction of vomiting, dilution of the substance with water or milk, and neutralization of the substance with a liquid having the opposite pH of the originally ingested substance. Each of these approaches may impose additional risk and, in most cases, have been abandoned. The induction of vomiting essentially re-exposes the esophagus to the caustic substance and creates an additional risk for aspiration. Dilution, usually in the form of a large volume of water intake, creates a risk for gastric upset and serial reflux of the original substance. Although controversial in animal studies, neutralization attempts have been thought to create exothermic reactions, which may further exacerbate trauma to the aerodigestive tract.[14] Activated charcoal has also been used alone or in combination with these potential therapies but has been shown to be of little value and has also been largely abandoned as a treatment option.[1]

Rather than directly modulate the caustic substance itself, current management focuses on assessing the damage done and tailoring subsequent medical therapy to attempt to avoid the development of complications resulting from this damage.

Assessment of the patient with caustic injury involves observation and consideration for endoscopy. Children with a questionable history of ingestion may be released after only a few hours if completely asymptomatic. All other children should be considered for admission and overnight observation. Children known to have ingested a potentially dangerous caustic agent, and all children with active symptoms should be made nil per os (NPO), admitted for overnight observation, and hydrated with intravenous fluids. Although some controversy exists regarding the need for endoscopy in all admitted patients, most current studies advocate a low threshold for esophagoscopy after 12–48 hours of observation.[8,15] This particular window in time is chosen to allow for the injury to demarcate but not progress beyond the point of possible early intervention. Almost all authors agree that patients with intentional caustic ingestion, irrespective of symptoms, should undergo endoscopy.

A number of grading systems have been proposed for esophageal caustic injury patterns. The most commonly referenced system is defined by Zargar et al.[16] Using this system, a normal esophageal examination is given a Grade 0. Grade 1 injury is defined by mucosal edema and hyperemia. Grade 2a injury is defined by friability, erosions, hemorrhage, blisters, exudates, whitish membranes, and shallow ulcers. Grade 2b injury is defined by Grade 2a findings with deep or circumferential penetration. Grade 3a injury is defined by small or scattered areas of necrosis and Grade 3b by extensive necrosis.

Children found to have a Grade 0 or 1 examination have a low likelihood of complications and can be discharged home after establishing a normal oral intake. Children with a Grade 2 findings may also begin a normal oral intake and can be discharged home but must be followed closely as they have been reported to form esophageal strictures in 50–77% of cases.[8,16] When they do develop, strictures most commonly become apparent between 3 and 8 weeks after injury.[23] Children with Grade 3 injuries will almost certainly develop strictures.[17] If possible, children with Grade 3 injuries should have a nasogastric feeding tube placed at the time of endoscopy. This tube serves as both stent and conduit for feeding. Children with Grade 3 injury require serial dilations, if possible, and can require esophageal resection in specific cases.

Medication management is directed toward minimizing stricture formation. Although a range of medications are frequently used in the treatment of patients with caustic ingestion, none are without controversy. Antireflux agents, including the proton pump inhibitors, tend to be started early after Grade 2 and Garde 3 injuries but no specific evidence exists to support their use. Antibiotics were shown to be of benefit. Benefit in a single animal model >60 years ago and have been subsequently used in most series with Grade 2 and 3 injuries.[18] Despite their widespread use in these cases, no clear evidence of benefit exists. The exception to this paucity of data would be cases where potential perforation and mediastinitis or peritonitis exists. In these cases, antibiotics are clearly indicated.

As distinct from other medications, a broad range of data exists for the use of steroids in patients with caustic ingestion. Most case series have focused on Grade 2 injuries as Grade 1 injuries are unlikely to stricture and Grade 3 injuries are felt to possibly be exacerbated by the use of steroids. Prospective studies of steroid use in Grade 2 patients are mixed in their results.[8,19,20] Two meta-analyses of available data failed to show significant benefit with steroid use.[21,22] Due to the conflicting nature of the original studies and the low incidence of side effects or complications, steroid use in patients with Grade 2 disease continues to be commonly used medical therapy in practice. If used, steroids are often given for 1–6 weeks with a constant dose of 1–2 mg/kg/day of prednisone for the first 7–21 days and then slowly tapered, if longer durations of therapy are chosen.

In most cases, children with Grade 2 findings should undergo fluoroscopic swallow testing before beginning oral intake and being discharged home. Children with Grade 3 injuries and NG tubes in place may also undergo fluoroscopic swallow evaluations before being discharged home.

Children with Grade 0 or 1 findings should both have follow-up examinations to ensure normal dietary intake and swallow function. Children having difficulties with oral intake should generally undergo repeat swallow testing at 3–6 weeks after injury and dilation procedures if strictures begin to develop. All children with Grade 2 or 3 findings should undergo subsequent evaluations of their swallowing function. Most authors advocate fluoroscopic studies to begin during the time that strictures may begin to develop, usually around 3 weeks postinjury. In patients who ultimately develop strictures, 80% will develop within 8 weeks of injury.[23] Again, when evidence of stricture formation begins to develop, dilation procedures can be used as treatment. The development of a long-segment stricture or total obstruction often results in the requirement for a segmental resection or consideration of esophagectomy. Children found to have evidence of stricture development should be considered as candidates for esophageal dilation. While bougie dilation remains an option, balloon dilation techniques have become far more common and are now most frequently cited. Although not proven to be superior to bougie dilation, balloon techniques are often described as having the advantage of avoiding the shearing forces created by the introduction of bougie dilators. Irrespective of technique, frequency of dilation should be based on patient exam and response to initial therapy. Most authors report the need for multiple procedures, accomplished at bi-weekly intervals. Mitomycin-C has been studied as an adjuvant therapy for use at the time of stricture dilation. When used, it is topically placed at concentrations between 0.1 and 1 mg/ml. A recently published review of the 11 publications regarding its use concluded "encouraging" results but cited a lack of prospective evidence.[24]

When compared with the general population, patients with a history of a caustic ingestion are reported to have a thousand-fold increase in the risk of developing esophageal carcinoma, both adenocarcinoma and squamous cell carcinoma. Incidence rates range from 2% to 30% of patients who are followed for long durations of time. Given this concern, serial screening for evidence of dysplasia would seem reasonable.

## HOUSEHOLD BLEACH

Household bleach products are one of the most frequent sources of accidental pediatric ingestion and deserve individual comment. Sodium hypochlorite, the primary chemical found in liquid household bleach, is known to form hypochlorous acid when combined with water. Although potentially caustic in concentrations above 10%, a wide range of studies have shown lower concentrations to be an irritant rather than truly caustic. Current household bleach products are limited to concentrations of 5%. Children who have accidentally ingested liquid household bleach products most often present with vomiting but may also display mild skin irritation, drooling, dysphagia, cough, and abdominal pain. Despite these initial concerning symptoms, serious distal injury is extremely rare. Most children experience a rapid resolution of symptoms and, having undergone a complete examination without significant findings, can be released without further observation. Children with continued symptoms can be admitted for observations but rarely require endoscopy or further intervention.[25] As with any other purposeful ingestions, children with purposeful ingestion of a bleach product should undergo full evaluation with endoscopy. Industrial bleach products are often formulated at higher concentrations and should be considered as caustic.

## FOREIGN BODIES

As long as children will innately be driven to explore their environment, they will put things in their mouth. Despite United States regulations designed to limit small parts in toys and articles designed for use by children <3 years of age, foreign body ingestion remains common. The 2011 Annual Report of the American Association of Poison Control Centers National Poison Data System lists >112,000 calls for foreign body ingestion with >82,000 of the cases occurring in children <5 years of age. This is almost certainly a large underestimate as many, if not the majority, of foreign body ingestion cases do not result in a call to a poison control center. Overall, the peak incidence of foreign body ingestion occurs between the age of 6 months and 3 years. Thankfully, it is estimated that 80% of ingested foreign bodies will pass through the gastrointestinal system without complication. The remaining 20% become lodged in the aerodigestive tract and require either endoscopic or open surgical removal.[26]

Although rarely analyzed together, airway foreign body cases are far outnumbered by gastrointestinal foreign body cases. We will discuss each separately.

## Airway Foreign Bodies

Foreign body aspiration most commonly occurs in children <3 years of age and often reflects a male preponderance. Organic matter is the most commonly aspirated material, although most series demonstrate a wide range of possible objects. In two large reviews of aspirated foreign bodies, vegetable matter made up between 67% and 84% of cases. Nuts were the most commonly encountered material in both series.[25,27] In the acute phase of aspiration, children display gagging and choking that may last for seconds to minutes. As the foreign body lodges and the child habituates, the distress of a small or nonobstructive object subsides and patients may become asymptomatic for an extended period of time. If not directly witnessed, the events may be missed altogether. As a result, studies report between 36% and 60% of cases present >24 hours after aspiration.[25,28] Many present days, weeks, or even months after actual aspiration.

Given the wide window of time for presentation, a high index of suspicion is the single most important factor in diagnosis. In children, virtually any pulmonary symptom that is either atypical or unresponsive to routine therapy should raise the possibility of an aspirated foreign body. Frequent misdiagnoses include pneumonia, bronchitis, asthma, and laryngitis. Classically, an aspirated foreign body "triad" is described. This includes a history of coughing and/or choking with an examination finding both wheezing and unilateral decreased breath sounds. When each part of the triad is evaluated individually, a history of coughing and/or choking is present in >90% of children. Wheezing is reported to be present in >80% of children and unilateral decreased breath sounds in approximately 50% of patients.[25,27,28]

Plain film chest X-ray (CXR) examinations remain the initial study of choice for any child undergoing consideration for foreign body aspiration. CXR results are found to be abnormal in 75–85% of patients, although specific delineation of the foreign body is only visible in the 15% of cases, where the foreign body is radiopaque. More common findings include mediastinal shift due to air trapping, hyperinflation, and atelectasis. Computerized tomographic examinations are felt to have a slightly higher sensitivity. Fluoroscopic examinations have also been used to evaluate for dynamic air trapping. Given our increasing awareness of the recent exponential increase in the overall use of medical radiation and its potentially harmful effects in children, both of these studies should be used only after special consideration and nondiagnostic plain film evaluation.

The majority of aspirated foreign objects lodge in the right main bronchus due to its less acute angle as it departs the trachea. Large case series report just over 50% of all foreign bodies lodging in the right main bronchus. Between 30% and 40% of remaining objects are found on the left main bronchus, whereas the remainder are found in the trachea or larynx itself.[25,27]

If history, physical examination, or radiologic investigation results in the possible diagnosis of an aspirated foreign object, endoscopy should be considered both for definitive diagnosis and treatment.

Rigid endoscopy remains the technique of choice for the evaluation and removal of airway foreign bodies. Close coordination between the surgical and anesthetic teams is imperative to success. While induction with inhalational anesthesia agents remains expedient, anesthetic maintenance is often best achieved with intravenous agents. Anesthesia where the patient maintains spontaneous ventilation can be achieved with highly trained anesthesia providers and is ideal for both diagnostic and therapeutic endoscopy. Intravenous anesthesia ensures a steady level of anesthesia while the airway is instrumented and alternating levels of gas exchange occurs (Fig. 44.2). With spontaneous anesthesia, an endoscope can be directly introduced via a laryngoscope. Without a bronchoscope, the endoscope has a much wider range of motion in the distal trachea and, with head turning, a zero-degree scope can be used to fully evaluate both bronchi and often multiple subsegmental

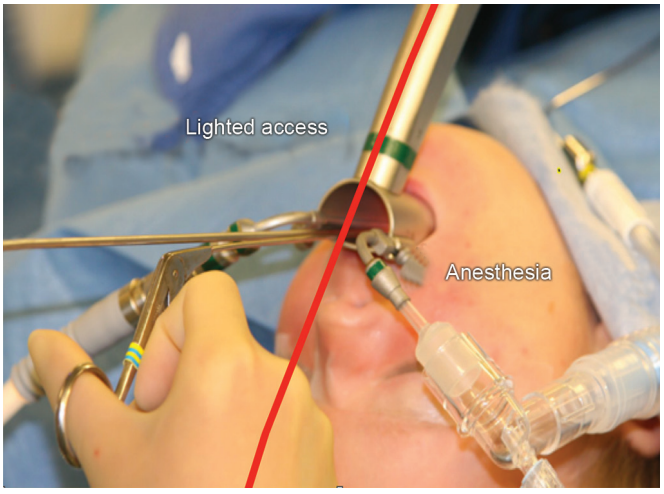

**Fig. 44.2:** Patient undergoing evaluation for airway foreign body using spontaneous anesthesia. Fiberoptic light located on left and anesthesia circuit located on right.

bronchi. If no foreign body is encountered, the procedure can be completed. If a foreign body is identified, it is closely examined to determine the appropriate optical forceps be used for removal. At all times, suction should be available and can be gently carried out using either rigid suction cannulas or atraumatic flexible suctions ranging in size from 4 to 6 French. If the patient continues to achieve spontaneous ventilation, the surgeon has the option to suspend the patient and introduce the optical forceps directly. This allows for continued maximization of movement. If spontaneous ventilation is difficult or intermittent, a bronchoscope is introduced into the airway and the anesthesia circuit attached to the 15-mm port. Optical forceps can then be introduced through the bronchoscope. Once the object is grasped with the optical forceps, it is gently brought to the distal end of the bronchoscope. Sharp points, if present, should be brought into the lumen of the distal bronchoscope but the entire system, bronchoscope and forceps, should then be brought out of the airway as a unit. The glottis provides a second area of constriction and can "strip" a foreign body from the forceps if not passed slowly and with a firm hold. Once a foreign body is removed, a secondary diagnostic examination should be undertaken to ensure complete removal, evaluate for trauma to the airway, and to ensure no additional foreign bodies are present.

Postoperatively, children are observed in a monitored care setting. A postoperative CXR is ordered to rule out pneumothorax. It is common practice to treat patients with perioperative steroids to minimize edema from the procedure.

## Esophageal Foreign Bodies

As with aspirated foreign bodies, the peak incidence for esophageal foreign body ingestion is approximately 3 years of age. As opposed to aspirated foreign bodies, esophageal foreign bodies are most commonly non-vegetable matter with coins being the most common object found in large case-series. In these series, coins make up between 27% and 80% of the total objects encountered. Other objects typically include toy parts, jewelry, hardware, and disk batteries (which will be discussed separately).[29,30]

Children who have ingested a foreign body that has become lodged in the esophagus present with highly variable symptoms that include choking, drooling, poor feeding, dysphagia, odynophagia, chest pain, nausea, vomiting, and respiratory symptoms secondary to tracheal compression. In some cases, children can be entirely asymptomatic.

The CXR evaluation should be ordered for any child with a suspected ingested foreign body. The most common location at which a foreign body lodges within the esophagus is the upper esophageal sphincter or thoracic inlet. This occurs in 60–70% of cases.[30,31] Two secondary areas of narrowing, the mid-esophagus at the level of the aortic arch and the lower esophageal sphincter, each tend to trap remaining foreign objects in equal proportion.

Children with suspected esophageal foreign body ingestion and respiratory symptoms of any kind should undergo endoscopic removal as soon as is practical. Children with inert objects, coins in particular, and without respiratory or severe symptoms can be considered for period of observation. This not only allows for gastric emptying in preparation for general anesthesia but may also allow time for the object to pass. In one large prospective study, 25–30% of coins were found to pass without complication over an 8–16 hour period of time. Of note, proximal coins were found to pass in only 14% of patients, whereas middle and distal coins were found to pass in 43% and 67% of patients, respectively.[32,33] Objects that are found to pass to the stomach most often continue to pass through the gastrointestinal tract without complication. Parents are often asked to screen stools to ensure object passage. Objects not passing by 4–6 weeks should be considered for endoscopic or surgical removal.[31]

Symptomatic objects and objects not found to pass after a period of observation should be removed endoscopically. Evidence supports both rigid and flexible endoscopic techniques. If rigid endoscopy is chosen, a brief diagnostic laryngoscopy and bronchoscopy is often done before intubation. This allows tracheobronchial involvement to be ruled out. Once intubation is completed, the proximal esophagus in small children can often be visualized with firm upward retraction of the overlying skin of the neck. This is most successful in children <1 year of age but may be possible in older children as well. If unsuccessful, an esophagoscope can be introduced and endoscopy used to evaluate the full length of the esophagus. The central lumen of the esophagus should be kept in view at all times and minimal pressure used to pass the esophagoscope. Once located, the foreign body is often surrounded by secretions and debris and must be isolated with gentle suction. Once complete, an optical forceps can be passed and used to retrieve the object. As with aspirated objects, the esophageal object is brought to the distal end of the esophagoscope and the entire unit is removed in unison. Repeat diagnostic endoscopy can be used to confirm object removal and to evaluate any associated mucosal trauma. Children with evidence of

esophageal trauma should undergo subsequent contrast swallow studies to rule out perforation before a normal diet is resumed.

## DISK BATTERIES

Disk batteries represent an especially dangerous hybrid between a potential foreign body and a potential caustic agent. As such, they require special consideration and management. Accidental ingestion of these batteries is becoming an unfortunately more common problem in the pediatric population. During 1985–2009, there was a 6.7-fold increase in the percentage of button battery ingestions with major or fatal outcomes. This was in comparison to two-fold increase of similar outcomes for all human poison exposure during the same time period.[34] Despite this increase in incidence and risk, guidelines for treatment remain to be well established.

Disk battery ingestions have a bimodal distribution with peak frequencies in 1–3 years old and the elderly. The elderly are more likely to ingest smaller, hearing aid batteries that are often confused for medication. Children, on the other hand, are the frequent ingesters of larger, button batteries (Fig. 44.3).[35]

The clinical course of a child with a button battery depends on location of the battery, duration of mucosal exposure, remaining voltage, and chemical composition of the battery.[36] Outcomes are significantly worse for large-diameter lithium cells (>20 mm) and children who are <4 years at the time of ingestion.[35] Lithium-cell batteries have 3 V of electrical charge compared with 1.5 V of other batteries. Significant esophageal injury from lithium batteries can occur within 30 minutes of ingestion.[37] Twenty-five years of retrospective data reported that all deaths related to disk battery ingestion were from 20- to 25-mm lithium batteries ingested in children 1–2 years old.[34]

Four mechanisms of injury have been proposed to account for the damage produced by a button battery lodged in the esophagus: caustic injury due to leakage of the battery contents, electrical discharge and mucosal burn, pressure necrosis, and toxic heavy metal absorption.[36,38-41] It is thought that the alkaline leakage is the major force inciting injury, and battery ingestions are treated as caustic ingestions. Interestingly, lithium batteries do not contain alkali but are associated with significantly worse outcomes.[34] More severe tissue damage may be produced by this type of battery by the flow of electric current through tissue, because they have a higher voltage.[37]

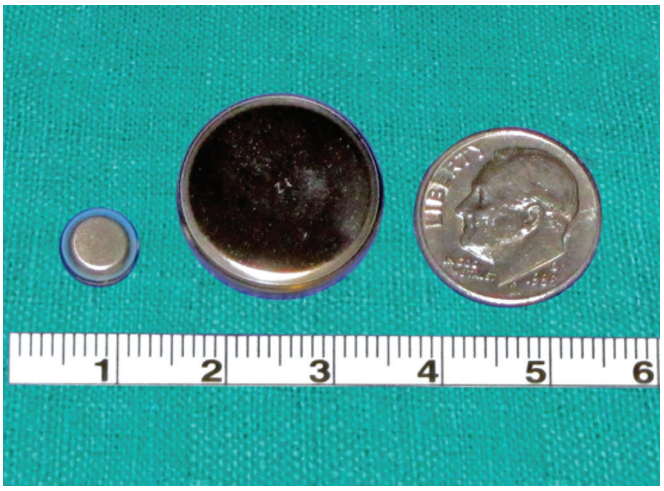

**Fig. 44.3:** Various sizes of common disk batteries.

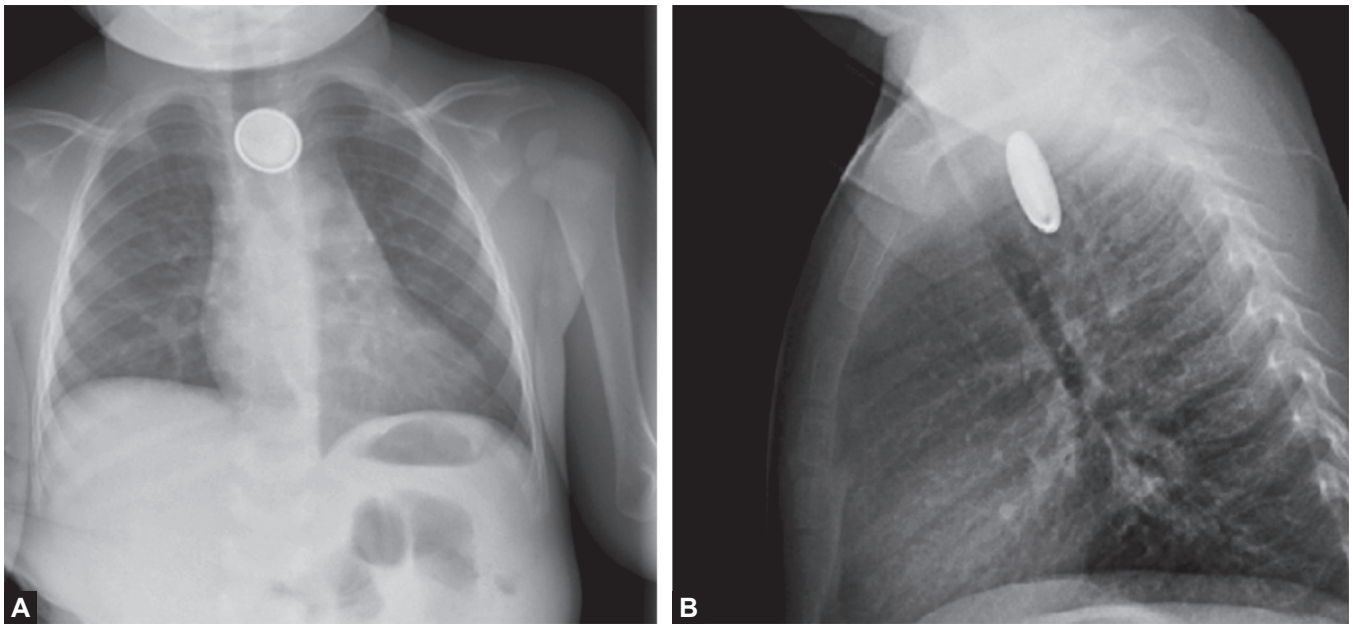
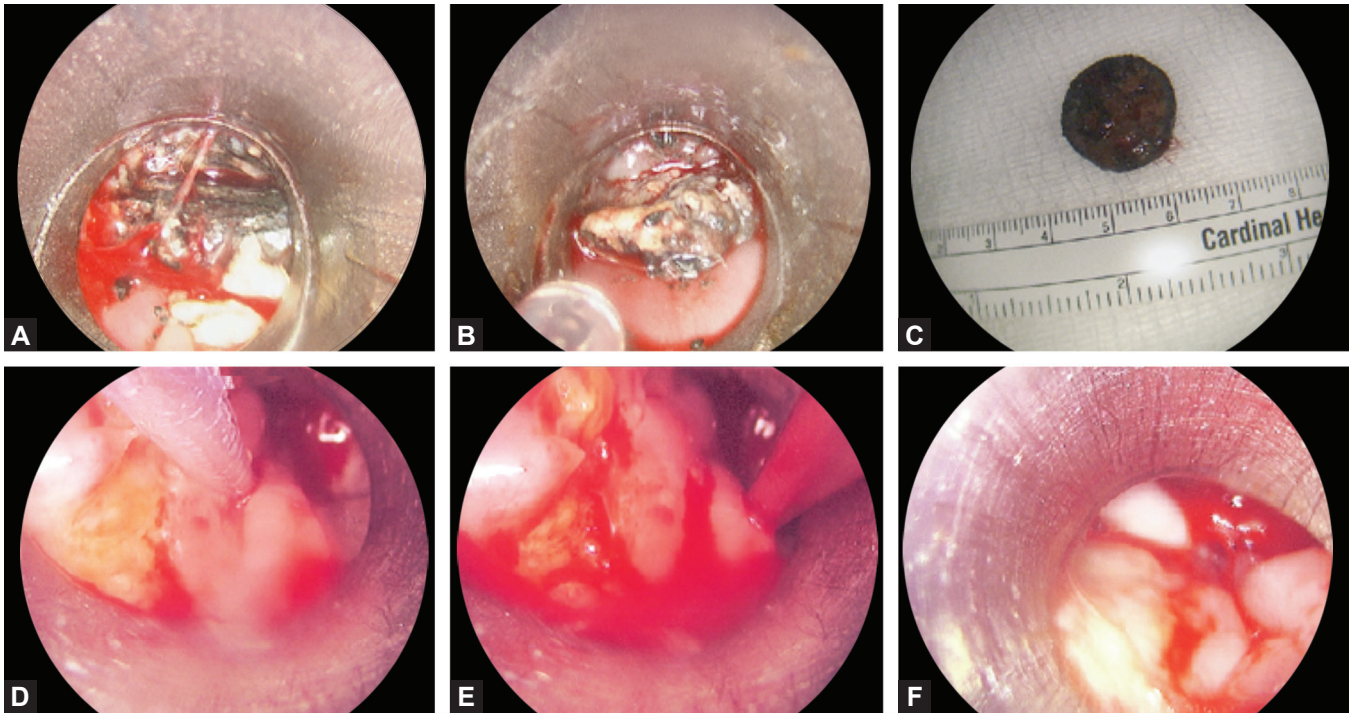
Esophageal injury occurs by flow of a direct current and not by outflow of the alkaline content or compression.[42] No report has demonstrated morbidity due to heavy metal toxicity from battery ingestion; however, it may be prudent to monitor serum levels if a patient ingests a mercury battery as they are more likely to fragment and increase serum levels of mercury.[43] Animal studies have shown the cathode side of the battery becomes increasingly alkaline while the anode side becomes acidic.[44]

Disk batteries are likely to lodge in the same locations as do other esophageal foreign bodies: the cervical esophagus, aortic arch area, and the lower esophageal sphincter. An anteroposterior and lateral chest X-ray is paramount in promptly identifying a battery trapped in the esophagus. The double shadow or "halo" effect is an easily recognized feature of button batteries on radiographs; however, its absence does not rule out its presence (Figs. 44.4A and B).[45] A disk battery can lose its "halo" appearance during the active corrosion process and may actually represent a more urgent situation.

Immediate rigid endoscopy is the foundation in removing esophageal button batteries.[39] Esophagoscopy directly after removal is often difficult to interpret as inflammation is severe and products of the resulting chemical reaction often appear as a thick exudative debris clinging to the esophageal wall. Some authors advocate a second endoscopy one day after battery removal; however, no management standard exists.[39] In data to be published, this author has found a close second-look esophagoscopy, done 2–4 days after initial battery removal, allows for much improved visualization of demarcated injury patterns and an overall downgrade in injury assessment in the majority of cases (Figs. 44.5A to F).



**Figs. 44.4A and B:** Anteroposterior (AP) and lateral plain film X-ray of child with button battery ingestion. Battery demonstrates halo effect on AP view and classic coronal position found in most esophageal ingestions.



**Figs. 44.5A to F:** Serial views of endoscopy during button battery removal. Top row—initial view of esophagus with thick coagulum and apparent circumferential injury. Top right—severely corroded battery after removal. Bottom row—second-look endoscopy done 48 hours after initial battery removal showing partial circumferential injury and limited edema.

CHAPTER

# 45

# Congenital and Acquired Laryngeal Anomalies

***Gresham T Richter, Abby R Nolder, Ramey Marshell***

## INTRODUCTION

The larynx is the single conduit by which air passes into the tracheobronchial tree and ultimately the lungs. It provides a barrier to aspiration and is the primary means of phonation. Normal laryngeal function is critical to respiration, eating, and oral communication. Thus, congenital and acquired laryngeal anomalies can lead to respiratory compromise, dysphagia, and voice disturbances. Even minor abnormalities can significantly affect laryngeal function. This chapter addresses both common and rare disorders of the pediatric larynx in terms of presentation and management. Many of these conditions require surgical intervention. The treatment goal of pediatric laryngeal disorders is generally to provide a widely patent larynx with normal vocal fold function.

## LARYNGEAL ANATOMY

The larynx is defined by the area involving the most superior part of the epiglottis to the inferior border of the cricoid cartilage. It is subdivided into the supraglottis, glottis, and subglottis. The supraglottis includes the epiglottis, aryepiglottic folds, supra-arytenoid cartilages (cuneiform and corniculate) and tissue, the false vocal folds, and superior half of the laryngeal ventricle (Fig. 45.1). The true vocal folds are the principle structure of the glottis composed of the thyroarytenoid muscle, ligament, and its surrounding mucosa. The glottis includes the sites of vocal fold insertion into the arytenoid and thyroid cartilages as well as 1–2 mm above and below these structures. The subglottis, the narrowest part of the pediatric larynx, includes the area 1–2 mm below the true vocal folds to the lower border of the cricoid cartilage. The recurrent and superior laryngeal nerves, arising from the vagus nerve (CNX), provide the primary motor and sensory neural input to the larynx respectively.

Disorders of the larynx cause site-specific functional problems that are particularly sensitive in the pediatric population. In general, supraglottic anomalies typically lead to inspiratory stridor, airway compromise, and dysphagia. Glottic lesions can lead to biphasic stridor, voice disturbances, and sometime swallowing problems. Subglottic disorders frequently cause significant airway obstruction that is accompanied by biphasic stridor. According to Poiseuille's law [$R \propto (n.L/r^4)$], small changes in the radius of the subglottis will dramatically impact resistance to air entering the tracheobronchial tree.

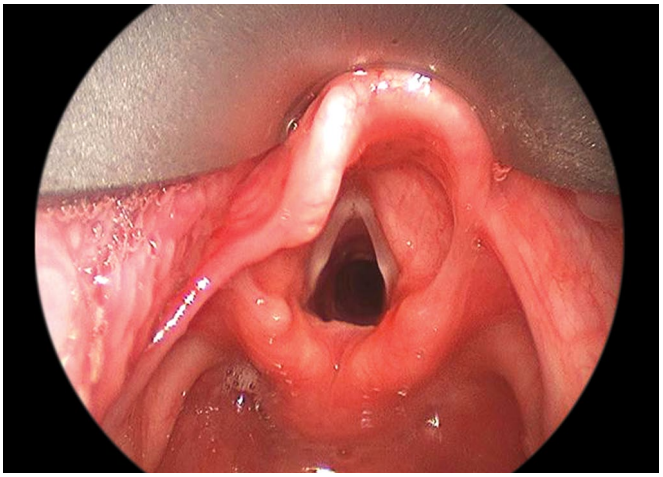

**Fig. 45.1:** Normal pediatric larynx. Endoscopic view of normal pediatric larynx.

# LARYNGOMALACIA

## Background

Laryngomalacia (LM) is the most common congenital anomaly of the pediatric larynx and the most common cause of newborn stridor.[1,2] LM, literally meaning "weak larynx", refers to the collapse of supraglottic structures during inspiration. Reduced laryngeal tone, shortened aryepiglottic folds, and supraglottic redundancy contribute to flaccid inspiratory collapse and airway obstruction in this condition.[3] When present in infants, LM is often accompanied with feeding issues due to discoordination of the suck–swallow–breathe sequence.[4] Stridor is the result of turbulent airflow upon inspiration across abnormally positioned supraglottic tissues. Four to twenty percent of infants with LM require surgical management when the airway and feeding are severely compromised.[5-7] LM may also be present in older children under conditions that impact normal laryngeal sensation and tone. Feeding issues, sleep apnea, and exercise intolerance have been attributed to LM in older children with this condition.[7,8]

## Etiology

The exact etiology of LM remains unclear. Anatomic, cartilaginous, and neurologic theories have been postulated. The anatomic theory implies that anomalous congenital development of the supraglottis leads to LM. This theory suggests that redundant supraglottic laryngeal tissue, high-riding cuneiform cartilages, and foreshortened aryepiglottic folds lead to airway obstruction and stridor. This can be seen in newborns with airway symptoms immediately after birth and often requires surgical correction. Underlying cartilage weakness termed "chondromalacia" has also been proposed as an etiology.

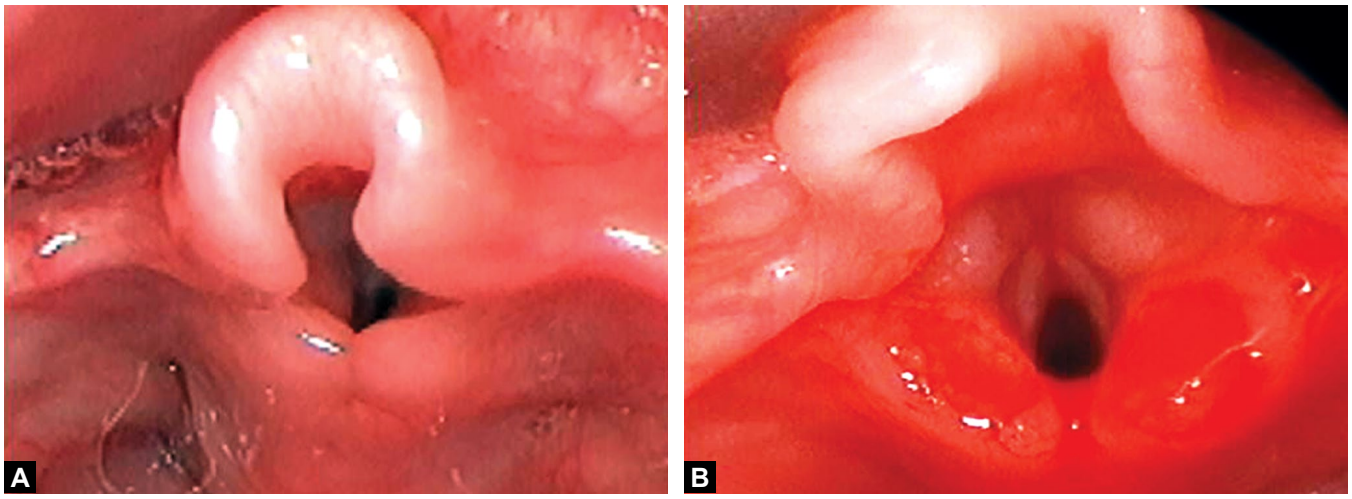
The current prevailing concept, with more evidence, is the neurologic theory of LM. The theory implicates neuromuscular immaturity or weakness as the most likely cause of this condition. Reduced laryngeal tone secondary to inhibited neurosensory input is proposed[4] and thought to be the result of an insult to the central nervous system or sensory fibers of the supraglottis.[9] The association of LM with gastroesophageal reflux disease (GERD) and neuromuscular disorders (cerebral palsy, Chiari malformation, stroke victims) implicates this theory. Neural hypertrophy, as seen in distal gastrointestinal conditions, has been found in supra-arytenoid samples of affected infants.[10]

## Clinical Presentation

The classic presentation of LM is an infant with high-pitched inspiratory stridor that worsens with feeding, crying, supine positioning, and agitation.[11] Symptoms arise during the first 2 weeks of life, increase over several months (especially in the presence of reflux), and peak at 3–6 months of age. Most cases (70–90%) of LM are benign and self-limiting with complete resolution between 12 and 24 months of age.[4,12] Stridor has been reported to resolve in mild to moderate LM by 7–9 months of age.[3,6] Associated manifestations of LM include dyspnea, respiratory distress with accessory muscle use, feeding difficulties, microaspiration, cyanotic spells, perioral cyanosis, obstructive sleep apnea, hypoxia, and failure to thrive.[13] The most common symptoms related to feeding include regurgitation, emesis, coughing, choking, and slow intake. Up to 80% of infants with LM have GERD or laryngopharyngeal reflux (LPR).[4] Older children and adults with evidence of LM frequently have LPR.[8] LM in this population may be the re-emergence of disease thought resolved at infancy. Patients with neuromuscular disorders and weakness (e.g. cerebral palsy) may present with late onset symptoms and a high degree of supraglottic collapse.

### *Diagnosis*

Prompt diagnosis of LM is important to avoid the complications of acute and chronic airway obstruction, such as cyanosis, apnea, failure to thrive, developmental delay, pulmonary hypertension, core pulmonale, cardiac failure, and asphyxiation. With a heightened suspicion, confirmation of LM is made using awake flexible fiberoptic laryngoscopy in the clinic. Supraglottic tissue collapse and obstruction during inspiration is the classic finding. Specific laryngoscopy findings include posteriorly positioned arytenoid cartilages and mucosa into the airway during inspiration, and a shortened distance between the arytenoid and epiglottis (aryepiglottic fold). Shortened aryepiglottic folds and lateral collapse with an "omega"-shaped, or curled, epiglottis are characteristic findings on intraoperative examination with direct microlaryngoscopy (Figs. 45.2A and B). An "omega"-shaped epiglottis, however, may present in up to 50% of normal infants.[4] Pharyngeal dysphagia (oropharyngeal dysphagia, microaspiration) is assessed in patients with LM with coughing and choking during feeds by speech therapy at the time of diagnosis.



**Figs. 45.2A and B:** Laryngomalacia. Intraoperative microlaryngoscopy of an infant's supraglottis with severe laryngomalacia (A) Before; (B) After supraglottoplasty.

Severity of LM is qualified as mild, moderate, or severe and solely based upon clinical symptoms. In general, mild LM is defined by mild inspiratory stridor with no other symptoms and evidence of laryngeal prolapse on flexible laryngoscopy. Patients with stridor, choking, and feeding difficulties in the presence of retractions, but no blue spells represent moderate LM. Severe LM denotes those patients with significant airway obstruction and discoordinated swallowing leading apnea, cyanosis, failure to thrive, or derivations of these symptoms.[14] Severe LM may also be qualified by sleep apnea in an affected infant.[15]

The anatomic appearance of the larynx may contribute to severity but does not necessarily dictate management. Surgical candidates are selected on the degree of airway obstruction and feeding difficulties, rather than the stridor intensity and extent of laryngeal collapse.[14] In patients with moderate to severe symptoms, in whom endoscopic intervention is considered, intraoperative microlaryngoscopy, and bronchoscopy can aid in the diagnosis and determination of surgical intervention. This also allows the opportunity to explore for synchronous large airway lesions, such as tracheomalacia, subglottic stenosis (SGS), and bronchomalacia that accompany LM in > 50% of cases.[16]

## Management

After the diagnosis of LM is made management is determined on the basis of severity of symptoms.[3,14,17]

- Mild LM management includes a 1-month symptom check with flexible laryngoscopy, followed by a 3-month symptom with or without laryngoscopy, until resolution of airway symptoms. Acid suppression therapy may be instituted to prevent disease progression in the setting of an already refluxing patient
- Moderate LM management includes acid suppression medication with a 1-month symptom check followed by symptom checks with or without flexible laryngoscopy every 3 months until resolution. A small percentage of patients (20–30%) with moderate LM will progress to severe disease depending on anatomic variation and control of reflux. This can be determined as early as the first-month follow-up
- Severe LM patients need to be managed with maximum acid suppression, microlaryngoscopy, and bronchoscopy, and supraglottoplasty (Figs. 45.2A and B). Follow-up for these patients with a 1-month postoperative visit is necessary. Recurrence of disease is rare (3–10%) but common in neurologically affected infants and those with uncontrolled reflux.[5,18] Repeat awake laryngoscopy is suggested, but surgical intervention is based upon clinical severity. If doing well then continued follow-ups every 3 months and subsequent weaning of acid suppression therapy is offered.

## Supraglottoplasty

Supraglottoplasty is the process by which the supraglottic larynx is relieved of obstructing collapsible supraglottic structures with preservation of the interarytenoid space. Supraglottoplasty was originally termed "epiglottoplasty" as defined by the reduction of the lateral surface of the

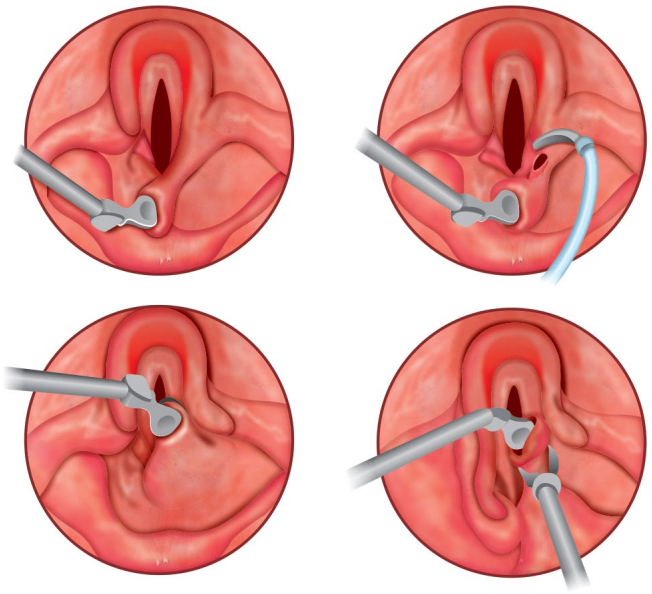


**Fig. 45.3:** Supraglottoplasty. Diagram of cold knife supraglottoplasty technique.[14]
Adapted from Richter et al.[14]

epiglottis in infants with severe LM. This is no longer performed, but the tenants of surgical intervention remain the same. During a supraglottoplasty the aryepiglottic folds are incised and redundant supra-aryteniod tissue is remove with or without the cuneiform cartilage with is often prominent and contributing to obstruction (Fig. 45.3). The procedure is safe, relatively bloodless, and can be performed with $CO_2$ laser or cold knife technique. Reported success rates vary from 79–93% in that a tracheostomy or revision procedure is not required. Infants and children with neurologic or comorbid cardiopulmonary conditions are more likely to fail.[5] Complications are rare. Aspiration improves in the majority of normal infants with severe LM after supraglottoplasty.[19] Patients with "late onset" or "persistent" LM improve with supraglottoplasty when comorbid conditions are not present.[20]

## SUBGLOTTIC STENOSIS

### Background

Subglottic stenosis (SGS) refers to the narrowing of the subglottic airway, a region extending from the undersurface of the true vocal cords to the distal surface of the cricoid cartilage. Subglottic stenosis is specifically defined by an airway lumen diameter of ≤ 4 mm in a full-term infant or ≤ 3 mm in a premature infant.[21,22] Expected internal diameter of the subglottic lumen by age is demonstrated in Table 45.1. SGS is a common cause of airway obstruction and the second most common cause of stridor in infants and children.[23,24] It accounts for more tracheostomies in children <1 year of age than any other laryngotracheal anomaly.[25] Subglottic stenosis can be acquired (95%) or congenital (5%). Although the pathophysiology of each is variable, the accompanying symptoms and ensuing management of the two stenosis types are virtually the same. Congenital subglottic stenosis is typically less severe than the acquired type but may be the underlying cause of acquired disease that is undetected in the presence of injury and inflammation.

**Table 45.1:** Expected minimal subglottic lumen size-based upon age

| *Age* | *Minimal internal diameter (mm)* |

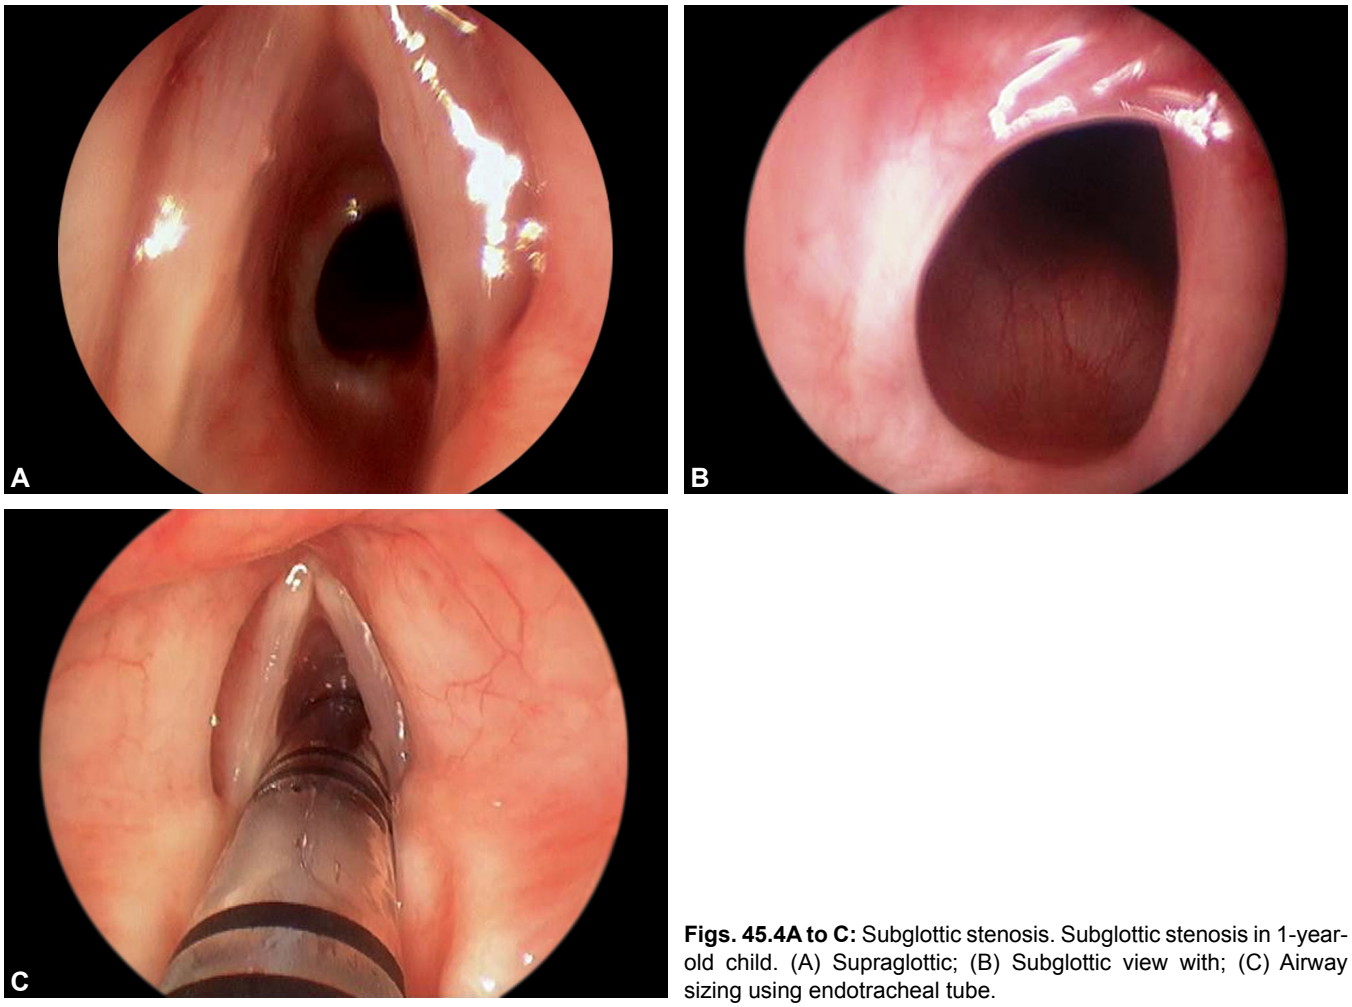
### Etiology

Acquired subglottic stenosis arises as a consequence of subglottic injury, most frequently secondary to endotracheal intubation. Mucosal injury, ischemia, granulation formation, and subsequent fibrosis lead to the constriction of the already narrowest element of the pediatric airway (Figs. 45.4A to C). Inappropriate endotracheal tube size has been attributed to subglottic injury, but the length of intubation tends to be the most important factor for stenosis formation. Other factors, which may precipitate SGS, especially in the setting of injury, include LPR, infection (respiratory syncytial virus, bacterial tracheitis), and other causes of local inflammatory response.[26] It is important to note that while approximately 90% of acquired SGS results from endotracheal intubation, the reported incidence of subglottic stenosis among intubated patients is now < 1%.[27,28]

Congenital SGS is found in a child without a prior history of airway trauma or endotracheal intubation. The majority of congenital SGS are of cartilaginous origin with anomalous cricoid ring development. The most common



**Figs. 45.4A to C:** Subglottic stenosis. Subglottic stenosis in 1-year-old child. (A) Supraglottic; (B) Subglottic view with; (C) Airway sizing using endotracheal tube.

anomaly is the "elliptic cricoid", which describes a reduced ratio of the transverse diameter relative to the anteroposterior diameter of the cricoid plate. Congenital SGS occurs in an estimated 5% of all subglottic stenosis and is identified earlier than the acquired type, typically in infancy.[29] The only risk factor consistently associated with congenital subglottic stenosis is prematurity.[30] Subglottis stenosis is further classified on the basis of several characteristics, cartilaginous versus membranous, the degree of narrowing, and by histopathology.[23,31] Membranous soft tissue stenosis occurs as the result of submucosal fibrosis, submucosal gland hyperplasia, ductal cysts, or granulation tissue. A soft tissue, or membranous, stenosis commonly is symmetric and circumferential.[26]

## Clinical Presentation

Inspiratory or biphasic stridor is the most common presenting manifestation of SGS. Associated symptoms include retractions, dyspnea, tachypnea, cyanosis, respiratory distress, restlessness, irritability, and feeding difficulties. Newborns with mild to moderate stenosis may remain asymptomatic until 1 to 3 months of age as this correlates with a period of increased activity levels. Both acquired and congenital SGS share similar symptoms. In acquired, a latency period of 2 to 4 weeks after the inciting event of airway injury is common. Severe cases of the congenital type can present with stridor and respiratory distress at birth.[32] Severity of SGS often correlates with symptoms. A fatigued child with suspected SGS with no audible stridor is an ominous sign and needs urgent intervention. The differential diagnosis for SGS includes LM, subglottic hemangioma, and croup.

## Diagnosis

The diagnostic workup of SGS relies on a thorough history and physical examination that is supplemented by both

radiologic imaging and an endoscopic evaluation. Historic clues of significance include continuous "noisy breathing", "wheezing", feeding difficulties, or prior episodes of endotracheal intubation especially in the presence of respiratory syncytial virus.[32] Radiologic evaluation includes anteroposterior and lateral neck and chest X-rays to assess for concomitant respiratory injuries and determination of stenosis location, length, and symmetry.[23] Computed tomography (CT) of the neck and chest in not commonly employed in the diagnostic work-up of pediatric SGS.

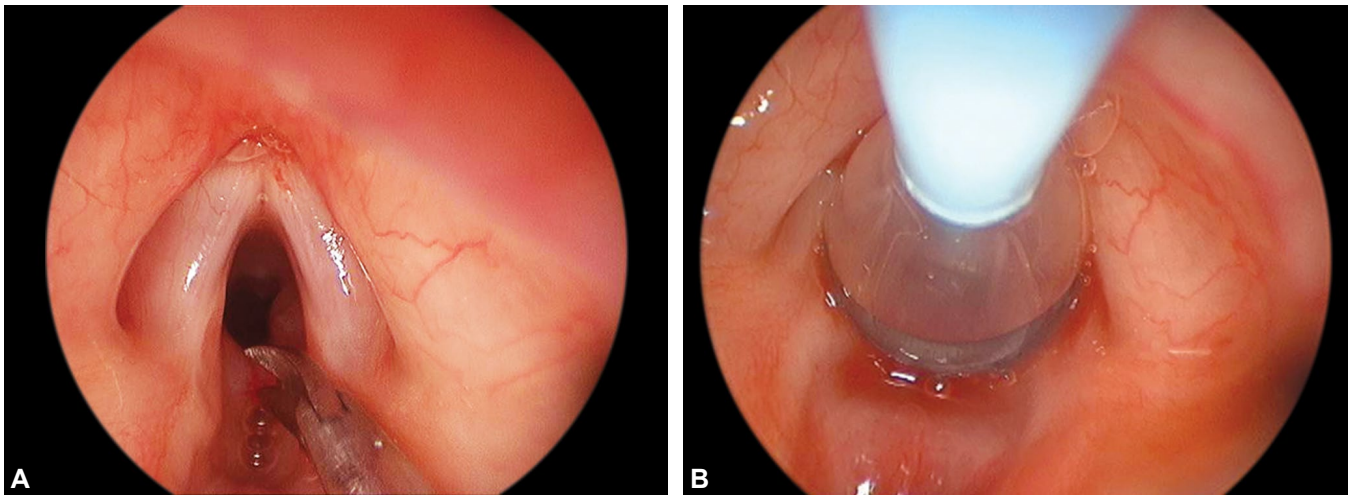
The gold standard for diagnosis of SGS remains to be direct microlaryngoscopy and rigid bronchoscopy. Both procedures require general anesthesia in the pediatric population thus negating the use of CT. During diagnostic laryngoscopy, a subglottic lumen less than the expected size for the child's age is determined to be stenotic.[33] Dynamic and secondary airway lesions, such as concomitant distal stenosis, vocal cord weakness, and tracheobronchomalacia, are also evaluated at bronchoscopy, as they will impact the patient's airway status and success of intervention. Length of stenosis may also be important. A universally accepted staging approach to pediatric SGS is the Myer–O'Connor–Cotton Grading System, which categorizes the degree of stenosis as grade I (0–50% obstruction), grade II (51–70%), grade III (71–99%), and grade VI (complete obstruction). This is determined on the basis of the outer diameter of the expected endotracheal tube for the patient's age (Figs. 45.4A to C). If a leak is present between 10- and 25-cm $H_2O$ with the age appropriate tube, then a stenosis is not present. When a smaller tube is required, then the stenosis grade can be calculated using the formula; actual size/expected size x 100.[33]

The Myer–Cotton staging system roughly correlates with prognosis and surgical outcomes.[34] Some patients may be considered to have a functional SGS in the setting of a flaccid, and not fixed, stenosis. Reflux is associated with the development and severity of subglottic stenosis.[35]

## Management

### *Endoscopic Techniques*

The majority of cases of SGS require surgical intervention. Subtle or mildly symptomatic grade I SGS may be following with nonoperative management and expected improvement with advancing age and size of the child. This is common for congenital low-grade SGS. For acquired and higher grade congenital SGS, surgical management is often required and based upon the degree of stenosis, its anatomic characteristics, and presence of inflammation. Techniques for subglottic expansion are broadly categorized as either endoscopic or open. Endoscopic dilation, with balloons or rigid dilators, is employed for low-grade soft tissue SGS (Figs. 45.5A and B).[36,37] The improved lumen size can then be determined by measuring it with the next larger endotracheal tube. The ensuing inflammation and healing from subglottic dilation will require repeat evaluation and possible dilatation at a later date under general anesthesia. In thick or long-standing fibrotic stenosis, mucosal incisions using cold steel or carbon dioxide laser can be performed in a radial fashion to augment the effect of dilation (Figs. 45.5A and B). Repeat dilatations are often required to achieve continued symptomatic improvement and a less severe stenosis. Intervals between dilatation increase during subsequent visits to the operating room but



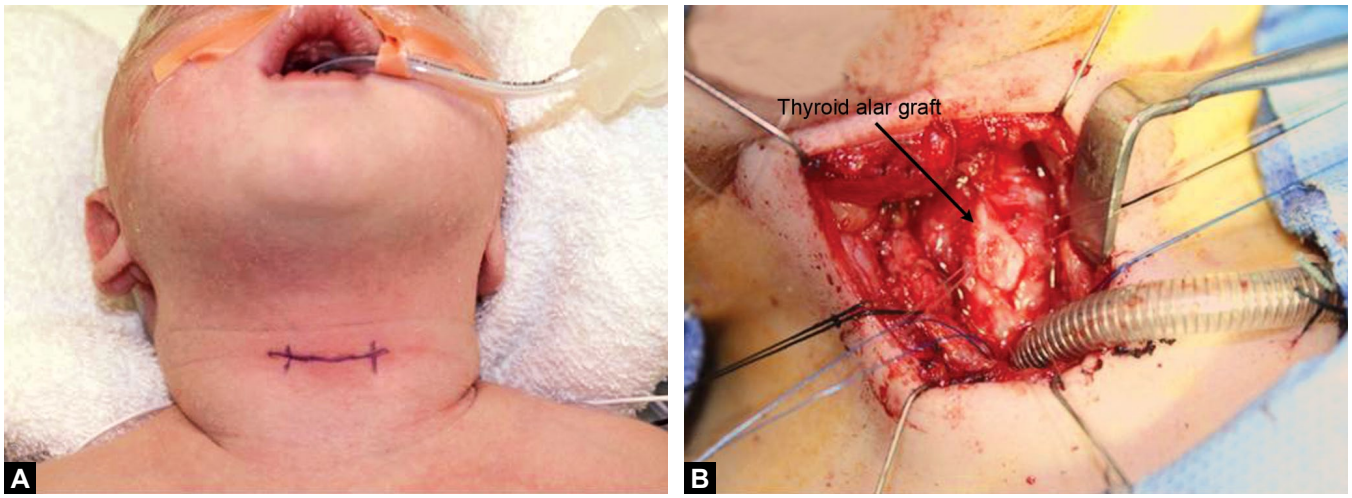
**Figs. 45.5A and B:** SGS intervention. Subglottic stenosis with (A) Radial scar band lysis; (B) Endoscopic balloon dilatation.

are necessary to achieve ultimately a larger, albeit scarred, subglottic diameter. When dilatation repeatedly fails in the persistently symptomatic patient, then open laryngeal augmentation is the next best step in management. Nonetheless, endoscopic dilatation can be employed in the postoperative maintenance of open airway procedures during the immediate and late phases of healing.[38-40]

### *Open Airway Reconstruction*

Endoscopic techniques are not routinely sufficient in treating cartilaginous and long-standing fibrotic stenosis.[41] First describe by Rethi and revisited by Cotton and Seid, the anterior cricoid split (ACS), is used for the relief of acquired or congenital stenosis in infants nonresponsive to endoscopic techniques.[42,43] The ACS is an open anterior neck procedure constituting a vertical midline incision of the anterior cricoid plate, lower third of the thyroid cartilage, and first tracheal rings.[43] The child is intubated with the next size larger endotracheal tube to stent the airway for several days as healing occurs between the opposing cartilage cuts. Although successful, the ACS has been replaced with the use of the thyroid alar graft.[44] A 3–4 mm × 6 mm graft is harvested from the superior lateral thyroid cartilage, and secured between the opposing cut cricoid plates to expand and stabilize the widened subglottic lumen (Figs. 45.6A and B). This laryngotracheoplasty (LTP) was first described by Forte and is best suited for young patients (< 18 months) not requiring more robust cartilage.[44] The ACS and the thyroid alar LTP are beneficial in children who otherwise would require tracheotomy for SGS. Success rates of decannulation are above 80%.[45-47] The primary health of the patient is important for success and the criteria for ACS and LTP with thyroid alar graft are listed in Table 45.2.

In older children with severe SGS (grade III and IV) laryngotracheal reconstruction (LTR or LTP) may be required with more robust cartilage. Autogenous costal cartilage grafts are considered the most effective graft for LTR and can be used to expand both the anterior and posterior cricoid plate, depending upon the degree and location of stenosis.[48] The technique used for LTR includes a horizontal skin incision and vertical split in the stenosis involving the cricoid cartilage, the tracheal rings, and the lower third of the thyroid cartilage. Once the airway is opened, the posterior cricoid plate may also be divided to allow for expansion. The grafts are measured and carved with superior and inferior tapered ends, replicating a boat, and leaving the perichondrium destined for the internal airway surface.[49] The grafts are then secured between the cut cricoid edges (Figs. 45.7A to D). In a single-stage approach, the airway is stented with an age-appropriately sized endotracheal tube for approximately 5 to 7 days. Repeat endoscopy is performed to help monitor the healing and graft coverage in weeks and months after the repair (Figs. 45.8A and B). In more complex patients, with concomitant airway or cardiopulmonary comorbidities, a tracheostomy below the repaired stenosis may be performed.[50] A stent is placed at the repaired subglottis above the tracheostomy and removed several weeks later. This is known as a double-stage LTP. Overall, success of LTP is determined by the ability to decannulate the child to provide normal upper respiratory tract function. Success rates vary depending upon the degree of stenosis.



**Figs. 45.6A and B:** Cricoid split. (A) Approach to anterior cricoid split in 8-month-old infant; (B) Laryngotracheoplasty with thyroid alar graft.

**Table 45.2:** Patient criteria for performing anterior cricoid split with or without thyroid alar laryngotracheoplasty

| |
|---|
| Extubation failure on at least two occasions secondary to laryngeal anatomy |
| Infant weight > 1500 g |
| No congestive heart failure in a month prior to open airway surgery |
| No ventilator support for 1–2 months |
| Minimal supplemental oxygen requirements (< 35% $FiO_2$) |
| Absence of acute upper or lower respiratory tract infections |
| Controlled aerodigestive tract conditions (GERD/LPR) |
| No need for antihypertensives |

(GERD: Gastroesophageal reflux disease; LPR: Laryngopharyngeal reflux).

Overall, decannulation rates average 80% both single- and double-stage techniques. Multiple operations may be required for high-grade lesions.[34] Voice outcomes are now being analyzed.

Cricotracheal resection may also be employed as an alternative to LTR for severe congenital and acquired stenosis (grades III and IV) that begins at least 2 mm below the true vocal cords.[51,52] This technique involves resection of the anterior arch of the cricoid ring followed by thyrotracheal anastomosis. Although this procedure is particularly beneficial to patients with severe stenosis, it comes with a risk of anastomotic dehiscence, recurrent laryngeal nerve injury (< 5% of cases), and poor voice outcomes.[53] The cervical slide tracheoplasty is also an alternative open airway approach to expanding recurrent or long segment subglottic and tracheal stenosis.[54]

## LARYNGEAL CLEFT

### Background

First reported in 1792 by Richter, the laryngeal (laryngoesophageal) cleft is an anomalous communication between the posterior laryngotracheal complex and esophagus. It is a vertical defect in the septum that normally divides the airway from the esophagus. Although present at birth, a laryngeal cleft may not be detected for several years. Symptoms vary from mild aspiration to severe neonatal distress, depending on the extent of penetration into the airway. Thus, several classification schemes have been proposed with increasing severity associated with deeper vertical penetration. The most widely accepted classification of laryngeal clefts is that proposed by Benjamin and Inglis and later modified by Sandu and Monnier (Table 45.3).[55,56] Symptom severity and morbidity correlates with higher levels of classification.

Tucker and Maddalozzo proposed the Type 0 laryngeal cleft as a defect in the posterior cricoid plate with an intact interartenoid muscle and mucosa.[57]

Laryngeal clefts may be present in 1:10,000–1:50,000 newborns. They approximate 1% of all discovered congenital airway anomalies.[58] Among normal children treated for chronic aspiration this percentage of patients may be as high as 7%.[59] The more shallow the cleft, the greater the frequency in which it occurs. Type IV clefts are exceedingly rare but carry a significantly greater morbidity rate. Syndromes and other anomalies of the aerodigestive tract commonly occur with a laryngeal cleft.

**Table 45.3:** Classification of laryngeal clefts

| | |
|---|---|
| Type 0 | Submucosal cricoid defect |
| Type I | Interarytenoid defect to the level of true vocal folds or below but no defect in cricoid plate |
| Type II | Partial cricoid cleft<br>Below level of true vocal folds but not completely through cricoid cartilage |
| Type IIIa | Total cricoid cleft down to inferior border of cricoid plate completely through |
| Type IIIb | Posterior cleft extending into trachea but not below the level of the sternal notch |
| Type IVa | Cleft extending into intrathoracic inlet down to the carina |
| Type IVb | Extension of cleft into one mainstem bronchus |

### Etiology

Around 3–4 weeks' gestation, the trachea and esophagus share a common lumen as the respiratory tree arises from the ventral foregut. During its propagation caudally the trachea separates from the digestive tract with the simultaneous formation of tracheoesophageal septum. Laryngoesophageal clefts result from the failed fusion of the posterior septal endoderm and/or the mesoderm arising from the 4th and 6th branchial arches.[60] The exact mechanism by which this occurs is unclear. The majority of laryngeal clefts are believed to be sporadic occurrences. No specific toxin or uterine event has been linked to laryngeal clefts. However, syndromes associated with midline defects, including Optiz-G (Frias), Pallister Hall,

CHARGE, VATER, and VACTERL, increase the risk of having a laryngeal cleft. Autosomal dominant transmission of laryngeal clefts has been reported in some families but this is very uncommon.

## Clinical Presentation

Patients with posterior laryngeal clefts may present with copious secretions, aspiration, cyanosis while feeding, inspiratory stridor, choking, and/or recurrent pulmonary infections.[61] Naturally, the deeper the cleft, the more severe the symptoms, the earlier the presentation, and greater the risk of the cleft is to the patient. In cases of Type I clefts, infants may present with a weak cry and stridor. LM may mask the initial symptoms of a Type I cleft. Late identification of shallow clefts may be triggered by chronic aspiration, recurrent pneumonias (16–54%), and chronic cough (27–35%) in the toddler.

Type II–IV laryngeal clefts will invariably present in the newborn with respiratory distress, airway obstruction, and life-threatening pulmonary compromise. Early diagnosis and intervention are paramount for survival in these patients. Type IV clefts carry a 50% mortality rate.

Other aerodigestive anomalies occur in 16–68% of patients with laryngeal clefts. Associated airway conditions include LM, tracheomalacia, bronchomalacia, and tracheoesophageal fistulas (TEF).[59,62] Craniofacial anomalies, genitourinary, and gastrointestinal malformations, GERD, and functional subglottic stenosis are also common in patients with laryngeals clefts.

## Diagnosis

Chest radiographs, barium swallow studies, and esophagrams often predicate the diagnosis of a laryngeal cleft. These studies neither confirm nor deny the presence of a laryngeal cleft but may suggest its presence based upon evidence of acute or chronic aspiration and pulmonary inflammation. The diagnostic challenge occurs when radiographic swallow studies demonstrate persistent laryngeal penetration and aspiration of thin liquids in the normal child.[63] A discreet pattern of aspiration on swallow studies has not yet been correlated with shallow laryngeal clefts. Diagnostic flexible laryngoscopy can be performed in clinic to examine for supraglottic and vocal fold anomalies that may be associated with, or mask, laryngeal clefts such as LM and vocal fold immobility. Functional endoscopic evaluation of swallowing function can be performed in synchrony with flexible laryngoscopy. This endoscopic swallow study allows direct examination of the posterior larynx during the pharyngeal phase of swallowing and may assist in the diagnosis of a cleft.[64]

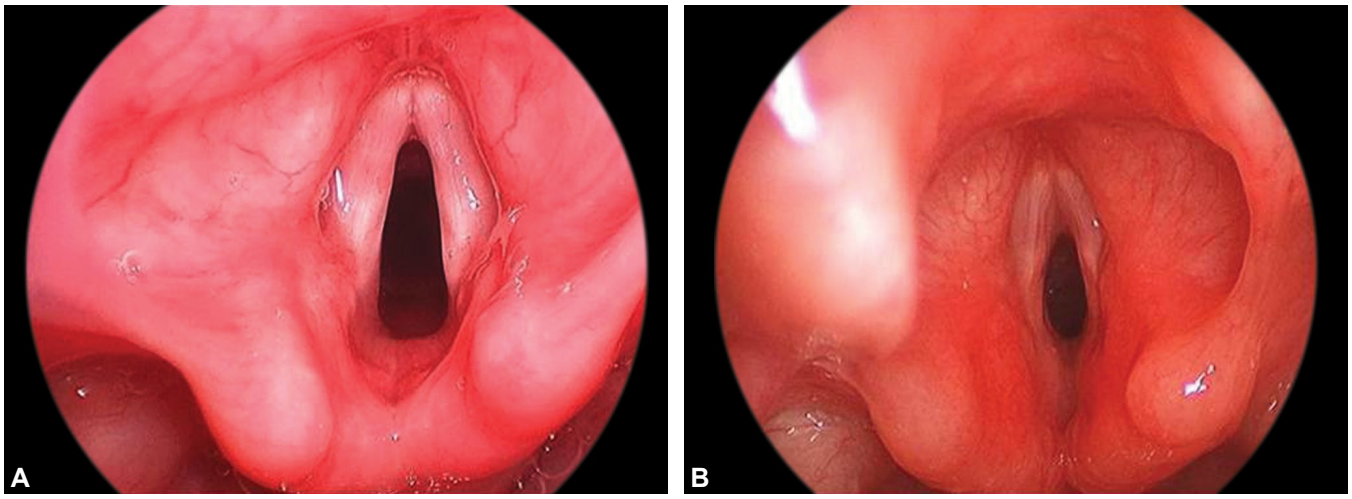
The gold standard for diagnosing a laryngeal cleft is rigid endoscopy with microlaryngoscopy and bronchoscopy under general anesthesia.[61] High-grade clefts (II–IV) are amenable to expedient diagnosis as evident by the defect and redundant mucosa between the arytenoid and cricoid cartilage. The confirmation and depth of a cleft is determined by passing a right-angled probe into the posterior defect. A Type I cleft is not as easily identified and may require additional clinical and diagnostic information to confirm its presence. A missed diagnosis during bronchoscopy with a delayed identification of Type I clefts can occur even in experienced hands. The average age at diagnosis of a Type I cleft is between 2 and 4 years.[65]

Bronchoalveolar lavage can provide evidence of chronic aspiration, by the lipid laden macrophage index, in an otherwise healthy child with a Type I cleft.[66] Similarly, an injection into the interarytenoid space with temporary filler may improve symptoms and swallow study findings if a Type I cleft is present.[67,68] The endoscopic difference between a Type I and Type II laryngeal cleft can be seen in Figures 45.9A and B. LM may also mask the presence of a Type I cleft on rigid diagnostic laryngoscopy.

Examination of the entire tracheobronchial tree and esophagus during endoscopy is important to rule out commonly associated anomalies such as TEF and tracheobronchomalacia.[69] Identifying and passing a thin probe or suction through a small posterior tracheal pouch may diagnose a simultaneous H-type TEF. A genetic consultation should be considered in any patient with a high-grade laryngeal cleft.

## Management

The management of laryngeal clefts consists predominately of endoscopic or open surgical repair. The objective behind any treatment algorithm is to properly diagnose the cleft and prevent the risks of acute and chronic aspiration. Generally speaking, open surgical techniques are employed for Type III and Type IV laryngeal clefts as exposure and access to deep intrathoracic structures is endoscopically difficult. The approach to open repair is largely depending upon the skill and experience of the surgeon. The most common technique is the anterior translaryngotracheal approach. This approach provides exposure of the cleft via a midline vertical incision of the cricoid, trachea, and thyroid cartilages. A complete



**Figs. 45.9A and B:** Laryngeal cleft. Endoscopic view of (A) Type 1; (B) Type II laryngeal clefts. Notice depth of interarytenoid space relative to posterior insertion of true vocal fold to the vocal process.

thyrotomy may be required for adequate exposure. Alternatively, a laryngeal cleft can be accessed by a lateral posterior pharyngotomy incision. The advantage of the anterior approach is a wide-angled exposure and reduced risk to the recurrent laryngeal nerves. The repair is performed in a two-layer closure. Some surgeons offset the suture lines. An interposition graft is frequently employed for long clefts to provide additional support to the repair site. Sternocleidomastoid muscle, fascia, perichondrium, costal cartilage, and periosteum have been used with similar efficacy. Redundant mucosa often needs to be trimmed to prevent postoperative tracheomalacia with posterior laryngotrachea obstruction. The airway is controlled during the procedure with intubation at the inferior aspect of the tracheotomy.[70]

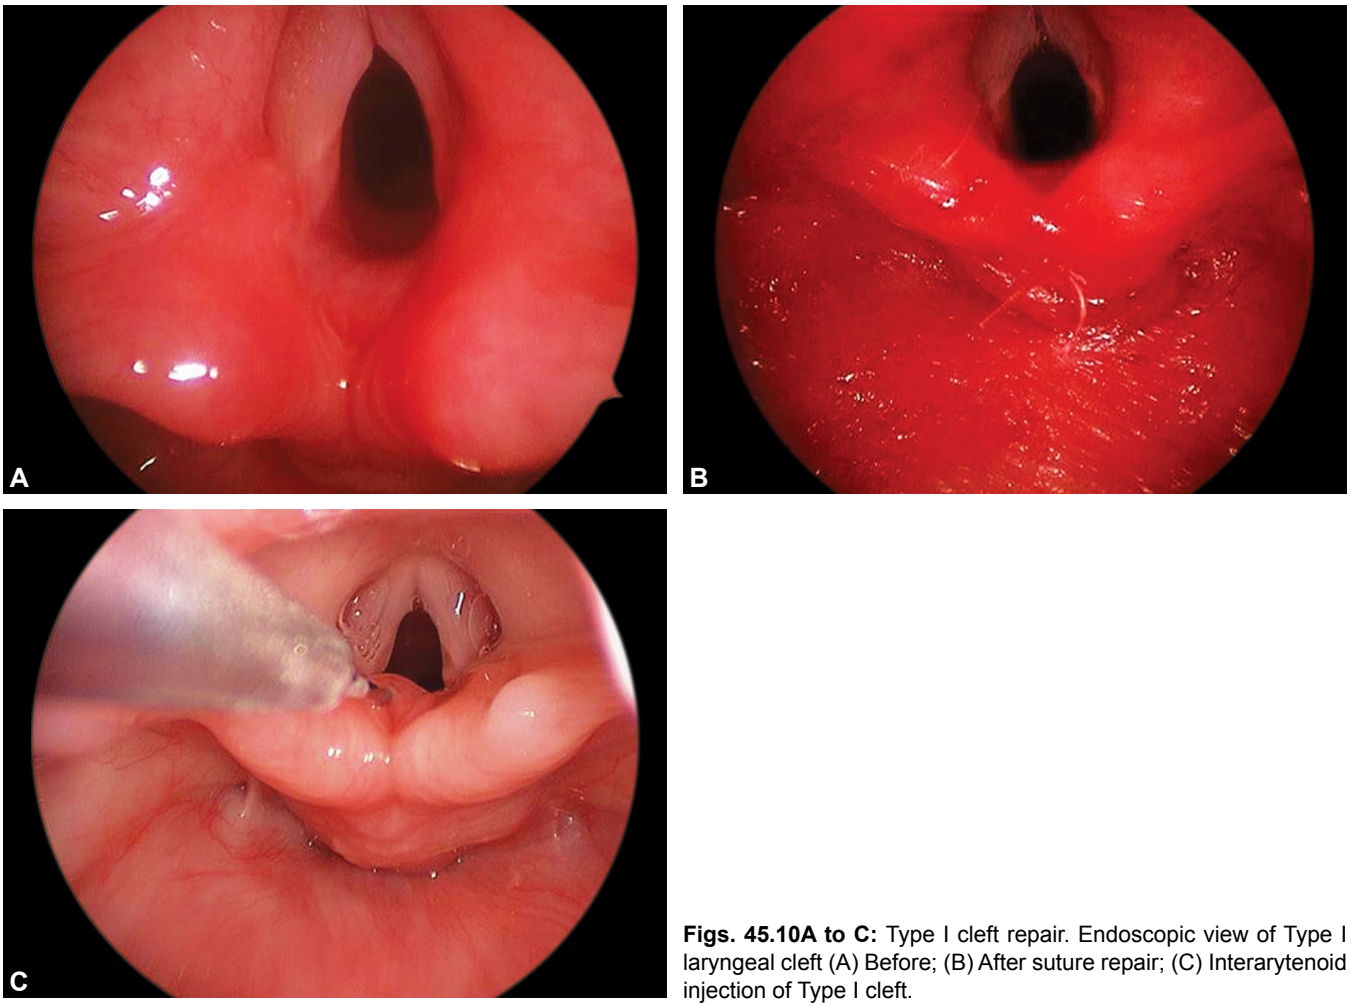
Type I and II, and sometimes Type III clefts, can be repaired endoscopically. Endoscopic repair of a Type III cleft again is dependent upon surgeon skill and the underlying health of the patient. Reflux precautions and medical therapy is preferred to allow for appropriate healing of the tenuous repair. Nissen fundoplication may be required before surgery in patients with severe LPR or recurrent aspiration pneumonia.[69] Type I and II endoscopic repairs have complete closure success rates and improved aspiration above 80%.[62] Type I clefts may be managed initially with thickened liquids, upright feeding, and antireflux medications as symptoms may improve with enhanced age and coordination of swallowing around the shallow defect. Interarytenoid injections, with Gelfoam or hydroxyapatite gel, have gained recent favor to help diagnose a cleft and predict the outcome of future repair (Figs. 45.10A to C).[67,68]

Endoscopic repair is generally performed under general anesthesia with spontaneous respiration. The interarytenoid and cleft mucosa is excised or ablated using cold knife or $CO_2$ laser, respectively. It is paramount to remove every fragment of mucosa prior to suture placement as retained mucosa can lead to recannulation, poor repair, or recurrence of the cleft. Double layer closure has been advocated but single-layer closures is more feasible and as successful using simple interrupted or figure-eight dissolvable sutures (Figs. 45.10A to C). The knots are left extraluminal.

## SUBGLOTTIC HEMANGIOMAS

### Background

Infantile subglottic hemangiomas (SGH) are benign, yet potentially fatal, vascular anomalies arising from endothelial cell proliferation of hemangiopoetic cells of placental or embryonic origin.[71,72] These rare neoplasms account for 1.5% of all congenital laryngeal anomalies. Like their cutaneous counterparts, which occur in 4–5% of all infants, SGH have a 2:1 female to male propensity.[71] They arise within the first few weeks to months of life, undergo a rapid growth phase during the first 6–8 months, and typically stabilize between months 10 and 18.[73] By 5 years of age, most cutaneous and SGH involute. While the inciting factors for proliferation are unknown, the proliferative phase is evident by increased levels of vascular endothelial growth factor and basic fibroblast growth factor. Involution is the result of endothelial apoptosis, angiogenesis downregulation, and tissue inhibitor metalloproteinase invasion.



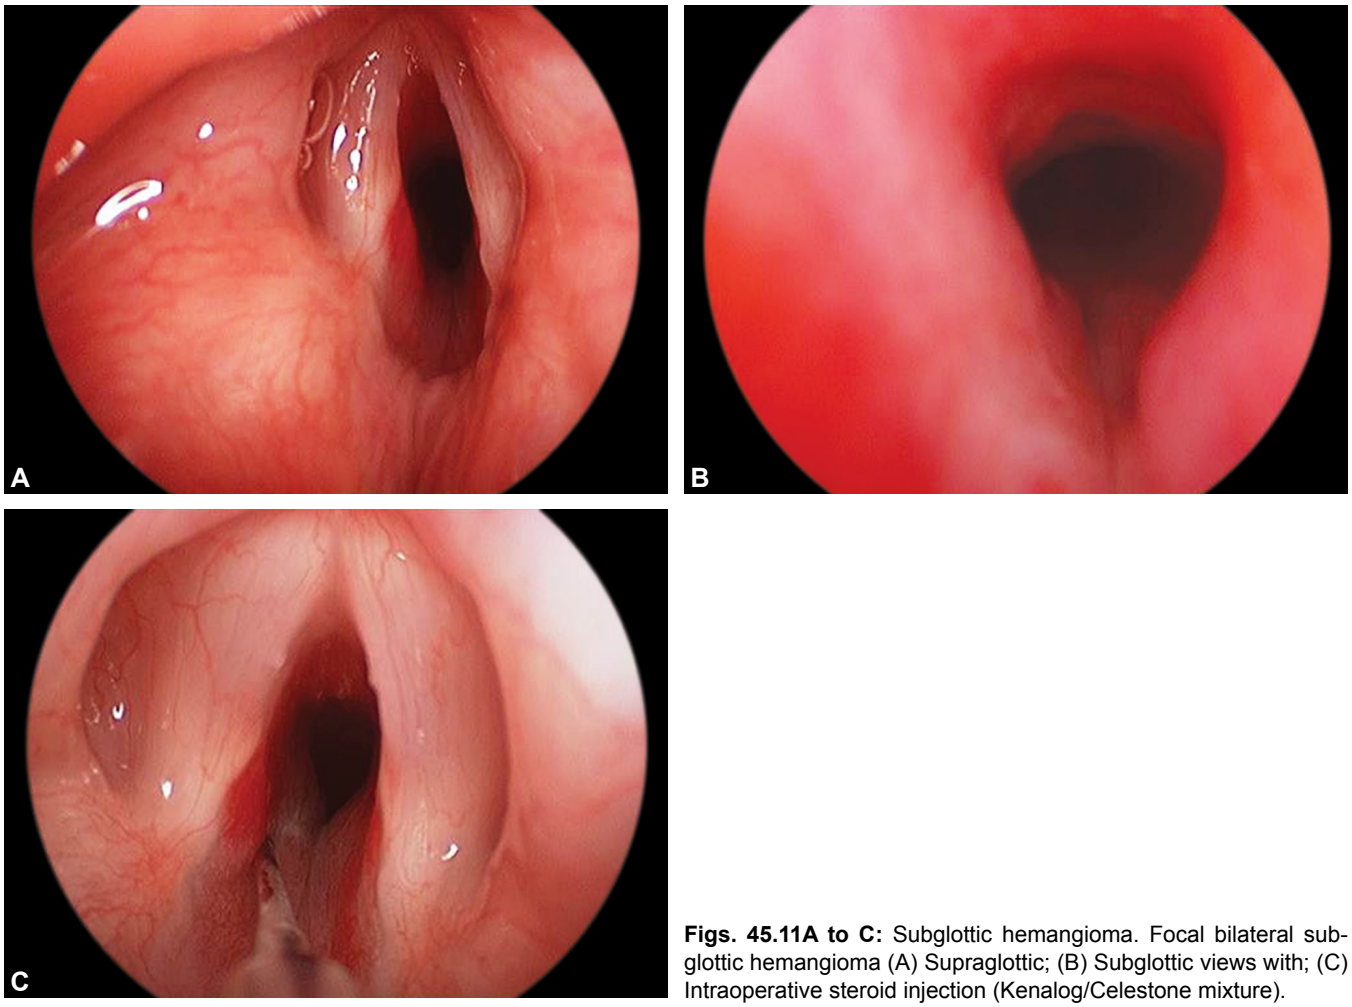
**Figs. 45.10A to C:** Type I cleft repair. Endoscopic view of Type I laryngeal cleft (A) Before; (B) After suture repair; (C) Interarytenoid injection of Type I cleft.

## Clinical Presentation

Subglottic hemangiomas most commonly produce biphasic stridor, although a croup-like cough, cyanosis, and hoarseness may also be present. Airway obstruction is slow and progressive during the first few months of life during the hemangioma's proliferative phase. Upper respiratory tract infections or crying will worsen and intensify these symptoms. Cutaneous hemangiomas are present in approximately 50% of cases, although the reported incidence of SGH in children with cutaneous lesions is only 1–2%.[74] In 50–60% of infants with segmental hemangioma in the beard distribution (trigeminal nerve-V3), an SGH will be present. Importantly, most cases of SGH exhibit symptom resolution after the first year of life once involution begins. However, expeditious diagnosis and treatment is of great importance during the hemangioma's rapid growth within the narrowest part of the newborn larynx.[25]

## Diagnosis

Like other laryngeal anomalies, a thorough history and physical examination should direct the working diagnosis. Awake flexible laryngoscopy in clinic will help rule out other laryngeal anomalies and may demonstrated evidence of a subglottic mass. Direct laryngoscopy and bronchoscopy is required, however, to confirm the diagnosis. A compressible submucosal lesion is consistent with an SGH. Nonobstructive segmental supraglottic and hypopharyngeal cutaneous staining may also be present in patients with segmental facial hemangiomas. An SGH will range in color from blue to red on the basis of the degree of overlying mucosa and vascularity. Focal lesions are most commonly located posterolaterally and can be bilateral (Figs. 45.11A to C). In even mildly symptomatic patients with V3 beard distribution infantile hemangiomas, endoscopic laryngeal evaluation is recommended.[75] If



**Figs. 45.11A to C:** Subglottic hemangioma. Focal bilateral subglottic hemangioma (A) Supraglottic; (B) Subglottic views with; (C) Intraoperative steroid injection (Kenalog/Celestone mixture).

endoscopic evidence is equivocal, biopsy may be required though this carries a risk of hemorrhage. Plain film radiographs of the neck may exhibit the pathognomonic finding of asymmetric subglottic airway narrowing.[72] A magnetic resonance imaging (MRI) will likely yield additional diagnostic support including the extent of paralaryngotracheal disease.

## Management

The majority of SGH will require intervention. In a rare few, SGH may be subcordal and not obstruct the subglottic lumen enough to be symptomatic. Similarly, segmental lesions above subglottis are typically flat and nonobstructive. These lesions may be identified and observed until involution. Tracheotomy is a surgical option for bypassing large SGH as involution is anticipated. However, this approach is rarely employed as less invasive surgical and medical options have emerged.

Treatment options for SGH include pharmacologic, endoscopic, and surgical approaches.[76] Pharmacologic agents include propranolol and systemic or direct intralesional steroids. Potassium titanyl phosphate and carbon dioxide ($CO_2$) laser ablation have good outcomes but require repeat procedures and may pose a risk of subglottic stenosis if perichondrial injury occurs.[77]

Propranolol is a nonselective beta-blocker serendipitously discovered to induce regression of cutaneous hemangiomas at subclinical cardiac doses (2 mg/kg/day). Propranolol is also effective and employed in the management for the majority of SGH.[78,79] Treatment with either propranolol alone or in combination with intraoperative steroid injection has supplanted other treatment modalities for SGH (Figs. 45.11A to C). Open resection of large and obstructive focal SGH may be necessary and successful for lesions nonresponsive to pharmacologic and endoscopic approaches. Extralaryngeal expansion

with LTP using a thyroid alar graft will simultaneously augment the subglottic lumen size.

## CONGENITAL LARYNGEAL WEB

Congenital laryngeal web is a rare entity that can present with dysphonia or aphonia, stridor, or severe respiratory distress, depending on the type and severity of the web. Failure of recanalization of the fetal airway at around 8–10 weeks' gestation is thought to be the embryologic basis for a spectrum of congenital laryngeal anomalies, including webs, stenosis, and atresia.[80] Laryngeal webs can occur in the posterior glottis but more commonly involve a portion of the anterior glottis with extension into the subglottis.[81] The type, severity, and associated symptoms of the laryngeal web dictate the need for surgical management of these congenital anomalies. Cohen devised a classification system (Table 45.4) for laryngeal webs that can be helpful in evaluating and managing these patients.[70]

Laryngeal web should be suspected in a child with hoarseness, weak cry, or aphonia since birth. Cyanotic spells, stridor, and/or dysphagia can also be seen. Flexible fiberoptic laryngoscopy is used for initial evaluation with direct microlaryngoscopy and bronchoscopy to confirm the diagnosis (Figs. 45.12A and B).[70]

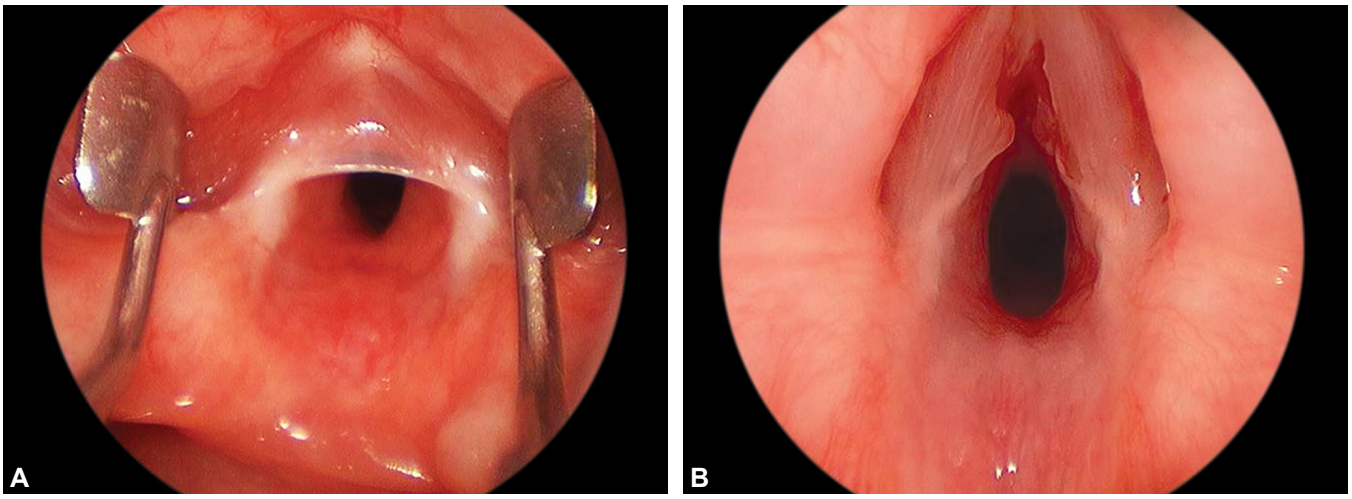
**Table 45.4:** Cohen classification of laryngeal webs

| | |
|---|---|
| Type I | Involves £ 35% of the glottis with minimal or no subglottic extension |
| Type II | Involves 35–50% of the glottis with thick anterior webbing extending to the subglottis |
| Type III | Involves 50–75% of the glottis, often with vocal cord and cricoid abnormalities |
| Type IV | Involves 75–90% of the glottis, with significant vocal cord abnormalities and cricoid narrowing. Usually requires a surgical airway |

A finding of laryngeal web should prompt work-up for other congenital anomalies, including cardiovascular and chromosomal anomalies. Several reports have suggested the association of congenital laryngeal web with chromosome 22q11 deletion, which can lead to various phenotypes such as DiGeorge syndrome and velocardiofacial syndrome (VCFS).[82] Miyamoto et al. presented a series of 17 patients with anterior glottic web who underwent genetic testing by standard fluorescence in situ hybridization analysis. About 11 of 17 (65%) patients were found to have chromosome 22q11 deletion and subsequently diagnosed with VCFS.[83] Cardiovascular anomalies are common among patients with chromosome 22q11 deletion and include atrial septal defect, ventricular septal defect, aortic arch abnormalities, and vascular rings.[82] Based on these associations, it is recommended that patients diagnosed with anterior glottic web undergo genetic screening for 22q11 deletion and if positive should undergo cardiovascular evaluation.

Treatment of laryngeal webs is surgical and ranges from endoscopic microlaryngeal techniques to open laryngofissure and reconstruction with costal cartilage grafting.[80,84] Surgical treatment plans should be individualized to optimize outcomes.

Endoscopic techniques are more often employed in laryngeal web Types I and II and can be delayed until 3–4 years of age if symptoms are minimal.[26] In patients with thin anterior glottic webs (Type I), endoscopic



**Figs. 45.12A and B:** Laryngeal web. Anterior Type II laryngeal web (A) Before; (B) After endoscopic division.

division with cold steel or $CO_2$ laser can be successful in one stage (Figs. 45.12A and B). Type II webs may require a staged procedure with serial dilations with or without keel placement. Endoscopic and open techniques have been used for keel placement. Tracheotomy may or may not be required while the keel is in place.

Type III and IV laryngeal webs often require initial placement of a tracheotomy to secure the airway with delayed surgical reconstruction. Open LTR techniques are used to address the subglottic stenosis component. Laryngofissure is performed with division of the web and the subglottic stenosis. Rib cartilage grafts are used as needed for reconstruction of the cricoid defect. A silastic keel stent is inserted for stenting, or in the case of single-stage LTR an endotracheal tube is left in place for stenting and no tracheotomy is required at the conclusion of the procedure.[80]

Posterior glottic webs usually present with stridor and symptoms similar to bilateral vocal cord paralysis due to poor vocal fold abduction. Management is similar to that of bilateral vocal fold paralysis and includes tracheotomy, repeated division and dilation of the web, arytenoidectomy, and LTR with posterior cartilage graft augmentation.[85]

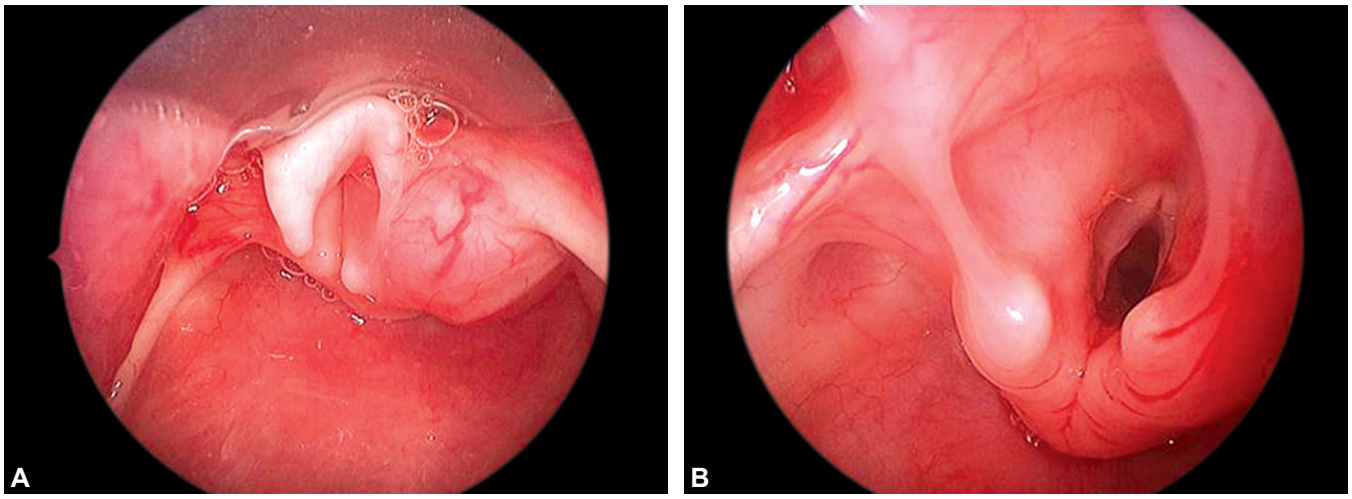
## CONGENITAL LARYNGEAL ATRESIA

Laryngeal atresia represents complete failure of recanalization of the fetal larynx during embryogenesis and presents at birth with aphonia and severe respiratory distress. Congenital high airway obstruction syndrome (CHAOS) is marked by enlarged fluid-filled lungs, dilated distal airways, polyhydramnios, and fetal ascites on prenatal ultrasound and/or MRI and is an indicator of laryngeal atresia.[86] Failure to establish a surgical airway via tracheotomy immediately upon birth can result in death of the infant. Prenatal diagnosis of CHAOS with ultrasound and/or MRI allows for planning of delivery by EXIT (ex-utero intrapartum treatment) to airway, in which a tracheotomy is performed while neonatal oxygenation is maintained by placental support.[87] Infants with laryngeal atresia often have other congenital anomalies including tracheoesophageal fistula, esophageal atresia, renal and/or ureteral agenesis, and duodenal atresia, making morbidity and mortality rates high.[88] Definitive surgical treatment usually involves delayed LTR. However, there has been report of successful endoscopic management of laryngeal atresia.[87]

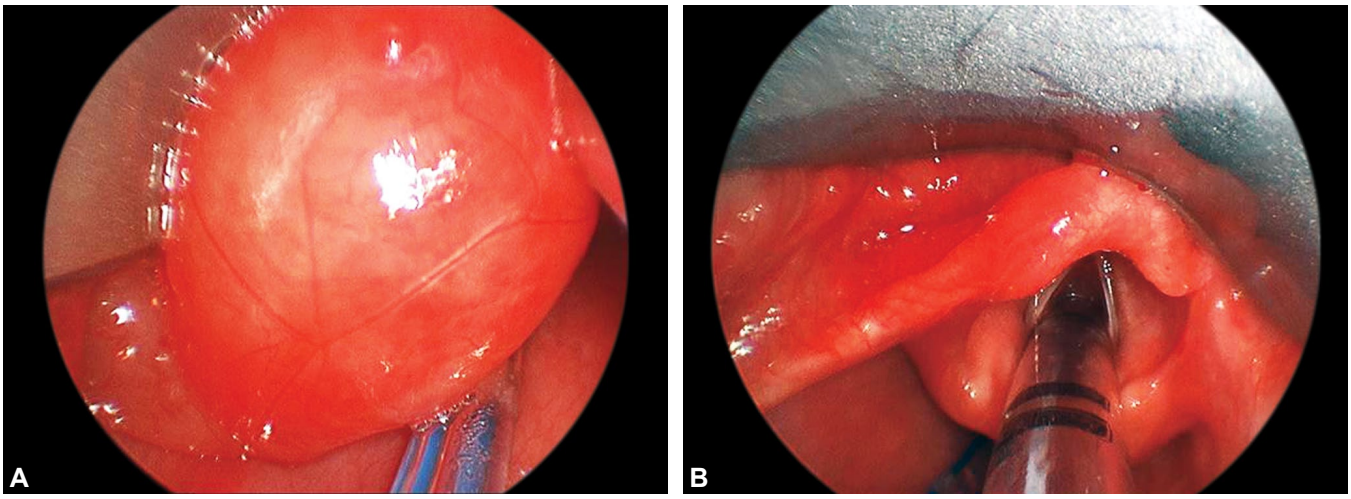
## CONGENITAL LARYNGEAL CYSTS

Congenital laryngeal cysts are a rare cause of stridor, dysphonia, airway obstruction, and dysphagia in infants and children. Several classification systems have been proposed for congenital laryngeal cysts on the basis of the location, extent, histology, and embryologic tissue origin.[71] Surgical treatment depends on the cyst type and severity of symptoms.

Congenital saccular cysts are fluid-filled cysts involving the laryngeal saccule, a small outpouching at the anterior end of the laryngeal ventricle between the false vocal fold, epiglottis, and thyroid cartilage (Figs. 45.13A and B).[89] Saccular cysts are submucosal lesions that can extend laterally into the false fold and aryepiglottic fold or anteriorly into the glottic lumen causing progressive



**Figs. 45.13A and B:** Right laryngeal saccular cyst (A) Before; (B) After endoscopic reduction.



**Figs. 45.14A and B:** Vallecular cyst of newborn airway (A) Before; (B) After excision.

airway obstruction.[90] Diagnosis is made by microlaryngoscopy and the airway is secured, sometimes requiring tracheotomy. Endoscopic aspiration, marsupialization, or excision can be used to treat these lesions; however, recurrence after multiple endoscopic treatments is not uncommon and if encountered necessitates open excision. Radiographic imaging is not necessary for initial diagnosis but may be helpful for surgical planning if open excision is required.[91,92]

A laryngocele is an air-filled dilation of the laryngeal saccule that communicates with the laryngeal lumen.[93,94] Laryngoceles can be classified as internal (medial to the thyrohyoid membrane) or external (extending through the thyrohyoid membrane into the neck). Presenting symptoms include dysphonia, dysphagia, respiratory distress, and neck swelling that may be intermittent and increase with crying.[94] Microlaryngoscopy is diagnostic and radiographic imaging (CT or MRI) is helpful in evaluating these lesions and guiding surgical treatment. Endoscopic marsupialization may be used for small internal laryngoceles while open cervical approaches are favored for larger external laryngoceles.[89]

A mucus retention cyst at the base of the tongue is known as a vallecular cyst (Figs. 45.14A and B). Vallecular cysts are smooth, submucosal lesions that may be present at birth and enlarge with time causing stridor, dyspnea, and dysphagia.[95] Diagnosis is usually with flexible endoscopy in the clinic or microlaryngoscopy in the operating room as part of the work-up for noisy breathing and/or feeding difficulties. The differential diagnosis for a vallecular cyst should also include a thyroglossal duct cyst that arises from the foramen cecum and can present very similarly to a vallecular cyst. Surgical treatment is necessary and can usually be performed endoscopically and sometimes in conjunction with a supraglottoplasty. Endoscopic marsupialization is an option; however, complete excision is favored for large with cold knife or $CO_2$ laser.[96]
